            dLdAlpha = min(0,X) .* dLdZ;
            dLdAlpha = sum(dLdAlpha,[1 2]);

            % Sum over all observations in mini-batch.
            dLdAlpha = sum(dLdAlpha,4);
        end
    end
end
```

GPU Compatibility

If the layer forward functions fully support `dlarray` objects, then the layer is GPU compatible. Otherwise, to be GPU compatible, the layer functions must support inputs and return outputs of type `gpuArray`.

Many MATLAB built-in functions support `gpuArray` and `dlarray` input arguments. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. For a list of functions that execute on a GPU, see “Run MATLAB Functions on a GPU” (Parallel Computing Toolbox). To use a GPU for deep learning, you must also have a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). For more information on working with GPUs in MATLAB, see “GPU Computing in MATLAB” (Parallel Computing Toolbox).

Specify Custom Output Layer Backward Loss Function

If Deep Learning Toolbox does not provide the layer you require for your classification or regression problem, then you can define your own custom layer. For a list of built-in layers, see “List of Deep Learning Layers” on page 1-21.

The example “Define Custom Classification Output Layer” on page 18-91 shows how to define and create a custom classification output layer with sum of squares error (SSE) loss and goes through the following steps:

1. Name the layer – Give the layer a name so it can be used in MATLAB.
2. Declare the layer properties – Specify the properties of the layer.
3. Create a constructor function (optional) – Specify how to construct the layer and initialize its properties. If you do not specify a constructor function, then the software initializes the properties with `''` at creation.
4. Create a forward loss function – Specify the loss between the predictions and the training targets.
5. Create a backward loss function (optional) – Specify the derivative of the loss with respect to the predictions. If you do not specify a backward loss function, then the forward loss function must support `dlarray` objects.

Creating a backward loss function is optional. If the forward loss function only uses functions that support `dlarray` objects, then software determines the derivatives automatically using automatic differentiation. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. If you want to use functions that do not support `dlarray` objects, or want to use a specific algorithm for the backward loss function, then you can define a custom backward function using this example as a guide.

Create Custom Layer

The example “Define Custom Classification Output Layer” on page 18-91 shows how to create a SSE classification layer.

A classification SSE layer computes the sum of squares error loss for classification problems. SSE is an error measure between two continuous random variables. For predictions Y and training targets T, the SSE loss between Y and T is given by

$$L = \frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{K}(Y_{ni} - T_{ni})^2,$$

where N is the number of observations and K is the number of classes.

View the layer created in the example “Define Custom Classification Output Layer” on page 18-91. This layer does not have a `backwardLoss` function.

```
classdef sseClassificationLayer < nnet.layer.ClassificationLayer
    % Example custom classification layer with sum of squares error loss.

    methods
        function layer = sseClassificationLayer(name)
```

```
            % layer = sseClassificationLayer(name) creates a sum of squares
            % error classification layer and specifies the layer name.

            % Set layer name.
            layer.Name = name;

            % Set layer description.
            layer.Description = 'Sum of squares error';
        end

        function loss = forwardLoss(layer, Y, T)
            % loss = forwardLoss(layer, Y, T) returns the SSE loss between
            % the predictions Y and the training targets T.

            % Calculate sum of squares.
            sumSquares = sum((Y-T).^2);

            % Take mean over mini-batch.
            N = size(Y,4);
            loss = sum(sumSquares)/N;
        end
    end
end
```

Create Backward Loss Function

Implement the `backwardLoss` function that returns the derivatives of the loss with respect to the input data and the learnable parameters.

The syntax for `backwardLoss` is `dLdY = backwardLoss(layer,Y,T)`. The input `Y` contains the predictions made by the network and `T` contains the training targets. The output `dLdY` is the derivative of the loss with respect to the predictions `Y`. The output `dLdY` must be the same size as the layer input `Y`.

The dimensions of `Y` and `T` are the same as the inputs in `forwardLoss`.

The derivative of the SSE loss with respect to the predictions Y is given by

$$\frac{\delta L}{\delta Y_i} = \frac{2}{N}(Y_i - T_i),$$

where N is the number of observations in the input.

Create the backward loss function that returns these derivatives.

```
        function dLdY = backwardLoss(layer, Y, T)
            % dLdY = backwardLoss(layer, Y, T) returns the derivatives of
            % the SSE loss with respect to the predictions Y.

            N = size(Y,4);
            dLdY = 2*(Y-T)/N;
        end
```

Complete Layer

View the completed layer class file.

```
classdef sseClassificationLayer < nnet.layer.ClassificationLayer
    % Example custom classification layer with sum of squares error loss.
```

```
    methods
        function layer = sseClassificationLayer(name)
            % layer = sseClassificationLayer(name) creates a sum of squares
            % error classification layer and specifies the layer name.

            % Set layer name.
            layer.Name = name;

            % Set layer description.
            layer.Description = 'Sum of squares error';
        end

        function loss = forwardLoss(layer, Y, T)
            % loss = forwardLoss(layer, Y, T) returns the SSE loss between
            % the predictions Y and the training targets T.

            % Calculate sum of squares.
            sumSquares = sum((Y-T).^2);

            % Take mean over mini-batch.
            N = size(Y,4);
            loss = sum(sumSquares)/N;
        end

        function dLdY = backwardLoss(layer, Y, T)
            % dLdY = backwardLoss(layer, Y, T) returns the derivatives of
            % the SSE loss with respect to the predictions Y.

            N = size(Y,4);
            dLdY = 2*(Y-T)/N;
        end
    end
end
```

GPU Compatibility

If the layer forward functions fully support `dlarray` objects, then the layer is GPU compatible. Otherwise, to be GPU compatible, the layer functions must support inputs and return outputs of type `gpuArray`.

Many MATLAB built-in functions support `gpuArray` and `dlarray` input arguments. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. For a list of functions that execute on a GPU, see “Run MATLAB Functions on a GPU” (Parallel Computing Toolbox). To use a GPU for deep learning, you must also have a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). For more information on working with GPUs in MATLAB, see “GPU Computing in MATLAB” (Parallel Computing Toolbox).

Deep Learning Network Composition

To create a custom layer that itself defines a layer graph, you can declare a `dlnetwork` object as a learnable parameter in the `properties (Learnable)` section of the layer definition. This method is known as *network composition*. You can use network composition to:

- Create a single custom layer that represents a block of learnable layers, for example, a residual block.
- Create a network with control flow, for example, a network with a section that can dynamically change depending on the input data.
- Create a network with loops, for example, a network with sections that feed the output back into itself.

For nested networks that have both learnable and state parameters, for example, networks with batch normalization or LSTM layers, declare the network in the `properties (Learnable, State)` section of the layer definition.

For an example showing how to define a custom layer containing a learnable `dlnetwork` object, see “Define Nested Deep Learning Layer” on page 18-120.

For an example showing how to train a network with nested layers, see “Train Deep Learning Network with Nested Layers” on page 18-135.

Automatically Initialize Learnable dlnetwork Objects for Training

You can create a custom layer and allow the software to automatically initialize the learnable parameters of any nested `dlnetwork` objects after the parent network is fully constructed. Automatic initialization of the nested network means that you do not need to keep track of the size and shape of the inputs passed to each custom layer containing a nested `dlnetwork`

To take advantage of automatic initialization, you must specify that the constructor function creates an uninitialized `dlnetwork` object. To create an uninitialized `dlnetwork` object, set the `Initialize` name-value option to false. You do not need to specify an input layer, so you do not need to specify an input size for the layer.

```
function layer = myLayer

    % Initialize layer properties.
    ...

    % Define network.
    layers = [
        % Network layers go here.
        ];

    layer.Network = dlnetwork(lgraph,'Initialize',false);
end
```

When the parent network is initialized, the learnable parameters of any nested `dlnetwork` objects are initialized at the same time. The size of the learnable parameters depends on the size of the input data of the custom layer. The software propagates the data through the nested network and automatically initializes the parameters according to the propagated sizes and the initialization properties of the layers of the nested network.

If the parent network is trained using the `trainNetwork` function, then any nested `dlnetwork` objects are initialized when you call `trainNetwork`. If the parent network is a `dlnetwork`, then any nested `dlnetwork` objects are initialized when the parent network is constructed (if the parent `dlnetwork` is initialized at construction) or when you use the `initialize` function with the parent network (if the parent `dlnetwork` is not initialized at construction).

If you do not want to make use of automatic initialization, you can construct the custom layer with the nested network already initialized. In this case, the nested network is initialized before the parent network. To initialize the nested network at construction, you must manually specify the size of any inputs to the nested network. This requires manually specifying the size of any inputs to the nested network. You can do so either by using input layers or by providing example inputs to the `dlnetwork` constructor function. Because you must specify the sizes of any inputs to the `dlnetwork` object, you might need to specify input sizes when you create the layer. For help determining the size of the inputs to the layer, you can use the `analyzeNetwork` function and check the size of the activations of the previous layers.

Predict and Forward Functions

Some layers behave differently during training and during prediction. For example, a dropout layer performs dropout only during training and has no effect during prediction. A layer uses one of two functions to perform a forward pass: `predict` or `forward`. If the forward pass is at prediction time, then the layer uses the `predict` function. If the forward pass is at training time, then the layer uses the `forward` function. If you do not require two different functions for prediction time and training time, then you can omit the `forward` function. In this case, the layer uses `predict` at training time.

When implementing the `predict` and the `forward` functions of the custom layer, to ensure that the layers in the `dlnetwork` object behave in the correct way, use the `predict` and `forward` functions for `dlnetwork` objects, respectively.

Custom layers with learnable `dlnetwork` objects do not support custom backward functions.

You must still assign a value to the memory output argument of the `forward` function.

This example code shows how to use the `predict` and `forward` functions with `dlnetwork` input.

```
function Z = predict(layer,X)

    % Convert input data to formatted dlarray.
    X = dlarray(X,"SSCB");

    % Predict using network.
    dlnet = layer.Network;
    Z = predict(dlnet,X);

    % Strip dimension labels.
    Z = stripdims(Z);
end

function Z = forward(layer,X)

    % Convert input data to formatted dlarray.
    X = dlarray(X,"SSCB");

    % Forward pass using network.
    dlnet = layer.Network;
```

```
    Z = forward(dlnet,X);

    % Strip dimension labels.
    Z = stripdims(Z);
end
```

If the `dlnetwork` object does not behave differently during training and prediction, then you can omit the forward function. In this case, the software uses the `predict` function during training.

GPU Compatibility

If the layer forward functions fully support `dlarray` objects, then the layer is GPU compatible. Otherwise, to be GPU compatible, the layer functions must support inputs and return outputs of type `gpuArray`.

Many MATLAB built-in functions support `gpuArray` and `dlarray` input arguments. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. For a list of functions that execute on a GPU, see “Run MATLAB Functions on a GPU” (Parallel Computing Toolbox). To use a GPU for deep learning, you must also have a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). For more information on working with GPUs in MATLAB, see “GPU Computing in MATLAB” (Parallel Computing Toolbox).

Define Nested Deep Learning Layer

If Deep Learning Toolbox does not provide the layer you require for your classification or regression problem, then you can define your own custom layer using this example as a guide. For a list of built-in layers, see “List of Deep Learning Layers” on page 1-21.

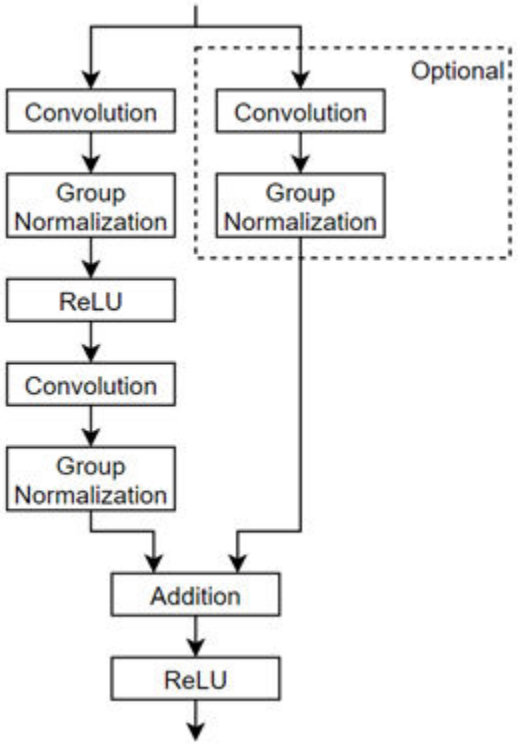
To create a custom layer that itself defines a layer graph, you can declare a `dlnetwork` object as a learnable parameter in the `properties (Learnable)` section of the layer definition. This method is known as *network composition*. You can use network composition to:

- Create a single custom layer that represents a block of learnable layers, for example, a residual block.
- Create a network with control flow, for example, a network with a section that can dynamically change depending on the input data.
- Create a network with loops, for example, a network with sections that feed the output back into itself.

For nested networks that have both learnable and state parameters, for example, networks with batch normalization or LSTM layers, declare the network in the `properties (Learnable, State)` section of the layer definition.

For more information, see “Deep Learning Network Composition” on page 18-117.

This example shows how to create a custom layer representing a residual block. The custom layer `residualBlockLayer` contains a learnable block of layers consisting of convolution, group normalization, ReLU, and addition layers, and also includes a skip connection and an optional convolution layer and group normalization layer in the skip connection. The layer has a single input that is used twice, as the input to each branch. This diagram highlights the residual block structure.



To define a custom deep learning layer, you can use the template provided in this example, which takes you through the following steps:

1. Name the layer — Give the layer a name so that you can use it in MATLAB.
2. Declare the layer properties — Specify the properties of the layer including learnable parameters and state parameters.
3. Create a constructor function (optional) — Specify how to construct the layer and initialize its properties. If you do not specify a constructor function, then at creation, the software initializes the `Name`, `Description`, and `Type` properties with `[]` and sets the number of layer inputs and outputs to 1.
4. Create forward functions — Specify how data passes forward through the layer (forward propagation) at prediction time and at training time.
5. Create reset state function (optional) — Specify how to reset state parameters.
6. Create a backward function (optional) — Specify the derivatives of the loss with respect to the input data and the learnable parameters (backward propagation). If you do not specify a backward function, then the forward functions must support `dlarray` objects.

Intermediate Layer Template

Copy the intermediate layer template into a new file in MATLAB. This template outlines the structure of an intermediate layer class definition. It outlines:

- The optional `properties` blocks for the layer properties, learnable parameters, and state parameters.
- The layer constructor function.
- The `predict` function and the optional `forward` function.
- The optional `resetState` function for layers with state properties.
- The optional `backward` function.

```
classdef myLayer < nnet.layer.Layer % & nnet.layer.Formattable (Optional)

    properties
        % (Optional) Layer properties.

        % Declare layer properties here.
    end

    properties (Learnable)
        % (Optional) Layer learnable parameters.

        % Declare learnable parameters here.
    end

    properties (State)
        % (Optional) Layer state parameters.

        % Declare state parameters here.
    end

    properties (Learnable, State)
        % (Optional) Nested dlnetwork objects with both learnable
        % parameters and state.

        % Declare nested networks with learnable and state parameters here.
    end

    methods
```

```
function layer = myLayer()
    % (Optional) Create a myLayer.
    % This function must have the same name as the class.

    % Define layer constructor function here.
end

function [Z,state] = predict(layer,X)
    % Forward input data through the layer at prediction time and
    % output the result and updated state.
    %
    % Inputs:
    %         layer - Layer to forward propagate through
    %         X     - Input data
    % Outputs:
    %         Z     - Output of layer forward function
    %         state - (Optional) Updated layer state.
    %
    %  - For layers with multiple inputs, replace X with X1,...,XN,
    %    where N is the number of inputs.
    %  - For layers with multiple outputs, replace Z with
    %    Z1,...,ZM, where M is the number of outputs.
    %  - For layers with multiple state parameters, replace state
    %    with state1,...,stateK, where K is the number of state
    %    parameters.

    % Define layer predict function here.
end

function [Z,state,memory] = forward(layer,X)
    % (Optional) Forward input data through the layer at training
    % time and output the result, updated state, and a memory
    % value.
    %
    % Inputs:
    %         layer - Layer to forward propagate through
    %         X     - Layer input data
    % Outputs:
    %         Z      - Output of layer forward function
    %         state  - (Optional) Updated layer state
    %         memory - (Optional) Memory value for custom backward
    %                  function
    %
    %  - For layers with multiple inputs, replace X with X1,...,XN,
    %    where N is the number of inputs.
    %  - For layers with multiple outputs, replace Z with
    %    Z1,...,ZM, where M is the number of outputs.
    %  - For layers with multiple state parameters, replace state
    %    with state1,...,stateK, where K is the number of state
    %    parameters.

    % Define layer forward function here.
end

function layer = resetState(layer)
    % (Optional) Reset layer state.

    % Define reset state function here.
end

function [dLdX,dLdW,dLdSin] = backward(layer,X,Z,dLdZ,dLdSout,memory)
    % (Optional) Backward propagate the derivative of the loss
    % function through the layer.
    %
    % Inputs:
    %         layer   - Layer to backward propagate through
    %         X       - Layer input data
    %         Z       - Layer output data
    %         dLdZ    - Derivative of loss with respect to layer
    %                   output
    %         dLdSout - (Optional) Derivative of loss with respect
    %                   to state output
```

```
            %         memory  - Memory value from forward function
            % Outputs:
            %         dLdX   - Derivative of loss with respect to layer input
            %         dLdW   - (Optional) Derivative of loss with respect to
            %                  learnable parameter
            %         dLdSin - (Optional) Derivative of loss with respect to
            %                  state input
            %
            %  - For layers with state parameters, the backward syntax must
            %    include both dLdSout and dLdSin, or neither.
            %  - For layers with multiple inputs, replace X and dLdX with
            %    X1,...,XN and dLdX1,...,dLdXN, respectively, where N is
            %    the number of inputs.
            %  - For layers with multiple outputs, replace Z and dlZ with
            %    Z1,...,ZM and dLdZ,...,dLdZM, respectively, where M is the
            %    number of outputs.
            %  - For layers with multiple learnable parameters, replace
            %    dLdW with dLdW1,...,dLdWP, where P is the number of
            %    learnable parameters.
            %  - For layers with multiple state parameters, replace dLdSin
            %    and dLdSout with dLdSin1,...,dLdSinK and
            %    dLdSout1,...dldSoutK, respectively, where K is the number
            %    of state parameters.

            % Define layer backward function here.
        end
    end
end
```

Name Layer

First, give the layer a name. In the first line of the class file, replace the existing name `myLayer` with `residualBlockLayer`.

```
classdef residualBlockLayer < nnet.layer.Layer
    ...
end
```

Next, rename the `myLayer` constructor function (the first function in the `methods` section) so that it has the same name as the layer.

```
    methods
        function layer = residualBlockLayer()
            ...
        end

        ...
     end
```

Save Layer

Save the layer class file in a new file named `residualBlockLayer.m`. The file name must match the layer name. To use the layer, you must save the file in the current folder or in a folder on the MATLAB path.

Declare Properties and Learnable Parameters

Declare the layer properties in the `properties` section and declare learnable parameters by listing them in the `properties (Learnable)` section.

By default, custom intermediate layers have these properties. Do not declare these properties in the `properties` section.

Property	Description
`Name`	Layer name, specified as a character vector or a string scalar. For `Layer` array input, the `trainNetwork`, `assembleNetwork`, `layerGraph`, and `dlnetwork` functions automatically assign names to layers with `Name` set to `''`.
`Description`	One-line description of the layer, specified as a string scalar or a character vector. This description appears when the layer is displayed in a `Layer` array. If you do not specify a layer description, then the software displays the layer class name.
`Type`	Type of the layer, specified as a character vector or a string scalar. The value of `Type` appears when the layer is displayed in a `Layer` array. If you do not specify a layer type, then the software displays the layer class name.
`NumInputs`	Number of inputs of the layer, specified as a positive integer. If you do not specify this value, then the software automatically sets `NumInputs` to the number of names in `InputNames`. The default value is 1.
`InputNames`	Input names of the layer, specified as a cell array of character vectors. If you do not specify this value and `NumInputs` is greater than 1, then the software automatically sets `InputNames` to `{'in1',...,'inN'}`, where `N` is equal to `NumInputs`. The default value is `{'in'}`.
`NumOutputs`	Number of outputs of the layer, specified as a positive integer. If you do not specify this value, then the software automatically sets `NumOutputs` to the number of names in `OutputNames`. The default value is 1.
`OutputNames`	Output names of the layer, specified as a cell array of character vectors. If you do not specify this value and `NumOutputs` is greater than 1, then the software automatically sets `OutputNames` to `{'out1',...,'outM'}`, where `M` is equal to `NumOutputs`. The default value is `{'out'}`.

If the layer has no other properties, then you can omit the `properties` section.

Tip If you are creating a layer with multiple inputs, then you must set either the `NumInputs` or `InputNames` properties in the layer constructor. If you are creating a layer with multiple outputs,

then you must set either the `NumOutputs` or `OutputNames` properties in the layer constructor. For an example, see “Define Custom Deep Learning Layer with Multiple Inputs” on page 18-48.

The residual block layer does not require any additional properties, so you can remove the `properties` section.

This custom layer has only one learnable parameter, the residual block itself specified as a `dlnetwork` object. Declare this learnable parameter in the `properties (Learnable)` section and call the parameter `Network`.

```
properties (Learnable)
    % Layer learnable parameters

    % Residual block.
    Network
end
```

Create Constructor Function

Create the function that constructs the layer and initializes the layer properties. Specify any variables required to create the layer as inputs to the constructor function.

The residual block layer constructor function requires four input arguments:

- Number of convolutional filters
- Stride (optional, with default stride 1)
- Flag to include convolution in skip connection (optional, with default flag `false`)
- Layer name (optional, with default name `''`)

In the constructor function `residualBlockLayer`, specify the required input argument `numFilters` and the optional arguments as name-value pairs with the name `NameValueArgs`. Add a comment to the top of the function that explains the syntax of the function.

```
function layer = residualBlockLayer(numFilters,NameValueArgs)
    % layer = residualBlockLayer(numFilters) creates a residual
    % block layer with the specified number of filters.
    %
    % layer = residualBlockLayer(numFilters,Name,Value) specifies
    % additional options using one or more name-value pair
    % arguments:
    %
    %     'Stride'                - Stride of convolution operation
    %                               (default 1)
    %
    %     'IncludeSkipConvolution' - Flag to include convolution in
    %                               skip connection
    %                               (default false)
    %
    %     'Name'                  - Layer name
    %                               (default '')

    ...
end
```

Parse Input Arguments

Parse the input arguments using an `arguments` block. List the arguments in the same order as the function syntax and specify the default values. Then, extract the values from the `NameValueArgs` input.

```
% Parse input arguments.
arguments
    numFilters
    NameValueArgs.Stride = 1
    NameValueArgs.IncludeSkipConvolution = false
    NameValueArgs.Name = ''
end

stride = NameValueArgs.Stride;
includeSkipConvolution = NameValueArgs.IncludeSkipConvolution;
name = NameValueArgs.Name;
```

Initialize Layer Properties

In the constructor function, initialize the layer properties, including the `dlnetwork` object. Replace the comment `% Layer constructor function goes here` with code that initializes the layer properties.

Set the `Name` property to the input argument `name`.

```
% Set layer name.
layer.Name = name;
```

Give the layer a one-line description by setting the `Description` property of the layer. Set the description to describe the layer and any optional properties.

```
% Set layer description.
description = "Residual block with " + numFilters + " filters, stride " + stride;
if includeSkipConvolution
    description = description + ", and skip convolution";
end
layer.Description = description;
```

Specify the type of the layer by setting the `Type` property. The value of `Type` appears when the layer is displayed in a `Layer` array.

```
% Set layer type.
layer.Type = "Residual Block";
```

Define the residual block. You can create the residual block layers as an uninitialized nested `dlnetwork` object without an input layer and allow the software to automatically initialize the learnable and state parameters at training time. For more information, see “Automatically Initialize Learnable dlnetwork Objects for Training” on page 18-117.

First, create a layer array containing the main layers of the block and convert it to a layer graph.

```
% Define nested layer graph.
layers = [
    convolution2dLayer(3,numFilters,'Padding','same','Stride',stride,'Name','conv1')
    groupNormalizationLayer('all-channels','Name','gn1')
    reluLayer('Name','relu1')
    convolution2dLayer(3,numFilters,'Padding','same','Name','conv2')
    groupNormalizationLayer('channel-wise','Name','gn2')

    additionLayer(2,'Name','add')
    reluLayer('Name','relu2')];

lgraph = layerGraph(layers);
```

Next, add the skip connection. If the `includeSkipConvolution` flag is `true`, then also include a convolution layer and group normalization layer in the skip connection.

```
% Add skip connection.
if includeSkipConvolution
    layers = [
        convolution2dLayer(1,numFilters,'Stride',stride,'Name','convSkip')
        groupNormalizationLayer('all-channels','Name','gnSkip')];

    lgraph = addLayers(lgraph,layers);
```

```
        lgraph = connectLayers(lgraph,'gnSkip','add/in2');
    end
```

Since there is no input layer, this network has two unconnected inputs. If the network does not have the skip connection, the input to the `'conv2'` layer and one of the inputs to the `'add'` layer are unconnected. If the network does have the skip connection, then the unconnected inputs are the inputs to the `'conv1'` and `'convSkip'` layers.

Finally, convert the layer graph to a `dlnetwork` object and set the layer `Network` property. Create an uninitialized `dlnetwork` object. The weights and learnable parameters in the `dlnetwork` object are automatically initialized when the complete network is assembled for training.

```
% Convert to dlnetwork.
dlnet = dlnetwork(lgraph,'Initialize',false);

% Set Network property.
layer.Network = dlnet;
```

View the completed constructor function.

```
function layer = residualBlockLayer(numFilters,NameValueArgs)
    % layer = residualBlockLayer(numFilters) creates a residual
    % block layer with the specified number of filters.
    %
    % layer = residualBlockLayer(numFilters,Name,Value) specifies
    % additional options using one or more name-value pair
    % arguments:
    %
    %     'Stride'                - Stride of convolution operation
    %                               (default 1)
    %
    %     'IncludeSkipConvolution' - Flag to include convolution in
    %                               skip connection
    %                               (default false)
    %
    %     'Name'                  - Layer name
    %                               (default '')

    % Parse input arguments.
    arguments
        numFilters
        NameValueArgs.Stride = 1
        NameValueArgs.IncludeSkipConvolution = false
        NameValueArgs.Name = ''
    end

    stride = NameValueArgs.Stride;
    includeSkipConvolution = NameValueArgs.IncludeSkipConvolution;
    name = NameValueArgs.Name;

    % Set layer name.
    layer.Name = name;

    % Set layer description.
    description = "Residual block with " + numFilters + " filters, stride " + stride;
    if includeSkipConvolution
        description = description + ", and skip convolution";
    end
    layer.Description = description;

    % Set layer type.
    layer.Type = "Residual Block";

    % Define nested layer graph.
    layers = [
        convolution2dLayer(3,numFilters,'Padding','same','Stride',stride,'Name','conv1')
        groupNormalizationLayer('all-channels','Name','gn1')
        reluLayer('Name','relu1')
        convolution2dLayer(3,numFilters,'Padding','same','Name','conv2')
        groupNormalizationLayer('channel-wise','Name','gn2')

        additionLayer(2,'Name','add')
        reluLayer('Name','relu2')];
```

```
        lgraph = layerGraph(layers);

        % Add skip connection.
        if includeSkipConvolution
            layers = [
                convolution2dLayer(1,numFilters,'Stride',stride,'Name','convSkip')
                groupNormalizationLayer('all-channels','Name','gnSkip')];

            lgraph = addLayers(lgraph,layers);
            lgraph = connectLayers(lgraph,'gnSkip','add/in2');
        end

        % Convert to dlnetwork.
        dlnet = dlnetwork(lgraph,'Initialize',false);

        % Set Network property.
        layer.Network = dlnet;
    end
```

With this constructor function, the command `residualBlockLayer(64,'Stride',2,'IncludeSkipConvolution',true,'Name','res5')` creates a residual block layer with 64 filters, a stride of 2, a convolution in the skip connection, and with the name `'res5'`. The required sizes of weights and parameters are determined when the completed network is assembled for training.

Create Forward Functions

Create the layer forward functions to use at prediction time and training time.

Create a function named `predict` that propagates the data forward through the layer at *prediction time* and outputs the result.

The `predict` function syntax depends on the type of layer.

- `Z = predict(layer,X)` forwards the input data `X` through the layer and outputs the result `Z`, where `layer` has a single input, a single output.
- `[Z,state] = predict(layer,X)` also outputs the updated state parameter `state`, where `layer` has a single state parameter.

You can adjust the syntaxes for layers with multiple inputs, multiple outputs, or multiple state parameters:

- For layers with multiple inputs, replace `X` with `X1,...,XN`, where `N` is the number of inputs. The `NumInputs` property must match `N`.
- For layers with multiple outputs, replace `Z` with `Z1,...,ZM`, where `M` is the number of outputs. The `NumOutputs` property must match `M`.
- For layers with multiple state parameters, replace `state` with `state1,...,stateK`, where `K` is the number of state parameters.

Tip If the number of inputs to the layer can vary, then use `varargin` instead of `X1,…,XN`. In this case, `varargin` is a cell array of the inputs, where `varargin{i}` corresponds to `Xi`.

If the number of outputs can vary, then use `varargout` instead of `Z1,…,ZN`. In this case, `varargout` is a cell array of the outputs, where `varargout{j}` corresponds to `Zj`.

Tip If the custom layer has a `dlnetwork` object for a learnable parameter, then in the `predict` function of the custom layer, use the `predict` function for the `dlnetwork`. Using the `dlnetwork` object `predict` function ensures that the software uses the correct layer operations for prediction.

Because the residual block has only one input and one output, the syntax for predict for the custom layer is `Z = predict(layer,X)`.

By default, the layer uses `predict` as the forward function at training time. To use a different forward function at training time, or retain a value required for a custom backward function, you must also create a function named `forward`.

The dimensions of the inputs depend on the type of data and the output of the connected layers.

Layer Input	Input Size	Observation Dimension
Feature vectors	*c*-by-*N*, where *c* corresponds to the number of channels and *N* is the number of observations.	2
2-D images	*h*-by-*w*-by-*c*-by-*N*, where *h*, *w*, and *c* correspond to the height, width, and number of channels of the images, respectively, and *N* is the number of observations.	4
3-D images	*h*-by-*w*-by-*d*-by-*c*-by-*N*, where *h*, *w*, *d*, and *c* correspond to the height, width, depth, and number of channels of the 3-D images, respectively, and *N* is the number of observations.	5
Vector sequences	*c*-by-*N*-by-*S*, where *c* is the number of features of the sequences, *N* is the number of observations, and *S* is the sequence length.	2
2-D image sequences	*h*-by-*w*-by-*c*-by-*N*-by-*S*, where *h*, *w*, and *c* correspond to the height, width, and number of channels of the images, respectively, *N* is the number of observations, and *S* is the sequence length.	4
3-D image sequences	*h*-by-*w*-by-*d*-by-*c*-by-*N*-by-*S*, where *h*, *w*, *d*, and *c* correspond to the height, width, depth, and number of channels of the 3-D images, respectively, *N* is the number of observations, and *S* is the sequence length.	5

For layers that output sequences, the layers can output sequences of any length or output data with no time dimension. Note that when training a network that outputs sequences using the `trainNetwork` function, the lengths of the input and output sequences must match.

For the residual block layer, a forward pass of the layer is simply a forward pass of the `dlnetwork` object. To pass the input data to the `dlnetwork` object, you must first convert it to a formatted `dlarray` object.

Implement this operation in the custom layer function `predict`. To perform a forward pass of the `dlnetwork` for prediction, use the `predict` function for `dlnetwork` objects. In this case, the input to the residual block layer is used as the input to both of the unconnected inputs to the `dlnetwork` object, so the syntax for `predict` for the `dlnetwork` object is `Z = predict(dlnet,X,X)`.

Because the layers in the `dlnetwork` object do not behave differently during training and that the residual block layer does not require memory or a different forward function for training, you can remove the `forward` function from the class file.

Create the `predict` function and add a comment to the top of the function that explains the syntaxes of the function.

```
function Z = predict(layer, X)
    % Forward input data through the layer at prediction time and
    % output the result.
    %
    % Inputs:
    %         layer - Layer to forward propagate through
    %         X     - Input data
    % Outputs:
    %         Z - Output of layer forward function

    % Convert input data to formatted dlarray.
    X = dlarray(X,'SSCB');

    % Predict using network.
    dlnet = layer.Network;
    Z = predict(dlnet,X,X);

    % Strip dimension labels.
    Z = stripdims(Z);
end
```

Because the `predict` function only uses functions that support `dlarray` objects, defining the `backward` function is optional. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

Completed Layer

View the completed layer class file.

```
classdef residualBlockLayer < nnet.layer.Layer
    % Example custom residual block layer.

    properties (Learnable)
        % Layer learnable parameters

        % Residual block.
        Network
    end

    methods
        function layer = residualBlockLayer(numFilters,NameValueArgs)
            % layer = residualBlockLayer(numFilters) creates a residual
            % block layer with the specified number of filters.
```

```
%
% layer = residualBlockLayer(numFilters,Name,Value) specifies
% additional options using one or more name-value pair
% arguments:
%
%     'Stride'                - Stride of convolution operation
%                               (default 1)
%
%     'IncludeSkipConvolution' - Flag to include convolution in
%                               skip connection
%                               (default false)
%
%     'Name'                  - Layer name
%                               (default '')

% Parse input arguments.
arguments
    numFilters
    NameValueArgs.Stride = 1
    NameValueArgs.IncludeSkipConvolution = false
    NameValueArgs.Name = ''
end

stride = NameValueArgs.Stride;
includeSkipConvolution = NameValueArgs.IncludeSkipConvolution;
name = NameValueArgs.Name;

% Set layer name.
layer.Name = name;

% Set layer description.
description = "Residual block with " + numFilters + " filters, stride " + stride;
if includeSkipConvolution
    description = description + ", and skip convolution";
end
layer.Description = description;

% Set layer type.
layer.Type = "Residual Block";

% Define nested layer graph.
layers = [
    convolution2dLayer(3,numFilters,'Padding','same','Stride',stride,'Name','conv1')
    groupNormalizationLayer('all-channels','Name','gn1')
    reluLayer('Name','relu1')
    convolution2dLayer(3,numFilters,'Padding','same','Name','conv2')
    groupNormalizationLayer('channel-wise','Name','gn2')

    additionLayer(2,'Name','add')
    reluLayer('Name','relu2')];

lgraph = layerGraph(layers);

% Add skip connection.
if includeSkipConvolution
    layers = [
        convolution2dLayer(1,numFilters,'Stride',stride,'Name','convSkip')
        groupNormalizationLayer('all-channels','Name','gnSkip')];
```

```
                lgraph = addLayers(lgraph,layers);
                lgraph = connectLayers(lgraph,'gnSkip','add/in2');
            end

            % Convert to dlnetwork.
            dlnet = dlnetwork(lgraph,'Initialize',false);

            % Set Network property.
            layer.Network = dlnet;
        end

        function Z = predict(layer, X)
            % Forward input data through the layer at prediction time and
            % output the result.
            %
            % Inputs:
            %         layer - Layer to forward propagate through
            %         X     - Input data
            % Outputs:
            %         Z - Output of layer forward function

            % Convert input data to formatted dlarray.
            X = dlarray(X,'SSCB');

            % Predict using network.
            dlnet = layer.Network;
            Z = predict(dlnet,X,X);

            % Strip dimension labels.
            Z = stripdims(Z);
        end
    end
end
```

GPU Compatibility

If the layer forward functions fully support `dlarray` objects, then the layer is GPU compatible. Otherwise, to be GPU compatible, the layer functions must support inputs and return outputs of type `gpuArray`.

Many MATLAB built-in functions support `gpuArray` and `dlarray` input arguments. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. For a list of functions that execute on a GPU, see “Run MATLAB Functions on a GPU” (Parallel Computing Toolbox). To use a GPU for deep learning, you must also have a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). For more information on working with GPUs in MATLAB, see “GPU Computing in MATLAB” (Parallel Computing Toolbox).

In this example, the MATLAB functions used in `predict` all support `dlarray` objects, so the layer is GPU compatible.

Check Validity of Layer Using checkLayer

Check the layer validity of the custom layer `residualBlockLayer` using the `checkLayer` function.

Create an instance of a residual block layer. To access this layer, open this example as a live script.

```
numFilters = 64;

layer = residualBlockLayer(numFilters)
```

```
layer =
  residualBlockLayer with properties:

       Name: ''

   Learnable Parameters
    Network: [1x1 dlnetwork]

   State Parameters
    No properties.

  Show all properties
```

Check the layer validity using the `checkLayer` function. The layer expects 4-D array inputs, where the first three dimensions correspond to the height, width, and number of channels of the previous layer output, and the fourth dimension corresponds to the observations. Specify a typical input size and set the `'ObservationDimension'` option to 4.

```
validInputSize = [56 56 64];
checkLayer(layer,validInputSize,'ObservationDimension',4)
```

```
Skipping GPU tests. No compatible GPU device found.

Skipping code generation compatibility tests. To check validity of the layer for code generation

Running nnet.checklayer.TestLayerWithoutBackward
.......... ........
Done nnet.checklayer.TestLayerWithoutBackward
__________

Test Summary:
     18 Passed, 0 Failed, 0 Incomplete, 10 Skipped.
     Time elapsed: 7.1651 seconds.
```

The function does not detect any issues with the layer.

Train Deep Learning Network with Nested Layers

This example shows how to train a network with nested layers.

To create a custom layer that itself defines a layer graph, you can specify a `dlnetwork` object as a learnable parameter. This method is known as *network composition*. You can use network composition to:

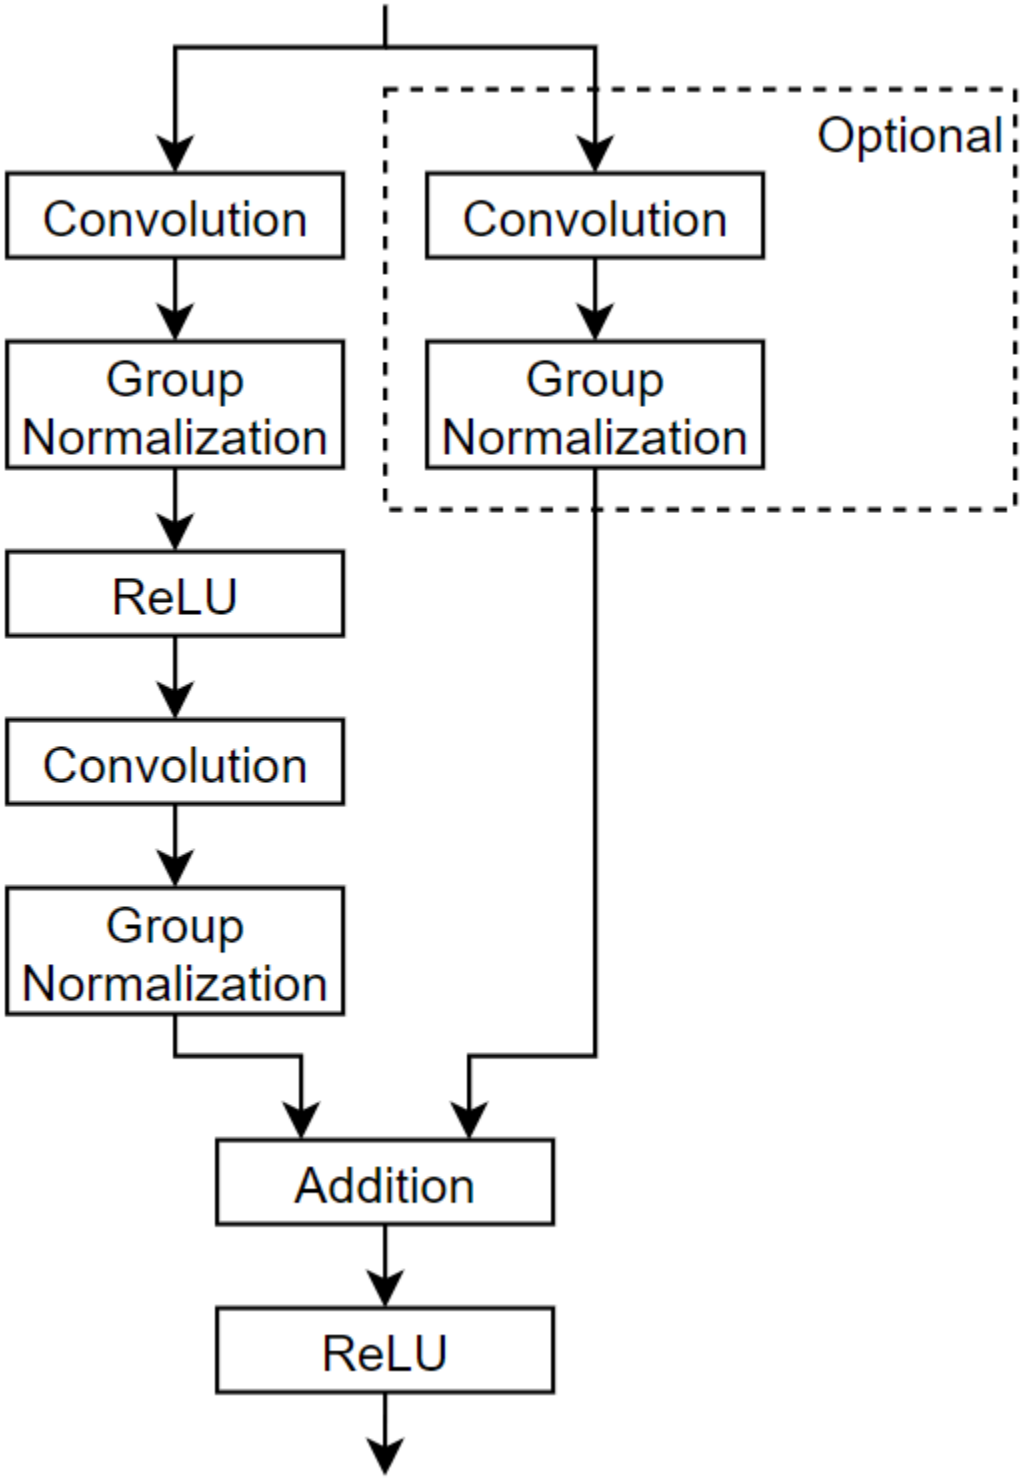
- Create a single custom layer that represents a block of learnable layers, for example, a residual block.
- Create a network with control flow. For example, a network with a section that can dynamically change depending on the input data.
- Create a network with loops. For example, a network with sections that feed the output back into itself.

For more information, see “Deep Learning Network Composition” on page 18-117.

This example shows how to train a network using custom layers representing residual blocks, each containing multiple convolution, group normalization, and ReLU layers with a skip connection. For an example showing how to create a residual network *without* using custom layers, see “Train Residual Network for Image Classification” on page 3-13.

Residual connections are a popular element in convolutional neural network architectures. A residual network is a type of network that has residual (or shortcut) connections that bypass the main network layers. Using residual connections improves gradient flow through the network and enables the training of deeper networks. This increased network depth can yield higher accuracies on more difficult tasks.

This example uses the custom layer `residualBlockLayer`, which contains a learnable block of layers consisting of convolution, group normalization, ReLU, and addition layers, and also includes a skip connection and an optional convolution layer and group normalization layer in the skip connection. This diagram highlights the residual block structure.



For an example showing how to create the custom layer `residualBlockLayer`, see “Define Nested Deep Learning Layer” on page 18-120.

Prepare Data

Download and extract the Flowers data set [1].

```
url = 'http://download.tensorflow.org/example_images/flower_photos.tgz';
downloadFolder = tempdir;
filename = fullfile(downloadFolder,'flower_dataset.tgz');

imageFolder = fullfile(downloadFolder,'flower_photos');
if ~exist(imageFolder,'dir')
    disp('Downloading Flowers data set (218 MB)...')
    websave(filename,url);
    untar(filename,downloadFolder)
end
```

Create an image datastore containing the photos.

```
datasetFolder = fullfile(imageFolder);
imds = imageDatastore(datasetFolder, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

Partition the data into training and validation data sets. Use 70% of the images for training and 30% for validation.

```
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.7,'randomized');
```

View the number of classes of the data set.

```
classes = categories(imds.Labels);
numClasses = numel(classes)
```

```
numClasses = 5
```

Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images. Resize and augment the images for training using an `imageDataAugmenter` object:

- Randomly reflect the images in the vertical axis.
- Randomly translate the images up to 30 pixels vertically and horizontally.
- Randomly rotate the images up to 45 degrees clockwise and counterclockwise.
- Randomly scale the images up to 10% vertically and horizontally.

```
pixelRange = [-30 30];
scaleRange = [0.9 1.1];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange, ...
    'RandRotation',[-45 45], ...
    'RandXScale',scaleRange, ...
    'RandYScale',scaleRange);
```

Create an augmented image datastore containing the training data using the image data augmenter. To automatically resize the images to the network input size, specify the height and width of the input size of the network. This example uses a network with input size `[224 224 3]`.

```
inputSize = [224 224 3];
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain,'DataAugmentation',imageAugmente
```

To automatically resize the validation images without performing further data augmentation, use an augmented image datastore without specifying any additional preprocessing operations.

```
augimdsValidation = augmentedImageDatastore([224 224],imdsValidation);
```

Define Network Architecture

Define a residual network with six residual blocks using the custom layer `residualBlockLayer`. To access this layer, open the example as a live script. For an example showing how to create this custom layer, see “Define Nested Deep Learning Layer” on page 18-120.

Because you must specify the input size of the input layer of the `dlnetwork` object, you must specify the input size when creating the layer. To help determine the input size to the layer, you can use the `analyzeNetwork` function and check the size of the activations of the previous layer.

```
numFilters = 32;

layers = [
    imageInputLayer(inputSize)
    convolution2dLayer(7,numFilters,'Stride',2,'Padding','same')
    groupNormalizationLayer('all-channels')
    reluLayer
    maxPooling2dLayer(3,'Stride',2)
    residualBlockLayer(numFilters)
    residualBlockLayer(numFilters)
    residualBlockLayer(2*numFilters,'Stride',2,'IncludeSkipConvolution',true)
    residualBlockLayer(2*numFilters)
    residualBlockLayer(4*numFilters,'Stride',2,'IncludeSkipConvolution',true)
    residualBlockLayer(4*numFilters)
    globalAveragePooling2dLayer
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer]
```

```
layers =
  15×1 Layer array with layers:

     1   ''   Image Input              224×224×3 images with 'zerocenter' normalization
     2   ''   Convolution              32 7×7 convolutions with stride [2  2] and padding 'same'
     3   ''   Group Normalization      Group normalization
     4   ''   ReLU                     ReLU
     5   ''   Max Pooling              3×3 max pooling with stride [2  2] and padding [0  0  0  0
     6   ''   Residual Block           Residual block with 32 filters, stride 1
     7   ''   Residual Block           Residual block with 32 filters, stride 1
     8   ''   Residual Block           Residual block with 64 filters, stride 2, and skip convolu
     9   ''   Residual Block           Residual block with 64 filters, stride 1
    10   ''   Residual Block           Residual block with 128 filters, stride 2, and skip convo
    11   ''   Residual Block           Residual block with 128 filters, stride 1
    12   ''   Global Average Pooling   Global average pooling
    13   ''   Fully Connected          5 fully connected layer
    14   ''   Softmax                  softmax
    15   ''   Classification Output    crossentropyex
```

Train Network

Specify training options:

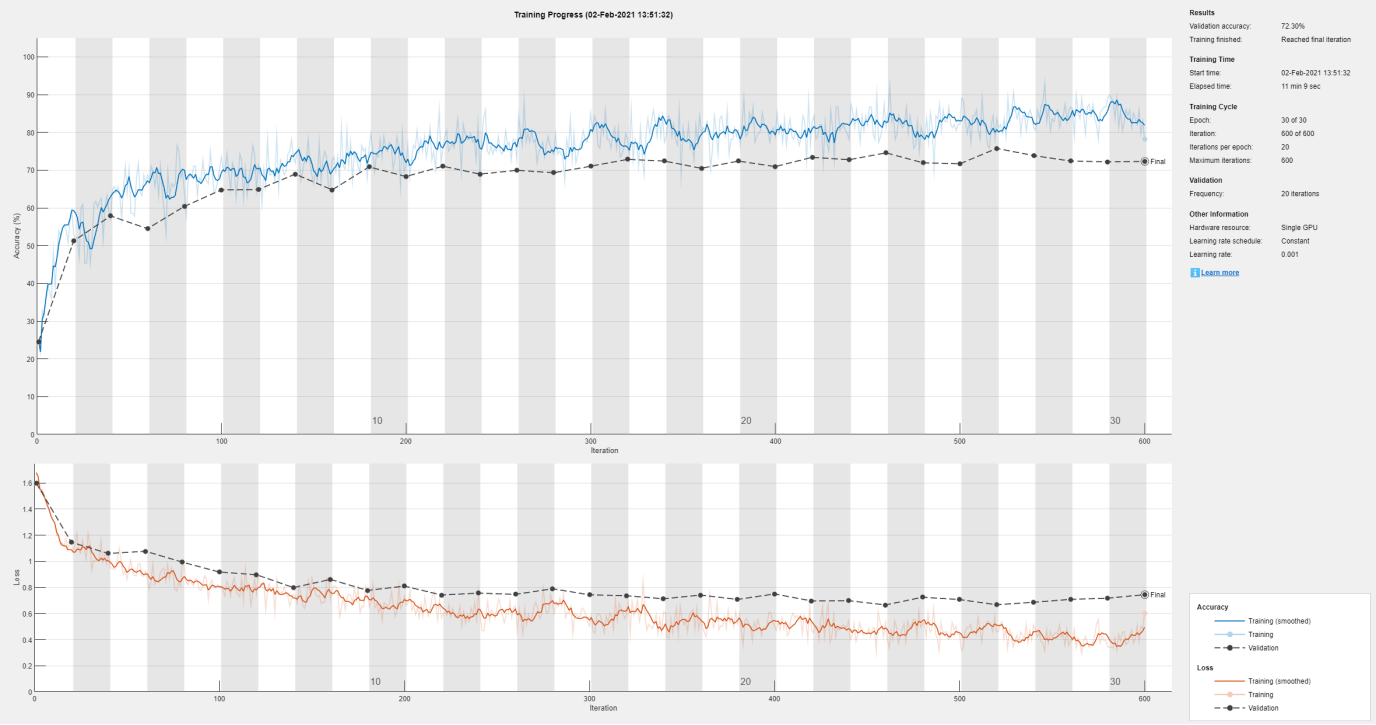
- Train the network with a mini-batch size of 128.
- Shuffle the data every epoch.
- Validate the network once per epoch using the validation data.
- Display the training progress in a plot and disable the verbose output.

```
miniBatchSize = 128;
numIterationsPerEpoch = floor(augimdsTrain.NumObservations/miniBatchSize);

options = trainingOptions('adam', ...
    'MiniBatchSize',miniBatchSize, ...
    'Shuffle','every-epoch', ...
    'ValidationData',augimdsValidation, ...
    'ValidationFrequency',numIterationsPerEpoch, ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the network using the `trainNetwork` function. By default, `trainNetwork` uses a GPU if one is available, otherwise, it uses a CPU. Training on a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`.

```
net = trainNetwork(augimdsTrain,layers,options);
```



Evaluate Trained Network

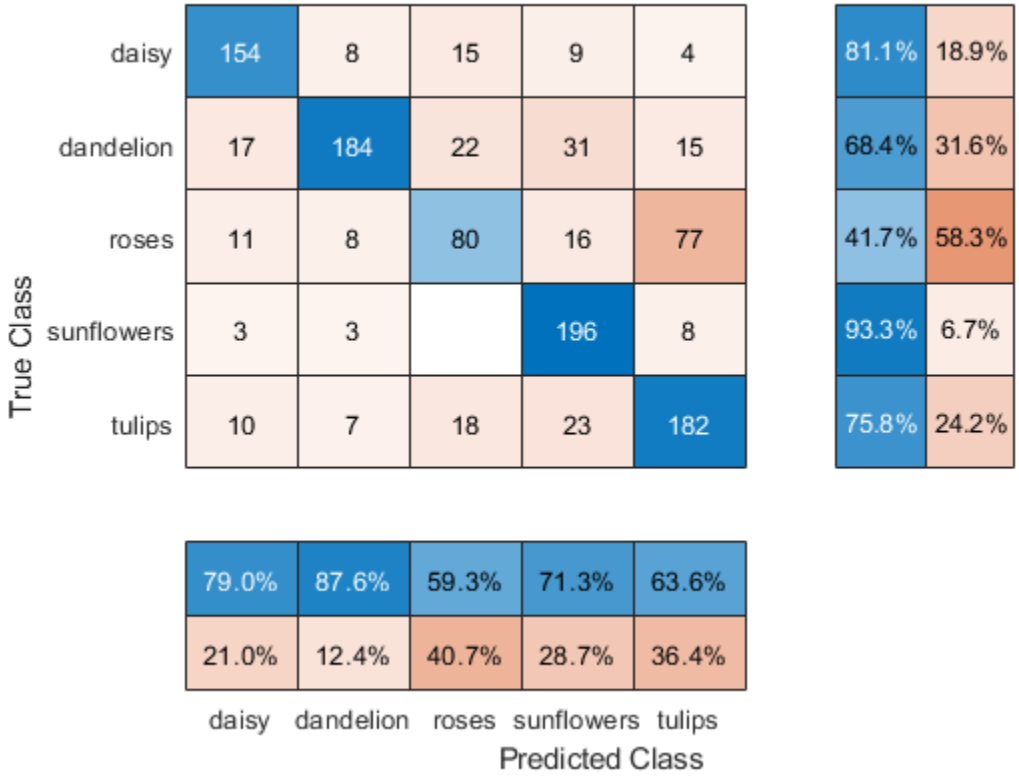
Calculate the final accuracy of the network on the training set (without data augmentation) and validation set. The accuracy is the proportion of images that the network classifies correctly.

```
YPred = classify(net,augimdsValidation);
YValidation = imdsValidation.Labels;
accuracy = mean(YPred == YValidation)
```

```
accuracy = 0.7230
```

Visualize the classification accuracy in a confusion matrix. Display the precision and recall for each class by using column and row summaries.

```
figure
confusionchart(YValidation,YPred, ...
    'RowSummary','row-normalized', ...
    'ColumnSummary','column-normalized');
```



You can display four sample validation images with predicted labels and the predicted probabilities of the images having those labels using the following code.

```
idx = randperm(numel(imdsValidation.Files),4);
figure
for i = 1:4
    subplot(2,2,i)
    I = readimage(imdsValidation,idx(i));
    imshow(I)
    label = YPred(idx(i));
    title("Predicted class: " + string(label));
end
```

Define Custom Deep Learning Layer for Code Generation

If Deep Learning Toolbox does not provide the layer you require for your classification or regression problem, then you can define your own custom layer using this example as a guide. For a list of built-in layers, see “List of Deep Learning Layers” on page 1-21.

To define a custom deep learning layer, you can use the template provided in this example, which takes you through the following steps:

1. Name the layer — Give the layer a name so that you can use it in MATLAB.
2. Declare the layer properties — Specify the properties of the layer including learnable parameters and state parameters.
3. Create a constructor function (optional) — Specify how to construct the layer and initialize its properties. If you do not specify a constructor function, then at creation, the software initializes the `Name`, `Description`, and `Type` properties with `[]` and sets the number of layer inputs and outputs to 1.
4. Create forward functions — Specify how data passes forward through the layer (forward propagation) at prediction time and at training time.
5. Create reset state function (optional) — Specify how to reset state parameters.
6. Create a backward function (optional) — Specify the derivatives of the loss with respect to the input data and the learnable parameters (backward propagation). If you do not specify a backward function, then the forward functions must support `dlarray` objects.

To create a custom layer that supports code generation:

- The layer must specify the pragma `%#codegen` in the layer definition.
- The inputs of `predict` must be:
  - Consistent in dimension. Each input must have the same number of dimensions.
  - Consistent in batch size. Each input must have the same batch size.
- The outputs of `predict` must be consistent in dimension and batch size with the layer inputs.
- Nonscalar properties must have type single, double, or character array.
- Scalar properties must have type numeric, logical, or string.

Code generation supports intermediate layers with 2-D image or feature input only. Code generation does not support layers with state properties (properties with attribute `State`).

This example shows how to create a PReLU layer [1], which is a layer with a learnable parameter, and use it in a convolutional neural network. A PReLU layer performs a threshold operation, where for each channel, any input value less than zero is multiplied by a scalar learned at training time. For values less than zero, a PReLU layer applies scaling coefficients α_i to each channel of the input. These coefficients form a learnable parameter, which the layer learns during training.

This figure from [1] compares the ReLU and PReLU layer functions.

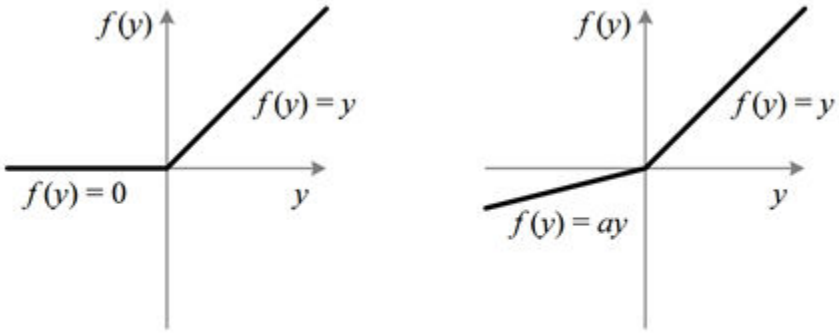

Figure 1. ReLU vs. PReLU. For PReLU, the coefficient of the negative part is not constant and is adaptively learned.

Intermediate Layer Template

Copy the intermediate layer template into a new file in MATLAB. This template outlines the structure of an intermediate layer class definition. It outlines:

- The optional `properties` blocks for the layer properties, learnable parameters, and state parameters.
- The layer constructor function.
- The `predict` function and the optional `forward` function.
- The optional `resetState` function for layers with state properties.
- The optional `backward` function.

```
classdef myLayer < nnet.layer.Layer % & nnet.layer.Formattable (Optional)

    properties
        % (Optional) Layer properties.

        % Declare layer properties here.
    end

    properties (Learnable)
        % (Optional) Layer learnable parameters.

        % Declare learnable parameters here.
    end

    properties (State)
        % (Optional) Layer state parameters.

        % Declare state parameters here.
    end

    properties (Learnable, State)
        % (Optional) Nested dlnetwork objects with both learnable
        % parameters and state.

        % Declare nested networks with learnable and state parameters here.
    end

    methods
        function layer = myLayer()
            % (Optional) Create a myLayer.
            % This function must have the same name as the class.
```

```
    % Define layer constructor function here.
end

function [Z,state] = predict(layer,X)
    % Forward input data through the layer at prediction time and
    % output the result and updated state.
    %
    % Inputs:
    %         layer - Layer to forward propagate through
    %         X     - Input data
    % Outputs:
    %         Z     - Output of layer forward function
    %         state - (Optional) Updated layer state.
    %
    %  - For layers with multiple inputs, replace X with X1,...,XN,
    %    where N is the number of inputs.
    %  - For layers with multiple outputs, replace Z with
    %    Z1,...,ZM, where M is the number of outputs.
    %  - For layers with multiple state parameters, replace state
    %    with state1,...,stateK, where K is the number of state
    %    parameters.

    % Define layer predict function here.
end

function [Z,state,memory] = forward(layer,X)
    % (Optional) Forward input data through the layer at training
    % time and output the result, updated state, and a memory
    % value.
    %
    % Inputs:
    %         layer - Layer to forward propagate through
    %         X     - Layer input data
    % Outputs:
    %         Z      - Output of layer forward function
    %         state  - (Optional) Updated layer state
    %         memory - (Optional) Memory value for custom backward
    %                  function
    %
    %  - For layers with multiple inputs, replace X with X1,...,XN,
    %    where N is the number of inputs.
    %  - For layers with multiple outputs, replace Z with
    %    Z1,...,ZM, where M is the number of outputs.
    %  - For layers with multiple state parameters, replace state
    %    with state1,...,stateK, where K is the number of state
    %    parameters.

    % Define layer forward function here.
end

function layer = resetState(layer)
    % (Optional) Reset layer state.

    % Define reset state function here.
end

function [dLdX,dLdW,dLdSin] = backward(layer,X,Z,dLdZ,dLdSout,memory)
    % (Optional) Backward propagate the derivative of the loss
    % function through the layer.
    %
    % Inputs:
    %         layer   - Layer to backward propagate through
    %         X       - Layer input data
    %         Z       - Layer output data
    %         dLdZ    - Derivative of loss with respect to layer
    %                   output
    %         dLdSout - (Optional) Derivative of loss with respect
    %                   to state output
    %         memory  - Memory value from forward function
    % Outputs:
    %         dLdX   - Derivative of loss with respect to layer input
```

```
            %         dLdW   - (Optional) Derivative of loss with respect to
            %                  learnable parameter
            %         dLdSin - (Optional) Derivative of loss with respect to
            %                  state input
            %
            %  - For layers with state parameters, the backward syntax must
            %    include both dLdSout and dLdSin, or neither.
            %  - For layers with multiple inputs, replace X and dLdX with
            %    X1,...,XN and dLdX1,...,dLdXN, respectively, where N is
            %    the number of inputs.
            %  - For layers with multiple outputs, replace Z and dlZ with
            %    Z1,...,ZM and dLdZ,...,dLdZM, respectively, where M is the
            %    number of outputs.
            %  - For layers with multiple learnable parameters, replace
            %    dLdW with dLdW1,...,dLdWP, where P is the number of
            %    learnable parameters.
            %  - For layers with multiple state parameters, replace dLdSin
            %    and dLdSout with dLdSin1,...,dLdSinK and
            %    dLdSout1,...dldSoutK, respectively, where K is the number
            %    of state parameters.

            % Define layer backward function here.
        end
    end
end
```

Name Layer and Specify Superclasses

First, give the layer a name. In the first line of the class file, replace the existing name `myLayer` with `codegenPreluLayer` and add a comment describing the layer.

```
classdef codegenPreluLayer < nnet.layer.Layer & nnet.layer.Formattable
    % Example custom PReLU layer with codegen support.

    ...
end
```

If you do not specify a backward function, then the layer functions, by default, receive *unformatted* `dlarray` objects as input. To specify that the layer receives *formatted* `dlarray` objects as input and also outputs formatted `dlarray` objects, also inherit from the `nnet.layer.Formattable` class when defining the custom layer.

The layer does not require formattable inputs, so remove the optional `nnet.layer.Formattable` superclass.

```
classdef codegenPreluLayer < nnet.layer.Layer
    % Example custom PReLU layer with codegen support.

    ...
end
```

Next, rename the `myLayer` constructor function (the first function in the `methods` section) so that it has the same name as the layer.

```
    methods
        function layer = codegenPreluLayer()
            ...
        end

        ...
     end
```

Save Layer

Save the layer class file in a new file named `codegenPreluLayer.m`. The file name must match the layer name. To use the layer, you must save the file in the current folder or in a folder on the MATLAB path.

Specify Code Generation Pragma

Add the `%#codegen` directive (or pragma) to your layer definition to indicate that you intend to generate code for this layer. Adding this directive instructs the MATLAB Code Analyzer to help you diagnose and fix violations that result in errors during code generation.

```
classdef codegenPreluLayer < nnet.layer.Layer
    % Example custom PReLU layer with codegen support.

    %#codegen

    ...
end
```

Declare Properties and Learnable Parameters

Declare the layer properties in the `properties` section and declare learnable parameters by listing them in the `properties (Learnable)` section.

By default, custom intermediate layers have these properties. Do not declare these properties in the `properties` section.

Property	Description
`Name`	Layer name, specified as a character vector or a string scalar. For `Layer` array input, the `trainNetwork`, `assembleNetwork`, `layerGraph`, and `dlnetwork` functions automatically assign names to layers with `Name` set to `''`.
`Description`	One-line description of the layer, specified as a string scalar or a character vector. This description appears when the layer is displayed in a `Layer` array. If you do not specify a layer description, then the software displays the layer class name.
`Type`	Type of the layer, specified as a character vector or a string scalar. The value of `Type` appears when the layer is displayed in a `Layer` array. If you do not specify a layer type, then the software displays the layer class name.

Property	Description
`NumInputs`	Number of inputs of the layer, specified as a positive integer. If you do not specify this value, then the software automatically sets `NumInputs` to the number of names in `InputNames`. The default value is 1.
`InputNames`	Input names of the layer, specified as a cell array of character vectors. If you do not specify this value and `NumInputs` is greater than 1, then the software automatically sets `InputNames` to `{'in1',...,'inN'}`, where `N` is equal to `NumInputs`. The default value is `{'in'}`.
`NumOutputs`	Number of outputs of the layer, specified as a positive integer. If you do not specify this value, then the software automatically sets `NumOutputs` to the number of names in `OutputNames`. The default value is 1.
`OutputNames`	Output names of the layer, specified as a cell array of character vectors. If you do not specify this value and `NumOutputs` is greater than 1, then the software automatically sets `OutputNames` to `{'out1',...,'outM'}`, where `M` is equal to `NumOutputs`. The default value is `{'out'}`.

If the layer has no other properties, then you can omit the `properties` section.

Tip If you are creating a layer with multiple inputs, then you must set either the `NumInputs` or `InputNames` properties in the layer constructor. If you are creating a layer with multiple outputs, then you must set either the `NumOutputs` or `OutputNames` properties in the layer constructor. For an example, see “Define Custom Deep Learning Layer with Multiple Inputs” on page 18-48.

To support code generation:

- Nonscalar properties must have type single, double, or character array.
- Scalar properties must be numeric or have type logical or string.

A PReLU layer does not require any additional properties, so you can remove the `properties` section.

A PReLU layer has only one learnable parameter, the scaling coefficient a. Declare this learnable parameter in the `properties (Learnable)` section and call the parameter `Alpha`.

```
properties (Learnable)
    % Layer learnable parameters

    % Scaling coefficient
    Alpha
end
```

Create Constructor Function

Create the function that constructs the layer and initializes the layer properties. Specify any variables required to create the layer as inputs to the constructor function.

The PReLU layer constructor function requires two input arguments: the number of channels of the expected input data and the layer name. The number of channels specifies the size of the learnable parameter `Alpha`. Specify two input arguments named `numChannels` and `name` in the `codegenPreluLayer` function. Add a comment to the top of the function that explains the syntax of the function.

```
function layer = codegenPreluLayer(numChannels, name)
    % layer = codegenPreluLayer(numChannels) creates a PReLU layer with
    % numChannels channels and specifies the layer name.

    ...
end
```

Code generation does not support `arguments` blocks.

Initialize Layer Properties

Initialize the layer properties, including learnable parameters, in the constructor function. Replace the comment `% Layer constructor function goes here` with code that initializes the layer properties.

Set the `Name` property to the input argument `name`.

```
% Set layer name.
layer.Name = name;
```

Give the layer a one-line description by setting the `Description` property of the layer. Set the description to describe the type of layer and its size.

```
% Set layer description.
layer.Description = "PReLU with " + numChannels + " channels";
```

For a PReLU layer, when the input values are negative, the layer multiplies each channel of the input by the corresponding channel of `Alpha`. Initialize the learnable parameter `Alpha` as a random vector of size 1-by-1-by-`numChannels`. With the third dimension specified as size `numChannels`, the layer can use element-wise multiplication of the input in the forward function. `Alpha` is a property of the layer object, so you must assign the vector to `layer.Alpha`.

```
% Initialize scaling coefficient.
layer.Alpha = rand([1 1 numChannels]);
```

View the completed constructor function.

```
function layer = codegenPreluLayer(numChannels, name)
    % layer = codegenPreluLayer(numChannels, name) creates a PReLU
    % layer for 2-D image input with numChannels channels and specifies
    % the layer name.

    % Set layer name.
    layer.Name = name;

    % Set layer description.
    layer.Description = "PReLU with " + numChannels + " channels";
```

```
        % Initialize scaling coefficient.
        layer.Alpha = rand([1 1 numChannels]);
    end
```

With this constructor function, the command `codegenPreluLayer(3,'prelu')` creates a PReLU layer with three channels and the name `'prelu'`.

Create Forward Functions

Create the layer forward functions to use at prediction time and training time.

Create a function named `predict` that propagates the data forward through the layer at *prediction time* and outputs the result.

The `predict` function syntax depends on the type of layer.

- `Z = predict(layer,X)` forwards the input data `X` through the layer and outputs the result `Z`, where `layer` has a single input, a single output.
- `[Z,state] = predict(layer,X)` also outputs the updated state parameter `state`, where `layer` has a single state parameter.

You can adjust the syntaxes for layers with multiple inputs, multiple outputs, or multiple state parameters:

- For layers with multiple inputs, replace `X` with `X1,...,XN`, where `N` is the number of inputs. The `NumInputs` property must match `N`.
- For layers with multiple outputs, replace `Z` with `Z1,...,ZM`, where `M` is the number of outputs. The `NumOutputs` property must match `M`.
- For layers with multiple state parameters, replace `state` with `state1,...,stateK`, where `K` is the number of state parameters.

Tip If the number of inputs to the layer can vary, then use `varargin` instead of `X1,…,XN`. In this case, `varargin` is a cell array of the inputs, where `varargin{i}` corresponds to `Xi`.

If the number of outputs can vary, then use `varargout` instead of `Z1,…,ZN`. In this case, `varargout` is a cell array of the outputs, where `varargout{j}` corresponds to `Zj`.

Because a PReLU layer has only one input and one output, the syntax for `predict` for a PReLU layer is `Z = predict(layer,X)`.

Code generation supports custom intermediate layers with 2-D image input only. The inputs are *h*-by-*w*-by-*c*-by-*N* arrays, where *h*, *w*, and *c* correspond to the height, width, and number of channels of the images, respectively, and *N* is the number of observations. The observation dimension is 4.

For code generation support, all the layer inputs must have the same number of dimensions and batch size.

By default, the layer uses `predict` as the forward function at training time. To use a different forward function at training time, or retain a value required for a custom backward function, you must also create a function named `forward`. The software does not generate code for the `forward` function but it must be code generation compatible.

The `forward` function propagates the data forward through the layer at *training time* and also outputs a memory value.

The `forward` function syntax depends on the type of layer:

- `Z = forward(layer,X)` forwards the input data `X` through the layer and outputs the result `Z`, where `layer` has a single input, a single output.
- `[Z,state] = forward(layer,X)` also outputs the updated state parameter `state`, where `layer` has a single state parameter.
- `[__,memory] = forward(layer,X)` also returns a memory value for a custom `backward` function using any of the previous syntaxes. If the layer has both a custom `forward` function and a custom `backward` function, then the forward function must return a memory value.

You can adjust the syntaxes for layers with multiple inputs, multiple outputs, or multiple state parameters:

- For layers with multiple inputs, replace `X` with `X1,...,XN`, where `N` is the number of inputs. The `NumInputs` property must match `N`.
- For layers with multiple outputs, replace `Z` with `Z1,...,ZM`, where `M` is the number of outputs. The `NumOutputs` property must match `M`.
- For layers with multiple state parameters, replace `state` with `state1,...,stateK`, where `K` is the number of state parameters.

Tip If the number of inputs to the layer can vary, then use `varargin` instead of `X1,…,XN`. In this case, `varargin` is a cell array of the inputs, where `varargin{i}` corresponds to `Xi`.

If the number of outputs can vary, then use `varargout` instead of `Z1,…,ZN`. In this case, `varargout` is a cell array of the outputs, where `varargout{j}` corresponds to `Zj`.

The PReLU operation is given by

$$f(x_i) = \begin{cases} x_i & \text{if } x_i > 0 \\ \alpha_i x_i & \text{if } x_i \le 0 \end{cases}$$

where x_i is the input of the nonlinear activation f on channel i, and α_i is the coefficient controlling the slope of the negative part. The subscript i in α_i indicates that the nonlinear activation can vary on different channels.

Implement this operation in `predict`. In `predict`, the input `X` corresponds to x in the equation. The output `Z` corresponds to $f(x_i)$.

Add a comment to the top of the function that explains the syntaxes of the function.

Tip If you preallocate arrays using functions such as `zeros`, then you must ensure that the data types of these arrays are consistent with the layer function inputs. To create an array of zeros of the same data type as another array, use the `"like"` option of `zeros`. For example, to initialize an array of zeros of size `sz` with the same data type as the array `X`, use `Z = zeros(sz,"like",X)`.

Implementing the `backward` function is optional when the forward functions fully support `dlarray` input. For code generation support, the `predict` function must also support numeric input.

One way to calculate the output of the PReLU operation is to use the following code.

```
Z = max(X,0) + layer.Alpha .* min(0,X);
```

Because code generation does not support implicit expansion via the `.*` operation, you can use the `bsxfun` function instead.

```
Z = max(X,0) + bsxfun(@times, layer.Alpha, min(0,X));
```

However, the `bsxfun` does not support `dlarray` input. To implement the `predict` function, which supports both code generation and `dlarray` input, use an `if` statement with the `isdlarray` function to select the appropriate code for the type of input.

```
        function Z = predict(layer, X)
            % Z = predict(layer, X) forwards the input data X through the
            % layer and outputs the result Z.

            if isdlarray(X)
                Z = max(X,0) + layer.Alpha .* min(0,X);
            else
                Z = max(X,0) + bsxfun(@times, layer.Alpha, min(0,X));
            end
        end
```

Because the `predict` function fully supports `dlarray` objects, defining the `backward` function is optional. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

            end
        end
    end
end
```

Check Custom Layer for Code Generation Compatibility

Check the code generation compatibility of the custom layer `codegenPreluLayer`.

The custom layer `codegenPreluLayer`, attached to this is example as a supporting file, applies the PReLU operation to the input data. To access this layer, open this example as a live script.

Create an instance of the layer and check its validity using `checkLayer`. Specify the valid input size as the size of a single observation of typical input to the layer. The layer expects 4-D array inputs, where the first three dimensions correspond to the height, width, and number of channels of the previous layer output, and the fourth dimension corresponds to the observations.

Specify the typical size of the input of an observation and set the `'ObservationDimension'` option to 4. To check for code generation compatibility, set the `CheckCodegenCompatibility` option to `true`. The `checkLayer` function does not check for functions that are not compatible with code generation. To check that the custom layer definition is supported for code generation, first use the **Code Generation Readiness** app. For more information, see “Check Code by Using the Code Generation Readiness Tool” (MATLAB Coder).

```
layer = codegenPreluLayer(20,"prelu");
validInputSize = [24 24 20];
checkLayer(layer,validInputSize,ObservationDimension=4,CheckCodegenCompatibility=true)
```

```
Skipping GPU tests. No compatible GPU device found.

Running nnet.checklayer.TestLayerWithoutBackward
.......... .......... ...
Done nnet.checklayer.TestLayerWithoutBackward
__________

Test Summary:
     23 Passed, 0 Failed, 0 Incomplete, 5 Skipped.
     Time elapsed: 1.0234 seconds.
```

The function does not detect any issues with the layer.

Check Custom Layer Validity

If you create a custom deep learning layer, then you can use the `checkLayer` function to check that the layer is valid. The function checks layers for validity, GPU compatibility, correctly defined gradients, and code generation compatibility. To check that a layer is valid, run the following command:

```
checkLayer(layer,validInputSize)
```

where `layer` is an instance of the layer, `validInputSize` is a vector or cell array specifying the valid input sizes to the layer. To check with multiple observations, use the `ObservationDimension` option. To check for code generation compatibility, set the `CheckCodegenCompatibility` option to `1` (true). For large input sizes, the gradient checks take longer to run. To speed up the tests, specify a smaller valid input size.

Check Custom Layer Validity

Check the validity of the example custom layer `preluLayer`.

The custom layer `preluLayer`, attached to this is example as a supporting file, applies the PReLU operation to the input data. To access this layer, open this example as a live script.

Create an instance of the layer and check that it is valid using `checkLayer`. Set the valid input size to the typical size of a single observation input to the layer. For a single input, the layer expects observations of size *h*-by-*w*-by-*c*, where *h*, *w*, and *c* are the height, width, and number of channels of the previous layer output, respectively.

Specify `validInputSize` as the typical size of an input array.

```
layer = preluLayer(20);
validInputSize = [5 5 20];
checkLayer(layer,validInputSize)
```

```
Skipping multi-observation tests. To enable tests with multiple observations, specify the 'Observ
For 2-D image data, set 'ObservationDimension' to 4.
For 3-D image data, set 'ObservationDimension' to 5.
For sequence data, set 'ObservationDimension' to 2.

Skipping GPU tests. No compatible GPU device found.

Skipping code generation compatibility tests. To check validity of the layer for code generation

Running nnet.checklayer.TestLayerWithoutBackward
.......... ..
Done nnet.checklayer.TestLayerWithoutBackward
__________

Test Summary:
     12 Passed, 0 Failed, 0 Incomplete, 16 Skipped.
     Time elapsed: 0.17942 seconds.
```

The results show the number of passed, failed, and skipped tests. If you do not specify the `ObservationsDimension` option, or do not have a GPU, then the function skips the corresponding tests.

Check Multiple Observations

For multi-observation input, the layer expects an array of observations of size *h*-by-*w*-by-*c*-by-*N*, where *h*, *w*, and *c* are the height, width, and number of channels, respectively, and *N* is the number of observations.

To check the layer validity for multiple observations, specify the typical size of an observation and set the `ObservationDimension` option to 4.

```
layer = preluLayer(20);
validInputSize = [5 5 20];
checkLayer(layer,validInputSize,ObservationDimension=4)
```

```
Skipping GPU tests. No compatible GPU device found.

Skipping code generation compatibility tests. To check validity of the layer for code generation

Running nnet.checklayer.TestLayerWithoutBackward
.......... ........
Done nnet.checklayer.TestLayerWithoutBackward
__________

Test Summary:
     18 Passed, 0 Failed, 0 Incomplete, 10 Skipped.
     Time elapsed: 0.077629 seconds.
```

In this case, the function does not detect any issues with the layer.

List of Tests

The `checkLayer` function checks the validity of a custom layer by performing a series of tests.

Intermediate Layers

The `checkLayer` function uses these tests to check the validity of custom intermediate layers (layers of type `nnet.layer.Layer`).

Test	Description
`functionSyntaxesAreCorrect`	The syntaxes of the layer functions are correctly defined.
`predictDoesNotError`	`predict` function does not error.
`forwardDoesNotError`	When specified, the `forward` function does not error.
`forwardPredictAreConsistentInSize`	When `forward` is specified, `forward` and `predict` output values of the same size.
`backwardDoesNotError`	When specified, `backward` does not error.

Test	Description
`backwardIsConsistentInSize`	When `backward` is specified, the outputs of `backward` are consistent in size: • The derivatives with respect to each input are the same size as the corresponding input. • The derivatives with respect to each learnable parameter are the same size as the corresponding learnable parameter.
`predictIsConsistentInType`	The outputs of `predict` are consistent in type with the inputs.
`forwardIsConsistentInType`	When `forward` is specified, the outputs of `forward` are consistent in type with the inputs.
`backwardIsConsistentInType`	When `backward` is specified, the outputs of `backward` are consistent in type with the inputs.
`gradientsAreNumericallyCorrect`	When `backward` is specified, the gradients computed in `backward` are consistent with the numerical gradients.
`backwardPropagationDoesNotError`	When `backward` is not specified, the derivatives can be computed using automatic differentiation.
`predictReturnsValidStates`	For layers with state properties, the `predict` function returns valid states.
`forwardReturnsValidStates`	For layers with state properties, the `forward` function, if specified, returns valid states.
`resetStateDoesNotError`	For layers with state properties, the `resetState` function, if specified, does not error and resets the states to valid states.
`codegenPragmaDefinedInClassDef`	The pragma `"%#codegen"` for code generation is specified in class file.
`checkForSupportedLayerPropertiesForCodegen`	The layer properties support code generation.
`predictIsValidForCodeGeneration`	`predict` is valid for code generation.
`doesNotHaveStateProperties`	For code generation, the layer does not have state properties.
`supportedFunctionLayer`	For code generation, the layer is not a `FunctionLayer` object.

Some tests run multiple times. These tests also check different data types and for GPU compatibility:

- `predictIsConsistentInType`
- `forwardIsConsistentInType`
- `backwardIsConsistentInType`

To execute the layer functions on a GPU, the functions must support inputs and outputs of type `gpuArray` with the underlying data type `single`.

Output Layers

The `checkLayer` function uses these tests to check the validity of custom output layers (layers of type `nnet.layer.ClassificationLayer` or `nnet.layer.RegressionLayer`).

Test	Description
`forwardLossDoesNotError`	`forwardLoss` does not error.
`backwardLossDoesNotError`	`backwardLoss` does not error.
`forwardLossIsScalar`	The output of `forwardLoss` is scalar.
`backwardLossIsConsistentInSize`	When `backwardLoss` is specified, the output of `backwardLoss` is consistent in size: `dLdY` is the same size as the predictions `Y`.
`forwardLossIsConsistentInType`	The output of `forwardLoss` is consistent in type: `loss` is the same type as the predictions `Y`.
`backwardLossIsConsistentInType`	When `backwardLoss` is specified, the output of `backwardLoss` is consistent in type: `dLdY` must be the same type as the predictions `Y`.
`gradientsAreNumericallyCorrect`	When `backwardLoss` is specified, the gradients computed in `backwardLoss` are numerically correct.
`backwardPropagationDoesNotError`	When `backwardLoss` is not specified, the derivatives can be computed using automatic differentiation.

The `forwardLossIsConsistentInType` and `backwardLossIsConsistentInType` tests also check for GPU compatibility. To execute the layer functions on a GPU, the functions must support inputs and outputs of type `gpuArray` with the underlying data type `single`.

Generated Data

To check the layer validity, the `checkLayer` function generates data depending on the type of layer:

Layer Type	Description of Generated Data
Intermediate	Values in the range [-1,1]
Regression output	Predictions and targets with values in the range [-1,1]
Classification output	Predictions with values in the range [0,1]. If you specify the `ObservationDimension` option, then the targets are one-hot encoded vectors (vectors containing a single 1, and 0 elsewhere). If you do not specify the `ObservationDimension` option, then the targets are values in the range [0,1].

To check for multiple observations, specify the observation dimension using the `ObservationDimension` option. If you specify the observation dimension, then the `checkLayer`

function checks that the layer functions are valid using generated data with mini-batches of size 1 and 2. If you do not specify this name-value pair, then the function skips the tests that check that the layer functions are valid for multiple observations.

Diagnostics

If a test fails when you use `checkLayer`, then the function provides a test diagnostic and a framework diagnostic. The test diagnostic highlights any issues found with the layer. The framework diagnostic provides more detailed information.

Function Syntaxes

The test `functionSyntaxesAreCorrect` checks that the layer functions have correctly defined syntaxes.

Test Diagnostic	Description	Possible Solution
`Incorrect number of input arguments for 'predict' in Layer.`	The syntax for the `predict` function is not consistent with the number of layer inputs.	Specify the correct number of input and output arguments in `predict`. The `predict` function syntax depends on the type of layer. • `Z = predict(layer,X)` forwards the input data `X` through the layer and outputs the result `Z`, where `layer` has a single input, a single output. • `[Z,state] = predict(layer,X)` also outputs the updated state parameter `state`, where `layer` has a single state parameter. You can adjust the syntaxes for layers with multiple inputs, multiple outputs, or multiple state parameters: • For layers with multiple inputs, replace `X` with `X1,...,XN`, where `N` is the number of inputs. The `NumInputs` property must match `N`. • For layers with multiple outputs, replace `Z` with `Z1,...,ZM`, where `M` is the number of outputs. The

Test Diagnostic	Description	Possible Solution
`Incorrect number of output arguments for 'predict' in Layer`	The syntax for the `predict` function is not consistent with the number of layer outputs.	`NumOutputs` property must match `M`. • For layers with multiple state parameters, replace `state` with `state1,...,stateK`, where `K` is the number of state parameters. **Tip** If the number of inputs to the layer can vary, then use `varargin` instead of `X1,…,XN`. In this case, `varargin` is a cell array of the inputs, where `varargin{i}` corresponds to `Xi`. If the number of outputs can vary, then use `varargout` instead of `Z1,…,ZN`. In this case, `varargout` is a cell array of the outputs, where `varargout{j}` corresponds to `Zj`. **Tip** If the custom layer has a `dlnetwork` object for a learnable parameter, then in the `predict` function of the custom layer, use the `predict` function for the `dlnetwork`. Using the `dlnetwork` object `predict` function ensures that the software uses the correct layer operations for prediction.
`Incorrect number of input arguments for 'forward' in Layer`	The syntax for the optional `forward` function is not consistent with the number of layer inputs.	Specify the correct number of input and output arguments in `forward`. The `forward` function syntax depends on the type of layer: • `Z = forward(layer,X)` forwards the input data `X` through the layer and outputs the result `Z`, where `layer` has a single input, a single output. • `[Z,state] = forward(layer,X)` also

Test Diagnostic	Description	Possible Solution
`Incorrect number of output arguments for 'forward' in Layer`	The syntax for the optional `forward` function is not consistent with the number of layer outputs.	outputs the updated state parameter `state`, where `layer` has a single state parameter. • `[__,memory] = forward(layer,X)` also returns a memory value for a custom `backward` function using any of the previous syntaxes. If the layer has both a custom `forward` function and a custom `backward` function, then the forward function must return a memory value. You can adjust the syntaxes for layers with multiple inputs, multiple outputs, or multiple state parameters: • For layers with multiple inputs, replace `X` with `X1,...,XN`, where `N` is the number of inputs. The `NumInputs` property must match `N`. • For layers with multiple outputs, replace `Z` with `Z1,...,ZM`, where `M` is the number of outputs. The `NumOutputs` property must match `M`. • For layers with multiple state parameters, replace `state` with `state1,...,stateK`, where `K` is the number of state parameters. **Tip** If the number of inputs to the layer can vary, then use `varargin` instead of `X1,…,XN`. In this case, `varargin` is a cell array of the inputs, where `varargin{i}` corresponds to `Xi`. If the number of outputs can vary, then use `varargout` instead of `Z1,…,ZN`. In this

Test Diagnostic	Description	Possible Solution
		case, `varargout` is a cell array of the outputs, where `varargout{j}` corresponds to `Zj`. **Tip** If the custom layer has a `dlnetwork` object for a learnable parameter, then in the `forward` function of the custom layer, use the `forward` function of the `dlnetwork` object. Using the `dlnetwork` object `forward` function ensures that the software uses the correct layer operations for training.
`Incorrect number of input arguments for 'backward' in Layer`	The syntax for the optional `backward` function is not consistent with the number of layer inputs and outputs.	Specify the correct number of input and output arguments in `backward`. The `backward` function syntax depends on the type of layer. • `dLdX = backward(layer,X,Z,dLdZ,memory)` returns the derivatives `dLdX` of the loss with respect to the layer input, where `layer` has a single input and a single output. `Z` corresponds to the forward function output and `dLdZ` corresponds to the derivative of the loss with respect to `Z`. The function input `memory` corresponds to the memory output of the forward function. • `[dLdX,dLdW] = backward(layer,X,Z,dLdZ,memory)` also returns the derivative `dLdW` of the loss with respect to the learnable parameter, where `layer` has a single learnable parameter. • `[dLdX,dLdSin] = backward(layer,X,Z,dLdZ,dLdSout,memory)` also returns the derivative `dLdSin` of the loss with

Test Diagnostic	Description	Possible Solution
`Incorrect number of output arguments for 'backward' in Layer`	The syntax for the optional `backward` function is not consistent with the number of layer outputs.	respect to the state input using any of the previous syntaxes, where `layer` has a single state parameter and `dLdSout` corresponds to the derivative of the loss with respect to the layer state output. • `[dLdX,dLdW,dLdSin] = backward(layer,X,Z,dLdZ,dLdSout,memory)` also returns the derivative `dLdW` of the loss with respect to the learnable parameter and returns the derivative `dLdSin` of the loss with respect to the layer state input using any of the previous syntaxes, where `layer` has a single state parameter and single learnable parameter. You can adjust the syntaxes for layers with multiple inputs, multiple outputs, multiple learnable parameters, or multiple state parameters: • For layers with multiple inputs, replace `X` and `dLdX` with `X1,...,XN` and `dLdX1,...,dLdXN`, respectively, where `N` is the number of inputs. • For layers with multiple outputs, replace `Z` and `dLdZ` with `Z1,...,ZM` and `dLdZ1,...,dLdZM`, respectively, where `M` is the number of outputs. • For layers with multiple learnable parameters, replace `dLdW` with `dLdW1,...,dLdWP`, where `P` is the number of learnable parameters. • For layers with multiple state parameters, replace `dLdSin` and `dLdSout` with

Test Diagnostic	Description	Possible Solution
		`dLdSin1,...,dLdSinK` and `dLdSout1,...,dLdSoutK`, respectively, where `K` is the number of state parameters. To reduce memory usage by preventing unused variables being saved between the forward and backward pass, replace the corresponding input arguments with ~. **Tip** If the number of inputs to `backward` can vary, then use `varargin` instead of the input arguments after `layer`. In this case, `varargin` is a cell array of the inputs, where the first `N` elements correspond to the `N` layer inputs, the next `M` elements correspond to the `M` layer outputs, the next `M` elements correspond to the derivatives of the loss with respect to the `M` layer outputs, the next `K` elements correspond to the `K` derivatives of the loss with respect to the `K` states outputs, and the last element corresponds to `memory`. If the number of outputs can vary, then use `varargout` instead of the output arguments. In this case, `varargout` is a cell array of the outputs, where the first `N` elements correspond to the `N` the derivatives of the loss with respect to the `N` layer inputs, the next `P` elements correspond to the derivatives of the loss with respect to the `P` learnable parameters, and the next `K` elements correspond to the derivatives of the loss with respect to the `K` state inputs. **Tip** If the layer forward functions support `dlarray`

Test Diagnostic	Description	Possible Solution
		objects, then the software automatically determines the backward function and you do not need to specify the `backward` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

For layers with multiple inputs or outputs, you must set the values of the layer properties `NumInputs` (or alternatively, `InputNames`) and `NumOutputs` (or alternatively, `OutputNames`) in the layer constructor function, respectively.

Multiple Observations

The `checkLayer` function checks that the layer functions are valid for single and multiple observations. To check for multiple observations, specify the observation dimension using the `ObservationDimension` option. If you specify the observation dimension, then the `checkLayer` function checks that the layer functions are valid using generated data with mini-batches of size 1 and 2. If you do not specify this name-value pair, then the function skips the tests that check that the layer functions are valid for multiple observations.

Test Diagnostic	Description	Possible Solution
`Skipping multi-observation tests. To enable checks with multiple observations, specify the 'ObservationDimension' parameter in checkLayer.`	If you do not specify the `'ObservationDimension'` parameter in `checkLayer`, then the function skips the tests that check data with multiple observations.	Use the command `checkLayer(layer,validInputSize,'ObservationDimension',dim)`, where `layer` is an instance of the custom layer, `validInputSize` is a vector specifying the valid input size to the layer, and `dim` specifies the dimension of the observations in the layer input. For more information, see “Layer Input Sizes”.

Functions Do Not Error

These tests check that the layers do not error when passed input data of valid size.

Intermediate Layers

The tests `predictDoesNotError`, `forwardDoesNotError`, and `backwardDoesNotError` check that the layer functions do not error when passed inputs of valid size. If you specify an observation dimension, then the function checks the layer for both a single observation and multiple observations.

Test Diagnostic	Description	Possible Solution
`The function 'predict' threw an error:`	The `predict` function errors when passed data of size `validInputSize`.	Address the error described in the `Framework Diagnostic` section. **Tip** If the layer forward functions support `dlarray` objects, then the software automatically determines the backward function and you do not need to specify the `backward` function. For a list of functions that support `dlarray` objects, see "List of Functions with dlarray Support" on page 18-423.
`The function 'forward' threw an error:`	The optional `forward` function errors when passed data of size `validInputSize`.	
`The function 'backward' threw an error:`	The optional `backward` function errors when passed the output of `predict`.	

Output Layers

The tests `forwardLossDoesNotError` and `backwardLossDoesNotError` check that the layer functions do not error when passed inputs of valid size. If you specify an observation dimension, then the function checks the layer for both a single observation and multiple observations.

Test Diagnostic	Description	Possible Solution
`The function 'forwardLoss' threw an error:`	The `forwardLoss` function errors when passed data of size `validInputSize`.	Address the error described in the `Framework Diagnostic` section. **Tip** If the `forwardLoss` function supports `dlarray` objects, then the software automatically determines the backward loss function and you do not need to specify the `backwardLoss` function. For a list of functions that support `dlarray` objects, see "List of Functions with dlarray Support" on page 18-423.
`The function 'backwardLoss' threw an error:`	The optional `backwardLoss` function errors when passed data of size `validInputSize`.	

Outputs Are Consistent in Size

These tests check that the layer function outputs are consistent in size.

Intermediate Layers

The test `backwardIsConsistentInSize` checks that the `backward` function outputs derivatives of the correct size.

The `backward` function syntax depends on the type of layer.

- `dLdX = backward(layer,X,Z,dLdZ,memory)` returns the derivatives `dLdX` of the loss with respect to the layer input, where `layer` has a single input and a single output. `Z` corresponds to the forward function output and `dLdZ` corresponds to the derivative of the loss with respect to `Z`. The function input `memory` corresponds to the memory output of the forward function.
- `[dLdX,dLdW] = backward(layer,X,Z,dLdZ,memory)` also returns the derivative `dLdW` of the loss with respect to the learnable parameter, where `layer` has a single learnable parameter.
- `[dLdX,dLdSin] = backward(layer,X,Z,dLdZ,dLdSout,memory)` also returns the derivative `dLdSin` of the loss with respect to the state input using any of the previous syntaxes, where `layer` has a single state parameter and `dLdSout` corresponds to the derivative of the loss with respect to the layer state output.
- `[dLdX,dLdW,dLdSin] = backward(layer,X,Z,dLdZ,dLdSout,memory)` also returns the derivative `dLdW` of the loss with respect to the learnable parameter and returns the derivative `dLdSin` of the loss with respect to the layer state input using any of the previous syntaxes, where `layer` has a single state parameter and single learnable parameter.

You can adjust the syntaxes for layers with multiple inputs, multiple outputs, multiple learnable parameters, or multiple state parameters:

- For layers with multiple inputs, replace `X` and `dLdX` with `X1,...,XN` and `dLdX1,...,dLdXN`, respectively, where `N` is the number of inputs.
- For layers with multiple outputs, replace `Z` and `dLdZ` with `Z1,...,ZM` and `dLdZ1,...,dLdZM`, respectively, where `M` is the number of outputs.
- For layers with multiple learnable parameters, replace `dLdW` with `dLdW1,...,dLdWP`, where `P` is the number of learnable parameters.
- For layers with multiple state parameters, replace `dLdSin` and `dLdSout` with `dLdSin1,...,dLdSinK` and `dLdSout1,...,dLdSoutK`, respectively, where `K` is the number of state parameters.

To reduce memory usage by preventing unused variables being saved between the forward and backward pass, replace the corresponding input arguments with `~`.

Tip If the number of inputs to `backward` can vary, then use `varargin` instead of the input arguments after `layer`. In this case, `varargin` is a cell array of the inputs, where the first `N` elements correspond to the `N` layer inputs, the next `M` elements correspond to the `M` layer outputs, the next `M` elements correspond to the derivatives of the loss with respect to the `M` layer outputs, the next `K` elements correspond to the `K` derivatives of the loss with respect to the `K` states outputs, and the last element corresponds to `memory`.

If the number of outputs can vary, then use `varargout` instead of the output arguments. In this case, `varargout` is a cell array of the outputs, where the first `N` elements correspond to the `N` the derivatives of the loss with respect to the `N` layer inputs, the next `P` elements correspond to the derivatives of the loss with respect to the `P` learnable parameters, and the next `K` elements correspond to the derivatives of the loss with respect to the `K` state inputs.

The derivatives `dLdX1`, ..., `dLdXn` must be the same size as the corresponding layer inputs, and `dLdW1,…,dLdWk` must be the same size as the corresponding learnable parameters. The sizes must be consistent for input data with single and multiple observations.

Test Diagnostic	Description	Possible Solution
`Incorrect size of 'dLdX' for 'backward'.`	The derivatives of the loss with respect to the layer inputs must be the same size as the corresponding layer input.	Return the derivatives `dLdX1,…,dLdXn` with the same size as the corresponding layer inputs `X1,…,Xn`.
`Incorrect size of the derivative of the loss with respect to the input 'in1' for 'backward'`		
`The size of 'Z' returned from 'forward' must be the same as for 'predict'.`	The outputs of `predict` must be the same size as the corresponding outputs of `forward`.	Return the outputs `Z1,…,Zm` of `predict` with the same size as the corresponding outputs `Z1,…,Zm` of `forward`.
`Incorrect size of the derivative of the loss with respect to 'W' for 'backward'.`	The derivatives of the loss with respect to the learnable parameters must be the same size as the corresponding learnable parameters.	Return the derivatives `dLdW1,…,dLdWk` with the same size as the corresponding learnable parameters `W1,…,Wk`.

Tip If the layer forward functions support `dlarray` objects, then the software automatically determines the backward function and you do not need to specify the `backward` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

Output Layers

The test `forwardLossIsScalar` checks that the output of the `forwardLoss` function is scalar. When the `backwardLoss` function is specified, the test `backwardLossIsConsistentInSize` checks that the outputs of `forwardLoss` and `backwardLoss` are of the correct size.

The syntax for `forwardLoss` is `loss = forwardLoss(layer,Y,T)`. The input `Y` corresponds to the predictions made by the network. These predictions are the output of the previous layer. The input `T` corresponds to the training targets. The output `loss` is the loss between `Y` and `T` according to the specified loss function. The output `loss` must be scalar.

If the `forwardLoss` function supports `dlarray` objects, then the software automatically determines the backward loss function and you do not need to specify the `backwardLoss` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

The syntax for `backwardLoss` is `dLdY = backwardLoss(layer,Y,T)`. The input `Y` contains the predictions made by the network and `T` contains the training targets. The output `dLdY` is the derivative of the loss with respect to the predictions `Y`. The output `dLdY` must be the same size as the layer input `Y`.

Test Diagnostic	Description	Possible Solution
`Incorrect size of 'loss' for 'forwardLoss'.`	The output `loss` of `forwardLoss` must be a scalar.	Return the output `loss` as a scalar. For example, if you have multiple values of the loss, then you can use `mean` or `sum`.

Test Diagnostic	Description	Possible Solution
`Incorrect size of the derivative of loss 'dLdY' for 'backwardLoss'.`	When `backwardLoss` is specified, the derivatives of the loss with respect to the layer input must be the same size as the layer input.	Return derivative `dLdY` with the same size as the layer input `Y`. If the `forwardLoss` function supports `dlarray` objects, then the software automatically determines the backward loss function and you do not need to specify the `backwardLoss` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

Consistent Data Types and GPU Compatibility

These tests check that the layer function outputs are consistent in type and that the layer functions are GPU compatible.

If the layer forward functions fully support `dlarray` objects, then the layer is GPU compatible. Otherwise, to be GPU compatible, the layer functions must support inputs and return outputs of type `gpuArray`.

Many MATLAB built-in functions support `gpuArray` and `dlarray` input arguments. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. For a list of functions that execute on a GPU, see “Run MATLAB Functions on a GPU” (Parallel Computing Toolbox). To use a GPU for deep learning, you must also have a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). For more information on working with GPUs in MATLAB, see “GPU Computing in MATLAB” (Parallel Computing Toolbox).

Intermediate Layers

The tests `predictIsConsistentInType`, `forwardIsConsistentInType`, and `backwardIsConsistentInType` check that the layer functions output variables of the correct data type. The tests check that the layer functions return consistent data types when given inputs of the data types `single`, `double`, and `gpuArray` with the underlying types `single` or `double`.

Tip If you preallocate arrays using functions such as `zeros`, then you must ensure that the data types of these arrays are consistent with the layer function inputs. To create an array of zeros of the same data type as another array, use the `"like"` option of `zeros`. For example, to initialize an array of zeros of size `sz` with the same data type as the array `X`, use `Z = zeros(sz,"like",X)`.

Test Diagnostic	Description	Possible Solution
`Incorrect type of 'Z' for 'predict'.`	The types of the outputs `Z1,…,Zm` of the `predict` function must be consistent with the inputs `X1,…,Xn`.	Return the outputs `Z1,…,Zm` with the same type as the inputs `X1,…,Xn`.
`Incorrect type of output 'out1' for 'predict'.`		

Test Diagnostic	Description	Possible Solution
`Incorrect type of 'Z' for 'forward'.`	The types of the outputs `Z1,…,Zm` of the optional `forward` function must be consistent with the inputs `X1,…,Xn`.	
`Incorrect type of output 'out1' for 'forward'.`		
`Incorrect type of 'dLdX' for 'backward'.`	The types of the derivatives `dLdX1,…,dLdXn` of the optional `backward` function must be consistent with the inputs `X1,…,Xn`.	Return the derivatives `dLdX1,…,dLdXn` with the same type as the inputs `X1,…,Xn`.
`Incorrect type of the derivative of the loss with respect to the input 'in1' for 'backward'.`		
`Incorrect type of the derivative of loss with respect to 'W' for 'backward'.`	The type of the derivative of the loss of the learnable parameters must be consistent with the corresponding learnable parameters.	For each learnable parameter, return the derivative with the same type as the corresponding learnable parameter.

Tip If the layer forward functions support `dlarray` objects, then the software automatically determines the backward function and you do not need to specify the `backward` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

Output Layers

The tests `forwardLossIsConsistentInType` and `backwardLossIsConsistentInType` check that the layer functions output variables of the correct data type. The tests check that the layers return consistent data types when given inputs of the data types `single`, `double`, and `gpuArray` with the underlying types `single` or `double`.

Test Diagnostic	Description	Possible Solution
`Incorrect type of 'loss' for 'forwardLoss'.`	The type of the output `loss` of the `forwardLoss` function must be consistent with the input `Y`.	Return `loss` with the same type as the input `Y`.
`Incorrect type of the derivative of loss 'dLdY' for 'backwardLoss'.`	The type of the output `dLdY` of the optional `backwardLoss` function must be consistent with the input `Y`.	Return `dLdY` with the same type as the input `Y`.

Tip If the `forwardLoss` function supports `dlarray` objects, then the software automatically determines the backward loss function and you do not need to specify the `backwardLoss` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

Correct Gradients

The test `gradientsAreNumericallyCorrect` checks that the gradients computed by the layer functions are numerically correct. The test `backwardPropagationDoesNotError` checks that the derivatives can be computed using automatic differentiation.

Intermediate Layers

When the optional `backward` function is not specified, the test `backwardPropagationDoesNotError` checks that the derivatives can be computed using automatic differentiation. When the optional `backward` function is specified, the test `gradientsAreNumericallyCorrect` tests that the gradients computed in `backward` are numerically correct.

Test Diagnostic	Description	Possible Solution
`Expected a dlarray with no dimension labels, but instead found labels.`	When the optional `backward` function is not specified, the layer forward functions must output `dlarray` objects without dimension labels.	Ensure that any `dlarray` objects created in the layer forward functions do not contain dimension labels.
`Unable to backward propagate through the layer. Check that the 'forward' function fully supports automatic differentiation. Alternatively, implement the 'backward' function manually.`	One or more of the following: • When the optional `backward` function is not specified, the layer forward functions do not support `dlarray` objects. • When the optional `backward` function is not specified, the tracing of the input `dlarray` objects in the forward functions have been broken. For example, by using the `extractdata` function.	Check that the forward functions support `dlarray` objects. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. Check that the derivatives of the input `dlarray` objects can be traced. To learn more about the derivative trace of `dlarray` objects, see “Derivative Trace” on page 18-206. Alternatively, define a custom backward function by creating a function named `backward`. To learn more, see .
`Unable to backward propagate through the layer. Check that the 'predict' function fully supports automatic differentiation. Alternatively, implement the 'backward' function manually.`		
`The derivative 'dLdX' for 'backward' is inconsistent with the numerical gradient.`	One or more of the following: • When the optional `backward` function is specified, the derivative is incorrectly computed • The forward functions are non-differentiable at some input points • Error tolerance is too small	If the layer forward functions support `dlarray` objects, then the software automatically determines the backward function and you can omit the backward function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.
`The derivative of the loss with respect to the input 'in1' for 'backward' is inconsistent with the numerical gradient.`		

Test Diagnostic	Description	Possible Solution
`The derivative of loss with respect to 'W' for 'backward' is inconsistent with the numerical gradient.`		Check that the derivatives in `backward` are correctly computed. If the derivatives are correctly computed, then in the `Framework Diagnostic` section, manually check the absolute and relative error between the actual and expected values of the derivative. If the absolute and relative errors are within an acceptable margin of the tolerance, then you can ignore this test diagnostic.

Tip If the layer forward functions support `dlarray` objects, then the software automatically determines the backward function and you do not need to specify the `backward` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

Output Layers

When the optional `backwardLoss` function is not specified, the test `backwardPropagationDoesNotError` checks that the derivatives can be computed using automatic differentiation. When the optional `backwardLoss` function is specified, the test `gradientsAreNumericallyCorrect` tests that the gradients computed in `backwardLoss` are numerically correct.

Test Diagnostic	Description	Possible Solution
`Expected a dlarray with no dimension labels, but instead found labels`	When the optional `backwardLoss` function is not specified, the `forwardLoss` function must output `dlarray` objects without dimension labels.	Ensure that any `dlarray` objects created in the `forwardLoss` function does not contain dimension labels.

Test Diagnostic	Description	Possible Solution
`Unable to backward propagate through the layer. Check that the 'forwardLoss' function fully supports automatic differentiation. Alternatively, implement the 'backwardLoss' function manually`	One or more of the following: • When the optional `backwardLoss` function is not specified, the layer `forwardLoss` function does not support `dlarray` objects. • When the optional `backwardLoss` function is not specified, the tracing of the input `dlarray` objects in the `forwardLoss` function has been broken. For example, by using the `extractdata` function.	Check that the `forwardLoss` function supports `dlarray` objects. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423. Check that the derivatives of the input `dlarray` objects can be traced. To learn more about the derivative trace of `dlarray` objects, see “Derivative Trace” on page 18-206. Alternatively, define a custom backward loss function by creating a function named `backwardLoss`. To learn more, see .
`The derivative 'dLdY' for 'backwardLoss' is inconsistent with the numerical gradient.`	One or more of the following: • The derivative with respect to the predictions `Y` is incorrectly computed • Function is non-differentiable at some input points • Error tolerance is too small	Check that the derivatives in `backwardLoss` are correctly computed. If the derivatives are correctly computed, then in the `Framework Diagnostic` section, manually check the absolute and relative error between the actual and expected values of the derivative. If the absolute and relative errors are within an acceptable margin of the tolerance, then you can ignore this test diagnostic.

Tip If the `forwardLoss` function supports `dlarray` objects, then the software automatically determines the backward loss function and you do not need to specify the `backwardLoss` function. For a list of functions that support `dlarray` objects, see “List of Functions with dlarray Support” on page 18-423.

Valid States

For layers with state properties, the test `predictReturnsValidStates` checks that the predict function returns valid states. When `forward` is specified, the test `forwardReturnsValidStates`

checks that the forward function returns valid states. The test `resetStateDoesNotError` checks that the `resetState` function returns a layer with valid state properties.

Test Diagnostic	Description	Possible Solution
`Error using 'predict' in Layer. 'State' must be real-values numeric array or unformatted dlarray object.`	State outputs must be real-valued numeric arrays or unformatted `dlarray` objects.	Ensure that the states identified in the `Framework Diagnostic` are real-valued numeric arrays or unformatted `dlarray` objects.
`Error using 'resetState' in Layer. 'State' must be real-values numeric array or unformatted dlarray object`	State properties of returned layer must be real-valued numeric arrays or unformatted `dlarray` objects.	

Code Generation Compatibility

If you set the `CheckCodegenCompatibility` option to `1` (true), then the `checkLayer` function checks the layer for code generation compatibility.

The test `codegenPragmaDefinedInClassDef` checks that the layer definition contains the code generation pragma `%#codegen`. The test `checkForSupportedLayerPropertiesForCodegen` checks that the layer properties support code generation. The test `predictIsValidForCodegeneration` checks that the outputs of `predict` are consistent in dimension and batch size.

Code generation supports intermediate layers with 2-D image or feature input only. Code generation does not support layers with state properties (properties with attribute `State`).

The `checkLayer` function does not check that functions used by the layer are compatible with code generation. To check that functions used by the custom layer also support code generation, first use the **Code Generation Readiness** app. For more information, see “Check Code by Using the Code Generation Readiness Tool” (MATLAB Coder).

Test Diagnostic	Description	Possible Solution
`Specify '%#codegen' in the class definition of custom layer`	The layer definition does not include the pragma `"%#codegen"` for code generation.	Add the `%#codegen` directive (or pragma) to your layer definition to indicate that you intend to generate code for this layer. Adding this directive instructs the MATLAB Code Analyzer to help you diagnose and fix violations that result in errors during code generation.

Test Diagnostic	Description	Possible Solution
`Nonscalar layer properties must be type single or double or character array for custom layer`	The layer contains non-scalar properties of type other than single, double, or character array.	Convert non-scalar properties to use a representation of type single, double, or character array. For example, convert a categorical array to an array of integers of type `double` representing the categories.
`Scalar layer properties must be numeric, logical, or string for custom layer`	The layer contains scalar properties of type other than numeric, logical, or string.	Convert scalar properties to use a numeric representation, or a representation of type logical or string. For example, convert a categorical scalar to an integer of type `double` representing the category.
`For code generation, 'Z' must have the same number of dimensions as the layer input.`	The number of dimensions of the output `Z` of `predict` does not match the number of dimensions of the layer inputs.	In the `predict` function, return the outputs with the same number of dimensions as the layer inputs.
`For code generation, 'Z' must have the same batch size as the layer input.`	The size of the batch size of the output `Z` of `predict` does not match the size of the batch size of the layer inputs.	In the `predict` function, return the outputs with the batch size as the layer inputs.

Specify Custom Weight Initialization Function

This example shows how to create a custom He weight initialization function for convolution layers followed by leaky ReLU layers.

The He initializer for convolution layers followed by leaky ReLU layers samples from a normal distribution with zero mean and variance $\sigma^2 = \frac{2}{(1+a^2)n}$, where a is the scale of the leaky ReLU layer that follows the convolution layer and `n = FilterSize(1) * FilterSize(2) * NumChannels`.

For learnable layers, when setting the options `'WeightsInititializer'`, `'InputWeightsInitializer'`, or `'RecurrentWeightsInitializer'` to `'he'`, the software uses $a=0$. To set a to different value, create a custom function to use as a weights initializer.

Load Data

Load the digit sample data as an image datastore. The `imageDatastore` function automatically labels the images based on folder names.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet','nndemos', ...
    'nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

Divide the data into training and validation data sets, so that each category in the training set contains 750 images, and the validation set contains the remaining images from each label. `splitEachLabel` splits the datastore into two new datastores for training and validation.

```
numTrainFiles = 750;
[imdsTrain,imdsValidation] = splitEachLabel(imds,numTrainFiles,'randomize');
```

Define Network Architecture

Define the convolutional neural network architecture:

- Image input layer size of `[28 28 1]`, the size of the input images
- Three 2-D convolution layers with filter size 3 and with 8, 16, and 32 filters respectively
- A leaky ReLU layer following each convolutional layer
- Fully connected layer of size 10, the number of classes
- Softmax layer
- Classification layer

For each of the convolutional layers, set the weights initializer to the `leakyHe` function. The `leakyHe` function, listed at the end of the example, takes the input `sz` (the size of the layer weights) and returns an array of weights given by the He Initializer for convolution layers followed by a leaky ReLU layer.

```
inputSize = [28 28 1];
numClasses = 10;

layers = [
    imageInputLayer(inputSize)
    convolution2dLayer(3,8,'WeightsInitializer',@leakyHe)
```

```
    leakyReluLayer
    convolution2dLayer(3,16,'WeightsInitializer',@leakyHe)
    leakyReluLayer
    convolution2dLayer(3,32,'WeightsInitializer',@leakyHe)
    leakyReluLayer
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Train Network

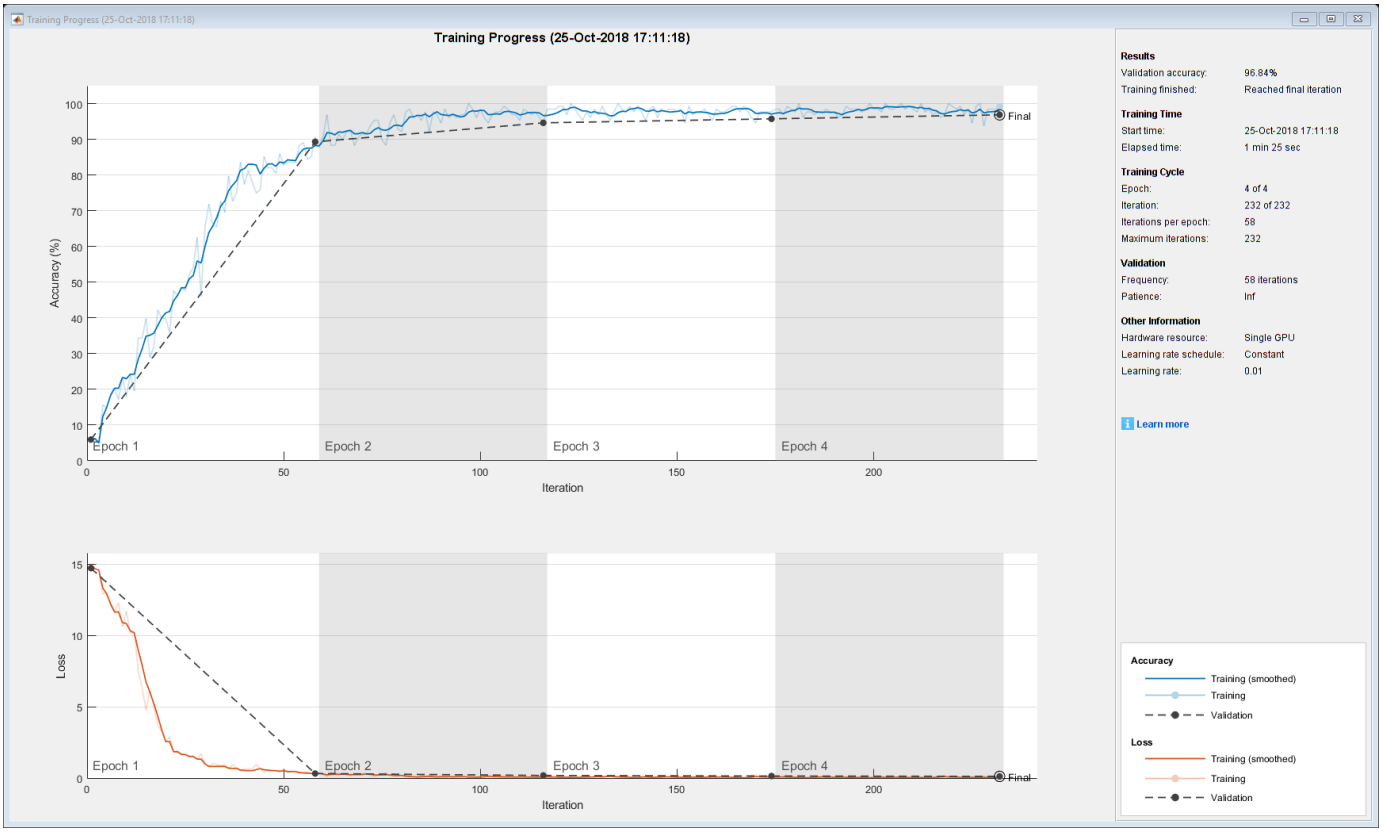
Specify the training options and train the network. Train for four epochs. To prevent the gradients from exploding, set the gradient threshold to 2. Validate the network once per epoch. View the training progress plot.

By default, `trainNetwork` uses a GPU if one is available, otherwise, it uses a CPU. Training on a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`.

```
maxEpochs = 4;
miniBatchSize = 128;
numObservations = numel(imdsTrain.Files);
numIterationsPerEpoch = floor(numObservations / miniBatchSize);

options = trainingOptions('sgdm', ...
    'MaxEpochs',maxEpochs, ...
    'MiniBatchSize',miniBatchSize, ...
    'GradientThreshold',2, ...
    'ValidationData',imdsValidation, ...
    'ValidationFrequency',numIterationsPerEpoch, ...
    'Verbose',false, ...
    'Plots','training-progress');

[netDefault,infoDefault] = trainNetwork(imdsTrain,layers,options);
```



Test Network

Classify the validation data and calculate the classification accuracy.

```
YPred = classify(netDefault,imdsValidation);
YValidation = imdsValidation.Labels;
accuracy = mean(YPred == YValidation)
```

```
accuracy = 0.9684
```

Specify Additional Options

The `leakyHe` function accepts the optional input argument `scale`. To input extra variables into the custom weight initialization function, specify the function as an anonymous function that accepts a single input `sz`. To do this, replace instances of `@leakyHe` with `@(sz) leakyHe(sz,scale)`. Here, the anonymous function accepts the single input argument `sz` only and calls the `leakyHe` function with the specified `scale` input argument.

Create and train the same network as before with the following changes:

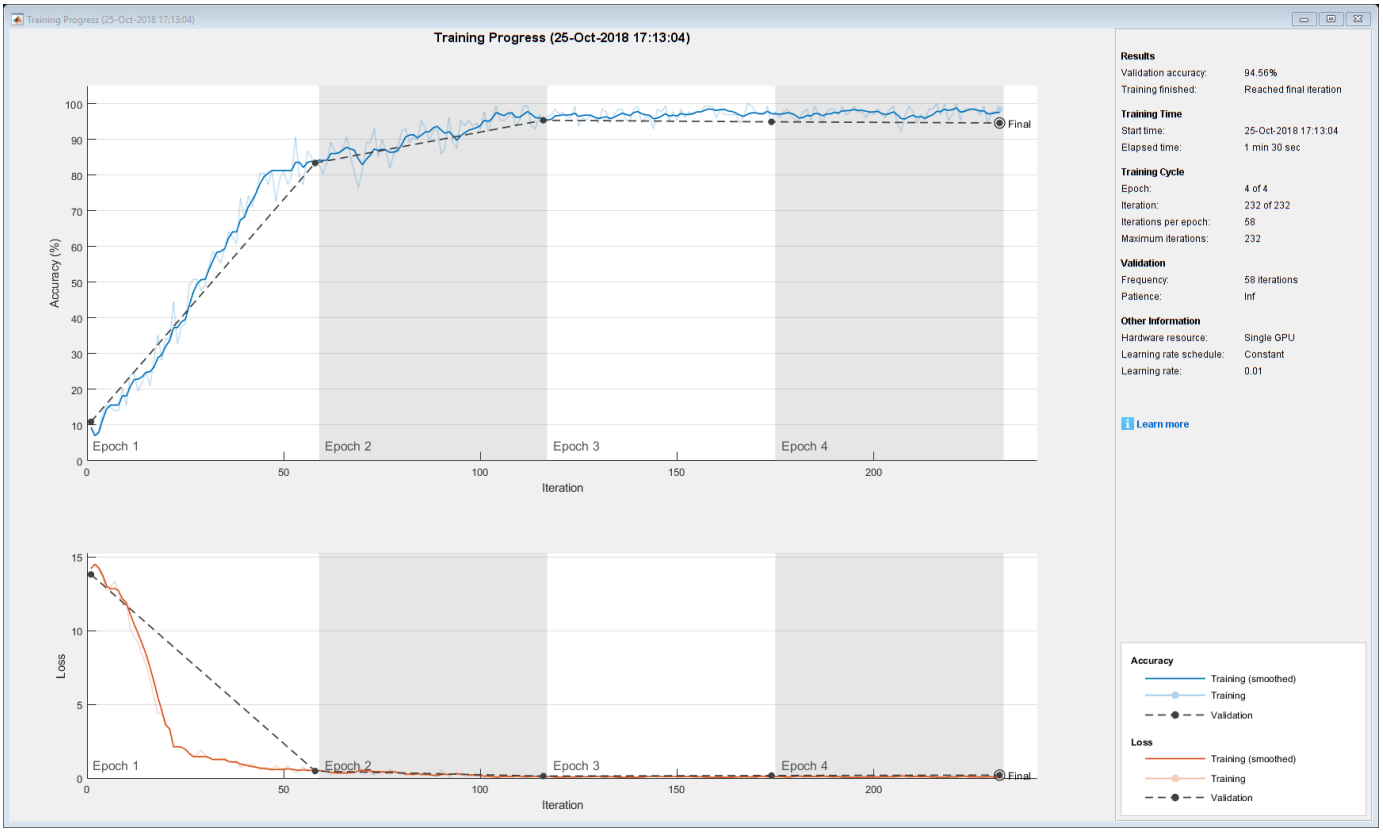
- For the leaky ReLU layers, specify a scale multiplier of 0.01.
- Initialize the weights of the convolutional layers with the `leakyHe` function and also specify the scale multiplier.

```
scale = 0.01;

layers = [
    imageInputLayer(inputSize)
```

```
    convolution2dLayer(3,8,'WeightsInitializer',@(sz) leakyHe(sz,scale))
    leakyReluLayer(scale)
    convolution2dLayer(3,16,'WeightsInitializer',@(sz) leakyHe(sz,scale))
    leakyReluLayer(scale)
    convolution2dLayer(3,32,'WeightsInitializer',@(sz) leakyHe(sz,scale))
    leakyReluLayer(scale)
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];

[netCustom,infoCustom] = trainNetwork(imdsTrain,layers,options);
```



Classify the validation data and calculate the classification accuracy.

```
YPred = classify(netCustom,imdsValidation);
YValidation = imdsValidation.Labels;
accuracy = mean(YPred == YValidation)
```

```
accuracy = 0.9456
```

Compare Results

Extract the validation accuracy from the information structs output from the `trainNetwork` function.

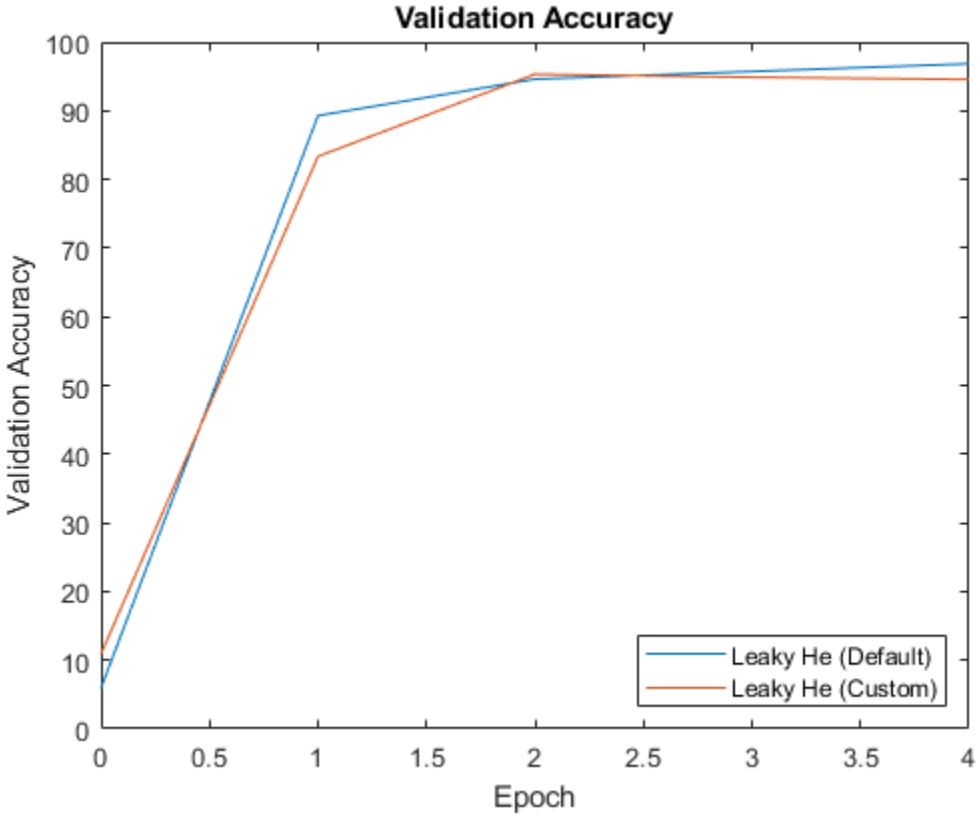
```
validationAccuracy = [
    infoDefault.ValidationAccuracy;
    infoCustom.ValidationAccuracy];
```

The vectors of validation accuracy contain `NaN` for iterations that the validation accuracy was not computed. Remove the `NaN` values.

```
idx = all(isnan(validationAccuracy));
validationAccuracy(:,idx) = [];
```

For each of the networks, plot the epoch numbers against the validation accuracy.

```
figure
epochs = 0:maxEpochs;
plot(epochs,validationAccuracy)
title("Validation Accuracy")
xlabel("Epoch")
ylabel("Validation Accuracy")
legend(["Leaky He (Default)" "Leaky He (Custom)"],'Location','southeast')
```



Custom Weight Initialization Function

The `leakyHe` function takes the input `sz` (the size of the layer weights) and returns an array of weights given by the He Initializer for convolution layers followed by a leaky ReLU layer. The function also accepts the optional input argument `scale` which specifies the scale multiplier for the leaky ReLU layer.

```
function weights = leakyHe(sz,scale)

% If not specified, then use default scale = 0.1
if nargin < 2
    scale = 0.1;
```

```
end

filterSize = [sz(1) sz(2)];
numChannels = sz(3);
numIn = filterSize(1) * filterSize(2) * numChannels;

varWeights = 2 / ((1 + scale^2) * numIn);
weights = randn(sz) * sqrt(varWeights);

end
```

Compare Layer Weight Initializers

This example shows how to train deep learning networks with different weight initializers.

When training a deep learning network, the initialization of layer weights and biases can have a big impact on how well the network trains. The choice of initializer has a bigger impact on networks without batch normalization layers.

Depending on the type of layer, you can change the weights and bias initialization using the `'WeightsInitializer'`, `'InputWeightsInitializer'`, `'RecurrentWeightsInitializer'`, and `'BiasInitializer'` options.

This example shows the effect of using these three different weight initializers when training an LSTM network:

1. **Glorot Initializer** – Initialize the input weights with the Glorot initializer. [1]
2. **He Initializer** – Initialize the input weights with the He initializer. [2]
3. **Narrow-Normal Initializer** – Initialize the input weights by independently sampling from a normal distribution with zero mean and standard deviation 0.01.

Load Data

Load the Japanese Vowels data set. `XTrain` is a cell array containing 270 sequences of varying length with a feature dimension of 12. `Y` is a categorical vector of labels 1,2,...,9. The entries in `XTrain` are matrices with 12 rows (one row for each feature) and a varying number of columns (one column for each time step).

```
[XTrain,YTrain] = japaneseVowelsTrainData;
[XValidation,YValidation] = japaneseVowelsTestData;
```

Specify Network Architecture

Specify the network architecture. For each initializer, use the same network architecture.

Specify the input size as 12 (the number of features of the input data). Specify an LSTM layer with 100 hidden units and to output the last element of the sequence. Finally, specify nine classes by including a fully connected layer of size 9, followed by a softmax layer and a classification layer.

```
numFeatures = 12;
numHiddenUnits = 100;
numClasses = 9;

layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer]
```

```
layers =
  5x1 Layer array with layers:

     1   ''   Sequence Input          Sequence input with 12 dimensions
     2   ''   LSTM                    LSTM with 100 hidden units
     3   ''   Fully Connected         9 fully connected layer
```

```
     4   ''   Softmax                 softmax
     5   ''   Classification Output   crossentropyex
```

Training Options

Specify the training options. For each initializer, use the same training options to train the network.

```
maxEpochs = 30;
miniBatchSize = 27;
numObservations = numel(XTrain);
numIterationsPerEpoch = floor(numObservations / miniBatchSize);

options = trainingOptions('adam', ...
    'ExecutionEnvironment','cpu', ...
    'MaxEpochs',maxEpochs, ...
    'MiniBatchSize',miniBatchSize, ...
    'GradientThreshold',2, ...
    'ValidationData',{XValidation,YValidation}, ...
    'ValidationFrequency',numIterationsPerEpoch, ...
    'Verbose',false, ...
    'Plots','training-progress');
```

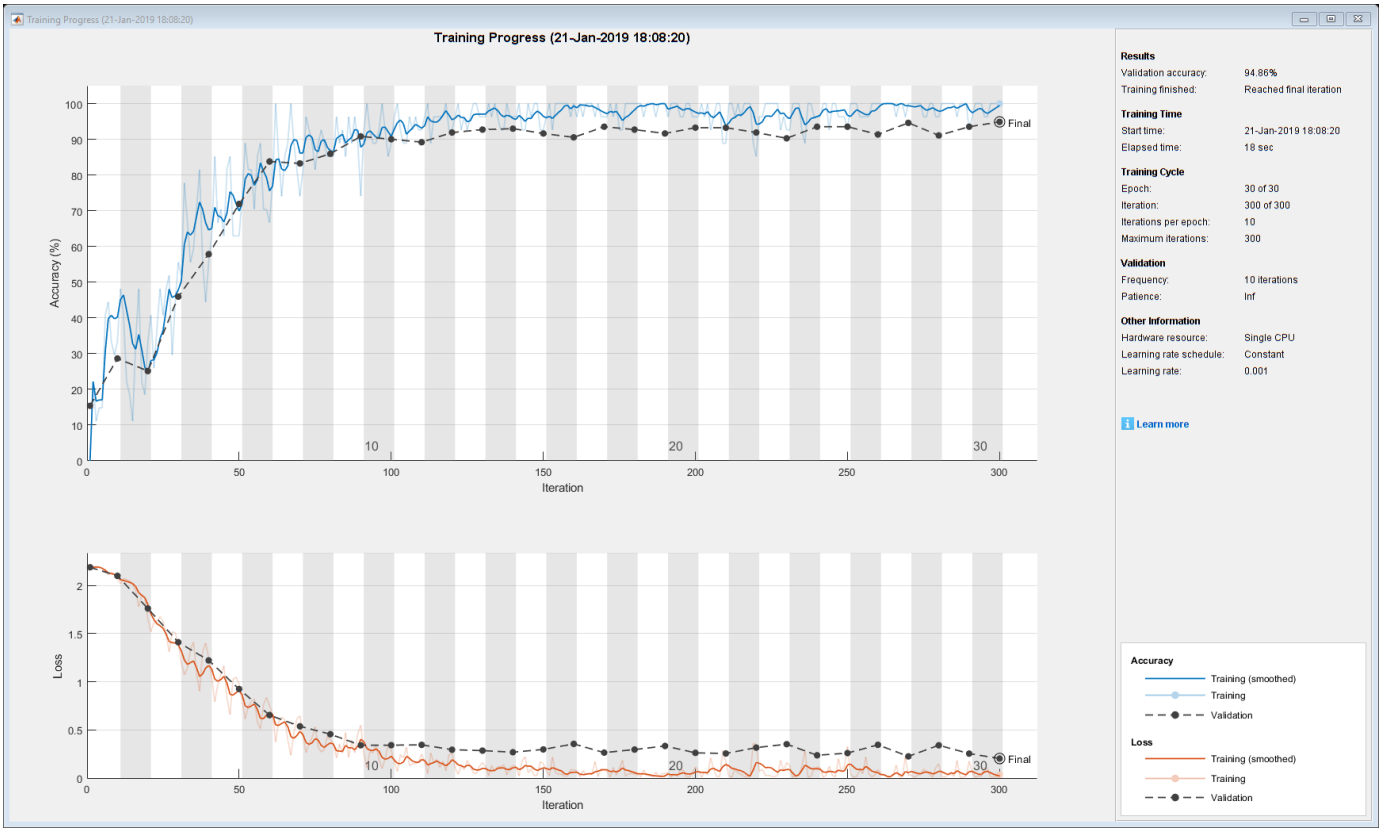
Glorot Initializer

Specify the network architecture listed earlier in the example and set the input weights initializer of the LSTM layer and the weights initializer of the fully connected layer to `'glorot'`.

```
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last','InputWeightsInitializer','glorot')
    fullyConnectedLayer(numClasses,'WeightsInitializer','glorot')
    softmaxLayer
    classificationLayer];
```

Train the network using the layers with the Glorot weights initializers.

```
[netGlorot,infoGlorot] = trainNetwork(XTrain,YTrain,layers,options);
```



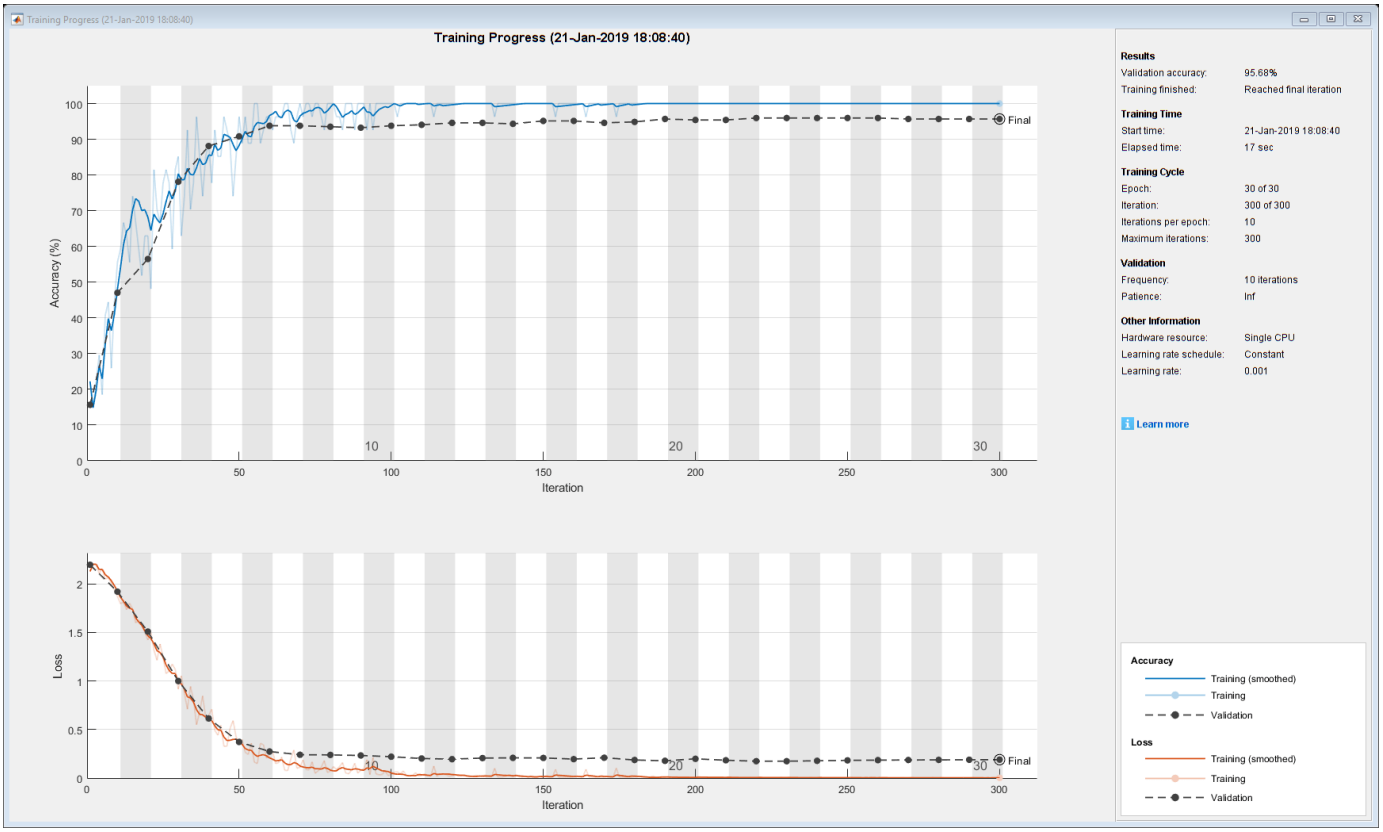
He Initializer

Specify the network architecture listed earlier in the example and set the input weights initializer of the LSTM layer and the weights initializer of the fully connected layer to `'he'`.

```
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last','InputWeightsInitializer','he')
    fullyConnectedLayer(numClasses,'WeightsInitializer','he')
    softmaxLayer
    classificationLayer];
```

Train the network using the layers with the He weights initializers.

```
[netHe,infoHe] = trainNetwork(XTrain,YTrain,layers,options);
```



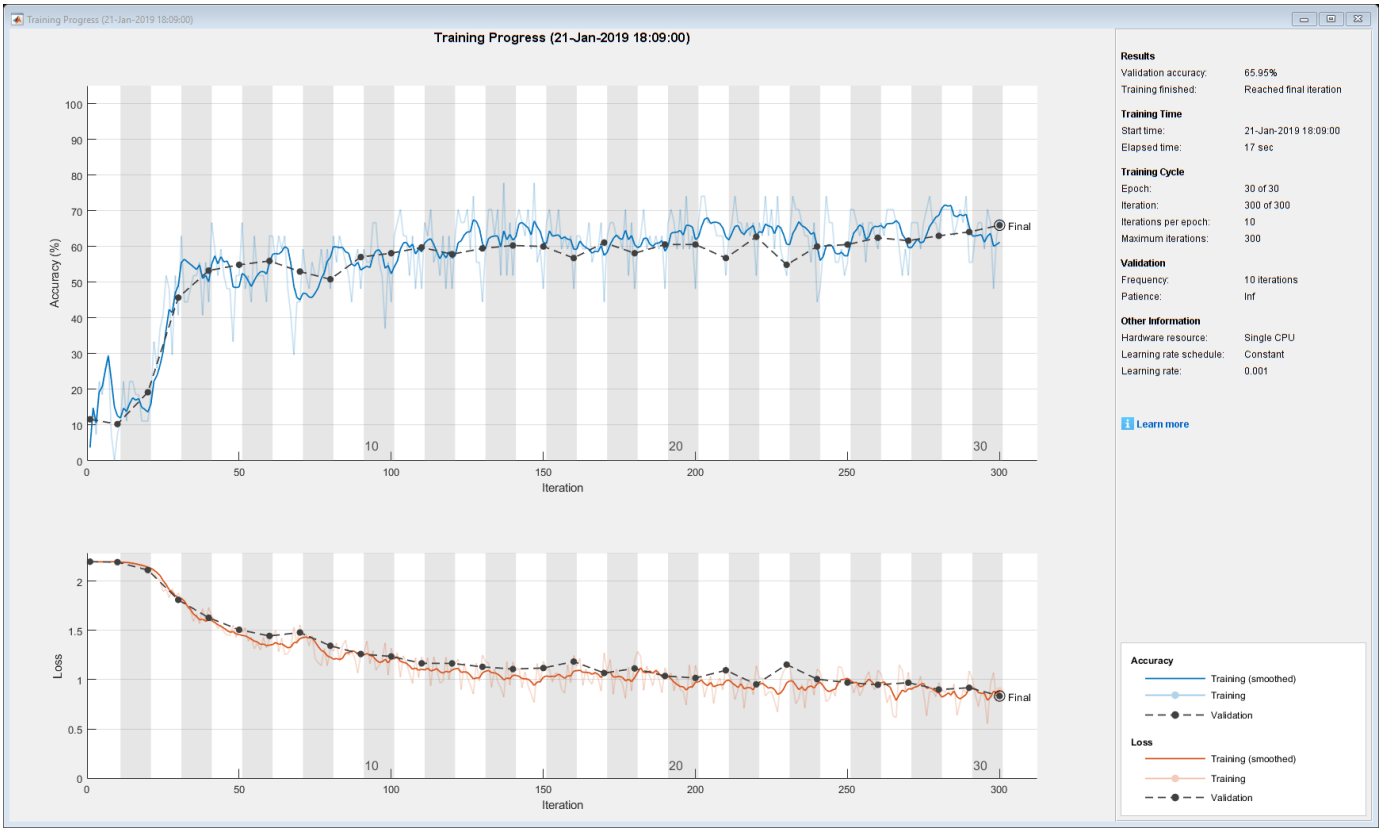
Narrow-Normal Initializer

Specify the network architecture listed earlier in the example and set the input weights initializer of the LSTM layer and the weights initializer of the fully connected layer to `'narrow-normal'`.

```
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last','InputWeightsInitializer','narrow-normal')
    fullyConnectedLayer(numClasses,'WeightsInitializer','narrow-normal')
    softmaxLayer
    classificationLayer];
```

Train the network using the layers with the narrow-normal weights initializers.

```
[netNarrowNormal,infoNarrowNormal] = trainNetwork(XTrain,YTrain,layers,options);
```



Plot Results

Extract the validation accuracy from the information structs output from the `trainNetwork` function.

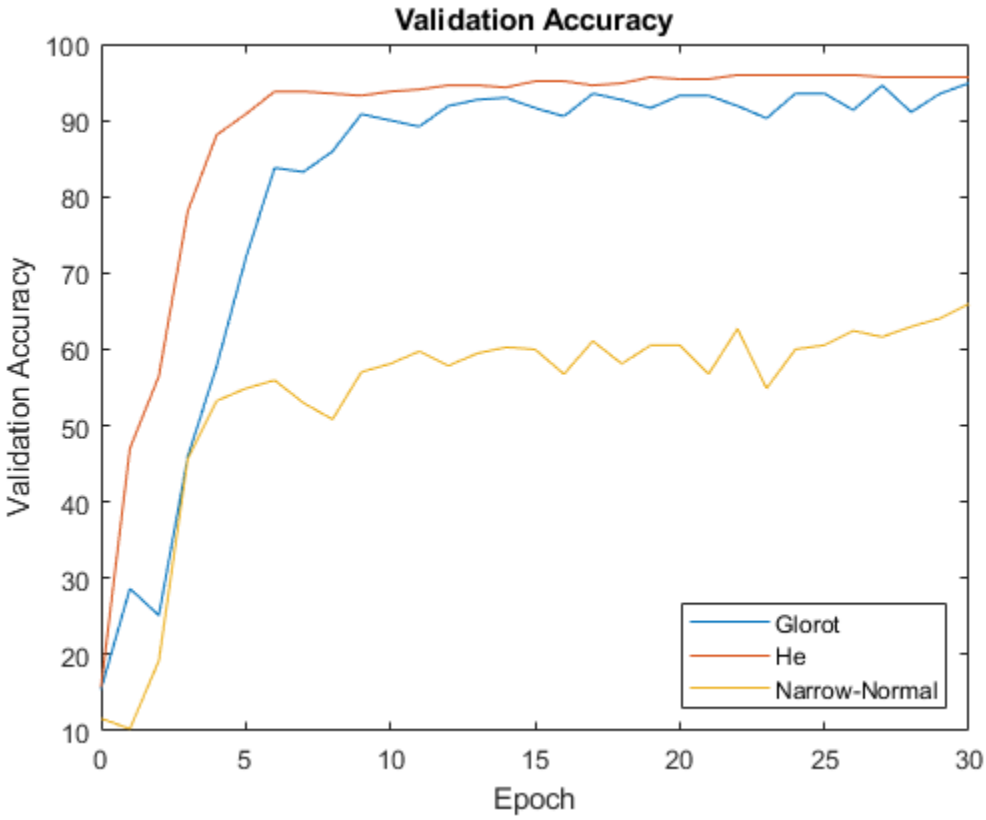
```
validationAccuracy = [
    infoGlorot.ValidationAccuracy;
    infoHe.ValidationAccuracy;
    infoNarrowNormal.ValidationAccuracy];
```

The vectors of validation accuracy contain `NaN` for iterations that the validation accuracy was not computed. Remove the `NaN` values.

```
idx = all(isnan(validationAccuracy));
validationAccuracy(:,idx) = [];
```

For each of the initializers, plot the epoch numbers against the validation accuracy.

```
figure
epochs = 0:maxEpochs;
plot(epochs,validationAccuracy)
title("Validation Accuracy")
xlabel("Epoch")
ylabel("Validation Accuracy")
legend(["Glorot" "He" "Narrow-Normal"],'Location','southeast')
```



This plot shows the overall effect of the different initializers and how quickly the training converges for each one.

Assemble Network from Pretrained Keras Layers

This example shows how to import the layers from a pretrained Keras network, replace the unsupported layers with custom layers, and assemble the layers into a network ready for prediction.

Import Keras Network

Import the layers from a Keras network model. The network in `'digitsDAGnetwithnoise.h5'` classifies images of digits.

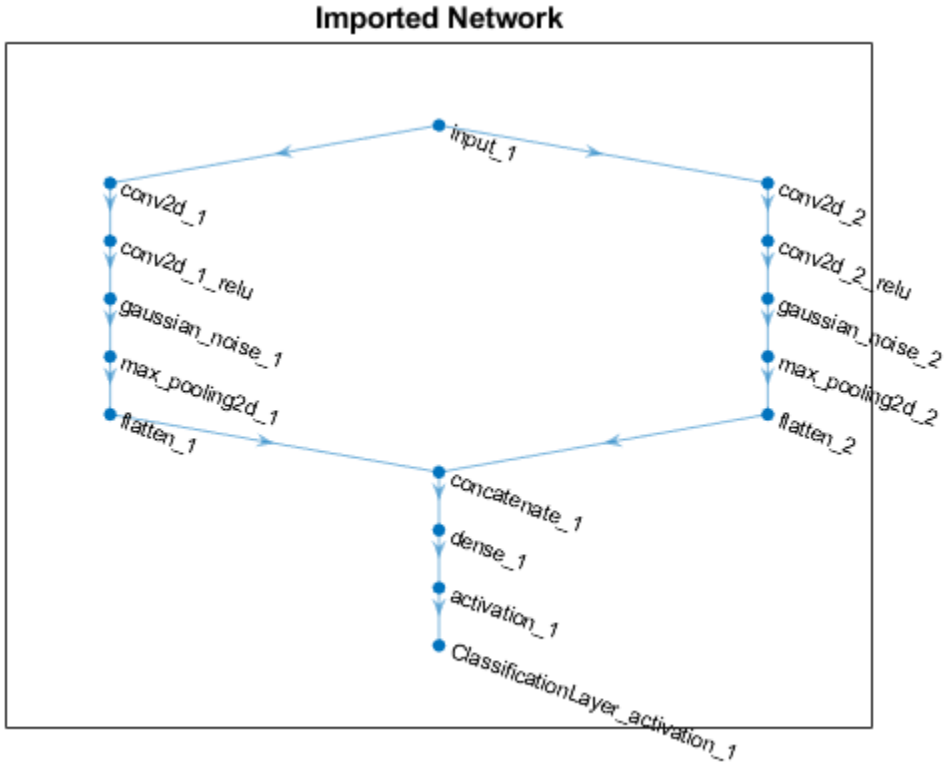
```
filename = 'digitsDAGnetwithnoise.h5';
lgraph = importKerasLayers(filename,'ImportWeights',true);
```

```
Warning: Unable to import some Keras layers, because they are not supported by the Deep Learning
```

The Keras network contains some layers that are not supported by Deep Learning Toolbox. The `importKerasLayers` function displays a warning and replaces the unsupported layers with placeholder layers.

Plot the layer graph using `plot`.

```
figure
plot(lgraph)
title("Imported Network")
```



Replace Placeholder Layers

To replace the placeholder layers, first identify the names of the layers to replace. Find the placeholder layers using `findPlaceholderLayers`.

```
placeholderLayers = findPlaceholderLayers(lgraph)
```

```
placeholderLayers =
  2x1 PlaceholderLayer array with layers:

     1   'gaussian_noise_1'   PLACEHOLDER LAYER   Placeholder for 'GaussianNoise' Keras layer
     2   'gaussian_noise_2'   PLACEHOLDER LAYER   Placeholder for 'GaussianNoise' Keras layer
```

Display the Keras configurations of these layers.

```
placeholderLayers.KerasConfiguration
```

```
ans = struct with fields:
    trainable: 1
         name: 'gaussian_noise_1'
       stddev: 1.5000

ans = struct with fields:
    trainable: 1
         name: 'gaussian_noise_2'
       stddev: 0.7000
```

Define a custom Gaussian noise layer. To create this layer, save the file `gaussianNoiseLayer.m` in the current folder. Then, create two Gaussian noise layers with the same configurations as the imported Keras layers.

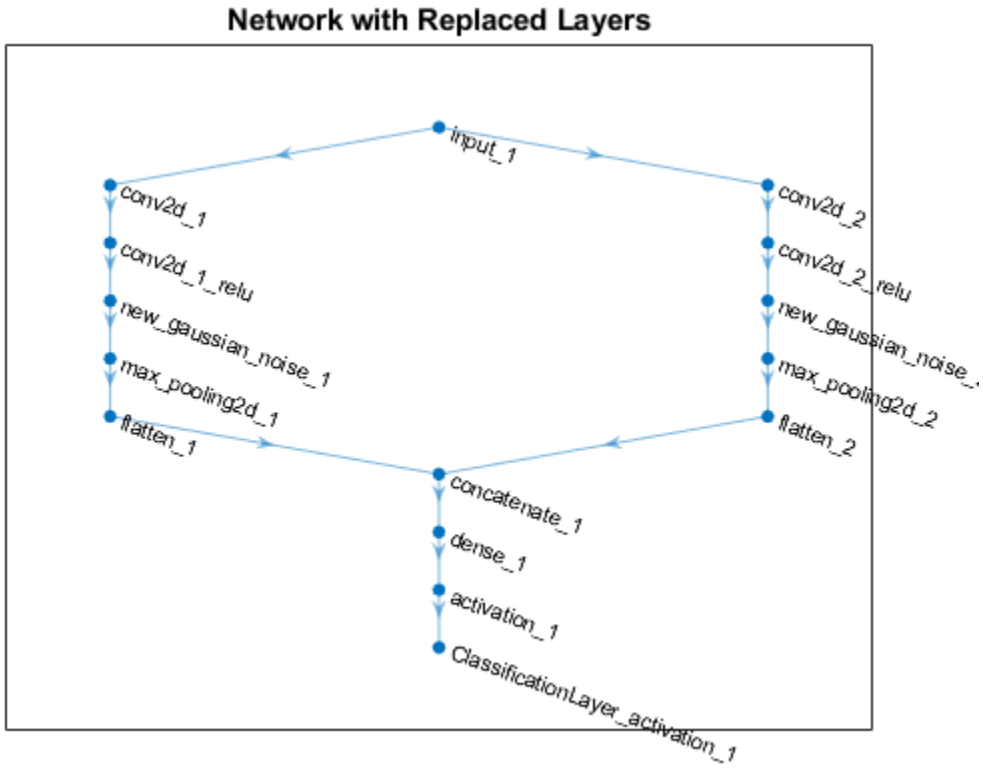
```
gnLayer1 = gaussianNoiseLayer(1.5,'new_gaussian_noise_1');
gnLayer2 = gaussianNoiseLayer(0.7,'new_gaussian_noise_2');
```

Replace the placeholder layers with the custom layers using `replaceLayer`.

```
lgraph = replaceLayer(lgraph,'gaussian_noise_1',gnLayer1);
lgraph = replaceLayer(lgraph,'gaussian_noise_2',gnLayer2);
```

Plot the updated layer graph using `plot`.

```
figure
plot(lgraph)
title("Network with Replaced Layers")
```



Specify Class Names

If the imported classification layer does not contain the classes, then you must specify these before prediction. If you do not specify the classes, then the software automatically sets the classes to `1`, `2`, ..., `N`, where `N` is the number of classes.

Find the index of the classification layer by viewing the `Layers` property of the layer graph.

```
lgraph.Layers
```

```
ans =
  15x1 Layer array with layers:

     1   'input_1'                          Image Input             28x28x1 images
     2   'conv2d_1'                         Convolution             20 7x7x1 convolutions with
     3   'conv2d_1_relu'                    ReLU                    ReLU
     4   'conv2d_2'                         Convolution             20 3x3x1 convolutions with
     5   'conv2d_2_relu'                    ReLU                    ReLU
     6   'new_gaussian_noise_1'             Gaussian Noise          Gaussian noise with standar
     7   'new_gaussian_noise_2'             Gaussian Noise          Gaussian noise with standar
     8   'max_pooling2d_1'                  Max Pooling             2x2 max pooling with stride
     9   'max_pooling2d_2'                  Max Pooling             2x2 max pooling with stride
    10   'flatten_1'                        Keras Flatten           Flatten activations into 1
    11   'flatten_2'                        Keras Flatten           Flatten activations into 1
    12   'concatenate_1'                    Depth concatenation     Depth concatenation of 2 in
    13   'dense_1'                          Fully Connected         10 fully connected layer
    14   'activation_1'                     Softmax                 softmax
    15   'ClassificationLayer_activation_1' Classification Output   crossentropyex
```

The classification layer has the name `'ClassificationLayer_activation_1'`. View the classification layer and check the `Classes` property.

```
cLayer = lgraph.Layers(end)
```

```
cLayer =
  ClassificationOutputLayer with properties:

            Name: 'ClassificationLayer_activation_1'
         Classes: 'auto'
    ClassWeights: 'none'
      OutputSize: 'auto'

   Hyperparameters
    LossFunction: 'crossentropyex'
```

Because the `Classes` property of the layer is `'auto'`, you must specify the classes manually. Set the classes to `0`, `1`, ..., `9`, and then replace the imported classification layer with the new one.

```
cLayer.Classes = string(0:9)
```

```
cLayer =
  ClassificationOutputLayer with properties:

            Name: 'ClassificationLayer_activation_1'
         Classes: [0    1    2    3    4    5    6    7    8    9]
    ClassWeights: 'none'
      OutputSize: 10

   Hyperparameters
    LossFunction: 'crossentropyex'
```

```
lgraph = replaceLayer(lgraph,'ClassificationLayer_activation_1',cLayer);
```

Assemble Network

Assemble the layer graph using `assembleNetwork`. The function returns a `DAGNetwork` object that is ready to use for prediction.

```
net = assembleNetwork(lgraph)
```

```
net =
  DAGNetwork with properties:

         Layers: [15x1 nnet.cnn.layer.Layer]
    Connections: [15x2 table]
     InputNames: {'input_1'}
    OutputNames: {'ClassificationLayer_activation_1'}
```

Replace Unsupported Keras Layer with Function Layer

This example shows how to import the layers from a pretrained Keras network, replace the unsupported layers with function layers, and assemble the layers into a network ready for prediction.

Import Keras Network

Import the layers from a Keras network model. The network in `"digitsNet.h5"` classifies images of digits.

```
filename = "digitsNet.h5";
layers = importKerasLayers(filename,ImportWeights=true)
```

```
Warning: Unable to import layer. Keras layer 'Activation' with the specified settings is not supp

Warning: Unable to import layer. Keras layer 'Activation' with the specified settings is not supp

Warning: Unable to import some Keras layers, because they are not supported by the Deep Learning

layers =
  13x1 Layer array with layers:

     1   'ImageInputLayer'               Image Input             28x28x1 images
     2   'conv2d'                        Convolution             8 3x3x1 convolutions with stride
     3   'conv2d_softsign'               PLACEHOLDER LAYER       Placeholder for 'Activation' Ker
     4   'max_pooling2d'                 Max Pooling             2x2 max pooling with stride [2
     5   'conv2d_1'                      Convolution             16 3x3x8 convolutions with strid
     6   'conv2d_1_softsign'             PLACEHOLDER LAYER       Placeholder for 'Activation' Ker
     7   'max_pooling2d_1'               Max Pooling             2x2 max pooling with stride [2
     8   'flatten'                       Keras Flatten           Flatten activations into 1-D ass
     9   'dense'                         Fully Connected         100 fully connected layer
    10   'dense_relu'                    ReLU                    ReLU
    11   'dense_1'                       Fully Connected         10 fully connected layer
    12   'dense_1_softmax'               Softmax                 softmax
    13   'ClassificationLayer_dense_1'   Classification Output   crossentropyex
```

The Keras network contains some layers that are not supported by Deep Learning Toolbox. The `importKerasLayers` function displays a warning and replaces the unsupported layers with placeholder layers.

Replace Placeholder Layers

To replace the placeholder layers, first identify the names of the layers to replace. Find the placeholder layers using the `findPlaceholderLayers` function.

```
placeholderLayers = findPlaceholderLayers(layers)
```

```
placeholderLayers =
  2x1 PlaceholderLayer array with layers:

     1   'conv2d_softsign'     PLACEHOLDER LAYER   Placeholder for 'Activation' Keras layer
     2   'conv2d_1_softsign'   PLACEHOLDER LAYER   Placeholder for 'Activation' Keras layer
```

Replace the placeholder layers with function layers with function specified by the `softsign` function, listed at the end of the example.

Create a function layer with function specified by the `softsign` function, attached to this example as a supporting file. To access this function, open this example as a live script. Set the layer description to `"softsign"`.

```
layer = functionLayer(@softsign,Description="softsign");
```

Replace the layers using the `replaceLayer` function. To use the `replaceLayer` function, first convert the layer array to a layer graph.

```
lgraph = layerGraph(layers);
lgraph = replaceLayer(lgraph,"conv2d_softsign",layer);
lgraph = replaceLayer(lgraph,"conv2d_1_softsign",layer);
```

Specify Class Names

If the imported classification layer does not contain the classes, then you must specify these before prediction. If you do not specify the classes, then the software automatically sets the classes to `1`, `2`, ..., `N`, where `N` is the number of classes.

Find the index of the classification layer by viewing the `Layers` property of the layer graph.

```
lgraph.Layers
```

```
ans =
  13x1 Layer array with layers:

     1   'ImageInputLayer'              Image Input             28x28x1 images
     2   'conv2d'                       Convolution             8 3x3x1 convolutions with stride
     3   'layer'                        Function                softsign
     4   'max_pooling2d'                Max Pooling             2x2 max pooling with stride [2
     5   'conv2d_1'                     Convolution             16 3x3x8 convolutions with strid
     6   'layer_1'                      Function                softsign
     7   'max_pooling2d_1'              Max Pooling             2x2 max pooling with stride [2
     8   'flatten'                      Keras Flatten           Flatten activations into 1-D ass
     9   'dense'                        Fully Connected         100 fully connected layer
    10   'dense_relu'                   ReLU                    ReLU
    11   'dense_1'                      Fully Connected         10 fully connected layer
    12   'dense_1_softmax'              Softmax                 softmax
    13   'ClassificationLayer_dense_1'  Classification Output   crossentropyex
```

The classification layer has the name `'ClassificationLayer_dense_1'`. View the classification layer and check the `Classes` property.

```
cLayer = lgraph.Layers(end)
```

```
cLayer =
  ClassificationOutputLayer with properties:

            Name: 'ClassificationLayer_dense_1'
         Classes: 'auto'
    ClassWeights: 'none'
      OutputSize: 'auto'

   Hyperparameters
    LossFunction: 'crossentropyex'
```

Because the `Classes` property of the layer is `"auto"`, you must specify the classes manually. Set the classes to `0`, `1`, ..., `9`, and then replace the imported classification layer with the new one.

```
cLayer.Classes = string(0:9);
lgraph = replaceLayer(lgraph,"ClassificationLayer_dense_1",cLayer);
```

Assemble Network

Assemble the layer graph using `assembleNetwork`. The function returns a `DAGNetwork` object that is ready to use for prediction.

```
net = assembleNetwork(lgraph)
```

```
net =
  DAGNetwork with properties:

         Layers: [13x1 nnet.cnn.layer.Layer]
    Connections: [12x2 table]
     InputNames: {'ImageInputLayer'}
    OutputNames: {'ClassificationLayer_dense_1'}
```

Test Network

Make predictions with the network using a test data set.

```
[XTest,YTest] = digitTest4DArrayData;
YPred = classify(net,XTest);
```

View the accuracy.

```
mean(YPred == YTest)
```

```
ans = 0.9900
```

Visualize the predictions in a confusion matrix.

```
confusionchart(YTest,YPred)
```

Assemble Multiple-Output Network for Prediction

This example shows how to assemble a multiple output network for prediction.

Instead of using the `dlnetwork` object for prediction, you can assemble the network into a `DAGNetwork` ready for prediction using the `assembleNetwork` function. This lets you use the `predict` function with other data types such as datastores.

Load Model Function and Parameters

Load the model parameters from the MAT file `dlnetDigits.mat`. The MAT file contains a `dlnetwork` object that predicts both the scores for categorical labels and numeric angles of rotation of images of digits, and the corresponding class names.

```
s = load("dlnetDigits.mat");
dlnet = s.dlnet;
classNames = s.classNames;
```

Assemble Network for Prediction

Extract the layer graph from the `dlnetwork` object using the `layerGraph` function.

```
lgraph = layerGraph(dlnet);
```

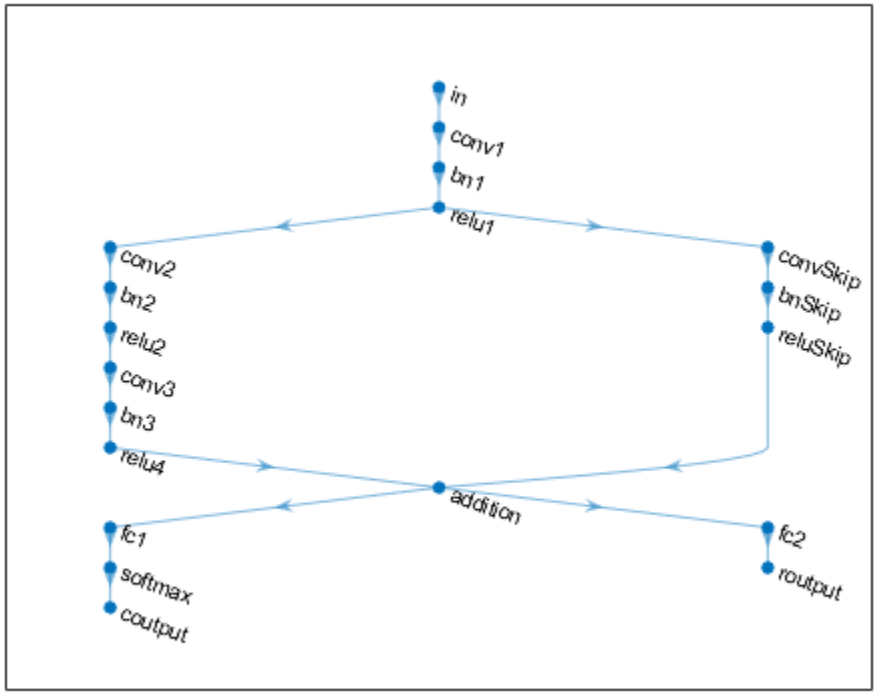
The layer graph does not include output layers. Add a classification layer and a regression layer to the layer graph using the `addLayers` and `connectLayers` functions.

```
layers = classificationLayer('Classes',classNames,'Name','coutput');
lgraph = addLayers(lgraph,layers);
lgraph = connectLayers(lgraph,'softmax','coutput');

layers = regressionLayer('Name','routput');
lgraph = addLayers(lgraph,layers);
lgraph = connectLayers(lgraph,'fc2','routput');
```

View a plot of the network.

```
figure
plot(lgraph)
```



Assemble the network using the `assembleNetwork` function.

```
net = assembleNetwork(lgraph)
```

```
net =
  DAGNetwork with properties:

         Layers: [19x1 nnet.cnn.layer.Layer]
    Connections: [19x2 table]
     InputNames: {'in'}
    OutputNames: {'coutput'  'routput'}
```

Make Predictions on New Data

Load the test data.

```
[XTest,Y1Test,Y2Test] = digitTest4DArrayData;
```

To make predictions using the assembled network, use the `predict` function. To return categorical labels for the classification output, set the `'ReturnCategorical'` option to `true`.

```
[Y1Pred,Y2Pred] = predict(net,XTest,'ReturnCategorical',true);
```

Evaluate the classification accuracy.

```
accuracy = mean(Y1Pred==Y1Test)
```

```
accuracy = 0.9870
```

Evaluate the regression accuracy.

```
angleRMSE = sqrt(mean((Y2Pred - Y2Test).^2))
```

```
angleRMSE = single
    6.0091
```

View some of the images with their predictions. Display the predicted angles in red and the correct labels in green.

```
idx = randperm(size(XTest,4),9);
figure
for i = 1:9
    subplot(3,3,i)
    I = XTest(:,:,:,idx(i));
    imshow(I)
    hold on

    sz = size(I,1);
    offset = sz/2;

    thetaPred = Y2Pred(idx(i));
    plot(offset*[1-tand(thetaPred) 1+tand(thetaPred)],[sz 0],'r--')

    thetaValidation = Y2Test(idx(i));
    plot(offset*[1-tand(thetaValidation) 1+tand(thetaValidation)],[sz 0],'g--')

    hold off
    label = string(Y1Pred(idx(i)));
    title("Label: " + label)
end
```

Automatic Differentiation Background

What Is Automatic Differentiation?

Automatic differentiation (also known as autodiff, AD, or algorithmic differentiation) is a widely used tool for deep learning. See Books on Automatic Differentiation. It is particularly useful for creating and training complex deep learning models without needing to compute derivatives manually for optimization. For examples showing how to create and customize deep learning models, training loops, and loss functions, see “Define Custom Training Loops, Loss Functions, and Networks” on page 18-209.

Automatic differentiation is a set of techniques for evaluating derivatives (gradients) numerically. The method uses symbolic rules for differentiation, which are more accurate than finite difference approximations. Unlike a purely symbolic approach, automatic differentiation evaluates expressions numerically early in the computations, rather than carrying out large symbolic computations. In other words, automatic differentiation evaluates derivatives at particular numeric values; it does not construct symbolic expressions for derivatives.

- Forward mode evaluates a numerical derivative by performing elementary derivative operations concurrently with the operations of evaluating the function itself. As detailed in the next section, the software performs these computations on a computational graph.
- Reverse mode automatic differentiation uses an extension of the forward mode computational graph to enable the computation of a gradient by a reverse traversal of the graph. As the software runs the code to compute the function and its derivative, it records operations in a data structure called a trace.

As many researchers have noted (for example, Baydin, Pearlmutter, Radul, and Siskind [1]), for a scalar function of many variables, reverse mode calculates the gradient more efficiently than forward mode. Because a deep learning loss function is a scalar function of all the weights, Deep Learning Toolbox automatic differentiation uses reverse mode.

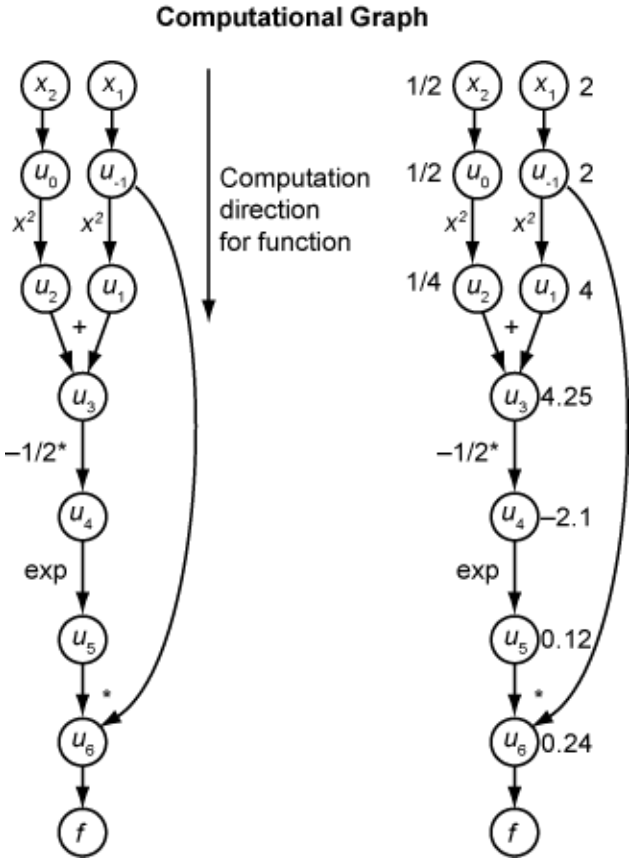
Forward Mode

Consider the problem of evaluating this function and its gradient:

$$f(x) = x_1 \exp\left(-\frac{1}{2}\left(x_1^2 + x_2^2\right)\right).$$

Automatic differentiation works at particular points. In this case, take $x_1 = 2$, $x_2 = 1/2$.

The following computational graph encodes the calculation of the function $f(x)$.



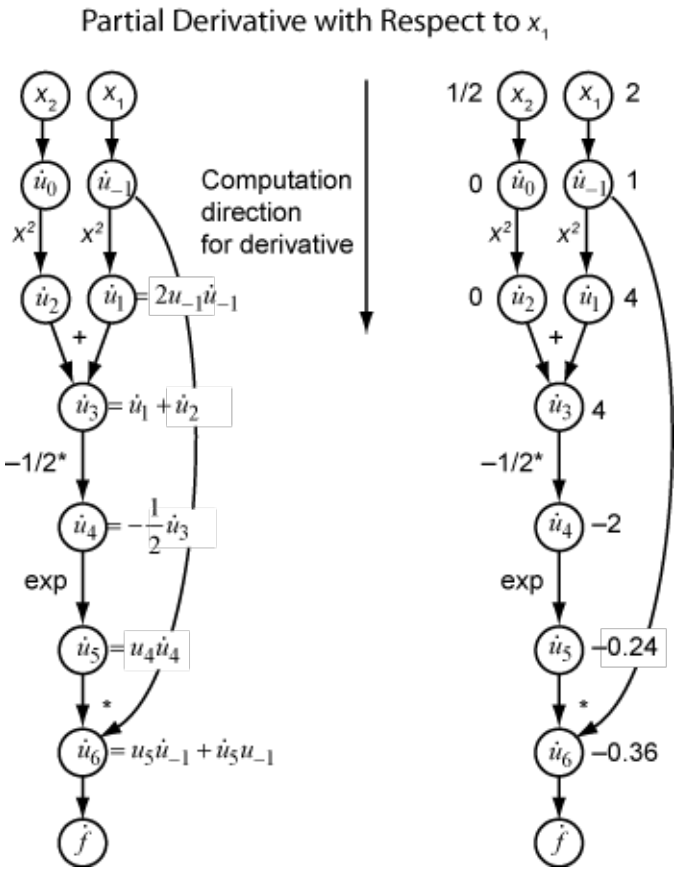
To compute the gradient of $f(x)$ using forward mode, you compute the same graph in the same direction, but modify the computation based on the elementary rules of differentiation. To further simplify the calculation, you fill in the value of the derivative of each subexpression u_i as you go. To compute the entire gradient, you must traverse the graph twice, once for the partial derivative with respect to each independent variable. Each subexpression in the chain rule has a numeric value, so the entire expression has the same sort of evaluation graph as the function itself.

The computation is a repeated application of the chain rule. In this example, the derivative of f with respect to x_1 expands to this expression:

$$\begin{aligned}\frac{df}{dx_1} &= \frac{du_6}{dx_1}\\ &= \frac{\partial u_6}{\partial u_{-1}} + \frac{\partial u_6}{\partial u_5}\frac{\partial u_5}{\partial x_1}\\ &= \frac{\partial u_6}{\partial u_{-1}} + \frac{\partial u_6}{\partial u_5}\frac{\partial u_5}{\partial u_4}\frac{\partial u_4}{\partial x_1}\\ &= \frac{\partial u_6}{\partial u_{-1}} + \frac{\partial u_6}{\partial u_5}\frac{\partial u_5}{\partial u_4}\frac{\partial u_4}{\partial u_3}\frac{\partial u_3}{\partial x_1}\\ &= \frac{\partial u_6}{\partial u_{-1}} + \frac{\partial u_6}{\partial u_5}\frac{\partial u_5}{\partial u_4}\frac{\partial u_4}{\partial u_3}\frac{\partial u_3}{\partial u_1}\frac{\partial u_1}{\partial x_1}.\end{aligned}$$

Let $\dot{u}_i$ represent the derivative of the expression u_i with respect to x_1. Using the evaluated values of the u_i from the function evaluation, you compute the partial derivative of f with respect to x_1 as shown

in the following figure. Notice that all the values of the $\dot{u}_i$ become available as you traverse the graph from top to bottom.



To compute the partial derivative with respect to x_2, you traverse a similar computational graph. Therefore, when you compute the gradient of the function, the number of graph traversals is the same as the number of variables. This process is too slow for typical deep learning applications, which have thousands or millions of variables.

Reverse Mode

Reverse mode uses one forward traversal of a computational graph to set up the trace. Then it computes the entire gradient of the function in one traversal of the graph in the opposite direction. For deep learning applications, this mode is far more efficient.

The theory behind reverse mode is also based on the chain rule, along with associated adjoint variables denoted with an overbar. The adjoint variable for u_i is

$$\bar{u}_i = \frac{\partial f}{\partial u_i}.$$

In terms of the computational graph, each outgoing arrow from a variable contributes to the corresponding adjoint variable by its term in the chain rule. For example, the variable u_{-1} has outgoing arrows to two variables, u_1 and u_6. The graph has the associated equation

$$\frac{\partial f}{\partial u_{-1}} = \frac{\partial f}{\partial u_1}\frac{\partial u_1}{\partial u_{-1}} + \frac{\partial f}{\partial u_6}\frac{\partial u_6}{\partial u_{-1}}$$
$$= \bar{u}_1\frac{\partial u_1}{\partial u_{-1}} + \bar{u}_6\frac{\partial u_6}{\partial u_{-1}}.$$

In this calculation, recalling that $u_1 = u_{-1}^2$ and $u_6 = u_5u_{-1}$, you obtain

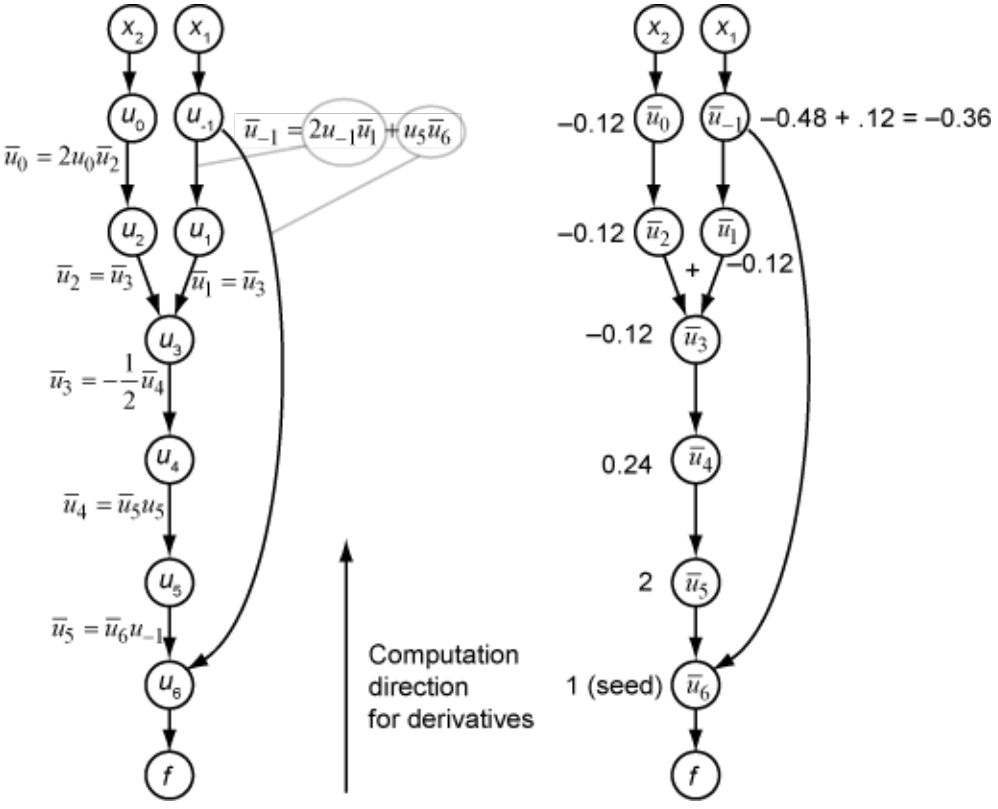
$$\bar{u}_{-1} = \bar{u}_1 2u_{-1} + \bar{u}_6u_5.$$

During the forward traversal of the graph, the software calculates the intermediate variables u_i. During the reverse traversal, starting from the seed value $\bar{u}_6 = \frac{\partial f}{\partial f} = 1$, the reverse mode computation obtains the adjoint values for all variables. Therefore, the reverse mode computes the gradient in just one computation, saving a great deal of time compared to forward mode.

The following figure shows the computation of the gradient in reverse mode for the function

$$f(x) = x_1\exp\left(-\frac{1}{2}\left(x_1^2 + x_2^2\right)\right).$$

Again, the computation takes $x_1 = 2$, $x_2 = 1/2$. The reverse mode computation relies on the u_i values that are obtained during the computation of the function in the original computational graph. In the right portion of the figure, the computed values of the adjoint variables appear next to the adjoint variable names, using the formulas from the left portion of the figure.



The final gradient values appear as $\bar{u}_0 = \frac{\partial f}{\partial u_0} = \frac{\partial f}{\partial x_2}$ and $\bar{u}_{-1} = \frac{\partial f}{\partial u_{-1}} = \frac{\partial f}{\partial x_1}$.

For more details, see Baydin, Pearlmutter, Radul, and Siskind [1] or the Wikipedia article on automatic differentiation [2].

Use Automatic Differentiation In Deep Learning Toolbox

In this section...

Custom Training and Calculations Using Automatic Differentiation

Automatic differentiation makes it easier to create custom training loops, custom layers, and other deep learning customizations.

Generally, the simplest way to customize deep learning training is to create a `dlnetwork`. Include the layers you want in the network. Then perform training in a custom loop by using some sort of gradient descent, where the gradient is the gradient of the objective function. The objective function can be classification error, cross-entropy, or any other relevant scalar function of the network weights. See “List of Functions with dlarray Support” on page 18-423.

This example is a high-level version of a custom training loop. Here, `f` is the objective function, such as loss, and `g` is the gradient of the objective function with respect to the weights in the network `net`. The `update` function represents some type of gradient descent.

```
% High-level training loop
n = 1;
while (n < nmax)
    [f,g] = dlfeval(@model,net,dlX,t);
    net = update(net,g);
    n = n + 1;
end
```

You call `dlfeval` to compute the numeric value of the objective and gradient. To enable the automatic computation of the gradient, the data `dlX` must be a `dlarray`.

```
dlX = dlarray(X);
```

The objective function has a `dlgradient` call to calculate the gradient. The `dlgradient` call must be inside of the function that `dlfeval` evaluates.

```
function [f,g] = model(net,dlX,T)
% Calculate objective using supported functions for dlarray
    y = forward(net,dlX);
    f = fcnvalue(y,T); % crossentropy or similar
    g = dlgradient(f,net.Learnables); % Automatic gradient
end
```

For an example using a `dlnetwork` with a `dlfeval`-`dlgradient`-`dlarray` syntax and a custom training loop, see “Train Network Using Custom Training Loop” on page 18-225. For further details on custom training using automatic differentiation, see “Define Custom Training Loops, Loss Functions, and Networks” on page 18-209.

Use dlgradient and dlfeval Together for Automatic Differentiation

To use automatic differentiation, you must call `dlgradient` inside a function and evaluate the function using `dlfeval`. Represent the point where you take a derivative as a `dlarray` object, which manages the data structures and enables tracing of evaluation. For example, the Rosenbrock function is a common test function for optimization.

```
function [f,grad] = rosenbrock(x)

f = 100*(x(2) - x(1).^2).^2 + (1 - x(1)).^2;
grad = dlgradient(f,x);

end
```

Calculate the value and gradient of the Rosenbrock function at the point `x0` = [–1,2]. To enable automatic differentiation in the Rosenbrock function, pass `x0` as a `dlarray`.

```
x0 = dlarray([-1,2]);
[fval,gradval] = dlfeval(@rosenbrock,x0)
```

```
fval =

  1x1 dlarray

   104

gradval =

  1x2 dlarray

   396   200
```

For an example using automatic differentiation, see “Train Network Using Custom Training Loop” on page 18-225.

Derivative Trace

To evaluate a gradient numerically, a `dlarray` constructs a data structure for reverse mode differentiation, as described in “Automatic Differentiation Background” on page 18-200. This data structure is the trace of the derivative computation. Keep in mind these guidelines when using automatic differentiation and the derivative trace:

- Do not introduce a new `dlarray` inside of an objective function calculation and attempt to differentiate with respect to that object. For example:

  ```
  function [dy,dy1] = fun(x1)
  x2 = dlarray(0);
  y = x1 + x2;
  dy = dlgradient(y,x2); % Error: x2 is untraced
  dy1 = dlgradient(y,x1); % No error even though y has an untraced portion
  end
  ```

- Do not use `extractdata` with a traced argument. Doing so breaks the tracing. For example:

  ```
  fun = @(x)dlgradient(x + atan(extractdata(x)),x);
  % Gradient for any point is 1 due to the leading 'x' term in fun.
  dlfeval(fun,dlarray(2.5))
  ```

```
ans =

  1x1 dlarray

     1
```

However, you can use `extractdata` to introduce a new independent variable from a dependent one.

- When working in parallel, moving traced dlarray objects between the client and workers breaks the tracing. The traced dlarray object is saved on the worker and loaded in the client as an untraced dlarray object. To avoid breaking tracing when working in parallel, compute all required gradients on the worker and then combine the gradients on the client. For an example, see “Train Network in Parallel with Custom Training Loop” on page 7-55.
- Use only supported functions. For a list of supported functions, see “List of Functions with dlarray Support” on page 18-423. To use an unsupported function *f*, try to implement *f* using supported functions.

Characteristics of Automatic Derivatives

- You can evaluate gradients using automatic differentiation only for scalar-valued functions. Intermediate calculations can have any number of variables, but the final function value must be scalar. If you need to take derivatives of a vector-valued function, take derivatives of one component at a time. In this case, consider setting the `dlgradient` `'RetainData'` name-value pair argument to `true`.
- A call to `dlgradient` evaluates derivatives at a particular point. The software generally makes an arbitrary choice for the value of a derivative when there is no theoretical value. For example, the `relu` function, `relu(x) = max(x,0)`, is not differentiable at `x = 0`. However, `dlgradient` returns a value for the derivative.

```
x = dlarray(0);
y = dlfeval(@(t)dlgradient(relu(t),t),x)

y =

  1x1 dlarray

     0
```

The value at the nearby point `eps` is different.

```
x = dlarray(eps);
y = dlfeval(@(t)dlgradient(relu(t),t),x)

y =

  1x1 dlarray

     1
```

Define Custom Training Loops, Loss Functions, and Networks

In this section...

For most deep learning tasks, you can use a pretrained network and adapt it to your own data. For an example showing how to use transfer learning to retrain a convolutional neural network to classify a new set of images, see “Train Deep Learning Network to Classify New Images” on page 3-6. Alternatively, you can create and train networks from scratch using `layerGraph` objects with the `trainNetwork` and `trainingOptions` functions.

If the `trainingOptions` function does not provide the training options that you need for your task, then you can create a custom training loop using automatic differentiation. To learn more, see “Define Deep Learning Network for Custom Training Loops” on page 18-209.

If Deep Learning Toolbox does not provide the layers you need for your task (including output layers that specify loss functions), then you can create a custom layer. To learn more, see “Define Custom Deep Learning Layers” on page 18-9. For loss functions that cannot be specified using an output layer, you can specify the loss in a custom training loop. To learn more, see “Specify Loss Functions” on page 18-212. For networks that cannot be created using layer graphs, you can define custom networks as a function. To learn more, see “Define Network as Model Function” on page 18-209.

For more information about which training method to use for which task, see “Train Deep Learning Model in MATLAB” on page 18-3.

Define Deep Learning Network for Custom Training Loops

Define Network as dlnetwork Object

For most tasks, you can control the training algorithm details using the `trainingOptions` and `trainNetwork` functions. If the `trainingOptions` function does not provide the options you need for your task (for example, a custom learning rate schedule), then you can define your own custom training loop using a `dlnetwork` object. A `dlnetwork` object allows you to train a network specified as a layer graph using automatic differentiation.

For networks specified as a layer graph, you can create a `dlnetwork` object from the layer graph by using the `dlnetwork` function directly.

```
dlnet = dlnetwork(lgraph);
```

For a list of layers supported by `dlnetwork` objects, see the “Supported Layers” section of the `dlnetwork` page. For an example showing how to train a network with a custom learning rate schedule, see “Train Network Using Custom Training Loop” on page 18-225.

Define Network as Model Function

For architectures that cannot be created using layer graphs (for example, a Siamese network that requires shared weights), you can define the model as a function of the form `[dlY1,...,dlYM] = model(parameters,dlX1,...,dlXN)`, where `parameters` contains the network parameters, `dlX1,...,dlXN` corresponds to the input data for the `N` model inputs, and `dlY1,...,dlYM`

corresponds to the `M` model outputs. To train a deep learning model defined as a function, use a custom training loop. For an example, see “Train Network Using Model Function” on page 18-259.

When you define a deep learning model as a function, you must manually initialize the layer weights. For more information, see “Initialize Learnable Parameters for Model Function” on page 18-292.

If you define a custom network as a function, then the model function must support automatic differentiation. You can use the following deep learning operations. The functions listed here are only a subset. For a complete list of functions that support `dlarray` input, see “List of Functions with dlarray Support” on page 18-423.

Function	Description
`avgpool`	The average pooling operation performs downsampling by dividing the input into pooling regions and computing the average value of each region.
`batchnorm`	The batch normalization operation normalizes the input data across all observations for each channel independently. To speed up training of the convolutional neural network and reduce the sensitivity to network initialization, use batch normalization between convolution and nonlinear operations such as `relu`.
`crossentropy`	The cross-entropy operation computes the cross-entropy loss between network predictions and target values for single-label and multi-label classification tasks.
`crosschannelnorm`	The cross-channel normalization operation uses local responses in different channels to normalize each activation. Cross-channel normalization typically follows a `relu` operation. Cross-channel normalization is also known as local response normalization.
`ctc`	The CTC operation computes the connectionist temporal classification (CTC) loss between unaligned sequences.
`dlconv`	The convolution operation applies sliding filters to the input data. Use the `dlconv` function for deep learning convolution, grouped convolution, and channel-wise separable convolution.
`dlode45`	The neural ordinary differential equation (ODE) operation returns the solution of a specified ODE.
`dltranspconv`	The transposed convolution operation upsamples feature maps.
`embed`	The embed operation converts numeric indices to numeric vectors, where the indices correspond to discrete data. Use embeddings to map discrete data such as categorical values or words to numeric vectors.

Function	Description
`fullyconnect`	The fully connect operation multiplies the input by a weight matrix and then adds a bias vector.
`groupnorm`	The group normalization operation normalizes the input data across grouped subsets of channels for each observation independently. To speed up training of the convolutional neural network and reduce the sensitivity to network initialization, use group normalization between convolution and nonlinear operations such as `relu`.
`gru`	The gated recurrent unit (GRU) operation allows a network to learn dependencies between time steps in time series and sequence data.
`huber`	The Huber operation computes the Huber loss between network predictions and target values for regression tasks. When the `'TransitionPoint'` option is 1, this is also known as *smooth L_1 loss*.
`instancenorm`	The instance normalization operation normalizes the input data across each channel for each observation independently. To improve the convergence of training the convolutional neural network and reduce the sensitivity to network hyperparameters, use instance normalization between convolution and nonlinear operations such as `relu`.
`l1loss`	The L_1 loss operation computes the L_1 loss given network predictions and target values. When the `Reduction` option is `"sum"` and the `NormalizationFactor` option is `"batch-size"`, the computed value is known as the mean absolute error (MAE).
`l2loss`	The L_2 loss operation computes the L_2 loss (based on the squared L_2 norm) given network predictions and target values. When the `Reduction` option is `"sum"` and the `NormalizationFactor` option is `"batch-size"`, the computed value is known as the mean squared error (MSE).
`layernorm`	The layer normalization operation normalizes the input data across all channels for each observation independently. To speed up training of recurrent and multilayer perceptron neural networks and reduce the sensitivity to network initialization, use layer normalization after the learnable operations, such as LSTM and fully connect operations.

Function	Description
`leakyrelu`	The leaky rectified linear unit (ReLU) activation operation performs a nonlinear threshold operation, where any input value less than zero is multiplied by a fixed scale factor.
`lstm`	The long short-term memory (LSTM) operation allows a network to learn long-term dependencies between time steps in time series and sequence data.
`maxpool`	The maximum pooling operation performs downsampling by dividing the input into pooling regions and computing the maximum value of each region.
`maxunpool`	The maximum unpooling operation unpools the output of a maximum pooling operation by upsampling and padding with zeros.
`mse`	The half mean squared error operation computes the half mean squared error loss between network predictions and target values for regression tasks.
`onehotdecode`	The one-hot decode operation decodes probability vectors, such as the output of a classification network, into classification labels. The input `A` can be a `dlarray`. If `A` is formatted, the function ignores the data format.
`relu`	The rectified linear unit (ReLU) activation operation performs a nonlinear threshold operation, where any input value less than zero is set to zero.
`sigmoid`	The sigmoid activation operation applies the sigmoid function to the input data.
`softmax`	The softmax activation operation applies the softmax function to the channel dimension of the input data.

Specify Loss Functions

When you use a custom training loop, you must calculate the loss in the model gradients function. Use the loss value when computing gradients for updating the network weights. To compute the loss, you can use the following functions.

Function	Description
`softmax`	The softmax activation operation applies the softmax function to the channel dimension of the input data.

Function	Description
`sigmoid`	The sigmoid activation operation applies the sigmoid function to the input data.
`crossentropy`	The cross-entropy operation computes the cross-entropy loss between network predictions and target values for single-label and multi-label classification tasks.
`l1loss`	The L_1 loss operation computes the L_1 loss given network predictions and target values. When the `Reduction` option is `"sum"` and the `NormalizationFactor` option is `"batch-size"`, the computed value is known as the mean absolute error (MAE).
`l2loss`	The L_2 loss operation computes the L_2 loss (based on the squared L_2 norm) given network predictions and target values. When the `Reduction` option is `"sum"` and the `NormalizationFactor` option is `"batch-size"`, the computed value is known as the mean squared error (MSE).
`huber`	The Huber operation computes the Huber loss between network predictions and target values for regression tasks. When the `'TransitionPoint'` option is 1, this is also known as *smooth L_1 loss*.
`mse`	The half mean squared error operation computes the half mean squared error loss between network predictions and target values for regression tasks.
`ctc`	The CTC operation computes the connectionist temporal classification (CTC) loss between unaligned sequences.

Alternatively, you can use a custom loss function by creating a function of the form `loss = myLoss(Y,T)`, where `Y` and `T` correspond to the network predictions and targets, respectively, and `loss` is the returned loss.

For an example showing how to train a generative adversarial network (GAN) that generates images using a custom loss function, see “Train Generative Adversarial Network (GAN)” on page 3-76.

Update Learnable Parameters Using Automatic Differentiation

When you train a deep learning model with a custom training loop, the software minimizes the loss with respect to the learnable parameters. To minimize the loss, the software uses the gradients of the loss with respect to the learnable parameters. To calculate these gradients using automatic differentiation, you must define a model gradients function.

Define Model Gradients Function

For a model specified as a `dlnetwork` object, create a function of the form `gradients = modelGradients(dlnet,dlX,T)`, where `dlnet` is the network, `dlX` is the network input, `T` contains the targets, and `gradients` contains the returned gradients. Optionally, you can pass extra arguments to the gradients function (for example, if the loss function requires extra information), or return extra arguments (for example, metrics for plotting the training progress).

For a model specified as a function, create a function of the form `gradients = modelGradients(parameters,dlX,T)`, where `parameters` contains the learnable parameters, `dlX` is the model input, `T` contains the targets, and `gradients` contains the returned gradients. Optionally, you can pass extra arguments to the gradients function (for example, if the loss function requires extra information), or return extra arguments (for example, metrics for plotting the training progress).

To learn more about defining model gradients functions for custom training loops, see “Define Model Gradients Function for Custom Training Loop” on page 18-231.

Update Learnable Parameters

To evaluate the model gradients using automatic differentiation, use the `dlfeval` function, which evaluates a function with automatic differentiation enabled. For the first input of `dlfeval`, pass the model gradients function specified as a function handle. For the following inputs, pass the required variables for the model gradients function. For the outputs of the `dlfeval` function, specify the same outputs as the model gradients function.

To update the learnable parameters using the gradients, you can use the following functions.

Function	Description
`adamupdate`	Update parameters using adaptive moment estimation (Adam)
`rmspropupdate`	Update parameters using root mean squared propagation (RMSProp)
`sgdmupdate`	Update parameters using stochastic gradient descent with momentum (SGDM)
`dlupdate`	Update parameters using custom function

Specify Training Options in Custom Training Loop

For most tasks, you can control the training algorithm details using the `trainingOptions` and `trainNetwork` functions. If the `trainingOptions` function does not provide the options you need for your task (for example, a custom learning rate schedule), then you can define your own custom training loop using a `dlnetwork` object. A `dlnetwork` object allows you to train a network specified as a layer graph using automatic differentiation.

To specify the same options as the `trainingOptions`, use these examples as a guide:

Training Option	`trainingOptions` Argument	Example
Adam solver	• `solverName` • `'GradientDecayFactor'` • `'SquaredGradientDecayFactor'`	"Adaptive Moment Estimation (ADAM)" on page 18-217
RMSProp solver	• `solverName` • `'Epsilon'`	"Root Mean Square Propagation (RMSProp)" on page 18-217
SGDM solver	• `solverName` • `'Momentum'`	"Stochastic Gradient Descent with Momentum (SGDM)" on page 18-217
Learn rate	`'InitialLearnRate'`	"Learn Rate" on page 18-217
Learn rate schedule	• `'LearnRateSchedule'` • `'LearnRateDropPeriod'` • `'LearnRateDropFactor'`	"Piecewise Learn Rate Schedule" on page 18-217
Training progress	`'Plots'`	"Plots" on page 18-218
Verbose output	• `'Verbose'` • `'VerboseFrequency'`	"Verbose Output" on page 18-219
Mini-batch size	`'MiniBatchSize'`	"Mini-Batch Size" on page 18-220
Number of epochs	`'MaxEpochs'`	"Number of Epochs" on page 18-220
Validation	• `'ValidationData` • `'ValidationPatience'`	"Validation" on page 18-220
L_2 regularization	`'L2Regularization'`	"L2 Regularization" on page 18-222
Gradient clipping	• `'GradientThreshold'` • `'GradientThresholdMethod'`	"Gradient Clipping" on page 18-222
Single CPU or GPU training	`'ExecutionEnvironment'`	"Single CPU or GPU Training" on page 18-223
Checkpoints	`'CheckpointPath'`	"Checkpoints" on page 18-223

Solver Options

To specify the solver, use the `adamupdate`, `rmspropupdate`, and `sgdmupdate` functions for the update step in your training loop. To implement your own custom solver, update the learnable parameters using the `dlupdate` function.

Adaptive Moment Estimation (ADAM)

To update your network parameters using Adam, use the `adamupdate` function. Specify the gradient decay and the squared gradient decay factors using the corresponding input arguments.

Root Mean Square Propagation (RMSProp)

To update your network parameters using RMSProp, use the `rmspropupdate` function. Specify the denominator offset (epsilon) value using the corresponding input argument.

Stochastic Gradient Descent with Momentum (SGDM)

To update your network parameters using SGDM, use the `sgdmupdate` function. Specify the momentum using the corresponding input argument.

Learn Rate

To specify the learn rate, use the learn rate input arguments of the `adamupdate`, `rmspropupdate`, and `sgdmupdate` functions.

To easily adjust the learn rate or use it for custom learn rate schedules, set the initial learn rate before the custom training loop.

```
learnRate = 0.01;
```

Piecewise Learn Rate Schedule

To automatically drop the learn rate during training using a piecewise learn rate schedule, multiply the learn rate by a given drop factor after a specified interval.

To easily specify a piecewise learn rate schedule, create the variables `learnRate`, `learnRateSchedule`, `learnRateDropFactor`, and `learnRateDropPeriod`, where `learnRate` is the initial learn rate, `learnRateScedule` contains either `"piecewise"` or `"none"`, `learnRateDropFactor` is a scalar in the range [0, 1] that specifies the factor for dropping the learning rate, and `learnRateDropPeriod` is a positive integer that specifies how many epochs between dropping the learn rate.

```
learnRate = 0.01;
learnRateSchedule = "piecewise"
learnRateDropPeriod = 10;
learnRateDropFactor = 0.1;
```

Inside the training loop, at the end of each epoch, drop the learn rate when the `learnRateSchedule` option is `"piecewise"` and the current epoch number is a multiple of `learnRateDropPeriod`. Set the new learn rate to the product of the learn rate and the learn rate drop factor.

```
if learnRateSchedule == "piecewise" && mod(epoch,learnRateDropPeriod) == 0
    learnRate = learnRate * learnRateDropFactor;
end
```

Plots

To plot the training loss and accuracy during training, calculate the mini-batch loss and either the accuracy or the root-mean-squared-error (RMSE) in the model gradients function and plot them using an animated line.

To easily specify that the plot should be on or off, create the variable `plots` that contains either `"training-progress"` or `"none"`. To also plot validation metrics, use the same options `validationData` and `validationFrequency` described in “Validation” on page 18-220.

```
plots = "training-progress";

validationData = {XValidation, YValidation};
validationFrequency = 50;
```

Before training, initialize the animated lines using the `animatedline` function. For classification tasks create a plot for the training accuracy and the training loss. Also initialize animated lines for validation metrics when validation data is specified.

```
if plots == "training-progress"
    figure
    subplot(2,1,1)
    lineAccuracyTrain = animatedline;
    ylabel("Accuracy")

    subplot(2,1,2)
    lineLossTrain = animatedline;
    xlabel("Iteration")
    ylabel("Loss")

    if ~isempty(validationData)
        subplot(2,1,1)
        lineAccuracyValidation = animatedline;

        subplot(2,1,2)
        lineLossValidation = animatedline;
    end
end
```

For regression tasks, adjust the code by changing the variable names and labels so that it initializes plots for the training and validation RMSE instead of the training and validation accuracy.

Inside the training loop, at the end of an iteration, update the plot so that it includes the appropriate metrics for the network. For classification tasks, add points corresponding to the mini-batch accuracy and the mini-batch loss. If the validation data is nonempty, and the current iteration is either 1 or a multiple of the validation frequency option, then also add points for the validation data.

```
if plots == "training-progress"
    addpoints(lineAccuracyTrain,iteration,accuracyTrain)
    addpoints(lineLossTrain,iteration,lossTrain)

    if ~isempty(validationData) && (iteration == 1 || mod(iteration,validationFrequency) == 0)
        addpoints(lineAccuracyValidation,iteration,accuracyValidation)
        addpoints(lineLossValidation,iteration,lossValidation)
    end
end
```

where `accuracyTrain` and `lossTrain` correspond to the mini-batch accuracy and loss calculated in the model gradients function. For regression tasks, use the mini-batch RMSE losses instead of the mini-batch accuracies.

Tip The `addpoints` function requires the data points to have type `double`. To extract numeric data from `dlarray` objects, use the `extractdata` function. To collect data from a GPU, use the `gather` function.

To learn how to compute validation metrics, see “Validation” on page 18-220.

Verbose Output

To display the training loss and accuracy during training in a verbose table, calculate the mini-batch loss and either the accuracy (for classification tasks) or the RMSE (for regression tasks) in the model gradients function and display them using the `disp` function.

To easily specify that the verbose table should be on or off, create the variables `verbose` and `verboseFrequency`, where `verbose` is `true` or `false` and `verbosefrequency` specifies how many iterations between printing verbose output. To display validation metrics, use the same options `validationData` and `validationFrequency` described in “Validation” on page 18-220.

```
verbose = true
verboseFrequency = 50;

validationData = {XValidation, YValidation};
validationFrequency = 50;
```

Before training, display the verbose output table headings and initialize a timer using the `tic` function.

```
disp("|========================================================================================================================|")
disp("|  Epoch  |  Iteration  |  Time Elapsed  |  Mini-batch  |  Validation  |  Mini-batch  |  Validation  |  Base Learning  |")
disp("|         |             |   (hh:mm:ss)   |   Accuracy   |   Accuracy   |     Loss     |     Loss     |      Rate       |")
disp("|========================================================================================================================|")

start = tic;
```

For regression tasks, adjust the code so that it displays the training and validation RMSE instead of the training and validation accuracy.

Inside the training loop, at the end of an iteration, print the verbose output when the `verbose` option is `true` and it is either the first iteration or the iteration number is a multiple of `verboseFrequency`.

```
if verbose && (iteration == 1 || mod(iteration,verboseFrequency) == 0
    D = duration(0,0,toc(start),'Format','hh:mm:ss');

    if isempty(validationData) || mod(iteration,validationFrequency) ~= 0
        accuracyValidation = "";
        lossValidation = "";
    end

    disp("| " + ...
        pad(epoch,7,'left') + " | " + ...
        pad(iteration,11,'left') + " | " + ...
        pad(D,14,'left') + " | " + ...
        pad(accuracyTrain,12,'left') + " | " + ...
        pad(accuracyValidation,12,'left') + " | " + ...
        pad(lossTrain,12,'left') + " | " + ...
        pad(lossValidation,12,'left') + " | " + ...
        pad(learnRate,15,'left') + " |")
end
```

For regression tasks, adjust the code so that it displays the training and validation RMSE instead of the training and validation accuracy.

When training is finished, print the last border of the verbose table.

```
disp("|=======================================================================================================================|")
```

To learn how to compute validation metrics, see “Validation” on page 18-220.

Mini-Batch Size

Setting the mini-batch size depends on the format of data or type of datastore used.

To easily specify the mini-batch size, create a variable `miniBatchSize`.

```
miniBatchSize = 128;
```

For data in an image datastore, before training, set the `ReadSize` property of the datastore to the mini-batch size.

```
imds.ReadSize = miniBatchSize;
```

For data in an augmented image datastore, before training, set the `MiniBatchSize` property of the datastore to the mini-batch size.

```
augimds.MiniBatchSize = miniBatchSize;
```

For in-memory data, during training at the start of each iteration, read the observations directly from the array.

```
idx = ((iteration - 1)*miniBatchSize + 1):(iteration*miniBatchSize);
X = XTrain(:,:,:,idx);
```

Number of Epochs

Specify the maximum number of epochs for training in the outer `for` loop of the training loop.

To easily specify the maximum number of epochs, create the variable `maxEpochs` that contains the maximum number of epochs.

```
maxEpochs = 30;
```

In the outer `for` loop of the training loop, specify to loop over the range 1, 2, ..., `maxEpochs`.

```
for epoch = 1:maxEpochs
    ...
end
```

Validation

To validate your network during training, set aside a held-out validation set and evaluate how well the network performs on that data.

To easily specify validation options, create the variables `validationData` and `validationFrequency`, where `validationData` contains the validation data or is empty and `validationFrequency` specifies how many iterations between validating the network.

```
validationData = {XValidation,YValidation};
validationFrequency = 50;
```

During the training loop, after updating the network parameters, test how well the network performs on the held-out validation set using the `predict` function. Validate the network only when validation

data is specified and it is either the first iteration or the current iteration is a multiple of the `validationFrequency` option.

```
if iteration == 1 || mod(iteration,validationFrequency) == 0
    dlYPredValidation = predict(dlnet,dlXValidation);
    lossValidation = crossentropy(softmax(dlYPredValidation), YValidation);

    [~,idx] = max(dlYPredValidation);
    labelsPredValidation = classNames(idx);

    accuracyValidation = mean(labelsPredValidation == labelsValidation);
end
```

Here, `YValidation` is a dummy variable corresponding to the labels in `classNames`. To calculate the accuracy, convert `YValidation` to an array of labels.

For regression tasks, adjust the code so that it calculates the validation RMSE instead of the validation accuracy.

Early Stopping

To stop training early when the loss on the held-out validation stops decreasing, use a flag to break out of the training loops.

To easily specify the validation patience (the number of times that the validation loss can be larger than or equal to the previously smallest loss before network training stops), create the variable `validationPatience`.

```
validationPatience = 5;
```

Before training, initialize a variables `earlyStop` and `validationLosses`, where `earlyStop` is a flag to stop training early and `validationLosses` contains the losses to compare. Initialize the early stopping flag with `false` and array of validation losses with `inf`.

```
earlyStop = false;
if isfinite(validationPatience)
    validationLosses = inf(1,validationPatience);
end
```

Inside the training loop, in the loop over mini-batches, add the `earlyStop` flag to the loop condition.

```
while hasdata(ds) && ~earlyStop
    ...
end
```

During the validation step, append the new validation loss to the array `validationLosses`. If the first element of the array is the smallest, then set the `earlyStop` flag to `true`. Otherwise, remove the first element.

```
if isfinite(validationPatience)
    validationLosses = [validationLosses validationLoss];
    if min(validationLosses) == validationLosses(1)
        earlyStop = true;
    else
        validationLosses(1) = [];
    end
end
```

L2 Regularization

To apply L_2 regularization to the weights, use the `dlupdate` function.

To easily specify the L_2 regularization factor, create the variable `l2Regularization` that contains the L_2 regularization factor.

```
l2Regularization = 0.0001;
```

During training, after computing the model gradients, for each of the weight parameters, add the product of the L_2 regularization factor and the weights to the computed gradients using the `dlupdate` function. To update only the weight parameters, extract the parameters with name `"Weights"`.

```
idx = dlnet.Learnables.Parameter == "Weights";
gradients(idx,:) = dlupdate(@(g,w) g + l2Regularization*w, gradients(idx,:), dlnet.Learnables(idx,:));
```

After adding the L_2 regularization parameter to the gradients, update the network parameters.

Gradient Clipping

To clip the gradients, use the `dlupdate` function.

To easily specify gradient clipping options, create the variables `gradientThresholdMethod` and `gradientThreshold`, where `gradientThresholdMethod` contains `"global-l2norm"`, `"l2norm"`, or `"absolute-value"`, and `gradientThreshold` is a positive scalar containing the threshold or `inf`.

```
gradientThresholdMethod = "global-l2norm";
gradientThreshold = 2;
```

Create functions named `thresholdGlobalL2Norm`, `thresholdL2Norm`, and `thresholdAbsoluteValue` that apply the `"global-l2norm"`, `"l2norm"`, and `"absolute-value"` threshold methods, respectively.

For the `"global-l2norm"` option, the function operates on all gradients of the model.

```
function gradients = thresholdGlobalL2Norm(gradients,gradientThreshold)

globalL2Norm = 0;
for i = 1:numel(gradients)
    globalL2Norm = globalL2Norm + sum(gradients{i}(:).^2);
end
globalL2Norm = sqrt(globalL2Norm);

if globalL2Norm > gradientThreshold
    normScale = gradientThreshold / globalL2Norm;
    for i = 1:numel(gradients)
        gradients{i} = gradients{i} * normScale;
    end
end

end
```

For the `"l2norm"` and `"absolute-value"` options, the functions operate on each gradient independently.

```
function gradients = thresholdL2Norm(gradients,gradientThreshold)

gradientNorm = sqrt(sum(gradients(:).^2));
if gradientNorm > gradientThreshold
    gradients = gradients * (gradientThreshold / gradientNorm);
end

end
```

```
function gradients = thresholdAbsoluteValue(gradients,gradientThreshold)

gradients(gradients > gradientThreshold) = gradientThreshold;
gradients(gradients < -gradientThreshold) = -gradientThreshold;

end
```

During training, after computing the model gradients, apply the appropriate gradient clipping method to the gradients using the `dlupdate` function. Because the `"global-l2norm"` option requires all the model gradients, apply the `thresholdGlobalL2Norm` function directly to the gradients. For the `"l2norm"` and `"absolute-value"` options, update the gradients independently using the `dlupdate` function.

```
switch gradientThresholdMethod
    case "global-l2norm"
        gradients = thresholdGlobalL2Norm(gradients, gradientThreshold);
    case "l2norm"
        gradients = dlupdate(@(g) thresholdL2Norm(g, gradientThreshold),gradients);
    case "absolute-value"
        gradients = dlupdate(@(g) thresholdAbsoluteValue(g, gradientThreshold),gradients);
end
```

After applying the gradient threshold operation, update the network parameters.

Single CPU or GPU Training

The software, by default, performs calculations using only the CPU. To train on a single GPU, convert the data to `gpuArray` objects. Using a GPU requires Parallel Computing Toolbox and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

To easily specify the execution environment, create the variable `executionEnvironment` that contains either `"cpu"`, `"gpu"`, or `"auto"`.

```
executionEnvironment = "auto"
```

During training, after reading a mini-batch, check the execution environment option and convert the data to a `gpuArray` if necessary. The `canUseGPU` function checks for useable GPUs.

```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlX = gpuArray(dlX);
end
```

Checkpoints

To save checkpoint networks during training save the network using the `save` function.

To easily specify whether checkpoints should be switched on, create the variable `checkpointPath` contains the folder for the checkpoint networks or is empty.

```
checkpointPath = fullfile(tempdir,"checkpoints");
```

If the checkpoint folder does not exist, then before training, create the checkpoint folder.

```
if ~exist(checkpointPath,"dir")
    mkdir(checkpointPath)
end
```

During training, at the end of an epoch, save the network in a MAT file. Specify a file name containing the current iteration number, date, and time.

```
if ~isempty(checkpointPath)
    D = datestr(now,'yyyy_mm_dd__HH_MM_SS');
    filename = "dlnet_checkpoint__" + iteration + "__" + D + ".mat";
    save(filename,"dlnet")
end
```

where `dlnet` is the `dlnetwork` object to be saved.

Train Network Using Custom Training Loop

This example shows how to train a network that classifies handwritten digits with a custom learning rate schedule.

If `trainingOptions` does not provide the options you need (for example, a custom learning rate schedule), then you can define your own custom training loop using automatic differentiation.

This example trains a network to classify handwritten digits with the *time-based decay* learning rate schedule: for each iteration, the solver uses the learning rate given by $\rho_t = \frac{\rho_0}{1 + k\,t}$, where t is the iteration number, ρ_0 is the initial learning rate, and k is the decay.

Load Training Data

Load the digits data as an image datastore using the `imageDatastore` function and specify the folder containing the image data.

```
dataFolder = fullfile(toolboxdir('nnet'),'nndemos','nndatasets','DigitDataset');
imds = imageDatastore(dataFolder, ...
    'IncludeSubfolders',true, ....
    'LabelSource','foldernames');
```

Partition the data into training and validation sets. Set aside 10% of the data for validation using the `splitEachLabel` function.

```
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9,'randomize');
```

The network used in this example requires input images of size 28-by-28-by-1. To automatically resize the training images, use an augmented image datastore. Specify additional augmentation operations to perform on the training images: randomly translate the images up to 5 pixels in the horizontal and vertical axes. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
inputSize = [28 28 1];
pixelRange = [-5 5];
imageAugmenter = imageDataAugmenter( ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain,'DataAugmentation',imageAugmente
```

To automatically resize the validation images without performing further data augmentation, use an augmented image datastore without specifying any additional preprocessing operations.

```
augimdsValidation = augmentedImageDatastore(inputSize(1:2),imdsValidation);
```

Determine the number of classes in the training data.

```
classes = categories(imdsTrain.Labels);
numClasses = numel(classes);
```

Define Network

Define the network for image classification.

```
layers = [
    imageInputLayer(inputSize,'Normalization','none','Name','input')
```

```
    convolution2dLayer(5,20,'Name','conv1')
    batchNormalizationLayer('Name','bn1')
    reluLayer('Name','relu1')
    convolution2dLayer(3,20,'Padding','same','Name','conv2')
    batchNormalizationLayer('Name','bn2')
    reluLayer('Name','relu2')
    convolution2dLayer(3,20,'Padding','same','Name','conv3')
    batchNormalizationLayer('Name','bn3')
    reluLayer('Name','relu3')
    fullyConnectedLayer(numClasses,'Name','fc')
    softmaxLayer('Name','softmax')];
lgraph = layerGraph(layers);
```

Create a `dlnetwork` object from the layer graph.

```
dlnet = dlnetwork(lgraph)
```

```
dlnet =
  dlnetwork with properties:

         Layers: [12×1 nnet.cnn.layer.Layer]
    Connections: [11×2 table]
     Learnables: [14×3 table]
          State: [6×3 table]
     InputNames: {'input'}
    OutputNames: {'softmax'}
```

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, that takes a `dlnetwork` object, a mini-batch of input data with corresponding labels and returns the gradients of the loss with respect to the learnable parameters in the network and the corresponding loss.

Specify Training Options

Train for ten epochs with a mini-batch size of 128.

```
numEpochs = 10;
miniBatchSize = 128;
```

Specify the options for SGDM optimization. Specify an initial learn rate of 0.01 with a decay of 0.01, and momentum 0.9.

```
initialLearnRate = 0.01;
decay = 0.01;
momentum = 0.9;
```

Train Model

Create a `minibatchqueue` object that processes and manages mini-batches of images during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to convert the labels to one-hot encoded variables.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels.

- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(augimdsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn',@preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB',''});
```

Initialize the training progress plot.

```
figure
lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Initialize the velocity parameter for the SGDM solver.

```
velocity = [];
```

Train the network using a custom training loop. For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients, state, and loss using the `dlfeval` and `modelGradients` functions and update the network state.
- Determine the learning rate for the time-based decay learning rate schedule.
- Update the network parameters using the `sgdmupdate` function.
- Display the training progress.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs
    % Shuffle data.
    shuffle(mbq);

    % Loop over mini-batches.
    while hasdata(mbq)
        iteration = iteration + 1;

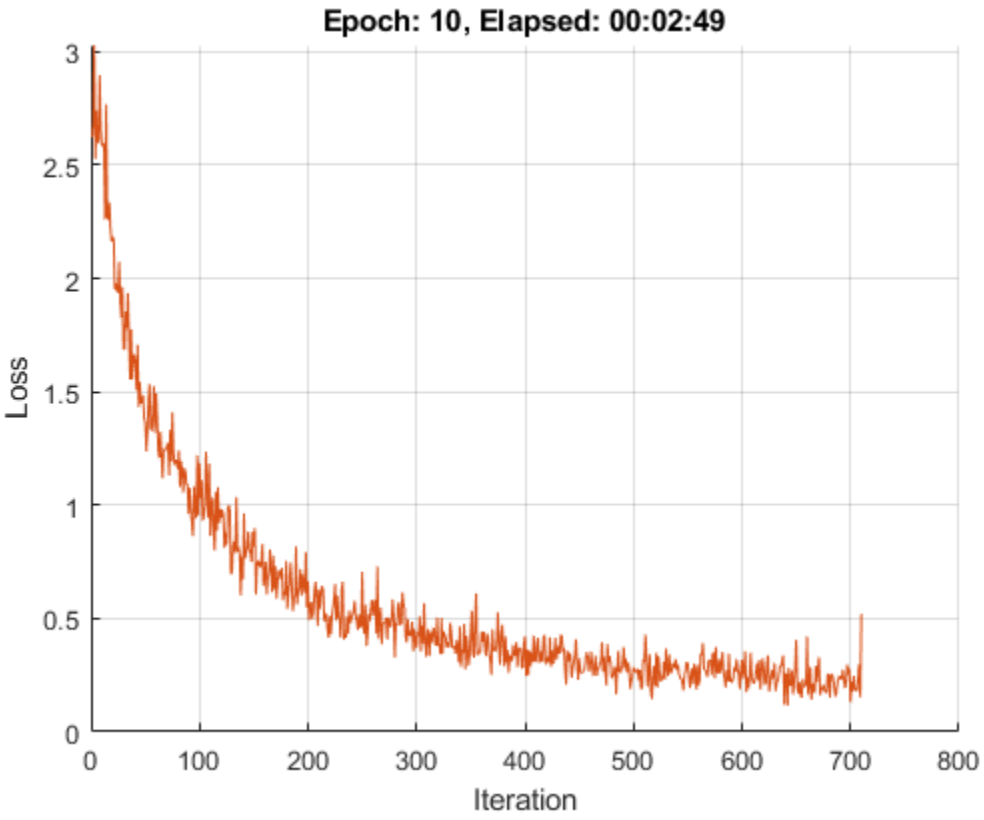
        % Read mini-batch of data.
        [dlX, dlY] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function and update the network state.
        [gradients,state,loss] = dlfeval(@modelGradients,dlnet,dlX,dlY);
        dlnet.State = state;

        % Determine learning rate for time-based decay learning rate schedule.
        learnRate = initialLearnRate/(1 + decay*iteration);

        % Update the network parameters using the SGDM optimizer.
        [dlnet,velocity] = sgdmupdate(dlnet,gradients,velocity,learnRate,momentum);
```

```
        % Display the training progress.
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        addpoints(lineLossTrain,iteration,loss)
        title("Epoch: " + epoch + ", Elapsed: " + string(D))
        drawnow
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on the validation set with the true labels.

After training, making predictions on new data does not require the labels. Create `minibatchqueue` object containing only the predictors of the test data:

- To ignore the labels for testing, set the number of outputs of the mini-batch queue to 1.
- Specify the same mini-batch size used for training.
- Preprocess the predictors using the `preprocessMiniBatchPredictors` function, listed at the end of the example.
- For the single output of the datastore, specify the mini-batch format `'SSCB'` (spatial, spatial, channel, batch).

```
numOutputs = 1;
mbqTest = minibatchqueue(augimdsValidation,numOutputs, ...
```

```
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFcn',@preprocessMiniBatchPredictors, ...
    'MiniBatchFormat','SSCB');
```

Loop over the mini-batches and classify the images using `modelPredictions` function, listed at the end of the example.

```
predictions = modelPredictions(dlnet,mbqTest,classes);
```

Evaluate the classification accuracy.

```
YTest = imdsValidation.Labels;
accuracy = mean(predictions == YTest)
```

```
accuracy = 0.9530
```

Model Gradients Function

The `modelGradients` function takes a `dlnetwork` object `dlnet`, a mini-batch of input data `dlX` with corresponding labels `Y` and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, the network state, and the loss. To compute the gradients automatically, use the `dlgradient` function.

```
function [gradients,state,loss] = modelGradients(dlnet,dlX,Y)

[dlYPred,state] = forward(dlnet,dlX);

loss = crossentropy(dlYPred,Y);
gradients = dlgradient(loss,dlnet.Learnables);

loss = double(gather(extractdata(loss)));

end
```

Model Predictions Function

The `modelPredictions` function takes a `dlnetwork` object `dlnet`, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in the `minibatchqueue` object. The function uses the `onehotdecode` function to find the predicted class with the highest score.

```
function predictions = modelPredictions(dlnet,mbq,classes)

predictions = [];

while hasdata(mbq)

    dlXTest = next(mbq);
    dlYPred = predict(dlnet,dlXTest);

    YPred = onehotdecode(dlYPred,classes,1)';

    predictions = [predictions; YPred];
end

end
```

Mini Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses a mini-batch of predictors and labels using the following steps:

1. Preprocess the images using the `preprocessMiniBatchPredictors` function.
2. Extract the label data from the incoming cell array and concatenate into a categorical array along the second dimension.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y] = preprocessMiniBatch(XCell,YCell)

% Preprocess predictors.
X = preprocessMiniBatchPredictors(XCell);

% Extract label data from cell and concatenate.
Y = cat(2,YCell{1:end});

% One-hot encode labels.
Y = onehotencode(Y,1);

end
```

Mini-Batch Predictors Preprocessing Function

The `preprocessMiniBatchPredictors` function preprocesses a mini-batch of predictors by extracting the image data from the input cell array and concatenate into a numeric array. For grayscale input, concatenating over the fourth dimension adds a third dimension to each image, to use as a singleton channel dimension.

```
function X = preprocessMiniBatchPredictors(XCell)

% Concatenate.
X = cat(4,XCell{1:end});

end
```

Define Model Gradients Function for Custom Training Loop

When you train a deep learning model with a custom training loop, the software minimizes the loss with respect to the learnable parameters. To minimize the loss, the software uses the gradients of the loss with respect to the learnable parameters. To calculate these gradients using automatic differentiation, you must define a model gradients function.

For an example showing how to train deep learning model with a `dlnetwork` object, see “Train Network Using Custom Training Loop” on page 18-225. For an example showing how to training a deep learning model defined as a function, see “Train Network Using Model Function” on page 18-259.

Create Model Gradients Function for Model Defined as dlnetwork Object

If you have a deep learning model defined as a `dlnetwork` object, then create a model gradients function that takes the `dlnetwork` object as input.

For a model specified as a `dlnetwork` object, create a function of the form `gradients = modelGradients(dlnet,dlX,T)`, where `dlnet` is the network, `dlX` is the network input, `T` contains the targets, and `gradients` contains the returned gradients. Optionally, you can pass extra arguments to the gradients function (for example, if the loss function requires extra information), or return extra arguments (for example, metrics for plotting the training progress).

For example, this function returns the gradients and the cross entropy loss for the specified `dlnetwork` object `dlnet`, input data `dlX`, and targets `T`.

```
function [gradients, loss] = modelGradients(dlnet, dlX, T)

    % Forward data through the dlnetwork object.
    dlY = forward(dlnet,dlX);

    % Compute loss.
    loss = crossentropy(dlY,T);

    % Compute gradients.
    gradients = dlgradient(loss,dlnet);

end
```

Create Model Gradients Function for Model Defined as Function

If you have a deep learning model defined as a function, then create a model gradients function that takes the model learnable parameters as input.

For a model specified as a function, create a function of the form `gradients = modelGradients(parameters,dlX,T)`, where `parameters` contains the learnable parameters, `dlX` is the model input, `T` contains the targets, and `gradients` contains the returned gradients. Optionally, you can pass extra arguments to the gradients function (for example, if the loss function requires extra information), or return extra arguments (for example, metrics for plotting the training progress).

For example, this function returns the gradients and the cross-entropy loss for the deep learning model function `model` with the specified learnable parameters `parameters`, input data `dlX`, and targets `T`.

```
function [gradients, loss] = modelGradients(parameters, dlX, T)

    % Forward data through the model function.
    dlY = model(parameters,dlX);

    % Compute loss.
    loss = crossentropy(dlY,T);

    % Compute gradients.
    gradients = dlgradient(loss,parameters);

end
```

Evaluate Model Gradients Function

To evaluate the model gradients using automatic differentiation, use the `dlfeval` function, which evaluates a function with automatic differentiation enabled. For the first input of `dlfeval`, pass the model gradients function specified as a function handle. For the following inputs, pass the required variables for the model gradients function. For the outputs of the `dlfeval` function, specify the same outputs as the model gradients function.

For example, evaluate the model gradients function `modelGradients` with a `dlnetwork` object `dlnet`, input data `dlX`, and targets `T`, and return the model gradients and loss.

```
[gradients, loss] = dlfeval(@modelGradients,dlnet,dlX,T);
```

Similarly, evaluate the model gradients function `modelGradients` using a model function with learnable parameters specified by the structure `parameters`, input data `dlX`, and targets `T`, and return the model gradients and loss.

```
[gradients, loss] = dlfeval(@modelGradients,parameters,dlX,T);
```

Update Learnable Parameters Using Gradients

To update the learnable parameters using the gradients, you can use the following functions.

Function	Description
`adamupdate`	Update parameters using adaptive moment estimation (Adam)
`rmspropupdate`	Update parameters using root mean squared propagation (RMSProp)
`sgdmupdate`	Update parameters using stochastic gradient descent with momentum (SGDM)
`dlupdate`	Update parameters using custom function

For example, update the learnable parameters of a `dlnetwork` object `dlnet` using the `adamupdate` function.

```
[dlnet,trailingAvg,trailingAvgSq] = adamupdate(dlnet,gradients, ...
    trailingAvg,trailingAverageSq,iteration);
```

`gradients` is the output of the model gradients function, and `trailingAvg`, `trailingAvgSq`, and `iteration` are the hyperparameters required by the `adamupdate` function.

Similarly, update the learnable parameters for a model function `parameters` using the `adamupdate` function.

```
[parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
    trailingAvg,trailingAverageSq,iteration);
```

`gradients` is the output of the model gradients function, and `trailingAvg`, `trailingAvgSq`, and `iteration` are the hyperparameters required by the `adamupdate` function.

Use Model Gradients Function in Custom Training Loop

When training a deep learning model using a custom training loop, evaluate the model gradients and update the learnable parameters for each mini-batch.

This code snippet shows an example of using the `dlfeval` and `adamupdate` functions in a custom training loop.

```
iteration = 0;

% Loop over epochs.
for epoch = 1:numEpochs

    % Loop over mini-batches.
    for i = 1:numIterationsPerEpoch
        iteration = iteration + 1;

        % Prepare mini-batch.
        % ...

        % Evaluate model gradients.
        [gradients, loss] = dlfeval(@modelGradients,dlnet,dlX,T);

        % Update learnable parameters.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
            trailingAvg,trailingAverageSq,iteration);

    end
end
```

For an example showing how to train a deep learning model with a `dlnetwork` object, see “Train Network Using Custom Training Loop” on page 18-225. For an example showing how to training a deep learning model defined as a function, see “Train Network Using Model Function” on page 18-259.

Debug Model Gradients Functions

If the implementation of the model gradients function has an issue, then the call to `dlfeval` can throw an error. Sometimes, when you use the `dlfeval` function, it is not clear which line of code is throwing the error. To help locate the error, you can try the following.

Call Model Gradients Function Directly

Try calling the model gradients function directly (that is, without using the `dlfeval` function) with generated inputs of the expected sizes. If any of the lines of code throw an error, then the error

message provides extra detail. Note that when you do not use the `dlfeval` function, any calls to the `dlgradient` function throw an error.

```
% Generate image input data.
X = rand([28 28 1 100],'single');
dlX = dlarray(dlX);

% Generate one-hot encoded target data.
T = repmat(eye(10,'single'),[1 10]);

[gradients, loss] = modelGradients(dlnet,dlX,T);
```

Run Model Gradients Code Manually

Run the code inside the model gradients function manually with generated inputs of the expected sizes and inspect the output and any thrown error messages.

For example, consider the following model gradients function.

```
function [gradients, loss] = modelGradients(dlnet, dlX, T)

    % Forward data through the dlnetwork object.
    dlY = forward(dlnet,dlX);

    % Compute loss.
    loss = crossentropy(dlY,T);

    % Compute gradients.
    gradients = dlgradient(loss,dlnet);

end
```

Check the model gradients function by running the following code.

```
% Generate image input data.
X = rand([28 28 1 100],'single');
dlX = dlarray(dlX);

% Generate one-hot encoded target data.
T = repmat(eye(10,'single'),[1 10]);

% Check forward pass.
dlY = forward(dlnet,dlX);

% Check loss calculation.
loss = crossentropy(dlX,T)
```

Update Batch Normalization Statistics in Custom Training Loop

This example shows how to update the network state in a custom training loop.

A batch normalization layer normalizes each input channel across a mini-batch. To speed up training of convolutional neural networks and reduce the sensitivity to network initialization, use batch normalization layers between convolutional layers and nonlinearities, such as ReLU layers.

During training, batch normalization layers first normalize the activations of each channel by subtracting the mini-batch mean and dividing by the mini-batch standard deviation. Then, the layer shifts the input by a learnable offset β and scales it by a learnable scale factor γ.

When network training finishes, batch normalization layers calculate the mean and variance over the full training set and stores the values in the `TrainedMean` and `TrainedVariance` properties. When you use a trained network to make predictions on new images, the batch normalization layers use the trained mean and variance instead of the mini-batch mean and variance to normalize the activations.

To compute the data set statistics, batch normalization layers keep track of the mini-batch statistics by using a continually updating state. If you are implementing a custom training loop, then you must update the network state between mini-batches.

Load Training Data

The `digitTrain4DArrayData` function loads images of handwritten digits and their digit labels. Create an `arrayDatastore` object for the images and the angles, and then use the `combine` function to make a single datastore that contains all of the training data. Extract the class names.

```
[XTrain,YTrain] = digitTrain4DArrayData;

dsXTrain = arrayDatastore(XTrain,'IterationDimension',4);
dsYTrain = arrayDatastore(YTrain);

dsTrain = combine(dsXTrain,dsYTrain);

classNames = categories(YTrain);
numClasses = numel(classNames);
```

Define Network

Define the network and specify the average image using the `'Mean'` option in the image input layer.

```
layers = [
    imageInputLayer([28 28 1], 'Name', 'input', 'Mean', mean(XTrain,4))
    convolution2dLayer(5, 20, 'Name', 'conv1')
    batchNormalizationLayer('Name','bn1')
    reluLayer('Name', 'relu1')
    convolution2dLayer(3, 20, 'Padding', 1, 'Name', 'conv2')
    batchNormalizationLayer('Name','bn2')
    reluLayer('Name', 'relu2')
    convolution2dLayer(3, 20, 'Padding', 1, 'Name', 'conv3')
    batchNormalizationLayer('Name','bn3')
    reluLayer('Name', 'relu3')
    fullyConnectedLayer(numClasses, 'Name', 'fc')
    softmaxLayer('Name','softmax')];
lgraph = layerGraph(layers);
```

Create a `dlnetwork` object from the layer graph.

```
dlnet = dlnetwork(lgraph)

dlnet =
  dlnetwork with properties:

         Layers: [12×1 nnet.cnn.layer.Layer]
    Connections: [11×2 table]
     Learnables: [14×3 table]
          State: [6×3 table]
     InputNames: {'input'}
    OutputNames: {'softmax'}
```

View the network state. Each batch normalization layer has a `TrainedMean` parameter and a `TrainedVariance` parameter containing the data set mean and variance, respectively.

```
dlnet.State
```

```
ans=6×3 table
    Layer        Parameter             Value
    _____    ________________    _______________

    "bn1"    "TrainedMean"       {1×1×20 single}
    "bn1"    "TrainedVariance"   {1×1×20 single}
    "bn2"    "TrainedMean"       {1×1×20 single}
    "bn2"    "TrainedVariance"   {1×1×20 single}
    "bn3"    "TrainedMean"       {1×1×20 single}
    "bn3"    "TrainedVariance"   {1×1×20 single}
```

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, which takes as input a `dlnetwork` object `dlnet`, and a mini-batch of input data `dlX` with corresponding labels `Y`, and returns the gradients of the loss with respect to the learnable parameters in `dlnet` and the corresponding loss.

Specify Training Options

Train for five epochs using a mini-batch size of 128. For the SGDM optimization, specify a learning rate of 0.01 and a momentum of 0.9.

```
numEpochs = 5;
miniBatchSize = 128;

learnRate = 0.01;
momentum = 0.9;
```

Visualize the training progress in a plot.

```
plots = "training-progress";
```

Train Model

Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to one-hot encode the class labels.

- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see "GPU Support by Release" (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB',''});
```

Train the model using a custom training loop. For each epoch, shuffle the data and loop over mini-batches of data. At the end of each iteration, display the training progress. For each mini-batch:

- Evaluate the model gradients, state, and loss using `dlfeval` and the `modelGradients` function and update the network state.
- Update the network parameters using the `sgdmupdate` function.

Initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Initialize the velocity parameter for the SGDM solver.

```
velocity = [];
```

Train the network.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs
    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches.
    while hasdata(mbq)

        iteration = iteration + 1;

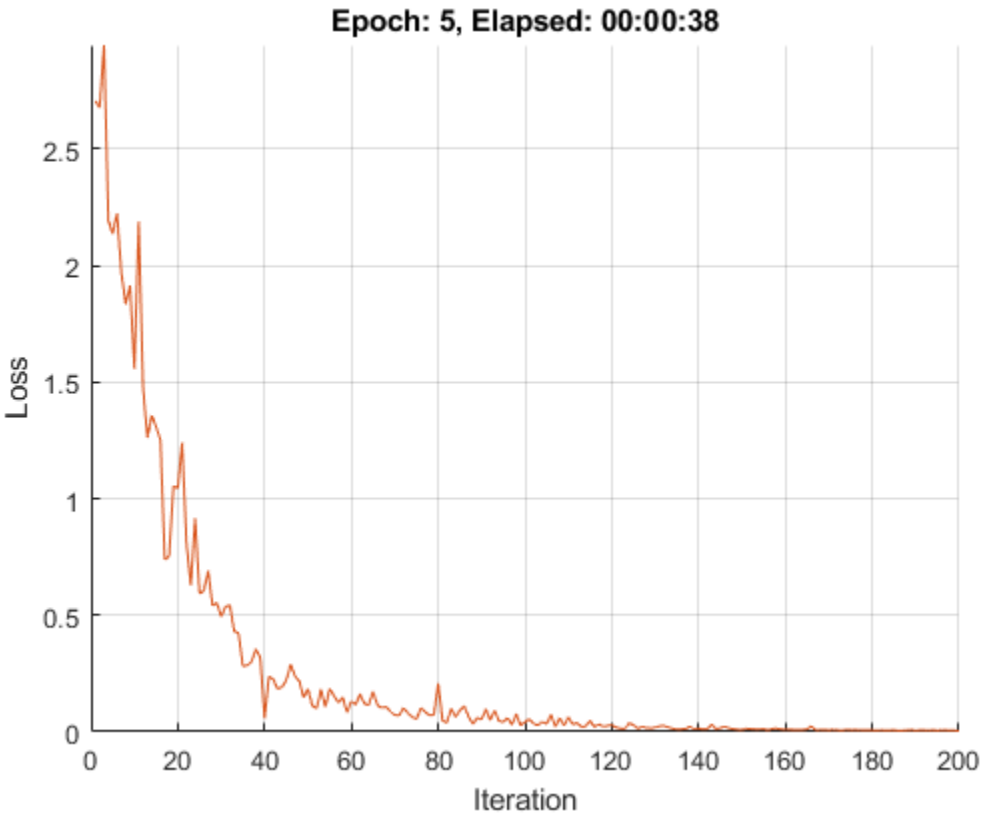
        % Read mini-batch of data and convert the labels to dummy
        % variables.
        [dlX,dlY] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function and update the network state.
        [gradients,state,loss] = dlfeval(@modelGradients,dlnet,dlX,dlY);
```

```
        dlnet.State = state;

        % Update the network parameters using the SGDM optimizer.
        [dlnet, velocity] = sgdmupdate(dlnet, gradients, velocity, learnRate, momentum);

        % Display the training progress.
        if plots == "training-progress"
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
            title("Epoch: " + epoch + ", Elapsed: " + string(D))
            drawnow
        end
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on a test set with the true labels and angles. Manage the test data set using a `minibatchqueue` object with the same setting as the training data.

```
[XTest,YTest] = digitTest4DArrayData;

dsXTest = arrayDatastore(XTest,'IterationDimension',4);
dsYTest = arrayDatastore(YTest);

dsTest = combine(dsXTest,dsYTest);
```

```
mbqTest = minibatchqueue(dsTest,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB',''});
```

Classify the images using the `modelPredictions` function, listed at the end of the example. The function returns the predicted classes and the comparison with the true values.

```
[classesPredictions,classCorr] = modelPredictions(dlnet,mbqTest,classNames);
```

Evaluate the classification accuracy.

```
accuracy = mean(classCorr)
```

```
accuracy = 0.9946
```

Model Gradients Function

The `modelGradients` function takes as input a `dlnetwork` object `dlnet` and a mini-batch of input data `dlX` with corresponding labels `Y`, and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, the network state, and the loss. To compute the gradients automatically, use the `dlgradient` function.

```
function [gradients,state,loss] = modelGradients(dlnet,dlX,Y)

    [dlYPred,state] = forward(dlnet,dlX);

    loss = crossentropy(dlYPred,Y);
    gradients = dlgradient(loss,dlnet.Learnables);

end
```

Model Predictions Function

The `modelPredictions` function takes as input a `dlnetwork` object `dlnet`, a `minibatchqueue` of input data `mbq`, and computes the model predictions by iterating all data in the `minibatchqueue`. The function uses the `onehotdecode` function to find the predicted class with the highest score and then compares the prediction with the true class. The function returns the predictions and a vector of ones and zeros that represents correct and incorrect predictions.

```
function [classesPredictions,classCorr] = modelPredictions(dlnet,mbq,classes)

    classesPredictions = [];
    classCorr = [];

    while hasdata(mbq)
        [dlX,dlY] = next(mbq);

        % Make predictions using the model function.
        dlYPred = predict(dlnet,dlX);

        % Determine predicted classes.
        YPredBatch = onehotdecode(dlYPred,classes,1);
        classesPredictions = [classesPredictions YPredBatch];

        % Compare predicted and true classes
        Y = onehotdecode(dlY,classes,1);
        classCorr = [classCorr YPredBatch == Y];
```

```
    end

end
```

Mini Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label data from the incoming cell arrays and concatenate into a categorical array along the second dimension..
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y] = preprocessMiniBatch(XCell,YCell)

    % Extract image data from cell and concatenate
    X = cat(4,XCell{:});
    % Extract label data from cell and concatenate
    Y = cat(2,YCell{:});

    % One-hot encode labels
    Y = onehotencode(Y,1);

end
```

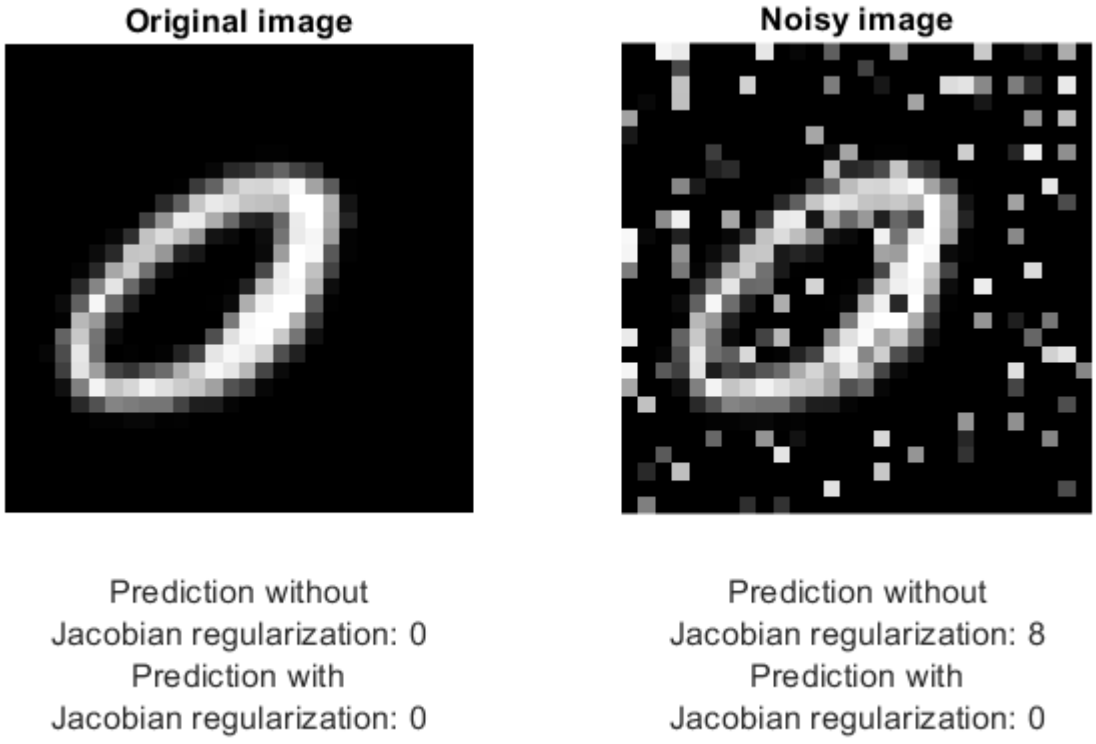
Train Robust Deep Learning Network with Jacobian Regularization

This example shows how to train a neural network that is robust to adversarial examples using a Jacobian regularization scheme [1].

Neural networks can be susceptible to a phenomenon known as *adversarial examples* [2], where very small changes to an input can cause it to be misclassified. These changes are often imperceptible to humans. Second-order methods such as Jacobian regularization have been shown to help increase the robustness of networks against adversaries [3].

For example, consider the figure below. On the left is an image of a zero, and on the right is the same image with white noise added to create an adversarial example. A network trained without Jacobian regularization classifies the original image of a zero correctly but misclassifies the adversarial example. In contrast, a network trained with Jacobian regularization classifies both the original and the noisy image correctly.



This example shows how to:

1. Train a robust image classification network using a Jacobian regularization scheme.
2. Compare its predictions to a network trained without Jacobian regularization.

Load Training Data

The `digitTrain4DArrayData` function loads the images and their digit labels. Create an `arrayDatastore` object for the images and the labels, and then use the `combine` function to make a single datastore that contains all of the training data.

```
[XTrain,YTrain] = digitTrain4DArrayData;

dsXTrain = arrayDatastore(XTrain,'IterationDimension',4);
dsYTrain = arrayDatastore(YTrain);

dsTrain = combine(dsXTrain,dsYTrain);
```

Determine the number of classes in the training data.

```
classes = categories(YTrain);
numClasses = numel(classes);
```

Next, apply noise to the training images to create adversarial examples. Compare images from the training data with no noise and with noise affecting 10% of the pixels.

Select 16 images at random.

```
numImages = size(XTrain,4);
randompick = randperm(numImages,16);
XOriginal = XTrain(:,:,:,randompick);
```

Create the noisy images by setting a proportion of the pixels to a random grayscale value.

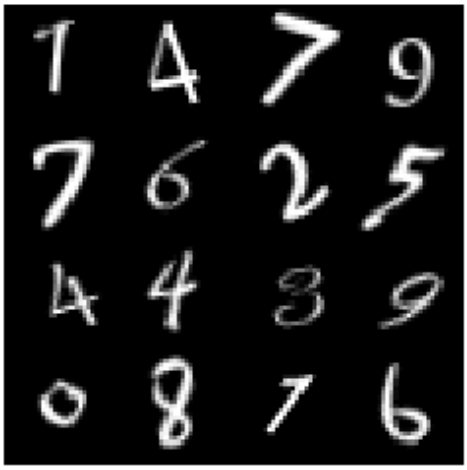
```
noiseProp = 0.1;
noise = rand(size(XOriginal));
idx = rand(size(XOriginal)) < noiseProp;

XNoisy = XOriginal;
XNoisy(idx) = noise(idx);
```

Plot the original images next to the noisy images.

```
I1 = imtile(XOriginal);
I2 = imtile(XNoisy);

figure;
subplot(1,2,1)
imshow(I1)
subplot(1,2,2)
imshow(I2)
```



Define Network

Define the architecture of the network.

Specify an image input layer of the same size as the training images.

```
imageInputSize = size(XTrain, 1:3)
```

```
imageInputSize = 1×3

    28    28     1
```

```
layers = [
    imageInputLayer(imageInputSize,'Name','input','Mean',mean(XTrain,4))
    convolution2dLayer(5,20,'Name','conv1')
    batchNormalizationLayer('Name','bn1')
    reluLayer('Name','relu1')
    convolution2dLayer(3,20,'Padding',1,'Name','conv2')
    batchNormalizationLayer('Name','bn2')
    reluLayer('Name','relu2')
```

```
    convolution2dLayer(3,20,'Padding',1,'Name','conv3')
    batchNormalizationLayer('Name','bn3')
    reluLayer('Name','relu3')
    fullyConnectedLayer(10,'Name','fc')
    softmaxLayer('Name','softmax')];
lgraph = layerGraph(layers);
```

Create a `dlnetwork` object from the layer graph.

```
dlnet = dlnetwork(lgraph);
```

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, which takes a `dlnetwork` object, and a mini-batch of input data with corresponding labels, and returns the gradients of the loss with respect to the learnable parameters in the network, the state of the network, and the loss.

Specify Training Options

Train for 15 epochs with a mini-batch size of 32.

```
numEpochs = 15;
miniBatchSize = 32;
```

Specify the options for SGDM optimization. Specify a learning rate of 0.01 and a momentum of 0.9.

```
learningRate = 0.01;
momentum = 0.9;
```

The Jacobian regularization $\lambda_{JR}$is a hyperparameter that controls the effect of the Jacobian regularization term on the training of the network. If the coefficient is too large, then the cross-entropy term is not effectively minimized and the accuracy of the network classification is poor. If the coefficient is too small, the trained network does not have the expected robustness to white noise. For example, choose $\lambda_{JR} = 1$.

```
jacobianRegularizationCoefficient = 1;
```

Train Model

Create a `minibatchqueue` object that processes and manages mini-batches of images during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to convert the labels to one-hot encoded variables.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels.
- Train on a GPU if one is available. If a GPU is available, the `minibatchqueue` object converts each output to a `gpuArray` by default. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'PartialMiniBatch',"discard",...
    'MiniBatchFormat',{'SSCB',''});
```

Initialize the training progress plot.

```
figure;
lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Initialize the velocity parameter for the SGDM solver.

```
velocity = [];
```

Train the network using a custom training loop.

For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients, state, and loss using the `dlfeval` and `modelGradients` functions and update the network state.
- Update the network parameters using the `sgdmupdate` function.
- Display the training progress.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Reset and shuffle mini-batch queue.
    shuffle(mbq);

    while hasdata(mbq)
        iteration = iteration + 1;

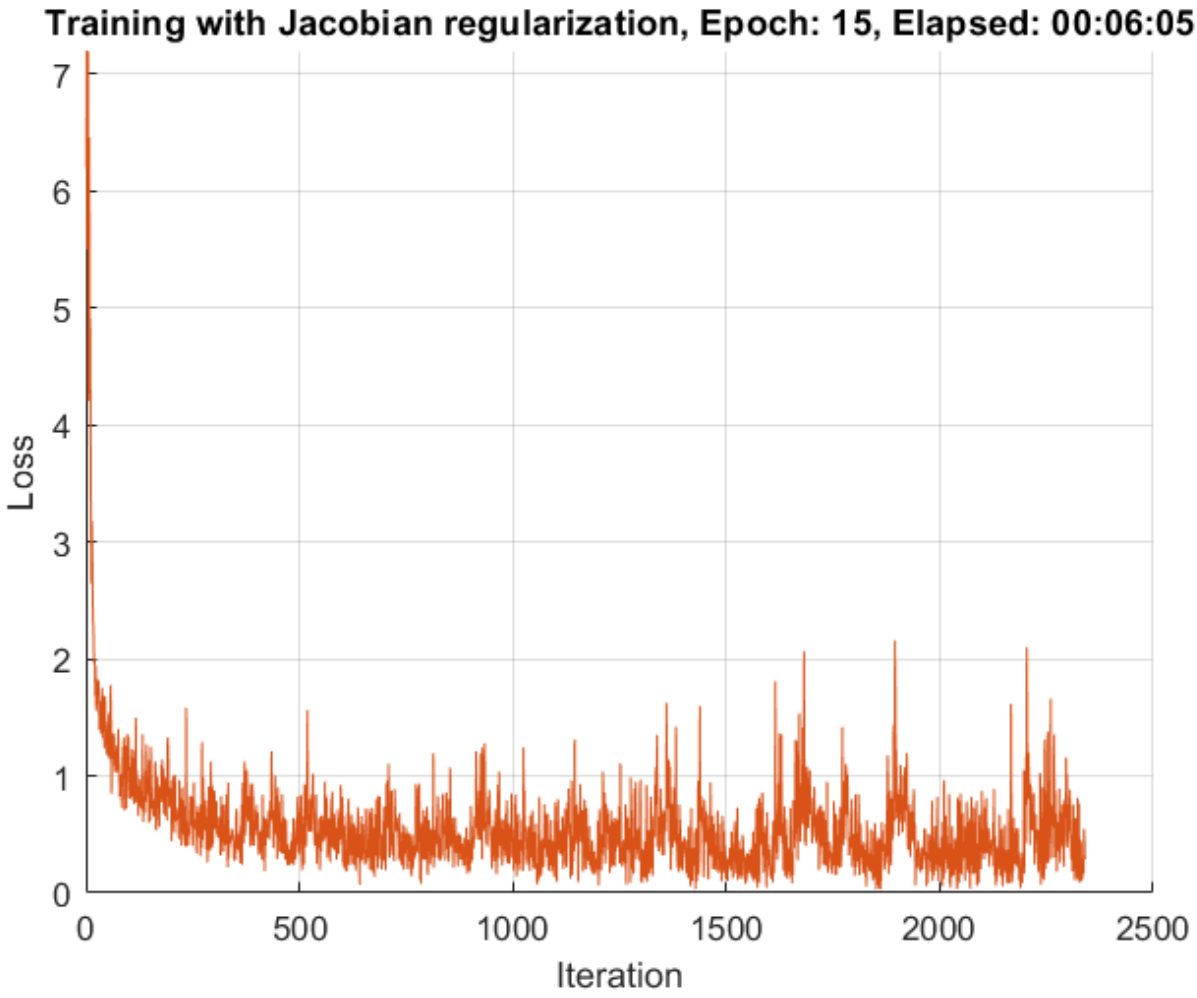
        % Read mini-batch of data.
        [dlX, dlY] = next(mbq);

        % Evaluate the model gradients and the network state using
        % dlfeval and the modelGradients function listed at the end of the example.
        [gradTotalLoss, state, totalLoss] = dlfeval(@modelGradients, dlnet, dlX, dlY, ...
            miniBatchSize, jacobianRegularizationCoefficient);
        dlnet.State = state;

        % Update the network parameters.
        [dlnet, velocity] = sgdmupdate(dlnet,gradTotalLoss,velocity,learningRate,momentum);

        % Plot the training progress.
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        addpoints(lineLossTrain,iteration,double(gather(extractdata(totalLoss))))
        title("Training with Jacobian regularization" + ", Epoch: " + epoch + ", Elapsed: " + st
        drawnow

    end
end
```



Load Reference Network

Load a reference network, with the same layers, but trained without Jacobian regularization.

```
dlnetReference = load("dlnetWithoutJacobian.mat").dlnetReference;
```

Test Model

Load the test data for a comparison test between the network trained with Jacobian regularization and the reference network.

```
[XTest, YTest] = digitTest4DArrayData;
classes = categories(YTest);
```

Pass through test images that the networks have not seen before. With each pass, add noise affecting 0% to 50% of the pixels in increments of 5%.

```
% Initialize test parameters and arrays.
noiseProps = 0:0.05:0.5;

% Prepare arguments for mini-batch queue.
```

```
dsYTest = arrayDatastore(YTest);
miniBatchSize = 5000;

for i = 1:numel(noiseProps)
    % Load the noise proportion.
    noiseProp = noiseProps(i);
    fprintf("Testing robustness to noise proportion %1.2g\n", noiseProp)

    % Set a proportion of the pixels to a random grayscale value.
    noise = rand(size(XTest));
    idx = rand(size(XTest)) < noiseProp;
    XNoisy = XTest;
    XNoisy(idx) = noise(idx);

    % Prepare mini-batch queue with noisy test data.
    dsXTest = arrayDatastore(XNoisy,'IterationDimension',4);
    dsTest = combine(dsXTest,dsYTest);
    mbq = minibatchqueue(dsTest,...
        'MiniBatchSize',miniBatchSize,...
        'MiniBatchFcn', @preprocessMiniBatch,...
        'MiniBatchFormat',{'SSCB',''});

    % Loop over batches to find predicted classifications.
    while hasdata(mbq)
        [dlXNoisy, dlY] = next(mbq);

        % Classify noisy data with the robust network.
        dlYPredNoisy = predict(dlnet, dlXNoisy);

        % Convert the predictions into labels.
        YPred = onehotdecode(dlYPredNoisy, classes, 1)';
        YTestBatch = onehotdecode(dlY, classes, 1)';

        % Evaluate accuracy of predictions.
        accuracyRobust(i) =  mean(YPred == YTestBatch);

        % Classify noisy data with reference network.
        dlYPredNoisy = predict(dlnetReference, dlXNoisy);

        % Convert the predictions into labels.
        YPred = onehotdecode(dlYPredNoisy, classes, 1)';

        % Evaluate accuracy of predictions.
        accuracyReference(i) =  mean(YPred == YTestBatch);
    end

end
```

```
Testing robustness to noise proportion 0
Testing robustness to noise proportion 0.05
Testing robustness to noise proportion 0.1
Testing robustness to noise proportion 0.15
Testing robustness to noise proportion 0.2
Testing robustness to noise proportion 0.25
Testing robustness to noise proportion 0.3
Testing robustness to noise proportion 0.35
Testing robustness to noise proportion 0.4
```

```
Testing robustness to noise proportion 0.45
Testing robustness to noise proportion 0.5
```

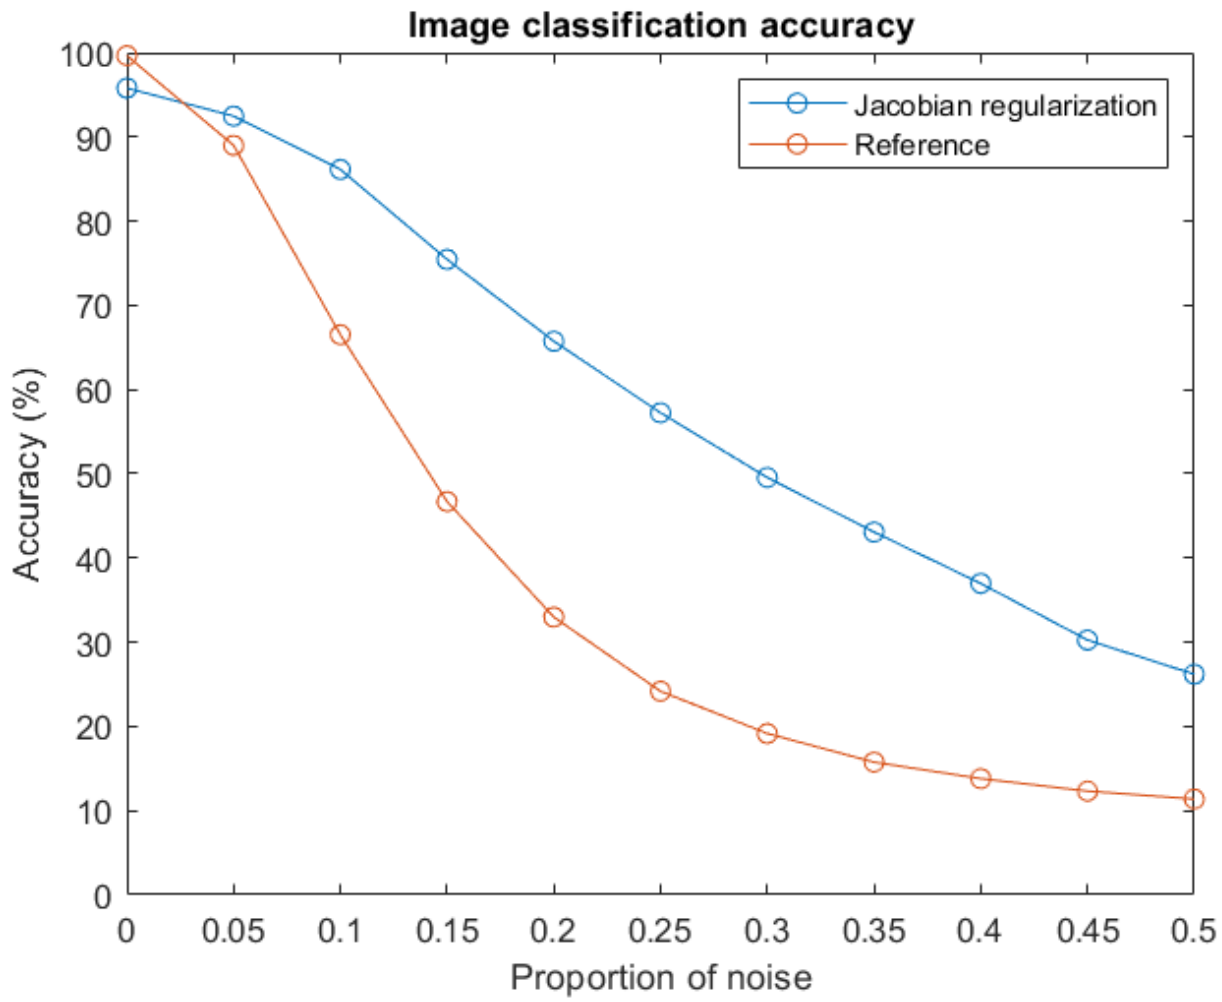
Plot the results of the percentage accuracy of both networks against the proportion of the white noise.

Note that the network trained with Jacobian regularization has a slightly lower accuracy when the noise proportion is equal to 0 but achieves higher accuracy than the reference network when noise is added to the images.

```
x = noiseProps';

figure;

plot(x,accuracyRobust*100, '-o', x,accuracyReference*100, '-o')
xlabel('Proportion of noise')
ylabel('Accuracy (%)')
xlim([0,0.5]);
ylim([0,100]);
title('Image classification accuracy')
legend('Jacobian regularization', 'Reference');
```



Test Specific Example

Add noise affecting 15% of the pixels to the first test image, which contains the number 0. Plot both the original image and the image perturbed by the white noise. Use the network trained with Jacobian regularization and the reference network to classify the image.

```
% Choose test image
testchoice = 1;

% Add noise, with a proportion of 0.15, to the first image.
noise = rand(size(XTest(:,:,:,testchoice)));
idx = rand(size(XTest(:,:,:,testchoice))) < 0.15;
XNoisy = XTest(:,:,:,testchoice);
XNoisy(idx) = noise(idx);

% Convert to dlarray.
dlXTest  = dlarray(XTest(:,:,:,testchoice),'SSCB');
dlXNoisy = dlarray(XNoisy,'SSCB');

% Print true number classification
disp("True digit label: " + char(YTest(testchoice)));
```

```
True digit label: 0
```

Classify the original image by using the network trained with Jacobian regularization.

```
dlYPredTestJR = predict(dlnet, dlXTest);
YPredTestJR = onehotdecode(dlYPredTestJR, classes, 1)';
disp("Robust network classification of original image: " + char(YPredTestJR));
```

```
Robust network classification of original image: 0
```

Classify the noisy image by using the network trained with Jacobian regularization.

```
dlYPredNoisyJR = predict(dlnet, dlXNoisy);
YPredNoisyJR = onehotdecode(dlYPredNoisyJR, classes, 1)';
disp("Robust network classification of noisy image: " + char(YPredNoisyJR));
```

```
Robust network classification of noisy image: 0
```

Classify the original image by using the network trained without Jacobian regularization.

```
dlYPredTest = predict(dlnetReference, dlXTest);
YPredTestR = onehotdecode(dlYPredTest, classes, 1)';
disp("Reference network classification of original image: " + char(YPredTestR));
```

```
Reference network classification of original image: 0
```

Classify the noisy image by using the network trained without Jacobian regularization.

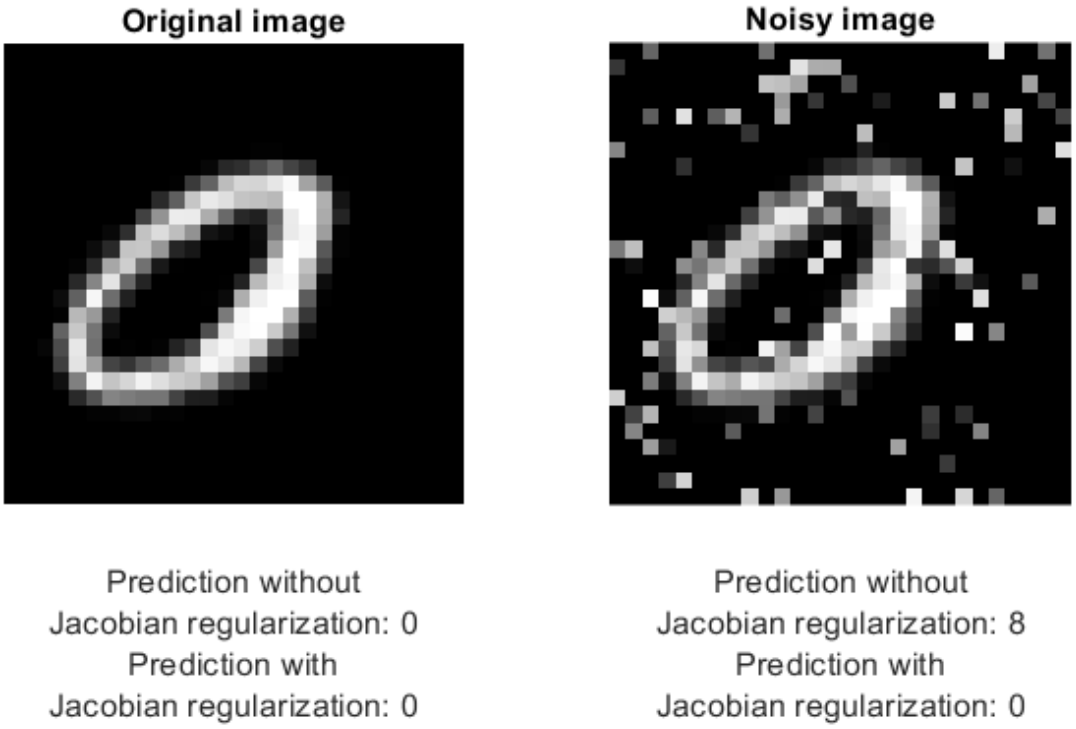
```
dlYPredNoisy = predict(dlnetReference, dlXNoisy);
YPredNoisyR = onehotdecode(dlYPredNoisy, classes, 1)';
disp("Reference network classification of noisy image: " + char(YPredNoisyR));
```

```
Reference network classification of noisy image: 8
```

Plot the original and noisy images and display the predictions given by each network.

```
figure;
I1 = XTest(:,:,:,testchoice);
```

```
subplot(1,2,1)
imshow(I1)
title('Original image')
xlabel({"Prediction without"; "Jacobian regularization: " + char(YPredTestR);...
    "Prediction with"; "Jacobian regularization: " + char(YPredTestJR)})
I2 = XNoisy;
subplot(1,2,2)
imshow(I2)
title('Noisy image')
xlabel({"Prediction without"; "Jacobian regularization: " + char(YPredNoisyR);...
    "Prediction with"; "Jacobian regularization: " + char(YPredNoisyJR)})
```



Model Gradients Function

The goal of Jacobian regularization is to penalize large changes of the prediction y with respect to small changes in the input x. Doing so makes the network more robust to input data polluted by noise. The Jacobian J encodes the change of prediction with respect to the input by containing the partial derivatives of y with respect to x.

$$J = \begin{bmatrix} \frac{\partial y_1}{\partial x_1} & \cdots & \frac{\partial y_1}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial y_m}{\partial x_1} & \cdots & \frac{\partial y_m}{\partial x_n} \end{bmatrix}$$

Jacobian regularization is achieved by adding the Frobenius norm of the Jacobian to the loss function that is subsequently minimized when you train the network. However, the Jacobian can be expensive to compute, requiring m backward passes through the network, where m is the size of the output y. Therefore, instead of computing the full Jacobian, an approximation to the Frobenius norm of the Jacobian (JR) is computed as follows [4]:

$$\| J \|_F^2 = \mathrm{tr}\left(J J^\top\right) = E_{v \sim N(0, I_m)} v^\top J J^\top v \approx \frac{1}{m_{\mathrm{proj}}} \sum_{k=1}^{m_{\mathrm{proj}}} \left\| v_k^\top J \right\|_2^2 = \frac{1}{m_{\mathrm{proj}}} \sum_{k=1}^{m_{\mathrm{proj}}} \left\| \nabla_x \left[v_k^\top y \right] \right\|_2^2.$$

where $v_k \sim N(0, I_m)$ is a draw from the standard Normal distribution and I_m is is the m-by-m identity matrix. This can be implemented as follows:

JR = 0

Choose a mini-batch size B

For $i = 1, \ldots, m_{\mathrm{proj}}$

1. Sample a random vector $v \sim N(0, I_m)$
2. Normalize the random vector $v = \frac{v}{\|v\|_2}$
3. Compute the derivative $\nabla_x\left(v^\top y\right)$
4. $\mathrm{JR} = \mathrm{JR} + \frac{m \left\| \nabla_x\left(v^\top y\right) \right\|_2^2}{B\, m_{\mathrm{proj}}}$

The gradient of the vector inner product requires one backward pass to compute. So, this approximation requires only m_{proj} backward passes to compute, and in practice, $m_{\mathrm{proj}} = 1$.

In this example, the cross-entropy between the predicted classification y and the true classification z is used, resulting in the loss function

$$\mathrm{loss} = \mathrm{crossentropy} + \frac{\lambda_{\mathrm{JR}}}{2} \mathrm{JR}$$

where λ_{JR} is the Jacobian regularization coefficient. The approximation of the Frobenius norm of the Jacobian requires taking gradients with respect to x, and the training phase requires taking gradients of the loss with respect to the parameters. These calculations require support for second-order automatic differentiation.

The `modelGradients` function is used during the training of the network. It takes as input the network, the input data `dlX`, their respective classifications `dlY`, the mini-batch size `miniBatchSize`, and the Jacobian regularization coefficient `jacobianRegularizationCoefficient`. The function returns the gradient of the loss with respect to the network parameters `gradTotalLoss`, the state of the network `state`, and the total loss `totalLoss.` To compute the approximation to the norm of the Jacobian, a derivative of a vector-

vector dot product is taken. Since a second order derivative is necessary to compute the gradient of the loss function with respect to the network parameters, you must set the option `'EnableHigherDerivatives'` to `'true'` when calling the function `dlgradient`.

```
function [gradTotalLoss, state, totalLoss] = modelGradients(net, dlX, dlY, miniBatchSize, jacobia

% Find prediction and loss.
[dlZ,state] = forward(net, dlX);
loss = crossentropy(dlZ, dlY);

numClasses = size(dlZ,1);
numProjections = 1;
regularizationTerm = 0;

% Compute Jacobian term and its gradient.
for i = 1:numProjections

    % Sample a matrix whose elements are drawn from the standard Normal distribution.
    rndarray = randn(numClasses, miniBatchSize);

    % Normalize the columns of the random matrix.
    rndarray = normc(rndarray);

    % Compute the vector-vector product.
    vectorproduct = rndarray(:)' * dlZ(:);

    % Compute the gradient of the vector-vector product. Since another
    % derivative will be taken, set EnableHigherDerivatives to true.
    vectorJacobianTerm = dlgradient(vectorproduct, dlX, 'EnableHigherDerivatives', true);

    % Multiply by necessary constants to obtain approximation of the
    % Frobenius norm of the Jacobian.
    regularizationTerm = regularizationTerm + numClasses*sum(vectorJacobianTerm.^2,'all') /(numP
end
totalLoss = loss + jacobianRegularizationCoefficient/2 * regularizationTerm;

% Calculate the gradient of the loss.
gradTotalLoss = dlgradient(totalLoss, net.Learnables);
end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label data from the incoming cell array and concatenate the data into a categorical array along the second dimension.
3. One-hot encode the categorical labels into numeric arrays. Encoding the labels into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X, Y] = preprocessMiniBatch(XCell,YCell)
    % Extract image data from cell and concatenate
    X = cat(4,XCell{1:end});

    % Extract label data from cell and concatenate
```

```
    Y = cat(2,YCell{1:end});

    % One-hot encode labels
    Y = onehotencode(Y,1);
end
```

Make Predictions Using dlnetwork Object

This example shows how to make predictions using a `dlnetwork` object by splitting data into mini-batches.

For large data sets, or when predicting on hardware with limited memory, make predictions by splitting the data into mini-batches. When making predictions with `SeriesNetwork` or `DAGNetwork` objects, the `predict` function automatically splits the input data into mini-batches. For `dlnetwork` objects, you must split the data into mini-batches manually.

Load `dlnetwork` Object

Load a trained `dlnetwork` object and the corresponding classes.

```
s = load("digitsCustom.mat");
dlnet = s.dlnet;
classes = s.classes;
```

Load Data for Prediction

Load the digits data for prediction.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet','nndemos', ...
    'nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true);
```

Make Predictions

Loop over the mini-batches of the test data and make predictions using a custom prediction loop.

Use `minibatchqueue` to process and manage the mini-batches of images. Specify a mini-batch size of 128. Set the read size property of the image datastore to the mini-batch size.

For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to concatenate the data into a batch and normalize the images.
- Format the images with the dimensions `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`.
- Make predictions on a GPU if one is available. By default, the `minibatchqueue` object converts the output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
miniBatchSize = 128;
imds.ReadSize = miniBatchSize;

mbq = minibatchqueue(imds,...
    "MiniBatchSize",miniBatchSize,...
    "MiniBatchFcn", @preprocessMiniBatch,...
    "MiniBatchFormat","SSCB");
```

Loop over the minibatches of data and make predictions using the `predict` function. Use the `onehotdecode` function to determing the class labels. Store the predicted class labels.

```
numObservations = numel(imds.Files);
YPred = strings(1,numObservations);

predictions = [];

% Loop over mini-batches.
while hasdata(mbq)

    % Read mini-batch of data.
    dlX = next(mbq);

    % Make predictions using the predict function.
    dlYPred = predict(dlnet,dlX);

    % Determine corresponding classes.
    predBatch = onehotdecode(dlYPred,classes,1);
    predictions = [predictions predBatch];

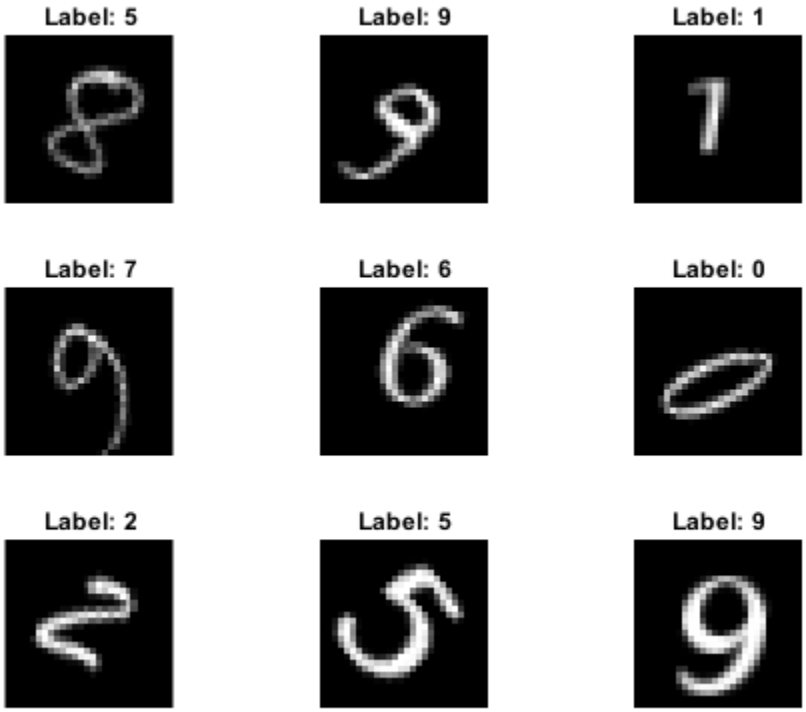
end
```

Visualize some of the predictions.

```
idx = randperm(numObservations,9);

figure
for i = 1:9
    subplot(3,3,i)
    I = imread(imds.Files{idx(i)});
    label = predictions(idx(i));
    imshow(I)
    title("Label: " + string(label))

end
```



Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the data from the incoming cell array and concatenate into a numeric array. Concatenating over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Normalize the pixel values between `0` and `1`.

```
function X = preprocessMiniBatch(data)
    % Extract image data from cell and concatenate
    X = cat(4,data{:});

    % Normalize the images.
    X = X/255;
end
```

Train Network Using Model Function

This example shows how to create and train a deep learning network by using functions rather than a layer graph or a `dlnetwork`. The advantage of using functions is the flexibility to describe a wide variety of networks. The disadvantage is that you must complete more steps and prepare your data carefully. This example uses images of handwritten digits, with the dual objectives of classifying the digits and determining the angle of each digit from the vertical.

Load Training Data

The `digitTrain4DArrayData` function loads the images, their digit labels, and their angles of rotation from the vertical. Create `arrayDatastore` objects for the images, labels, and angles, and then use the `combine` function to make a single datastore that contains all of the training data. Extract the class names and number of nondiscrete responses.

```
[XTrain,YTrain,anglesTrain] = digitTrain4DArrayData;

dsXTrain = arrayDatastore(XTrain,'IterationDimension',4);
dsYTrain = arrayDatastore(YTrain);
dsAnglesTrain = arrayDatastore(anglesTrain);

dsTrain = combine(dsXTrain,dsYTrain,dsAnglesTrain);

classNames = categories(YTrain);
numClasses = numel(classNames);
numResponses = size(anglesTrain,2);
numObservations = numel(YTrain);
```

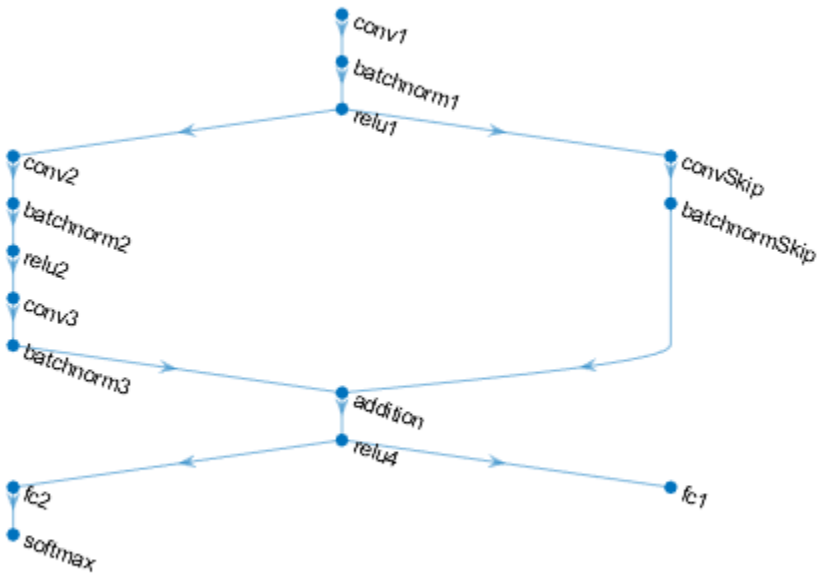
View some images from the training data.

```
idx = randperm(numObservations,64);
I = imtile(XTrain(:,:,:,idx));
figure
imshow(I)
```

Define Deep Learning Model

Define the following network that predicts both labels and angles of rotation.

- A convolution-batchnorm-ReLU block with 16 5-by-5 filters.
- A branch of two convolution-batchnorm blocks each with 32 3-by-3 filters with a ReLU operation between
- A skip connection with a convolution-batchnorm block with 32 1-by-1 convolutions.
- Combine both branches using addition followed by a ReLU operation
- For the regression output, a branch with a fully connected operation of size 1 (the number of responses).
- For classification output, a branch with a fully connected operation of size 10 (the number of classes) and a softmax operation.



Define and Initialize Model Parameters and State

Define the parameters for each of the operations and include them in a struct. Use the format `parameters.OperationName.ParameterName` where `parameters` is the struct, `OperationName` is the name of the operation (for example "conv1") and `ParameterName` is the name of the parameter (for example, "Weights").

Create a struct `parameters` containing the model parameters. Initialize the learnable layer weights and biases using the `initializeGlorot` and `initializeZeros` example functions, respectively. Initialize the batch normalization offset and scale parameters with the `initializeZeros` and `initializeOnes` example functions, respectively.

To perform training and inference using batch normalization layers, you must also manage the network state. Before prediction, you must specify the dataset mean and variance derived from the training data. Create a struct `state` containing the state parameters. The batch normalization statistics must not be `dlarray` objects. Initialize the batch normalization trained mean and trained variance states using the `zeros` and `ones` functions, respectively.

The initialization example functions are attached to this example as supporting files.

Initialize the parameters for the first convolutional layer.

```
filterSize = [5 5];
numChannels = 1;
numFilters = 16;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv1.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the first batch normalization layer.

```
parameters.batchnorm1.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm1.Scale = initializeOnes([numFilters 1]);
state.batchnorm1.TrainedMean = zeros(numFilters,1,'single');
state.batchnorm1.TrainedVariance = ones(numFilters,1,'single');
```

Initialize the parameters for the second convolutional layer.

```
filterSize = [3 3];
numChannels = 16;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv2.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the second batch normalization layer.

```
parameters.batchnorm2.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm2.Scale = initializeOnes([numFilters 1]);
state.batchnorm2.TrainedMean = zeros(numFilters,1,'single');
state.batchnorm2.TrainedVariance = ones(numFilters,1,'single');
```

Initialize the parameters for the third convolutional layer.

```
filterSize = [3 3];
numChannels = 32;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;
```

```
parameters.conv3.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv3.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the third batch normalization layer.

```
parameters.batchnorm3.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm3.Scale = initializeOnes([numFilters 1]);
state.batchnorm3.TrainedMean = zeros(numFilters,1,'single');
state.batchnorm3.TrainedVariance = ones(numFilters,1,'single');
```

Initialize the parameters for the convolutional layer in the skip connection.

```
filterSize = [1 1];
numChannels = 16;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.convSkip.Weights = initializeGlorot(sz,numOut,numIn);
parameters.convSkip.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the batch normalization layer in the skip connection.

```
parameters.batchnormSkip.Offset = initializeZeros([numFilters 1]);
parameters.batchnormSkip.Scale = initializeOnes([numFilters 1]);
state.batchnormSkip.TrainedMean = zeros([numFilters 1],'single');
state.batchnormSkip.TrainedVariance = ones([numFilters 1],'single');
```

Initialize the parameters for the fully connected layer corresponding to the classification output.

```
sz = [numClasses 6272];
numOut = numClasses;
numIn = 6272;
parameters.fc1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc1.Bias = initializeZeros([numClasses 1]);
```

Initialize the parameters for the fully connected layer corresponding to the regression output.

```
sz = [numResponses 6272];
numOut = numResponses;
numIn = 6272;
parameters.fc2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc2.Bias = initializeZeros([numResponses 1]);
```

View the struct of the parameters.

```
parameters
```

```
parameters = struct with fields:
            conv1: [1×1 struct]
       batchnorm1: [1×1 struct]
            conv2: [1×1 struct]
       batchnorm2: [1×1 struct]
            conv3: [1×1 struct]
       batchnorm3: [1×1 struct]
          convSkip: [1×1 struct]
    batchnormSkip: [1×1 struct]
```

```
              fc1: [1×1 struct]
              fc2: [1×1 struct]
```

View the parameters for the "conv1" operation.

```
parameters.conv1
```

```
ans = struct with fields:

    TrainedVariance: [16×1 single]
```

Define Model Function

Create the function `model`, listed at the end of the example, that computes the outputs of the deep learning model described earlier.

The function `model` takes the model parameters `parameters`, the input data `dlX`, the flag `doTraining` which specifies whether to model should return outputs for training or prediction, and the network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, that takes the model parameters, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

Specify Training Options

Specify the training options. Train for 20 epochs with a mini-batch size of 128.

```
numEpochs = 20;
miniBatchSize = 128;
```

To monitor the training progress, you can plot the training loss after each iteration. Create the variable plots that contains "training-progress". If you do not want to plot the training progress, then set this value to "none".

```
plots = "training-progress";
```

Train Model

Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to one-hot encode the class labels.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels or angles.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','',''});
```

For each epoch, shuffle the data and loop over mini-batches of data. At the end of each iteration, display the training progress. For each mini-batch:

- Evaluate the model gradients and loss using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.

Initialize parameters for Adam.

```
trailingAvg = [];
trailingAvgSq = [];
```

Initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Train the model.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
```

```
    shuffle(mbq)

    % Loop over mini-batches
    while hasdata(mbq)

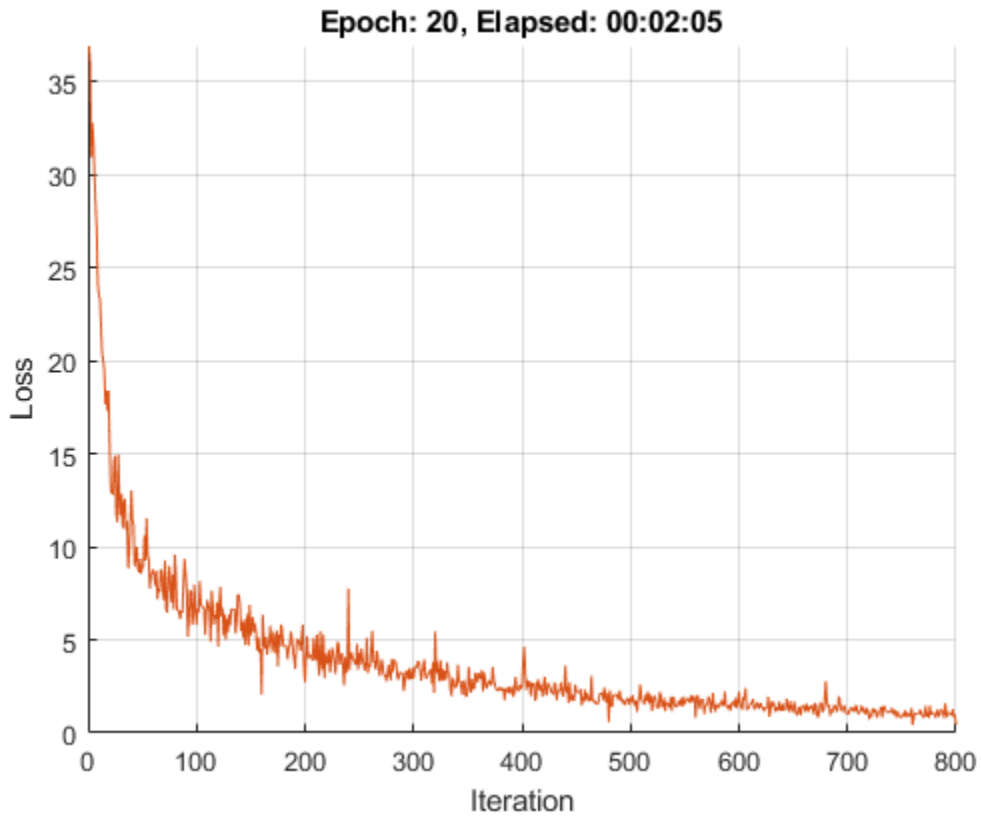
        iteration = iteration + 1;

        [dlX,dlY1,dlY2] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function.
        [gradients,state,loss] = dlfeval(@modelGradients, parameters, dlX, dlY1, dlY2, state);

        % Update the network parameters using the Adam optimizer.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
            trailingAvg,trailingAvgSq,iteration);

        % Display the training progress.
        if plots == "training-progress"
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
            title("Epoch: " + epoch + ", Elapsed: " + string(D))
            drawnow
        end
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on a test set with the true labels and angles. Manage the test data set using a `minibatchqueue` object with the same setting as the training data.

```
[XTest,YTest,anglesTest] = digitTest4DArrayData;

dsXTest = arrayDatastore(XTest,'IterationDimension',4);
dsYTest = arrayDatastore(YTest);
dsAnglesTest = arrayDatastore(anglesTest);

dsTest = combine(dsXTest,dsYTest,dsAnglesTest);

mbqTest = minibatchqueue(dsTest,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','',''});
```

To predict the labels and angles of the validation data, loop over the mini-batches and use the model function with the `doTraining` option set to `false`. Store the predicted classes and angles. Compare the predicted and true classes and angles and store the results.

```
doTraining = false;

classesPredictions = [];
anglesPredictions = [];
classCorr = [];
angleDiff = [];

% Loop over mini-batches.
while hasdata(mbqTest)

    % Read mini-batch of data.
    [dlXTest,dlY1Test,dlY2Test] = next(mbqTest);

    % Make predictions using the predict function.
    [dlY1Pred,dlY2Pred] = model(parameters,dlXTest,doTraining,state);

    % Determine predicted classes.
    Y1PredBatch = onehotdecode(dlY1Pred,classNames,1);
    classesPredictions = [classesPredictions Y1PredBatch];

    % Dermine predicted angles
    Y2PredBatch = extractdata(dlY2Pred);
    anglesPredictions = [anglesPredictions Y2PredBatch];

    % Compare predicted and true classes
    Y1Test = onehotdecode(dlY1Test,classNames,1);
    classCorr = [classCorr Y1PredBatch == Y1Test];

    % Compare predicted and true angles
    angleDiffBatch = Y2PredBatch - dlY2Test;
    angleDiff = [angleDiff extractdata(gather(angleDiffBatch))];

end
```

Evaluate the classification accuracy.

```
accuracy = mean(classCorr)
```

```
accuracy = 0.9730
```

Evaluate the regression accuracy.

```
angleRMSE = sqrt(mean(angleDiff.^2))
```

```
angleRMSE = single
    6.6909
```

View some of the images with their predictions. Display the predicted angles in red and the correct labels in green.

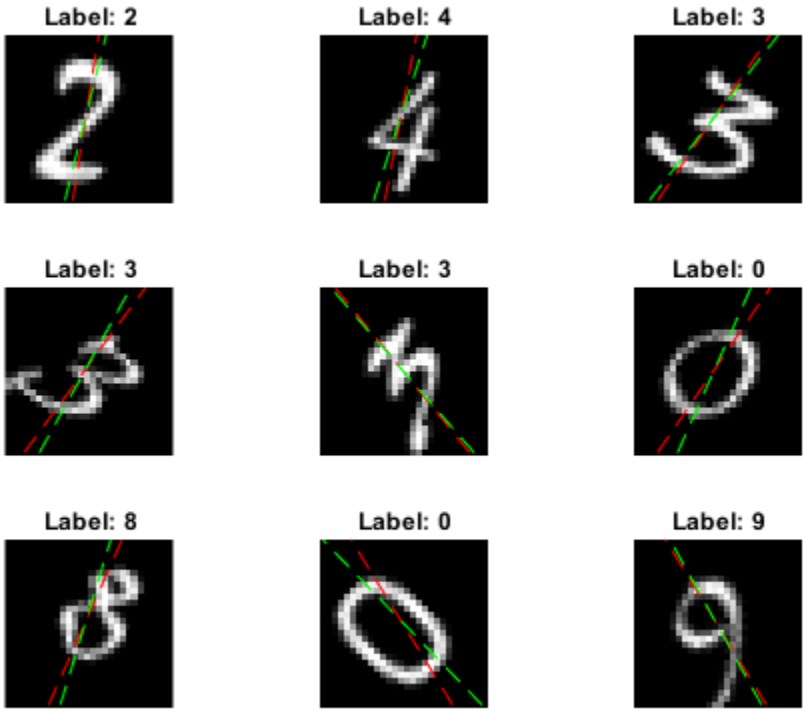
```
idx = randperm(size(XTest,4),9);
figure
for i = 1:9
    subplot(3,3,i)
    I = XTest(:,:,:,idx(i));
    imshow(I)
    hold on

    sz = size(I,1);
    offset = sz/2;

    thetaPred = anglesPredictions(idx(i));
    plot(offset*[1-tand(thetaPred) 1+tand(thetaPred)],[sz 0],'r--')

    thetaValidation = anglesTest(idx(i));
    plot(offset*[1-tand(thetaValidation) 1+tand(thetaValidation)],[sz 0],'g--')

    hold off
    label = string(classesPredictions(idx(i)));
    title("Label: " + label)
end
```



Model Function

The function `model` takes the model parameters `parameters`, the input data `dlX`, the flag `doTraining` which specifies whether to model should return outputs for training or prediction, and the network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

```
function [dlY1,dlY2,state] = model(parameters,dlX,doTraining,state)

% Convolution
weights = parameters.conv1.Weights;
bias = parameters.conv1.Bias;
dlY = dlconv(dlX,weights,bias,'Padding','same');

% Batch normalization, ReLU
offset = parameters.batchnorm1.Offset;
scale = parameters.batchnorm1.Scale;
trainedMean = state.batchnorm1.TrainedMean;
trainedVariance = state.batchnorm1.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm1.TrainedMean = trainedMean;
    state.batchnorm1.TrainedVariance = trainedVariance;
else
```

```
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution, batch normalization (Skip connection)
weights = parameters.convSkip.Weights;
bias = parameters.convSkip.Bias;
dlYSkip = dlconv(dlY,weights,bias,'Stride',2);

offset = parameters.batchnormSkip.Offset;
scale = parameters.batchnormSkip.Scale;
trainedMean = state.batchnormSkip.TrainedMean;
trainedVariance = state.batchnormSkip.TrainedVariance;

if doTraining
    [dlYSkip,trainedMean,trainedVariance] = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVa

    % Update state
    state.batchnormSkip.TrainedMean = trainedMean;
    state.batchnormSkip.TrainedVariance = trainedVariance;
else
    dlYSkip = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVariance);
end

% Convolution
weights = parameters.conv2.Weights;
bias = parameters.conv2.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same','Stride',2);

% Batch normalization, ReLU
offset = parameters.batchnorm2.Offset;
scale = parameters.batchnorm2.Scale;
trainedMean = state.batchnorm2.TrainedMean;
trainedVariance = state.batchnorm2.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm2.TrainedMean = trainedMean;
    state.batchnorm2.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution
weights = parameters.conv3.Weights;
bias = parameters.conv3.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same');

% Batch normalization
offset = parameters.batchnorm3.Offset;
scale = parameters.batchnorm3.Scale;
trainedMean = state.batchnorm3.TrainedMean;
trainedVariance = state.batchnorm3.TrainedVariance;
```

```
if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm3.TrainedMean = trainedMean;
    state.batchnorm3.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

% Addition, ReLU
dlY = dlYSkip + dlY;
dlY = relu(dlY);

% Fully connect, softmax (labels)
weights = parameters.fc1.Weights;
bias = parameters.fc1.Bias;
dlY1 = fullyconnect(dlY,weights,bias);
dlY1 = softmax(dlY1);

% Fully connect (angles)
weights = parameters.fc2.Weights;
bias = parameters.fc2.Bias;
dlY2 = fullyconnect(dlY,weights,bias);

end
```

Model Gradients Function

The `modelGradients` function, takes the model parameters, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

```
function [gradients,state,loss] = modelGradients(parameters,dlX,T1,T2,state)

doTraining = true;
[dlY1,dlY2,state] = model(parameters,dlX,doTraining,state);

lossLabels = crossentropy(dlY1,T1);
lossAngles = mse(dlY2,T2);

loss = lossLabels + 0.1*lossAngles;
gradients = dlgradient(loss,parameters);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label and angle data from the incoming cell arrays and concatenate along the second dimension into a categorical array and a numeric array, respectively.

3 One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y,angle] = preprocessMiniBatch(XCell,YCell,angleCell)

    % Extract image data from cell and concatenate
    X = cat(4,XCell{:});
    % Extract label data from cell and concatenate
    Y = cat(2,YCell{:});
    % Extract angle data from cell and concatenate
    angle = cat(2,angleCell{:});

    % One-hot encode labels
    Y = onehotencode(Y,1);

end
```

Update Batch Normalization Statistics Using Model Function

This example shows how to update the network state in a network defined as a function.

A batch normalization operation normalizes each input channel across a mini-batch. To speed up training of convolutional neural networks and reduce the sensitivity to network initialization, use batch normalization operations between convolutions and nonlinearities, such as ReLU layers.

During training, batch normalization operations first normalize the activations of each channel by subtracting the mini-batch mean and dividing by the mini-batch standard deviation. Then, the operation shifts the input by a learnable offset β and scales it by a learnable scale factor γ.

When you use a trained network to make predictions on new data, the batch normalization operations use the trained data set mean and variance instead of the mini-batch mean and variance to normalize the activations.

To compute the data set statistics, you must keep track of the mini-batch statistics by using a continually updating state.

If you use batch normalization operations in a model function, then you must define the behavior for both training and prediction. For example, you can specify a Boolean option `doTraining` to control whether the model uses mini-batch statistics for training or data set statistics for prediction.

This example piece of code from a model function shows how to apply a batch normalization operation and update only the data set statistics during training.

```
if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm1.TrainedMean = trainedMean;
    state.batchnorm1.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end
```

Load Training Data

The `digitTrain4DArrayData` function loads the images, their digit labels, and their angles of rotation from the vertical. Create an `arrayDatastore` object for the images, labels, and the angles, and then use the `combine` function to make a single datastore that contains all of the training data. Extract the class names and number of nondiscrete responses.

```
[XTrain,YTrain,anglesTrain] = digitTrain4DArrayData;

dsXTrain = arrayDatastore(XTrain,'IterationDimension',4);
dsYTrain = arrayDatastore(YTrain);
dsAnglesTrain = arrayDatastore(anglesTrain);

dsTrain = combine(dsXTrain,dsYTrain,dsAnglesTrain);

classNames = categories(YTrain);
numClasses = numel(classNames);
numResponses = size(anglesTrain,2);
numObservations = numel(YTrain);
```

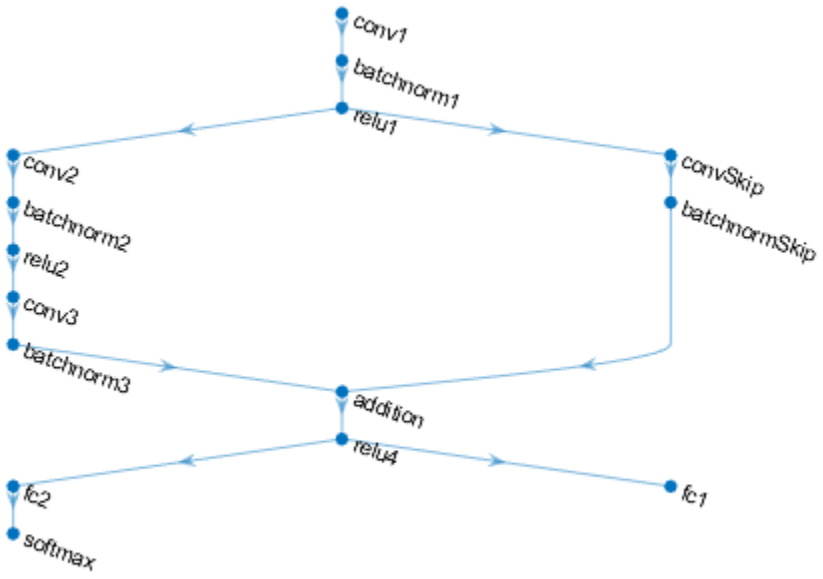
View some images from the training data.

```
idx = randperm(numObservations,64);
I = imtile(XTrain(:,:,:,idx));
figure
imshow(I)
```

Define Deep Learning Model

Define the following network that predicts both labels and angles of rotation.

- A convolution-batchnorm-ReLU block with 16 5-by-5 filters.
- A branch of two convolution-batchnorm blocks each with 32 3-by-3 filters with a ReLU operation between
- A skip connection with a convolution-batchnorm block with 32 1-by-1 convolutions.
- Combine both branches using addition followed by a ReLU operation
- For the regression output, a branch with a fully connected operation of size 1 (the number of responses).
- For classification output, a branch with a fully connected operation of size 10 (the number of classes) and a softmax operation.



Define and Initialize Model Parameters and State

Define the parameters for each of the operations and include them in a struct. Use the format `parameters.OperationName.ParameterName` where `parameters` is the struct, `OperationName` is the name of the operation (for example "conv1") and `ParameterName` is the name of the parameter (for example, "Weights").

Create a struct `parameters` containing the model parameters. Initialize the learnable layer weights and biases using the `initializeGlorot` and `initializeZeros` example functions, respectively. Initialize the batch normalization offset and scale parameters with the `initializeZeros` and `initializeOnes` example functions, respectively.

To perform training and inference using batch normalization layers, you must also manage the network state. Before prediction, you must specify the dataset mean and variance derived from the training data. Create a struct `state` containing the state parameters. The batch normalization statistics must not be `dlarray` objects. Initialize the batch normalization trained mean and trained variance states using the `zeros` and `ones` functions, respectively.

The initialization example functions are attached to this example as supporting files.

Initialize the parameters for the first convolutional layer.

```
filterSize = [5 5];
numChannels = 1;
numFilters = 16;
```

```
sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv1.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the first batch normalization layer.

```
parameters.batchnorm1.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm1.Scale = initializeOnes([numFilters 1]);
state.batchnorm1.TrainedMean = zeros(numFilters,1,'single');
state.batchnorm1.TrainedVariance = ones(numFilters,1,'single');
```

Initialize the parameters for the second convolutional layer.

```
filterSize = [3 3];
numChannels = 16;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv2.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the second batch normalization layer.

```
parameters.batchnorm2.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm2.Scale = initializeOnes([numFilters 1]);
state.batchnorm2.TrainedMean = zeros(numFilters,1,'single');
state.batchnorm2.TrainedVariance = ones(numFilters,1,'single');
```

Initialize the parameters for the third convolutional layer.

```
filterSize = [3 3];
numChannels = 32;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv3.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv3.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the third batch normalization layer.

```
parameters.batchnorm3.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm3.Scale = initializeOnes([numFilters 1]);
state.batchnorm3.TrainedMean = zeros(numFilters,1,'single');
state.batchnorm3.TrainedVariance = ones(numFilters,1,'single');
```

Initialize the parameters for the convolutional layer in the skip connection.

```
filterSize = [1 1];
numChannels = 16;
numFilters = 32;
```

```
sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.convSkip.Weights = initializeGlorot(sz,numOut,numIn);
parameters.convSkip.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters and state for the batch normalization layer in the skip connection.

```
parameters.batchnormSkip.Offset = initializeZeros([numFilters 1]);
parameters.batchnormSkip.Scale = initializeOnes([numFilters 1]);
state.batchnormSkip.TrainedMean = zeros([numFilters 1],'single');
state.batchnormSkip.TrainedVariance = ones([numFilters 1],'single');
```

Initialize the parameters for the fully connected layer corresponding to the classification output.

```
sz = [numClasses 6272];
numOut = numClasses;
numIn = 6272;
parameters.fc1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc1.Bias = initializeZeros([numClasses 1]);
```

Initialize the parameters for the fully connected layer corresponding to the regression output.

```
sz = [numResponses 6272];
numOut = numResponses;
numIn = 6272;
parameters.fc2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc2.Bias = initializeZeros([numResponses 1]);
```

View the struct of the state.

```
state
```

```
state = struct with fields:
       batchnorm1: [1×1 struct]
       batchnorm2: [1×1 struct]
       batchnorm3: [1×1 struct]
    batchnormSkip: [1×1 struct]
```

View the state parameters for the `batchnorm1` operation.

```
state.batchnorm1
```

```
ans = struct with fields:
        TrainedMean: [16×1 single]
    TrainedVariance: [16×1 single]
```

Define Model Function

Create the function `model`, listed at the end of the example, which computes the outputs of the deep learning model described earlier.

The function `model` takes as input the model parameters `parameters`, input data `dlX`, the flag `doTraining`, which specifies whether the model returns outputs for training or prediction, and the

network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, which takes as input a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

Specify Training Options

Specify the training options.

```
numEpochs = 20;
miniBatchSize = 128;

plots = "training-progress";
```

Train Model

Train the model using a custom training loop. Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to one-hot encode the class labels.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels or the angles.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','',''});
```

For each epoch, shuffle the data and loop over mini-batches of data. At the end of each epoch, display the training progress. For each mini-batch:

- Evaluate the model gradients and loss using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.

Initialize the parameters for the Adam solver.

```
trailingAvg = [];
trailingAvgSq = [];
```

Initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
```

```
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Train the model.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbq)

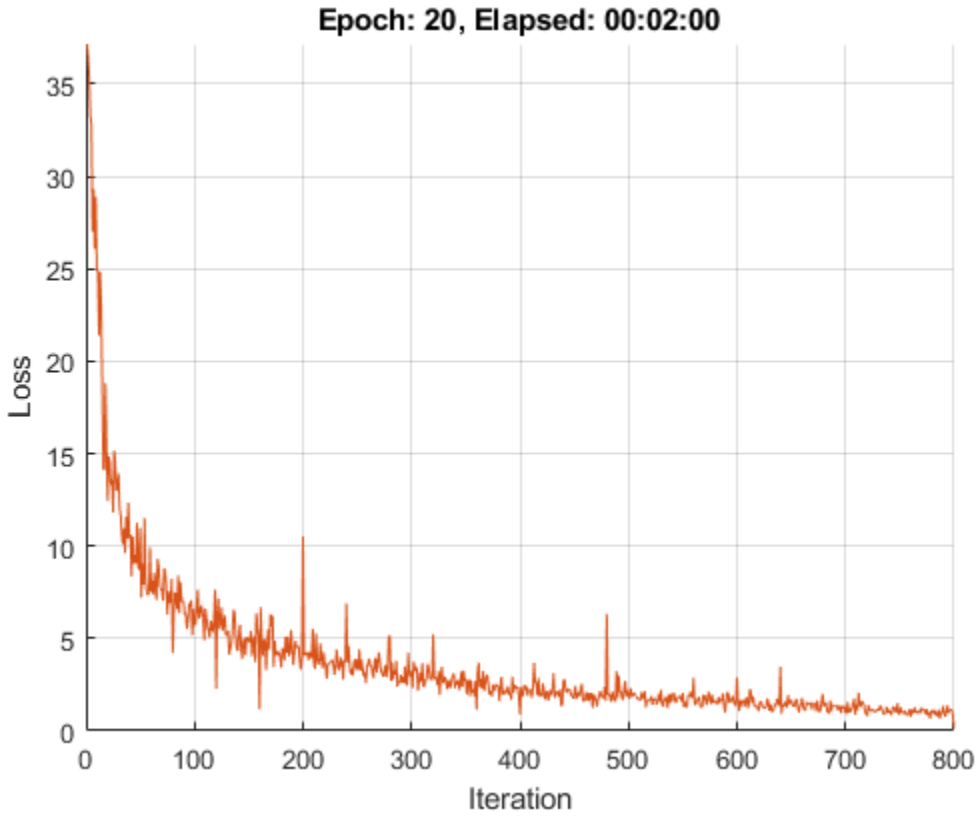
    % Loop over mini-batches
    while hasdata(mbq)
        iteration = iteration + 1;

        [dlX,dlY1,dlY2] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function.
        [gradients,state,loss] = dlfeval(@modelGradients, parameters, dlX, dlY1, dlY2, state);

        % Update the network parameters using the Adam optimizer.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
            trailingAvg,trailingAvgSq,iteration);

        % Display the training progress.
        if plots == "training-progress"
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
            title("Epoch: " + epoch + ", Elapsed: " + string(D))
            drawnow
        end
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on a test set with the true labels and angles. Manage the test data set using a `minibatchqueue` object with the same setting as the training data.

```
[XTest,Y1Test,anglesTest] = digitTest4DArrayData;

dsXTest = arrayDatastore(XTest,'IterationDimension',4);
dsYTest = arrayDatastore(Y1Test);
dsAnglesTest = arrayDatastore(anglesTest);

dsTest = combine(dsXTest,dsYTest,dsAnglesTest);

mbqTest = minibatchqueue(dsTest,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','',''});
```

To predict the labels and angles of the validation data, use the `modelPredictions` function, listed at the end of the example. The function returns the predicted classes and angles, as well as comparison with the true values.

```
[classesPredictions,anglesPredictions,classCorr,angleDiff] = modelPredictions(parameters,state,mb
```

Evaluate the classification accuracy.

```
accuracy = mean(classCorr)
```

```
accuracy = 0.9840
```

Evaluate the regression accuracy.

```
angleRMSE = sqrt(mean(angleDiff.^2))
```

```
angleRMSE = single
    6.3669
```

View some of the images with their predictions. Display the predicted angles in red and the correct angles in green.

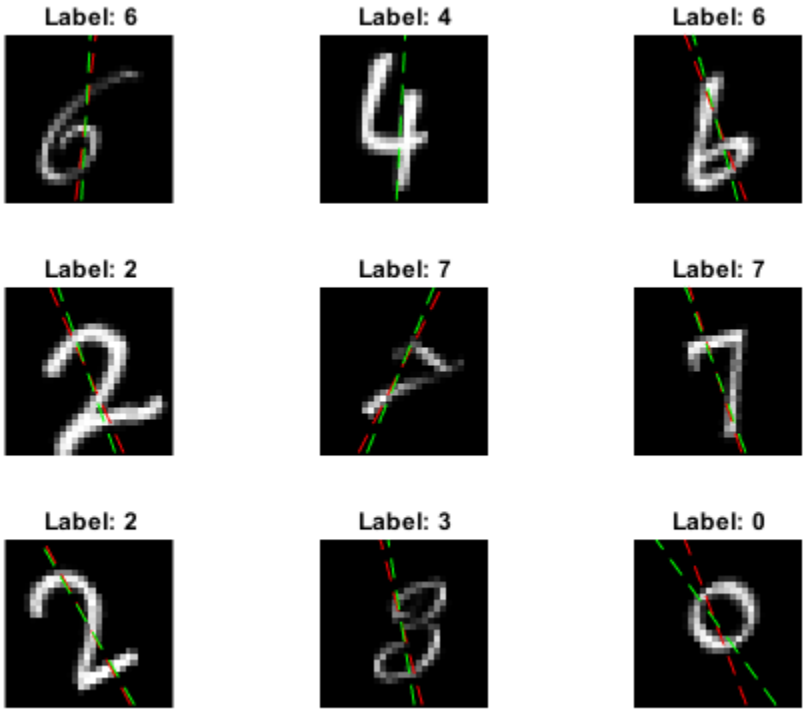
```
idx = randperm(size(XTest,4),9);
figure
for i = 1:9
    subplot(3,3,i)
    I = XTest(:,:,:,idx(i));
    imshow(I)
    hold on

    sz = size(I,1);
    offset = sz/2;

    thetaPred = anglesPredictions(idx(i));
    plot(offset*[1-tand(thetaPred) 1+tand(thetaPred)],[sz 0],'r--')

    thetaValidation = anglesTest(idx(i));
    plot(offset*[1-tand(thetaValidation) 1+tand(thetaValidation)],[sz 0],'g--')

    hold off
    label = string(classesPredictions(idx(i)));
    title("Label: " + label)
end
```



Model Function

The function `model` takes as input the model parameters `parameters`, the input data `dlX`, the flag `doTraining`, which specifies whether the model returns the outputs for training or prediction, and the network state `state`. The function returns the predictions for the labels, the predictions for the angles, and the updated network state.

```
function [dlY1,dlY2,state] = model(parameters,dlX,doTraining,state)

    % Convolution
    weights = parameters.conv1.Weights;
    bias = parameters.conv1.Bias;
    dlY = dlconv(dlX,weights,bias,'Padding',2);

    % Batch normalization, ReLU
    offset = parameters.batchnorm1.Offset;
    scale = parameters.batchnorm1.Scale;
    trainedMean = state.batchnorm1.TrainedMean;
    trainedVariance = state.batchnorm1.TrainedVariance;

    if doTraining
        [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVarianc

        % Update state
        state.batchnorm1.TrainedMean = trainedMean;
        state.batchnorm1.TrainedVariance = trainedVariance;
    else
```

```
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution, batch normalization (skip connection)
weights = parameters.convSkip.Weights;
bias = parameters.convSkip.Bias;
dlYSkip = dlconv(dlY,weights,bias,'Stride',2);

offset = parameters.batchnormSkip.Offset;
scale = parameters.batchnormSkip.Scale;
trainedMean = state.batchnormSkip.TrainedMean;
trainedVariance = state.batchnormSkip.TrainedVariance;

if doTraining
    [dlYSkip,trainedMean,trainedVariance] = batchnorm(dlYSkip,offset,scale,trainedMean,traine

    % Update state
    state.batchnormSkip.TrainedMean = trainedMean;
    state.batchnormSkip.TrainedVariance = trainedVariance;
else
    dlYSkip = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVariance);
end

% Convolution
weights = parameters.conv2.Weights;
bias = parameters.conv2.Bias;
dlY = dlconv(dlY,weights,bias,'Padding',1,'Stride',2);

% Batch normalization, ReLU
offset = parameters.batchnorm2.Offset;
scale = parameters.batchnorm2.Scale;
trainedMean = state.batchnorm2.TrainedMean;
trainedVariance = state.batchnorm2.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVarianc

    % Update state
    state.batchnorm2.TrainedMean = trainedMean;
    state.batchnorm2.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution
weights = parameters.conv3.Weights;
bias = parameters.conv3.Bias;
dlY = dlconv(dlY,weights,bias,'Padding',1);

% Batch normalization
offset = parameters.batchnorm3.Offset;
scale = parameters.batchnorm3.Scale;
trainedMean = state.batchnorm3.TrainedMean;
trainedVariance = state.batchnorm3.TrainedVariance;
```

```
    if doTraining
        [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVarianc

        % Update state
        state.batchnorm3.TrainedMean = trainedMean;
        state.batchnorm3.TrainedVariance = trainedVariance;
    else
        dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
    end

    % Addition, ReLU
    dlY = dlYSkip + dlY;
    dlY = relu(dlY);

    % Fully connect, softmax (labels)
    weights = parameters.fc1.Weights;
    bias = parameters.fc1.Bias;
    dlY1 = fullyconnect(dlY,weights,bias);
    dlY1 = softmax(dlY1);

    % Fully connect (angles)
    weights = parameters.fc2.Weights;
    bias = parameters.fc2.Bias;
    dlY2 = fullyconnect(dlY,weights,bias);

end
```

Model Gradients Function

The `modelGradients` function takes as input the model parameters, a mini-batch of the input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

```
function [gradients,state,loss] = modelGradients(parameters,dlX,T1,T2,state)

    doTraining = true;
    [dlY1,dlY2,state] = model(parameters,dlX,doTraining,state);

    lossLabels = crossentropy(dlY1,T1);
    lossAngles = mse(dlY2,T2);

    loss = lossLabels + 0.1*lossAngles;
    gradients = dlgradient(loss,parameters);

end
```

Model Predictions Function

The `modelPredictions` function takes the model parameters, the network state, a `minibatchqueue` of input data `mbq`, and the network classes, and returns the model predictions by iterating over all data in the `minibatchqueue` using the `model` function with the `doTraining` option set to `false`. The function returns the predicted classes and angles, as well as comparison with the true values. For the classes, the comparison is a vector of ones and zeros that represents correct and incorrect predictions. For the angles, the comparison is the difference between the predicted angle and the true value.

```
function [classesPredictions,anglesPredictions,classCorr,angleDiff] = modelPredictions(parameters

    doTraining = false;

    classesPredictions = [];
    anglesPredictions = [];
    classCorr = [];
    angleDiff = [];

    while hasdata(mbq)
        [dlX,dlY1,dlY2] = next(mbq);

        % Make predictions using the model function.
        [dlY1Pred,dlY2Pred] = model(parameters,dlX,doTraining,state);

        % Determine predicted classes.
        Y1PredBatch = onehotdecode(dlY1Pred,classes,1);
        classesPredictions = [classesPredictions Y1PredBatch];

        % Dermine predicted angles
        Y2PredBatch = extractdata(dlY2Pred);
        anglesPredictions = [anglesPredictions Y2PredBatch];

        % Compare predicted and true classes
        Y1 = onehotdecode(dlY1,classes,1);
        classCorr = [classCorr Y1PredBatch == Y1];

        % Compare predicted and true angles
        angleDiffBatch = Y2PredBatch - dlY2;
        angleDiff = [angleDiff extractdata(gather(angleDiffBatch))];

    end

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label and angle data from the incoming cell arrays and concatenate into a categorical array and a numeric array, respectively.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y,angle] = preprocessMiniBatch(XCell,YCell,angleCell)

    % Extract image data from cell and concatenate
    X = cat(4,XCell{:});
    % Extract label data from cell and concatenate
    Y = cat(2,YCell{:});
    % Extract angle data from cell and concatenate
    angle = cat(2,angleCell{:});

    % One-hot encode labels
```

```
    Y = onehotencode(Y,1);

end
```

Make Predictions Using Model Function

This example shows how to make predictions using a model function by splitting data into mini-batches.

For large data sets, or when predicting on hardware with limited memory, make predictions by splitting the data into mini-batches. When making predictions with `SeriesNetwork` or `DAGNetwork` objects, the `predict` function automatically splits the input data into mini-batches. For model functions, you must split the data into mini-batches manually.

Create Model Function and Load Parameters

Load the model parameters from the MAT file `digitsMIMO.mat`. The MAT file contains the model parameters in a struct named `parameters`, the model state in a struct named `state`, and the class names in `classNames`.

```
s = load("digitsMIMO.mat");
parameters = s.parameters;
state = s.state;
classNames = s.classNames;
```

The model function `model`, listed at the end of the example, defines the model given the model parameters and state.

Load Data for Prediction

Load the digits data for prediction.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet','nndemos', ...
    'nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');

numObservations = numel(imds.Files);
```

Make Predictions

Loop over the mini-batches of the test data and make predictions using a custom prediction loop.

Use `minibatchqueue` to process and manage the mini-batches of images. Specify a mini-batch size of 128. Set the read size property of the image datastore to the mini-batch size.

For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to concatenate the data into a batch and normalize the images.
- Format the images with the dimensions `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`.
- Make predictions on a GPU if one is available. By default, the `minibatchqueue` object converts the output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
miniBatchSize = 128;
imds.ReadSize = miniBatchSize;
```

```
mbq = minibatchqueue(imds,...
    "MiniBatchSize",miniBatchSize,...
    "MiniBatchFcn", @preprocessMiniBatch,...
    "MiniBatchFormat","SSCB");
```

Loop over the minibatches of data and make predictions using the `predict` function. Use the `onehotdecode` function to determine the class labels. Store the predicted class labels.

```
doTraining = false;

Y1Predictions = [];
Y2Predictions = [];

% Loop over mini-batches.
while hasdata(mbq)

    % Read mini-batch of data.
    dlX = next(mbq);

    % Make predictions using the predict function.
    [dlY1Pred,dlY2Pred] = model(parameters,dlX,doTraining,state);

    % Determine corresponding classes.
    Y1PredBatch = onehotdecode(dlY1Pred,classNames,1);
    Y1Predictions = [Y1Predictions Y1PredBatch];

    Y2PredBatch = extractdata(dlY2Pred);
    Y2Predictions = [Y2Predictions Y2PredBatch];

end
```

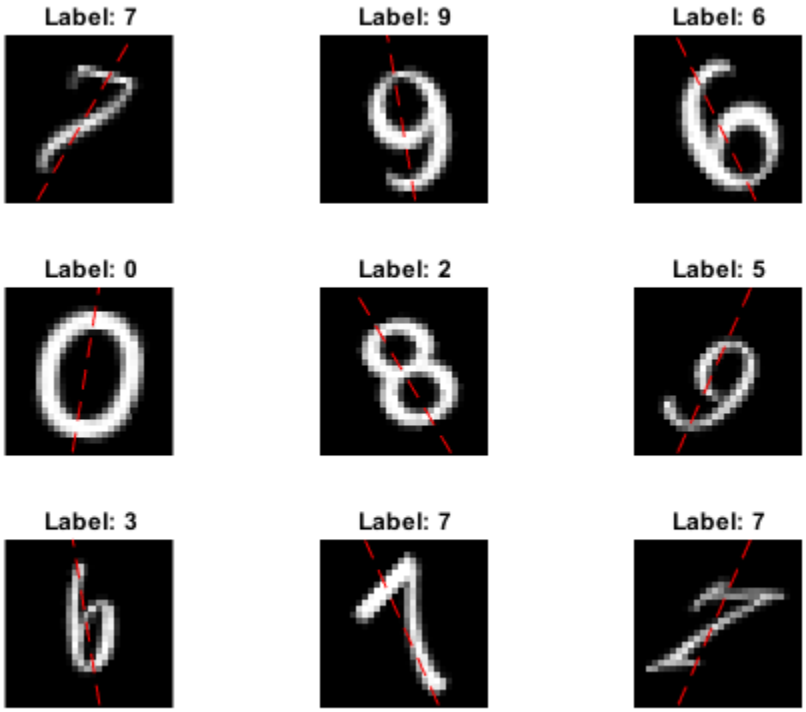
View some of the images with their predictions.

```
idx = randperm(numObservations,9);
figure
for i = 1:9
    subplot(3,3,i)
    I = imread(imds.Files{idx(i)});
    imshow(I)
    hold on

    sz = size(I,1);
    offset = sz/2;

    thetaPred = Y2Predictions(idx(i));
    plot(offset*[1-tand(thetaPred) 1+tand(thetaPred)],[sz 0],'r--')

    hold off
    label = string(Y1Predictions(idx(i)));
    title("Label: " + label)
end
```



Model Function

The function `model` takes the model parameters `parameters`, the input data `dlX`, the flag `doTraining` which specifies whether to model should return outputs for training or prediction, and the network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

```
function [dlY1,dlY2,state] = model(parameters,dlX,doTraining,state)

% Convolution
weights = parameters.conv1.Weights;
bias = parameters.conv1.Bias;
dlY = dlconv(dlX,weights,bias,'Padding','same');

% Batch normalization, ReLU
offset = parameters.batchnorm1.Offset;
scale = parameters.batchnorm1.Scale;
trainedMean = state.batchnorm1.TrainedMean;
trainedVariance = state.batchnorm1.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm1.TrainedMean = trainedMean;
    state.batchnorm1.TrainedVariance = trainedVariance;
else
```

```
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution, batch normalization (Skip connection)
weights = parameters.convSkip.Weights;
bias = parameters.convSkip.Bias;
dlYSkip = dlconv(dlY,weights,bias,'Stride',2);

offset = parameters.batchnormSkip.Offset;
scale = parameters.batchnormSkip.Scale;
trainedMean = state.batchnormSkip.TrainedMean;
trainedVariance = state.batchnormSkip.TrainedVariance;

if doTraining
    [dlYSkip,trainedMean,trainedVariance] = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVa

    % Update state
    state.batchnormSkip.TrainedMean = trainedMean;
    state.batchnormSkip.TrainedVariance = trainedVariance;
else
    dlYSkip = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVariance);
end

% Convolution
weights = parameters.conv2.Weights;
bias = parameters.conv2.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same','Stride',2);

% Batch normalization, ReLU
offset = parameters.batchnorm2.Offset;
scale = parameters.batchnorm2.Scale;
trainedMean = state.batchnorm2.TrainedMean;
trainedVariance = state.batchnorm2.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm2.TrainedMean = trainedMean;
    state.batchnorm2.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution
weights = parameters.conv3.Weights;
bias = parameters.conv3.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same');

% Batch normalization
offset = parameters.batchnorm3.Offset;
scale = parameters.batchnorm3.Scale;
trainedMean = state.batchnorm3.TrainedMean;
trainedVariance = state.batchnorm3.TrainedVariance;
```

```
if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm3.TrainedMean = trainedMean;
    state.batchnorm3.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

% Addition, ReLU
dlY = dlYSkip + dlY;
dlY = relu(dlY);

% Fully connect, softmax (labels)
weights = parameters.fc1.Weights;
bias = parameters.fc1.Bias;
dlY1 = fullyconnect(dlY,weights,bias);
dlY1 = softmax(dlY1);

% Fully connect (angles)
weights = parameters.fc2.Weights;
bias = parameters.fc2.Bias;
dlY2 = fullyconnect(dlY,weights,bias);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the data from the incoming cell array and concatenate into a numeric array. Concatenating over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Normalize the pixel values between `0` and `1`.

```
function X = preprocessMiniBatch(data)
    % Extract image data from cell and concatenate
    X = cat(4,data{:});

    % Normalize the images.
    X = X/255;
end
```

Initialize Learnable Parameters for Model Function

When you train a network using layers, layer graphs, or `dlnetwork` objects, the software automatically initializes the learnable parameters according to the layer initialization properties. When you define a deep learning model as a function, you must initialize the learnable parameters manually.

How you initialize learnable parameters (for example, weights and biases) can have a big impact on how quickly a deep learning model converges.

Tip This topic explains how to initialize learnable parameters for a deep learning model defined a function in a custom training loop. To learn how to specify the learnable parameter initialization for a deep learning layer, use the corresponding layer property. For example, to set the weights initializer of a `convolution2dLayer` object, use the `WeightsInitializer` property.

Default Layer Initializations

This table shows the default initializations for the learnable parameters for each layer, and provides links that show how to initialize learnable parameters for model functions by using the same initialization.

Layer	Learnable Parameter	Default Initialization
`convolution2dLayer`	Weights	“Glorot Initialization” on page 18-296
	Bias	“Zeros Initialization” on page 18-302
`convolution3dLayer`	Weights	“Glorot Initialization” on page 18-296

`wordEmbeddingLayer`	Weights	“Gaussian Initialization” on page 18-299, with mean 0 and standard deviation 0.01

Learnable Parameter Sizes

When initializing learnable parameters for model functions, you must specify parameters of the correct size. The size of the learnable parameters depends on the type of deep learning operation.

Operation	Learnable Parameter	Size
`batchnorm`	Offset	`[numChannels 1]`, where `numChannels` is the number of input channels
	Scale	`[numChannels 1]`, where `numChannels` is the number of input channels
`dlconv`	Weights	`[filterSize numChannels numFilters]`, where `filterSize` is a 1-by-`K` vector specifying the filter size, `numChannels` is the number of input channels, `numFilters` is the number of filters, and `K` is the number of spatial dimensions

Operation	Learnable Parameter	Size
	Bias	One of the following: • `[numFilters 1]`, where `numFilters` is the number of filters • `[1 1]`
`dlconv` (grouped)	Weights	`[filterSize numChannelsPerGroup numFiltersPerGroup numGroups]`, where `filterSize` is a 1-by-`K` vector specifying the filter size, `numChannelsPerGroup` is the number of input channels for each group, `numFiltersPerGroup` is the number of filters for each group, `numGroups` is the number of groups, and `K` is the number of spatial dimensions
	Bias	One of the following: • `[numFiltersPerGroup 1]`, where `numFiltersPerGroup` is the number of filters for each group. • `[1 1]`
`dltranspconv`	Weights	`[filterSize numFilters numChannels]`, where `filterSize` is a 1-by-`K` vector specifying the filter size, `numChannels` is the number of input channels, `numFilters` is the number of filters, and `K` is the number of spatial dimensions
	Bias	One of the following: • `[numFilters 1]`, where `numFilters` is the number of filters for each group. • `[1 1]`

Operation	Learnable Parameter	Size
`dltranspconv` (grouped)	Weights	`[filterSize numFiltersPerGroup numChannelsPerGroup numGroups]`, where `filterSize` is a 1-by-`K` vector specifying the filter size, `numChannelsPerGroup` is the number of input channels for each group, `numFiltersPerGroup` is the number of filters for each group, `numGroups` is the number of groups, and `K` is the number of spatial dimensions
	Bias	One of the following: • `[numFiltersPerGroup 1]`, where `numFiltersPerGroup` is the number of filters for each group. • `[1 1]`
`fullyconnect`	Weights	`[outputSize inputSize]`, where `outputSize` and `inputSize` is the number of output and input channels, respectively
	Bias	`[outputSize 1]`, where `outputSize` is the number of output channels
`gru`	Input weights	`[3*numHiddenUnits inputSize]`, where `numHiddenUnits` is the number of hidden units of the operation and `inputSize` is the number of input channels
	Recurrent weights	`[3*numHiddenUnits numHiddenUnits]`, where `numHiddenUnits` is the number of hidden units of the operation
	Bias	`[3*numHiddenUnits 1]`, where `numHiddenUnits` is the number of hidden units of the operation

Operation	Learnable Parameter	Size
`lstm`	Input weights	`[4*numHiddenUnits inputSize]`, where `numHiddenUnits` is the number of hidden units of the operation and `inputSize` is the number of input channels
	Recurrent weights	`[4*numHiddenUnits numHiddenUnits]`, where `numHiddenUnits` is the number of hidden units of the operation
	Bias	`[4*numHiddenUnits 1]`, where `numHiddenUnits` is the number of hidden units of the operation

Glorot Initialization

The Glorot (also known as Xavier) initializer [1] samples weights from the uniform distribution with bounds $\left[-\sqrt{\frac{6}{N_o + N_i}}, \sqrt{\frac{6}{N_o + N_i}}\right]$, where the values of N_o and N_i depend on the type of deep learning operation.

Operation	Learnable Parameter	N_o	N_i
`dlconv`	Weights	`prod(filterSize)*numFilters`, where `filterSize` is a 1-by-`K` vector containing the filter size, `numFilters` is the number of filters, and `K` is the number of spatial dimensions	`prod(filterSize)*numChannels`, where `filterSize` is a 1-by-`K` vector containing the filter size, `numChannels` is the number of input channels, and `K` is the number of spatial dimensions
`dlconv` (grouped)	Weights	`prod(filterSize)*numFiltersPerGroup`, where `filterSize` is a 1-by-`K` vector containing the filter size, `numFiltersPerGroup` is the number of filters for each group, and `K` is the number of spatial dimensions	`prod(filterSize)*numChannelsPerGroup`, where `filterSize` is a 1-by-`K` vector containing the filter size, `numChannelsPerGroup` is the number of input channels for each group, and `K` is the number of spatial dimensions

Operation	Learnable Parameter	N_o	N_i
`dltranspconv`	Weights	`prod(filterSize)*numFilters`, where `filterSize` is a 1-by-K vector containing the filter size, `numFilters` is the number of filters, and K is the number of spatial dimensions	`prod(filterSize)*numChannels`, where `filterSize` is a 1-by-K vector containing the filter size, `numChannels` is the number of input channels, and K is the number of spatial dimensions
`dltranspconv` (grouped)	Weights	`prod(filterSize)*numFiltersPerGroup`, where `filterSize` is a 1-by-K vector containing the filter size, `numFiltersPerGroup` is the number of filters for each group, and K is the number of spatial dimensions	`prod(filterSize)*numChannelsPerGroup`, where `filterSize` is a 1-by-K vector containing the filter size, `numChannelsPerGroup` is the number of input channels for each group, and K is the number of spatial dimensions
`fullyconnect`	Weights	Number of output channels of the operation	Number of input channels of the operation
`gru`	Input weights	`3*numHiddenUnits`, where `numHiddenUnits` is the number of hidden units of the operation	Number of input channels of the operation
	Recurrent weights	`3*numHiddenUnits`, where `numHiddenUnits` is the number of hidden units of the operation	Number of hidden units of the operation
`lstm`	Input weights	`4*numHiddenUnits`, where `numHiddenUnits` is the number of hidden units of the operation	Number of input channels of the operation
	Recurrent weights	`4*numHiddenUnits`, where `numHiddenUnits` is the number of hidden units of the operation	Number of hidden units of the operation

To initialize learnable parameters using the Glorot initializer easily, you can define a custom function. The function `initializeGlorot` takes as input the size of the learnable parameters `sz` and the

values N_o and N_i (`numOut` and `numIn`, respectively), and returns the sampled weights as a `dlarray` object with underlying type `'single'`.

```
function weights = initializeGlorot(sz,numOut,numIn)

Z = 2*rand(sz,'single') - 1;
bound = sqrt(6 / (numIn + numOut));

weights = bound * Z;
weights = dlarray(weights);

end
```

Example

Initialize the weights for a convolutional operation with 128 filters of size 5-by-5 and 3 input channels.

```
filterSize = [5 5];
numChannels = 3;
numFilters = 128;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv.Weights = initializeGlorot(sz,numOut,numIn);
```

He Initialization

The He initializer [2] samples weights from the normal distribution with zero mean and variance $\frac{2}{N_i}$, where the value N_i depends on the type of deep learning operation.

Operation	Learnable Parameter	N_i
`dlconv`	Weights	`prod(filterSize)*numChannelsPerGroup`, where `filterSize` is a 1-by-K vector containing the filter size, `numChannelsPerGroup` is the number of input channels for each group, and K is the number of spatial dimensions
`dltranspconv`	Weights	`prod(filterSize)*numChannelsPerGroup`, where `filterSize` is a 1-by-K vector containing the filter size, `numChannelsPerGroup` is the number of input channels for each group, and K is the number of spatial dimensions

Operation	Learnable Parameter	N_i
`fullyconnect`	Weights	Number of input channels of the operation
`gru`	Input weights	Number of input channels of the operation
	Recurrent weights	Number of hidden units of the operation.
`lstm`	Input weights	Number of input channels of the operation
	Recurrent weights	Number of hidden units of the operation.

To initialize learnable parameters using the He initializer easily, you can define a custom function. The function `initializeHe` takes as input the size of the learnable parameters `sz`, and the value N_i, and returns the sampled weights as a `dlarray` object with underlying type `'single'`.

```
function weights = initializeHe(sz,numIn)

weights = randn(sz,'single') * sqrt(2/numIn);
weights = dlarray(weights);

end
```

Example

Initialize the weights for a convolutional operation with 128 filters of size 5-by-5 and 3 input channels.

```
filterSize = [5 5];
numChannels = 3;
numFilters = 128;

sz = [filterSize numChannels numFilters];
numIn = prod(filterSize) * numFilters;

parameters.conv.Weights = initializeHe(sz,numIn);
```

Gaussian Initialization

The Gaussian initializer samples weights from a normal distribution.

To initialize learnable parameters using the Gaussian initializer easily, you can define a custom function. The function `initializeGaussian` takes as input the size of the learnable parameters `sz`, the distribution mean `mu`, and the distribution standard deviation `sigma`, and returns the sampled weights as a `dlarray` object with underlying type `'single'`.

```
function weights = initializeGaussian(sz,mu,sigma)

weights = randn(sz,'single')*sigma + mu;
weights = dlarray(weights);

end
```

Example

Initialize the weights for an embedding operation with a dimension of 300 and vocabulary size of 5000 using the Gaussian initializer with mean 0 and standard deviation 0.01.

```
embeddingDimension = 300;
vocabularySize = 5000;
mu = 0;
sigma = 0.01;

sz = [embeddingDimension vocabularySize];

parameters.emb.Weights = initializeGaussian(sz,mu,sigma);
```

Uniform Initialization

The uniform initializer samples weights from a uniform distribution.

To initialize learnable parameters using the uniform initializer easily, you can define a custom function. The function `initializeUniform` takes as input the size of the learnable parameters `sz`, and the distribution bound `bound`, and returns the sampled weights as a `dlarray` object with underlying type `'single'`.

```
function parameter = initializeUniform(sz,bound)

Z = 2*rand(sz,'single') - 1;
parameter = bound * Z;
parameter = dlarray(parameter);

end
```

Example

Initialize the weights for an attention mechanism with size 100-by-100 and bound 0.1 using the uniform initializer.

```
sz = [100 100];
bound = 0.1;

parameters.attentionn.Weights = initializeUniform(sz,bound);
```

Orthogonal Initialization

The orthogonal initializer returns the orthogonal matrix Q given by the QR decomposition of $Z = QR$, where Z is sampled from a unit normal distribution and the size of Z matches the size of the learnable parameter.

To initialize learnable parameters using the orthogonal initializer easily, you can define a custom function. The function `initializeOrthogonal` takes as input the size of the learnable parameters `sz`, and returns the orthogonal matrix as a `dlarray` object with underlying type `'single'`.

```
function parameter = initializeOrthogonal(sz)

Z = randn(sz,'single');
[Q,R] = qr(Z,0);
```

```
D = diag(R);
Q = Q * diag(D ./ abs(D));

parameter = dlarray(Q);

end
```

Example

Initialize the recurrent weights for an LSTM operation with 100 hidden units using the orthogonal initializer.

```
numHiddenUnits = 100;

sz = [4*numHiddenUnits numHiddenUnits];

parameters.lstm.RecurrentWeights = initializeOrthogonal(sz);
```

Unit Forget Gate Initialization

The unit forget gate initializer initializes the bias for an LSTM operation such that the forget gate component of the biases are ones and the remaining entries are zeros.

To initialize learnable parameters using the orthogonal initializer easily, you can define a custom function. The function `initializeUnitForgetGate` takes as input the number of hidden units in the LSTM operation, and returns the bias as a `dlarray` object with underlying type `'single'`.

```
function bias = initializeUnitForgetGate(numHiddenUnits)

bias = zeros(4*numHiddenUnits,1,'single');

idx = numHiddenUnits+1:2*numHiddenUnits;
bias(idx) = 1;

bias = dlarray(bias);

end
```

Example

Initialize the bias of an LSTM operation with 100 hidden units using the unit forget gate initializer.

```
numHiddenUnits = 100;

parameters.lstm.Bias = initializeUnitForgetGate(numHiddenUnits,'single');
```

Ones Initialization

To initialize learnable parameters with ones easily, you can define a custom function. The function `initializeOnes` takes as input the size of the learnable parameters `sz`, and returns the parameters as a `dlarray` object with underlying type `'single'`.

```
function parameter = initializeOnes(sz)

parameter = ones(sz,'single');
parameter = dlarray(parameter);
```

```
end
```

Example

Initialize the scale for a batch normalization operation with 128 input channels with ones.

```
numChannels = 128;

sz = [numChannels 1];

parameters.bn.Scale = initializeOnes(sz);
```

Zeros Initialization

To initialize learnable parameters with zeros easily, you can define a custom function. The function `initializeZeros` takes as input the size of the learnable parameters `sz`, and returns the parameters as a `dlarray` object with underlying type `'single'`.

```
function parameter = initializeZeros(sz)

parameter = zeros(sz,'single');
parameter = dlarray(parameter);

end
```

Example

Initialize the offset for a batch normalization operation with 128 input channels with zeros.

```
numChannels = 128;

sz = [numChannels 1];

parameters.bn.Offset = initializeZeros(sz);
```

Storing Learnable Parameters

It is recommended to store the learnable parameters for a given model function in a single object, such as a struct, table, or cell array. For an example showing how to initialize learnable parameters as a struct, see “Train Network Using Model Function” on page 18-259.

Storing Parameters on GPU

If you train your model using training data that is stored on the GPU, the learnable parameters of the model function are converted to gpuArray objects and stored on the GPU.

Before saving your learnable parameters, it is recommended practice to gather all parameters, in case they are loaded onto a machine without a GPU. Use `dlupdate` to gather learnable parameters stored as a struct, table, or cell array. For example, if you have network learnable parameters stored on the GPU in the struct, table, or cell array `parameters`, you can gather all parameters on the to CPU by using the following code:

```
parameters = dlupdate(@gather,parameters);
```

If you load learnable parameters that are not on the GPU, you can move the parameters onto the GPU using `dlupdate`. Doing so ensures that your network executes on the GPU for training and inference, regardless of where the input data is stored. To move the learnable parameters onto the GPU, use the `dlupdate` function:

```
parameters = dlupdate(@gpuArray,parameters);
```

Deep Learning Function Acceleration for Custom Training Loops

When using the `dlfeval` function in a custom training loop, the software traces each input `dlarray` object of the model gradients function to determine the computation graph used for automatic differentiation. This tracing process can take some time and can spend time recomputing the same trace. By optimizing, caching, and reusing the traces, you can speed up gradient computation in deep learning functions. You can also optimize, cache, and reuse traces to accelerate other deep learning functions that do not require automatic differentiation, for example you can also accelerate model functions and functions used for prediction.

To speed up calls to deep learning functions, you can use the `dlaccelerate` function to create an `AcceleratedFunction` object that automatically optimizes, caches, and reuses the traces. You can use the `dlaccelerate` function to accelerate model functions and model gradients functions directly.

The returned `AcceleratedFunction` object caches the traces of calls to the underlying function and reuses the cached result when the same input pattern reoccurs.

Try using `dlaccelerate` for function calls that:

- are long-running
- have `dlarray` objects, structures of `dlarray` objects, or `dlnetwork` objects as inputs
- do not have side effects like writing to files or displaying output

Invoke the accelerated function as you would invoke the underlying function. Note that the accelerated function is not a function handle.

Note When using the `dlfeval` function, the software automatically accelerates the `forward` and `predict` functions for `dlnetwork` input. If you accelerate a deep learning function where the majority of the computation takes place in calls to the `forward` or `predict` functions for `dlnetwork` input, then you might not see an improvement in training time.

Because of the nature of caching traces, not all functions support acceleration.

The caching process can cache values that you might expect to change or that depend on external factors. You must take care when accelerating functions that:

- have inputs with random or frequently changing values
- have outputs with frequently changing values
- generate random numbers
- use `if` statements and `while` loops with conditions that depend on the values of `dlarray` objects
- have inputs that are handles or that depend on handles
- Read data from external sources (for example, by using a datastore or a `minibatchqueue` object)

Accelerated functions can do the following when calculating a new trace only.

- modify the global state such as, the random number stream or global variables

- use file input or output
- display data using graphics or the command line display

When using accelerated functions in parallel, such as when using a `parfor` loop, then each worker maintains its own cache. The cache is not transferred to the host.

Functions and custom layers used in accelerated functions must also support acceleration.

You can nest and recursively call accelerated functions. However, it is usually more efficient to have a single accelerated function.

Accelerate Deep Learning Function Directly

In most cases, you can accelerate deep learning functions directly. For example, you can accelerate the model gradients function directly by replacing calls to the model gradients function with calls to the corresponding accelerated function:

Consider the following use of the `dlfeval` function in a custom training loop.

```
[gradients,state,loss] = dlfeval(@modelGradients,parameters,dlX,dlT,state)
```

To accelerate the model gradients function and evaluate the accelerated function, use the `dlaccelerate` function and evaluate the returned `AcceleratedFunction` object:

```
accfun = dlaccelerate(@modelGradients);
[gradients,state,loss] = dlfeval(accfun,parameters,dlX,dlT,state)
```

Because the cached traces are not directly attached to the `AcceleratedFunction` object and that they are shared between `AcceleratedFunction` objects that use the same underlying function, you can create the `AcceleratedFunction` either in or before the custom training loop body.

Accelerate Parts of Deep Learning Function

If a deep learning function does not fully support acceleration, for example, functions that require an `if` statement with a condition that depends on the value of a `dlarray` object, then you can accelerate parts of a deep learning function by creating a separate function contains any supported function calls you want to accelerate.

For example, consider the following code snippet that calls different functions depending on whether the sum of the `dlarray` object `dlX` is negative or nonnegative.

```
if sum(dlX,'all') < 0
   dlX = negFun1(parameters,dlX);
   dlX = negFun2(parameters,dlX);
else
   dlX = posFun1(parameters,dlX);
   dlX = posFun2(parameters,dlX);
end
```

Because the `if` statement depends on the value of a `dlarray` object, a function that contains this code snippet does not support acceleration. However, if the blocks of code used inside the body of the `if` statement support acceleration, then you can accelerate these parts separately by creating a new function containing those blocks and accelerating the new functions instead.

For example, create the functions `negFunAll` and `posFunAll` that contain the blocks of code used in the body of the `if` statement.

```
function dlX = negFunAll(parameters,dlX)

dlX = negFun1(parameters,dlX);
dlX = negFun2(parameters,dlX);

end

function dlX = posFunAll(parameters,dlX)

dlX = posFun1(parameters,dlX);
dlX = posFun2(parameters,dlX);

end
```

Then, accelerate these functions and use them in the body of the `if` statement instead.

```
accfunNeg = dlaccelerate(@negFunAll)
accfunPos = dlaccelerate(@posFunAll)

if sum(dlX,'all') < 0
   dlX = accfunNeg(parameters,dlX);
else
   dlX = accfunPos(parameters,dlX);
end
```

Reusing Caches

Reusing a cached trace depends on the function inputs and outputs:

- For any `dlarray` object or structure of `dlarray` object inputs, the trace depends on the size, format, and underlying datatype of the `dlarray`. That is, the accelerated function triggers a new trace for `dlarray` inputs with size, format, or underlying datatype not contained in the cache. Any `dlarray` inputs differing only by value to a previously cached trace do not trigger a new trace.
- For any `dlnetwork` inputs, the trace depends on the size, format, and underlying datatype of the `dlnetwork` state and learnable parameters. That is, the accelerated function triggers a new trace for `dlnetwork` inputs with learnable parameters or state with size, format, and underlying datatype not contained in the cache. Any `dlnetwork` inputs differing only by the value of the state and learnable parameters to a previously cached trace do not trigger a new trace.
- For other types of input, the trace depends on the values of the input. That is, the accelerated function triggers a new trace for other types of input with value not contained in the cache. Any other inputs that have the same value as a previously cached trace do not trigger a new trace.
- The trace depends on the number of function outputs. That is, the accelerated function triggers a new trace for function calls with previously unseen numbers of output arguments. Any function calls with the same number of output arguments as a previously cached trace do not trigger a new trace.

When necessary, the software caches any new traces by evaluating the underlying function and caching the resulting trace in the `AcceleratedFunction` object.

Caution An `AcceleratedFunction` object is not aware of updates to the underlying function. If you modify the function associated with the accelerated function, then clear the cache using the `clearCache` object function or alternatively use the command `clear functions`.

Storing and Clearing Caches

`AcceleratedFunction` objects store the cache in a queue:

- The software adds new traces to the back of the queue.
- When the cache is full, the software discards the cached item at the head of the queue.
- When a cache is reused, the software moves the cached item towards the back of the queue. This helps prevents the software from discarding commonly reused cached items.

The `AcceleratedFunction` objects do not directly hold the cache. This means that:

- Multiple `AcceleratedFunction` objects that have the same underlying function share the same cache.
- Clearing or overwriting a variable containing an `AcceleratedFunction` object does not clear the cache.
- Overwriting a variable containing an `AcceleratedFunction` with another `AcceleratedFunction` with the same underlying function does not clear the cache.

Accelerated functions that have the same underlying function share the same cache.

To clear the cache of an accelerated function, use the `clearCache` object function. Alternatively, you can clear all functions in the current MATLAB session using the commands `clear functions` or `clear all`.

Note Clearing the `AcceleratedFunction` variable does not clear the cache associated with the input function. To clear the cache for an `AcceleratedFunction` object that no longer exists in the workspace, create a new `AcceleratedFunction` object to the same function, and use the `clearCache` function on the new object. Alternatively, you can clear all functions in the current MATLAB session using the commands `clear functions` or `clear all`.

Acceleration Considerations

Because of the nature of caching traces, not all functions support acceleration.

The caching process can cache values that you might expect to change or that depend on external factors. You must take care when accelerating functions that:

- have inputs with random or frequently changing values
- have outputs with frequently changing values
- generate random numbers
- use `if` statements and `while` loops with conditions that depend on the values of `dlarray` objects
- have inputs that are handles or that depend on handles
- Read data from external sources (for example, by using a datastore or a `minibatchqueue` object)

Accelerated functions can do the following when calculating a new trace only.

- modify the global state such as, the random number stream or global variables
- use file input or output

- display data using graphics or the command line display

When using accelerated functions in parallel, such as when using a `parfor` loop, then each worker maintains its own cache. The cache is not transferred to the host.

Functions and custom layers used in accelerated functions must also support acceleration.

Function Inputs with Random or Frequently Changing Values

You must take care when accelerating functions that take random or frequently changing values as input, such as a model gradients function that takes random noise as input and adds it to the input data. If any random or frequently changing inputs to an accelerated function are not `dlarray` objects, then the function trigger a new trace for each previously unseen value.

You can check for scenarios like this by inspecting the `Occupancy` and `HitRate` properties of the `AcceleratedFunction` object. If the `Occupancy` property is high and the `HitRate` is low, then this can indicate that the `AcceleratedFunction` object creates many new traces that it does not reuse.

For `dlarray` object input, changes in value to not trigger new traces. To prevent frequently changing input from triggering new traces for each evaluation, refactor your code such that the random inputs are `dlarray` inputs.

For example, consider the model gradients function that accepts a random array of noise values:

```
function [gradients,state,loss] = modelGradients(parameters,dlX,dlT,state,noise)

dlX = dlX + noise;
[dlYPred,state] = model(parameters,dlX,state);
loss = crossentropy(dlYPred,dlT);
gradients = dlgradient(loss,parameters);

end
```

To accelerate this model gradients function, convert the input `noise` to `dlarray` before evaluating the accelerated function. Because the `modelGradients` function also supports `dlarray` input for noise, you do not need to make changes to the function.

```
noise = dlarray(noise,'SSCB');
accfun = dlaccelerate(@modelGradients);
[gradients,state,loss] = dlfeval(accfun,parameters,dlX,dlT,state,noise);
```

Alternatively, you can accelerate the parts of the model gradients function that do not require the random input.

Functions with Random Number Generation

You must take care when accelerating functions that use random number generation, such as a model gradients function that generates random noise to add to the network input. When caching the trace of a function that generates random numbers that are not `dlarray` objects, the accelerated function caches resulting random numbers in the trace. When reusing the trace, the accelerated function uses the cached random values. The accelerated function does not generate new random values.

Random number generation using the `'like'` option of the `rand` function with a `dlarray` object supports acceleration. To use random number generation in an accelerated function, ensure that the function uses the `rand` function with the `'like'` option set to a traced `dlarray` object (a `dlarray` object that depends on an input `dlarray` object).

For example, consider the following model gradients function.

```
[gradients,state,loss] = modelGradients(parameters,dlX,dlT,state)

sz = size(dlX);
noise = rand(sz);
dlX = dlX + noise;

[dlYPred,state] = model(parameters,dlX,state);
loss = crossentropy(dlYPred,dlT);
gradients = dlgradient(loss,parameters);

end
```

To ensure that the `rand` function generates a new value for each evaluation, use the `'like'` option with the traced `dlarray` object `dlX`.

```
[gradients,state,loss] = modelGradients(parameters,dlX,dlT,state)

sz = size(dlX);
noise = rand(sz,'like',dlX);
dlX = dlX + noise;

[dlYPred,state] = model(parameters,dlX);
loss = crossentropy(dlYPred,dlT);
gradients = dlgradient(loss,parameters);

end
```

Alternatively, you can accelerate the parts of the model gradients function that do not require random number generation.

Using if Statements and while Loops

You must take care when accelerating functions that use `if` statements and `while` loops. In particular, `if` statements and `while` loops support acceleration only when the conditions do not depend on the values of `dlarray` objects.

Attempting to accelerate functions that have `if` statements and `while` loops with conditions that depend on `dlarray` values can lead to unexpected behavior. When the accelerated function caches a new trace, if the trace contains an `if` statement or `while` loop condition that depends on the value of a `dlarray` object, then the function caches the trace of the resulting code path given by the `if` statement or `while` loop for that value. Because changes in value of `dlarray` input do not trigger a new trace, when reusing the trace, the function uses the same cached trace (which represents the same code path) even when difference in value can result in a different code path.

To use `if` statements and `while` loops that depend on `dlarray` object values, accelerate the body of the `if` statement or `while` loop only.

Function Inputs that Depend on Handles

You must take care when accelerating functions that take objects that depend on handles as input, such as a `minibatchqueue` object that has a preprocessing function specified as a function handle. The `AcceleratedFunction` object throws an error when evaluating the function with inputs depending on handles.

Instead, you can accelerate the parts of the model gradients function that do not require inputs that depend on handles.

Debugging

You must take care when debugging accelerated functions. Cached traces do not support break points. When using accelerated functions, the software reaches break points in the underlying function during the tracing process only.

To debug the code in the underlying function using breakpoints, disable the acceleration by setting the `Enabled` property to `false`.

To debug the cached traces, you can compare the outputs of the accelerated functions with the outputs of the underlying function, by setting the `CheckMode` property to `'tolerance'`.

dlode45 Does Not Support Acceleration When GradientMode is "direct"

The `dlaccelerate` function does not support accelerating the `dlode45` function when the `GradientMode` option is `"direct"`. The resulting accelerated function might return unexpected results. To accelerate the code that calls the `dlode45` function, set the `GradientMode` option to `"adjoint"` or accelerate parts of your code that do not call the `dlode45` with the `GradientMode` option set to `"direct"`.

Accelerate Custom Training Loop Functions

This example shows how to accelerate deep learning custom training loop and prediction functions.

When using the `dlfeval` function in a custom training loop, the software traces each input `dlarray` object of the model gradients function to determine the computation graph used for automatic differentiation. This tracing process can take some time and can spend time recomputing the same trace. By optimizing, caching, and reusing the traces, you can speed up gradient computation in deep learning functions. You can also optimize, cache, and reuse traces to accelerate other deep learning functions that do not require automatic differentiation, for example you can also accelerate model functions and functions used for prediction.

To speed up calls to deep learning functions, use the `dlaccelerate` function to create an `AcceleratedFunction` object that automatically optimizes, caches, and reuses the traces. You can use the `dlaccelerate` function to accelerate model functions and model gradients functions directly, or to accelerate subfunctions used by these functions.

The returned `AcceleratedFunction` object caches the traces of calls to the underlying function and reuses the cached result when the same input pattern reoccurs.

Try using `dlaccelerate` for function calls that:

- are long-running
- have `dlarray` object, structures of `dlarray` objects, or `dlnetwork` objects as inputs
- do not have side effects like writing to files or displaying output

Load Training and Test Data

The `digitTrain4DArrayData` function loads the images, their digit labels, and their angles of rotation from the vertical. Create `arrayDatastore` objects for the images, labels, and angles, and then use the `combine` function to make a single datastore that contains all of the training data. Extract the class names and number of nondiscrete responses.

```
[imagesTrain,labelsTrain,anglesTrain] = digitTrain4DArrayData;

dsImagesTrain = arrayDatastore(imagesTrain,'IterationDimension',4);
dsLabelsTrain = arrayDatastore(labelsTrain);
dsAnglesTrain = arrayDatastore(anglesTrain);

dsTrain = combine(dsImagesTrain,dsLabelsTrain,dsAnglesTrain);

classNames = categories(labelsTrain);
numClasses = numel(classNames);
numResponses = size(anglesTrain,2);
numObservations = numel(labelsTrain);
```

View some images from the training data.

```
idx = randperm(numObservations,64);
I = imtile(imagesTrain(:,:,:,idx));
figure
imshow(I)
```

Create a datastore containing the test data given by the `digitTest4DArrayData` function using the same steps.

```
[imagesTest,labelsTest,anglesTest] = digitTest4DArrayData;

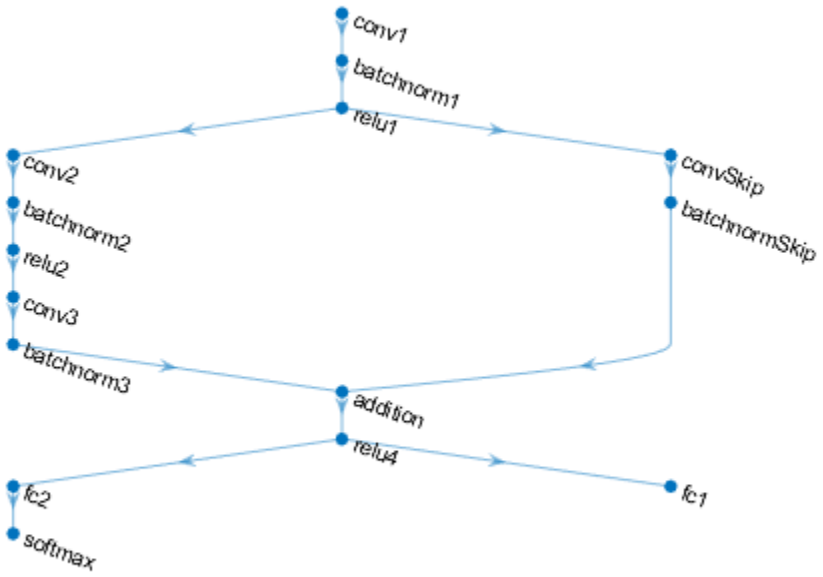
dsImagesTest = arrayDatastore(imagesTest,'IterationDimension',4);
dsLabelsTest = arrayDatastore(labelsTest);
dsAnglesTest = arrayDatastore(anglesTest);

dsTest = combine(dsImagesTest,dsLabelsTest,dsAnglesTest);
```

Define Deep Learning Model

Define the following network that predicts both labels and angles of rotation.

- A convolution-batchnorm-ReLU block with 16 5-by-5 filters.
- A branch of two convolution-batchnorm blocks each with 32 3-by-3 filters with a ReLU operation between
- A skip connection with a convolution-batchnorm block with 32 1-by-1 convolutions.
- Combine both branches using addition followed by a ReLU operation
- For the regression output, a branch with a fully connected operation of size 1 (the number of responses).
- For classification output, a branch with a fully connected operation of size 10 (the number of classes) and a softmax operation.



Define and Initialize Model Parameters and State

Create structures `parameters` and `state` that contain the initialized model parameters and state, respectively, using the `modelParameters` function, listed in the Model Parameters Function on page 18-0 section of the example.

The output uses the format `parameters.OperationName.ParameterName` where `parameters` is the structure, `OperationName` is the name of the operation (for example "conv1") and `ParameterName` is the name of the parameter (for example, "Weights").

```
[parameters,state] = modelParameters(numClasses,numResponses);
```

Define Model Function

Create the function `model`, listed at the end of the example, that computes the outputs of the deep learning model described earlier.

The function `model` takes the model parameters `parameters`, the input data `dlX`, the flag `doTraining` which specifies whether to model should return outputs for training or prediction, and the network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, that takes the model parameters, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the

labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

Specify Training Options

Specify the training options. Train for 20 epochs with a mini-batch size of 32. Displaying the plot can make training take longer to complete. Disable the plot by setting the `plots` variable to `"none"`. To enable the plot, set this variable to `"training-progress"`.

```
numEpochs = 20;
miniBatchSize = 32;
plots = "none";
```

Train Accelerated Model

Accelerate the model gradients function using the `dlaccelerate` function.

```
accfun = dlaccelerate(@modelGradients);
```

Clear any previoulsy cached traces of the accelerated function using the `clearCache` function.

```
clearCache(accfun)
```

Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to one-hot encode the class labels.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels or angles.
- Discard any partial mini-batches returned at the end of an epoch.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','',''}, ...
    'PartialMiniBatch','discard');
```

Initialize parameters for Adam.

```
trailingAvg = [];
trailingAvgSq = [];
```

If required, initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Train the model using the accelerated model gradients function. For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients and loss using `dlfeval` and the accelerated model gradients function.
- Update the network parameters using the `adamupdate` function.
- If required, update the training progress plot.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches
    while hasdata(mbq)

        iteration = iteration + 1;

        [dlX,dlT1,dlT2] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % accelerated function.
        [gradients,state,loss] = dlfeval(accfun, parameters, dlX, dlT1, dlT2, state);

        % Update the network parameters using the Adam optimizer.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
            trailingAvg,trailingAvgSq,iteration);

        % Display the training progress.
        if plots == "training-progress"
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            loss = double(gather(extractdata(loss)));
            addpoints(lineLossTrain,iteration,loss)
            title("Epoch: " + epoch + ", Elapsed: " + string(D))
            drawnow
        end
    end
end
```

Check the efficiency of the accelerated function by inspecting the `HitRate` property. The `HitRate` property contains the percentage of function calls that reuse a cached trace.

```
accfun.HitRate
```

```
ans = 99.9679
```

Accelerate Predictions

Measure the time required to make predictions using the test data set.

Because the model predictions function requires a mini-batch queue as input, the function does not support acceleration. To speed up prediction, accelerate the model function.

Accelerate the model function using the `dlaccelerate` function.

```
accfun2 = dlaccelerate(@model);
```

Clear any previoulsy cached traces of the accelerated function using the `clearCache` function.

```
clearCache(accfun2)
```

After training, making predictions on new data does not require the labels. Create `minibatchqueue` object containing only the predictors of the test data:

- To ignore the labels for testing, set the number of outputs of the mini-batch queue to 1.
- Specify the same mini-batch size used for training.
- Preprocess the predictors using the `preprocessMiniBatchPredictors` function, listed at the end of the example.
- For the single output of the datastore, specify the mini-batch format `'SSCB'` (spatial, spatial, channel, batch).

```
numOutputs = 1;
mbqTest = minibatchqueue(dsTest,numOutputs, ...
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFcn',@preprocessMiniBatchPredictors, ...
    'MiniBatchFormat','SSCB');
```

Loop over the mini-batches and classify the images using the `modelPredictions` function, listed at the end of the example.

```
[labelsPred,anglesPred] = modelPredictions(accfun2,parameters,state,mbqTest,classNames);
```

Check the efficiency of the accelerated function by inspecting the `HitRate` property. The `HitRate` property contains the percentage of function calls that reuse a cached trace.

```
accfun2.HitRate
```

```
ans = 98.7261
```

Model Parameters Function

The `modelParameters` function creates structures `parameters` and `state` that contain the initialized model parameters and state, respectively for the model described in the Define Deep Learning Model on page 18-0 section. The function takes as input the number of classes and the number of responses and initializes the learnable parameters. The function:

- initializes the layer weights using the `initializeGlorot` function
- initializes the layer biases using the `initializeZeros` function
- initializes the batch normalization offset and scale parameters with the `initializeZeros` function
- initializes the batch normalization scale parameters with the `initializeOnes` function
- initializes the batch normalization state trained mean with the `initializeZeros` function
- initializes the batch normalization state trained variance with the `initializeOnes` example function

The initialization example functions are attached to this example as supporting files. To access these files, open the example as a live script. To learn more about initializing learnable parameters for deep learning models, see “Initialize Learnable Parameters for Model Function” on page 18-292.

The output uses the format `parameters.OperationName.ParameterName` where `parameters` is the structure, `OperationName` is the name of the operation (for example "conv1") and `ParameterName` is the name of the parameter (for example, "Weights").

```
function [parameters,state] = modelParameters(numClasses,numResponses)

% First convolutional layer.
filterSize = [5 5];
numChannels = 1;
numFilters = 16;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv1.Bias = initializeZeros([numFilters 1]);

% First batch normalization layer.
parameters.batchnorm1.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm1.Scale = initializeOnes([numFilters 1]);
state.batchnorm1.TrainedMean = initializeZeros([numFilters 1]);
state.batchnorm1.TrainedVariance = initializeOnes([numFilters 1]);

% Second convolutional layer.
filterSize = [3 3];
numChannels = 16;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv2.Bias = initializeZeros([numFilters 1]);

% Second batch normalization layer.
parameters.batchnorm2.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm2.Scale = initializeOnes([numFilters 1]);
state.batchnorm2.TrainedMean = initializeZeros([numFilters 1]);
state.batchnorm2.TrainedVariance = initializeOnes([numFilters 1]);

% Third convolutional layer.
filterSize = [3 3];
numChannels = 32;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv3.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv3.Bias = initializeZeros([numFilters 1]);

% Third batch normalization layer.
parameters.batchnorm3.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm3.Scale = initializeOnes([numFilters 1]);
state.batchnorm3.TrainedMean = initializeZeros([numFilters 1]);
```

```
state.batchnorm3.TrainedVariance = initializeOnes([numFilters 1]);

% Convolutional layer in the skip connection.
filterSize = [1 1];
numChannels = 16;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.convSkip.Weights = initializeGlorot(sz,numOut,numIn);
parameters.convSkip.Bias = initializeZeros([numFilters 1]);

% Batch normalization layer in the skip connection.
parameters.batchnormSkip.Offset = initializeZeros([numFilters 1]);
parameters.batchnormSkip.Scale = initializeOnes([numFilters 1]);

state.batchnormSkip.TrainedMean = initializeZeros([numFilters 1]);
state.batchnormSkip.TrainedVariance = initializeOnes([numFilters 1]);

% Fully connected layer corresponding to the classification output.
sz = [numClasses 6272];
numOut = numClasses;
numIn = 6272;
parameters.fc1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc1.Bias = initializeZeros([numClasses 1]);

% Fully connected layer corresponding to the regression output.
sz = [numResponses 6272];
numOut = numResponses;
numIn = 6272;
parameters.fc2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc2.Bias = initializeZeros([numResponses 1]);

end
```

Model Function

The function `model` takes the model parameters `parameters`, the input data `dlX`, the flag `doTraining` which specifies whether to model should return outputs for training or prediction, and the network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

```
function [dlY1,dlY2,state] = model(parameters,dlX,doTraining,state)

% Convolution
weights = parameters.conv1.Weights;
bias = parameters.conv1.Bias;
dlY = dlconv(dlX,weights,bias,'Padding','same');

% Batch normalization, ReLU
offset = parameters.batchnorm1.Offset;
scale = parameters.batchnorm1.Scale;
trainedMean = state.batchnorm1.TrainedMean;
trainedVariance = state.batchnorm1.TrainedVariance;

if doTraining
```

```
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm1.TrainedMean = trainedMean;
    state.batchnorm1.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution, batch normalization (Skip connection)
weights = parameters.convSkip.Weights;
bias = parameters.convSkip.Bias;
dlYSkip = dlconv(dlY,weights,bias,'Stride',2);

offset = parameters.batchnormSkip.Offset;
scale = parameters.batchnormSkip.Scale;
trainedMean = state.batchnormSkip.TrainedMean;
trainedVariance = state.batchnormSkip.TrainedVariance;

if doTraining
    [dlYSkip,trainedMean,trainedVariance] = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVa

    % Update state
    state.batchnormSkip.TrainedMean = trainedMean;
    state.batchnormSkip.TrainedVariance = trainedVariance;
else
    dlYSkip = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVariance);
end

% Convolution
weights = parameters.conv2.Weights;
bias = parameters.conv2.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same','Stride',2);

% Batch normalization, ReLU
offset = parameters.batchnorm2.Offset;
scale = parameters.batchnorm2.Scale;
trainedMean = state.batchnorm2.TrainedMean;
trainedVariance = state.batchnorm2.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm2.TrainedMean = trainedMean;
    state.batchnorm2.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution
weights = parameters.conv3.Weights;
bias = parameters.conv3.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same');
```

```
% Batch normalization
offset = parameters.batchnorm3.Offset;
scale = parameters.batchnorm3.Scale;
trainedMean = state.batchnorm3.TrainedMean;
trainedVariance = state.batchnorm3.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm3.TrainedMean = trainedMean;
    state.batchnorm3.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

% Addition, ReLU
dlY = dlYSkip + dlY;
dlY = relu(dlY);

% Fully connect, softmax (labels)
weights = parameters.fc1.Weights;
bias = parameters.fc1.Bias;
dlY1 = fullyconnect(dlY,weights,bias);
dlY1 = softmax(dlY1);

% Fully connect (angles)
weights = parameters.fc2.Weights;
bias = parameters.fc2.Bias;
dlY2 = fullyconnect(dlY,weights,bias);

end
```

Model Gradients Function

The `modelGradients` function takes the model parameters, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

```
function [gradients,state,loss] = modelGradients(parameters,dlX,T1,T2,state)

doTraining = true;
[dlY1,dlY2,state] = model(parameters,dlX,doTraining,state);

lossLabels = crossentropy(dlY1,T1);
lossAngles = mse(dlY2,T2);

loss = lossLabels + 0.1*lossAngles;
gradients = dlgradient(loss,parameters);

end
```

Model Predictions Function

The `modelPredictions` function takes the model parameters, state, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in

the `minibatchqueue` object. The function uses the `onehotdecode` function to find the predicted class with the highest score.

```
function [predictions1, predictions2] = modelPredictions(modelFcn,parameters,state,mbq,classes)

doTraining = false;
predictions1 = [];
predictions2 = [];

while hasdata(mbq)

    dlXTest = next(mbq);

    [dlYPred1,dlYPred2] = modelFcn(parameters,dlXTest,doTraining,state);

    YPred1 = onehotdecode(dlYPred1,classes,1)';
    YPred2 = extractdata(dlYPred2)';

    predictions1 = [predictions1; YPred1];
    predictions2 = [predictions2; YPred2];
end

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label and angle data from the incoming cell arrays and concatenate along the second dimension into a categorical array and a numeric array, respectively.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y,angle] = preprocessMiniBatch(XCell,YCell,angleCell)

% Preprocess predictors.
X = preprocessMiniBatchPredictors(XCell);

% Extract label data from cell and concatenate
Y = cat(2,YCell{:});

% Extract angle data from cell and concatenate
angle = cat(2,angleCell{:});

% One-hot encode labels
Y = onehotencode(Y,1);

end
```

Mini-Batch Predictors Preprocessing Function

The `preprocessMiniBatchPredictors` function preprocesses a mini-batch of predictors by extracting the image data from the input cell array and then concatenating them into a numeric array.

For grayscale input, concatenating over the fourth dimension adds a third dimension to each image, to use as a singleton channel dimension.

```
function X = preprocessMiniBatchPredictors(XCell)

% Concatenate.
X = cat(4,XCell{1:end});

end
```

Evaluate Performance of Accelerated Deep Learning Function

This example shows how to evaluate the performance gains of using an accelerated function.

When using the `dlfeval` function in a custom training loop, the software traces each input `dlarray` object of the model gradients function to determine the computation graph used for automatic differentiation. This tracing process can take some time and can spend time recomputing the same trace. By optimizing, caching, and reusing the traces, you can speed up gradient computation in deep learning functions. You can also optimize, cache, and reuse traces to accelerate other deep learning functions that do not require automatic differentiation, for example you can also accelerate model functions and functions used for prediction.

To speed up calls to deep learning functions, use the `dlaccelerate` function to create an `AcceleratedFunction` object that automaticallyoptimizes, caches, and reuses the traces. You can use the `dlaccelerate` function to accelerate model functions and model gradients functions directly, or to accelerate subfunctions used by these functions. The performance gains are most noticeable for deeper networks and training loops with many epochs and iterations.

The returned `AcceleratedFunction` object caches the traces of calls to the underlying function and reuses the cached result when the same input pattern reoccurs.

Try using `dlaccelerate` for function calls that:

- are long-running
- have `dlarray` object, structures of `dlarray` objects, or `dlnetwork` objects as inputs
- do not have side effects like writing to files or displaying output

This example compares training and prediction times when using and not using acceleration.

Load Training and Test Data

The `digitTrain4DArrayData` function loads the images, their digit labels, and their angles of rotation from the vertical. Create `arrayDatastore` objects for the images, labels, and angles, and then use the `combine` function to make a single datastore that contains all of the training data. Extract the class names and number of nondiscrete responses.

```
[imagesTrain,labelsTrain,anglesTrain] = digitTrain4DArrayData;

dsImagesTrain = arrayDatastore(imagesTrain,'IterationDimension',4);
dsLabelsTrain = arrayDatastore(labelsTrain);
dsAnglesTrain = arrayDatastore(anglesTrain);

dsTrain = combine(dsImagesTrain,dsLabelsTrain,dsAnglesTrain);

classNames = categories(labelsTrain);
numClasses = numel(classNames);
numResponses = size(anglesTrain,2);
numObservations = numel(labelsTrain);
```

Create a datastore containing the test data given by the `digitTest4DArrayData` function using the same steps.

```
[imagesTest,labelsTest,anglesTest] = digitTest4DArrayData;

dsImagesTest = arrayDatastore(imagesTest,'IterationDimension',4);
```

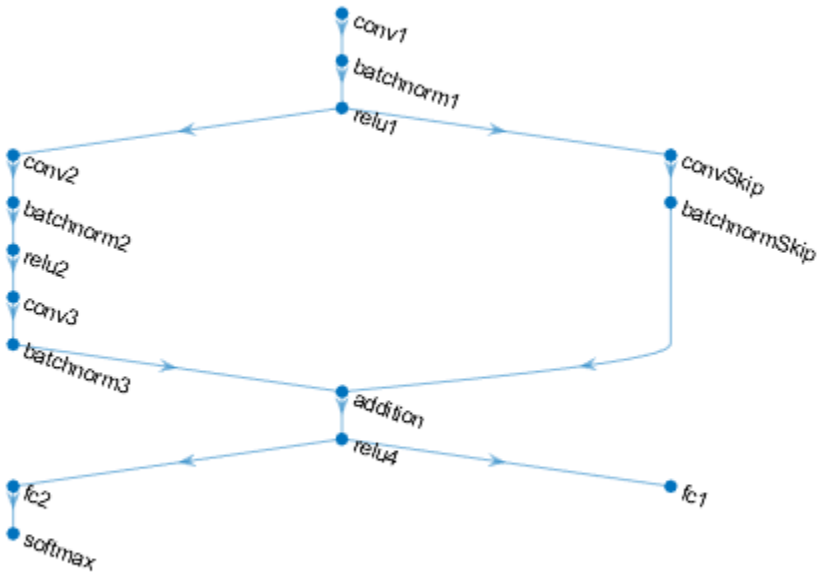
```
dsLabelsTest = arrayDatastore(labelsTest);
dsAnglesTest = arrayDatastore(anglesTest);

dsTest = combine(dsImagesTest,dsLabelsTest,dsAnglesTest);
```

Define Deep Learning Model

Define the following network that predicts both labels and angles of rotation.

- A convolution-batchnorm-ReLU block with 16 5-by-5 filters.
- A branch of two convolution-batchnorm blocks each with 32 3-by-3 filters with a ReLU operation between
- A skip connection with a convolution-batchnorm block with 32 1-by-1 convolutions.
- Combine both branches using addition followed by a ReLU operation
- For the regression output, a branch with a fully connected operation of size 1 (the number of responses).
- For classification output, a branch with a fully connected operation of size 10 (the number of classes) and a softmax operation.



Define and Initialize Model Parameters and State

Create a struct `parametersBaseline` containing the model parameters using the `modelParameters` function, listed at the end of the example. The `modelParameters` function creates structures `parameters` and `state` that contain the initialized model parameters and state, respectively.

The output uses the format `parameters.OperationName.ParameterName` where `parameters` is the structure, `OperationName` is the name of the operation (for example "conv1") and `ParameterName` is the name of the parameter (for example, "Weights").

```
[parametersBaseline,stateBaseline] = modelParameters(numClasses,numResponses);
```

Create a copy of the parameters and state for the baseline model to use for the accelerated model.

```
parametersAccelerated = parametersBaseline;
stateAccelerated = stateBaseline;
```

Define Model Function

Create the function `model`, listed at the end of the example, that computes the outputs of the deep learning model described earlier.

The function `model` takes the model parameters `parameters`, the input data `dlX`, the flag `doTraining` which specifies whether to model should return outputs for training or prediction, and the network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, that takes the model parameters, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

Specify Training Options

Specify the training options. Train for 20 epochs with a mini-batch size of 32. Displaying the plot can make training take longer to complete. Disable the plot by setting the `plots` variable to `"none"`. To enable the plot, set this variable to `"training-progress"`.

```
numEpochs = 20;
miniBatchSize = 32;
plots = "none";
```

Train Baseline Model

Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to one-hot encode the class labels.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels or angles.
- Discard any partial mini-batches returned at the end of an epoch.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
```

```
    'MiniBatchFcn',@preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','',''}, ...
    'PartialMiniBatch','discard');
```

Initialize parameters for Adam.

```
trailingAvg = [];
trailingAvgSq = [];
```

If required, initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Train the model. For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients and loss using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.
- Update the training progress plot.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches
    while hasdata(mbq)

        iteration = iteration + 1;

        [dlX,dlT1,dlT2] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % model gradients function.
        [gradients,stateBaseline,loss] = dlfeval(@modelGradients,parametersBaseline,dlX,dlT1,dlT

        % Update the network parameters using the Adam optimizer.
        [parametersBaseline,trailingAvg,trailingAvgSq] = adamupdate(parametersBaseline,gradients,
            trailingAvg,trailingAvgSq,iteration);

        % Display the training progress.
        if plots == "training-progress"
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            loss = double(gather(extractdata(loss)));
            addpoints(lineLossTrain,iteration,loss)
            title("Epoch: " + epoch + ", Elapsed: " + string(D))
```

```
            drawnow
        end
    end
end
elapsedBaseline = toc(start)
```

```
elapsedBaseline = 285.8978
```

Train Accelerated Model

Accelerate the model gradients function using the `dlaccelerate` function.

```
accfun = dlaccelerate(@modelGradients);
```

Clear any previously cached traces of the accelerated function using the `clearCache` function.

```
clearCache(accfun)
```

Initialize parameters for Adam.

```
trailingAvg = [];
trailingAvgSq = [];
```

If required, initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Train the model using the accelerated model gradients function in the call to the `dlfeval` function.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches
    while hasdata(mbq)

        iteration = iteration + 1;

        [dlX,dlT1,dlT2] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % accelerated function.
        [gradients,stateAccelerated,loss] = dlfeval(accfun, parametersAccelerated, dlX, dlT1, dl

        % Update the network parameters using the Adam optimizer.
        [parametersAccelerated,trailingAvg,trailingAvgSq] = adamupdate(parametersAccelerated,grad
            trailingAvg,trailingAvgSq,iteration);
```

```
        % Display the training progress.
        if plots == "training-progress"
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            loss = double(gather(extractdata(loss)));
            addpoints(lineLossTrain,iteration,loss)
            title("Epoch: " + epoch + ", Elapsed: " + string(D))
            drawnow
        end
    end
end
elapsedAccelerated = toc(start)
```

```
elapsedAccelerated = 188.5316
```

Check the efficiency of the accelerated function by inspecting the `HitRate` property. The `HitRate` property contains the percentage of function calls that reuse a cached trace.

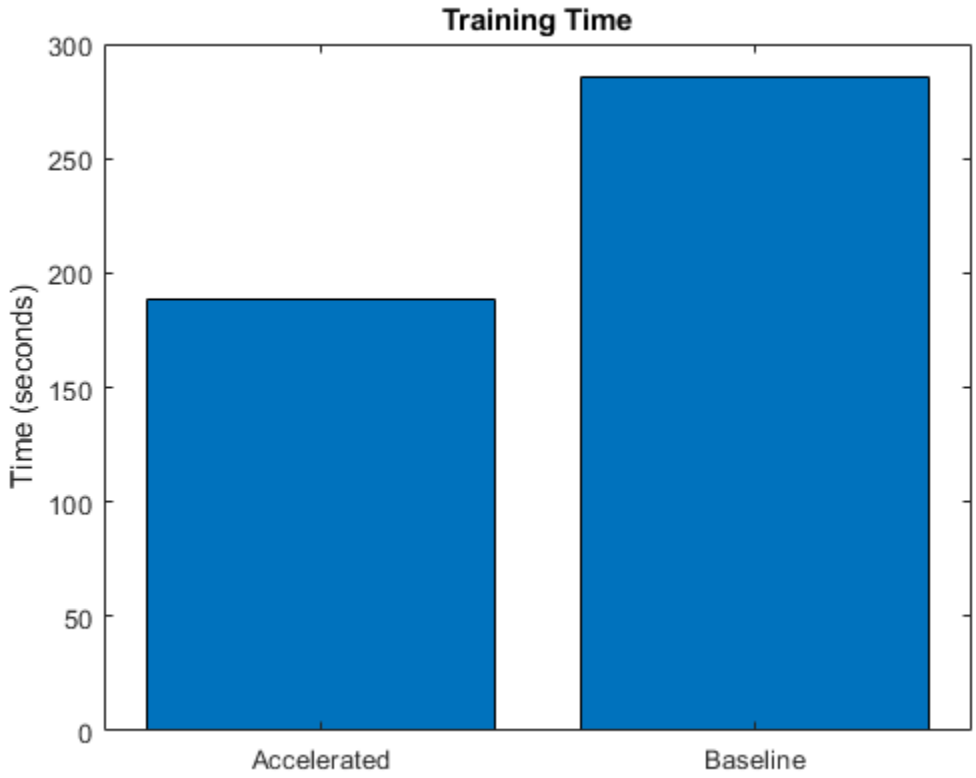
```
accfun.HitRate
```

```
ans = 99.9679
```

Compare Training Times

Compare the training times in a bar chart.

```
figure
bar(categorical(["Baseline" "Accelerated"]),[elapsedBaseline elapsedAccelerated]);
ylabel("Time (seconds)")
title("Training Time")
```



Calculate the speedup of acceleration.

```
speedup = elapsedBaseline / elapsedAccelerated
```

```
speedup = 1.5164
```

Time Baseline Predictions

Measure the time required to make predictions using the test data set.

After training, making predictions on new data does not require the labels. Create `minibatchqueue` object containing only the predictors of the test data:

- To ignore the labels for testing, set the number of outputs of the mini-batch queue to 1.
- Specify the same mini-batch size used for training.
- Preprocess the predictors using the `preprocessMiniBatchPredictors` function, listed at the end of the example.
- For the single output of the datastore, specify the mini-batch format `'SSCB'` (spatial, spatial, channel, batch).

```
numOutputs = 1;
mbqTest = minibatchqueue(dsTest,numOutputs, ...
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFcn',@preprocessMiniBatchPredictors, ...
    'MiniBatchFormat','SSCB');
```

Loop over the mini-batches and classify the images using the `modelPredictions` function, listed at the end of the example and measure the elapsed time.

```
tic
[labelsPred,anglesPred] = modelPredictions(@model,parametersBaseline,stateBaseline,mbqTest,classN
elapsedPredictionBaseline = toc
```

```
elapsedPredictionBaseline = 5.5070
```

Time Accelerated Predictions

Because the model predictions function requires a mini-batch queue as input, the function does not support acceleration. To speed up prediction, accelerate the model function.

Accelerate the model function using the `dlaccelerate` function.

```
accfun2 = dlaccelerate(@model);
```

Clear any previously cached traces of the accelerated function using the `clearCache` function.

```
clearCache(accfun2)
```

Reset the mini-batch queue.

```
reset(mbqTest)
```

Loop over the mini-batches and classify the images using the `modelPredictions` function, listed at the end of the example and measure the elapsed time.

```
tic
[labelsPred,anglesPred] = modelPredictions(accfun2,parametersBaseline,stateBaseline,mbqTest,class
elapsedPredictionAccelerated = toc
```

```
elapsedPredictionAccelerated = 4.3057
```

Check the efficiency of the accelerated function by inspecting the `HitRate` property. The `HitRate` property contains the percentage of function calls that reuse a cached trace.

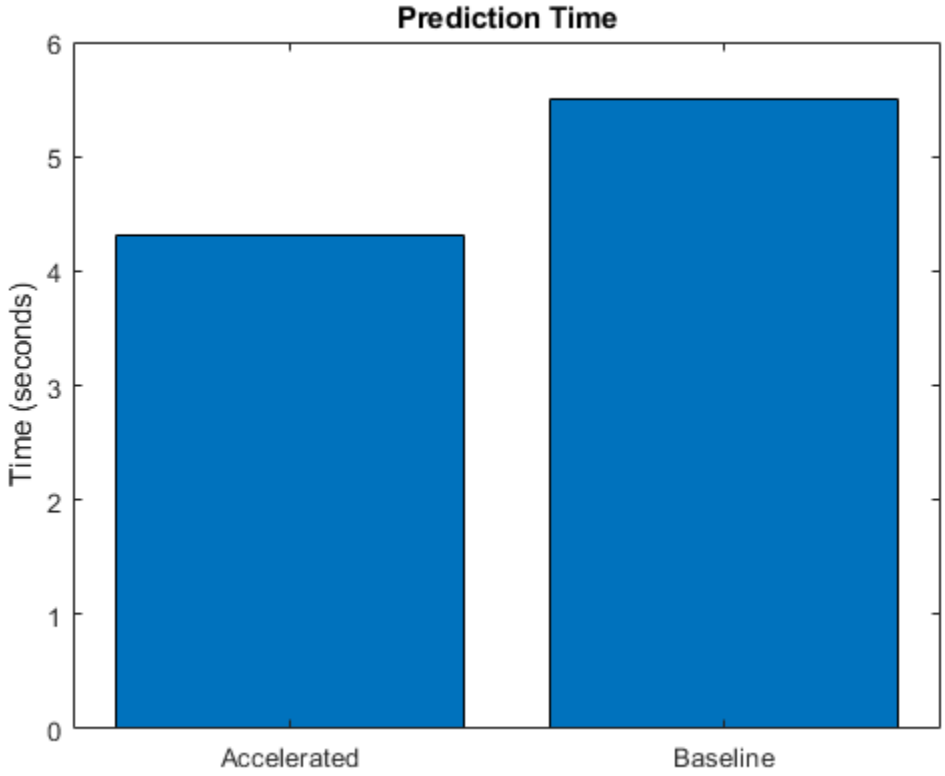
```
accfun2.HitRate
```

```
ans = 98.7261
```

Compare Prediction Times

Compare the prediction times in a bar chart.

```
figure
bar(categorical(["Baseline" "Accelerated"]),[elapsedPredictionBaseline elapsedPredictionAccelerat
ylabel("Time (seconds)")
title("Prediction Time")
```



Calculate the speedup of acceleration.

```
speedup = elapsedPredictionBaseline / elapsedPredictionAccelerated
```

```
speedup = 1.2790
```

Model Parameters Function

The `modelParameters` function creates structures `parameters` and `state` that contain the initialized model parameters and state, respectively for the model described in the Define Deep Learning Model on page 18-0 section. The function takes as input the number of classes and the number of responses and initializes the learnable parameters. The function:

- initializes the layer weights using the `initializeGlorot` function
- initializes the layer biases using the `initializeZeros` function
- initializes the batch normalization offset and scale parameters with the `initializeZeros` function
- initializes the batch normalization scale parameters with the `initializeOnes` function
- initializes the batch normalization state trained mean with the `initializeZeros` function
- initializes the batch normalization state trained variance with the `initializeOnes` example function

The initialization example functions are attached to this example as supporting files. To access these files, open the example as a live script. To learn more about initializing learnable parameters for deep learning models, see “Initialize Learnable Parameters for Model Function” on page 18-292.

The output uses the format `parameters.OperationName.ParameterName` where `parameters` is the structure, `OperationName` is the name of the operation (for example "conv1") and `ParameterName` is the name of the parameter (for example, "Weights").

```
function [parameters,state] = modelParameters(numClasses,numResponses)

% First convolutional layer.
filterSize = [5 5];
numChannels = 1;
numFilters = 16;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv1.Bias = initializeZeros([numFilters 1]);

% First batch normalization layer.
parameters.batchnorm1.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm1.Scale = initializeOnes([numFilters 1]);
state.batchnorm1.TrainedMean = initializeZeros([numFilters 1]);
state.batchnorm1.TrainedVariance = initializeOnes([numFilters 1]);

% Second convolutional layer.
filterSize = [3 3];
numChannels = 16;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv2.Bias = initializeZeros([numFilters 1]);

% Second batch normalization layer.
parameters.batchnorm2.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm2.Scale = initializeOnes([numFilters 1]);
state.batchnorm2.TrainedMean = initializeZeros([numFilters 1]);
state.batchnorm2.TrainedVariance = initializeOnes([numFilters 1]);

% Third convolutional layer.
filterSize = [3 3];
numChannels = 32;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv3.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv3.Bias = initializeZeros([numFilters 1]);

% Third batch normalization layer.
parameters.batchnorm3.Offset = initializeZeros([numFilters 1]);
parameters.batchnorm3.Scale = initializeOnes([numFilters 1]);
state.batchnorm3.TrainedMean = initializeZeros([numFilters 1]);
```

```
state.batchnorm3.TrainedVariance = initializeOnes([numFilters 1]);

% Convolutional layer in the skip connection.
filterSize = [1 1];
numChannels = 16;
numFilters = 32;

sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.convSkip.Weights = initializeGlorot(sz,numOut,numIn);
parameters.convSkip.Bias = initializeZeros([numFilters 1]);

% Batch normalization layer in the skip connection.
parameters.batchnormSkip.Offset = initializeZeros([numFilters 1]);
parameters.batchnormSkip.Scale = initializeOnes([numFilters 1]);

state.batchnormSkip.TrainedMean = initializeZeros([numFilters 1]);
state.batchnormSkip.TrainedVariance = initializeOnes([numFilters 1]);

% Fully connected layer corresponding to the classification output.
sz = [numClasses 6272];
numOut = numClasses;
numIn = 6272;
parameters.fc1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc1.Bias = initializeZeros([numClasses 1]);

% Fully connected layer corresponding to the regression output.
sz = [numResponses 6272];
numOut = numResponses;
numIn = 6272;
parameters.fc2.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc2.Bias = initializeZeros([numResponses 1]);

end
```

Model Function

The function `model` takes the model parameters `parameters`, the input data `dlX`, the flag `doTraining` which specifies whether to model should return outputs for training or prediction, and the network state `state`. The network outputs the predictions for the labels, the predictions for the angles, and the updated network state.

```
function [dlY1,dlY2,state] = model(parameters,dlX,doTraining,state)

% Convolution
weights = parameters.conv1.Weights;
bias = parameters.conv1.Bias;
dlY = dlconv(dlX,weights,bias,'Padding','same');

% Batch normalization, ReLU
offset = parameters.batchnorm1.Offset;
scale = parameters.batchnorm1.Scale;
trainedMean = state.batchnorm1.TrainedMean;
trainedVariance = state.batchnorm1.TrainedVariance;

if doTraining
```

```
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm1.TrainedMean = trainedMean;
    state.batchnorm1.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution, batch normalization (Skip connection)
weights = parameters.convSkip.Weights;
bias = parameters.convSkip.Bias;
dlYSkip = dlconv(dlY,weights,bias,'Stride',2);

offset = parameters.batchnormSkip.Offset;
scale = parameters.batchnormSkip.Scale;
trainedMean = state.batchnormSkip.TrainedMean;
trainedVariance = state.batchnormSkip.TrainedVariance;

if doTraining
    [dlYSkip,trainedMean,trainedVariance] = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVa

    % Update state
    state.batchnormSkip.TrainedMean = trainedMean;
    state.batchnormSkip.TrainedVariance = trainedVariance;
else
    dlYSkip = batchnorm(dlYSkip,offset,scale,trainedMean,trainedVariance);
end

% Convolution
weights = parameters.conv2.Weights;
bias = parameters.conv2.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same','Stride',2);

% Batch normalization, ReLU
offset = parameters.batchnorm2.Offset;
scale = parameters.batchnorm2.Scale;
trainedMean = state.batchnorm2.TrainedMean;
trainedVariance = state.batchnorm2.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm2.TrainedMean = trainedMean;
    state.batchnorm2.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

dlY = relu(dlY);

% Convolution
weights = parameters.conv3.Weights;
bias = parameters.conv3.Bias;
dlY = dlconv(dlY,weights,bias,'Padding','same');
```

```
% Batch normalization
offset = parameters.batchnorm3.Offset;
scale = parameters.batchnorm3.Scale;
trainedMean = state.batchnorm3.TrainedMean;
trainedVariance = state.batchnorm3.TrainedVariance;

if doTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state
    state.batchnorm3.TrainedMean = trainedMean;
    state.batchnorm3.TrainedVariance = trainedVariance;
else
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

% Addition, ReLU
dlY = dlYSkip + dlY;
dlY = relu(dlY);

% Fully connect, softmax (labels)
weights = parameters.fc1.Weights;
bias = parameters.fc1.Bias;
dlY1 = fullyconnect(dlY,weights,bias);
dlY1 = softmax(dlY1);

% Fully connect (angles)
weights = parameters.fc2.Weights;
bias = parameters.fc2.Bias;
dlY2 = fullyconnect(dlY,weights,bias);

end
```

Model Gradients Function

The `modelGradients` function, takes the model parameters, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

```
function [gradients,state,loss] = modelGradients(parameters,dlX,T1,T2,state)

doTraining = true;
[dlY1,dlY2,state] = model(parameters,dlX,doTraining,state);

lossLabels = crossentropy(dlY1,T1);
lossAngles = mse(dlY2,T2);

loss = lossLabels + 0.1*lossAngles;
gradients = dlgradient(loss,parameters);

end
```

Model Predictions Function

The `modelPredictions` function takes the model parameters, state, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in

the `minibatchqueue` object. The function uses the `onehotdecode` function to find the predicted class with the highest score.

```
function [predictions1, predictions2] = modelPredictions(modelFcn,parameters,state,mbq,classes)

doTraining = false;
predictions1 = [];
predictions2 = [];

while hasdata(mbq)

    dlXTest = next(mbq);

    [dlYPred1,dlYPred2] = modelFcn(parameters,dlXTest,doTraining,state);

    YPred1 = onehotdecode(dlYPred1,classes,1)';
    YPred2 = extractdata(dlYPred2)';

    predictions1 = [predictions1; YPred1];
    predictions2 = [predictions2; YPred2];
end

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label and angle data from the incoming cell arrays and concatenate along the second dimension into a categorical array and a numeric array, respectively.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y,angle] = preprocessMiniBatch(XCell,YCell,angleCell)

% Preprocess predictors.
X = preprocessMiniBatchPredictors(XCell);

% Extract label data from cell and concatenate
Y = cat(2,YCell{:});

% Extract angle data from cell and concatenate
angle = cat(2,angleCell{:});

% One-hot encode labels
Y = onehotencode(Y,1);

end
```

Mini-Batch Predictors Preprocessing Function

The `preprocessMiniBatchPredictors` function preprocesses a mini-batch of predictors by extracting the image data from the input cell array and concatenate into a numeric array. For

grayscale input, concatenating over the fourth dimension adds a third dimension to each image, to use as a singleton channel dimension.

```
function X = preprocessMiniBatchPredictors(XCell)

% Concatenate.
X = cat(4,XCell{1:end});

end
```

Check Accelerated Deep Learning Function Outputs

This example shows how to check that the outputs of accelerated functions match the outputs of the underlying function.

In some cases, the outputs of accelerated functions differ to the outputs of the underlying function. For example, you must take care when accelerating functions that use random number generation, such as a function that generates random noise to add to the network input. When caching the trace of a function that generates random numbers that are not `dlarray` objects, the accelerated function caches resulting random numbers in the trace. When reusing the trace, the accelerated function uses the cached random values. The accelerated function does not generate new random values.

To check that the outputs of the accelerated function match the outputs of the underlying function, use the `CheckMode` property of the accelerated function. When the `CheckMode` property of the accelerated function is `'tolerance'` and the outputs differ by more than a specified tolerance, the accelerated function throws a warning.

Accelerate the function `myUnsupportedFun`, listed at the end of the example using the `dlaccelerate` function. The function `myUnsupportedFun` generates random noise and adds it to the input. This function does not support acceleration because the function generates random numbers that are not `dlarray` objects.

```
accfun = dlaccelerate(@myUnsupportedFun)
```

```
accfun =
  AcceleratedFunction with properties:

         Function: @myUnsupportedFun
          Enabled: 1
        CacheSize: 50
          HitRate: 0
        Occupancy: 0
        CheckMode: 'none'
    CheckTolerance: 1.0000e-04
```

Cleare any previously cached traces using the `clearCache` function.

```
clearCache(accfun)
```

To check that the outputs of reused cached traces match the outputs of the underlying function, set the `CheckMode` property to `'tolerance'`.

```
accfun.CheckMode = 'tolerance'
```

```
accfun =
  AcceleratedFunction with properties:

         Function: @myUnsupportedFun
          Enabled: 1
        CacheSize: 50
          HitRate: 0
        Occupancy: 0
        CheckMode: 'tolerance'
    CheckTolerance: 1.0000e-04
```

Evaluate the accelerated function with an array of ones as input, specified as a `dlarray` input.

```
dlX = dlarray(ones(3,3));
dlY = accfun(dlX)
```

```
dlY =
  3x3 dlarray

    1.8147    1.9134    1.2785
    1.9058    1.6324    1.5469
    1.1270    1.0975    1.9575
```

Evaluate the accelerated function again with the same input. Because the accelerated function reuses the cached random noise values instead of generating new random values, the outputs of the reused trace differs from the outputs of the underlying function. When the `CheckMode` property of the accelerated function is `'tolerance'` and the outputs differ, the accelerated function throws a warning.

```
dlY = accfun(dlX)
```

```
Warning: Accelerated outputs differ from underlying function outputs.
```

```
dlY =
  3x3 dlarray

    1.8147    1.9134    1.2785
    1.9058    1.6324    1.5469
    1.1270    1.0975    1.9575
```

Random number generation using the `'like'` option of the `rand` function with a `dlarray` object supports acceleration. To use random number generation in an accelerated function, ensure that the function uses the `rand` function with the `'like'` option set to a traced `dlarray` object (a `dlarray` object that depends on an input `dlarray` object).

Accelerate the function `mySupportedFun`, listed at the end of the example. The function `mySupportedFun` adds noise to the input by generating noise using the `'like'` option with a traced `dlarray` object.

```
accfun2 = dlaccelerate(@mySupportedFun);
```

Cleare any previously cached traces using the `clearCache` function.

```
clearCache(accfun2)
```

To check that the outputs of reused cached traces match the outputs of the underlying function, set the `CheckMode` property to `'tolerance'`.

```
accfun2.CheckMode = 'tolerance';
```

Evaluate the accelerated function twice with the same input as before. Because the outputs of the reused cache match the outputs of the underlying function, the accelerated function does not throw a warning.

```
dlY = accfun2(dlX)
```

```
dlY =
  3x3 dlarray
```

```
    1.7922    1.0357    1.6787
    1.9595    1.8491    1.7577
    1.6557    1.9340    1.7431

dlY = accfun2(dlX)

dlY =
  3x3 dlarray

    1.3922    1.7060    1.0462
    1.6555    1.0318    1.0971
    1.1712    1.2769    1.8235
```

Checking the outputs match requires extra processing and increases the time required for function evaluation. After checking the outputs, set the `CheckMode` property to `'none'`.

```
accfun1.CheckMode = 'none';
accfun2.CheckMode = 'none';
```

Example Functions

The function `myUnsupportedFun` generates random noise and adds it to the input. This function does not support acceleration because the function generates random numbers that are not `dlarray` objects.

```
function out = myUnsupportedFun(dlX)

sz = size(dlX);
noise = rand(sz);
out = dlX + noise;

end
```

The function `mySupportedFun` adds noise to the input by generating noise using the `'like'` option with a traced `dlarray` object.

```
function out = mySupportedFun(dlX)

sz = size(dlX);
noise = rand(sz,'like',dlX);
out = dlX + noise;

end
```

Solve Partial Differential Equations Using Deep Learning

This example shows how to solve Burger's equation using deep learning.

The Burger's equation is a partial differential equation (PDE) that arises in different areas of applied mathematics. In particular, fluid mechanics, nonlinear acoustics, gas dynamics, and traffic flows.

Given the computational domain$[-1,1] \times [0,1]$, this examples uses a physics informed neural network (PINN) [1] and trains a multilayer perceptron neural network that takes samples (x,t) as input, where $x \in [-1,1]$ is the spatial variable, and $t \in [0,1]$ is the time variable, and returns $u(x,t)$, where u is the solution of the Burger's equation:

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} - \frac{0.01}{\pi}\frac{\partial^2 u}{\partial x^2} = 0,$$

with $u(x, t = 0) = -sin(\pi x)$as the initial condition, and $u(x = -1, t) = 0$ and $u(x = 1, t) = 0$ as the boundary conditions.

The example trains the model by enforcing that given an input (x,t), the output of the network $u(x,t)$ fulfills the Burger's equation, the boundary conditions, and the initial condition.

Training this model does not require collecting data in advance. You can generate data using the definition of the PDE and the constraints.

Generate Training Data

Training the model requires a data set of collocation points that enforce the boundary conditions, enforce the initial conditions, and fulfill the Burger's equation.

Select 25 equally spaced time points to enforce each of the boundary conditions $u(x = -1, t) = 0$ and $u(x = 1, t) = 0$.

```
numBoundaryConditionPoints = [25 25];

x0BC1 = -1*ones(1,numBoundaryConditionPoints(1));
x0BC2 = ones(1,numBoundaryConditionPoints(2));

t0BC1 = linspace(0,1,numBoundaryConditionPoints(1));
t0BC2 = linspace(0,1,numBoundaryConditionPoints(2));

u0BC1 = zeros(1,numBoundaryConditionPoints(1));
u0BC2 = zeros(1,numBoundaryConditionPoints(2));
```

Select 50 equally spaced spatial points to enforce the initial condition $u(x, t = 0) = -sin(\pi x)$.

```
numInitialConditionPoints  = 50;

x0IC = linspace(-1,1,numInitialConditionPoints);
t0IC = zeros(1,numInitialConditionPoints);
u0IC = -sin(pi*x0IC);
```

Group together the data for initial and boundary conditions.

```
X0 = [x0IC x0BC1 x0BC2];
T0 = [t0IC t0BC1 t0BC2];
U0 = [u0IC u0BC1 u0BC2];
```

Select 10,000 points to enforce the output of the network to fulfill the Burger's equation.

```
numInternalCollocationPoints = 10000;

pointSet = sobolset(2);
points = net(pointSet,numInternalCollocationPoints);

dataX = 2*points(:,1)-1;
dataT = points(:,2);
```

Create an array datastore containing the training data.

```
ds = arrayDatastore([dataX dataT]);
```

Define Deep Learning Model

Define a multilayer perceptron architecture with 9 fully connect operations with 20 hidden neurons. The first fully connect operation has two input channels corresponding to the inputs x and t. The last fully connect operation has one output $u(x,t)$.

Define and Initialize Model Parameters

Define the parameters for each of the operations and include them in a struct. Use the format `parameters.OperationName.ParameterName` where `parameters` is the struct, `OperationName` is the name of the operation (for example "fc1") and `ParameterName` is the name of the parameter (for example, "Weights").

Specify the number of layers and the number of neurons for each layer.

```
numLayers = 9;
numNeurons = 20;
```

Initialize the parameters for the first fully connect operation. The first fully connect operation has two input channels.

```
parameters = struct;

sz = [numNeurons 2];
parameters.fc1.Weights = initializeHe(sz,2);
parameters.fc1.Bias = initializeZeros([numNeurons 1]);
```

Initialize the parameters for each of the remaining intermediate fully connect operations.

```
for layerNumber=2:numLayers-1
    name = "fc"+layerNumber;

    sz = [numNeurons numNeurons];
    numIn = numNeurons;
    parameters.(name).Weights = initializeHe(sz,numIn);
    parameters.(name).Bias = initializeZeros([numNeurons 1]);
end
```

Initialize the parameters for the final fully connect operation. The final fully connect operation has one output channel.

```
sz = [1 numNeurons];
numIn = numNeurons;
```

```
parameters.("fc" + numLayers).Weights = initializeHe(sz,numIn);
parameters.("fc" + numLayers).Bias = initializeZeros([1 1]);
```

View the network parameters.

```
parameters
```

```
parameters = struct with fields:
    fc1: [1×1 struct]
    fc2: [1×1 struct]
    fc3: [1×1 struct]
    fc4: [1×1 struct]
    fc5: [1×1 struct]
    fc6: [1×1 struct]
    fc7: [1×1 struct]
    fc8: [1×1 struct]
    fc9: [1×1 struct]
```

View the parameters of the first fully connected layer.

```
parameters.fc1
```

```
ans = struct with fields:
    Weights: [20×2 dlarray]
       Bias: [20×1 dlarray]
```

Define Model and Model Gradients Functions

Create the function `model`, listed in the Model Function on page 18-0 section at the end of the example, that computes the outputs of the deep learning model. The function `model` takes as input the model parameters and the network inputs, and returns the model output.

Create the function `modelGradients`, listed in the Model Gradients Function on page 18-0 section at the end of the example, that takes as input the model parameters, the network inputs, and the initial and boundary conditions, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss.

Specify Training Options

Train the model for 3000 epochs with a mini-batch size of 1000.

```
numEpochs = 3000;
miniBatchSize = 1000;
```

To train on a GPU if one is available, specify the execution environment `"auto"`. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox) (Parallel Computing Toolbox).

```
executionEnvironment = "auto";
```

Specify ADAM optimization options.

```
initialLearnRate = 0.01;
decayRate = 0.005;
```

Train Network

Train the network using a custom training loop.

Create a `minibatchqueue` object that processes and manages mini-batches of data during training. For each mini-batch:

- Format the data with the dimension labels `'BC'` (batch, channel). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`.
- Train on a GPU according to the value of the `executionEnvironment` variable. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available.

```
mbq = minibatchqueue(ds, ...
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFormat','BC', ...
    'OutputEnvironment',executionEnvironment);
```

Convert the initial and boundary conditions to `dlarray`. For the input data points, specify format with dimensions `'CB'` (channel, batch).

```
dlX0 = dlarray(X0,'CB');
dlT0 = dlarray(T0,'CB');
dlU0 = dlarray(U0);
```

If training using a GPU, convert the initial and conditions to `gpuArray`.

```
if (executionEnvironment == "auto" && canUseGPU) || (executionEnvironment == "gpu")
    dlX0 = gpuArray(dlX0);
    dlT0 = gpuArray(dlT0);
    dlU0 = gpuArray(dlU0);
end
```

Initialize the parameters for the Adam solver.

```
averageGrad = [];
averageSqGrad = [];
```

Accelerate the model gradients function using the `dlaccelerate` function. To learn more, see “Accelerate Custom Training Loop Functions” on page 18-311.

```
accfun = dlaccelerate(@modelGradients);
```

Initialize the training progress plot.

```
figure
C = colororder;
lineLoss = animatedline('Color',C(2,:));
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Train the network.

For each iteration:

- Read a mini-batch of data from the mini-batch queue

- Evaluate the model gradients and loss using the accelerated model gradients and `dlfeval` functions.
- Update the learning rate.
- Update the learnable parameters using the `adamupdate` function.

At the end of each epoch, update the training plot with the loss values.

```
start = tic;

iteration = 0;

for epoch = 1:numEpochs
    reset(mbq);

    while hasdata(mbq)
        iteration = iteration + 1;

        dlXT = next(mbq);
        dlX = dlXT(1,:);
        dlT = dlXT(2,:);

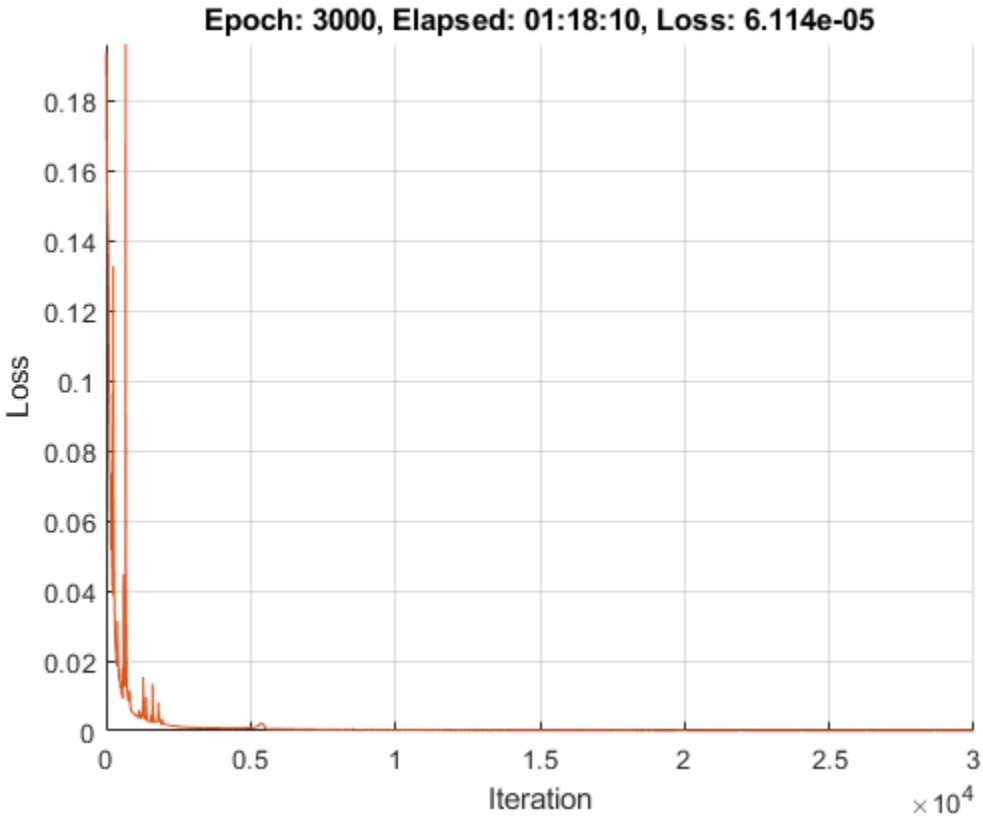
        % Evaluate the model gradients and loss using dlfeval and the
        % modelGradients function.
        [gradients,loss] = dlfeval(accfun,parameters,dlX,dlT,dlX0,dlT0,dlU0);

        % Update learning rate.
        learningRate = initialLearnRate / (1+decayRate*iteration);

        % Update the network parameters using the adamupdate function.
        [parameters,averageGrad,averageSqGrad] = adamupdate(parameters,gradients,averageGrad, ..
            averageSqGrad,iteration,learningRate);
    end

    % Plot training progress.
    loss = double(gather(extractdata(loss)));
    addpoints(lineLoss,iteration, loss);

    D = duration(0,0,toc(start),'Format','hh:mm:ss');
    title("Epoch: " + epoch + ", Elapsed: " + string(D) + ", Loss: " + loss)
    drawnow
end
```



Check the effectiveness of the accelerated function by checking the hit and occupancy rate.

```
accfun
```

```
accfun =
  AcceleratedFunction with properties:

          Function: @modelGradients
           Enabled: 1
         CacheSize: 50
           HitRate: 99.9984
         Occupancy: 2
         CheckMode: 'none'
    CheckTolerance: 1.0000e-04
```

Evaluate Model Accuracy

For values of t at 0.25, 0.5, 0.75, and 1, compare the predicted values of the deep learning model with the true solutions of the Burger's equation using the l^2 error.

Set the target times to test the model at. For each time, calculate the solution at 1001 equally spaced points in the range [-1,1].

```
tTest = [0.25 0.5 0.75 1];
numPredictions = 1001;
XTest = linspace(-1,1,numPredictions);
```

```
figure

for i=1:numel(tTest)
    t = tTest(i);
    TTest = t*ones(1,numPredictions);

    % Make predictions.
    dlXTest = dlarray(XTest,'CB');
    dlTTest = dlarray(TTest,'CB');
    dlUPred = model(parameters,dlXTest,dlTTest);

    % Calcualte true values.
    UTest = solveBurgers(XTest,t,0.01/pi);

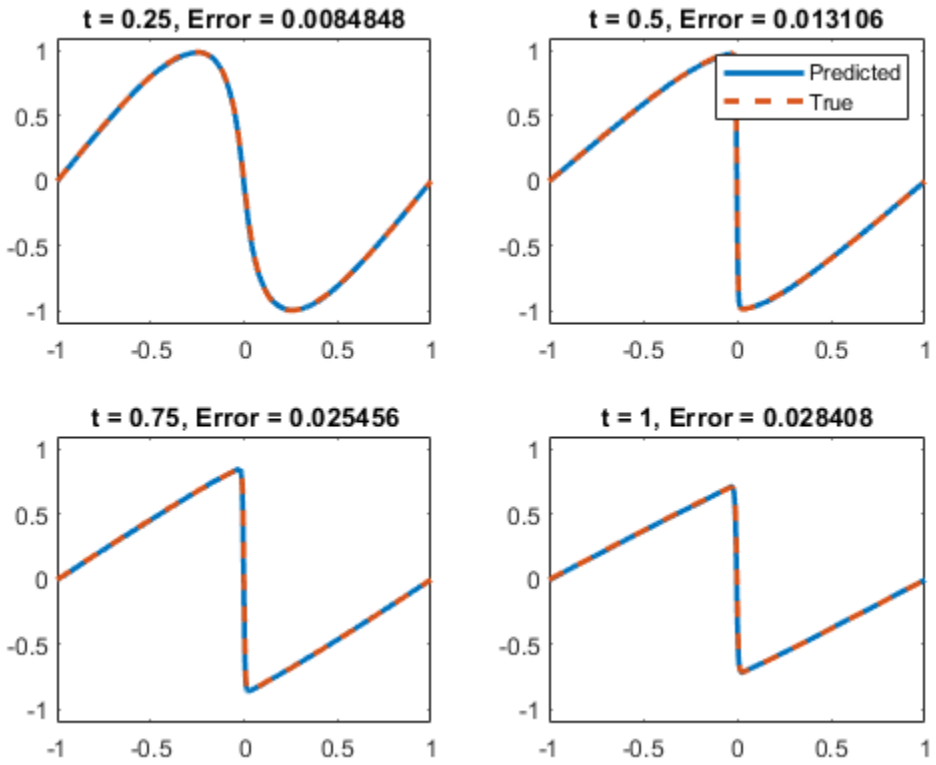
    % Calculate error.
    err = norm(extractdata(dlUPred) - UTest) / norm(UTest);

    % Plot predictions.
    subplot(2,2,i)
    plot(XTest,extractdata(dlUPred),'-','LineWidth',2);
    ylim([-1.1, 1.1])

    % Plot true values.
    hold on
    plot(XTest, UTest, '--','LineWidth',2)
    hold off

    title("t = " + t + ", Error = " + gather(err));
end

subplot(2,2,2)
legend('Predicted','True')
```



The plots show how close the predictions are to the true values.

Solve Burger's Equation Function

The `solveBurgers` function returns the true solution of Burger's equation at times `t` as outlined in [2].

```
function U = solveBurgers(X,t,nu)

% Define functions.
f = @(y) exp(-cos(pi*y)/(2*pi*nu));
g = @(y) exp(-(y.^2)/(4*nu*t));

% Initialize solutions.
U = zeros(size(X));

% Loop over x values.
for i = 1:numel(X)
    x = X(i);

    % Calculate the solutions using the integral function. The boundary
    % conditions in x = -1 and x = 1 are known, so leave 0 as they are
    % given by initialization of U.
    if abs(x) ~= 1
        fun = @(eta) sin(pi*(x-eta)) .* f(x-eta) .* g(eta);
        uxt = -integral(fun,-inf,inf);
        fun = @(eta) f(x-eta) .* g(eta);
```

```
        U(i) = uxt / integral(fun,-inf,inf);
    end
end

end
```

Model Gradients Function

The model is trained by enforcing that given an input (x,t) the output of the network $u(x,t)$ fulfills the Burger's equation, the boundary conditions, and the intial condition. In particular, two quantities contribute to the loss to be minimized:

loss = $\text{MSE}_f + \text{MSE}_u$,

where $\text{MSE}_f = \frac{1}{N_f}\sum_{i=1}^{N_f}\left|f(x_f^i, t_f^i)\right|^2$ and $\text{MSE}_u = \frac{1}{N_u}\sum_{i=1}^{N_u}\left|u(x_u^i, t_u^i) - u^i\right|^2$.

Here, $\{x_u^i, t_u^i\}_{i=1}^{N_u}$ correspond to collocation points on the boundary of the computational domain and account for both boundary and initial condition. $\{x_f^i, t_f^i\}_{i=1}^{N_f}$ are points in the interior of the domain.

Calculating MSE_f requires the derivatives $\frac{\partial u}{\partial t}, \frac{\partial u}{\partial x}, \frac{\partial^2 u}{\partial x^2}$ of the output u of the model.

The function `modelGradients` takes as input, the model parameters `parameters`, the network inputs `dlX` and `dlT`, the initial and boundary conditions `dlX0`, `dlT0`, and `dlU0`, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss.

```
function [gradients,loss] = modelGradients(parameters,dlX,dlT,dlX0,dlT0,dlU0)

% Make predictions with the initial conditions.
U = model(parameters,dlX,dlT);

% Calculate derivatives with respect to X and T.
gradientsU = dlgradient(sum(U,'all'),{dlX,dlT},'EnableHigherDerivatives',true);
Ux = gradientsU{1};
Ut = gradientsU{2};

% Calculate second-order derivatives with respect to X.
Uxx = dlgradient(sum(Ux,'all'),dlX,'EnableHigherDerivatives',true);

% Calculate lossF. Enforce Burger's equation.
f = Ut + U.*Ux - (0.01./pi).*Uxx;
zeroTarget = zeros(size(f), 'like', f);
lossF = mse(f, zeroTarget);

% Calculate lossU. Enforce initial and boundary conditions.
dlU0Pred = model(parameters,dlX0,dlT0);
lossU = mse(dlU0Pred, dlU0);

% Combine losses.
loss = lossF + lossU;

% Calculate gradients with respect to the learnable parameters.
gradients = dlgradient(loss,parameters);
```

```
end
```

Model Function

The model trained in this example consists of a series of fully connect operations with a tanh operation between each one.

The model function takes as input the model parameters `parameters` and the network inputs `dlX` and `dlT`, and returns the model output `dlU`.

```
function dlU = model(parameters,dlX,dlT)

dlXT = [dlX;dlT];
numLayers = numel(fieldnames(parameters));

% First fully connect operation.
weights = parameters.fc1.Weights;
bias = parameters.fc1.Bias;
dlU = fullyconnect(dlXT,weights,bias);

% tanh and fully connect operations for remaining layers.
for i=2:numLayers
    name = "fc" + i;

    dlU = tanh(dlU);

    weights = parameters.(name).Weights;
    bias = parameters.(name).Bias;
    dlU = fullyconnect(dlU, weights, bias);
end

end
```

Solve Partial Differential Equation with LBFGS Method and Deep Learning

This example shows how to train a Physics Informed Neural Network (PINN) to numerically compute the solution of the Burger's equation by using the limited-memory BFGS (LBFGS) algorithm.

The Burger's equation is a partial differential equation (PDE) that arises in different areas of applied mathematics. In particular, fluid mechanics, nonlinear acoustics, gas dynamics, and traffic flows.

Given the computational domain$[-1,1] \times [0,1]$, this examples uses a physics informed neural network (PINN) [1] and trains a multilayer perceptron neural network that takes samples (x,t) as input, where $x \in [-1,1]$ is the spatial variable, and $t \in [0,1]$ is the time variable, and returns $u(x,t)$, where u is the solution of the Burger's equation:

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} - \frac{0.01}{\pi}\frac{\partial^2 u}{\partial x^2} = 0,$$

with $u(x, t=0) = -sin(\pi x)$as the initial condition, and $u(x=-1,t) = 0$ and $u(x=1,t) = 0$ as the boundary conditions.

Instead of training the network using the `trainNetwork` function, or using a custom training loop that updates parametes using `sgdmupdate` or similar functions, this example estimates the learnable parameters by using the `fmincon` function (requires Optimization Toolbox™). The `fmincon` function finds the minimum of constrained nonlinear multivariable functions.

The example trains the model by enforcing that given an input (x,t), the output of the network $u(x,t)$ fulfills the Burger's equation, the boundary conditions, and the initial condition. To train the model, the exmaple uses the limited-memory BFGS (LBFGS) algorithm which is a quasi-Newton method that approximates the Broyden-Fletcher-Goldfarb-Shanno algorithm.

Training this model does not require collecting data in advance. You can generate data using the definition of the PDE and the constraints.

Generate Training Data

Training the model requires a data set of collocation points that enforce the boundary conditions, enforce the initial conditions, and fulfill the Burger's equation.

Select 25 equally spaced time points to enforce each of the boundary conditions $u(x=-1,t) = 0$ and $u(x=1,t) = 0$.

```
numBoundaryConditionPoints = [25 25];

x0BC1 = -1*ones(1,numBoundaryConditionPoints(1));
x0BC2 = ones(1,numBoundaryConditionPoints(2));

t0BC1 = linspace(0,1,numBoundaryConditionPoints(1));
t0BC2 = linspace(0,1,numBoundaryConditionPoints(2));

u0BC1 = zeros(1,numBoundaryConditionPoints(1));
u0BC2 = zeros(1,numBoundaryConditionPoints(2));
```

Select 50 equally spaced spatial points to enforce the initial condition $u(x, t=0) = -sin(\pi x)$.

```
numInitialConditionPoints  = 50;

x0IC = linspace(-1,1,numInitialConditionPoints);
t0IC = zeros(1,numInitialConditionPoints);
u0IC = -sin(pi*x0IC);
```

Group together the data for initial and boundary conditions.

```
X0 = [x0IC x0BC1 x0BC2];
T0 = [t0IC t0BC1 t0BC2];
U0 = [u0IC u0BC1 u0BC2];
```

Select 10,000 points to enforce the output of the network to fulfill the Burger's equation.

```
numInternalCollocationPoints = 10000;

pointSet = sobolset(2);
points = net(pointSet,numInternalCollocationPoints);

dataX = 2*points(:,1)-1;
dataT = points(:,2);
```

Create an array datastore containing the training data.

```
ds = arrayDatastore([dataX dataT]);
```

Define Deep Learning Model

Define a multilayer perceptron architecture with 9 fully connect operations with 20 hidden neurons. The first fully connect operation has two input channels corresponding to the inputs x and t. The last fully connect operation has one output $u(x,t)$.

Define and Initialize Model Parameters

Define the parameters for each of the operations and include them in a structure. Use the format `parameters.OperationName_ParameterName` where `parameters` is the structure, `OperationName` is the name of the operation (for example "fc1") and `ParameterName` is the name of the parameter (for example, "Weights").

The algorithm in this example requires learnable parameters to be in the first level of the stucture, so do not use nested structures in this step. The `fmincon` function requires the learnable to be doubles.

Specify the number of layers and the number of neurons for each layer.

```
numLayers = 9;
numNeurons = 20;
```

Initialize the parameters for the first fully connect operation. The first fully connect operation has two input channels.

```
parameters = struct;

sz = [numNeurons 2];
parameters.fc1_Weights = initializeHe(sz,2,'double');
parameters.fc1_Bias = initializeZeros([numNeurons 1],'double');
```

Initialize the parameters for each of the remaining intermediate fully connect operations.

```
for layerNumber=2:numLayers-1
    name = "fc"+layerNumber;

    sz = [numNeurons numNeurons];
    numIn = numNeurons;
    parameters.(name + "_Weights") = initializeHe(sz,numIn,'double');
    parameters.(name + "_Bias") = initializeZeros([numNeurons 1],'double');
end
```

Initialize the parameters for the final fully connect operation. The final fully connect operation has one output channel.

```
sz = [1 numNeurons];
numIn = numNeurons;
parameters.("fc" + numLayers + "_Weights") = initializeHe(sz,numIn,'double');
parameters.("fc" + numLayers + "_Bias") = initializeZeros([1 1],'double');
```

View the network parameters.

```
parameters
```

```
parameters = struct with fields:
    fc1_Weights: [20×2 dlarray]
       fc1_Bias: [20×1 dlarray]
    fc2_Weights: [20×20 dlarray]
       fc2_Bias: [20×1 dlarray]
    fc3_Weights: [20×20 dlarray]
       fc3_Bias: [20×1 dlarray]
    fc4_Weights: [20×20 dlarray]
       fc4_Bias: [20×1 dlarray]
    fc5_Weights: [20×20 dlarray]
       fc5_Bias: [20×1 dlarray]
    fc6_Weights: [20×20 dlarray]
       fc6_Bias: [20×1 dlarray]
    fc7_Weights: [20×20 dlarray]
       fc7_Bias: [20×1 dlarray]
    fc8_Weights: [20×20 dlarray]
       fc8_Bias: [20×1 dlarray]
    fc9_Weights: [1×20 dlarray]
       fc9_Bias: [1×1 dlarray]
```

Define Model and Model Gradients Functions

Create the function `model`, listed in the Model Function on page 18-0 section at the end of the example, that computes the outputs of the deep learning model. The function `model` takes as input the model parameters and the network inputs, and returns the model output.

Create the function `modelGradients`, listed in the Model Gradients Function on page 18-0 section at the end of the example, that takes as input the model parameters, the network inputs, and the initial and boundary conditions, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss.

Define `fmincon` Objective Function

Create the function `objectiveFunction`, listed in the `fmincon` Objective Function section of the example that returns the loss and gradients of the model. The function `objectiveFunction` takes as input, a vector of learnable parameters, the network inputs, the initial conditions, and the names

and sizes of the learnable parameters, and returns the loss to be minimized by the `fmincon` function and the gradients of the loss with respect to the learnable parameters.

Specify Optimization Options

Specify the optimization options:

- Optimize using the `fmincon` optmizer with the LBFGS algorithm for no more than 7500 iterations and function evaluations.
- Evaluate with optimality tolerance `1e-5`.
- Provide the gradients to the algorithm.

```
options = optimoptions('fmincon', ...
    'HessianApproximation','lbfgs', ...
    'MaxIterations',7500, ...
    'MaxFunctionEvaluations',7500, ...
    'OptimalityTolerance',1e-5, ...
    'SpecifyObjectiveGradient',true);
```

Train Network Using `fmincon`

Train the network using the `fmincon` function.

The `fmincon` function requires the learnable parameters to be specified as a vector. Convert the parameters to a vector using the `paramsStructToVector` function (attached to this example as a supporting file). To convert back to a structure of parameters, also return the parameter names and sizes.

```
[parametersV,parameterNames,parameterSizes] = parameterStructToVector(parameters);
parametersV = extractdata(parametersV);
```

Convert the training data to `dlarray` objects with format `'CB'` (channel, batch).

```
dlX = dlarray(dataX','CB');
dlT = dlarray(dataT','CB');
dlX0 = dlarray(X0,'CB');
dlT0 = dlarray(T0,'CB');
dlU0 = dlarray(U0,'CB');
```

Create a function handle with one input that defines the objective function.

```
objFun = @(parameters) objectiveFunction(parameters,dlX,dlT,dlX0,dlT0,dlU0,parameterNames,parame
```

Update the learnable parameters using the `fmincon` function. Depending on the number of iterations, this can take a while to run. To enable a detailed verbose output, set the `'Display'` optimization option to `'iter-detailed'`.

```
parametersV = fmincon(objFun,parametersV,[],[],[],[],[],[],[],options);
```

```
Solver stopped prematurely.

fmincon stopped because it exceeded the function evaluation limit,
options.MaxFunctionEvaluations = 7.500000e+03.
```

For prediction, convert the vector of parameters to a structure using the `parameterVectorToStruct` function (attached to this example as a supporting file).

```
parameters = parameterVectorToStruct(parametersV,parameterNames,parameterSizes);
```

Evaluate Model Accuracy

For values of t at 0.25, 0.5, 0.75, and 1, compare the predicted values of the deep learning model with the true solutions of the Burger's equation using the relative l^2 error.

Set the target times to test the model at. For each time, calculate the solution at 1001 equally spaced points in the range [-1,1].

```
tTest = [0.25 0.5 0.75 1];
numPredictions = 1001;
XTest = linspace(-1,1,numPredictions);
```

Test the model.

```
figure
for i=1:numel(tTest)
    t = tTest(i);
    TTest = t*ones(1,numPredictions);

    % Make predictions.
    dlXTest = dlarray(XTest,'CB');
    dlTTest = dlarray(TTest,'CB');
    dlUPred = model(parameters,dlXTest,dlTTest);

    % Calcualte true values.
    UTest = solveBurgers(XTest,t,0.01/pi);

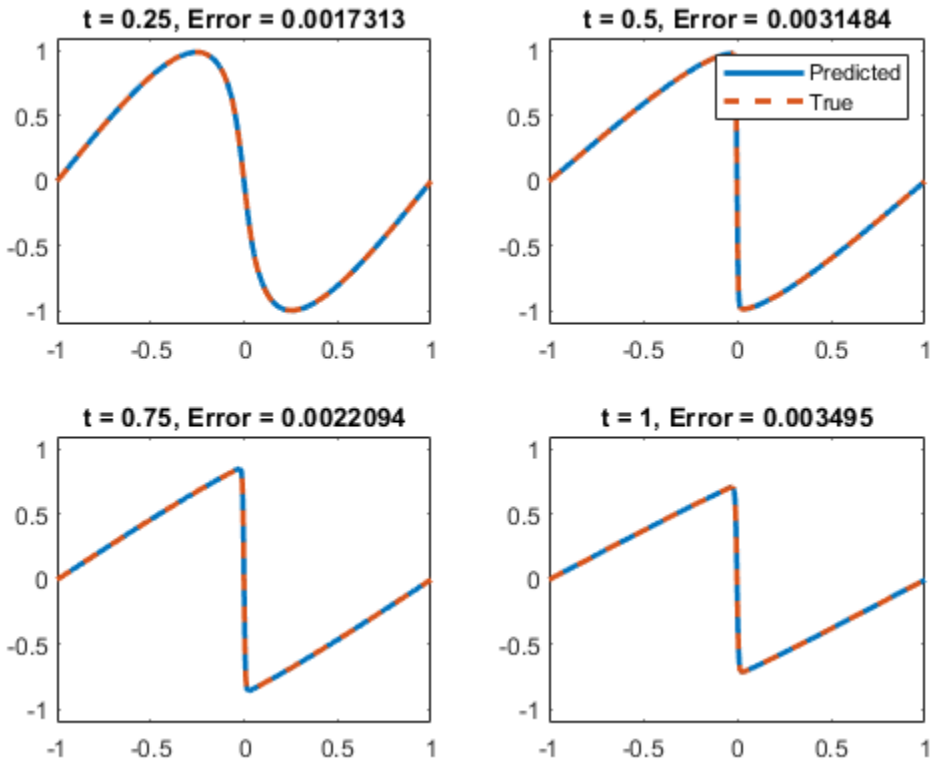
    % Calculate error.
    err = norm(extractdata(dlUPred) - UTest) / norm(UTest);

    % Plot predictions.
    subplot(2,2,i)
    plot(XTest,extractdata(dlUPred),'-','LineWidth',2);
    ylim([-1.1, 1.1])

    % Plot true values.
    hold on
    plot(XTest, UTest, '--','LineWidth',2)
    hold off

    title("t = " + t + ", Error = " + gather(err));
end

subplot(2,2,2)
legend('Predicted','True')
```



The plots show how close the predictions are to the true values.

Solve Burger's Equation Function

The `solveBurgers` function returns the true solution of Burger's equation at times `t` as outlined in [2].

```
function U = solveBurgers(X,t,nu)

% Define functions.
f = @(y) exp(-cos(pi*y)/(2*pi*nu));
g = @(y) exp(-(y.^2)/(4*nu*t));

% Initialize solutions.
U = zeros(size(X));

% Loop over x values.
for i = 1:numel(X)
    x = X(i);

    % Calculate the solutions using the integral function. The boundary
    % conditions in x = -1 and x = 1 are known, so leave 0 as they are
    % given by initialization of U.
    if abs(x) ~= 1
        fun = @(eta) sin(pi*(x-eta)) .* f(x-eta) .* g(eta);
        uxt = -integral(fun,-inf,inf);
        fun = @(eta) f(x-eta) .* g(eta);
```

```
        U(i) = uxt / integral(fun,-inf,inf);
    end
end

end
```

`fmincon` Objective Function

The `objectiveFunction` function defines the objective function to be used by the LBFGS algorithm.

This `objectiveFunction` funtion takes as input, a vector of learnable parameters `parametersV`, the network inputs, `dlX` and `dlT`, the initial and boundary conditions `dlX0, dlT0`, and `dlU0`, and the names and sizes of the learnable parameters `parameterNames` and `parameterSizes`, respectively, and returns the loss to be minimized by the `fmincon` function `loss` and a vector containing the gradients of the loss with respect to the learnable parameters `gradientsV`.

```
function [loss,gradientsV] = objectiveFunction(parametersV,dlX,dlT,dlX0,dlT0,dlU0,parameterNames,

% Convert parameters to structure of dlarray objects.
parametersV = dlarray(parametersV);
parameters = parameterVectorToStruct(parametersV,parameterNames,parameterSizes);

% Evaluate model gradients and loss.
[gradients,loss] = dlfeval(@modelGradients,parameters,dlX,dlT,dlX0,dlT0,dlU0);

% Return loss and gradients for fmincon.
gradientsV = parameterStructToVector(gradients);
gradientsV = extractdata(gradientsV);
loss = extractdata(loss);

end
```

Model Gradients Function

The model is trained by enforcing that given an input (x, t) the output of the network $u(x, t)$ fulfills the Burger's equation, the boundary conditions, and the intial condition. In particular, two quantities contribute to the loss to be minimized:

loss = $\text{MSE}_f + \text{MSE}_u$,

where $\text{MSE}_f = \frac{1}{N_f}\sum_{i=1}^{N_f}\left|f(x_f^i, t_f^i)\right|^2$ and $\text{MSE}_u = \frac{1}{N_u}\sum_{i=1}^{N_u}\left|u(x_u^i, t_u^i) - u^i\right|^2$.

Here, $\{x_u^i, t_u^i\}_{i=1}^{N_u}$ correspond to collocation points on the boundary of the computational domain and account for both boundary and initial condition. $\{x_f^i, t_f^i\}_{i=1}^{N_f}$ are points in the interior of the domain.

Calculating MSE_f requires the derivatives $\frac{\partial u}{\partial t}, \frac{\partial u}{\partial x}, \frac{\partial^2 u}{\partial x^2}$ of the output u of the model.

The function `modelGradients` takes as input, the model parameters `parameters`, the network inputs `dlX` and `dlT`, the initial and boundary conditions `dlX0`, `dlT0`, and `dlU0`, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss.

```
function [gradients,loss] = modelGradients(parameters,dlX,dlT,dlX0,dlT0,dlU0)
```

```
% Make predictions with the initial conditions.
U = model(parameters,dlX,dlT);

% Calculate derivatives with respect to X and T.
gradientsU = dlgradient(sum(U,'all'),{dlX,dlT},'EnableHigherDerivatives',true);
Ux = gradientsU{1};
Ut = gradientsU{2};

% Calculate second-order derivatives with respect to X.
Uxx = dlgradient(sum(Ux,'all'),dlX,'EnableHigherDerivatives',true);

% Calculate lossF. Enforce Burger's equation.
f = Ut + U.*Ux - (0.01./pi).*Uxx;
zeroTarget = zeros(size(f), 'like', f);
lossF = mse(f, zeroTarget);

% Calculate lossU. Enforce initial and boundary conditions.
dlU0Pred = model(parameters,dlX0,dlT0);
lossU = mse(dlU0Pred, dlU0);

% Combine losses.
loss = lossF + lossU;

% Calculate gradients with respect to the learnable parameters.
gradients = dlgradient(loss,parameters);

end
```

Model Function

The model trained in this example consists of a series of fully connect operations with a tanh operation between each one.

The model function takes as input the model parameters `parameters` and the network inputs `dlX` and `dlT`, and returns the model output `dlU`.

```
function dlU = model(parameters,dlX,dlT)

dlXT = [dlX;dlT];
numLayers = numel(fieldnames(parameters))/2;

% First fully connect operation.
weights = parameters.fc1_Weights;
bias = parameters.fc1_Bias;
dlU = fullyconnect(dlXT,weights,bias);

% tanh and fully connect operations for remaining layers.
for i=2:numLayers
    name = "fc" + i;

    dlU = tanh(dlU);

    weights = parameters.(name + "_Weights");
    bias = parameters.(name + "_Bias");
    dlU = fullyconnect(dlU, weights, bias);
end

end
```

Solve Ordinary Differential Equation Using Neural Network

This example shows how to solve an ordinary differential equation (ODE) using a neural network.

Not all differential equations have a closed-form solution. To find approximate solutions to these types of equations, many traditional numerical algorithms are available. However, you can also solve an ODE by using a neural network. This approach comes with several advantages, including that it provides differentiable approximate solutions in a closed analytic form [1].

This example shows you how to:

1. Generate training data in the range $x \in [0, 2]$.
2. Define a neural network that takes x as input and returns the approximate solution to the ODE $\dot{y} = -2xy$, evaluated at x, as output.
3. Train the network with a custom loss function.
4. Compare the network predictions with the analytic solution.

ODE and Loss Function

In this example, you solve the ODE

$$\dot{y} = -2xy,$$

with the initial condition $y(0) = 1$. This ODE has the analytic solution

$$y(x) = e^{-x^2}.$$

Define a custom loss function that penalizes deviations from satisfying the ODE and the initial condition. In this example, the loss function is a weighted sum of the ODE loss and the initial condition loss:

$$L_\theta(x) = \|\dot{y}_\theta + 2xy_\theta\|^2 + k\|y_\theta(0) - 1\|^2$$

θ is the network parameters, k is a constant coefficient, y_θ is the solution predicted by the network, and $\dot{y_\theta}$ is the derivative of the predicted solution computed using automatic differentiation. The term $\| \dot{y_\theta} + 2xy_\theta \|^2$ is the ODE loss and it quantifies how much the predicted solution deviates from satisfying the ODE definition. The term $\|y_\theta(0) - 1\|^2$ is the initial condition loss and it quantifies how much the predicted solution deviates from satisfying the initial condition.

Generate Input Data and Define Network

Generate 10,000 training data points in the range $x \in [0, 2]$.

```
x = linspace(0,2,10000)';
```

Define the network for solving the ODE. As the input is a real number $x \in \mathbb{R}$, specify an input size of 1.

```
inputSize = 1;
layers = [
    featureInputLayer(inputSize,Normalization="none")
    fullyConnectedLayer(10)
```

```
    sigmoidLayer
    fullyConnectedLayer(1)
    sigmoidLayer];
```

Create a `dlnetwork` object from the layer array.

```
dlnet = dlnetwork(layers)
```

```
dlnet =
  dlnetwork with properties:

         Layers: [5×1 nnet.cnn.layer.Layer]
    Connections: [4×2 table]
     Learnables: [4×3 table]
          State: [0×3 table]
     InputNames: {'input'}
    OutputNames: {'layer_2'}
    Initialized: 1
```

Define Model Gradients Function

Create the function `modelGradients` on page 18-0 , listed at the end of the example, which takes as inputs a `dlnetwork` object `dlnet`, a mini-batch of input data `dlX`, and the coefficient associated with the initial condition loss `icCoeff`. This function returns the gradients of the loss with respect to the learnable parameters in `dlnet` and the corresponding loss.

Specify Training Options

Train for 15 epochs with a mini-batch size of 100.

```
numEpochs = 15;
miniBatchSize = 100;
```

Specify the options for SGDM optimization. Specify a learning rate of 0.5, a learning rate drop factor of 0.5, a learning rate drop period of 5, and a momentum of 0.9.

```
initialLearnRate = 0.5;
learnRateDropFactor = 0.5;
learnRateDropPeriod = 5;
momentum = 0.9;
```

Specify the coefficient of the initial condition term in the loss function as 7. This coefficient specifies the relative contribution of the initial condition to the loss. Tweaking this parameter can help training converge faster.

```
icCoeff = 7;
```

Train Model

To use mini-batches of data during training:

1. Create an `arrayDatastore` object from the training data.
2. Create a `minibatchqueue` object that takes the `arrayDatastore` object as input, specify a mini-batch size, and format the training data with the dimension labels `'BC'` (batch, channel).

```
ads = arrayDatastore(x,IterationDimension=1);
mbq = minibatchqueue(ads,MiniBatchSize=miniBatchSize,MiniBatchFormat="BC");
```

By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`.

Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see "GPU Support by Release" (Parallel Computing Toolbox).

Initialize the training progress plot.

```
figure
set(gca,YScale="log")
lineLossTrain = animatedline(Color=[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss (log scale)")
grid on
```

Initialize the velocity parameter for the SGDM solver.

```
velocity = [];
```

Train the network using a custom training loop. For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients and loss using the `dlfeval` and `modelGradients` functions.
- Update the network parameters using the `sgdmupdate` function.
- Display the training progress.

Every `learnRateDropPeriod` epochs, multiply the learning rate by `learnRateDropFactor`.

```
iteration = 0;
learnRate = initialLearnRate;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    mbq.shuffle

    % Loop over mini-batches.
    while hasdata(mbq)

        iteration = iteration + 1;

        % Read mini-batch of data.
        dlX = next(mbq);

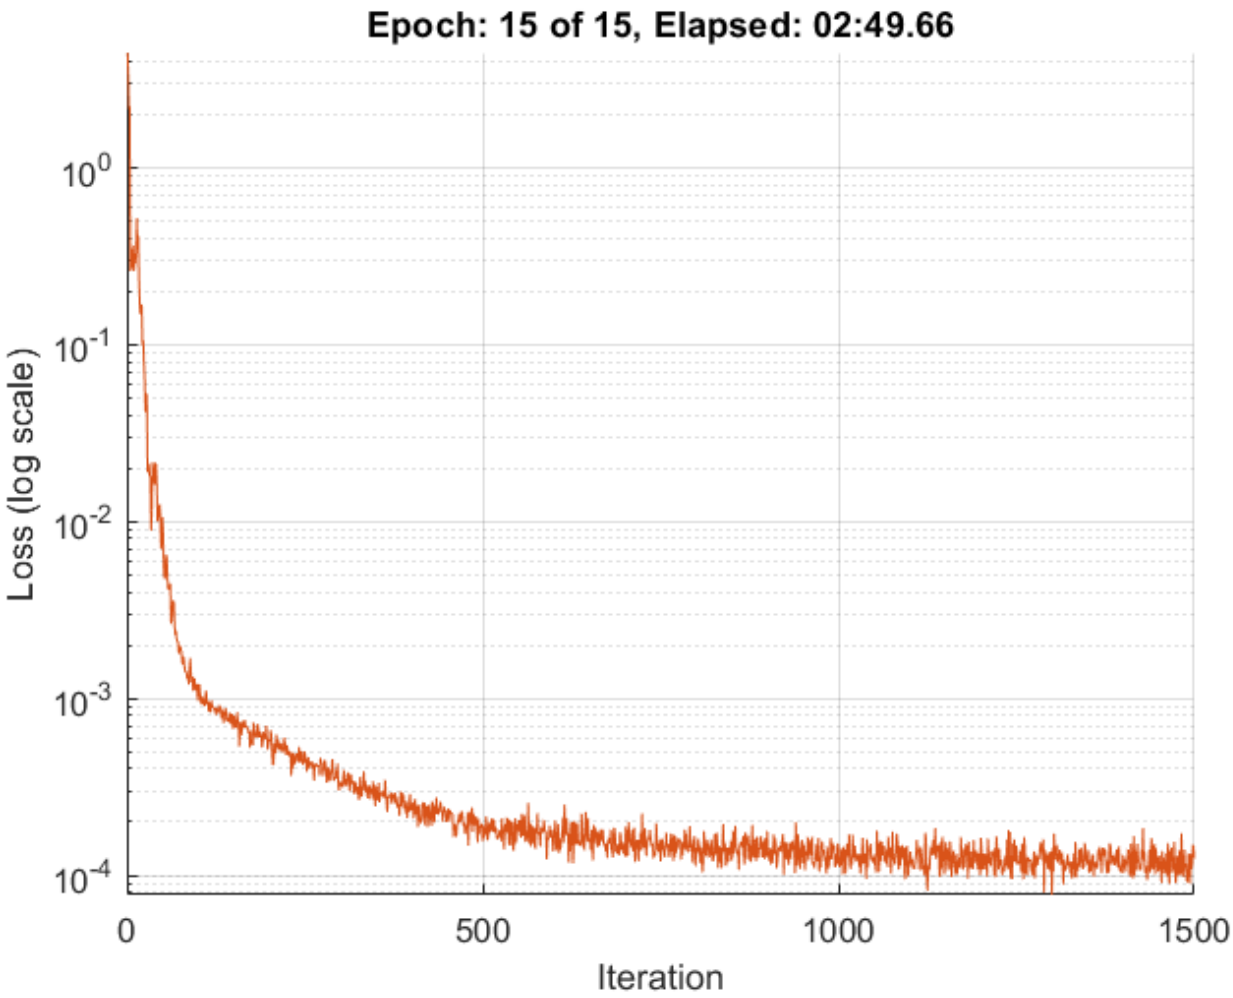
        % Evaluate the model gradients and loss using dlfeval and the modelGradients function.
        [gradients,loss] = dlfeval(@modelGradients, dlnet, dlX, icCoeff);

        % Update network parameters using the SGDM optimizer.
        [dlnet,velocity] = sgdmupdate(dlnet,gradients,velocity,learnRate,momentum);

        % To plot, convert the loss to double.
        loss = double(gather(extractdata(loss)));
```

```
        % Display the training progress.
        D = duration(0,0,toc(start),Format="mm:ss.SS");
        addpoints(lineLossTrain,iteration,loss)
        title("Epoch: " + epoch + " of " + numEpochs + ", Elapsed: " + string(D))
        drawnow

    end
    % Reduce the learning rate.
    if mod(epoch,learnRateDropPeriod)==0
        learnRate = learnRate*learnRateDropFactor;
    end
end
```



Test Model

Test the accuracy of the network by comparing its predictions with the analytic solution.

Generate test data in the range $x \in [0, 4]$ to see if the network is able to extrapolate outside the training range $x \in [0, 2]$.

```
xTest = linspace(0,4,1000)';
```

To use mini-batches of data during testing:

1. Create an `arrayDatastore` object from the testing data.
2. Create a `minibatchqueue` object that takes the `arrayDatastore` object as input, specify a mini-batch size of 100, and format the training data with the dimension labels `'BC'` (batch, channel).

```
adsTest = arrayDatastore(xTest,IterationDimension=1);
mbqTest = minibatchqueue(adsTest,MiniBatchSize=100,MiniBatchFormat="BC");
```

Loop over the mini-batches and make predictions using the `modelPredictions` function, listed at the end of the example.

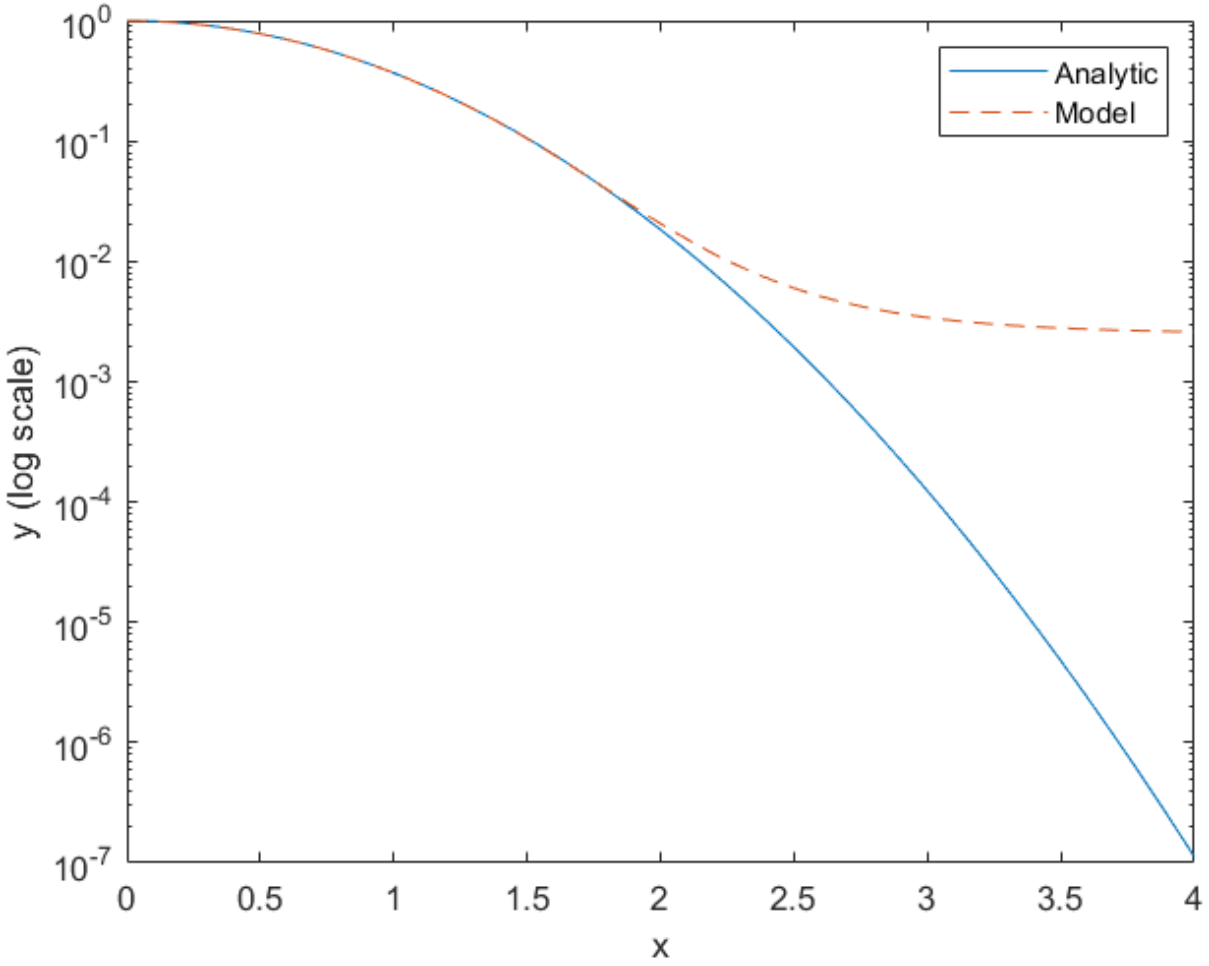
```
yModel = modelPredictions(dlnet,mbqTest);
```

Evaluate the analytic solution.

```
yAnalytic = exp(-xTest.^2);
```

Compare the analytic solution and the model prediction by plotting them on a logarithmic scale.

```
figure;
plot(xTest,yAnalytic,"-")
hold on
plot(xTest,yModel,"--")
legend("Analytic","Model")
xlabel("x")
ylabel("y (log scale)")
set(gca,YScale="log")
```



The model approximates the analytic solution accurately in the training range $x \in [0, 2]$ and it extrapolates in the range $x \in (2, 4]$ with lower accuracy.

Calculate the mean squared relative error in the training range $x \in [0, 2]$.

```
yModelTrain = yModel(1:500);
yAnalyticTrain = yAnalytic(1:500);

errorTrain = mean(((yModelTrain-yAnalyticTrain)./yAnalyticTrain).^2)
```

```
errorTrain = single
    4.3454e-04
```

Calculate the mean squared relative error in the extrapolated range $x \in (2, 4]$.

```
yModelExtra = yModel(501:1000);
yAnalyticExtra = yAnalytic(501:1000);

errorExtra = mean(((yModelExtra-yAnalyticExtra)./yAnalyticExtra).^2)
```

```
errorExtra = single
    17576612
```

Notice that the mean squared relative error is higher in the extrapolated range than it is in the training range.

Model Gradients Function

The `modelGradients` function takes as inputs a `dlnetwork` object `dlnet`, a mini-batch of input data `dlX`, and the coefficient associated with the initial condition loss `icCoeff`. This function returns the gradients of the loss with respect to the learnable parameters in `dlnet` and the corresponding loss. The loss is defined as a weighted sum of the ODE loss and the initial condition loss. The evaluation of this loss requires second order derivatives. To enable second order automatic differentiation, use the function `dlgradient` and set the `EnableHigherDerivatives` name-value argument to `true`.

```
function [gradients,loss] = modelGradients(dlnet, dlX, icCoeff)
y = forward(dlnet,dlX);

% Evaluate the gradient of y with respect to x.
% Since another derivative will be taken, set EnableHigherDerivatives to true.
dy = dlgradient(sum(y,"all"),dlX,EnableHigherDerivatives=true);

% Define ODE loss.
eq = dy + 2*y.*dlX;

% Define initial condition loss.
ic = forward(dlnet,dlarray(0,"CB")) - 1;

% Specify the loss as a weighted sum of the ODE loss and the initial condition loss.
loss = mean(eq.^2,"all") + icCoeff * ic.^2;

% Evaluate model gradients.
gradients = dlgradient(loss, dlnet.Learnables);

end
```

Model Predictions Function

The `modelPredictions` function takes a `dlnetwork` object `dlnet` and a `minibatchqueue` of input data `mbq` and computes the model predictions `y` by iterating over all data in the `minibatchqueue` object.

```
function Y = modelPredictions(dlnet,mbq)

Y = [];

while hasdata(mbq)

    % Read mini-batch of data.
    dlXTest = next(mbq);

    % Predict output using trained network.
    dlY = predict(dlnet,dlXTest);
    YPred = gather(extractdata(dlY));
    Y = [Y; YPred'];

end

end
```

Dynamical System Modeling Using Neural ODE

This example shows how to train a neural network with neural ordinary differential equations (ODEs) to learn the dynamics of a physical system.

Neural ODEs [1] are deep learning operations defined by the solution of an ODE. More specifically, neural ODE is an operation that can be used in any architecture and, given an input, defines its output as the numerical solution of the ODE

$$y' = f(t, y, \theta)$$

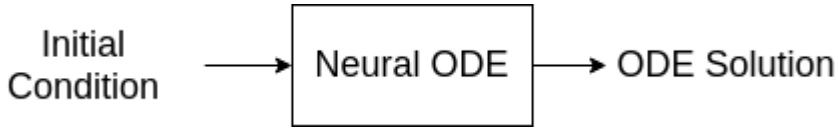
for the time horizon (t_0, t_1) and the initial condition $y(t_0) = y_0$. The right-hand side $f(t, y, \theta)$ of the ODE depends on a set of trainable parameters θ, which the model learns during the training process. In this example, $f(t, y, \theta)$ is modeled with a model function containing fully connected operations and nonlinear activations. The initial condition y_0 is either the input of the entire architecture, as in the case of this example, or is the output of a previous operation.

This example shows how to train a neural network with neural ODEs to learn the dynamics x of a given physical system, described by the following ODE:

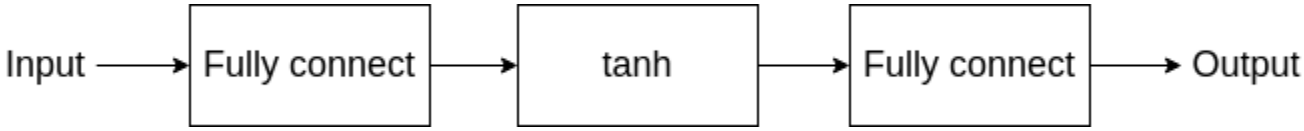
$x' = Ax$,

where A is a 2-by-2 matrix.

The neural network of this example takes as input an initial condition and computes the ODE solution through the learned neural ODE model.



The neural ODE operation, given an initial condition, outputs the solution of an ODE model. In this example, specify a block with a fully connected layer, a tanh layer, and another fully connected layer as the ODE model.



In this example, the ODE that defines the model is solved numerically with the explicit Runge-Kutta (4,5) pair of Dormand and Prince [2]. The backward pass uses automatic differentiation to learn the trainable parameters θ by backpropagating through each operation of the ODE solver.

The learned function $f(t, y, \theta)$ is used as the right-hand side for computing the solution of the same model for additional initial conditions.

Synthesize Data of Target Dynamics

Define the target dynamics as a linear ODE model $x' = Ax$, with `x0` as its initial condition, and compute its numerical solution `xTrain` with `ode45` in the time interval `[0 15]`. To compute an accurate ground truth data, set the relative tolerance of the `ode45` numerical solver to 10^{-7}. Later,

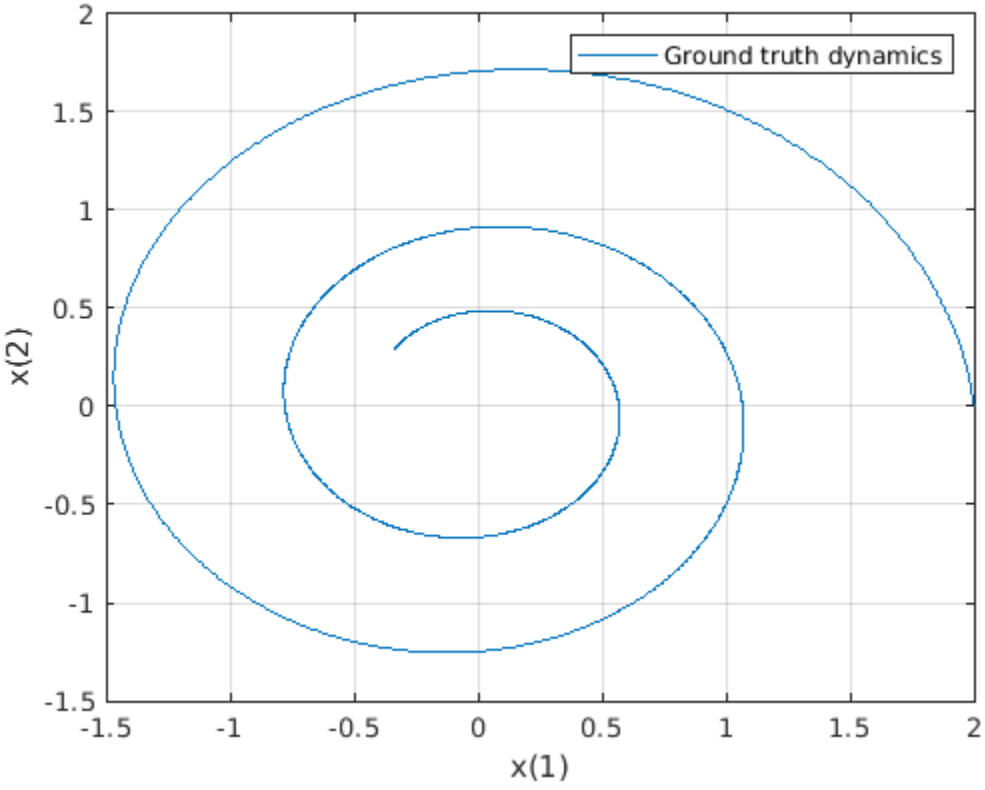
you use the value of `xTrain` as ground truth data for learning an approximated dynamics with a neural ODE model.

```
x0 = [2; 0];
A = [-0.1 -1; 1 -0.1];
trueModel = @(t,y) A*y;

numTimeSteps = 2000;
T = 15;
odeOptions = odeset(RelTol=1.e-7);
t = linspace(0, T, numTimeSteps);
[~, xTrain] = ode45(trueModel, t, x0, odeOptions);
xTrain = xTrain';
```

Visualize the training data in a plot.

```
plot(xTrain(1,:),xTrain(2,:))
legend("Ground truth dynamics")
xlabel("x(1)")
ylabel("x(2)")
grid on
```



Define and Initialize Model Parameters

The model function consists of a single call to `dlode45` to solve the ODE defined by the approximated dynamics $f(t, y, \theta)$ for 40 time steps.

```
neuralOdeTimesteps = 40;
dt = t(2);
timesteps = (0:neuralOdeTimesteps)*dt;
```

Define the learnable parameters to use in the call to `dlode45` and collect them in the variable `neuralOdeParameters`. The function `initializeGlorot` takes as input the size of the learnable parameters `sz` and the number of outputs and number of inputs of the fully connected operations, and returns a `dlarray` object with underlying type `'single'` with values set using Glorot initialization. The function `initializeZeros` takes as input the size of the learnable parameters, and returns the parameters as a `dlarray` object with underlying type `'single'`. The initialization example functions are attached to this example as supporting files. To access these functions, open this example as a live script. For more information about initializing learnable parameters for model functions, see “Initialize Learnable Parameters for Model Function” on page 18-292.

Initialize the parameters structure.

```
neuralOdeParameters = struct;
```

Initialize the parameters for the fully connected operations in the ODE model. The first fully connected operation takes as input a vector of size `stateSize` and increases its length to `hiddenSize`. Conversely, the second fully connected operation takes as input a vector of length `hiddenSize` and decreases its length to `stateSize`.

```
stateSize  = size(xTrain,1);
hiddenSize = 20;

neuralOdeParameters.fc1 = struct;
sz = [hiddenSize stateSize];
neuralOdeParameters.fc1.Weights = initializeGlorot(sz, hiddenSize, stateSize);
neuralOdeParameters.fc1.Bias    = initializeZeros([hiddenSize 1]);

neuralOdeParameters.fc2 = struct;
sz = [stateSize hiddenSize];
neuralOdeParameters.fc2.Weights = initializeGlorot(sz, stateSize, hiddenSize);
neuralOdeParameters.fc2.Bias    = initializeZeros([stateSize 1]);
```

Display the learnable parameters of the model.

```
neuralOdeParameters.fc1
```

```
ans = struct with fields:
    Weights: [20×2 dlarray]
       Bias: [20×1 dlarray]
```

```
neuralOdeParameters.fc2
```

```
ans = struct with fields:
    Weights: [2×20 dlarray]
       Bias: [2×1 dlarray]
```

Define Neural ODE Model

Create the function `odeModel`, listed in the ODE Model on page 18-0 section of the example, which takes as input the time input (unused), the corresponding solution, and the ODE function parameters. The function applies a fully connected operation, a tanh operation, and another fully connected operation to the input data using the weights and biases given by the parameters.

Define Model Function

Create the function `model`, listed in the Model Function on page 18-0 section of the example, which computes the outputs of the deep learning model. The function `model` takes as input the model parameters and the input data. The function outputs the solution of the neural ODE.

Define Model Gradients Function

Create the function `modelGradients`, listed in the Model Gradients Function on page 18-0 section of the example, which takes as input the model parameters, a mini-batch of input data with corresponding targets, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss.

Specify Training Options

Specify options for Adam optimization.

```
gradDecay = 0.9;
sqGradDecay = 0.999;
learnRate = 0.002;
```

Train for 1200 iterations with a mini-batch-size of 200.

```
numIter = 1200;
miniBatchSize = 200;
```

Every 50 iterations, solve the learned dynamics and display them against the ground truth in a phase diagram to show the training path.

```
plotFrequency = 50;
```

Train Model Using Custom Training Loop

Train the network using a custom training loop.

For each iteration:

- Construct a mini-batch of data from the synthesized data with the `createMiniBatch` function, listed in the Create Mini-Batches Function on page 18-0 section of the example.
- Evaluate the model gradients and loss using the `dlfeval` function and the `modelGradients` function, listed in the Model Gradients Function on page 18-0 section of the example.
- Update the model parameters using the `adamupdate` function.
- Update the training progress plot.

Initialize the training progress plot.

```
figure(2)
lineLossTrain = animatedline(Color=[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Initialize the `averageGrad` and `averageSqGrad` parameters for the Adam solver.

```
averageGrad   = [];
averageSqGrad = [];
```

Initialize the `lossHistory` array to record the evolution of the training loss.

```
lossHistory = [];
numTrainingTimesteps = numTimeSteps;
trainingTimesteps = 1:numTrainingTimesteps;
plottingTimesteps = 2:numTimeSteps;

start = tic;

for iter=1:numIter

    % Create batch
    [dlx0, targets] = createMiniBatch(numTrainingTimesteps, neuralOdeTimesteps, miniBatchSize, x

    % Evaluate network and compute gradients
    [grads,loss] = dlfeval(@modelGradients,timesteps,dlx0,neuralOdeParameters,targets);

    % Update network
    [neuralOdeParameters,averageGrad,averageSqGrad] = adamupdate(neuralOdeParameters,grads,averag
        learnRate,gradDecay,sqGradDecay);

    % Plot loss
    currentLoss = double(extractdata(loss));

    figure(2)
    addpoints(lineLossTrain, iter, currentLoss);
    drawnow

    % Plot predicted vs. real dynamics
    if mod(iter,plotFrequency) == 0  || iter == 1
        figure(3)
        clf

        % Use ode45 to compute the solution
        y = dlode45(@odeModel,t,dlarray(x0),neuralOdeParameters,DataFormat="CB");
        y = extractdata(y);

        plot(xTrain(1,plottingTimesteps),xTrain(2,plottingTimesteps),"r--")
        hold on
        plot(y(1,:),y(2,:),"b-")
        xlabel("x(1)")
        ylabel("x(2)")
        hold off
        D = duration(0,0,toc(start),Format="hh:mm:ss");
        title("Iter = " + iter + ", loss = " + num2str(currentLoss) + ", Elapsed: " + string(D))
        legend("Training ground truth", "Predicted")
    end
end

Evaluate Model

Use the model to compute approximated solutions with different initial conditions.

Define four new initial conditions different from the one used for training the model.

```
tPred = t;

x0Pred1 = sqrt([2;2]);
x0Pred2 = [-1;-1.5];
x0Pred3 = [0;2];
x0Pred4 = [-2;0];
```

Numerically solve the ODE true dynamics with `ode45` for the four new initial conditions.

```
[~, xTrue1] = ode45(trueModel, tPred, x0Pred1, odeOptions);

[~, xTrue2] = ode45(trueModel, tPred, x0Pred2, odeOptions);

[~, xTrue3] = ode45(trueModel, tPred, x0Pred3, odeOptions);

[~, xTrue4] = ode45(trueModel, tPred, x0Pred4, odeOptions);
```

Numerically solve the ODE with the learned neural ODE dynamics.

```
xPred1 = dlode45(@odeModel,tPred,dlarray(x0Pred1),neuralOdeParameters,DataFormat="CB");
xPred1 = extractdata(squeeze(xPred1))';
```

```
xPred2 = dlode45(@odeModel,tPred,dlarray(x0Pred2),neuralOdeParameters,DataFormat="CB");
xPred2 = extractdata(squeeze(xPred2))';

xPred3 = dlode45(@odeModel,tPred,dlarray(x0Pred3),neuralOdeParameters,DataFormat="CB");
xPred3 = extractdata(squeeze(xPred3))';

xPred4 = dlode45(@odeModel,tPred,dlarray(x0Pred4),neuralOdeParameters,DataFormat="CB");
xPred4 = extractdata(squeeze(xPred4))';
```

Visualize Predictions

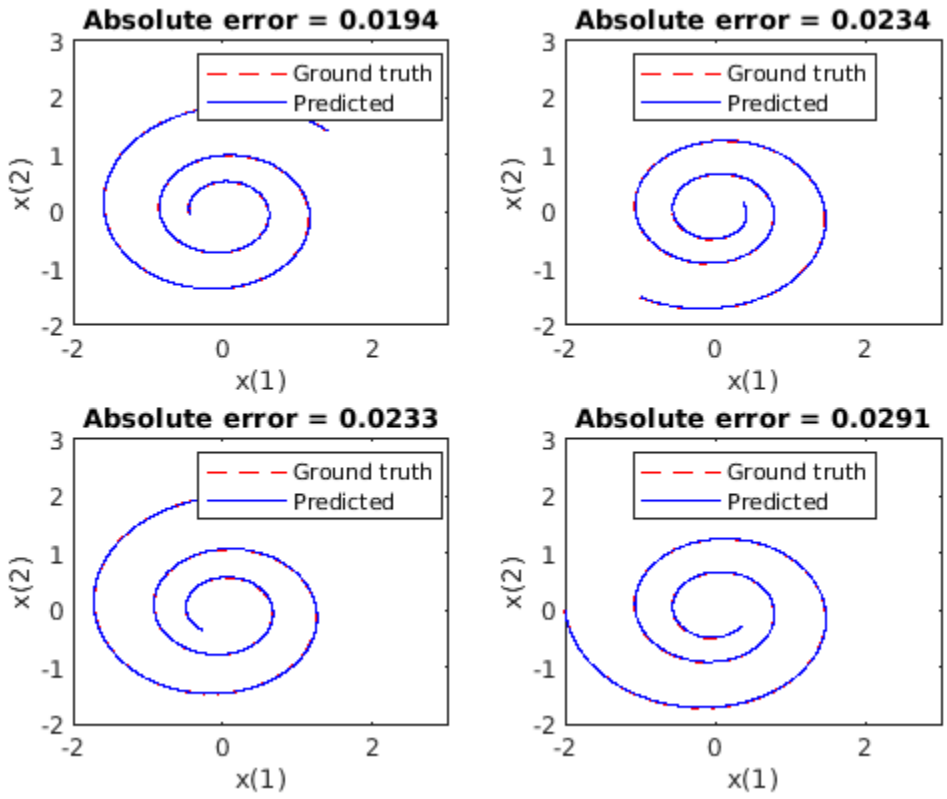
Visualize the predicted solutions for different initial conditions against the ground truth solutions with the function `plotTrueAndPredictedSolutions`, listed in the Plot True and Predicted Solutions Function on page 18-0 section of the example.

```
subplot(2,2,1)
plotTrueAndPredictedSolutions(xTrue1, xPred1);

subplot(2,2,2)
plotTrueAndPredictedSolutions(xTrue2, xPred2);

subplot(2,2,3)
plotTrueAndPredictedSolutions(xTrue3, xPred3);

subplot(2,2,4)
plotTrueAndPredictedSolutions(xTrue4, xPred4);
```



Helper Functions

Model Function

The `model` function, which defines the neural network used to make predictions, is composed of a single neural ODE call. For each observation, this function takes a vector of length `stateSize`, which is used as initial condition for solving numerically the ODE with the function `odeModel` on page 18-0 , which represents the learnable right-hand side $f(t, y, \theta)$ of the ODE to be solved, as right hand side and a vector of time points `tspan` defining the time at which the numerical solution is output. The function uses the vector `tspan` for each observation, regardless of the initial condition, since the learned system is autonomous. That is, the `odeModel` function does not explicitly depend on time.

```
function X = model(tspan,X0,neuralOdeParameters)

X = dlode45(@odeModel,tspan,X0,neuralOdeParameters,DataFormat="CB");

end
```

ODE Model

The `odeModel` function is the learnable right-hand side used in the call to `dlode45`. It takes as input a vector of size `stateSize`, enlarges it so that it has length `hiddenSize`, and applies a nonlinearity function `tanh`. Then the function compresses the vector again to have length `stateSize`.

```
function y = odeModel(~,y,theta)

y = tanh(theta.fc1.Weights*y + theta.fc1.Bias);
y = theta.fc2.Weights*y + theta.fc2.Bias;

end
```

Model Gradients Function

This function takes as inputs a vector `tspan`, a set of initial conditions `dlX0`, the learnable parameters `neuralOdeParameters`, and target sequences `targets`. It computes the predictions with the `model` function, and compares them with the given targets sequences. Finally, it computes the gradient with respect to the learnable parameters of the neural ODE.

```
function [gradients,loss] = modelGradients(tspan,dlX0,neuralOdeParameters,targets)

% Compute predictions.
dlX = model(tspan,dlX0,neuralOdeParameters);

% Compute L1 loss.
loss = l1loss(dlX,targets,NormalizationFactor="all-elements",DataFormat="CBT");

% Compute gradients.
gradients = dlgradient(loss,neuralOdeParameters);
end
```

Create Mini-Batches Function

The `createMiniBatch` function creates a batch of observations of the target dynamics. It takes as input the total number of time steps of the ground truth data `numTimesteps`, the number of consecutive time steps to be returned for each observation `numTimesPerObs`, the number of observations `miniBatchSize`, and the ground truth data `X`.

```
function [x0, targets] = createMiniBatch(numTimesteps,numTimesPerObs,miniBatchSize,X)

% Create batches of trajectories.
s = randperm(numTimesteps - numTimesPerObs, miniBatchSize);

x0 = dlarray(X(:, s));
targets = zeros([size(X,1) miniBatchSize numTimesPerObs]);

for i = 1:miniBatchSize
    targets(:, i, 1:numTimesPerObs) = X(:, s(i) + 1:(s(i) + numTimesPerObs));
end

end
```

Plot True and Predicted Solutions Function

The `plotTrueAndPredictedSolutions` function takes as input the true solution `xTrue`, the approximated solution `xPred` computed with the learned neural ODE model, and the corresponding initial condition `x0Str`. It computes the error between the true and predicted solutions and plots it in a phase diagram.

```
function plotTrueAndPredictedSolutions(xTrue,xPred)

err = mean(abs(xTrue(2:end,:) - xPred), "all");

plot(xTrue(:,1),xTrue(:,2),"r--",xPred(:,1),xPred(:,2),"b-",LineWidth=1)

title("Absolute error = " + num2str(err,'%.4f') )
xlabel("x(1)")
ylabel("x(2)")

xlim([-2 3])
ylim([-2 3])

legend("Ground truth","Predicted",Location="best")
end
```

Node Classification Using Graph Convolutional Network

This example shows how to classify nodes in a graph using Graph Convolutional Network (GCN).

The node classification task is one where an algorithm, in this example, a GCN [1], has to predict the labels of unlabelled nodes in a graph. In this example, a graph is represented by a molecule. Atoms in the molecule represent nodes in the graph and the chemical bonds between atoms represent edges in the graph. Node labels are the types of atom, for example, Carbon. As such, input to the GCN are molecules and the outputs are predictions of the type of atom of each unlabelled atom in the molecule.

To assign a categorical label to each node of a graph, the GCN models a function $f(X, A)$ on a graph $G = (V, E)$, where V denotes the set of nodes and E denotes the set of edges, such that$f(X, A)$ takes as input:

- X: A feature matrix of dimension $N \times C$, where $N = |V|$ is the number of nodes in G and C is number of input channels/features per node.
- A: An adjacency matrix of dimension $N \times N$ representing E and describing the structure of G.

and returns an output:

- Z: An Embedding or feature matrix of dimension $N \times F$, where F is number of output features per node. In other words, Z is the predictions of the network and F is the number of classes.

The model $f(X, A)$ is based on spectral graph convolution, with weights/filter parameters shared over all locations in G. The model can be represented as a layer-wise propagation model, such that the output of layer $l + 1$ is expressed as

$$Z_{l+1} = \sigma\left(\widehat{D}^{-1/2}\widehat{A}\widehat{D}^{-1/2}Z_l W_l\right),$$

where

- σ is an activation function.
- Z_l is the activation matrix of layer l, with $Z_1 = X$.
- W_l is the weight matrix of layer l.
- $\widehat{A} = A + I_N$ is the adjacency matrix of graph G with added self-connections. I_N is the identity matrix.
- $\widehat{D}$ is the degree matrix of $\widehat{A}$.

Expression $\widehat{D}^{-1/2}\widehat{A}\widehat{D}^{-1/2}$ can be referred to as the *normalized* adjacency matrix of the graph.

The GCN model in this example is a variant of the standard GCN model described above. The variant uses residual connections between layers [1]. The residual connections enable the model to carry over information from previous layer's input. Therefore, the output of layer $l + 1$of the GCN model in this example is

$$Z_{l+1} = \sigma\left(\widehat{D}^{-1/2}\widehat{A}\widehat{D}^{-1/2}Z_l W_l\right) + Z_l,$$

See [1] for more details about the GCN model.

This example uses the QM7 dataset [2] [3], which is a molecular dataset consisting of 7165 molecules composed of up to 23 atoms. That is, the molecule with the highest number of atoms has 23 atoms. Overall, the dataset consists of 5 unique atoms: Carbon, Hydrogen, Nitrogen, Oxygen, and Sulphur.

Download and Load QM7 data

Download the QM7 dataset from the following URL:

```
dataURL = 'http://quantum-machine.org/data/qm7.mat';
outputFolder = fullfile(tempdir,'qm7Data');
dataFile = fullfile(outputFolder,'qm7.mat');

if ~exist(dataFile, 'file')
    mkdir(outputFolder);
    fprintf('Downloading file ''%s'' ...\n', dataFile);
    websave(dataFile, dataURL);
end
```

Load QM7 data.

```
data = load(dataFile)
```

```
data = struct with fields:
    X: [7165×23×23 single]
    R: [7165×23×3 single]
    Z: [7165×23 single]
    T: [1×7165 single]
    P: [5×1433 int64]
```

The data consists of five different arrays. This example uses the arrays in fields `X` and `Z` of struct `data`. The array in `X` represents the Coulomb matrix [3] representation of each molecule, totalling 7165 molecules, and the array in `Z` represents the atomic charge/number of each atom in the molecules. The adjacency matrices of the graphs representing the molecules, and the feature matrices of the graphs, are extracted from the Coulomb matrices. The categorical array of labels is extracted from the array in `Z`.

Note that the data, for any molecule that does not have up to 23 atoms, contains padded zeros. For example, the data representing the atomic numbers of atoms in the molecule at index 1 is

```
data.Z(1,:)
```

```
ans = 1×23 single row vector

     6     1     1     1     1     0     0     0     0     0     0     0     0     0     0     0
```

This shows that this molecule is composed of five atoms; one atom with atomic number 6 and four atoms with atomic number 1, and the data is padded with 18 zeros.

Extract and Preprocess Graph Data

To extract graph data, get the Coulomb matrices and atomic numbers. Permute the data representing the Coulomb matrices and change the datatype to double. Sort the data representing the atomic charges so that it matches the data representing the Coulomb matrices.

```
coulombData = double(permute(data.X, [2 3 1]));
atomicNumber = sort(data.Z,2,'descend');
```

Reformat the Coulomb matrix representation of the molecules to binary adjacency matrices using the `coloumb2Adjacency` function attached to this example as a supporting file.

```
adjacencyData = coloumb2Adjacency(coulombData, atomicNumber);
```

Note that the `coloumb2Adjacency` function does not remove padded zeros from the data. They are left intentionally to make it easier to split the data into separate molecules for training, validation and inference. Therefore, ignoring the padded zeros, the adjacency matrix of the graph representing the molecule at index 1, which consists of 5 atoms, is

```
adjacencyData(1:5,1:5,1)
```

```
ans = 5×5

     0     1     1     1     1
     1     0     0     0     0
     1     0     0     0     0
     1     0     0     0     0
     1     0     0     0     0
```

Before preprocessing the data, use the `splitData` on page 18-0 function, provided at the end of the example, to randomly select and split the data into training, validation and test data. The function uses the ratio 80:10:10 to split the data.

The `adjacencyDataSplit` output of the `splitData` function is the `adjacencyData` input data split into three different arrays. Likewise, the `coulombDataSplit` and `atomicNumberSplit` outputs are the `coulombData` and `atomicNumber` input data split into three different arrays respectively.

```
[adjacencyDataSplit, coulombDataSplit, atomicNumberSplit] = splitData(adjacencyData, coulombData
```

Use the `preprocessData` on page 18-0 function, provided at the end of the example, to process the `adjacencyDataSplit`, `coulombDataSplit,` and `atomicNumberSplit` and return the adjacency matrix `adjacency`, feature matrix `features`, and categorical array `labels`.

The `preprocessData` function builds a sparse block-diagonal matrix of the adjacency matrices of different graph instances, such that, each block in the matrix corresponds to the adjacency matrix of one graph instance. This preprocessing is required because GCN accepts a single adjacency matrix as input, whereas this example deals with multiple graph instances. The function takes the non-zero diagonal elements of the Coulomb matrices and assigns them as features. Therefore, the number of input features per node in the example is 1.

```
[adjacency, features, labels] = cellfun(@preprocessData, adjacencyDataSplit, coulombDataSplit, at
```

View the adjacency matrices of the training, validation, and test data.

```
adjacency
```

```
adjacency=1×3 cell array
    {88722×88722 double}    {10942×10942 double}    {10986×10986 double}
```

This shows that there are 88722 nodes in the training data, 10942 nodes in the validation data, and 10986 nodes in the test data.

Normalize the feature array using the `normalizeFeatures` on page 18-0 function provided at the end of the example.

```
features = normalizeFeatures(features);
```

Get the training and the validation data.

```
featureTrain = features{1};
adjacencyTrain = adjacency{1};
targetTrain = labels{1};

featureValidation = features{2};
adjacencyValidation = adjacency{2};
targetValidation = labels{2};
```

Visualize Data and Data Statistics

Sample and specify indices of molecules to visualize.

For each specified index

- Remove padded zeros from the data representing unprocessed atomic numbers `atomicNumber` and unprocessed adjacency matrix `adjacencyData` of the sampled molecule. The unprocessed data are used here for easy sampling.
- Convert the adjacency matrix to graph using the `graph` function.
- Convert the atomic numbers to symbols.
- Plot the graph using the atomic symbols as node labels.

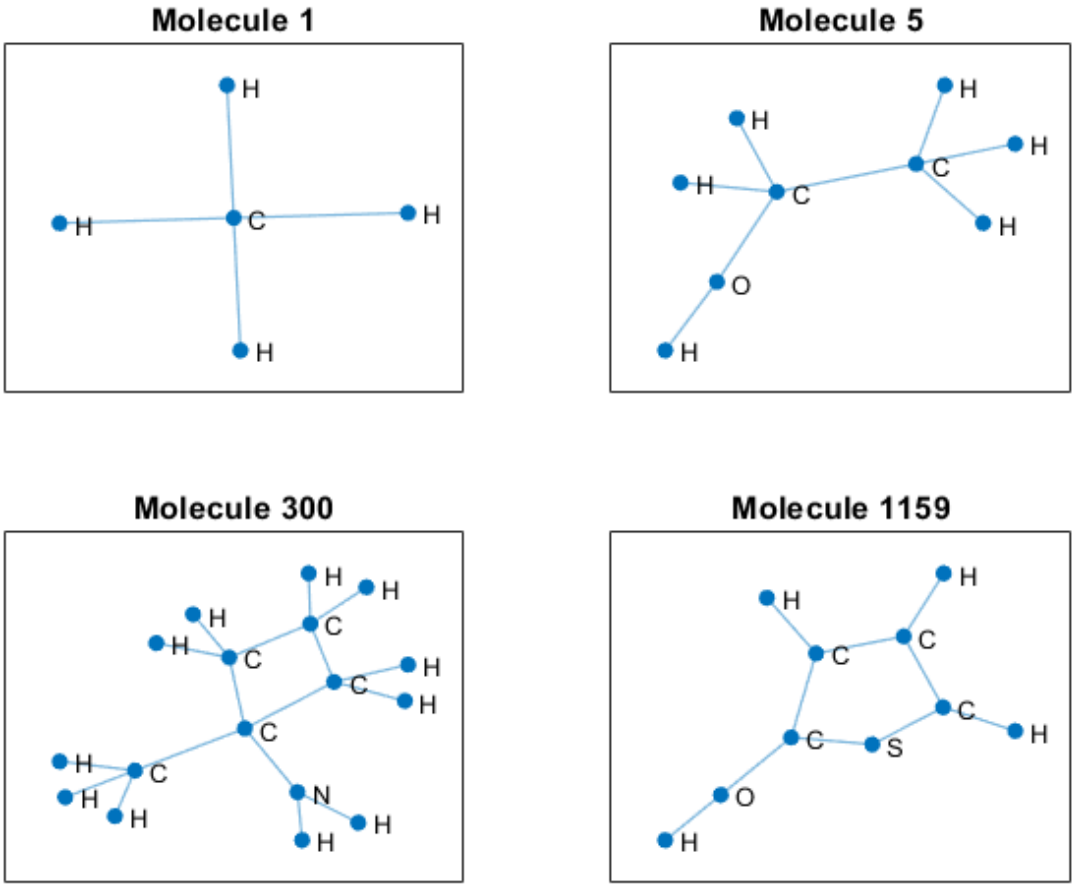
```
idx = [1 5 300 1159];
for j = 1:numel(idx)
    % Remove padded zeros from the data
    atomicNum = nonzeros(atomicNumber(idx(j),:));
    numOfNodes = numel(atomicNum);
    adj = adjacencyData(1:numOfNodes,1:numOfNodes,idx(j));

    % Convert adjacency matrix to graph
    compound = graph(adj);

    % Convert atomic numbers to symbols
    symbols = cell(numOfNodes, 1);
    for i = 1:numOfNodes
        if atomicNum(i) == 1
            symbols{i} = 'H';
        elseif atomicNum(i) == 6
            symbols{i} = 'C';
        elseif atomicNum(i) == 7
            symbols{i} = 'N';
        elseif atomicNum(i) == 8
            symbols{i} = 'O';
        else
            symbols{i} = 'S';
        end
    end

    % Plot graph
    subplot(2,2,j)
    plot(compound, 'NodeLabel', symbols, 'LineWidth', 0.75, ...
```

```
    'Layout', 'force')
    title("Molecule " + idx(j))
end
```



Get all the labels and the classes.

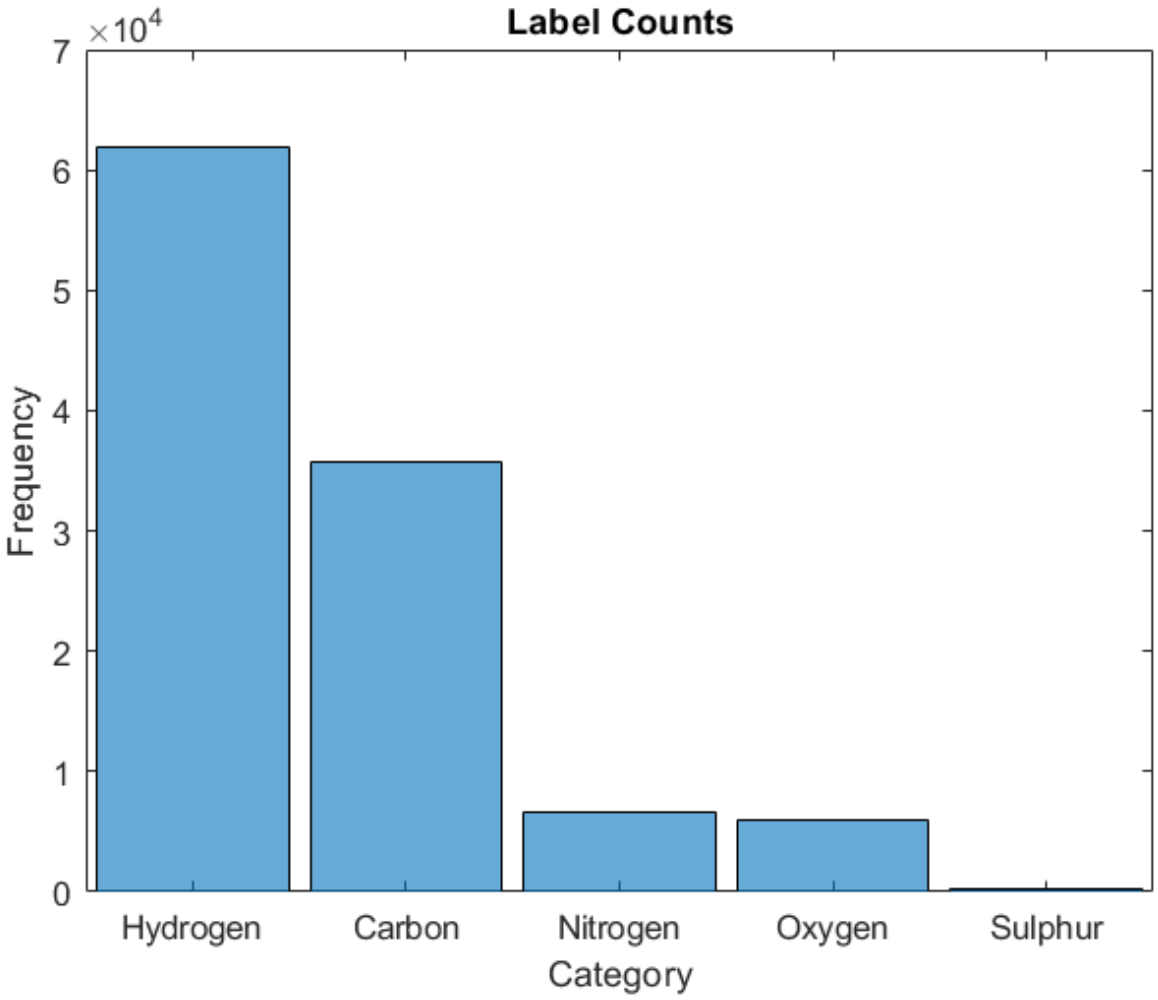
```
labelsAll = cat(1,labels{:});
classes = categories(labelsAll)
```

```
classes = 5×1 cell
    {'Hydrogen'}
    {'Carbon'  }
    {'Nitrogen'}
    {'Oxygen'  }
    {'Sulphur' }
```

Visualize frequency of each label category using a histogram.

```
figure
histogram(labelsAll)
```

```
xlabel('Category')
ylabel('Frequency')
title('Label Counts')
```



Define Model Function

Create the function model on page 18-0 , provided at the end of the example, that takes the feature data `dlX`, the adjacency matrix `A`, and the model parameters `parameters` as input and returns predictions for the label.

Initialize Model Parameters

Set the number of input features per node. This is the column length of the feature matrix.

```
numInputFeatures = size(featureTrain,2)
```

```
numInputFeatures = 1
```

Set the number of feature maps for the hidden layers.

```
numHiddenFeatureMaps = 32;
```

Set the number of output features as the number of categories.

```
numOutputFeatures = numel(classes)
```

```
numOutputFeatures = 5
```

Create a struct `parameters` containing the model weights. Initialize the weights using the `initializeGlorot` function attached to this example as a supporting file.

```
sz = [numInputFeatures numHiddenFeatureMaps];
numOut = numHiddenFeatureMaps;
numIn = numInputFeatures;
parameters.W1 = initializeGlorot(sz,numOut,numIn,'double');

sz = [numHiddenFeatureMaps numHiddenFeatureMaps];
numOut = numHiddenFeatureMaps;
numIn = numHiddenFeatureMaps;
parameters.W2 = initializeGlorot(sz,numOut,numIn,'double');

sz = [numHiddenFeatureMaps numOutputFeatures];
numOut = numOutputFeatures;
numIn = numHiddenFeatureMaps;
parameters.W3 = initializeGlorot(sz,numOut,numIn,'double');
parameters
```

```
parameters = struct with fields:
    W1: [1×32 dlarray]
    W2: [32×32 dlarray]
    W3: [32×5 dlarray]
```

Define Model Gradients Function

Create the function modelGradients on page 18-0 , provided at the end of the example, that takes the feature data `dlX`, the adjacency matrix `adjacencyTrain`, the one-hot encoded targets `T` of the labels, and the model parameters `parameters` as input and returns the gradients of the loss with respect to the parameters, the corresponding loss, and the network predictions.

Specify Training Options

Train for 1500 epochs and set the learn rate for Adam solver to 0.01.

```
numEpochs = 1500;
learnRate = 0.01;
```

Validate the network after every 300 epochs.

```
validationFrequency = 300;
```

Visualize the training progress in a plot.

```
plots = "training-progress";
```

To train on a GPU if one is available, specify the execution environment `"auto"`. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox) (Parallel Computing Toolbox).

```
executionEnvironment = "auto";
```

Train Model

Train the model using a custom training loop. The training uses full-batch gradient descent.

Initialize the training progress plot.

```
if plots == "training-progress"
    figure

    % Accuracy.
    subplot(2,1,1)
    lineAccuracyTrain = animatedline('Color',[0 0.447 0.741]);
    lineAccuracyValidation = animatedline( ...
        'LineStyle','--', ...
        'Marker','o', ...
        'MarkerFaceColor','black');
    ylim([0 1])
    xlabel("Epoch")
    ylabel("Accuracy")
    grid on

    % Loss.
    subplot(2,1,2)
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    lineLossValidation = animatedline( ...
        'LineStyle','--', ...
        'Marker','o', ...
        'MarkerFaceColor','black');
    ylim([0 inf])
    xlabel("Epoch")
    ylabel("Loss")
    grid on
end
```

Initialize parameters for Adam.

```
trailingAvg = [];
trailingAvgSq = [];
```

Convert training and validation feature data to dlarray.

```
dlX = dlarray(featureTrain);
dlXValidation = dlarray(featureValidation);
```

For GPU training, convert data to `gpuArray` objects.

```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlX = gpuArray(dlX);
end
```

Encode training and validation label data using `onehotencode`.

```
T = onehotencode(targetTrain, 2, 'ClassNames', classes);
TValidation = onehotencode(targetValidation, 2, 'ClassNames', classes);
```

Train the model.

For each epoch

- Evaluate the model gradients and loss using `dlfeval` and the `modelGradients` function.
- Update the network parameters using `adamupdate`.
- Compute the training accuracy score using the accuracy on page 18-0 function provided at the end of the example. The function takes the network predictions, the target containing the labels, and the categories `classes` as inputs and returns the accuracy score.
- If required, validate the network by making predictions using the `model` function and computing the validation loss and the validation accuracy score using `crossentropy` and the `accuracy` function.
- Update the training plot.

```
start = tic;
% Loop over epochs.
for epoch = 1:numEpochs

    % Evaluate the model gradients and loss using dlfeval and the
    % modelGradients function.
    [gradients, loss, dlYPred] = dlfeval(@modelGradients, dlX, adjacencyTrain, T, parameters);

    % Update the network parameters using the Adam optimizer.
    [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
        trailingAvg,trailingAvgSq,epoch,learnRate);

    % Display the training progress.
    if plots == "training-progress"
        subplot(2,1,1)
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        title("Epoch: " + epoch + ", Elapsed: " + string(D))

        % Loss.
        addpoints(lineLossTrain,epoch,double(gather(extractdata(loss))))

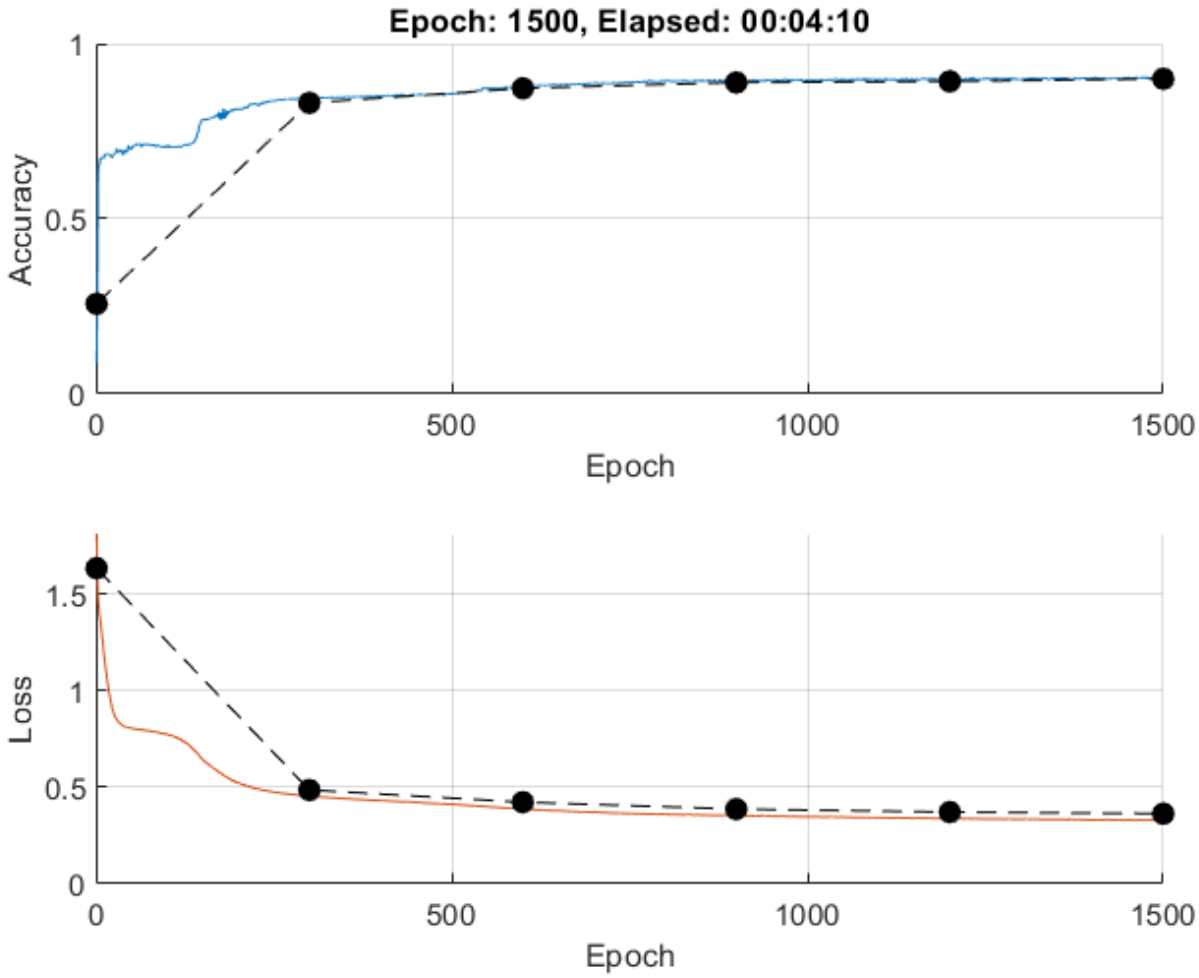
        % Accuracy score.
        score = accuracy(dlYPred, targetTrain, classes);
        addpoints(lineAccuracyTrain,epoch,double(gather(score)))

        drawnow

        % Display validation metrics.
        if epoch == 1 || mod(epoch,validationFrequency) == 0
            % Loss.
            dlYPredValidation = model(dlXValidation, adjacencyValidation, parameters);
            lossValidation = crossentropy(dlYPredValidation, TValidation, 'DataFormat', 'BC');
            addpoints(lineLossValidation,epoch,double(gather(extractdata(lossValidation))))

            % Accuracy score.
            scoreValidation = accuracy(dlYPredValidation, targetValidation, classes);
            addpoints(lineAccuracyValidation,epoch,double(gather(scoreValidation)))

            drawnow
        end
    end
end
```



Test Model

Test the model using the test data.

```
featureTest = features{3};
adjacencyTest = adjacency{3};
targetTest = labels{3};
```

Convert the test feature data to dlarray.

```
dlXTest = dlarray(featureTest);
```

Make predictions on the data.

```
dlYPredTest = model(dlXTest, adjacencyTest, parameters);
```

Calculate the accuracy score using the `accuracy` function. The `accuracy` function also returns a decoded network predictions `predTest` as class labels. The network predictions are decoded using `onehotdecode`.

```
[scoreTest, predTest] = accuracy(dlYPredTest, targetTest, classes);
```

View the accuracy score.

```
scoreTest
```

```
scoreTest = 0.9053
```

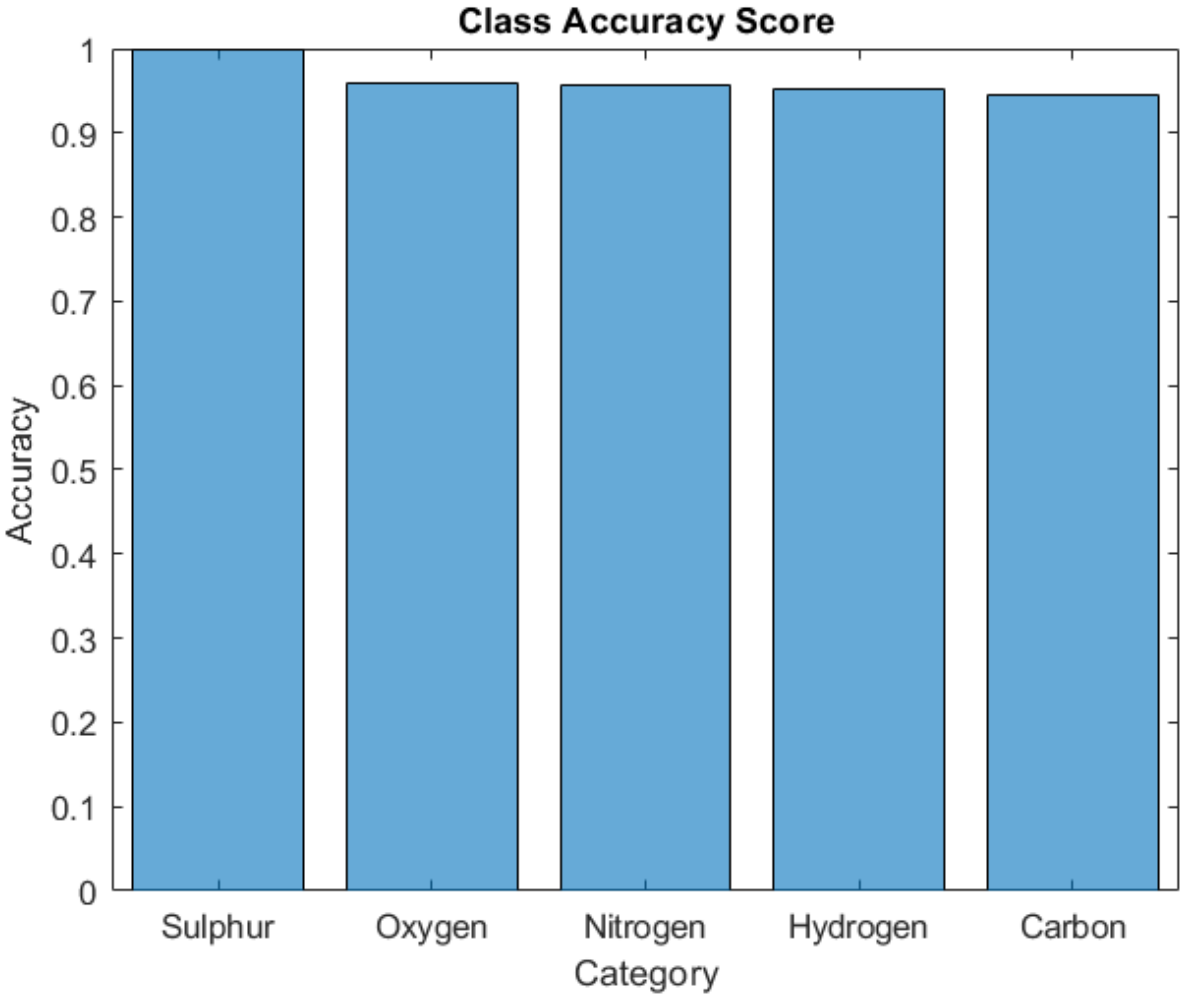
Visualize Predictions

To visualize the accuracy score for each category, compute the class-wise accuracy scores and visualize them using a histogram.

```
numOfSamples = numel(targetTest);
classTarget = zeros(numOfSamples, numOutputFeatures);
classPred = zeros(numOfSamples, numOutputFeatures);
for i = 1:numOutputFeatures
    classTarget(:,i) = targetTest==categorical(classes(i));
    classPred(:,i) = predTest==categorical(classes(i));
end

% Compute class-wise accuracy score
classAccuracy = sum(classPred == classTarget)./numOfSamples;

% Visualize class-wise accuracy score
figure
[~,idx] = sort(classAccuracy,'descend');
histogram('Categories',classes(idx), ...
    'BinCounts',classAccuracy(idx), ...
    'Barwidth',0.8)
xlabel("Category")
ylabel("Accuracy")
title("Class Accuracy Score")
```



The class-wise accuracy scores show how the model makes correct predictions using both the true positives and the true negatives. A true positive is an outcome where the model correctly predicts a class as present in an observation. A true negative is an outcome where the model correctly predicts a class as absent in an observation.

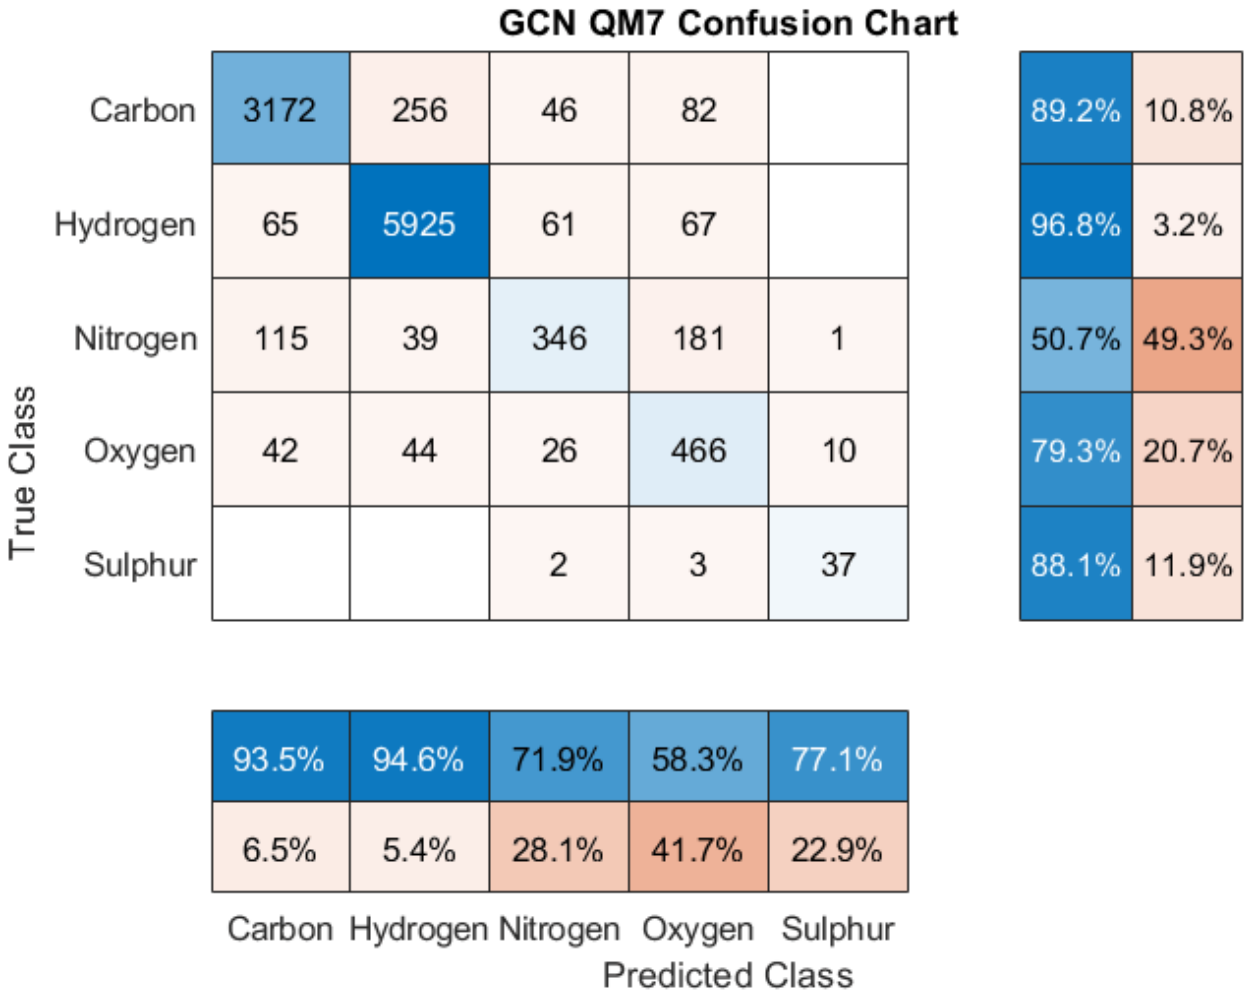
To visualize how the model makes incorrect predictions and evaluate the model based on class-wise precision and class-wise recall, calculate the confusion matrix using `confusionmat` and visualize the results using `confusionchart`.

Class-wise precision is the ratio of true positives to total positive predictions for a class. The total positive predictions include the true positives and false positives. A false positive is an outcome where the model incorrectly predicts a class as present in an observation.

Class-wise recall, also known as true positive rates, is the ratio of true positives to total positive observations for a class. The total positive observation includes the true positives and false negatives. A false negative is an outcome where the model incorrectly predicts a class as absent in an observation.

```
[confusionMatrix, order] = confusionmat(targetTest, predTest);
figure
```

```
cm = confusionchart(confusionMatrix, classes, ...
    'ColumnSummary','column-normalized', ...
    'RowSummary','row-normalized', ...
    'Title', 'GCN QM7 Confusion Chart');
```



The class-wise precision are the scores in the first row of the 'column summary' of the chart and the class-wise recall are the scores in the first column of the 'row summary' of the chart.

Split Data Function

The `splitData` function takes the `adjacencyData`, `coloumbData`, and `atomicNumber` data and randomly splits them into training, validation and test data in ratio 80:10:10. The function returns the corresponding split data `adjacencyDataSplit, coulombDataSplit, atomicNumberSplit` as cell arrays.

```
function [adjacencyDataSplit, coulombDataSplit, atomicNumberSplit] = splitData(adjacencyData, cou

adjacencyDataSplit = cell(1,3);
coulombDataSplit = cell(1,3);
atomicNumberSplit = cell(1,3);
```

```
numMolecules = size(adjacencyData, 3);

% Set initial random state for example reproducibility.
rng(0);

% Get training data
idx = randperm(size(adjacencyData, 3), floor(0.8*numMolecules));
adjacencyDataSplit{1} = adjacencyData(:,:,idx);
coulombDataSplit{1} = coulombData(:,:,idx);
atomicNumberSplit{1} = atomicNumber(idx,:);
adjacencyData(:,:,idx) = [];
coulombData(:,:,idx) = [];
atomicNumber(idx,:) = [];

% Get validation data
idx = randperm(size(adjacencyData, 3), floor(0.1*numMolecules));
adjacencyDataSplit{2} = adjacencyData(:,:,idx);
coulombDataSplit{2} = coulombData(:,:,idx);
atomicNumberSplit{2} = atomicNumber(idx,:);
adjacencyData(:,:,idx) = [];
coulombData(:,:,idx) = [];
atomicNumber(idx,:) = [];

% Get test data
adjacencyDataSplit{3} = adjacencyData;
coulombDataSplit{3} = coulombData;
atomicNumberSplit{3} = atomicNumber;

end
```

Preprocess Data Function

The `preprocessData` function preprocesses the input data as follows:

For each graph/molecule

- Remove padded zeros from `atomicNumber`.
- Concatenate the atomic number data with the atomic number data of other graph instances. It is necessary to concatenate the data since the example deals with multiple graph instances.
- Remove padded zeros from `adjacencyData`.
- Build a sparse block-diagonal matrix of the adjacency matrices of different graph instances. Each block in the matrix corresponds to the adjacency matrix of one graph instance. This step is also necessary because there are multiple graph instances in the example.
- Extract feature array from `coulombData`. The feature array is the non-zero diagonal elements of the Coulomb matrix in `coulombData`.
- Concatenate the feature array with feature arrays of other graph instances.

The function then converts the atomic number data to categorical arrays.

```
function [adjacency, features, labels] = preprocessData(adjacencyData, coulombData, atomicNumber

adjacency = sparse([]);
features = [];
labels = [];
for i = 1:size(adjacencyData, 3)
```

```
    % Remove padded zeros from atomicNumber
    tmpLabels = nonzeros(atomicNumber(i,:));
    labels = [labels; tmpLabels];

    % Get the indices of the un-padded data
    validIdx = 1:numel(tmpLabels);

    % Use the indices for un-padded data to remove padded zeros
    % from the adjacency data
    tmpAdjacency = adjacencyData(validIdx, validIdx, i);

    % Build the adjacency matrix into a block diagonal matrix
    adjacency = blkdiag(adjacency, tmpAdjacency);

    % Remove padded zeros from coulombData and extract the
    % feature array
    tmpFeatures = diag(coulombData(validIdx, validIdx, i));
    features = [features; tmpFeatures];
end

% Convert labels to categorical array
atomicNumbers = unique(labels);
atomNames = ["Hydrogen","Carbon","Nitrogen","Oxygen","Sulphur"];
labels = categorical(labels, atomicNumbers, atomNames);

end
```

Normalize Features Function

The `normalizeFeatures` function standardizes the input training, validation, and test feature data `features` using the mean and variance of the training data.

```
function features = normalizeFeatures(features)

% Get the mean and variance from the training data
meanFeatures = mean(features{1});
varFeatures = var(features{1}, 1);

% Standardize training, validation and test data
for i = 1:3
    features{i} = (features{i} - meanFeatures)./sqrt(varFeatures);
end

end
```

Model Function

The `model` function takes the feature matrix `dlX`, the adjacency matrix `A`, and the model parameters `parameters` and returns the network predictions. In a preprocessing step, the `model` function calculates the *normalized* adjacency matrix described earlier using the `normalizeAdjacency` function provided.

```
function dlY = model(dlX, A, parameters)

% Normalize adjacency matrix
L = normalizeAdjacency(A);

Z1 = dlX;
```

```
Z2 = L * Z1 * parameters.W1;
Z2 = relu(Z2) + Z1;

Z3 = L * Z2 * parameters.W2;
Z3 = relu(Z3) + Z2;

Z4 = L * Z3 * parameters.W3;
dlY = softmax(Z4, 'DataFormat', 'BC');

end
```

Normalize Adjacency Function

The `normalizeAdjacency` function calculates and returns the *normalized* adjacency matrix `normAdjacency` of the input adjacency matrix `adjacency`.

```
function normAdjacency = normalizeAdjacency(adjacency)

% Add self connections to adjacency matrix
adjacency = adjacency + speye(size(adjacency));

% Compute degree of nodes
degree = sum(adjacency, 2);

% Compute inverse square root of degree
degreeInvSqrt = sparse(sqrt(1./degree));

% Normalize adjacency matrix
normAdjacency = diag(degreeInvSqrt) * adjacency * diag(degreeInvSqrt);

end
```

Model Gradients Function

The `modelGradients` function takes the feature matrix `dlX`, the adjacency matrix `adjacencyTrain`, the one-hot encoded target data `T`, and the model parameters `parameters`, and returns the gradients of the loss with respect to the model parameters, the corresponding loss, and the network predictions.

```
function [gradients, loss, dlYPred] = modelGradients(dlX, adjacencyTrain, T, parameters)

dlYPred = model(dlX, adjacencyTrain, parameters);

loss = crossentropy(dlYPred, T, 'DataFormat', 'BC');

gradients = dlgradient(loss, parameters);

end
```

Accuracy Function

The accuracy function decodes the network predictions `YPred` and calculates accuracy using the decoded predictions and the target data `target`. The function returns the computed accuracy score and the decoded predictions `prediction`.

```
function [score, prediction] = accuracy(YPred, target, classes)
```

```
% Decode probability vectors into class labels
prediction = onehotdecode(YPred, classes, 2);
score = sum(prediction == target)/numel(target);

end
```

Train Network Using Cyclical Learning Rate for Snapshot Ensembling

This example shows how to train a network to classify images of objects using a cyclical learning rate schedule and snapshot ensembling for better test accuracy. In the example, you learn how to use a cosine function for the learning rate schedule, take snapshots of the network during training to create a model ensemble, and add L2-norm regularization (weight decay) to the training loss.

This example trains a residual network [1] on the CIFAR-10 data set [2] with a custom cyclical learning rate: for each iteration, the solver uses the learning rate given by a shifted cosine function [3] `alpha(t) = (alpha0/2)*cos(pi*mod(t-1,T/M)/(T/M)+1)`, where `t` is the iteration number, `T` is the total number of training iterations, `alpha0` is the initial learning rate, and `M` is the number of cycles/snapshots. This learning rate schedule effectively splits the training process into `M` cycles. Each cycle begins with a large learning rate that decays monotonically, forcing the network to explore different local minima. At the end of each training cycle, you take a snapshot of the network (that is, you save the model at this iteration) and later average the predictions of all the snapshot models, also known as snapshot ensembling [4], to improve the final test accuracy.

Prepare Data

Download the CIFAR-10 data set [2]. The data set contains 60,000 images. Each image is 32-by-32 in size and has three color channels (RGB). The size of the data set is 175 MB. Depending on your internet connection, the download process can take time.

```
datadir = tempdir;
downloadCIFARData(datadir);
```

Load the CIFAR-10 training and test images as 4-D arrays. The training set contains 50,000 images and the test set contains 10,000 images.

```
[XTrain,YTrain,XTest,YTest] = loadCIFARData(datadir);
classes = categories(YTrain);
numClasses = numel(classes);
```

You can display a random sample of the training images using the following code.

```
figure;
idx = randperm(size(XTrain,4),20);
im = imtile(XTrain(:,:,:,idx),'ThumbnailSize',[96,96]);
imshow(im)
```

Create an `augmentedImageDatastore` object to use for network training. During training, the datastore randomly flips the training images along the vertical axis and randomly translates them up to four pixels horizontally and vertically. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
imageSize = [32 32 3];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augimdsTrain = augmentedImageDatastore(imageSize,XTrain,YTrain, ...
    'DataAugmentation',imageAugmenter);
```

Define Network Architecture

Create a residual network [1] with six standard convolutional units (two units per stage) and a width of 16. The total network depth is 2*6+2 = 14. In addition, specify the average image using the `'Mean'` option in the image input layer.

```
netWidth = 16;
layers = [
    imageInputLayer(imageSize,'Name','input','Mean', mean(XTrain,4))
    convolution2dLayer(3,netWidth,'Padding','same','Name','convInp')
    batchNormalizationLayer('Name','BNInp')
    reluLayer('Name','reluInp')

    convolutionalUnit(netWidth,1,'S1U1')
    additionLayer(2,'Name','add11')
    reluLayer('Name','relu11')
    convolutionalUnit(netWidth,1,'S1U2')
    additionLayer(2,'Name','add12')
    reluLayer('Name','relu12')

    convolutionalUnit(2*netWidth,2,'S2U1')
    additionLayer(2,'Name','add21')
    reluLayer('Name','relu21')
    convolutionalUnit(2*netWidth,1,'S2U2')
    additionLayer(2,'Name','add22')
    reluLayer('Name','relu22')

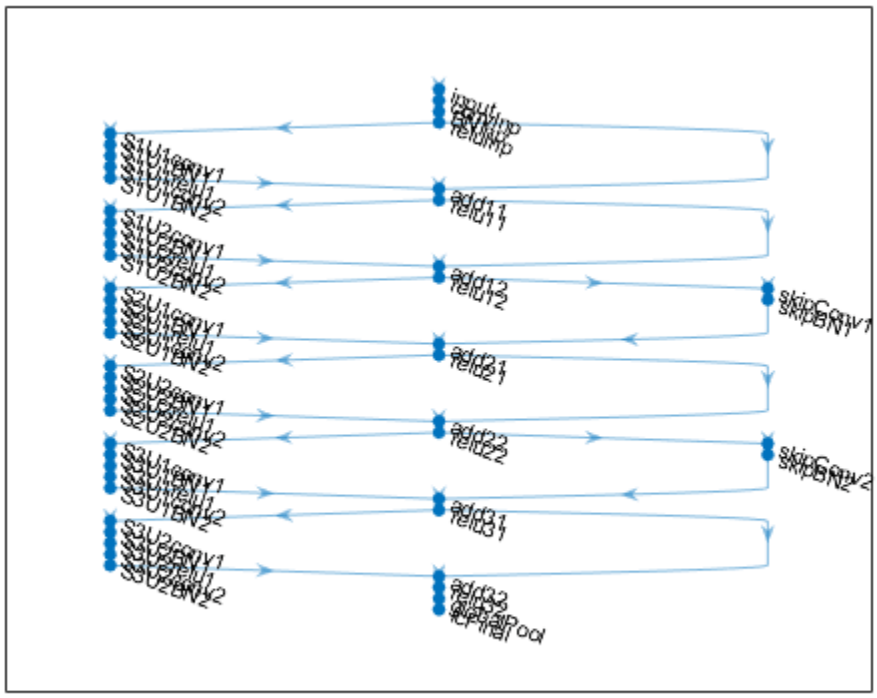
    convolutionalUnit(4*netWidth,2,'S3U1')
    additionLayer(2,'Name','add31')
    reluLayer('Name','relu31')
    convolutionalUnit(4*netWidth,1,'S3U2')
    additionLayer(2,'Name','add32')
    reluLayer('Name','relu32')

    averagePooling2dLayer(8,'Name','globalPool')
    fullyConnectedLayer(10,'Name','fcFinal')
    ];

lgraph = layerGraph(layers);
lgraph = connectLayers(lgraph,'reluInp','add11/in2');
lgraph = connectLayers(lgraph,'relu11','add12/in2');
skip1 = [
    convolution2dLayer(1,2*netWidth,'Stride',2,'Name','skipConv1')
    batchNormalizationLayer('Name','skipBN1')];
lgraph = addLayers(lgraph,skip1);
lgraph = connectLayers(lgraph,'relu12','skipConv1');
lgraph = connectLayers(lgraph,'skipBN1','add21/in2');
lgraph = connectLayers(lgraph,'relu21','add22/in2');
skip2 = [
    convolution2dLayer(1,4*netWidth,'Stride',2,'Name','skipConv2')
    batchNormalizationLayer('Name','skipBN2')];
lgraph = addLayers(lgraph,skip2);
lgraph = connectLayers(lgraph,'relu22','skipConv2');
lgraph = connectLayers(lgraph,'skipBN2','add31/in2');
lgraph = connectLayers(lgraph,'relu31','add32/in2');
```

Plot the ResNet architecture.

```
figure;
plot(lgraph)
```



Create a `dlnetwork` object from the layer graph.

```
dlnet = dlnetwork(lgraph);
```

Define Model Gradients Function

Create the helper function `modelGradients`, listed at the end of the example. The function takes in a `dlnetwork` object `dlnet and` a mini-batch of input data `dlX` with corresponding labels `Y,` and returns the gradients of the loss with respect to the learnable parameters in `dlnet`. This function also returns the loss and the state of the nonlearnable parameters of the network at a given iteration.

Specify Training Options

Specify the training options. Train for 200 epochs with a mini-batch size of 64.

```
numEpochs = 200;
miniBatchSize = 64;

numObservations = numel(YTrain);

velocity = [];
momentum = 0.9;
weightDecay = 1e-4;
```

Specify the training options specific to the cyclical learning rate. `Alpha0` is the initial learning rate and `numSnapshots` is the number of cycles or snapshots taken during training.

```
alpha0 = 0.1;
numSnapshots = 5;
epochsPerSnapshot = numEpochs./numSnapshots;
iterationsPerSnapshot = ceil(numObservations./miniBatchSize)*numEpochs./numSnapshots;
modelPrefix = "SnapshotEpoch";
```

Visualize the training progress in a plot.

```
plots = "training-progress";
```

Initialize the training figure.

```
if plots == "training-progress"
    [lossLine,learnRateLine] = plotLossAndLearnRate();
end
```

Train Model

Use `minibatchqueue` to process and manage mini-batches of images during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to one-hot encode the class labels.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
augimdsTrain.MiniBatchSize = miniBatchSize;

mbqTrain = minibatchqueue(augimdsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB',''});
```

Train the model using a custom training loop.For each epoch, shuffle the datastore, loop over mini-batches of data, and save the model (snapshot) if the current epoch is a multiple of `epochsPerSnapshot`. At the end of each epoch, display the training progress. For each mini-batch:

- Evaluate the model gradients and loss using `dlfeval` and the `modelGradients` function.
- Update the state of the nonlearnable parameters of the network.
- Determine the learning rate for the cyclical learning rate schedule.
- Update the network parameters using the `sgdmupdate` function.
- Plot the loss and learning rate at each iteration.

For this example, the training took approximately 14 hours on a NVIDIA™ TITAN RTX.

```
iteration = 0;
start = tic;
```

```
% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbqTrain);

    % Save snapshot model.
    if ~mod(epoch,epochsPerSnapshot)
        save(modelPrefix + epoch + ".mat",'dlnet');
    end

    % Loop over mini-batches.
    while hasdata(mbqTrain)
        iteration = iteration + 1;

        % Read mini-batch of data.
        [dlX,dlY] = next(mbqTrain);

        % Evaluate the model gradients and loss using dlfeval and the
        % modelGradients function.
        [gradients, loss, state] = dlfeval(@modelGradients,dlnet,dlX,dlY,weightDecay);

        % Update the state of nonlearnable parameters.
        dlnet.State = state;

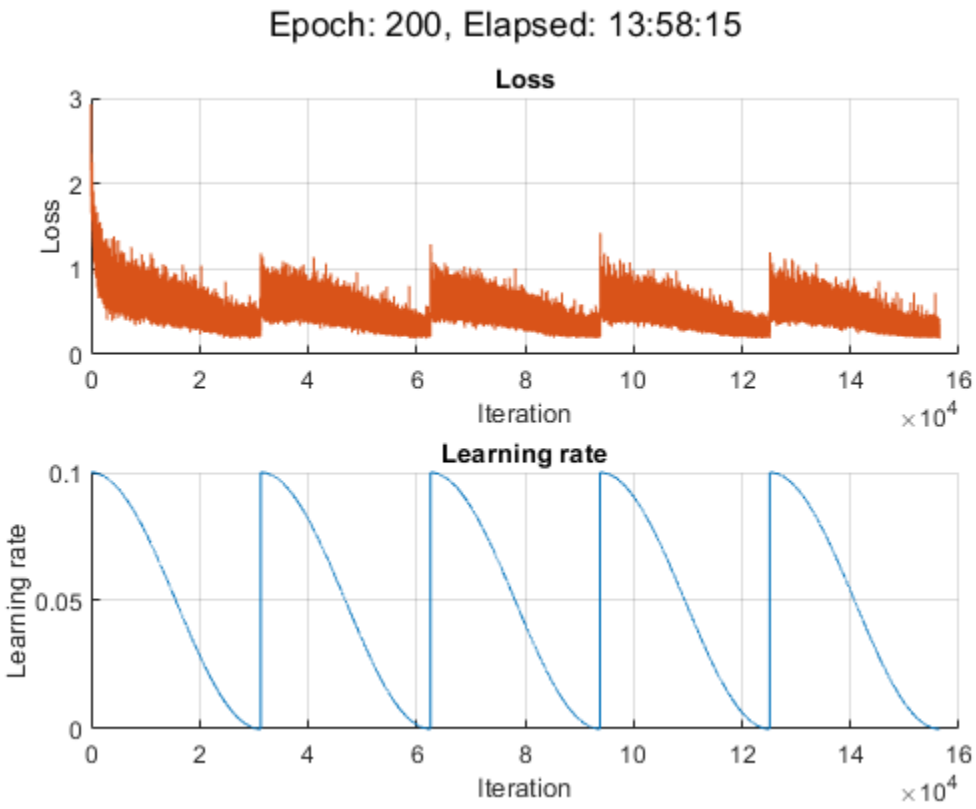
        % Determine learning rate for cyclical learning rate schedule.
        learnRate = 0.5*alpha0*(cos((pi*mod(iteration-1,iterationsPerSnapshot)./iterationsPerSnap

        % Update the network parameters using the SGDM optimizer.
        [dlnet.Learnables, velocity] = sgdmupdate(dlnet.Learnables, gradients, velocity, learnRa

        % Display the training progress.
        if plots == "training-progress"
                D = duration(0,0,toc(start),'Format','hh:mm:ss');
                addpoints(lossLine,iteration,double(gather(extractdata(loss))))
                addpoints(learnRateLine, iteration, learnRate);
                sgtitle("Epoch: " + epoch + ", Elapsed: " + string(D))
                drawnow
        end

    end

end
```



Create Snapshot Ensemble and Test Model

Combine the M snapshots of the network taken during training to form a final ensemble and test the classification accuracy of the model. The ensemble predictions correspond to the average of the output of the fully connected layer from all M individual models.

Test the model on the test data provided with the CIFAR-10 data set. Manage the test data set using a `minibatchqueue` object with the same setting as the training data.

```
augimdsTest = augmentedImageDatastore(imageSize,XTest,YTest);
augimdsTest.MiniBatchSize = miniBatchSize;

mbqTest = minibatchqueue(augimdsTest,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB',''});
```

Evaluate the accuracy of each snapshot network. Use the `modelPredictions` function defined at the end of this example to iterate over all the data in the test data set. The function returns the output of the fully connected layer from the model, the predicted classes, and the comparison with the true class.

```
modelName = cell(numSnapshots+1,1);
fcOutput = zeros(numClasses,numel(YTest),numSnapshots+1);
classPredictions = cell(1,numSnapshots+1);
modelAccuracy = zeros(numSnapshots+1,1);
```

```
for m = 1:numSnapshots
    modelName{m} = modelPrefix + m*epochsPerSnapshot;
    load(modelName{m} + ".mat");

    reset(mbqTest);
    [fcOutputTest,classPredTest,classCorrTest] = modelPredictions(dlnet,mbqTest,classes);

    fcOutput(:,:,m) = fcOutputTest;
    classPredictions{m} = classPredTest;
    modelAccuracy(m) = 100*mean(classCorrTest);

    disp(modelName{m} + " accuracy: " + modelAccuracy(m) + "%")
end
```

```
SnapshotEpoch40 accuracy: 88.35%
SnapshotEpoch80 accuracy: 89.93%
SnapshotEpoch120 accuracy: 90.51%
SnapshotEpoch160 accuracy: 90.33%
SnapshotEpoch200 accuracy: 90.63%
```

To determine the output of the ensemble networks, compute the average of the fully connected output of each snapshot network. Find the predicted classes from the ensemble network using the `onehotdecode` function. Compare with the true classes to evaluate the accuracy of the ensemble.

```
fcOutput(:,:,end) = mean(fcOutput(:,:,1:end-1),3);
classPredictions{end} = onehotdecode(softmax(fcOutput(:,:,end)),classes,1,'categorical');

classCorrEnsemble = classPredictions{end} == YTest';
modelAccuracy(end) = 100*mean(classCorrEnsemble);

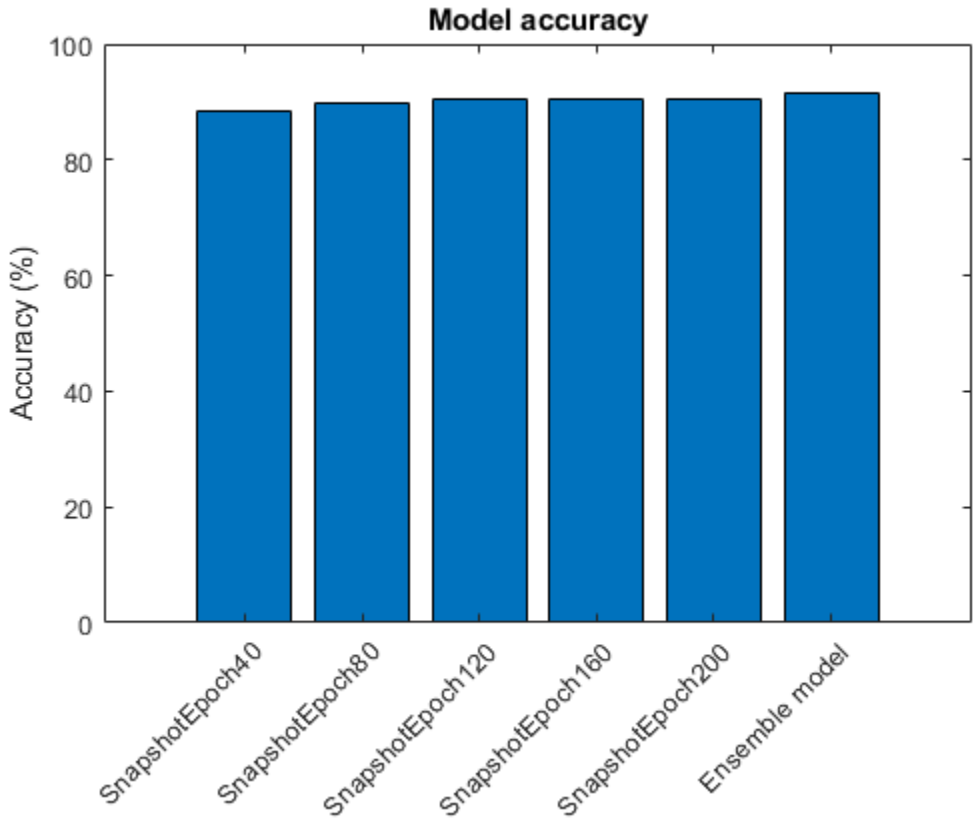
modelName{end} = "Ensemble model";
disp("Ensemble accuracy: " + modelAccuracy(end) + "%")
```

```
Ensemble accuracy: 91.59%
```

Plot Accuracy

Plot the accuracy on the test data set for all snapshot models and the ensemble model.

```
figure;bar(modelAccuracy);
ylabel('Accuracy (%)');
xticklabels(modelName)
xtickangle(45)
title('Model accuracy')
```



Helper Functions

Model Gradients Function

The `modelGradients` function takes in a `dlnetwork` object `dlnet`, a mini-batch of input data `dlX`, the labels `Y`, and the parameter for weight decay. The function returns the gradients, the loss, and the state of the nonlearnable parameters. To compute the gradients automatically, use the `dlgradient` function.

```
function [gradients,loss,state] = modelGradients(dlnet,dlX,Y,weightDecay)

    [dlYPred,state] = forward(dlnet,dlX);
    dlYPred = softmax(dlYPred);

    loss = crossentropy(dlYPred, Y);

    % L2-regularization (weight decay)
    allParams = dlnet.Learnables(dlnet.Learnables.Parameter == "Weights" | dlnet.Learnables.Paran
    l2Norm = cellfun(@(x) sum(x.^2,'All'),allParams,'UniformOutput',false);
    l2Norm = sum(cat(1,l2Norm{:}));
    loss = loss + weightDecay*0.5*l2Norm;

    gradients = dlgradient(loss,dlnet.Learnables);
end
```

Model Predictions Function

The `modelPredictions` function takes as input a `dlnetwork` object `dlnet`, a `minibatchqueue` of input data `mbq`, and computes the model predictions by iterating over all data in the `minibatchqueue`. The function uses the `onehotdecode` function to find the predicted class with the highest score and then compares the prediction with the true class. The function returns the network output, the class predictions, and a vector of ones and zeros that represents correct and incorrect predictions.

```
function [rawPredictions,classPredictions,classCorr] = modelPredictions(dlnet,mbq,classes)
    rawPredictions = [];
    classPredictions = [];
    classCorr = [];

    while hasdata(mbq)
        [dlX,dlY] = next(mbq);

        % Make predictions
        dlYPred = predict(dlnet,dlX);
        rawPredictions = [rawPredictions extractdata(gather(dlYPred))];

        % Convert network output to probabilities and determine predicted
        % classes
        dlYPred = softmax(dlYPred);
        YPredBatch = onehotdecode(dlYPred,classes,1);
        classPredictions = [classPredictions YPredBatch];

        % Compare predicted and true classes
        Y = onehotdecode(dlY,classes,1);
        classCorr = [classCorr YPredBatch == Y];
    end

end
```

Plot Loss and Learning Rate Function

The `plotLossAndLearnRate` function initiliaizes the plots for displaying the loss and learning rate at each iteration during training.

```
function [lossLine, learnRateLine] = plotLossAndLearnRate()
    figure

    subplot(2,1,1);
    lossLine = animatedline('Color',[0.85 0.325 0.098]);
    title('Loss');
    xlabel('Iteration')
    ylabel('Loss')
    grid on

    subplot(2,1,2);
    learnRateLine = animatedline('Color',[0 0.447 0.741]);
    title('Learning rate');
    xlabel('Iteration')
    ylabel('Learning rate')
    grid on
end
```

Convolutional Unit Function

The `convolutionalUnit(numF,stride,tag)` function creates an array of layers with two convolutional layers and corresponding batch normalization and ReLU layers. `numF` is the number of convolutional filters, `stride` is the stride of the first convolutional layer, and `tag` is a tag that is prepended to all layer names.

```
function layers = convolutionalUnit(numF,stride,tag)
    layers = [
        convolution2dLayer(3,numF,'Padding','same','Stride',stride,'Name',[tag,'conv1'])
        batchNormalizationLayer('Name',[tag,'BN1'])
        reluLayer('Name',[tag,'relu1'])
        convolution2dLayer(3,numF,'Padding','same','Name',[tag,'conv2'])
        batchNormalizationLayer('Name',[tag,'BN2'])];
end
```

Data Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label data from the incoming cell arrays and concatenate into a categorical array along the second dimension.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y] = preprocessMiniBatch(XCell,YCell)
    % Extract image data from cell and concatenate
    X = cat(4,XCell{:});
    % Extract label data from cell and concatenate
    Y = cat(2,YCell{:});

    % One-hot encode labels
    Y = onehotencode(Y,1);
end
```

Deploy Imported Network with MATLAB Compiler

This topic shows how to import a pretrained network and then deploy the imported network using MATLAB Compiler. You can import a pretrained TensorFlow-Keras or ONNX (Open Neural Network Exchange) network using `importKerasNetwork` or `importONNXNetwork`, respectively. These functions require the corresponding support package: Deep Learning Toolbox Converter for TensorFlow Models or Deep Learning Toolbox Converter for ONNX Model Format. If the required support package is not installed, then `importKerasNetwork` or `importONNXNetwork` provides a download link.

The imported network might include Keras or ONNX layers that MATLAB Coder does not support for deployment. For a list of supported layers, see “Networks and Layers Supported for Code Generation” (MATLAB Coder). In this case, you can deploy the imported network as a standalone application using MATLAB Compiler. The standalone executable you create with MATLAB Compiler is independent of MATLAB; therefore, you can deploy it to users who do not have access to MATLAB.

In the deployment workflow, you first define a classification function that loads the imported network and predicts class labels. Then, you compile the classification function into a standalone application either programmatically, using the `mcc` function, or interactively, using the **Application Compiler** app.

- Use `mcc` if you prefer to work at the command line. You must manually specify the path to the Keras or ONNX layers folder that MATLAB Compiler includes in the standalone application. For an example of deploying an imported Keras network, see “Deploy Imported Pretrained Network Using mcc” on page 18-406. You can use the same workflow to deploy a network imported from ONNX using `mcc`.
- Use the **Application Compiler** app if you prefer an interactive workflow. You can access the app using the `deploytool` function or the apps gallery. The app suggests the support packages that MATLAB Compiler can include in the standalone application. Then, the app automatically includes the paths to the Keras or ONNX layers folder in the selected support package. For an example of deploying an imported Keras network, see “Deploy Imported Pretrained Network Using Application Compiler App” on page 18-409. You can use the same workflow to deploy a network imported from ONNX using the **Application Compiler** app.

Deploy Imported Pretrained Network Using mcc

Import a pretrained Keras network to classify an image, and then compile the classification function into a standalone application using `mcc`. This example uses a helper function that imports the network with `importKerasNetwork`, specifies the class names, and saves the imported network. To view the code for this function, see Helper Function on page 18-0 .

Download Required Support Package

The function `importKerasNetwork` requires the Deep Learning Toolbox Converter for TensorFlow Models support package. If this support package is not installed, `importKerasNetwork` provides a download link to the required support package in the Add-On Explorer. A recommended practice is to download the support package to the default location for the version of MATLAB you are running. However, you can specify a different location during installation.

Display the support package root and the release number for the version of MATLAB you are running. You need this information when specifying the path to the Keras layers folder later in the example. The support package is located in the default location for MATLAB R2020b.

```
supportPKGFolder = matlabshared.supportpkg.getSupportPackageRoot
```

```
supportPKGFolder =
'C:\ProgramData\MATLAB\SupportPackages\R2020b'
```

```
version('-release')
```

```
ans =
'2020b'
```

Import Pretrained Network

Import and save the pretrained network `digitsDAGnet`, which contains a DAG (directed acyclic graph) convolutional neural network that classifies images of digits.

```
net = importDAGnet
```

```
net =
  DAGNetwork with properties:

         Layers: [13×1 nnet.cnn.layer.Layer]
    Connections: [13×2 table]
     InputNames: {'input_1'}
    OutputNames: {'ClassificationLayer_activation_1'}
```

Read and Save Image

Read and save the image to classify.

```
digitDatasetPath = fullfile(toolboxdir('nnet'),'nndemos','nndatasets','DigitDataset');
I = imread(fullfile(digitDatasetPath,'5','image4009.png'));
imwrite(I,'testImg.png')
```

Display the image.

```
imshow(I)
```

Define Classification Function

Define a classification function named `KerasNetClassify` that accepts a digit image, loads the imported Keras network, and predicts the class label using the loaded network.

```
type KerasNetClassify.m
```

```
function KerasNetClassify(imFile)
% KERASNETCLASSIFY Classify image using imported network
% KERASNETCLASSIFY loads the imported Keras pretrained network
% 'digitsDAGnet.mat', reads the image in imFile, and predicts the image
```

```
% label using the imported network.
load('digitsDAGnet.mat','net');
I = imread(imFile);
label = classify(net, I);
disp(label)
end
```

Create Executable File

To deploy the imported network using `mcc`, you must manually specify the path to the Keras layers folder. The layers folder is located in the support package folder. Display the path to the Keras layers folder.

```
fullfile(supportPKGFolder,'\toolbox\nnet\supportpackages\keras_importer\+nnet\+keras\+layer')
```

```
ans =
'C:\ProgramData\MATLAB\SupportPackages\R2020b\toolbox\nnet\supportpackages\keras_importer\+nnet\+
```

Compile the classification function into the standalone executable `KerasNetClassify.exe` by using the `mcc` function. Specify the path to the Keras layers folder that MATLAB Compiler includes in the standalone application by using `-a path`.

```
mcc -m KerasNetClassify.m...
    -a 'C:\ProgramData\MATLAB\SupportPackages\R2020b\toolbox\nnet\supportpackages\keras_importer\
    -n
```

Classify Image

Compare the labels classified using `classify`, `KerasNetClassify.m`, and `KerasNetClassify.exe`.

```
classify(net,I)
```

```
ans = categorical
     5
```

```
KerasNetClassify('testImg.png')
```

```
     5
```

```
!KerasNetClassify.exe 'testImg.png'
```

```
     5
```

All three ways to classify the image return the same label.

Helper Function

This section provides the code of the `importDAGnet` helper function. The `importDAGnet` function imports the pretrained network in the file `digitsDAGnet.h5`, specifies the class names, and saves the imported network to `digitsDAGnet.mat`.

```
function net = importDAGnet

    % Specify the model file.
    modelfile = 'digitsDAGnet.h5';
```

```
    % Specify the class names.
    classNames = {'0','1','2','3','4','5','6','7','8','9'};

    % Import the Keras network with the class names.
    net = importKerasNetwork(modelfile,'Classes',classNames);

    % Save the imported network to a MAT file.
    save('digitsDAGnet.mat', 'net');

end
```

Deploy Imported Pretrained Network Using Application Compiler App

Import the pretrained Keras network `digitsDAGnet` to classify an image, and then compile the classification function into a standalone application using the **Application Compiler** app.

Import Pretrained Network

Use `importKerasNetwork` to import the `digitsDAGnet` network, and then save it to a MAT file. The function `importKerasNetwork` requires the Deep Learning Toolbox Converter for TensorFlow Models support package. If this support package is not installed, `importKerasNetwork` provides a download link to the required support package in the Add-On Explorer. (For more details on how to import the pretrained network and save the image to classify, see “Deploy Imported Pretrained Network Using mcc” on page 18-406.)

Define Classification Function

Define a classification function named `KerasNetClassify` that accepts a digit image, loads the imported Keras network, and predicts the class label using the loaded network.

```
function KerasNetClassify(imFile)
% KERASNETCLASSIFY Classify image using imported network
% KERASNETCLASSIFY loads the imported Keras pretrained network
% 'digitsDAGnet.mat', reads the image in imFile, and predicts the image
% label using the imported network.
load('digitsDAGnet.mat','net');
I = imread(imFile);
label = classify(net, I);
disp(label)
end
```

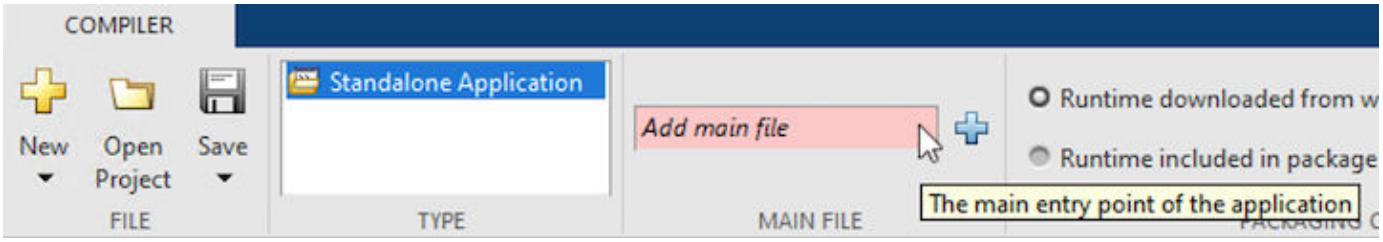
Create Executable File

Open a list of application deployment apps by using the `deploytool` function.

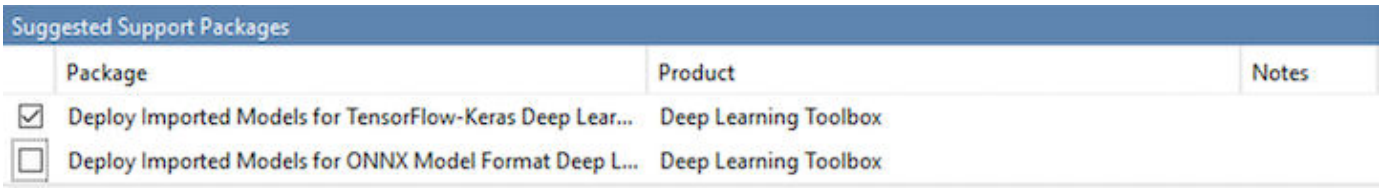
```
deploytool
```

In the **MATLAB Compiler** window, click **Application Compiler**. (You can also open the app by selecting it from the apps gallery, available from the **Apps** tab.)

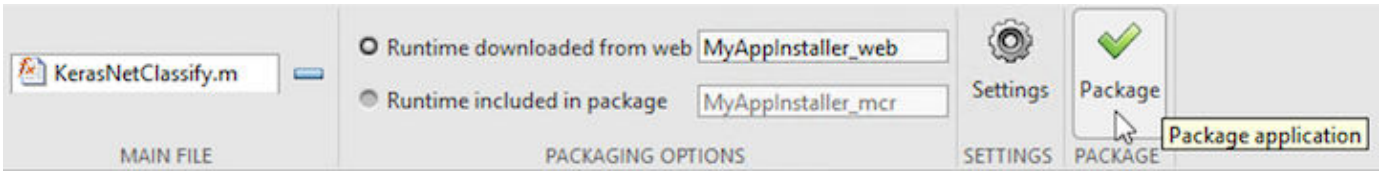
In the **Main File** section of the **Compiler** tab, add the main file of the application by clicking the plus sign. In the **Add Files** dialog box, specify the main file as the classification function `KerasNetClassify.m`.



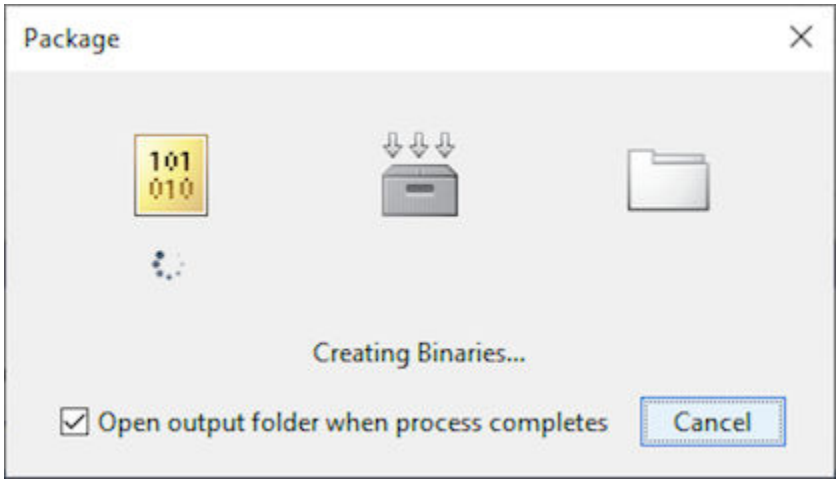
The app suggests software support packages from the installed support packages, which the executable can include. Because you have installed the Deep Learning Toolbox Converter for TensorFlow Models and Deep Learning Toolbox Converter for ONNX Model Format support packages, the app displays both. You must select the Deep Learning Toolbox Converter for TensorFlow Models support package. Selecting the Deep Learning Toolbox Converter for ONNX Model Format support package does not influence the execution of the application, but unnecessarily increases the application footprint.



In the **Package** section, click **Package** to save the standalone application.



The software compiles the standalone application. The default name for the output folder is `KerasNetClassify`, and the executable file `KerasNetClassify.exe` is located in the subfolder `for_redistribution_files_only`.



Classify Image

Copy the image file `testImg.png` (image of digit 5) to the folder containing the executable file. Change the current folder to the folder containing the executable file.

```
copyfile('testImg.png','KerasNetClassify\for_redistribution_files_only')
cd('KerasNetClassify\for_redistribution_files_only')
```

Run the executable file `KerasNetClassify.exe`, which you created with the **Application Compiler** app, to classify the image `testImg.png`.

```
!KerasNetClassify.exe testImg.png
```

```
     5
```

The classification label returned by `KerasNetClassify.exe` is correct.

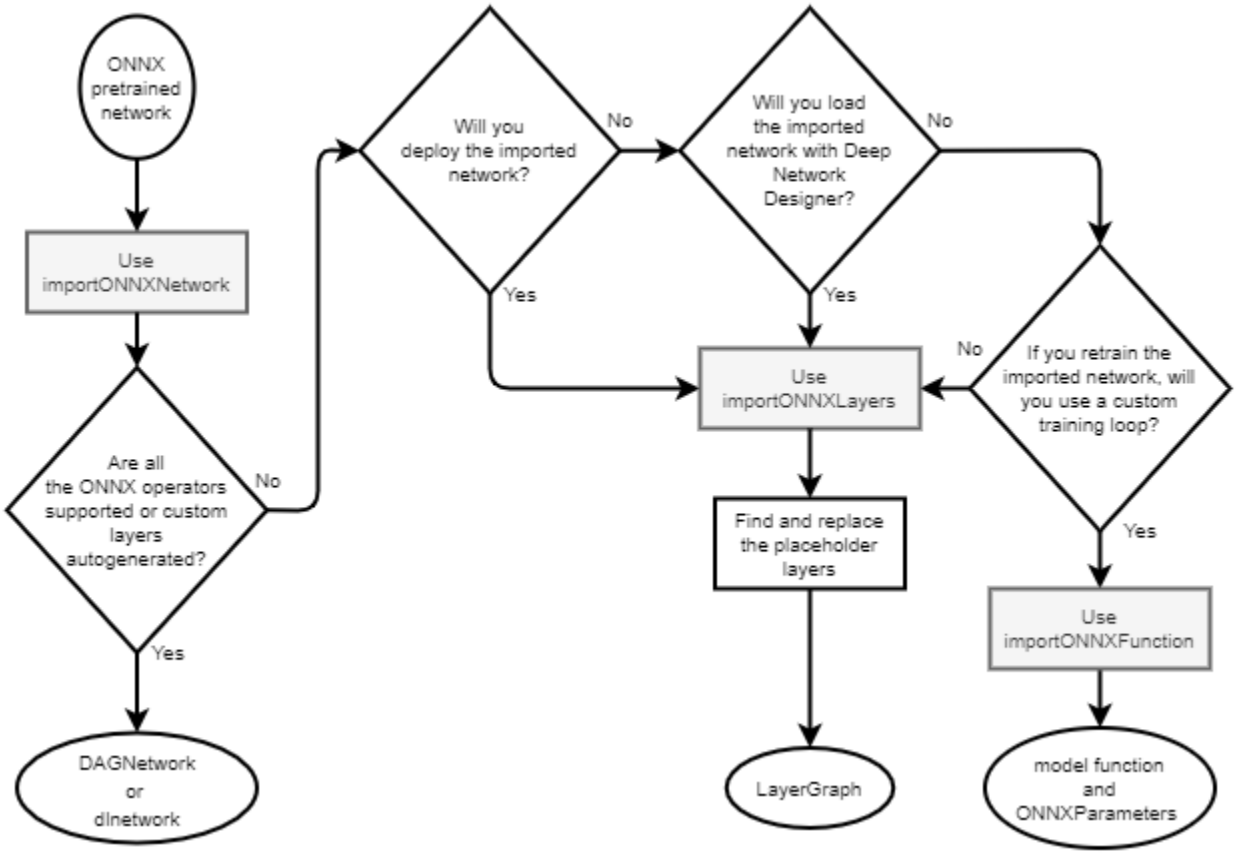
Select Function to Import ONNX Pretrained Network

Deep Learning Toolbox Converter for ONNX Model Format provides three functions to import a pretrained ONNX (Open Neural Network Exchange) network: `importONNXNetwork`, `importONNXLayers`, and `importONNXFunction`.

This flow chart illustrates which import function best suits different scenarios.



Note By default, `importONNXNetwork` and `importONNXLayers` try to generate a custom layer when the software cannot convert an ONNX operator into an equivalent built-in MATLAB layer. For a list of operators for which the software supports conversion, see “ONNX Operators Supported for Conversion into Built-In MATLAB Layers”.

`importONNXNetwork` and `importONNXLayers` save the generated custom layers in the package `+PackageName` in the current folder.

`importONNXNetwork` and `importONNXLayers` do not automatically generate a custom layer for each ONNX operator that is not supported for conversion into a built-in MATLAB layer.

Decisions

This table describes each decision in the workflow for selecting an ONNX import function.

Decision	Description
Are all the ONNX operators supported for conversion into equivalent built-in MATLAB layers or can the software automatically generate custom layers?	• If the imported network contains an ONNX operator not supported for conversion into a built-in MATLAB layer (see “ONNX Operators Supported for Conversion into Built-In MATLAB Layers”) and `importONNXNetwork` does not generate a custom layer, then `importONNXNetwork` returns an error. • If the imported network contains an ONNX operator not supported for conversion into a built-in MATLAB layer and `importONNXLayers` does not generate a custom layer, then `importONNXLayers` inserts a placeholder layer in place of the unsupported layer. • `importONNXFunction` supports most ONNX operators. For more information, see “ONNX Operators That importONNXFunction Supports”.
Will you deploy the imported network?	If you use `importONNXNetwork` or `importONNXLayers`, you can generate code for the imported network. To create a `DAGNetwork` object for code generation, see “Load Pretrained Networks for Code Generation” (MATLAB Coder).
Will you load the imported network with Deep Network Designer?	If you use `importONNXNetwork` or `importONNXLayers`, you can load the imported network with the **Deep Network Designer** app.
If you retrain the imported network, will you use a custom training loop?	• If you use `importONNXFunction`, you can retrain the imported network only with a custom training loop. For an example, see “Train Imported ONNX Function Using Custom Training Loop”. • Use `importONNXNetwork` with `TargetNetwork` specified as `"dlnetwork"` to import the network as a `dlnetwork` object. A `dlnetwork` enables support for custom training loops using automatic differentiation. • Use `importONNXLayers` with `TargetNetwork` specified as `"dlnetwork"` to import the network as a `LayerGraph` object compatible with a `dlnetwork` object. Then convert the layer graph to a `dlnetwork` by using `dlnetwork`. • For more information about training options, see “Train Deep Learning Model in MATLAB” on page 18-3.

Actions

This table describes each action in the workflow for selecting an ONNX import function.

Action	Description
Use `importONNXNetwork`	`importONNXNetwork` returns a `DAGNetwork` or `dlnetwork` object that is ready to use for prediction (for more information, see the `TargetNetwork` name-value argument). Predict class labels by using the `classify` function on the `DAGNetwork` object or the `predict` function on the `dlnetwork` object.
Use `importONNXLayers`	`importONNXLayers` returns a `LayerGraph` object compatible with a `DAGNetwork` or `dlnetwork` object (for more information, see the `TargetNetwork` name-value argument). `importONNXLayers` inserts placeholder layers in the place of unsupported layers. Find and replace the placeholder layers. Then, you can assemble the layer graph by using `assembleNetwork`, which returns a `DAGNetwork` object, or convert the layer graph to a `dlnetwork` object by using `dlnetwork`.
Use `importONNXFunction`	`importONNXFunction` returns an `ONNXParameters` object, which contains the network parameters, and a model function (see “Imported ONNX Model Function”), which contains the network architecture. The `ONNXParameters` object and the model function are ready to use for prediction. For an example, see “Predict Using Imported ONNX Function”.
Find and replace the placeholder layers	To find the names and indices of the placeholder layers in the imported network, use the `findPlaceholderLayers` function. You then can replace a placeholder layer with a new layer that you define. To replace a layer, use `replaceLayer`.

Classify Sequence of Images in Simulink with Imported TensorFlow Network

This example shows how to import a pretrained TensorFlow™ network in the saved model format by using `importTensorFlowNetwork`, and then use the Predict block to classify a sequence of images in Simulink®. The imported network contains layers that are not supported for conversion into built-in MATLAB® layers. `importTensorFlowNetwork` automatically generates custom layers when you import these layers. The Predict block predicts responses for the data at the input by using the trained network that you specify using the block parameters.

`importTensorFlowNetwork` requires the Deep Learning Toolbox™ Converter for TensorFlow Models support package. If this support package is not installed, then `importTensorFlowNetwork` provides a download link.

Load Image Data

Load the digit sample data as an image datastore. `imageDatastore` automatically labels the images based on folder names and stores the data as an `ImageDatastore` object.

```
digitDatasetPath = fullfile(matlabroot,"toolbox","nnet","nndemos", ...
    "nndatasets","DigitDataset");
imds = imageDatastore(digitDatasetPath, ...
    IncludeSubfolders=true,LabelSource="foldernames");
```

For reproducibility, specify the seed for the MATLAB random number generator. Randomly select eight images from the image datastore, create the array of images `inputIms`, and display the selected images by using `montage` (Image Processing Toolbox).

```
rng("default")
perm = randperm(10000,8);
for i = 1:8
    inputIms(:,:,:,i) = imread(imds.Files{perm(i)});
end
montage(inputIms,size=[1 NaN]);
```

Import Pretrained TensorFlow Network

Specify the model folder that contains the pretrained network `digitsDAGnetwithnoise` in the saved model format. `digitsDAGnetwithnoise` can classify images of digits.

```
if ~exist("digitsDAGnetwithnoise","dir")
    unzip("digitsDAGnetwithnoise.zip")
end
modelFolder = "./digitsDAGnetwithnoise";
```

Specify the class names.

```
classNames = {'0','1','2','3','4','5','6','7','8','9'};
```

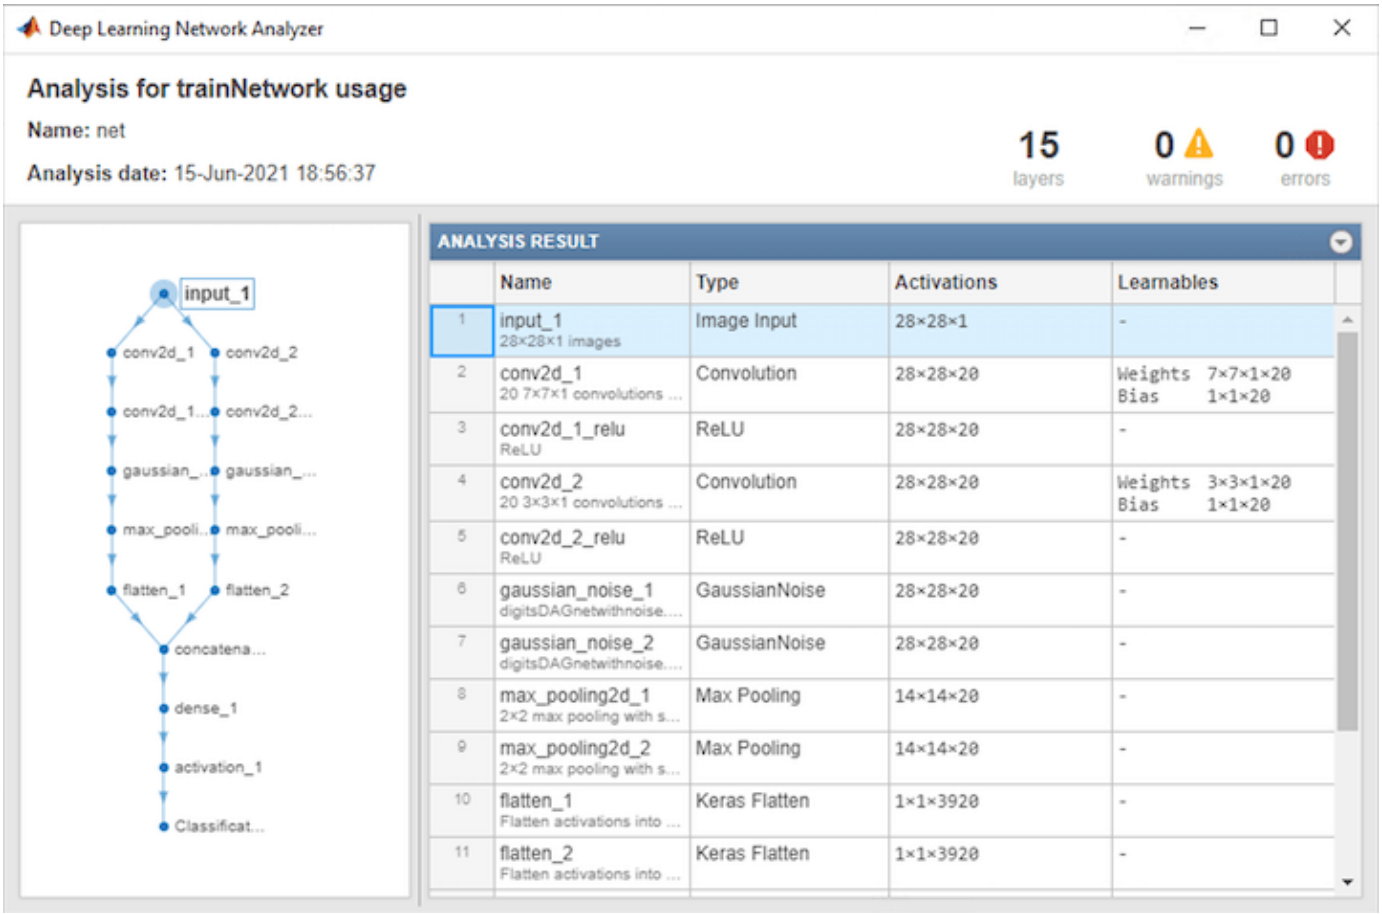
Import a TensorFlow network in the saved model format. By default, `importTensorFlowNetwork` imports the network as a `DAGNetwork` object.

```
net = importTensorFlowNetwork(modelFolder,Classes=classNames);
```

```
Importing the saved model...
Translating the model, this may take a few minutes...
Finished translation. Assembling network...
Import finished.
```

Analyze the imported network. `analyzeNetwork` displays an interactive plot of the network architecture and a table containing information about the network layers.

```
analyzeNetwork(net)
```



The imported network contains layers that are not supported for conversion into built-in MATLAB layers. The software automatically generates the custom layers `gaussian_noise_1` and `gaussian_noise_2`. The function `importTensorFlowNetwork` saves each generated custom layer to a separate `.m` file in the package `+digitsDAGnetwithnoise` in the current folder. For more information on these generated custom layers, see “Import TensorFlow Network with Autogenerated Custom Layers”.

Save the imported network in a MAT file.

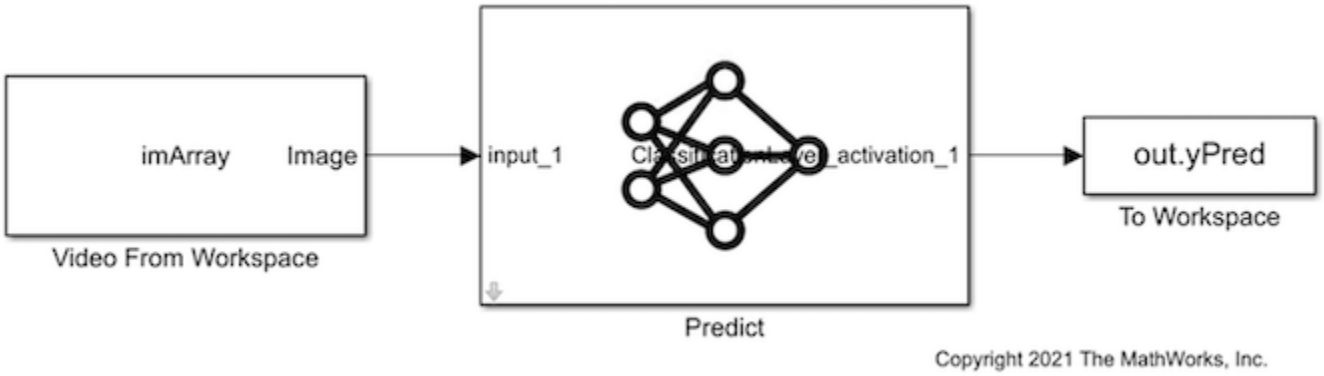
```
filename = "digitsNet.mat";
save(filename,"net")
```

Create Simulink Model

This example provides the Simulink model `slexDigitsImportedNetworkPredictExample.slx`. You can open the Simulink model (provided in this example) or create a new model by following the steps described in this section.

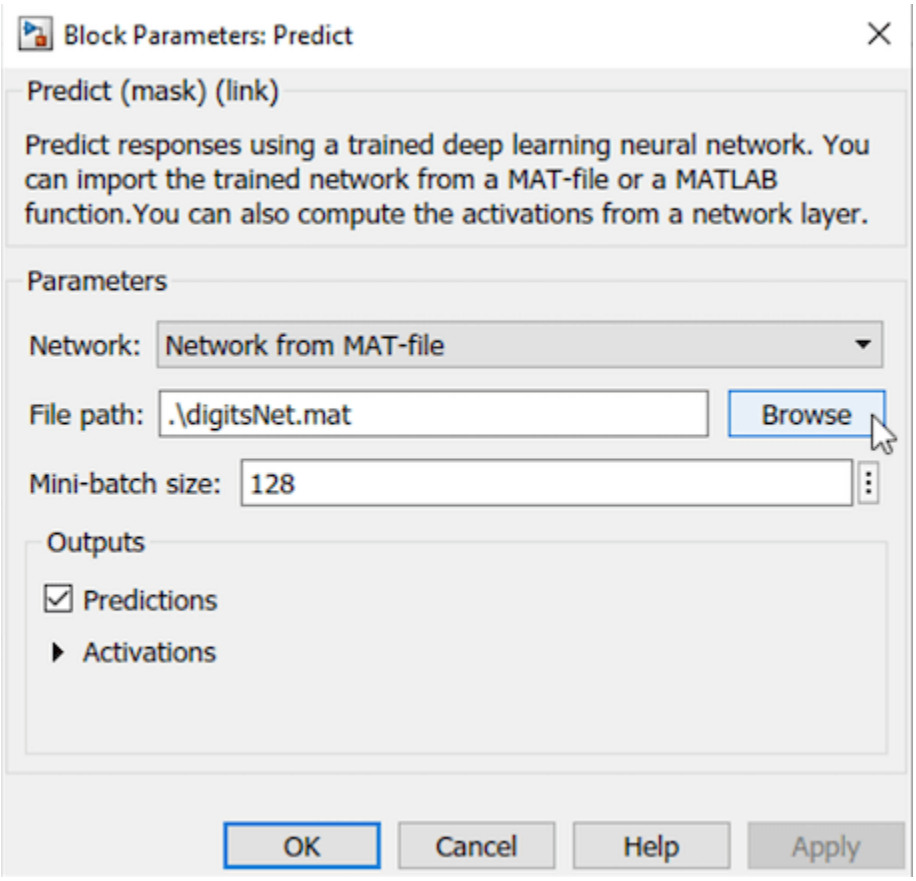
Open the Simulink model `slexDigitsImportedNetworkPredictExample.slx`.

```
SimMdlName = "slexDigitsImportedNetworkPredictExample";
open_system(SimMdlName)
```

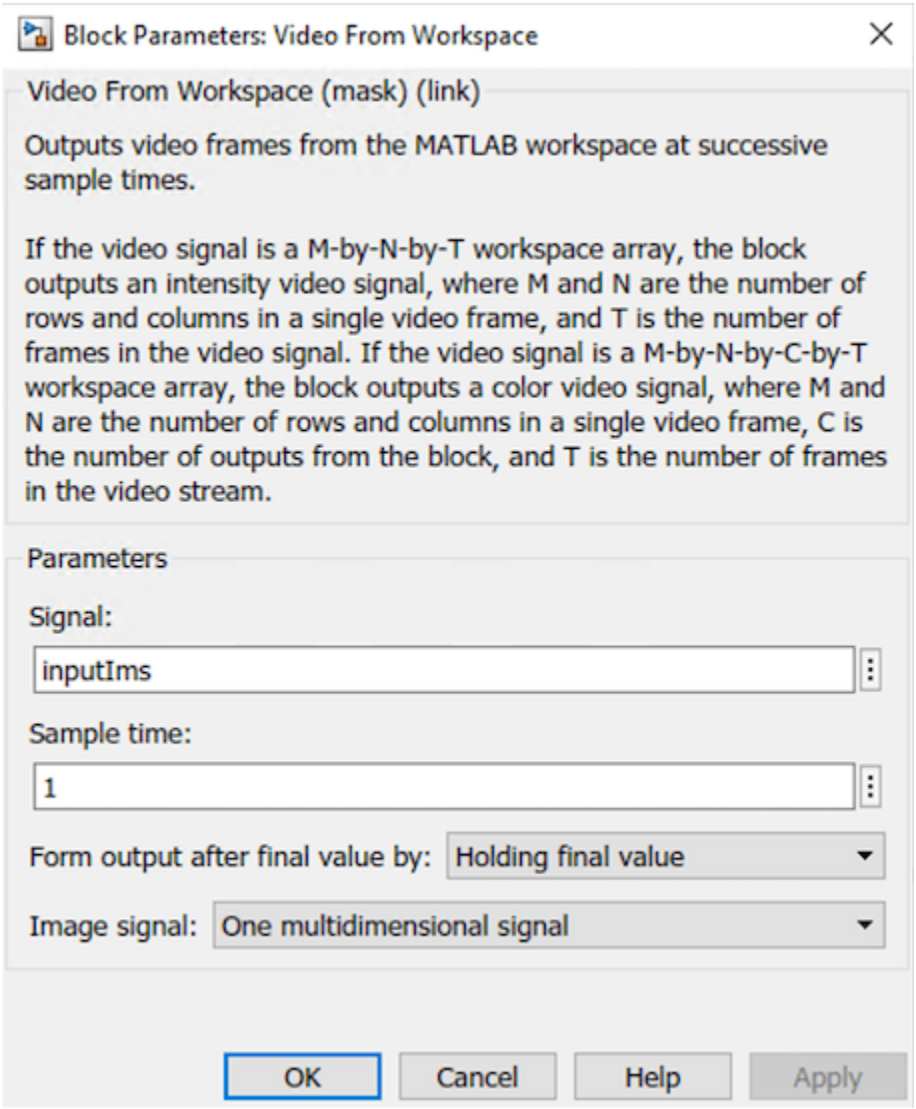


1. To create a new Simulink model, open the **Blank Model** template and add the Predict block from the Deep Learning Toolbox™ library. The Predict block predicts responses for the data at the input by using the trained network that you specify using the block parameters. The input to the block can be an *h*-by-*w*-by-*c*-by-*N* numeric array, where *h*, *w*, and *c* are the height, width, and number of channels of the images, respectively, and *N* is the number of images.

Double-click the Predict block to open the Block Parameters dialog box. Select **`Network from MAT-file`** for the **Network** parameter. Click **Browse** in the **File Path** section to specify the network as the `digitsNet.mat` network in the current folder.



2. Insert the Video from Workspace block from the Computer Vision Toolbox™ library. Double-click the Video from Workspace block to open the Block Parameters dialog box. Specify **Signal** as `inputIms`, **Sample time** as 1, and **Form output after final value by** as **Holding final value**.



3. Check if the size of the input images matches the network input size. If they do not match, you must resize the input data by adding the Resize block from the Computer Vision Toolbox library to the model.

Display the size of the image and the input size of the network.

```
size(inputIms)
```

```
ans = 1×4

    28    28     1     8
```

```
netInputSize = net.Layers(1).InputSize
```

```
netInputSize = 1×3

    28    28     1
```

The input is a sequence of eight grayscale (one-channel) images that are 28-by-28 pixels in size. The image size matches the network input size.

4. Add a To Workspace block to the model and change the variable name to `yPred`. Connect the Video from Workspace block to the input of the Predict block and the To Workspace block to the output of the Predict block.

5. Open the Configuration Parameters dialog box. On the **Modeling** tab, click **Model Settings**. Under **Solver selection**, set **Type** to `Fixed-step`, and set **Solver** to `discrete (no continuous states)`.

Predict Using Simulink Model

Simulate the model and save the simulation output to `modelOutput`. The field `modelOutput.yPred.Data` contains the classification results.

```
modelOutput = sim(SimMdlName)
```

```
modelOutput =
  Simulink.SimulationOutput:

                    tout: [8x1 double]
                   yPred: [1x1 timeseries]

     SimulationMetadata: [1x1 Simulink.SimulationMetadata]
           ErrorMessage: [0x0 char]
```

Display the sequence of images and the classification results.

```
tiledlayout(1,12,TileSpacing="None");
for i = 1:size(inputIms,4)
    nexttile
    imshow(inputIms(:,:,:,i))
    label = modelOutput.yPred.Data(:,:,i)==1;
    title([classNames{label}],FontSize=20)
end
```

List of Functions with dlarray Support

Deep Learning Toolbox Functions with dlarray Support

These tables list and briefly describe the Deep Learning Toolbox functions that operate on `dlarray` objects.

Deep Learning Operations

Function	Description
`avgpool`	The average pooling operation performs downsampling by dividing the input into pooling regions and computing the average value of each region.
`batchnorm`	The batch normalization operation normalizes the input data across all observations for each channel independently. To speed up training of the convolutional neural network and reduce the sensitivity to network initialization, use batch normalization between convolution and nonlinear operations such as `relu`.
`crossentropy`	The cross-entropy operation computes the cross-entropy loss between network predictions and target values for single-label and multi-label classification tasks.
`crosschannelnorm`	The cross-channel normalization operation uses local responses in different channels to normalize each activation. Cross-channel normalization typically follows a `relu` operation. Cross-channel normalization is also known as local response normalization.
`ctc`	The CTC operation computes the connectionist temporal classification (CTC) loss between unaligned sequences.
`dlconv`	The convolution operation applies sliding filters to the input data. Use the `dlconv` function for deep learning convolution, grouped convolution, and channel-wise separable convolution.
`dlode45`	The neural ordinary differential equation (ODE) operation returns the solution of a specified ODE.
`dltranspconv`	The transposed convolution operation upsamples feature maps.
`embed`	The embed operation converts numeric indices to numeric vectors, where the indices correspond to discrete data. Use embeddings to map discrete data such as categorical values or words to numeric vectors.

Function	Description
`fullyconnect`	The fully connect operation multiplies the input by a weight matrix and then adds a bias vector.
`groupnorm`	The group normalization operation normalizes the input data across grouped subsets of channels for each observation independently. To speed up training of the convolutional neural network and reduce the sensitivity to network initialization, use group normalization between convolution and nonlinear operations such as `relu`.
`gru`	The gated recurrent unit (GRU) operation allows a network to learn dependencies between time steps in time series and sequence data.
`huber`	The Huber operation computes the Huber loss between network predictions and target values for regression tasks. When the `'TransitionPoint'` option is 1, this is also known as *smooth L_1 loss*.
`instancenorm`	The instance normalization operation normalizes the input data across each channel for each observation independently. To improve the convergence of training the convolutional neural network and reduce the sensitivity to network hyperparameters, use instance normalization between convolution and nonlinear operations such as `relu`.
`l1loss`	The L_1 loss operation computes the L_1 loss given network predictions and target values. When the `Reduction` option is `"sum"` and the `NormalizationFactor` option is `"batch-size"`, the computed value is known as the mean absolute error (MAE).
`l2loss`	The L_2 loss operation computes the L_2 loss (based on the squared L_2 norm) given network predictions and target values. When the `Reduction` option is `"sum"` and the `NormalizationFactor` option is `"batch-size"`, the computed value is known as the mean squared error (MSE).
`layernorm`	The layer normalization operation normalizes the input data across all channels for each observation independently. To speed up training of recurrent and multilayer perceptron neural networks and reduce the sensitivity to network initialization, use layer normalization after the learnable operations, such as LSTM and fully connect operations.

Function	Description
`leakyrelu`	The leaky rectified linear unit (ReLU) activation operation performs a nonlinear threshold operation, where any input value less than zero is multiplied by a fixed scale factor.
`lstm`	The long short-term memory (LSTM) operation allows a network to learn long-term dependencies between time steps in time series and sequence data.
`maxpool`	The maximum pooling operation performs downsampling by dividing the input into pooling regions and computing the maximum value of each region.
`maxunpool`	The maximum unpooling operation unpools the output of a maximum pooling operation by upsampling and padding with zeros.
`mse`	The half mean squared error operation computes the half mean squared error loss between network predictions and target values for regression tasks.
`onehotdecode`	The one-hot decode operation decodes probability vectors, such as the output of a classification network, into classification labels. The input `A` can be a `dlarray`. If `A` is formatted, the function ignores the data format.
`relu`	The rectified linear unit (ReLU) activation operation performs a nonlinear threshold operation, where any input value less than zero is set to zero.
`sigmoid`	The sigmoid activation operation applies the sigmoid function to the input data.
`softmax`	The softmax activation operation applies the softmax function to the channel dimension of the input data.

dlarray-Specific Functions

Function	Description
`dims`	This function returns the data format of a `dlarray`.
`dlfeval`	This function evaluates a `dlarray` function using automatic differentiation.
`dlgradient`	This function computes gradients using automatic differentiation.
`extractdata`	This function extracts the data from a `dlarray`.

Function	Description
`finddim`	This function finds the indices of `dlarray` dimensions with a given dimension label.
`stripdims`	This function removes the data format from a `dlarray`.

Domain-Specific Functions with dlarray Support

These tables list and briefly describe the domain-specific functions that operate on `dlarray` objects.

Computer Vision

Function	Description
`focalCrossEntropy`	Calculate the focal cross-entropy loss between two `dlarray` objects that represent predicted and target classification labels.
`generalizedDice`	Measure the similarity between two `dlarray` objects that represent segmented images, using a generalized Dice metric that accounts for class weighting.
`roialign`	Perform ROI pooling of `dlarray` data.

Image Processing

Function	Description
`depthToSpace`	Rearrange `dlarray` data from the depth dimension into spatial blocks.
`dlresize`	Resize the spatial dimensions of a `dlarray`.
`multissim`	Measure the similarity between two `dlarray` objects that represent 2-D images, using the multiscale structural similarity (MS-SSIM) metric.
`multissim3`	Measure the similarity between two `dlarray` objects that represent 3-D images, using the 3-D MS-SSIM metric.
`psnr`	Measure the similarity between two `dlarray` objects that represent images using the peak signal-to-noise ratio (PSNR) metric.
`spaceToDepth`	Rearrange spatial blocks of `dlarray` data into the depth dimension.
`ssim`	Measure the similarity between two `dlarray` objects that represent images using the structural similarity (SSIM) metric.

Signal Processing

Function	Description
`dlstft`	Compute short-time Fourier transform.

MATLAB Functions with dlarray Support

Many MATLAB functions operate on `dlarray` objects. These tables list the usage notes and limitations for these functions when you use `dlarray` arguments.

Unary Element-wise Functions

Function	Notes and Limitations
`abs`	The output `dlarray` has the same data format as the input `dlarray`.
`acos`	
`acosh`	
`acot`	
`acsc`	
`angle`	
`asec`	
`asin`	
`asinh`	
`atan`	
`atan2`	
`atanh`	
`conj`	
`cos`	
`cosh`	
`cot`	
`csc`	
`exp`	
`imag`	
`log`	
`real`	
`reallog`	
`realsqrt`	
`sec`	
`sign`	
`sin`	
`sinh`	

Function	Notes and Limitations
sqrt	
tan	
tanh	
uminus, -	
uplus, +	

Binary Element-wise Operators

Function	Notes and Limitations
complex	For the one-input syntax, the output dlarray has the same data format as the input dlarray For the two-input syntax, if dlarray inputs are formatted, their data formats must match.
minus, -	If the two dlarray inputs are formatted, then the output dlarray is formatted with a combination of both of their data formats. The function uses implicit expansion to combine the inputs. For more information, see “Implicit Expansion with Data Formats” on page 18-436.
plus, +	
power, .^	
rdivide, ./	
realpow	
times, .*	

Reduction Functions

Function	Notes and Limitations
mean	• The output dlarray has the same data format as the input dlarray. • The 'omitnan' option is not supported. • If the input dlarray is on the GPU, the 'native' option is not supported.
prod	• The output dlarray has the same data format as the input dlarray. • The 'omitnan' option is not supported.
sum	

Extrema Functions

Function	Notes and Limitations
ceil	The output dlarray has the same data format as the input dlarray.
eps	• The output dlarray has the same data format as the input dlarray. • Use eps(ones(‘like’, x)) to get a scalar epsilon value based on the data type of a dlarray x.

Function	Notes and Limitations
`fix`	The output `dlarray` has the same data format as the input `dlarray`.
`floor`	The output `dlarray` has the same data format as the input `dlarray`.
`max` `min`	• When you find the maximum or minimum elements of a single `dlarray`, the output `dlarray` has the same data format as the input `dlarray`. • When you find the maximum or minimum elements between two formatted `dlarray` inputs, the output `dlarray` has a combination of both of their data formats. The function uses implicit expansion to combine the inputs. For more information, see “Implicit Expansion with Data Formats” on page 18-436. • The index output argument is not traced and cannot be used with automatic differentiation. For more information, see “Use Automatic Differentiation In Deep Learning Toolbox” on page 18-205.
`rescale`	• If the first input `dlarray` `A` is unformatted, all additional inputs must be unformatted. • If the first input `dlarray` `A` is formatted, all additional inputs must either be unformatted scalars, or have data formats that are a subset of the data format of `A`. In this case, each dimension must either be singleton or match the length of the corresponding dimension of `A`.
`round`	• Only the syntax `Y = round(X)` is supported. • The output `dlarray` has the same data format as the input `dlarray`.

Fourier Transforms

Function	Notes and Limitations
`fft`	Only unformatted input arrays are supported.

Function	Notes and Limitations
`ifft`	• Only unformatted input arrays are supported. • When you use the `'symmetric'` option, `ifft` treats the input `Y` as exactly symmetric. If you compute the derivative using automatic differentiation, then the derivative is also exactly symmetric. If `Y` is non-symmetric, then the function and gradient behavior might not match. To ensure that function and gradient behavior match for non-symmetric inputs, explicitly symmetrize `Y`.

Other Math Operations

Function	Notes and Limitations

`colon`, `:`	• The supported operations are:
	  • `a:b`
	  • `a:b:c`
	  For information on indexing into a `dlarray`, see “Indexing” on page 18-438.
	• All inputs must be real scalars. The output `dlarray` is unformatted.

`interp1`	• Sample points input `x` must be a finite, increasing vector without repeating elements. • `method` must be `'linear'` or `'nearest'`. • The piecewise polynomial syntax (`'pp'`) is not supported. • Only the sample values input `v` can be a formatted `dlarray`. All other inputs must be unformatted. If `v` is a formatted `dlarray`, query points input `xq` must be a vector, and the output `vq` has the same data format as `v`.
`mrdivide`, `/`	The second `dlarray` input must be a scalar. The output `dlarray` has the same data format as the first `dlarray` input.
`mtimes`, `*`	• One input can be a formatted `dlarray` only when the other input is an unformatted scalar. In this case, the output `dlarray` has the same data format as the formatted `dlarray` input. • Multiplying a `dlarray` with a non-`dlarray` sparse matrix is supported only when both inputs are non-scalar.

Function	Notes and Limitations
`ode45`	The supported syntaxes are: • `[t,y] = ode45(odefun,tspan,y0)` • `[t,y] = ode45(odefun,tspan,y0,options)` At least one of `y0` and `tspan` must be an unformatted `dlarray` object. If `tspan` is a `dlarray` object, then the output `t` is an unformatted `dlarray` object. If `y0` is a `dlarray` object, then the output `y` is an unformatted `dlarray` object. For `dlarray` input, the `ode45` function does not support the `OutputFcn`, `Mass`, `NonNegative`, and `Events` options. For `dlarray` input, the `ode45` function does not support acceleration using `dlaccelerate`. **Tip** For neural ODE workflows, use `dlode45`.
`pagemtimes`	One input can be a formatted `dlarray` only when the other input is unformatted, with scalar pages. In this case, the output `dlarray` has the same data format as the formatted `dlarray` input.

Logical Operations

Function	Notes and Limitations
`all`	The output `dlarray` has the same data format as the input `dlarray`.
`and`, `&`	If the two `dlarray` inputs are formatted, then the output `dlarray` is formatted with a combination of both of their data formats. The function uses implicit expansion to combine the inputs. For more information, see “Implicit Expansion with Data Formats” on page 18-436.
`any`	The output `dlarray` has the same data format as the input `dlarray`.
`eq`, `==`	If the two `dlarray` inputs are formatted, then the output `dlarray` is formatted with a combination of both of their data formats. The function uses implicit expansion to combine the inputs. For more information, see “Implicit Expansion with Data Formats” on page 18-436.
`ge`, `>=`	
`gt`, `>`	
`le`, `<=`	
`lt`, `<`	
`ne`, `~=`	

Function	Notes and Limitations
`not`, `~`	The output `dlarray` has the same data format as the input `dlarray`.
`or`, `|`	If the two `dlarray` inputs are formatted, then the output `dlarray` is formatted with a combination of both of their data formats. The function uses implicit expansion to combine the inputs. For more information, see “Implicit Expansion with Data Formats” on page 18-436.
`xor`	

Size Manipulation Functions

Function	Notes and Limitations
`reshape`	The output `dlarray` is unformatted, even if the input `dlarray` is formatted.
`squeeze`	Two-dimensional `dlarray` objects are unaffected by `squeeze`. If the input `dlarray` is formatted, the function removes dimension labels belonging to singleton dimensions. If the input `dlarray` has more than two dimensions and its third and above dimensions are singleton, then the function discards these dimensions and their labels.

Transposition Operations

Function	Notes and Limitations
`ctranspose`, `'`	If the input `dlarray` is formatted, then the labels of both dimensions must be the same. The function performs transposition implicitly, and transposes directly only if necessary for other operations.
`permute`	If the input `dlarray` is formatted, then the permutation must be among only those dimensions that have the same label. The function performs permutations implicitly, and permutes directly only if necessary for other operations.
`transpose`, `.'`	If the input `dlarray` is formatted, then the labels of both dimensions must be the same. The function performs transposition implicitly, and transposes directly only if necessary for other operations.

Concatenation Functions

Function	Notes and Limitations
`cat`	The `dlarray` inputs must have matching formats or be unformatted. Mixed formatted and unformatted inputs are supported. If any
`horzcat`	

Function	Notes and Limitations
`vertcat`	`dlarray` inputs are formatted, then the output `dlarray` is formatted with the same data format.

Conversion Functions

Function	Notes and Limitations
`cast`	• `cast(dlA,newdatatype)` copies the data in the `dlarray` `dlA` into a `dlarray` of the underlying data type `newdatatype`. The `newdatatype` option must be `'double'`, `'single'`, or `'logical'`. The output `dlarray` is formatted with the same data format as `dlA`. • `cast(A,'like',Y)` returns an array of the same type as `Y`. If `Y` is a `dlarray`, then the output is a `dlarray` that has the same underlying data type as `Y`. If `Y` is on the GPU, then the output is on the GPU. If both `A` and `Y` are `dlarray` objects, then the output `dlarray` is formatted with the same data format as the input `A`.
`double`	The output is a `dlarray` that contains data of type `double`.

`gather`	• The supported syntaxes are:
	  • `dlX = gather(dlA)`
	  • `[dlX,dlY,dlZ,...] = gather(dlA,dlB,dlC,...)`
	• `gather(dlA)` returns a `dlarray` containing numeric or logical data. This function applies `gather` to the underlying data in the `dlarray` `dlA`. If `dlA` is on the GPU, then `dlX` is in the local workspace, not on the GPU. If `dlA` is in the local workspace (not on the GPU), then `dlX` is equal to `dlA`.
	• `gather(dlA,dlB,dlC,...)` gathers multiple arrays.

`gpuArray`	• This function requires Parallel Computing Toolbox. • `gpuArray` returns a `dlarray` containing a `gpuArray`. This function applies `gpuArray` to the underlying data. If the input `dlarray` is in the local workspace, then its data is moved to the GPU and internally represented as a `gpuArray`. If the input `dlarray` is on the GPU, then the output `dlarray` is equal to the input `dlarray`.

Function	Notes and Limitations
`logical`	The output is a `dlarray` that contains data of type `logical`.
`single`	The output is a `dlarray` that contains data of type `single`.

Comparison Functions

Function	Notes and Limitations
`isequal`	• The syntax with more than two input arguments is not supported. • Two `dlarray` inputs are equal if the numeric data they represent are equal and if they both are either formatted with the same data format or unformatted.
`isequaln`	• The syntax with more than two input arguments is not supported. • Two `dlarray` inputs are equal if the numeric data they represent are equal (treating `NaN`s as equal) and if they both are either formatted with the same data format or unformatted.

Data Type and Value Identification Functions

Function	Notes and Limitations
`isdlarray`	N/A
`isfinite`	The software applies the function to the underlying data of an input `dlarray`.
`isfloat`	
`isgpuarray`	
`isinf`	
`islogical`	
`isnan`	
`isnumeric`	
`isreal`	
`isUnderlyingType`	N/A
`mustBeUnderlyingType`	
`underlyingType`	
`validateattributes`	If input array `A` is a formatted `dlarray`, its dimensions are permuted to match the order `"SCBTU"`. Size validation is applied after permutation.

Size Identification Functions

Function	Notes and Limitations
`iscolumn`	This function returns `true` for a `dlarray` that is a column vector, where each dimension except the first is a singleton. For example, a 3-by-1-by-1 `dlarray` is a column vector.
`ismatrix`	This function returns `true` for `dlarray` objects with only two dimensions and for `dlarray` objects where each dimension except the first two is a singleton. For example, a 3-by-4-by-1 `dlarray` is a matrix.
`isrow`	This function returns `true` for a `dlarray` that is a row vector, where each dimension except the second is a singleton. For example, a 1-by-3-by-1 `dlarray` is a row vector.
`isscalar`	N/A
`isvector`	This function returns `true` for a `dlarray` that is a row vector or column vector. Note that `isvector` does not consider a 1-by-1-by-3 `dlarray` to be a vector.
`length`	N/A
`ndims`	If the input `dlarray` `dlX` is formatted, then `ndims(dlX)` returns the number of dimension labels, even if some of the labeled dimensions are trailing singleton dimensions.
`numel`	N/A
`size`	If the input `dlarray` `dlX` is formatted, then `size(dlX)` returns a vector of length equal to the number of dimension labels, even if some of the labeled dimensions are trailing singleton dimensions.

Creator Functions

Function	Notes and Limitations
`false`	Only the `'like'` syntax is supported for `dlarray`.
`inf`	
`nan`	
`ones`	
`rand`	
`randi`	
`randn`	
`true`	
`zeros`	

String and Character Functions

Function	Notes and Limitations
compose	N/A
fprintf	
int2str	
mat2str	
num2str	
sprintf	

Notable dlarray Behaviors

Implicit Expansion with Data Formats

Some functions use implicit expansion to combine two formatted `dlarray` inputs. The function introduces labeled singleton dimensions (dimensions of size 1) into the inputs, as necessary, to make their formats match. The function inserts singleton dimensions at the end of each block of dimensions with the same label.

To see an example of this behavior, enter the following code.

```
X = ones(2,3,2);
dlX = dlarray(X,'SCB')
Y = 1:3;
dlY = dlarray(Y,'C')
dlZ = dlX.*dlY
```

```
dlX =

  2(S) × 3(C) × 2(B) dlarray

(:,:,1) =

     1     1     1
     1     1     1

(:,:,2) =

     1     1     1
     1     1     1

dlY =

  3(C) × 1(U) dlarray

     1
     2
     3
```

```
dlZ =

  2(S) × 3(C) × 2(B) dlarray

(:,:,1) =

     1     2     3
     1     2     3

(:,:,2) =

     1     2     3
     1     2     3
```

In this example, `dlZ(i,j,k) = dlX(i,j,k).*dlY(j)` for indices `i`, `j`, and `k`. The second dimension of `dlZ` (labeled `'C'`) corresponds to the second dimension of `dlX` and the first dimension of `dlY`.

In general, the format of one `dlarray` input does not need to be a subset of the format of another `dlarray` input. For example, if `dlX` and `dlY` are input arguments with `dims(dlX) = 'SCB'` and `dims(dlY) = 'SSCT'`, then the output `dlZ` has `dims(dlZ) = 'SSCBT'`. The `'S'` dimension of `dlX` maps to the first `'S'` dimension of `dlY`.

Special 'U' Dimension Behavior

The `'U'` dimension of a `dlarray` behaves differently from other labeled dimensions in that it exhibits the standard MATLAB singleton dimension behavior. You can think of a formatted `dlarray` as having infinitely many `'U'` dimensions of size 1 following the dimensions returned by `size`.

The software discards a `'U'` label unless the dimension is nonsingleton or it is one of the first two dimensions of the `dlarray`.

To see an example of this behavior, enter the following code.

```
X = ones(2,2);
dlX = dlarray(X,'SC')
dlX(:,:,2) = 2

dlX =

  2(S) × 2(C) dlarray

     1     1
     1     1

dlX =

  2(S) × 2(C) × 2(U) dlarray

(:,:,1) =

     1     1
     1     1
```

```
(:,:,2) =

     2     2
     2     2
```

In this example, the software expands a formatted two-dimensional `dlarray` to a three-dimensional `dlarray`, and labels the third dimension with `'U'` by default. For an example of how the `'U'` dimension is used in implicit expansion, see “Implicit Expansion with Data Formats” on page 18-436.

Indexing

Indexing with a `dlarray` is supported and exhibits the following behaviors:

- `dlX(idx1,...,idxn)` returns a `dlarray` with the same data format as `dlX` if `n` is greater than or equal to `ndims(dlX)`. Otherwise, it returns an unformatted `dlarray`.
- If you set `dlY(idx1,...,idxn) = dlX`, then the data format of `dlY` is preserved, although the software might add or remove trailing `'U'` dimension labels. The data format of `dlX` has no impact on this operation.
- If you delete parts of a `dlarray` using `dlX(idx1,…,idxn) = []`, then the data format of `dlX` is preserved if `n` is greater than or equal to `ndims(dlX)`. Otherwise, `dlX` is returned unformatted.

Round-off Error

When you use a function with a `dlarray` input, the order of the operations within the function can change based on the internal storage order of the `dlarray`. This change can result in differences on the order of round-off for two `dlarray` objects that are otherwise equal.

Deep Learning Data Preprocessing

Datastores for Deep Learning

Datastores in MATLAB are a convenient way of working with and representing collections of data that are too large to fit in memory at one time. Because deep learning often requires large amounts of data, datastores are an important part of the deep learning workflow in MATLAB.

Select Datastore

For many applications, the easiest approach is to start with a built-in datastore. For more information about the available built-in datastores, see “Select Datastore for File Format or Application”. However, only some types of built-in datastores can be used directly as input for network training, validation, and inference. These datastores are:

Datastore	Description	Additional Toolbox Required
`ImageDatastore`	Datastore for image data	none
`AugmentedImageDatastore`	Datastore for resizing and augmenting training images Datastore is nondeterministic	none
`PixelLabelDatastore`	Datastore for pixel label data	Computer Vision Toolbox
`PixelLabelImageDatastore`	Datastore for training semantic segmentation networks Datastore is nondeterministic	Computer Vision Toolbox
`boxLabelDatastore`	Datastore for bounding box label data	Computer Vision Toolbox
`RandomPatchExtractionDatastore`	Datastore for extracting random patches from image-based data Datastore is nondeterministic	Image Processing Toolbox
`blockedImageDatastore`	Datastore for blockwise reading and processing of image data, including large images that do not fit in memory	Image Processing Toolbox
`DenoisingImageDatastore`	Datastore to train an image denoising deep neural network Datastore is nondeterministic	Image Processing Toolbox

Other built-in datastores can be used as input for deep learning, but the data read from these datastores must be preprocessed into a format required by a deep learning network. For more information on the required format of read data, see “Input Datastore for Training, Validation, and Inference” on page 19-3. For more information on how to preprocess data read from datastores, see “Transform and Combine Datastores” on page 19-6.

For some applications, there may not be a built-in datastore type that fits your data well. For these problems, you can create a custom datastore. For more information, see “Develop Custom Datastore”. All custom datastores are valid inputs to deep learning interfaces as long as the `read` function of the custom datastore returns data in the required form.

Input Datastore for Training, Validation, and Inference

Datastores are valid inputs in Deep Learning Toolbox for training, validation, and inference.

Training and Validation

You can use an image datastore or other types of datastore as a source of training data when training using the `trainNetwork` function. To use a datastore for validation, use the `'ValidationData'` name-value pair argument in `trainingOptions`.

To be a valid input for training or validation, the `read` function of a datastore must return data as either a cell array or a table (with the exception of `ImageDatastore` objects which can output numeric arrays and custom mini-batch datastores which must output tables).

For networks with a single input, the table or cell array returned by the datastore must have two columns. The first column of data represents inputs to the network and the second column of data represents responses. Each row of data represents a separate observation. For `ImageDatastore` only, `trainNetwork` and `trainingOptions` support data returned as integer arrays and single-column cell array of integer arrays.

To use a datastore for networks with multiple input layers, use the `combine` and `transform` functions to create a datastore that outputs a cell array with (`numInputs` + 1) columns, where `numInputs` is the number of network inputs. In this case, the first `numInputs` columns specify the predictors for each input and the last column specifies the responses. The order of inputs is given by the `InputNames` property of the layer graph `layers`.

The following table shows example outputs of calling the `read` function for datastore `ds`.

Network Architecture	Datastore Output	Example Output

Single input layer	Table or cell array with two columns.
	
	The first and second columns specify the predictors and responses, respectively.
	
	Table elements must be scalars, row vectors, or 1-by-1 cell arrays containing a numeric array.
	
	Custom mini-batch datastores must output tables.
		Table for network with one input and one output:
		
		`data = read(ds)`
		
		`data =`
		
		`4×2 table`
		
		`Predictors  Response`
		`{224×224×3 double}  2`
		`{224×224×3 double}  7`
		`{224×224×3 double}  9`
		`{224×224×3 double}  9`

Network Architecture	Datastore Output	Example Output

		Cell array for network with one input and one output:
		`data = read(ds)`
		`data =`
		`4×2 cell array`
		`{224×224×3 double} {[2]}`
		`{224×224×3 double} {[7]}`
		`{224×224×3 double} {[9]}`
		`{224×224×3 double} {[9]}`

Multiple input layers	Cell array with (`numInputs` + 1) columns, where `numInputs` is the number of network inputs.
	The first `numInputs` columns specify the predictors for each input and the last column specifies the responses.
	The order of inputs is given by the `InputNames` property of the layer graph `layers`.
		Cell array for network with two inputs and one output.
		`data = read(ds)`
		`data =`
		`4×3 cell array`
		`{224×224×3 double} {128×128×3 do`
		`{224×224×3 double} {128×128×3 do`
		`{224×224×3 double} {128×128×3 do`
		`{224×224×3 double} {128×128×3 do`

The format of the predictors depend on the type of data.

Data	Format of Predictors
2-D image	*h*-by-*w*-by-*c* numeric array, where *h*, *w*, and *c* are the height, width, and number of channels of the image, respectively.
3-D image	*h*-by-*w*-by-*d*-by-*c* numeric array, where *h*, *w*, *d*, and *c* are the height, width, depth, and number of channels of the image, respectively.
Vector sequence	*c*-by-*s* matrix, where *c* is the number of features of the sequence and *s* is the sequence length.
1-D image sequence	*h*-by-*c*-by-*s* array, where *h* and *c* correspond to the height and number of channels of the image, respectively, and *s* is the sequence length. Each sequence in the mini-batch must have the same sequence length.
2-D image sequence	*h*-by-*w*-by-*c*-by-*s* array, where *h*, *w*, and *c* correspond to the height, width, and number of channels of the image, respectively, and *s* is the sequence length. Each sequence in the mini-batch must have the same sequence length.

Data	Format of Predictors
3-D image sequence	*h*-by-*w*-by-*d*-by-*c*-by-*s* array, where *h*, *w*, *d*, and *c* correspond to the height, width, depth, and number of channels of the image, respectively, and *s* is the sequence length. Each sequence in the mini-batch must have the same sequence length.
Features	*c*-by-1 column vector, where *c* is the number of features.

For predictors returned in tables, the elements must contain a numeric scalar, a numeric row vector, or a 1-by-1 cell array containing a numeric array.

The `trainNetwork` function does not support networks with multiple sequence input layers.

The format of the responses depend on the type of task.

Task	Format of Responses
Classification	Categorical scalar
Regression	• Scalar • Numeric vector • 3-D numeric array representing an image
Sequence-to-sequence classification	1-by-*s* sequence of categorical labels, where *s* is the sequence length of the corresponding predictor sequence.
Sequence-to-sequence regression	*R*-by-*s* matrix, where *R* is the number of responses and *s* is the sequence length of the corresponding predictor sequence.

For responses returned in tables, the elements must be a categorical scalar, a numeric scalar, a numeric row vector, or a 1-by-1 cell array containing a numeric array.

Prediction

For inference using `predict`, `classify`, and `activations`, a datastore is only required to yield the columns corresponding to the predictors. The inference functions use the first `NumInputs` columns and ignores the subsequent layers, where `NumInputs` is the number of network input layers.

Specify Read Size and Mini-Batch Size

A datastore may return any number of rows (observations) for each call to `read`. Functions such as `trainNetwork`, `predict`, `classify`, and `activations` that accept datastores and support specifying a `'MiniBatchSize'` call `read` as many times as is necessary to form complete mini-batches of data. As these functions form mini-batches, they use internal queues in memory to store read data. For example, if a datastore consistently returns 64 rows per call to `read` and `MiniBatchSize` is `128`, then to form each mini-batch of data requires two calls to `read`.

For best runtime performance, it is recommended to configure datastores such that the number of observations returned by `read` is equal to the `'MiniBatchSize'`. For datastores that have a

'ReadSize' property, set the 'ReadSize' to change the number of observations returned by the datastore for each call to read.

Transform and Combine Datastores

Deep learning frequently requires the data to be preprocessed and augmented before data is in an appropriate form to input to a network. The transform and combine functions of datastore are useful in preparing data to be fed into a network.

To use a datastore for networks with multiple input layers, use the combine and transform functions to create a datastore that outputs a cell array with (numInputs + 1) columns, where numInputs is the number of network inputs. In this case, the first numInputs columns specify the predictors for each input and the last column specifies the responses. The order of inputs is given by the InputNames property of the layer graph layers.

Transform Datastores

A transformed datastore applies a particular data transformation to an underlying datastore when reading data. To create a transformed datastore, use the transform function and specify the underlying datastore and the transformation.

- For complex transformations involving several preprocessing operations, define the complete set of transformations in your own function. Then, specify a handle to your function as the @fcn argument of transform. For more information, see “Create Functions in Files”.
- For simple transformations that can be expressed in one line of code, you can specify a handle to an anonymous function as the @fcn argument of transform. For more information, see “Anonymous Functions”.

The function handle provided to transform must accept input data in the same format as returned by the read function of the underlying datastore.

Example: Transform Image Datastore to Train Digit Classification Network

This example uses the transform function to create a training set in which randomized 90 degree rotation is added to each image within an image datastore. Pass the resulting TransformedDatastore to trainNetwork to train a simple digit classification network.

Create an image datastore containing digit images.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet', ...
    'nndemos','nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

Set the mini-batch size equal to the ReadSize of the image datastore.

```
miniBatchSize = 128;
imds.ReadSize = miniBatchSize;
```

Transform images in the image datastore by adding randomized 90 degree rotation. The transformation function, preprocessForTraining, is defined at the end of this example.

```
dsTrain = transform(imds,@preprocessForTraining,'IncludeInfo',true)
```

```
dsTrain =

  TransformedDatastore with properties:

    UnderlyingDatastore: [1×1 matlab.io.datastore.ImageDatastore]
             Transforms: {@preprocessForTraining}
            IncludeInfo: 1
```

Specify layers of the network and training options, then train the network using the transformed datastore `dsTrain` as a source of data.

```
layers = [
    imageInputLayer([28 28 1],'Normalization','none')
    convolution2dLayer(5,20)
    reluLayer
    maxPooling2dLayer(2,'Stride',2)
    fullyConnectedLayer(10);
    softmaxLayer
    classificationLayer];

options = trainingOptions('adam', ...
    'Plots','training-progress', ...
    'MiniBatchSize',miniBatchSize);

net = trainNetwork(dsTrain,layers,options);
```

Define the transformation function, `preprocessForTraining`. The input to the function is a batch of data, `data`, read from the underlying datastore. The function in this example loops through each read image and performs randomized rotation, then returns the transformed image and corresponding label as a cell array as expected by `trainNetwork`.

```
function [dataOut,info] = preprocessForTraining(data,info)

numRows = size(data,1);
dataOut = cell(numRows,2);

for idx = 1:numRows

    % Randomized 90 degree rotation
    imgOut = rot90(data{idx,1},randi(4)-1);

    % Return the label from info struct as the
    % second column in dataOut.
    dataOut(idx,:) = {imgOut,info.Label(idx)};

end

end
```

Combine Datastores

The `combine` function associates multiple datastores. Operating on the resulting `CombinedDatastore`, such as resetting the datastore, performs the same operation on all of the underlying datastores. Calling the `read` function of a combined datastore reads one batch of data from all of the *N* underlying datastores, which must return the same number of observations. Reading from a combined datastore returns the horizontally concatenated results in an *N*-column cell array that is suitable for training and validation. Shuffling a combined datastore results in an identical randomized ordering of files in the underlying datastores.

For example, if you are training an image-to-image regression network, then you can create the training data set by combining two image datastores. This sample code demonstrates combining two image datastores named `imdsX` and `imdsY`. The combined datastore `imdsTrain` returns data as a two-column cell array.

```
imdsX = imageDatastore(___);
imdsY = imageDatastore(___);
imdsTrain = combine(imdsX,imdsY)
```

```
imdsTrain =

  CombinedDatastore with properties:

    UnderlyingDatastores: {1×2 cell}
```

If you have Image Processing Toolbox, then the `randomPatchExtractionDatastore` provides an alternate solution to associating image-based data in `ImageDatastore`s, `PixelLabelDatastore`s, and `TransformedDatastore`s. A `randomPatchExtractionDatastore` has several advantages over associating data using the `combine` function. Specifically, a random patch extraction datastore:

- Provides an easy way to extract patches from both 2-D and 3-D data without requiring you to implement a custom cropping operation using `transform` and `combine`
- Provides an easy way to generate multiple patches per image per mini-batch without requiring you to define a custom concatenation operation using `transform`.
- Supports efficient conversion between categorical and numeric data when applying image transforms to categorical data
- Supports parallel training
- Improves performance by caching images

Use Datastore for Parallel Training and Background Dispatching

Datastores used for parallel training or multi-GPU training must be partitionable. To determine if a datastore is partitionable, use the function `isPartitionable`. Specify parallel or multi-GPU training using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`. Training in parallel or using single or multiple GPUs requires Parallel Computing Toolbox.

Many built-in datastores are already partitionable because they support the `partition` function. Using the `transform` and `combine` functions with built-in datastores frequently maintains support for parallel and multi-GPU training.

If you need to create a custom datastore that supports parallel or multi-GPU training, then your datastore must implement the `matlab.io.datastore.Partitionable` class.

Partitionable datastores support reading training data using background dispatching. Background dispatching queues data in memory while the GPU is working. Specify background dispatching using the `'DispatchInBackground'` name-value pair argument of `trainingOptions`. Background dispatching requires Parallel Computing Toolbox.

When training in parallel, datastores do not support specifying the `'Shuffle'` name-value pair argument of `trainingOptions` as `'none'`.

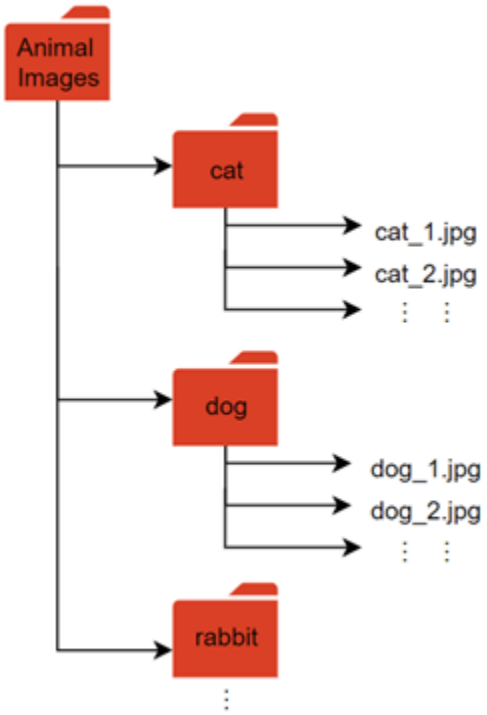
Create and Explore Datastore for Image Classification

This example shows how to create, read, and augment an image datastore for use in training a deep learning network. In particular, this example shows how to create an `ImageDatastore` object from a collection of images, read and extract the properties of the datastore, and create an `augmentedImageDatastore` for use during training.

Create Image Datastore

Use an `imageDatastore` object to manage a large collection of images that cannot altogether fit in memory. Large collections of images are common in deep learning applications, which regularly involve training on thousands of labeled images. These images are often stored in a folder, with subfolders containing images for each class.

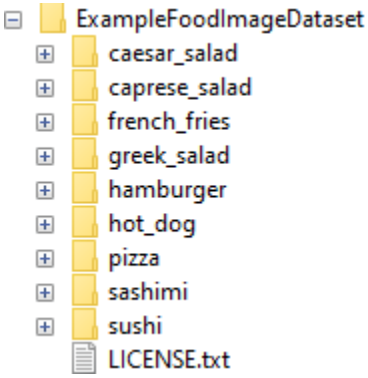


Download Data Set

This example uses the Example Food Images data set, which contains 978 photographs of food in nine classes and is approximately 77 MB in size. Download the `ExampleFoodImageDataset.zip` file from the MathWorks website, then unzip the file.

```
zipFile = matlab.internal.examples.downloadSupportFile('nnet','data/ExampleFoodImageDataset.zip'
filepath = fileparts(zipFile);
dataFolder = fullfile(filepath,'ExampleFoodImageDataset');
unzip(zipFile,dataFolder);
```

The images in this data set are separated into subfolders for each class.



Create an image datastore from the images in the path and their subfolders. Use the folder names as label names.

```
foodImds = imageDatastore(dataFolder, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

Properties of Datastore

Extract the properties of the datastore.

Find the total number of observations. This data set has 978 observations split into nine classes.

```
numObs = length(foodImds.Labels)
```

```
numObs = 978
```

Find the number of observations per class. You can see that this data set does not contain an equal number of observations in each class.

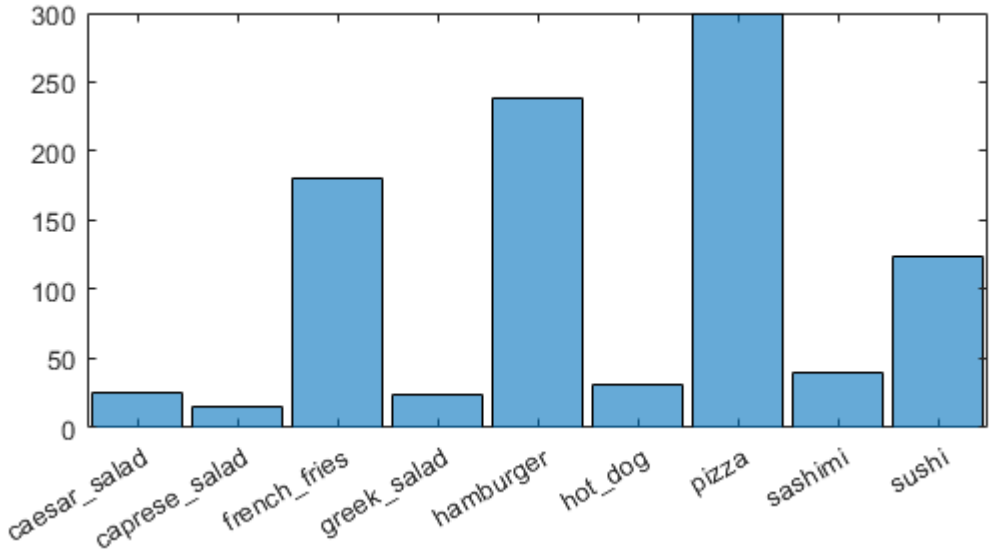
```
numObsPerClass = countEachLabel(foodImds)
```

```
numObsPerClass=9×2 table
        Label        Count
    _____________    _____

    caesar_salad       26
    caprese_salad      15
    french_fries      181
    greek_salad        24
    hamburger         238
    hot_dog            31
    pizza             299
    sashimi            40
    sushi             124
```

You can also visualize the distribution of the class labels using a histogram.

```
histogram(foodImds.Labels)
set(gca,'TickLabelInterpreter','none')
```



Explore Datastore

Check that the data is as expected by viewing a random selection of images from the datastore.

```
numObsToShow = 8;
idx = randperm(numObs,numObsToShow);
imshow(imtile(foodImds.Files(idx),'GridSize',[2 4],'ThumbnailSize',[100 100]))
```

You can also view images that belong to a specific class.

```
class = pizza;
idxClass = find(foodImds.Labels == class);
idx = randsample(idxClass,numObsToShow);
imshow(imtile(foodImds.Files(idx),'GridSize',[2 4],'ThumbnailSize',[100 100]));
```

To take a closer look at individual images in your datastore or folder, use the Image Browser (Image Processing Toolbox) app.

Image Augmentation

Augmentation enables you to train networks to be invariant to distortions in image data. For example, you can add randomized rotations to input images so that a network is invariant to the presence of rotation. An `augmentedImageDatastore` object provides a convenient way to apply a limited set of augmentations to 2-D images for classification problems.

Define an augmentation scheme. This scheme applies a random rotation between [–90,90] degrees and a random scaling between [1,2]. The augmented datastore automatically resizes the images to the `inputSize` value during training.

```
imageAugmenter = imageDataAugmenter( ...
    'RandRotation',[-90 90], ...
    'RandScale',[1 2]);

inputSize = [100 100];
```

Using the augmentation scheme, define the augmented image datastore.

```
augFoodImds = augmentedImageDatastore(inputSize,foodImds, ...
    'DataAugmentation',imageAugmenter);
```

The augmented datastore contains the same number of images as the original image datastore.

```
augFoodImds.NumObservations
```

```
ans = 978
```

When you use an augmented image datastore as a source of training images, the datastore randomly perturbs the training data for each epoch, where an epoch is a full pass of the training algorithm over the entire training data set. Therefore, each epoch uses a slightly different data set, but the actual number of training images in each epoch does not change.

Visualize Augmented Data

Visualize the augmented image data that you want to use to train the network.

Shuffle the datastore.

```
augFoodImds = shuffle(augFoodImds);
```

The `augmentedImageDatastore` object applies the transformations when reading the datastore and does not store the transformed images in memory. Consequently, each time you read the same images, you see a random combination of the augmentations defined.

Use the `read` function to read a subset of the augmented datastore.

```
subset1 = read(augFoodImds);
```

Reset the datastore to its state before calling read and read a subset of the datastore again.

```
reset(augFoodImds)
subset2 = read(augFoodImds);
```

Display the two subsets of the augmented images.

```
imshow(imtile(subset1.input,'GridSize',[2 4]))
```

```
imshow(imtile(subset2.input,'GridSize',[2 4]))
```

You can see that both instances show the same images with different transformations. Applying transformations to images is useful in deep learning applications, as you can train the network on randomly altered versions of an image. Doing so exposes the network to different variations of images from that class and enables it to learn to classify images even if they have different visual properties.

After creating your datastore object, use the Deep Network Designer app or `trainNetwork` function to train an image classification network. For an example, see "Transfer Learning Using Pretrained Network" on page 3-33.

For more information on preprocessing images for deep learning applications, see "Preprocess Images for Deep Learning" on page 19-16. You can also apply more advanced augmentations, such as varying levels of brightness or saturation, by using the `transform` and `combine` functions. For more information, see "Datastores for Deep Learning" on page 19-2.

Preprocess Images for Deep Learning

To train a network and make predictions on new data, your images must match the input size of the network. If you need to adjust the size of your images to match the network, then you can rescale or crop your data to the required size.

You can effectively increase the amount of training data by applying randomized augmentation to your data. Augmentation also enables you to train networks to be invariant to distortions in image data. For example, you can add randomized rotations to input images so that a network is invariant to the presence of rotation in input images. An `augmentedImageDatastore` provides a convenient way to apply a limited set of augmentations to 2-D images for classification problems.

For more advanced preprocessing operations, to preprocess images for regression problems, or to preprocess 3-D volumetric images, you can start with a built-in datastore. You can also preprocess images according to your own pipeline by using the `transform` and `combine` functions.

Resize Images Using Rescaling and Cropping

You can store image data as a numeric array, an `ImageDatastore` object, or a table. An `ImageDatastore` enables you to import data in batches from image collections that are too large to fit in memory. You can use an augmented image datastore or a resized 4-D array for training, prediction, and classification. You can use a resized 3-D array for prediction and classification only.

There are two ways to resize image data to match the input size of a network.

- Rescaling multiplies the height and width of the image by a scaling factor. If the scaling factor is not identical in the vertical and horizontal directions, then rescaling changes the spatial extents of the pixels and the aspect ratio.
- Cropping extracts a subregion of the image and preserves the spatial extent of each pixel. You can crop images from the center or from random positions in the image.

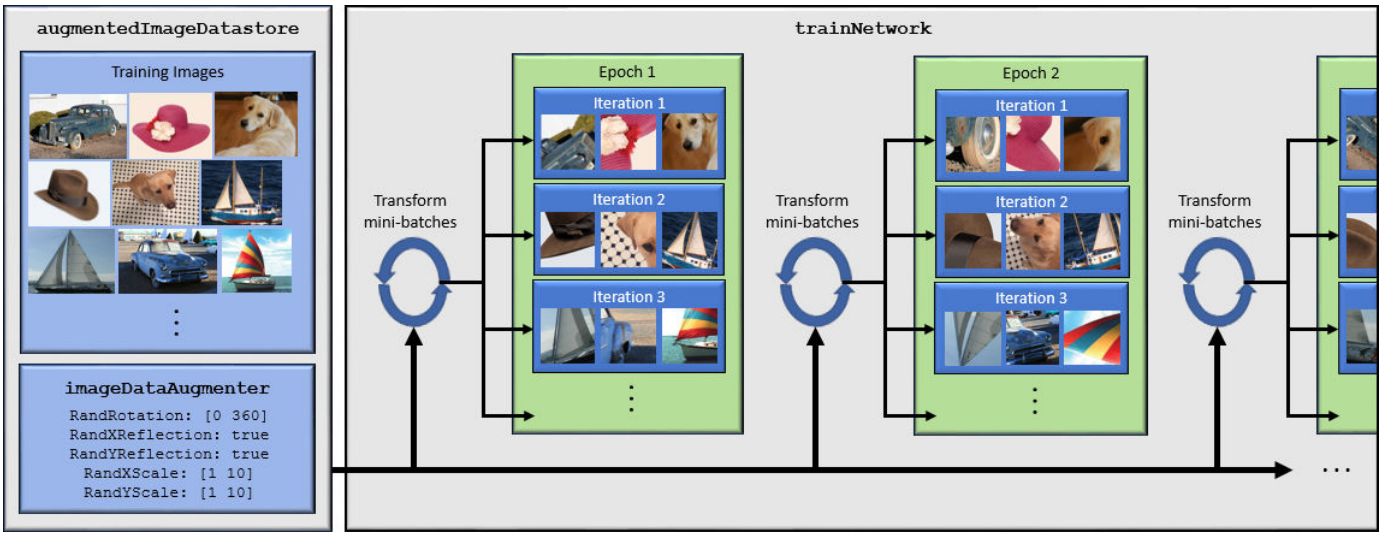
Resizing Option	Data Format	Resizing Function	Sample Code
Rescaling	• 3-D array representing a single color or multispectral image • 3-D array representing a stack of grayscale images • 4-D array representing a stack of images	`imresize`	`im = imresize(I,outputSize);` `outputSize` specifies the dimensions of the rescaled image.
	• 4-D array representing a stack of images • `ImageDatastore` • table	`augmentedImageDatastore`	`auimds = augmentedImageDatastore(outpu` `outputSize` specifies the dimensions of the rescaled image.
Cropping	• 3-D array representing a single color or multispectral image	`imcrop`	`im = imcrop(I,rect);` `rect` specifies the size and position of the 2-D cropping window.

Resizing Option	Data Format	Resizing Function	Sample Code
	• 3-D array representing a stack of grayscale images • 4-D array representing a stack of color or multispectral images	`imcrop3`	`im = imcrop3(I,cuboid);` `cuboid` specifies the size and position of the 3-D cropping window.
	• 4-D array representing a stack of images • `ImageDatastore` • table	`augmentedImageDatastore`	`auimds = augmentedImageDatastore(outpu` Specify `m` as `'centercrop'` to crop from the center of the input image. Specify `m` as `'randcrop'` to crop from a random location in the input image.

Augment Images for Training with Random Geometric Transformations

For image classification problems, you can use an `augmentedImageDatastore` to augment images with a random combination of resizing, rotation, reflection, shear, and translation transformations.

The diagram shows how `trainNetwork` uses an augmented image datastore to transform training data for each epoch. When you use data augmentation, one randomly augmented version of each image is used during each epoch of training. For an example of the workflow, see “Train Network with Augmented Images”.



1. Specify training images.
2. Configure image transformation options, such as the range of rotation angles and whether to apply reflection at random, by creating an `imageDataAugmenter`.

Tip To preview the transformations applied to sample images, use the `augment` function.

3. Create an `augmentedImageDatastore`. Specify the training images, the size of output images, and the `imageDataAugmenter`. The size of output images must be compatible with the size of the `imageInputLayer` of the network.
4. Train the network, specifying the augmented image datastore as the data source for `trainNetwork`. For each iteration of training, the augmented image datastore applies a random combination of transformations to images in the mini-batch of training data.

   When you use an augmented image datastore as a source of training images, the datastore randomly perturbs the training data for each epoch, so that each epoch uses a slightly different data set. The actual number of training images at each epoch does not change. The transformed images are not stored in memory.

Perform Additional Image Processing Operations Using Built-In Datastores

Some datastores perform specific and limited image preprocessing operations when they read a batch of data. These application-specific datastores are listed in the table. You can use these datastores as a source of training, validation, and test data sets for deep learning applications that use Deep Learning Toolbox. All of these datastores return data in a format supported by `trainNetwork`.

Datastore	Description
`augmentedImageDatastore`	Apply random affine geometric transformations, including resizing, rotation, reflection, shear, and translation, for training deep neural networks. For an example, see “Transfer Learning Using Pretrained Network” on page 3-33.
`pixelLabelImageDatastore`	Apply identical affine geometric transformations to images and corresponding ground truth labels for training semantic segmentation networks (requires Computer Vision Toolbox). For an example, see “Semantic Segmentation Using Deep Learning” on page 8-126.
`randomPatchExtractionDatastore`	Extract multiple pairs of random patches from images or pixel label images (requires Image Processing Toolbox). You optionally can apply identical random affine geometric transformations to the pairs of patches. For an example, see “Single Image Super-Resolution Using Deep Learning” on page 9-8.
`denoisingImageDatastore`	Apply randomly generated Gaussian noise for training denoising networks (requires Image Processing Toolbox).

Apply Custom Image Processing Pipelines Using Combine and Transform

To perform more general and complex image preprocessing operations than offered by the application-specific datastores, you can use the `transform` and `combine` functions. For more information, see “Datastores for Deep Learning” on page 19-2.

Transform Datastores with Image Data

The `transform` function creates an altered form of a datastore, called an underlying datastore, by transforming the data read by the underlying datastore according to a transformation function that you define.

The custom transformation function must accept data in the format returned by the `read` function of the underlying datastore. For image data in an `ImageDatastore`, the format depends on the `ReadSize` property .

- When `ReadSize` is 1, the transformation function must accept an integer array. The size of the array is consistent with the type of images in the `ImageDatastore`. For example, a grayscale image has dimensions *m*-by-*n*, a truecolor image has dimensions *m*-by-*n*-by-3, and a multispectral image with *c* channels has dimensions *m*-by-*n*-by-*c*.
- When `ReadSize` is greater than 1, the transformation function must accept a cell array of image data. Each element corresponds to an image in the batch.

The `transform` function must return data that matches the input size of the network. The `transform` function does not support one-to-many observation mappings.

Tip The `transform` function supports prefetching when the underlying `ImageDatastore` reads a batch of JPG or PNG image files. For these image types, do not use the `readFcn` argument of `ImageDatastore` to apply image preprocessing, as this option is usually significantly slower. If you use a custom read function, then `ImageDatastore` does not prefetch.

Combine Datastores with Image Data

The `combine` function concatenates the data read from multiple datastores and maintains parity between the datastores.

- Concatenate data into a two-column table or two-column cell array for training networks with a single input, such as image-to-image regression networks.
- Concatenate data to a (`numInputs`+1)-column cell array for training networks with multiple inputs.

Preprocess Volumes for Deep Learning

Read Volumetric Data

Supported file formats for volumetric image data include MAT-files, Digital Imaging and Communications in Medicine (DICOM) files, and Neuroimaging Informatics Technology Initiative (NIfTI) files.

Read volumetric image data into an `ImageDatastore`. Read volumetric pixel label data into a `PixelLabelDatastore`. For more information, see “Datastores for Deep Learning” on page 19-2.

The table shows typical usages of `imageDatastore` and `pixelLabelDatastore` for each of the supported file formats. When you create the datastore, specify the `'FileExtensions'` argument as the file extensions of your data. Specify the `ReadFcn` property as a function handle that reads data of the file format. The `filepath` argument specifies the path to the files or folder containing image data. For pixel label images, the additional `classNames` and `pixelLabelID` arguments specify the mapping of voxel label values to class names.

Image File Format	Create Image Datastore or Pixel Label Datastore

MAT	`volds = imageDatastore(filepath, ...`
	`  'FileExtensions','.mat','ReadFcn',@(x) fcn(x));`
	
	`pxds = pixelLabelDatastore(filepath,classNames,pixelLabelID, ...`
	`  'FileExtensions','.mat','ReadFcn',@(x) fcn(x));`
	
	`fcn` is a custom function that reads data from a MAT file. For example, this code defines a function called `matRead` that loads volume data from the first variable of a MAT file. Save the function in a file called `matRead.m`.
	
	`function data = matRead(filename)`
	`  inp = load(filename);`
	`  f = fields(inp);`
	`  data = inp.(f{1});`
	`end`

DICOM volume in single file	`volds = imageDatastore(filepath, ...`
	`  'FileExtensions','.dcm','ReadFcn',@(x) dicomread(x));`
	
	`pxds = pixelLabelDatastore(filepath,classNames,pixelLabelID, ...`
	`  'FileExtensions','.dcm','ReadFcn',@(x) dicomread(x));`
	
	For more information about reading DICOM files, see `dicomread`.

DICOM volume in multiple files	Follow these steps. For an example, see “Create Image Datastore Containing Single and Multi-File DICOM Volumes” (Image Processing Toolbox). • Aggregate the files into a single study by using the `dicomCollection` function. • Read the DICOM data in the study by using the `dicomreadVolume` function. • Write each volume as a MAT file. • Create the `ImageDatastore` or `PixelLabelDatastore` from the collection of MAT files by following the procedure for MAT files.

Image File Format	Create Image Datastore or Pixel Label Datastore

NIfTI	`volds = imageDatastore(filepath, ...`
	`  'FileExtensions','.nii','ReadFcn',@(x) niftiread(x));`
	
	`pxds = pixelLabelDatastore(filepath,classNames,pixelLabelID, ...`
	`  'FileExtensions','.nii','ReadFcn',@(x) niftiread(x));`
	
	For more information about reading NIfTI files, see `niftiread`.

Pair Image and Label Data

To associate volumetric image and label data for semantic segmentation, or two volumetric image datastores for regression, use a `randomPatchExtractionDatastore`. A random patch extraction datastore extracts corresponding randomly-positioned patches from two datastores. Patching is a common technique to prevent running out of memory when training with arbitrarily large volumes. Specify a patch size that matches the input size of the network and, for memory efficiency, is smaller than the full size of the volume, such as 64-by-64-by-64 voxels.

You can also use the `combine` function to associate two datastores. However, associating two datastores using a `randomPatchExtractionDatastore` has some benefits over `combine`.

- `randomPatchExtractionDatastore` supports parallel training, multi-GPU training, and prefetch reading. Specify parallel or multi-GPU training using the `'ExecutionEnvironment'` name-value argument of `trainingOptions`. Specify prefetch reading using the `'DispatchInBackground'` name-value argument of `trainingOptions`. Prefetch reading requires Parallel Computing Toolbox.
- `randomPatchExtractionDatastore` inherently supports patch extraction. In contrast, to extract patches from a `CombinedDatastore`, you must define your own function that crops images into patches, and then use the `transform` function to apply the cropping operations.
- `randomPatchExtractionDatastore` can generate several image patches from one test image. One-to-many patch extraction effectively increases the amount of available training data.

Preprocess Volumetric Data

Deep learning frequently requires the data to be preprocessed and augmented. For example, you may want to normalize image intensities, enhance image contrast, or add randomized affine transformations to prevent overfitting.

To preprocess volumetric data, use the `transform` function. `transform` creates an altered form of a datastore, called an underlying datastore, by transforming the data read by the underlying datastore according to the set of operations you define in a custom function. Image Processing Toolbox provides several functions that accept volumetric input. For a full list of functions, see 3-D Volumetric Image Processing (Image Processing Toolbox). You can also preprocess volumetric images using functions in MATLAB that work on multidimensional arrays.

The custom transformation function must accept data in the format returned by the `read` function of the underlying datastore.

Underlying Datastore	Format of Input to Custom Transformation Function
`ImageDatastore`	The input to the custom transformation function depends on the `ReadSize` property. • When `ReadSize` is 1, the transformation function must accept an integer array. The size of the array is consistent with the type of images in the `ImageDatastore`. For example, a grayscale image has size *m*-by-*n*, a truecolor image has size *m*-by-*n*-by-3, and a multispectral image with *c* channels has size *m*-by-*n*-by-*c*. • When `ReadSize` is greater than 1, the transformation function must accept a cell array of image data corresponding to each image in the batch. For more information, see the `read` function of `ImageDatastore`.
`PixelLabelDatastore`	The input to the custom transformation function depends on the `ReadSize` property. • When `ReadSize` is 1, the transformation function must accept a categorical matrix. • When `ReadSize` is greater than 1, the transformation function must accept a cell array of categorical matrices. For more information, see the `read` function of `PixelLabelDatastore`.
`RandomPatchExtractionDatastore`	The input to the custom transformation function must be a table with two columns. For more information, see the `read` function of `RandomPatchExtractionDatastore`.

The `transform` function must return data that matches the input size of the network. The `transform` function does not support one-to-many observation mappings.

To apply random affine transformations to volumetric data in `RandomPatchExtractionDatastore`, you must use the `transform` function. The `DataAugmentation` property of this datastore does not support volumetric data.

Examples

Transform Batch of Volumetric Data in Image Datastore

This example shows how to transform volumetric data in an image datastore using a sample image preprocessing pipeline.

Specify a set of volumetric images saved at MAT files.

```
filepath = fullfile(matlabroot,"toolbox","images","imdata","mristack.mat");
files = [filepath; filepath; filepath];
```

Create an image datastore that stores multiple volumetric images. Specify that the `ReadSize` of the datastore is greater than 1. Specify a custom read function, `matRead`. This function is defined in the Supporting Functions section of this example.

```
volDS = imageDatastore(files,"FileExtensions",".mat", ...
    "ReadSize",3,"ReadFcn",@(x) matRead(x));
```

Specify the input size of the network.

```
inputSize = [128 128];
```

Preprocess the volumetric images in `volDS` using the custom preprocessing pipeline defined in the `preprocessVolumetricIMDS` supporting function.

```
dsTrain = transform(volDS,@(x) preprocessVolumetricIMDS(x,inputSize));
```

Read a batch of data.

```
minibatch = read(dsTrain)
```

```
minibatch=3×1 cell array
    {128x128x21 uint8}
    {128x128x21 uint8}
    {128x128x21 uint8}
```

Supporting Functions

The `matRead` function loads volume data from the first variable of a MAT file.

```
function data = matRead(filename)
    inp = load(filename);
    f = fields(inp);
    data = inp.(f{1});
end
```

The `preprocessVolumetricIMDS` function performs the desired transformations of data read from an underlying image datastore. Because the read size of the image datastore is greater than 1, the function must accept a cell array of image data. The function loops through each read image and transforms the data according to this preprocessing pipeline:

- Randomly rotate the image about the *z*-axis.
- Resize the volume to the size expected by the network.
- Create a noisy version of the image with Gaussian noise.
- Return the image in a cell array.

```
function batchOut = preprocessVolumetricIMDS(batchIn,inputSize)

numRows = size(batchIn,1);
batchOut = cell(numRows,1);

for idx = 1:numRows

    % Perform randomized 90 degree rotation about the z-axis
    imRotated = imrotate3(batchIn{idx,1},90*(randi(4)-1),[0 0 1]);

    % Resize the volume to the size expected by the network
    imResized = imresize(imRotated,inputSize);

    % Add zero-mean Gaussian noise with a normalized variance of 0.01
    imNoisy = imnoise(imResized,'gaussian',0.01);
```

```
    % Return the preprocessed data
    batchOut(idx) = {imNoisy};

end
end
```

Transform Volumetric Data in Random Patch Extraction Datastore

This example shows how to transform pairs of volumetric data in a random patch extraction datastore using a sample image preprocessing pipeline.

Specify two sets of volumetric images saved at MAT files. Each set contains five volumetric images.

```
dir = fullfile(matlabroot,"toolbox","images","imdata","BrainMRILabeled");
filesVol1 = fullfile(dir,"images");
filesVol2 = fullfile(dir,"labels");
```

Store each set of volumetric images in an image datastore. Specify a custom read function, `matRead`. This function is defined in the Supporting Functions section of this example. Use the default `ReadSize` of 1.

```
vol1DS = imageDatastore(filesVol1,"FileExtensions",".mat","ReadFcn",@(x) matRead(x));
vol2DS = imageDatastore(filesVol2,"FileExtensions",".mat","ReadFcn",@(x) matRead(x));
```

Specify the input size of the network.

```
inputSize = [128 128];
```

Create a random patch extraction datastore that extracts corresponding patches from the two datastores. Select three patches per image.

```
patchVolDS = randomPatchExtractionDatastore(vol1DS,vol2DS,inputSize,"PatchesPerImage",3);
```

Preprocess the volumetric images in `patchVolDS` using the custom preprocessing pipeline defined in the `preprocessVolumetricPatchDS` supporting function.

```
dsTrain = transform(patchVolDS,@(x) preprocessVolumetricPatchDS(x));
```

Read a batch of data.

```
minibatch = read(dsTrain)
```

```
minibatch=15×2 table
         InputImage            ResponseImage
    ___________________    ___________________

    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
```

```
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
    {128x128x155 uint16}    {128x128x155 uint8}
```

Supporting Functions

The `matRead` function loads volume data from the first variable of a MAT file.

```
function data = matRead(filename)
    inp = load(filename);
    f = fields(inp);
    data = inp.(f{1});
end
```

The `preprocessVolumetricPatchDS` function performs the desired transformations of data read from the underlying random patch extraction datastore. The function must accept a table. The function transforms the data according to this preprocessing pipeline:

- Randomly select one of five augmentations.
- Apply the same augmentation to the data in both columns of the table.
- Return the augmented image pair in a table.

```
function batchOut = preprocessVolumetricPatchDS(batchIn)

numRows = size(batchIn,1);
batchOut = batchIn;

% 5 augmentations: nil,rot90,fliplr,flipud,rot90(fliplr)
augType = {@(x) x,@rot90,@fliplr,@flipud,@(x) rot90(fliplr(x))};

for idx = 1:numRows

    img = batchIn{idx,1}{1};
    resp = batchIn{idx,2}{1};

    rndIdx = randi(5,1);
    imgAug = augType{rndIdx}(img);
    respAug = augType{rndIdx}(resp);

    batchOut(idx,:) = {imgAug,respAug};

end
end
```

Preprocess Data for Domain-Specific Deep Learning Applications

Data preprocessing is used for training, validation, and inference. Preprocessing consists of a series of deterministic operations that normalize or enhance desired data features. For example, you can normalize data to a fixed range or rescale data to the size required by the network input layer.

Preprocessing can occur at two stages in the deep learning workflow.

- Commonly, preprocessing occurs as a separate step that you complete before preparing the data to be fed to the network. You load your original data, apply the preprocessing operations, then save the result to disk. The advantage of this approach is that the preprocessing overhead is only required once, then the preprocessed images are readily available as a starting place for all future trials of training a network.
- If you load your data into a datastore, then you can also apply preprocessing during training by using the `transform` and `combine` functions. For more information, see “Datastores for Deep Learning” on page 19-2. The transformed images are not stored in memory. This approach is convenient to avoid writing a second copy of training data to disk if your preprocessing operations are not computationally expensive and do not noticeably impact the speed of training the network.

Data augmentation consists of randomized operations that are applied to the training data while the network is training. Augmentation increases the effective amount of training data and helps to make the network invariant to common distortion in the data. For example, you can add artificial noise to training data so that the network is invariant to noise.

To augment training data, start by loading your data into a datastore. For more information, see “Datastores for Deep Learning” on page 19-2. Some built-in datastores apply a specific and limited set of augmentation to data for specific applications. You can also apply your own set of augmentation operations on data in the datastore by using the `transform` and `combine` functions. During training, the datastore randomly perturbs the training data for each epoch, so that each epoch uses a slightly different data set.

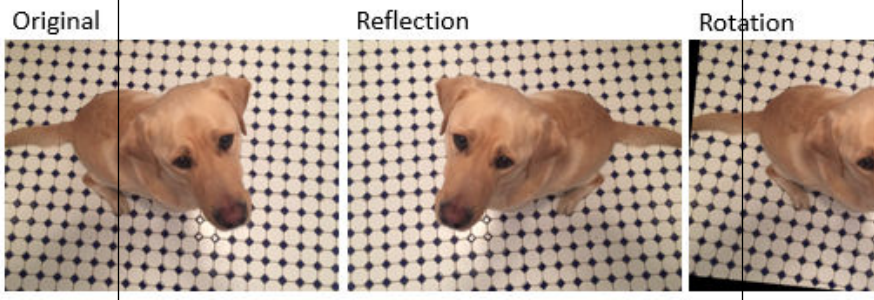
Image Processing Applications

Augment image data to simulate variations in the image acquisition. For example, the most common type of image augmentation operations are geometric transformations such as rotation and translation, which simulate variations in the camera orientation with respect to the scene. Color jitter simulates variations of lighting conditions and color in the scene. Artificial noise simulates distortions caused by the electrical fluctuations in the sensor and analog-to-digital conversion errors. Blur simulates an out-of-focus lens or movement of the camera with respect to the scene.

Common image preprocessing operations include noise removal, edge-preserving smoothing, color space conversion, contrast enhancement, and morphology.

If you have Image Processing Toolbox, then you can process data using these operations as well as any other functionality in the toolbox. For an example that shows how to create and apply these transformations, see “Augment Images for Deep Learning Workflows Using Image Processing Toolbox” on page 19-43.

Processing Type	Description	Sample Functions	Sample Output
Resize images	Resize images by a fixed scaling factor or to a target size	• `imresize`, `imresize3`	

Warp images	Apply random reflection, rotation, scale, shear, and translation to images	• `rand`
		`e2d`,
		`rand`
		`e3d`
			


Crop images	Crop an image to a target size from the center or a random position	• `centerCropWindow2d`, `centerCropWindow3d` • `randomWindow2d`, `randomCropWindow3d`	
Jitter color	Randomly adjust image hue, saturation, brightness, or contrast	• `jitt` `HSV`	
Processing Type	Description	Sample Functions	Sample Output
Simulate noise	Add random Gaussian, Poisson, salt and pepper, or multiplicative noise	• `imnoise`	Simulate blur	Add Gaussian or directional motion blur	• `imgaussfilt`, `imgaussfilt3` • `imfilter`	
Object Detection

Object detection data consists of an image and bounding boxes that describe the location and characteristics of objects in the image.

If you have Computer Vision Toolbox, then you can use the **Image Labeler** and the **Video Labeler** apps to interactively label ROIs and export the label data for training a neural network. If you have Automated Driving Toolbox™, then you also use the **Ground Truth Labeler** app to create labeled ground truth training data.

When you transform an image, you must perform an identical transformation to the corresponding bounding boxes. If you have Computer Vision Toolbox, then you can process bounding box data using the operations in the table. For an example that shows how to create and apply these transformations, see “Augment Bounding Boxes for Object Detection” on page 19-77. For more information, see “Getting Started with Object Detection Using Deep Learning” (Computer Vision Toolbox).

Processing Type	Description	Sample Functions	Sample Output
Resize bounding boxes	Resize bounding boxes by a fixed scaling factor or to a target size	• `bboxresize`	Crop bounding boxes	Crop a bounding box to a target size from the center or a random position	• `bboxcrop`	Warp bounding boxes	Apply reflection, rotation, scale, shear, and translation to bounding boxes	• `bbox`	
Semantic Segmentation

Semantic segmentation data consists of images and corresponding pixel labels represented as categorical arrays.

If you have Computer Vision Toolbox, then you can use the **Image Labeler** and the **Video Labeler** apps to interactively label pixels and export the label data for training a neural network. If you have Automated Driving Toolbox, then you also use the **Ground Truth Labeler** app to create labeled ground truth training data.

When you transform an image, you must perform an identical transformation to the corresponding pixel labeled image. If you have Image Processing Toolbox, then you can preprocess pixel label images using the functions in the table and any other toolbox function that supports categorical input. For an example that shows how to create and apply these transformations, see “Augment Pixel Labels for Semantic Segmentation” on page 19-67. For more information, see “Getting Started with Semantic Segmentation Using Deep Learning” (Computer Vision Toolbox).

Processing Type	Description	Sample Functions	Sample Output
Resize pixel labels	Resize pixel label images by a fixed scaling factor or to a target size	• `imresize`	Crop pixel labels	Crop a pixel label image to a target size from the center or a random position	• `imcrop` • `centerCropWindow2d`, `centerCropWindow3d` • `randomWindow2d`, `randomCropWindow3d`	Warp pixel labels	Apply random reflection, rotation, scale, shear, and translation to pixel label images	• `randomReflection2d`, `randomReflection3d`	
Signal Processing Applications

Signal Processing Toolbox™ enables you to denoise, smooth, detrend, and resample signals. You can augment training data with noise, multipath fading, and synthetic signals such as pulses and chirps. You can also create labeled sets of signals by using the **Signal Labeler** app and the `labeledSignalSet` object. For an example that shows how to create and apply these transformations, see “Waveform Segmentation Using Deep Learning” on page 12-41.

Wavelet Toolbox™ and Signal Processing Toolbox enable you to generate 2-D time-frequency representations of time series data that you can use as image inputs for signal classification applications. For an example, see “Classify Time Series Using Wavelet Analysis and Deep Learning” on page 12-94. Similarly, you can extract sequences from signal data to use as input for LSTM networks. For an example, see “Classify ECG Signals Using Long Short-Term Memory Networks” (Signal Processing Toolbox).

Communications Toolbox™ expands on signal processing functionality to enable you to perform error correction, interleaving, modulation, filtering, synchronization, and equalization of communication

systems. For an example that shows how to create and apply these transformations, see “Modulation Classification with Deep Learning” on page 13-38.

You can process signal data using the functions in the table as well as any other functionality in each toolbox.

Processing Type	Description	Sample Functions	Sample Output
Clean signals	• Apply median filtering or moving average to signal • Remove polynomial trend • Resample signal to new fixed rate	• `medfilt1`, `smoothdata` • `detrend` • `downsample`, `interp`, `upsample`	Filter signals	• Perform lowpass, highpass, and bandstop filtering of IIR and FIR signals • Design IIR and FIR filters • Apply IIR and FIR filters	• `bandpass`, `bandstop`, `highpass`, `lowpass` • `butter`, `designfilt`, `fir1`, `gaussdesign`, `rcosdesign` • `filter`	
Processing Type	Description	Sample Functions	Sample Output
Augment signals	• Add white Gaussian noise to signal using Communications Toolbox • Adjust time information of the signal, and perform multipath fading using Communications Toolbox • Add synthetic chirps and waveforms	• `awgn` • `chirp`, `square`, `rectpuls`, `sawtooth`	Create time-frequency representations	Create spectrograms, scalograms, and other 2-D representations of 1-D signals	• `pspe` `xspe` `m` • `fsst`, • `stft`, • `cwt`	Extract features from signals	Estimate instantaneous frequency and spectral entropy	• `inst` `pent`	
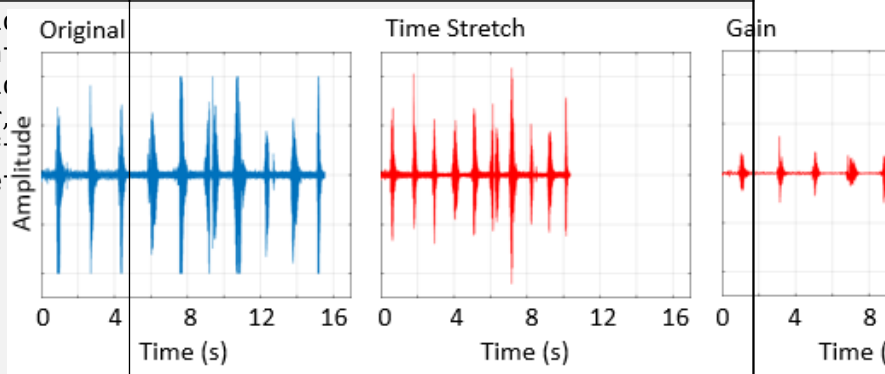
Audio Processing Applications

Audio Toolbox provides tools for audio processing, speech analysis, and acoustic measurement. Use these tools to extract auditory features and transform audio signals. Augment audio data with randomized or deterministic time scaling, time stretching, and pitch shifting. You can also create labeled ground truth training data by using the **Audio Labeler** app. You can process audio data using the functions in this table as well as any other functionality in the toolbox. For an example that shows how to create and apply these transformations, see “Augment Audio Dataset” (Audio Toolbox).

Processing Type	Description	Sample Functions	Sample Output

Augment audio data	Perform random or deterministic pitch shifting, time-scale modification, time shifting, noise addition, and volume control	• `audi`
		`gmen`
		`audi`
		`aler`,
		`shif`
		`stre`
		`o`
			


Extract audio features	Extract spectral parameters from audio segments	• `audioFeatur`
		`eExtractor`,
		`mfcc`
						Processed output:
			`ans = struct with fields:`
			`mfcc: [1 2 3 4 5 6 7 8 9 10 11 12 13`
			`mfccDelta: [14 15 16 17 18 19 20 21 22 23`
			`mfccDeltaDelta: [27 28 29 30 31 32 33 34 35 36`
			`spectralCentroid: 40`
			`pitch: 41`

Create time-frequency representations	Create mel spectrograms and other 2-D representations of audio signals	• `melS` `ram`,	
Text Analytics

Text Analytics Toolbox includes tools for processing raw text from sources such as equipment logs, news feeds, surveys, operator reports, and social media. Use these tools to extract text from popular file formats, preprocess raw text, extract individual words or multiword phrases (n-grams), convert text into numerical representations, and build statistical models. You can process text data using the functions in this table as well as any other functionality in the toolbox. For an example showing how to get started, see “Prepare Text Data for Analysis” (Text Analytics Toolbox).

Processing Type	Description	Sample Functions	Sample Output

Tokenize text	Parse text into words and punctuation	• `tokenizedDocument`	Original:
			`"A few tree limbs greater than 6 inches down on HWY 18 in Roseland."`
			Processed output:
			`15 tokens: A few tree limbs greater than 6 inches down on HWY 18 in Roseland .`

Clean text	• Remove variations in word forms and case
	• Remove punctuation
	• Remove stop words, short words, and long words
		• `normalizeWords`
		• `erasePunctuation`
		• `removeStopWords`, `removeShortWords`, `removeLongWords`
			Processed output:
			`15 tokens: a few tree limb great than 6 inch down on hwy 18 in roseland .`
			`14 tokens: a few tree limb great than 6 inch down on hwy 18 in roseland`
			`8 tokens: few tree limb great inch down hwy roseland`

Develop Custom Mini-Batch Datastore

A *mini-batch datastore* is an implementation of a datastore with support for reading data in batches. You can use a mini-batch datastore as a source of training, validation, test, and prediction data sets for deep learning applications that use Deep Learning Toolbox.

To preprocess sequence, time series, or text data, build your own mini-batch datastore using the framework described here. For an example showing how to use a custom mini-batch datastore, see “Train Network Using Custom Mini-Batch Datastore for Sequence Data” on page 19-104.

Overview

Build your custom datastore interface using the custom datastore classes and objects. Then, use the custom datastore to bring your data into MATLAB.

Designing your custom mini-batch datastore involves inheriting from the `matlab.io.Datastore` and `matlab.io.datastore.MiniBatchable` classes, and implementing the required properties and methods. You optionally can add support for shuffling during training.

Processing Needs	Classes
Mini-batch datastore for training, validation, test, and prediction data sets in Deep Learning Toolbox	`matlab.io.Datastore` and `matlab.io.datastore.MiniBatchable` See “Implement MiniBatchable Datastore” on page 19-36.
Mini-batch datastore with support for shuffling during training	`matlab.io.Datastore`, `matlab.io.datastore.MiniBatchable`, and `matlab.io.datastore.Shuffleable` See “Add Support for Shuffling” on page 19-41.

Implement MiniBatchable Datastore

To implement a custom mini-batch datastore named `MyDatastore`, create a script `MyDatastore.m`. The script must be on the MATLAB path and should contain code that inherits from the appropriate class and defines the required methods. The code for creating a mini-batch datastore for training, validation, test, and prediction data sets in Deep Learning Toolbox must:

- Inherit from the classes `matlab.io.Datastore` and `matlab.io.datastore.MiniBatchable`.
- Define these properties: `MiniBatchSize` and `NumObservations`.
- Define these methods: `hasdata`, `read`, `reset`, and `progress`.

In addition to these steps, you can define any other properties or methods that you need to process and analyze your data.

Note If you are training a network and `trainingOptions` specifies `'Shuffle'` as `'once'` or `'every-epoch'`, then you must also inherit from the `matlab.io.datastore.Shuffleable` class. For more information, see “Add Support for Shuffling” on page 19-41.

The datastore read function must return data in a table. The table elements must be scalars, row vectors, or 1-by-1 cell arrays containing a numeric array.

For networks with a single input layer, the first and second columns specify the predictors and responses, respectively.

Tip To use a datastore for networks with multiple input layers, use the `combine` and `transform` functions to create a datastore that outputs a cell array with (`numInputs` + 1) columns, where `numInputs` is the number of network inputs. In this case, the first `numInputs` columns specify the predictors for each input and the last column specifies the responses. The order of inputs is given by the `InputNames` property of the layer graph `layers`.

The format of the predictors depend on the type of data.

Data	Format of Predictors
2-D image	*h*-by-*w*-by-*c* numeric array, where *h*, *w*, and *c* are the height, width, and number of channels of the image, respectively.
3-D image	*h*-by-*w*-by-*d*-by-*c* numeric array, where *h*, *w*, *d*, and *c* are the height, width, depth, and number of channels of the image, respectively.
Vector sequence	*c*-by-*s* matrix, where *c* is the number of features of the sequence and *s* is the sequence length.
1-D image sequence	*h*-by-*c*-by-*s* array, where *h* and *c* correspond to the height and number of channels of the image, respectively, and *s* is the sequence length. Each sequence in the mini-batch must have the same sequence length.
2-D image sequence	*h*-by-*w*-by-*c*-by-*s* array, where *h*, *w*, and *c* correspond to the height, width, and number of channels of the image, respectively, and *s* is the sequence length. Each sequence in the mini-batch must have the same sequence length.
3-D image sequence	*h*-by-*w*-by-*d*-by-*c*-by-*s* array, where *h*, *w*, *d*, and *c* correspond to the height, width, depth, and number of channels of the image, respectively, and *s* is the sequence length. Each sequence in the mini-batch must have the same sequence length.
Features	*c*-by-1 column vector, where *c* is the number of features.

The table elements must contain a numeric scalar, a numeric row vector, or a 1-by-1 cell array containing a numeric array.

The `trainNetwork` function does not support networks with multiple sequence input layers.

The format of the responses depend on the type of task.

Task	Format of Responses
Classification	Categorical scalar
Regression	• Scalar • Numeric vector • 3-D numeric array representing an image
Sequence-to-sequence classification	1-by-*s* sequence of categorical labels, where *s* is the sequence length of the corresponding predictor sequence.
Sequence-to-sequence regression	*R*-by-*s* matrix, where *R* is the number of responses and *s* is the sequence length of the corresponding predictor sequence.

The table elements must contain a categorical scalar, a numeric scalar, a numeric row vector, or a 1-by-1 cell array containing a numeric array.

This example shows how to create a custom mini-batch datastore for processing sequence data. Save the script in a file called `MySequenceDatastore.m`.

Steps	Implementation

```
classdef MySequenceDatastore < matlab.io.Datastore & ...
                               matlab.io.datastore.MiniBatchable
```

1 Begin defining your class. Inherit from the base class `matlab.io.Datastore` and the `matlab.io.datastore.MiniBatchable` class.

2 Define properties.

- Redefine the `MiniBatchSize` and `NumObservations` properties. You optionally can assign additional property attributes to either property. For more information, see “Property Attributes”.
- You can also define properties unique to your custom mini-batch datastore.

```
    properties
        Datastore
        Labels
        NumClasses
        SequenceDimension
        MiniBatchSize
    end

    properties(SetAccess = protected)
        NumObservations
    end

    properties(Access = private)
        % This property is inherited from Datastore
        CurrentFileIndex
    end
```

3 Define methods.

- Implement the custom mini-batch datastore constructor.
- Implement the `hasdata` method.
- Implement the `read` method, which must return data as a table with the predictors in the first column and

```
    methods

        function ds = MySequenceDatastore(folder)
            % Construct a MySequenceDatastore object

            % Create a file datastore. The readSequence function is
            % defined following the class definition.
            fds = fileDatastore(folder, ...
                'ReadFcn',@readSequence, ...
                'IncludeSubfolders',true);
            ds.Datastore = fds;

            % Read labels from folder names
            numObservations = numel(fds.Files);
            for i = 1:numObservations
                file = fds.Files{i};
                filepath = fileparts(file);
                [~,label] = fileparts(filepath);
                labels{i,1} = label;
            end
            ds.Labels = categorical(labels);
            ds.NumClasses = numel(unique(labels));

            % Determine sequence dimension. When you define the LSTM
            % network architecture, you can use this property to
            % specify the input size of the sequenceInputLayer.
            X = preview(fds);
            ds.SequenceDimension = size(X,1);

            % Initialize datastore properties.
            ds.MiniBatchSize = 128;
            ds.NumObservations = numObservations;
            ds.CurrentFileIndex = 1;
        end

        function tf = hasdata(ds)
            % Return true if more data is available
            tf = ds.CurrentFileIndex + ds.MiniBatchSize - 1 ...
                <= ds.NumObservations;
        end

        function [data,info] = read(ds)
            % Read one mini-batch batch of data
            miniBatchSize = ds.MiniBatchSize;
            info = struct;

            for i = 1:miniBatchSize
                predictors{i,1} = read(ds.Datastore);
                responses(i,1) = ds.Labels(ds.CurrentFileIndex);
```

Steps	Implementation

responses in the second column.
 	
For sequence data, the sequences must be matrices of size *c*-by-*s*, where *c* is the number of features and *s* is sequence length. The value of *s* can vary between mini-batches.
• Implement the `reset` method.
• Implement the `progress` method.
• You can also define methods unique to your custom mini-batch datastore.
	`` ds.CurrentFileIndex = ds.CurrentFileIndex + 1;
	        end
	
	        data = preprocessData(ds,predictors,responses);
	    end
	
	    function data = preprocessData(ds,predictors,responses)
	        % data = preprocessData(ds,predictors,responses) preprocesses
	        % the data in predictors and responses and returns the table
	        % data
	
	        miniBatchSize = ds.MiniBatchSize;
	
	        % Pad data to length of longest sequence.
	        sequenceLengths = cellfun(@(X) size(X,2),predictors);
	        maxSequenceLength = max(sequenceLengths);
	        for i = 1:miniBatchSize
	            X = predictors{i};
	
	            % Pad sequence with zeros.
	            if size(X,2) < maxSequenceLength
	                X(:,maxSequenceLength) = 0;
	            end
	
	            predictors{i} = X;
	        end
	
	        % Return data as a table.
	        data = table(predictors,responses);
	    end
	
	    function reset(ds)
	        % Reset to the start of the data
	        reset(ds.Datastore);
	        ds.CurrentFileIndex = 1;
	    end
	
	end
	
	methods (Hidden = true)
	
	    function frac = progress(ds)
	        % Determine percentage of data read from datastore
	        frac = (ds.CurrentFileIndex - 1) / ds.NumObservations;
	    end
	
	end
	
	end % end class definition```

4 End the `classdef` section.	The implementation of the read method of your custom datastore uses a function called `readSequence`. You must create this function to read sequence data from a MAT-file.
	
	``function data = readSequence(filename)
	% data = readSequence(filename) reads the sequence X from the MAT-file
	% filename
	
	S = load(filename);
	data = S.X;
	end```

Add Support for Shuffling

To add support for shuffling, first follow the instructions in “Implement MiniBatchable Datastore” on page 19-36 and then update your implementation code in `MySequenceDatastore.m` to:

- Inherit from an additional class `matlab.io.datastore.Shuffleable`.
- Define the additional method `shuffle`.

This example code adds shuffling support to the `MySequenceDatastore` class. Vertical ellipses indicate where you should copy code from the `MySequenceDatastore` implementation.

Steps	Implementation

1 Update the class definition to also inherit from the `matlab.io.datastore.Shuffleable` class.	`classdef MySequenceDatastore < matlab.io.Datastore & ...`
	`  matlab.io.datastore.MiniBatchable & ...`
	`  matlab.io.datastore.Shuffleable`
	
	`  % previously defined properties`
	`  .`
	`  .`
	`  .`

2 Add the definition for `shuffle` to the existing `methods` section.	`  methods`
	
	`  % previously defined methods`
	`  .`
	`  .`
	`  .`
	
	`  function dsNew = shuffle(ds)`
	`  % dsNew = shuffle(ds) shuffles the files and the`
	`  % corresponding labels in the datastore.`
	
	`  % Create a copy of datastore`
	`  dsNew = copy(ds);`
	`  dsNew.Datastore = copy(ds.Datastore);`
	`  fds = dsNew.Datastore;`
	
	`  % Shuffle files and corresponding labels`
	`  numObservations = dsNew.NumObservations;`
	`  idx = randperm(numObservations);`
	`  fds.Files = fds.Files(idx);`
	`  dsNew.Labels = dsNew.Labels(idx);`
	`  end`
	
	`  end`
	
	`end`

Validate Custom Mini-Batch Datastore

If you have followed all the instructions presented here, then the implementation of your custom mini-batch datastore is complete. Before using this datastore, qualify it using the guidelines presented in “Testing Guidelines for Custom Datastores”.

Augment Images for Deep Learning Workflows Using Image Processing Toolbox

This example shows how MATLAB® and Image Processing Toolbox™ can perform common kinds of image augmentation as part of deep learning workflows.

Image Processing Toolbox functions enable you to implement common styles of image augmentation. This example demonstrates five common types of transformations:

- Random Image Warping Transformations on page 19-0
- Cropping Transformations on page 19-0
- Color Transformations on page 19-0
- Synthetic Noise on page 19-0
- Synthetic Blur on page 19-0

The example then shows how to apply augmentation to image data in datastores on page 19-0 using a combination of multiple types of transformations.

You can use augmented training data to train a network. For an example of training a network using augmented images, see “Prepare Datastore for Image-to-Image Regression” on page 19-91.

Read and display a sample image. To compare the effect of the different types of image augmentation, each transformation uses the same input image.

```
imOriginal = imread('kobi.png');
imshow(imOriginal)
```

Random Image Warping Transformations

The `randomAffine2d` (Image Processing Toolbox) function creates a randomized 2-D affine transformation from a combination of rotation, translation, scale (resizing), reflection, and shear. You can specify which transformations to include and the range of transformation parameters. If you specify the range as a 2-element numeric vector, then `randomAffine2d` selects the value of a parameter from a uniform probability distribution over the specified interval. For more control of the range of parameter values, you can specify the range using a function handle.

Control the spatial bounds and resolution of the warped image created by `imwarp` (Image Processing Toolbox) by using the `affineOutputView` (Image Processing Toolbox) function.

Rotation

Create a randomized rotation transformation that rotates the input image by an angle selected randomly from the range [-45, 45] degrees.

```
tform = randomAffine2d('Rotation',[-45 45]);
outputView = affineOutputView(size(imOriginal),tform);
imAugmented = imwarp(imOriginal,tform,'OutputView',outputView);
imshow(imAugmented)
```

Translation

Create a translation transformation that shifts the input image horizontally and vertically by a distance selected randomly from the range [-50, 50] pixels.

```
tform = randomAffine2d('XTranslation',[-50 50],'YTranslation',[-50 50]);
outputView = affineOutputView(size(imOriginal),tform);
imAugmented = imwarp(imOriginal,tform,'OutputView',outputView);
imshow(imAugmented)
```

Scale

Create a scale transformation that resizes the input image using a scale factor selected randomly from the range [1.2, 1.5]. This transformation resizes the image by the same factor in the horizontal and vertical directions.

```
tform = randomAffine2d('Scale',[1.2,1.5]);
outputView = affineOutputView(size(imOriginal),tform);
imAugmented = imwarp(imOriginal,tform,'OutputView',outputView);
imshow(imAugmented)
```

Reflection

Create a reflection transformation that flips the input image with 50% probability in each dimension.

```
tform = randomAffine2d('XReflection',true,'YReflection',true);
outputView = affineOutputView(size(imOriginal),tform);
imAugmented = imwarp(imOriginal,tform,'OutputView',outputView);
imshow(imAugmented)
```

Shear

Create a horizontal shear transformation with the shear angle selected randomly from the range [-30, 30].

```
tform = randomAffine2d('XShear',[-30 30]);
outputView = affineOutputView(size(imOriginal),tform);
imAugmented = imwarp(imOriginal,tform,'OutputView',outputView);
imshow(imAugmented)
```

Control Range of Transformation Parameters Using Custom Selection Function

In the preceding transformations, the range of transformation parameters was specified by two-element numeric vectors. For more control of the range of the transformation parameters, specify a function handle instead of a numeric vector. The function handle takes no input arguments and yields a valid value for each parameter.

For example, this code selects a rotation angle from a discrete set of 90 degree rotation angles.

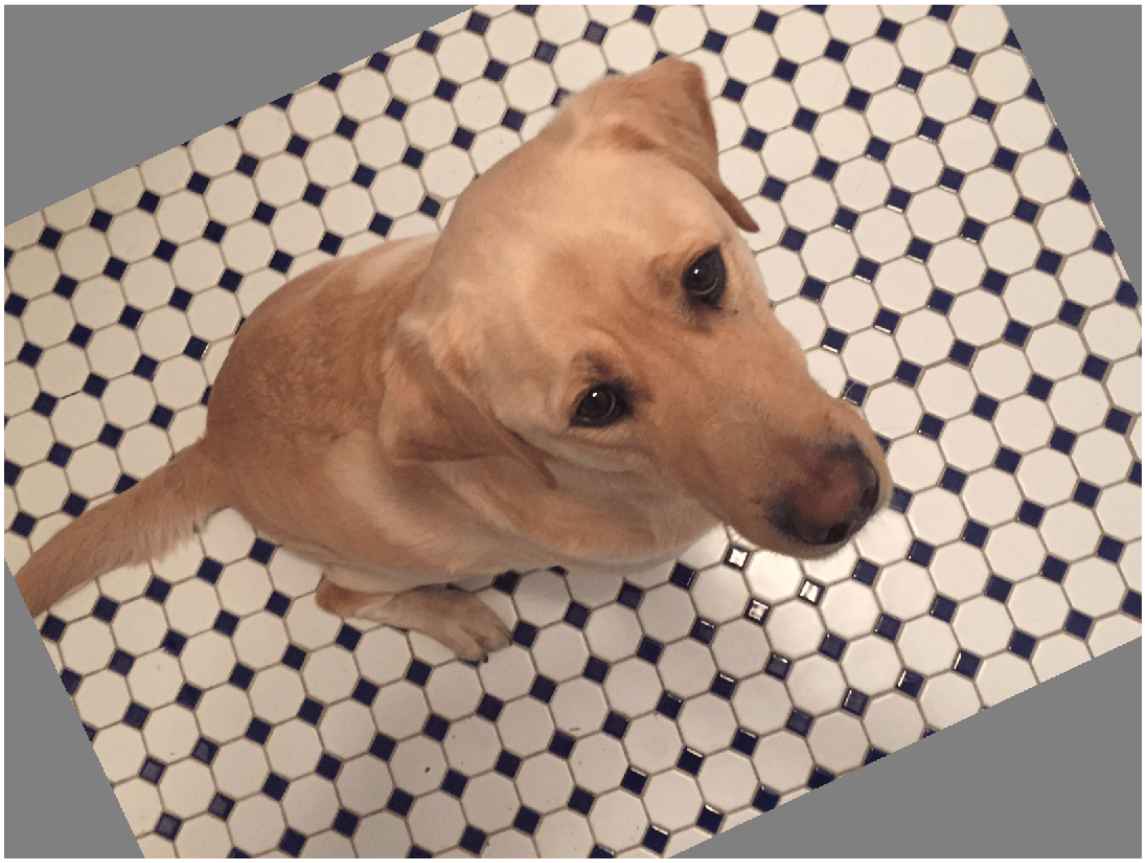
```
angles = 0:90:270;
tform = randomAffine2d('Rotation',@() angles(randi(4)));
outputView = affineOutputView(size(imOriginal),tform);
imAugmented = imwarp(imOriginal,tform,'OutputView',outputView);
imshow(imAugmented)
```

Control Fill Value

When you warp an image using a geometric transformation, pixels in the output image can map to a location outside the bounds of the input image. In that case, `imwarp` assigns a fill value to those pixels in the output image. By default, `imwarp` selects black as the fill value. You can change the fill value by specifying the `'FillValues'` name-value pair argument.

Create a random rotation transformation, then apply the transformation and specify a gray fill value.

```
tform = randomAffine2d('Rotation',[-45 45]);
outputView = affineOutputView(size(imOriginal),tform);
imAugmented = imwarp(imOriginal,tform,'OutputView',outputView,'FillValues',[128 128 128]);
imshow(imAugmented)
```



Cropping Transformations

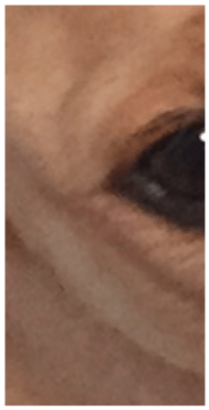
To create output images of a desired size, use the `randomWindow2d` (Image Processing Toolbox) and `centerCropWindow2d` (Image Processing Toolbox) functions. Be careful to select a window that includes the desired content in the image.

Specify the desired size of the cropped region as a 2-element vector of the form [*height, width*].

```
targetSize = [200,100];
```

Crop the image to the target size from the center of the image.

```
win = centerCropWindow2d(size(imOriginal),targetSize);
imCenterCrop = imcrop(imOriginal,win);
imshow(imCenterCrop)
```



Crop the image to the target size from a random location in the image.

```
win = randomWindow2d(size(imOriginal),targetSize);
imRandomCrop = imcrop(imOriginal,win);
imshow(imRandomCrop)
```

Color Transformations

You can randomly adjust the hue, saturation, brightness, and contrast of a color image by using the `jitterColorHSV` (Image Processing Toolbox) function. You can specify which color transformations are included and the range of transformation parameters.

You can randomly adjust the brightness and contrast of grayscale images by using basic math operations.

Hue Jitter

Hue specifies the shade of color, or a color's position on a color wheel. As hue varies from 0 to 1, colors vary from red through yellow, green, cyan, blue, purple, magenta, and back to red. Hue jitter shifts the apparent shade of colors in an image.

Adjust the hue of the input image by a small positive offset selected randomly from the range [0.05, 0.15]. Colors that were red now appear more orange or yellow, colors that were orange appear yellow or green, and so on.

```
imJittered = jitterColorHSV(imOriginal,'Hue',[0.05 0.15]);
montage({imOriginal,imJittered})
```

Saturation Jitter

Saturation is the purity of color. As saturation varies from 0 to 1, hues vary from gray (indicating a mixture of all colors) to a single pure color. Saturation jitter shifts how dull or vibrant colors are.

Adjust the saturation of the input image by an offset selected randomly from the range [-0.4, -0.1]. The colors in the output image appear more muted, as expected when the saturation decreases.

```
imJittered = jitterColorHSV(imOriginal,'Saturation',[-0.4 -0.1]);
montage({imOriginal,imJittered})
```

Brightness Jitter

Brightness is the amount of hue. As brightness varies from 0 to 1, colors go from black to white. Brightness jitter shifts the darkness and lightness of an input image.

Adjust the brightness of the input image by an offset selected randomly from the range [-0.3, -0.1]. The image appears darker, as expected when the brightness decreases.

```
imJittered = jitterColorHSV(imOriginal,'Brightness',[-0.3 -0.1]);
montage({imOriginal,imJittered})
```

Contrast Jitter

Contrast jitter randomly adjusts the difference between the darkest and brightest regions in an input image.

Adjust the contrast of the input image by a scale factor selected randomly from the range [1.2, 1.4]. The contrast increases, such that shadows become darker and highlights become brighter.

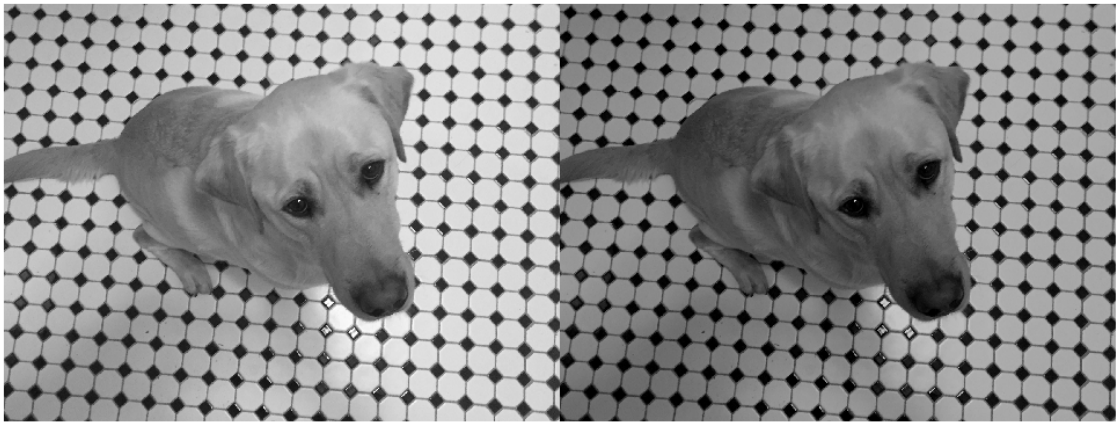
```
imJittered = jitterColorHSV(imOriginal,'Contrast',[1.2 1.4]);
montage({imOriginal,imJittered})
```

Brightness and Contrast Jitter of Grayscale Images

You can apply randomized brightness and contrast jitter to grayscale images by using basic math operations.

Convert the sample image to grayscale. Specify a random contrast scale factor in the range [0.8, 1] and a random brightness offset in the range [-0.15, 0.15]. Multiply the image by the contrast scale factor, then add the brightness offset.

```
imGray = rgb2gray(im2double(imOriginal));
contrastFactor = 1-0.2*rand;
brightnessOffset = 0.3*(rand-0.5);
imJittered = imGray.*contrastFactor + brightnessOffset;
imJittered = im2uint8(imJittered);
montage({imGray,imJittered})
```



Randomized Color-to-Grayscale

One type of color augmentation randomly drops the color information from an RGB image while preserving the number of channels expected by the network. This code shows a "random grayscale" transformation in which an RGB image is randomly converted with 80% probability to a three channel output image where R == G == B.

```
desiredProbability = 0.8;
if rand <= desiredProbability
    imJittered = repmat(rgb2gray(imOriginal),[1 1 3]);
end
imshow(imJittered)
```

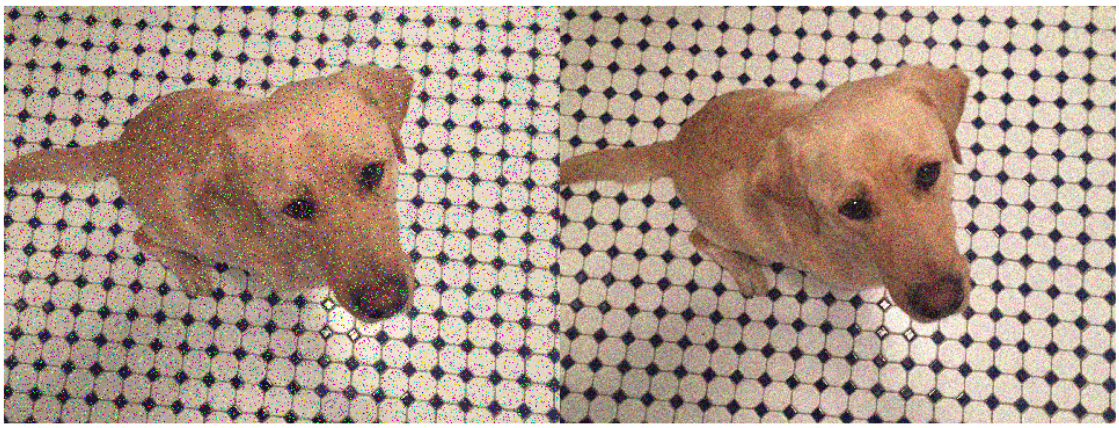
Other Image Processing Operations

Use the `transform` function to apply any combination of Image Processing Toolbox functions to input images. Adding noise and blur are two common image processing operations used in deep learning applications.

Synthetic Noise

To apply synthetic noise to an input image, use the `imnoise` (Image Processing Toolbox) function. You can specify which noise model to use, such as Gaussian, Poisson, salt and pepper, and multiplicative noise. You can also specify the strength of the noise.

```
imSaltAndPepperNoise = imnoise(imOriginal,'salt & pepper',0.1);
imGaussianNoise = imnoise(imOriginal,'gaussian');
montage({imSaltAndPepperNoise,imGaussianNoise})
```



Synthetic Blur

To apply randomized Gaussian blur to an image, use the `imgaussfilt` (Image Processing Toolbox) function. You can specify the amount of smoothing.

```
sigma = 1+5*rand;
imBlurred = imgaussfilt(imOriginal,sigma);
imshow(imBlurred)
```

Apply Augmentation to Image Data in Datastores

In practical deep learning problems, the image augmentation pipeline typically combines multiple operations. Datastores are a convenient way to read and augment collections of images.

This section of the example shows how to define data augmentation pipelines that augment datastores in the context of training image classification and image regression problems.

First, create an `imageDatastore` that contains unprocessed images. The image datastore in this example contains digit images with labels.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet', ...
    'nndemos','nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
imds.ReadSize = 6;
```

Image Classification

In image classification, the classifier should learn that a randomly altered version of an image still represents the same image class. To augment data for image classification, it is sufficient to augment the input images while leaving the corresponding categorical labels unchanged.

Augment images in the pristine image datastore with random Gaussian blur, salt and pepper noise, and randomized scale and rotation. These operations are defined in the helper function `classificationAugmentationPipeline` at the end of this example. Apply data augmentation to the training data by using the `transform` function.

```
dsTrain = transform(imds,@classificationAugmentationPipeline,'IncludeInfo',true);
```

Visualize a sample of the output coming from the augmented pipeline.

```
dataPreview = preview(dsTrain);
montage(dataPreview(:,1))
title("Augmented Images for Image Classification")
```

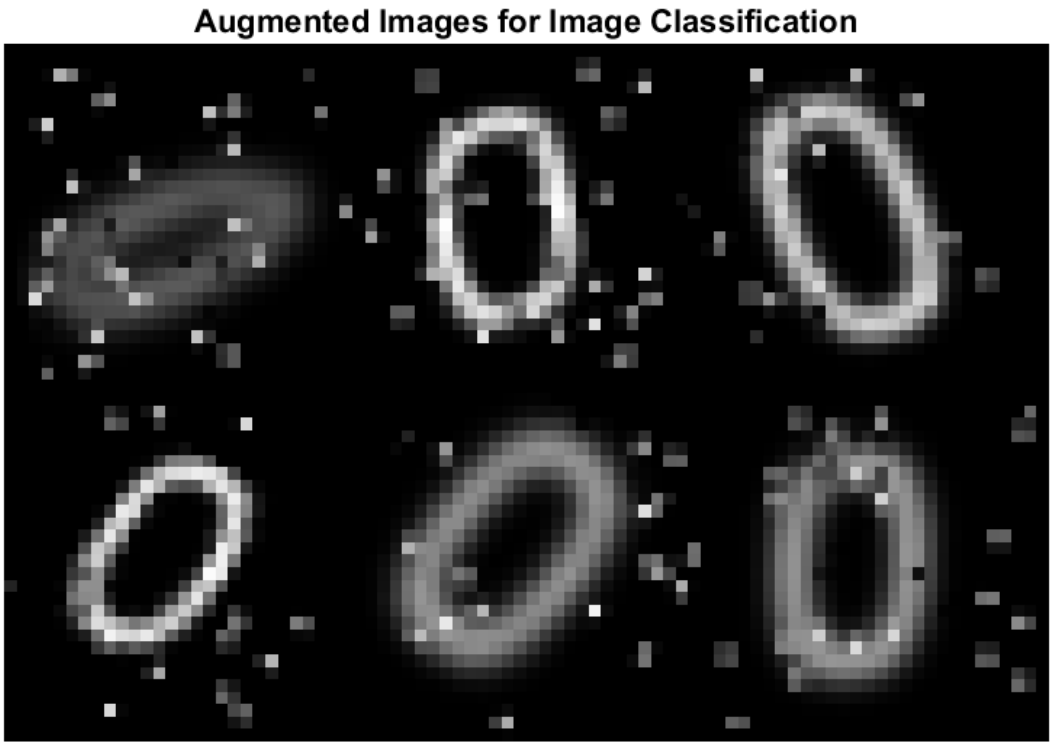


Image Regression

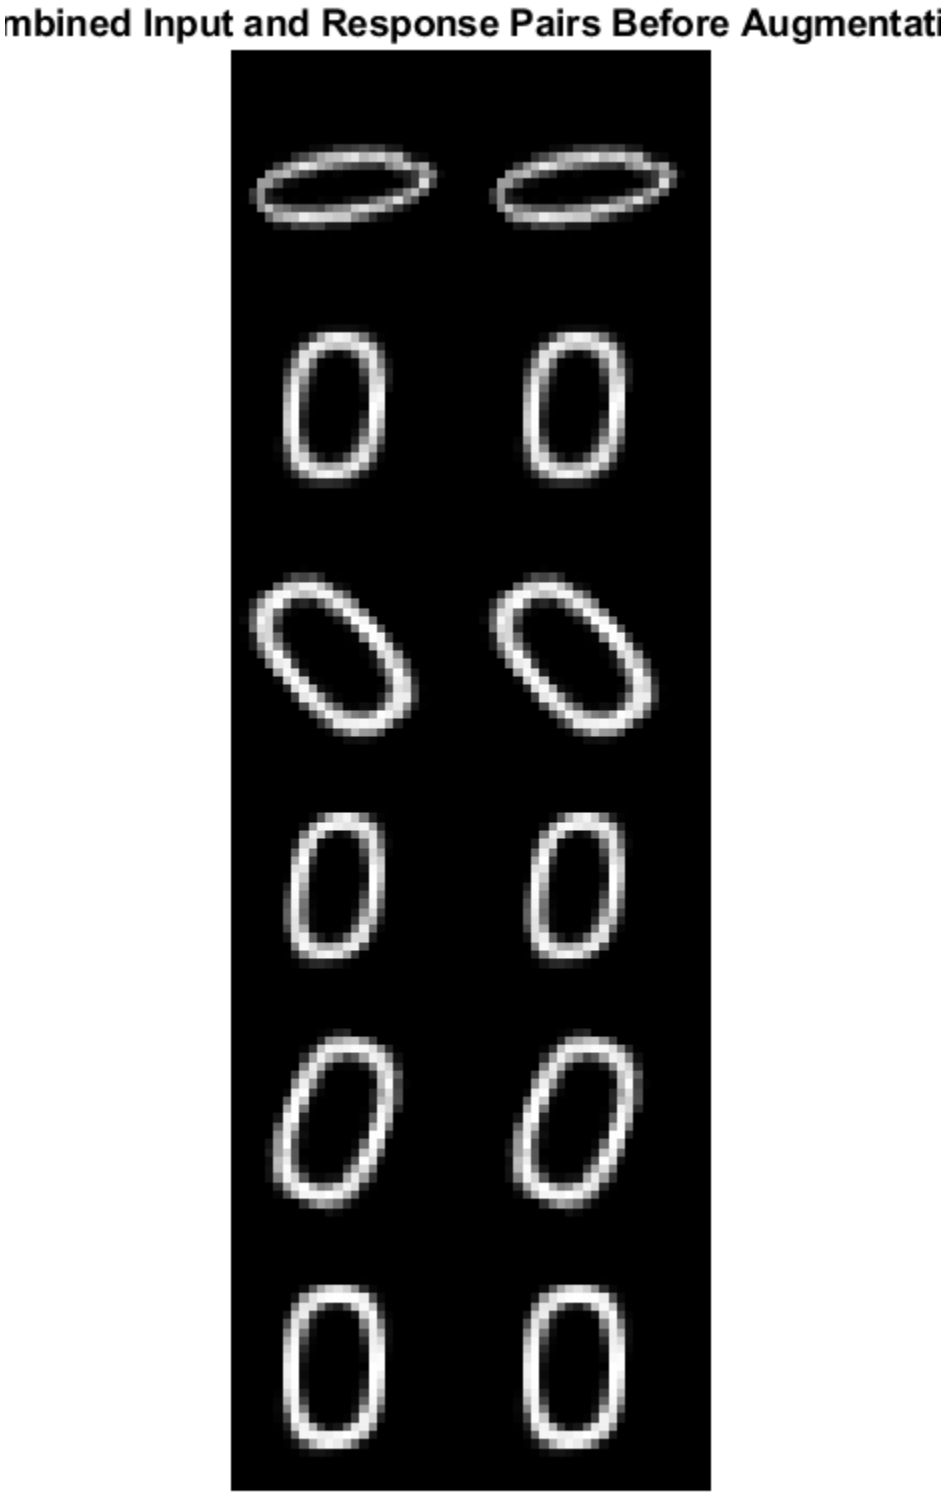
Image augmentation for image-to-image regression is more complicated because you must apply identical geometric transformations to the input and response images. Associate pairs of input and response images by using the `combine` function. Transform one or both images in each pair by using the `transform` function.

Combine two identical copies of the image datastore `imds`. When data is read from the combined datastore, image data is returned in a two-column cell array, where the first column represents network input images and the second column contains network responses.

```
dsCombined = combine(imds,imds);
montage(preview(dsCombined)','Size',[6 2])
title("Combined Input and Response Pairs Before Augmentation")
```



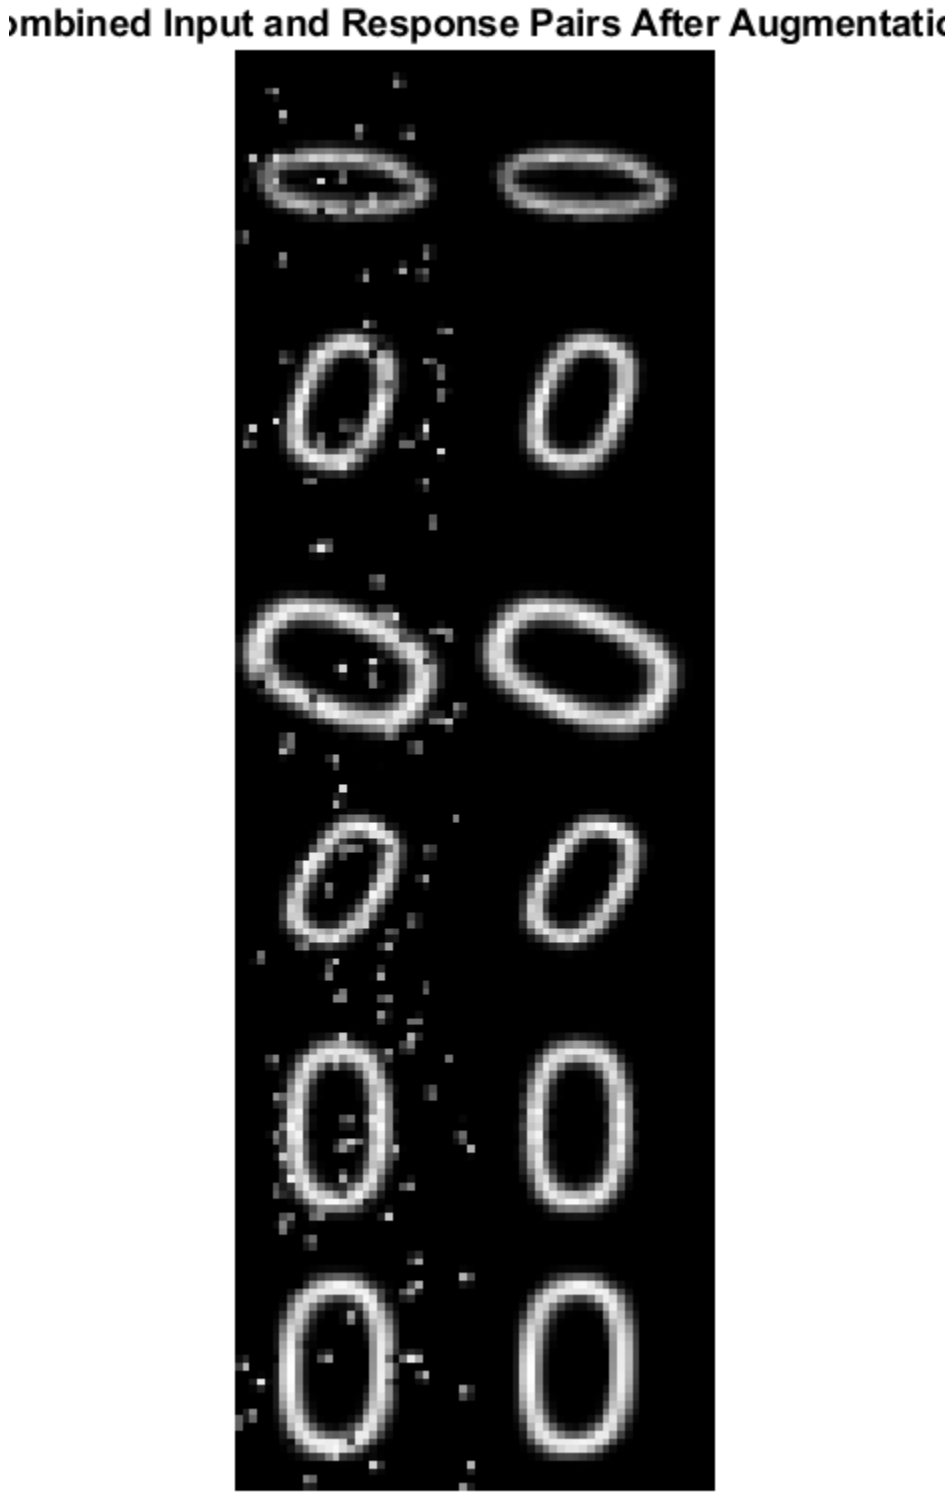
mbined Input and Response Pairs Before Augmentati

Augment each pair of training images with a series of image processing operations:

- Resize the input and response image to 32-by-32 pixels.
- Add salt and pepper noise to the input image only.
- Create a transformation that has randomized scale and rotation.
- Apply the same transformation to the input and response image.

These operations are defined in the helper function `imageRegressionAugmentationPipeline` at the end of this example. Apply data augmentation to the training data by using the `transform` function.

```
dsTrain = transform(dsCombined,@imageRegressionAugmentationPipeline);
montage(preview(dsTrain)','Size',[6 2])
title("Combined Input and Response Pairs After Augmentation")
```



ombined Input and Response Pairs After Augmentatic

For a complete example that includes training and evaluating an image-to-image regression network, see “Prepare Datastore for Image-to-Image Regression” on page 19-91.

Supporting Functions

The `classificationAugmentationPipeline` helper function augments images for classification. `dataIn` and `dataOut` are two-element cell arrays, where the first element is the network input image and the second element is the categorical label.

```
function [dataOut,info] = classificationAugmentationPipeline(dataIn,info)

dataOut = cell([size(dataIn,1),2]);

for idx = 1:size(dataIn,1)
    temp = dataIn{idx};

    % Add randomized Gaussian blur
    temp = imgaussfilt(temp,1.5*rand);

    % Add salt and pepper noise
    temp = imnoise(temp,'salt & pepper');

    % Add randomized rotation and scale
    tform = randomAffine2d('Scale',[0.95,1.05],'Rotation',[-30 30]);
    outputView = affineOutputView(size(temp),tform);
    temp = imwarp(temp,tform,'OutputView',outputView);

    % Form second column expected by trainNetwork which is the expected response,
    % the categorical label in this case
    dataOut(idx,:) = {temp,info.Label(idx)};
end

end
```

The `imageRegressionAugmentationPipeline` helper function augments images for image-to-image regression. `dataIn` and `dataOut` are two-element cell arrays, where the first element is the network input image and the second element is the network response image.

```
function dataOut = imageRegressionAugmentationPipeline(dataIn)

dataOut = cell([size(dataIn,1),2]);
for idx = 1:size(dataIn,1)

    % Resize images to 32-by-32 pixels and convert to data type single
    inputImage = im2single(imresize(dataIn{idx,1},[32 32]));
    targetImage = im2single(imresize(dataIn{idx,2},[32 32]));

    % Add salt and pepper noise
    inputImage = imnoise(inputImage,'salt & pepper');

    % Add randomized rotation and scale
    tform = randomAffine2d('Scale',[0.9,1.1],'Rotation',[-30 30]);
    outputView = affineOutputView(size(inputImage),tform);

    % Use imwarp with the same tform and outputView to augment both images
    % the same way
    inputImage = imwarp(inputImage,tform,'OutputView',outputView);
    targetImage = imwarp(targetImage,tform,'OutputView',outputView);
```

```
    dataOut(idx,:) = {inputImage,targetImage};
end

end
```

Augment Pixel Labels for Semantic Segmentation

This example shows how to perform common kinds of image and pixel label augmentation as part of semantic segmentation workflows.

Semantic segmentation training data consists of images represented by numeric matrices and pixel label images represented by categorical matrices. When you augment training data, you must apply identical transformations to the image and associated pixel labels. This example demonstrates three common types of transformations:

- Resize Image and Pixel Labels on page 19-0
- Crop Image and Pixel Labels on page 19-0
- Warp Image and Pixel Labels on page 19-0

The example then shows how to apply augmentation to semantic segmentation training data in datastores on page 19-0 using a combination of multiple types of transformations.

You can use augmented training data to train a network. For an example showing how to train a semantic segmentation network, see “Semantic Segmentation Using Deep Learning” (Computer Vision Toolbox).

To demonstrate the effects of the different types of augmentation, each transformation in this example uses the same input image and pixel label image.

Read a sample image.

```
filenameImage = 'kobi.png';
I = imread(filenameImage);
```

Read the pixel label image. The image has two classes.

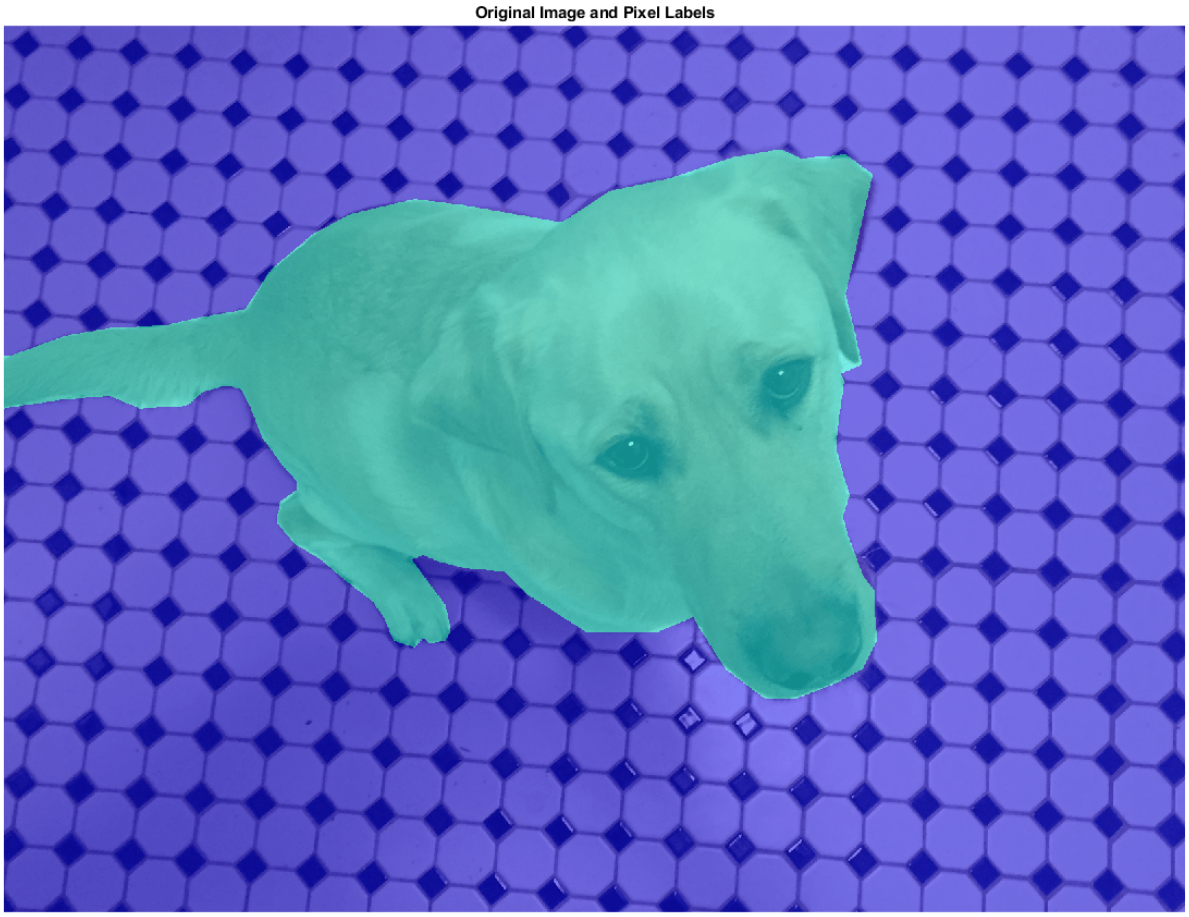
```
filenameLabels = 'kobiPixelLabeled.png';
L = imread(filenameLabels);
classes = ["floor","dog"];
ids = [1 2];
```

Convert the pixel label image to the categorical data type.

```
C = categorical(L,ids,classes);
```

Display the labels over the image by using the `labeloverlay` function. Pixels with the label "floor" have a blue tint and pixels with the label "dog" have a cyan tint.

```
B = labeloverlay(I,C);
imshow(B)
title('Original Image and Pixel Labels')
```



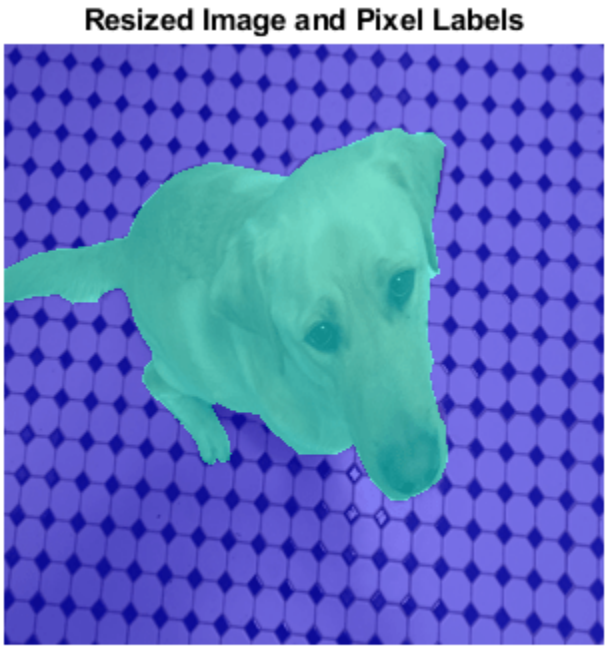
Resize Image and Pixel Labels

You can resize numeric and categorical images by using the `imresize` function. Resize the image and the pixel label image to the same size, and display the labels over the image.

```
targetSize = [300 300];
resizedI = imresize(I,targetSize);
resizedC = imresize(C,targetSize);
```

Display the resized labels over the resized image.

```
B = labeloverlay(resizedI,resizedC);
imshow(B)
title('Resized Image and Pixel Labels')
```



Crop Image and Pixel Labels

Cropping is a common preprocessing step to make the data match the input size of the network. To create output images of a desired size, first specify the size and position of the crop window by using the `randomWindow2d` (Image Processing Toolbox) and `centerCropWindow2d` (Image Processing Toolbox) functions. Make sure you select a cropping window that includes the desired content in the image. Then, crop the image and pixel label image to the same window by using `imcrop`.

Specify the desired size of the cropped region as a two-element vector of the form [*height, width*].

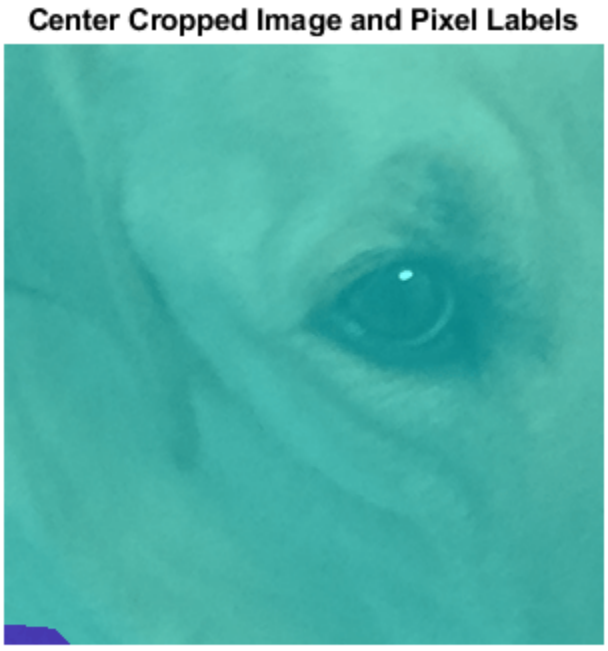
```
targetSize = [300 300];
```

Crop the image to the target size from the center of the image.

```
win = centerCropWindow2d(size(I),targetSize);
croppedI = imcrop(I,win);
croppedC = imcrop(C,win);
```

Display the cropped labels over the cropped image.

```
B = labeloverlay(croppedI,croppedC);
imshow(B)
title('Center Cropped Image and Pixel Labels')
```

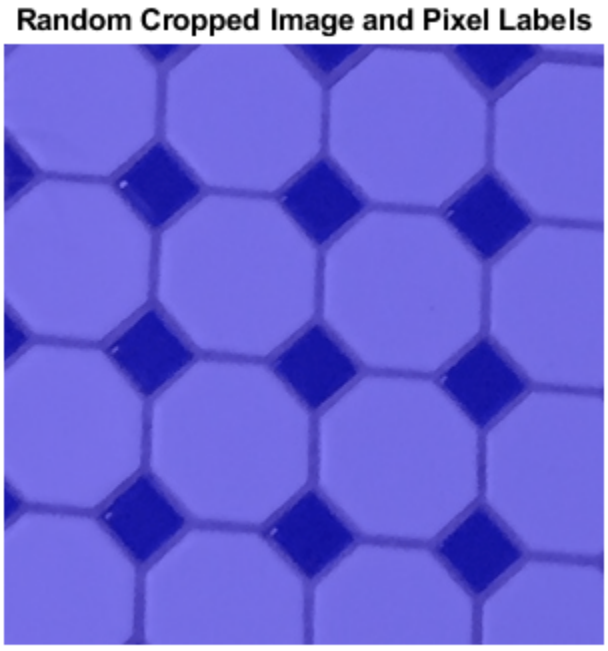


Crop the image to the target size from a random position in the image.

```
win = randomWindow2d(size(I),targetSize);
croppedI = imcrop(I,win);
croppedC = imcrop(C,win);
```

Display the cropped labels over the cropped image.

```
B = labeloverlay(croppedI,croppedC);
imshow(B)
title('Random Cropped Image and Pixel Labels')
```



Warp Image and Pixel Labels

The `randomAffine2d` (Image Processing Toolbox) function creates a randomized 2-D affine transformation from a combination of rotation, translation, scaling (resizing), reflection, and shearing. Apply the transformation to images and pixel label images by using `imwarp` (Image Processing Toolbox). Control the spatial bounds and resolution of the warped output by using the `affineOutputView` (Image Processing Toolbox) function.

Rotate the input image and pixel label image by an angle selected randomly from the range [-50,50] degrees.

```
tform = randomAffine2d("Rotation",[-50 50]);
```

Create an output view for the warped image and pixel label image.

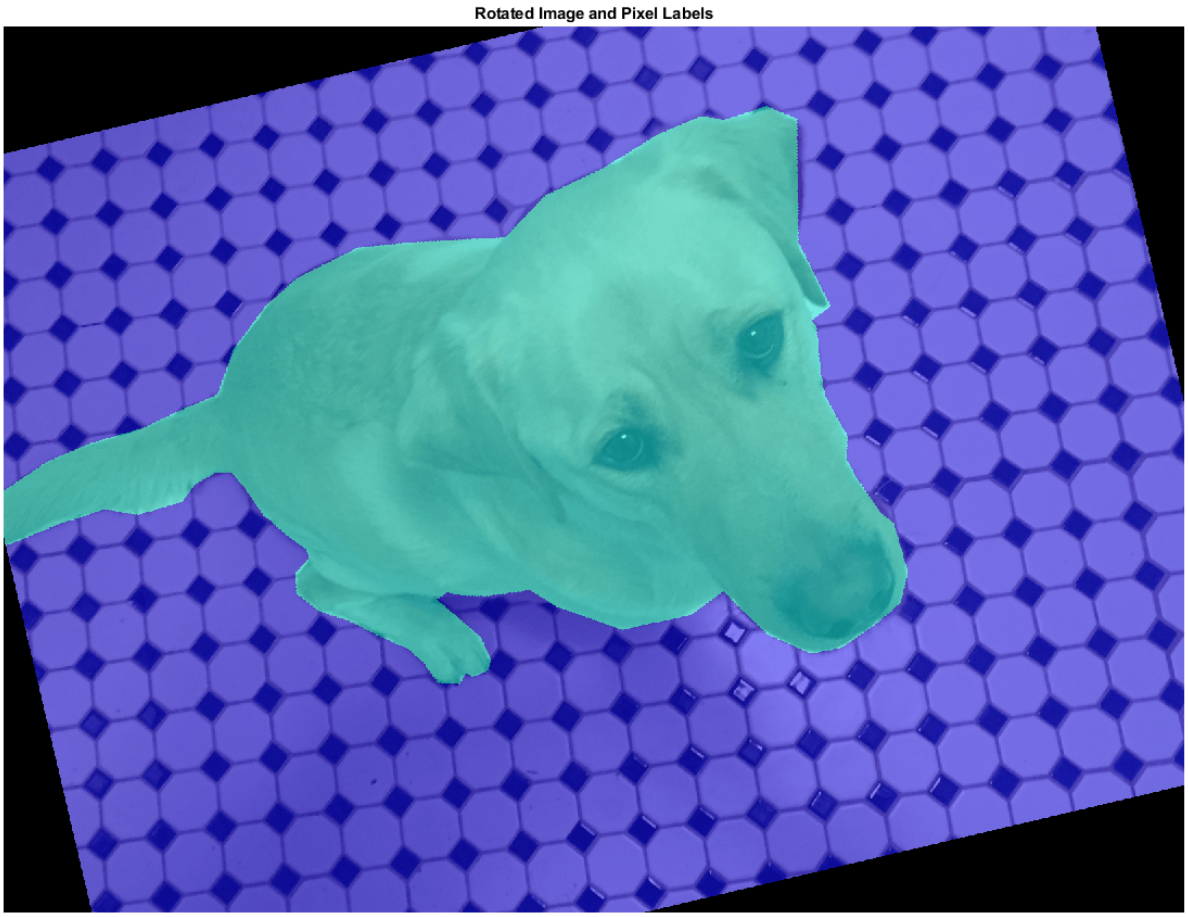
```
rout = affineOutputView(size(I),tform);
```

Use `imwarp` to rotate the image and pixel label image.

```
rotatedI = imwarp(I,tform,'OutputView',rout);
rotatedC = imwarp(C,tform,'OutputView',rout);
```

Display the rotated labels over the rotated image.

```
B = labeloverlay(rotatedI,rotatedC);
imshow(B)
title('Rotated Image and Pixel Labels')
```



Apply Augmentation to Semantic Segmentation Training Data in Datastores

Datastores are a convenient way to read and augment collections of images. Create a datastore that stores image and pixel label image data, and augment the data with a series of multiple operations.

Create Datastores Containing Image and Pixel Label Image Data

To increase the size of the sample datastores, replicate the filenames of the image and pixel label image.

```
numObservations = 4;
trainImages = repelem({filenameImage},numObservations,1);
trainLabels = repelem({filenameLabels},numObservations,1);
```

Create an `imageDatastore` from the training image files. Create a `pixelLabelDatastore` from the training pixel label files. The datastores contain multiple copies of the same data.

```
imds = imageDatastore(trainImages);
pxds = pixelLabelDatastore(trainLabels,classes,ids);
```

Associate the image and pixel label pairs by combining the image datastore and pixel label datastore.

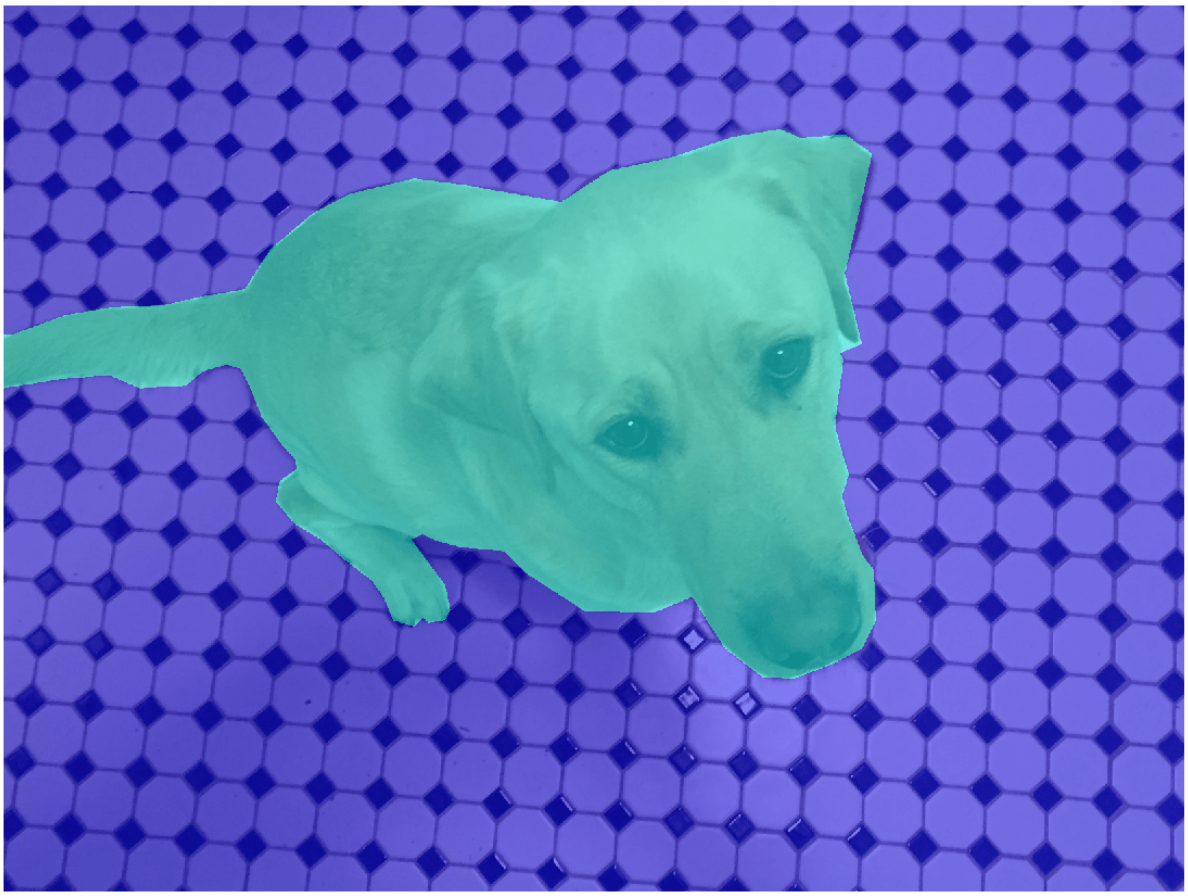
```
trainingData = combine(imds,pxds);
```

Read the first image and its associated pixel label image from the combined datastore.

```
data = read(trainingData);
I = data{1};
C = data{2};
```

Display the image and pixel label data.

```
B = labeloverlay(I,C);
imshow(B)
```



Apply Data Augmentation

Apply data augmentation to the training data by using the `transform` function. This example performs two separate augmentations to the training data.

The first augmentation jitters the color of the image and then performs identical random scaling, horizontal reflection, and rotation on the image and pixel label image pairs. These operations are defined in the `jitterImageColorAndWarp` helper function at the end of this example.

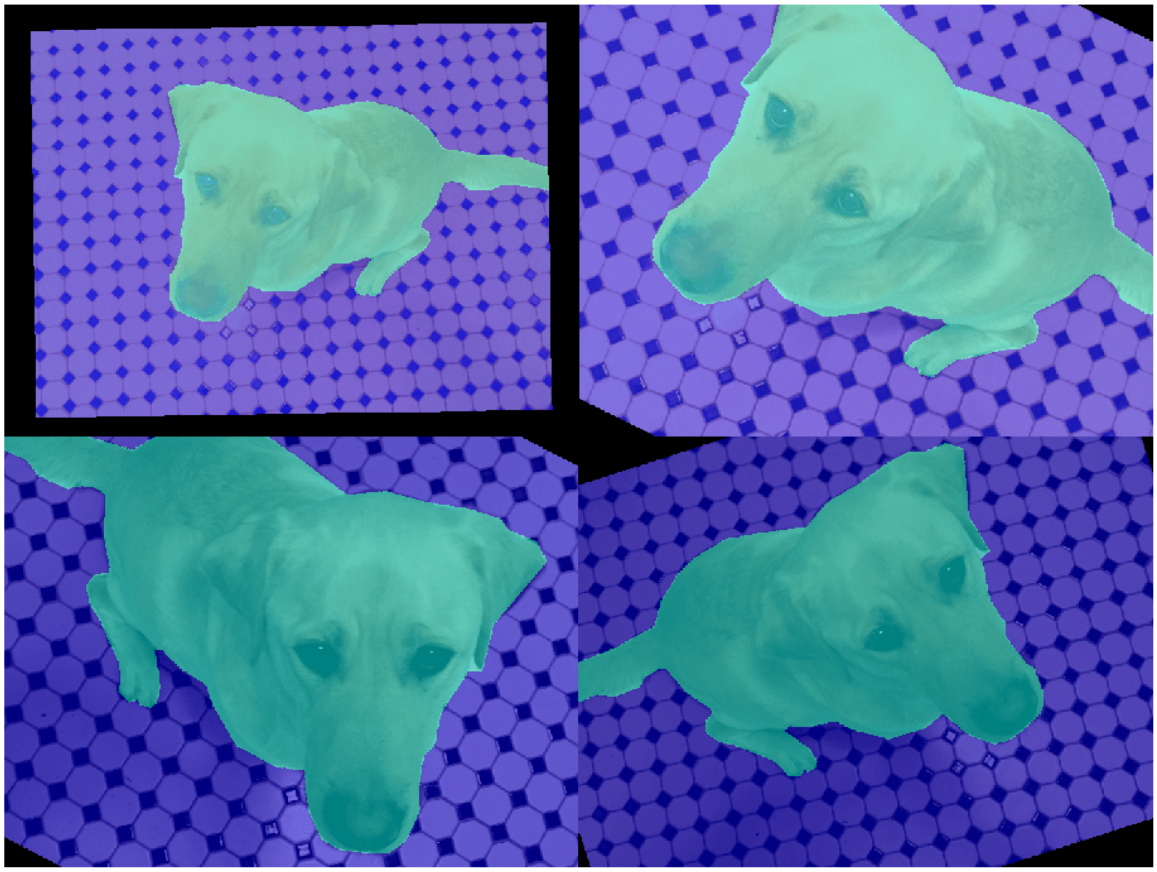
```
augmentedTrainingData = transform(trainingData,@jitterImageColorAndWarp);
```

Read all the augmented data.

```
data = readall(augmentedTrainingData);
```

Display the augmented image and pixel label data.

```
rgb = cell(numObservations,1);
for k = 1:numObservations
    I = data{k,1};
    C = data{k,2};
    rgb{k} = labeloverlay(I,C);
end
montage(rgb)
```



The second augmentation center crops the image and pixel label image to a target size. These operations are defined in the `centerCropImageAndLabel` helper function at the end of this example.

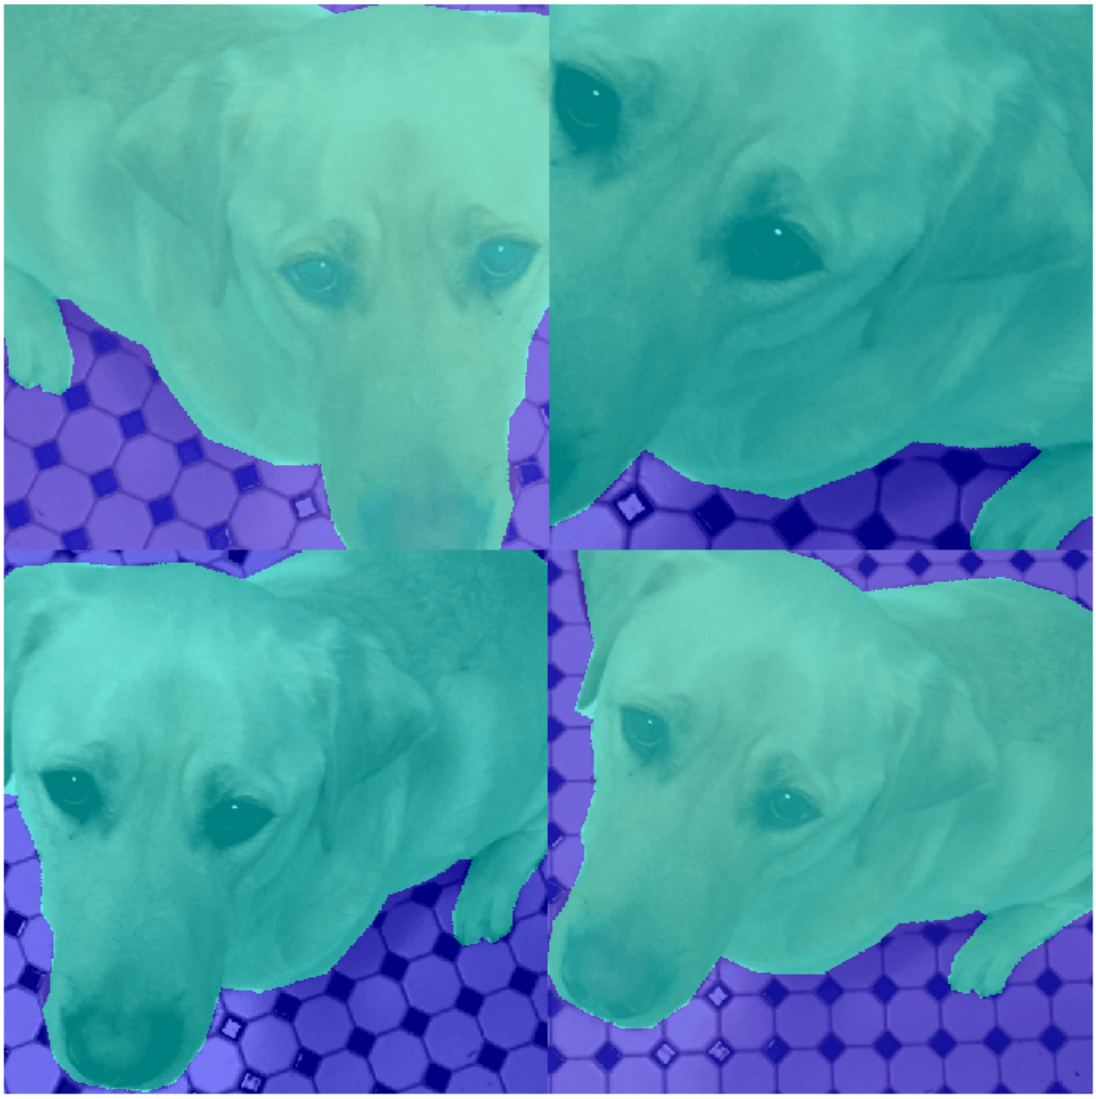
```
targetSize = [800 800];
preprocessedTrainingData = transform(augmentedTrainingData,...
    @(data)centerCropImageAndLabel(data,targetSize));
```

Read all of the preprocessed data.

```
data = readall(preprocessedTrainingData);
```

Display the preprocessed image and pixel label data.

```
rgb = cell(numObservations,1);
for k = 1:numObservations
    I = data{k,1};
    C = data{k,2};
    rgb{k} = labeloverlay(I,C);
end
montage(rgb)
```



Helper Functions for Augmentation

The `jitterImageColorAndWarp` helper function applies random color jitter to the image data, then applies an identical affine transformation to the image and pixel label image data. The transformation

consists of a random combination of scaling by a scale factor in the range [0.8 1.5], horizontal reflection, and rotation in the range [-30, 30] degrees. The input `data` and output `out` are two-element cell arrays, where the first element is the image data and the second element is the pixel label image data.

```
function out = jitterImageColorAndWarp(data)
% Unpack original data.
I = data{1};
C = data{2};

% Apply random color jitter.
I = jitterColorHSV(I,"Brightness",0.3,"Contrast",0.4,"Saturation",0.2);

% Define random affine transform.
tform = randomAffine2d("Scale",[0.8 1.5],"XReflection",true,'Rotation',[-30 30]);
rout = affineOutputView(size(I),tform);

% Transform image and bounding box labels.
augmentedImage = imwarp(I,tform,"OutputView",rout);
augmentedLabel = imwarp(C,tform,"OutputView",rout);

% Return augmented data.
out = {augmentedImage,augmentedLabel};
end
```

The `centerCropImageAndLabel` helper function creates a crop window centered on the image, then crops both the image and the pixel label image using the crop window. The input `data` and output `out` are two-element cell arrays, where the first element is the image data and the second element is the pixel label image data.

```
function out = centerCropImageAndLabel(data,targetSize)
win = centerCropWindow2d(size(data{1}),targetSize);
out{1} = imcrop(data{1},win);
out{2} = imcrop(data{2},win);
end
```

Augment Bounding Boxes for Object Detection

This example shows how to perform common kinds of image and bounding box augmentation as part of object detection workflows.

Object detector training data consists of images and associated bounding box labels. When you augment training data, you must apply identical transformations to the image and associated bounding boxes. This example demonstrates three common types of transformations:

- Resize Image and Bounding Box on page 19-0
- Crop Image and Bounding Box on page 19-0
- Warp Image and Bounding Box on page 19-0

The example then shows how to apply augmentation to training data in datastores on page 19-0 using a combination of multiple types of transformations.

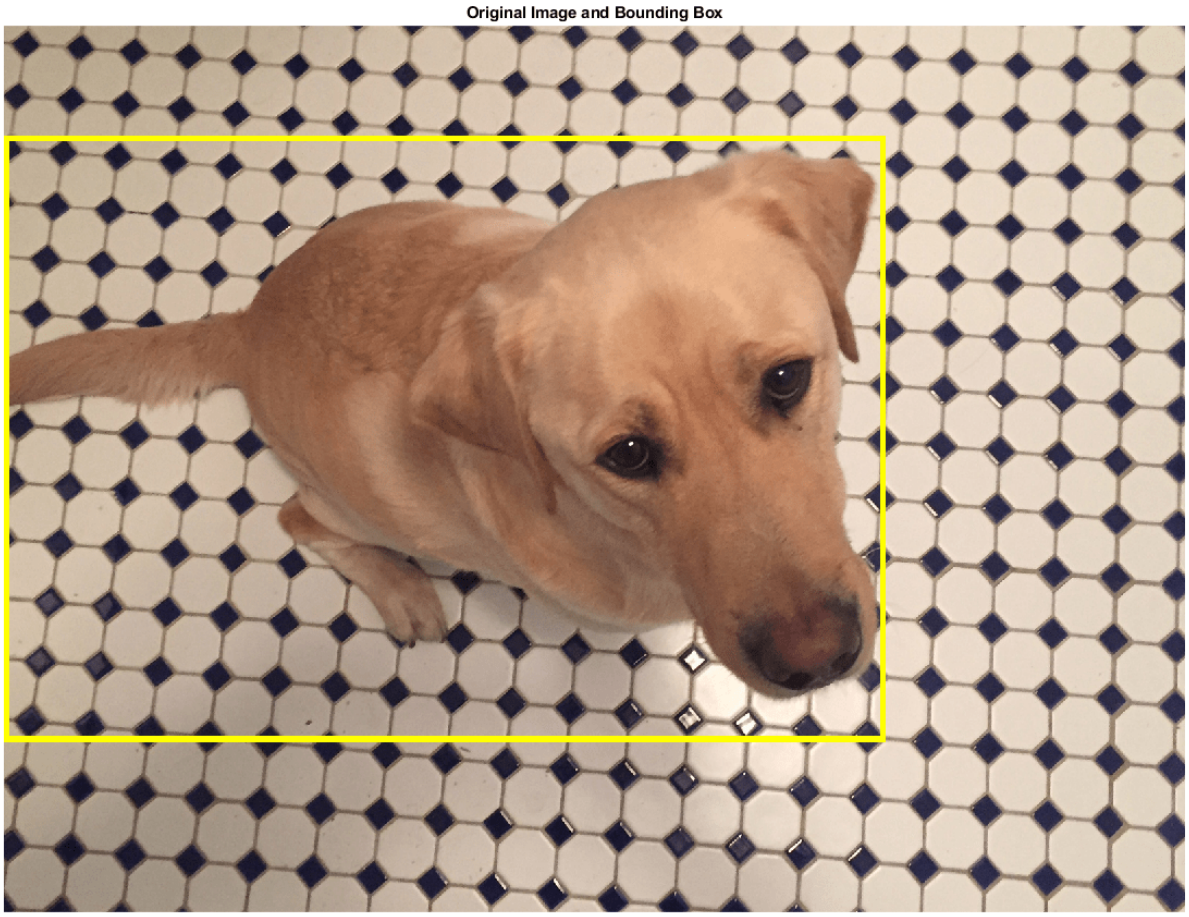
You can use augmented training data to train a network. For an example showing how to train an object detection network, see “Object Detection Using Faster R-CNN Deep Learning” (Computer Vision Toolbox).

Read and display a sample image and bounding box. To compare the effects of the different types of augmentation, each transformation in this example uses the same input image and bounding box.

```
filenameImage = 'kobi.png';
I = imread(filenameImage);
bbox = [4 156 1212 830];
label = "dog";
```

Display the image and bounding box.

```
annotatedImage = insertShape(I,"rectangle",bbox,"LineWidth",8);
imshow(annotatedImage)
title('Original Image and Bounding Box')
```



Resize Image and Bounding Box

Use `imresize` to scale down the image by a factor of 2.

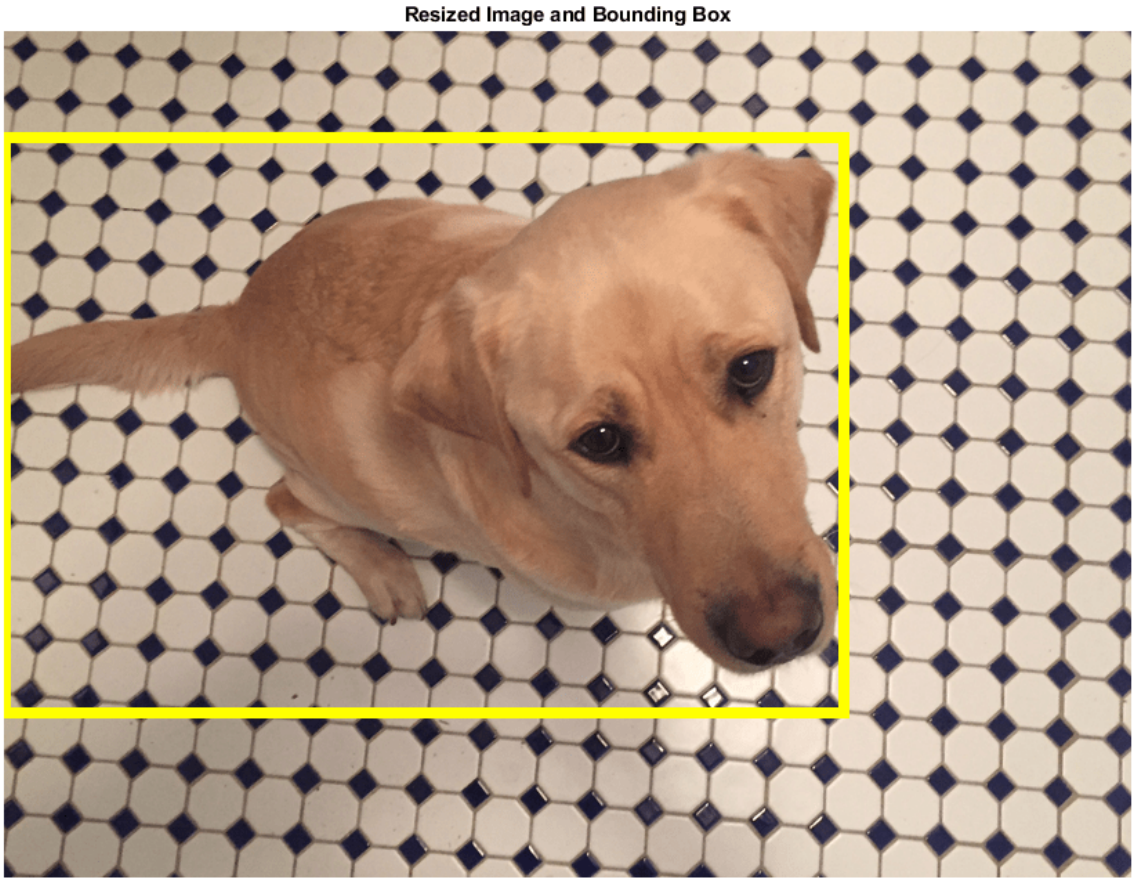
```
scale = 1/2;
J = imresize(I,scale);
```

Use `bboxresize` to apply the same scaling to the associated bounding box.

```
bboxResized = bboxresize(bbox,scale);
```

Display the resized image and bounding box.

```
annotatedImage = insertShape(J,"rectangle",bboxResized,"LineWidth",8);
imshow(annotatedImage)
title('Resized Image and Bounding Box')
```



Crop Image and Bounding Box

Cropping is a common preprocessing step to make the data match the input size of the network. To create output images of a desired size, first specify the size and position of the crop window by using the `randomWindow2d` (Image Processing Toolbox) or `centerCropWindow2d` (Image Processing Toolbox) function. Make sure you select a cropping window that includes the desired content in the image. Then, crop the image and pixel label image to the same window by using `imcrop`.

Specify the desired size of the cropped region as a two-element vector of the form [*height*, *width*].

```
targetSize = [1024 1024];
```

Crop the image to the target size from the center of the image by using `imcrop`.

```
win = centerCropWindow2d(size(I),targetSize);
J = imcrop(I,win);
```

Crop the bounding boxes using the same crop window by using `bboxcrop`. Specify `OverlapThreshold` as a value less than 1 so that the function clips the bounding boxes to the crop window instead of discarding them when the crop window does not completely enclose the bounding box. The overlap threshold enables you to control the amount of clipping that is tolerable for objects in your images. For example, clipping more than half a person is not useful for training a person detector, whereas clipping half a vehicle might be tolerable.

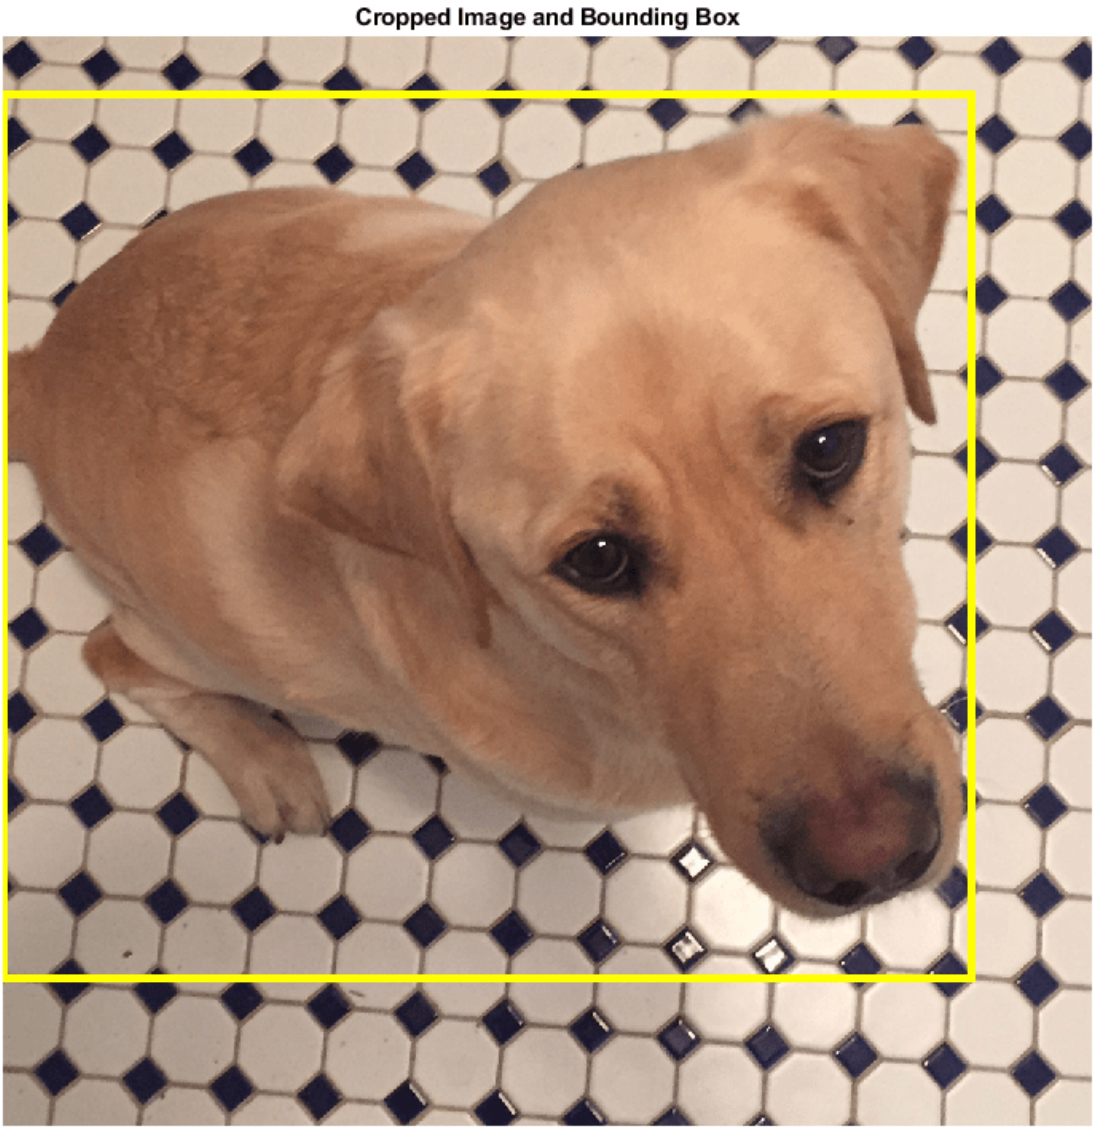
```
[bboxCropped,valid] = bboxcrop(bbox,win,"OverlapThreshold",0.7);
```

Keep labels that are inside the cropping window.

```
label = label(valid);
```

Display the cropped image and bounding box.

```
annotatedImage = insertShape(J,"rectangle",bboxCropped,"LineWidth",8);
imshow(annotatedImage)
title('Cropped Image and Bounding Box')
```



Crop and Resize Image and Bounding Box

Cropping and resizing are often performed together. You can use `bboxcrop` and `bboxresize` in series to implement the commonly used "*crop and resize*" transformation.

Create a crop window from a random position in the image. Crop the image and bounding box to the same crop window.

```
cropSize = [1024 1024];
win = randomWindow2d(size(I),cropSize);
J = imcrop(I,win);
croppedBox = bboxcrop(bbox,win,"OverlapThreshold",0.5);
```

Resize the image and box to a target size.

```
targetSize = [512 512];
J = imresize(J,targetSize);
croppedAndResizedBox = bboxresize(croppedBox,targetSize./cropSize);
```

Display the cropped and resized image and bounding box.

```
annotatedImage = insertShape(J,"rectangle",croppedAndResizedBox,"LineWidth",8);
imshow(annotatedImage)
title('Crop and Resized Image and Bounding Box')
```

Warp Image and Bounding Box

The `randomAffine2d` (Image Processing Toolbox) function creates a randomized 2-D affine transformation from a combination of rotation, translation, scaling (resizing), reflection, and shearing. Warp an image by using `imwarp` (Image Processing Toolbox). Warp bounding boxes by using `bboxwarp`. Control the spatial bounds and resolution of the warped output by using the `affineOutputView` (Image Processing Toolbox) function.

This example demonstrates two of the randomized affine transformations: scaling and rotation.

Random Scale

Create a scale transformation that resizes the input image and bounding box using a scale factor selected randomly from the range [1.5,1.8]. This transformation applies the same scale factor in the horizontal and vertical directions.

```
tform = randomAffine2d("Scale",[1.5 1.8]);
```

Create an output view for the affine transform.

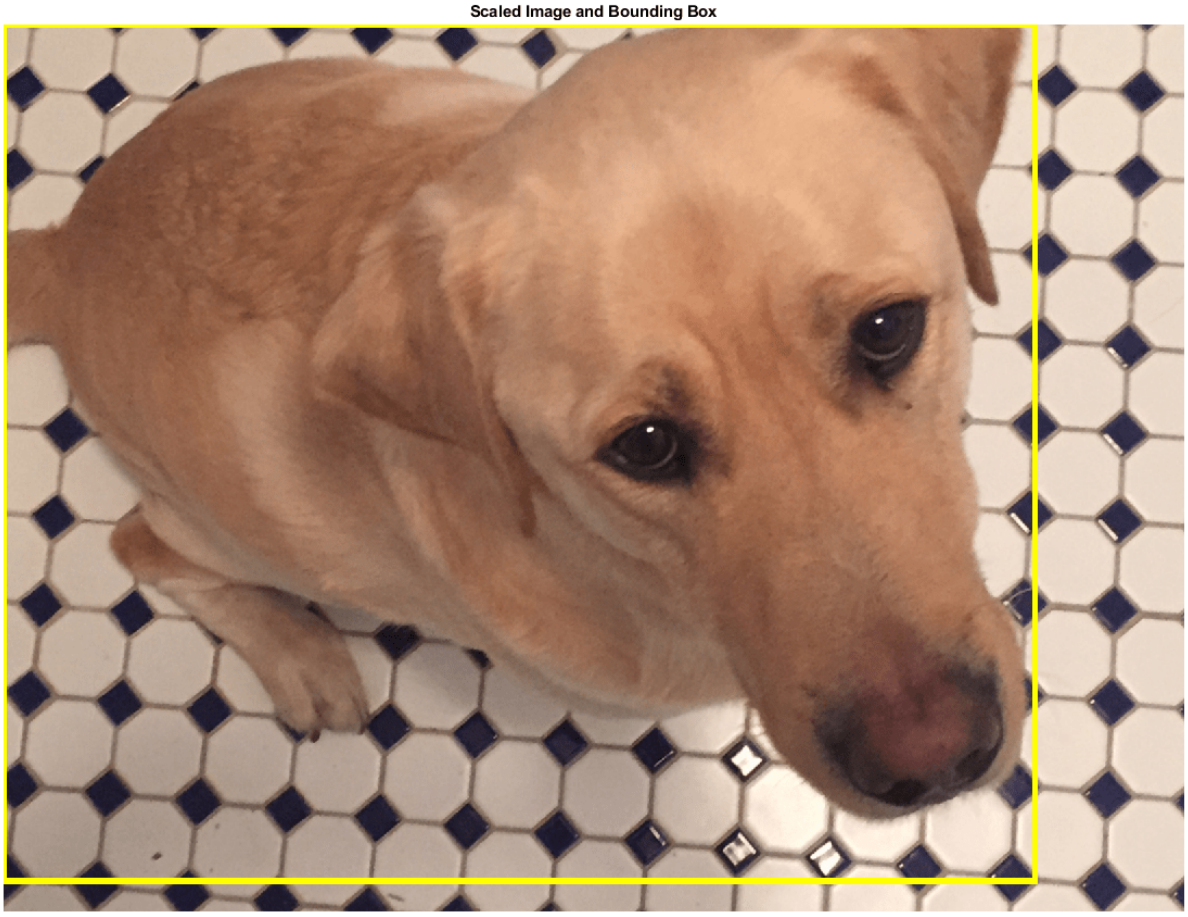
```
rout = affineOutputView(size(I),tform);
```

Rescale the image using `imwarp` and rescale the bounding box using `bboxwarp`. Specify an `OverlapThreshold` value of 0.5.

```
J = imwarp(I,tform,"OutputView",rout);
bboxScaled = bboxwarp(bbox,tform,rout,"OverlapThreshold",0.5);
```

Display the scaled image and bounding box.

```
annotatedImage = insertShape(J,"rectangle",bboxScaled,"LineWidth",8);
imshow(annotatedImage)
title('Scaled Image and Bounding Box')
```



Random Rotation

Create a randomized rotation transformation that rotates the image and box labels by an angle selected randomly from the range [-15,15] degrees.

```
tform = randomAffine2d("Rotation",[-15 15]);
```

Create an output view for `imwarp` and `bboxwarp`.

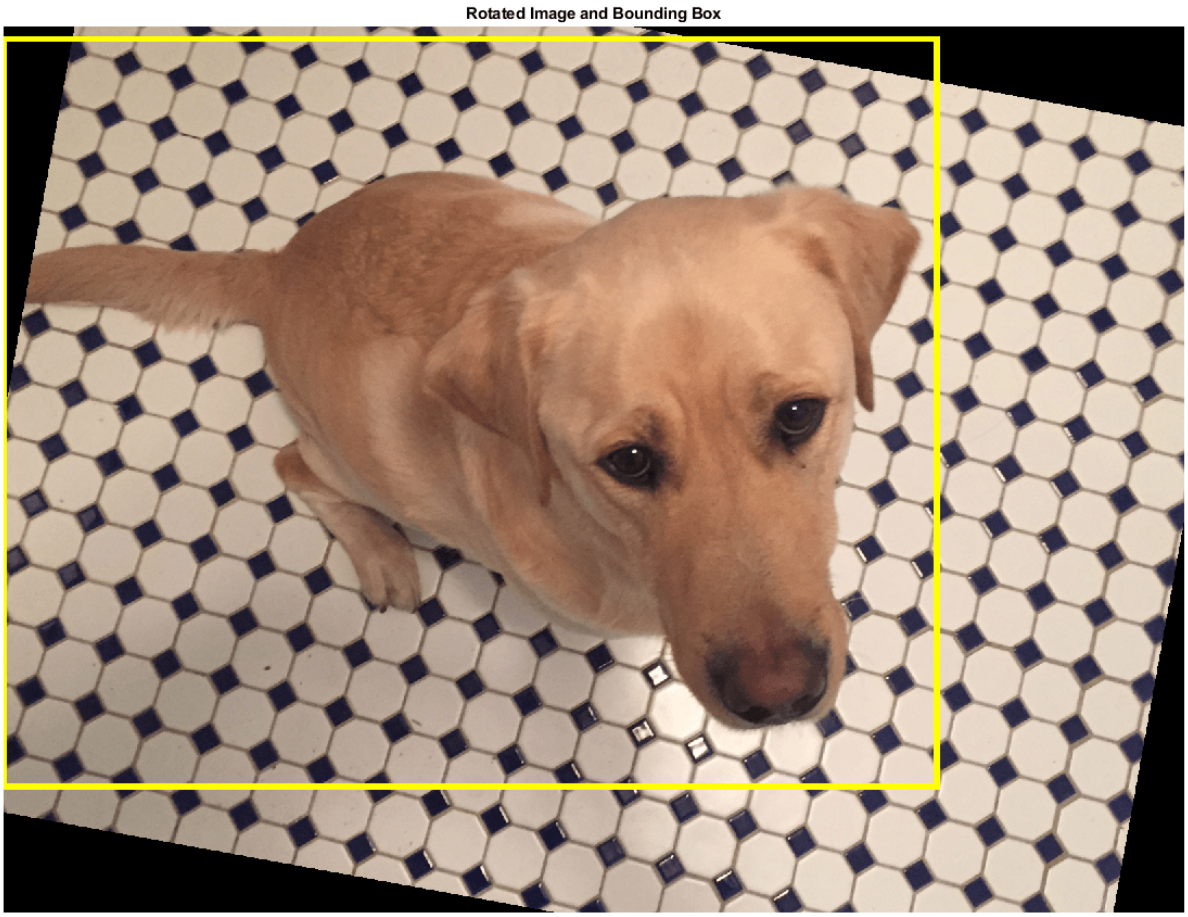
```
rout = affineOutputView(size(I),tform);
```

Rotate the image using `imwarp` and rotate the bounding box using `bboxwarp`. Specify an `OverlapThreshold` value of 0.5.

```
J = imwarp(I,tform,"OutputView",rout);
bboxRotated = bboxwarp(bbox,tform,rout,"OverlapThreshold",0.5);
```

Display the cropped image and bounding box. Note that the bounding box returned by `bboxwarp` is always aligned to the image axes. The size and aspect ratio of the bounding box changes to accommodate the rotated object.

```
annotatedImage = insertShape(J,"rectangle",bboxRotated,"LineWidth",8);
imshow(annotatedImage)
title('Rotated Image and Bounding Box')
```



Apply Augmentation to Training Data in Datastores

Datastores are a convenient way to read and augment collections of data. Create a datastore that stores image and bounding box data, and augment the data using a series of multiple operations.

Create Datastores Containing Image and Bounding Box Data

To increase the size of the sample datastores, replicate the file names of the image and the bounding box and labels.

```
numObservations = 4;
images = repelem({filenameImage},numObservations,1);
bboxes = repelem({bbox},numObservations,1);
labels = repelem({label},numObservations,1);
```

Create an `imageDatastore` from the training image files. Combine the bounding box and label data in a table, then create a `boxLabelDatastore` from the table.

```
imds = imageDatastore(images);

tbl = table(bboxes,labels);
blds = boxLabelDatastore(tbl);
```

Associate the image and box label pairs by combining the image datastore and box label datastore.

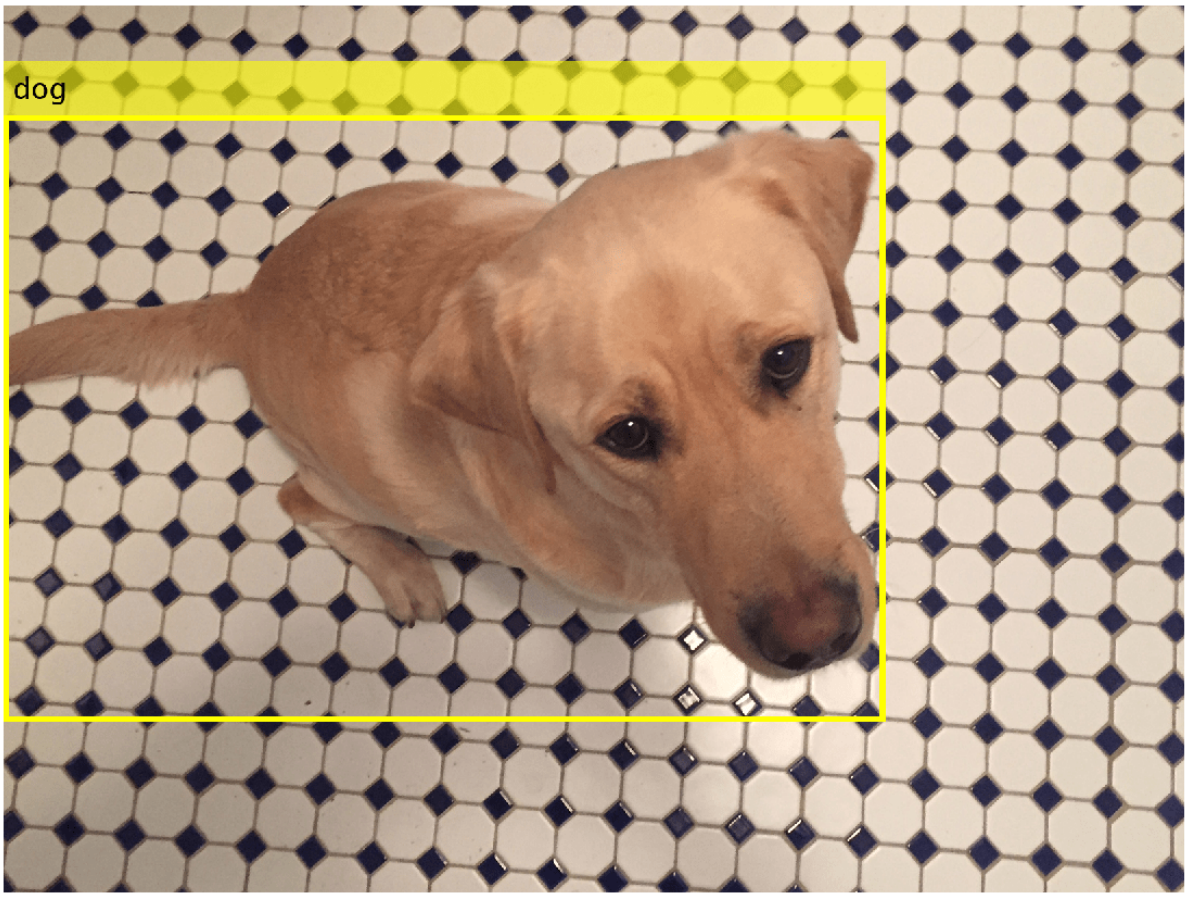
```
trainingData = combine(imds,blds);
```

Read the first image and its associated box label from the combined datastore.

```
data = read(trainingData);
I = data{1};
bboxes = data{2};
labels = data{3};
```

Display the image and box label data.

```
annotatedImage = insertObjectAnnotation(I,'rectangle',bbox,labels, ...
    'LineWidth',8,'FontSize',40);
imshow(annotatedImage)
```



Apply Data Augmentation

Apply data augmentation to the training data by using the `transform` function. This example performs two separate augmentations to the training data.

The first augmentation jitters the color of the image and then performs identical random horizontal reflection and rotation on the image and box label pairs. These operations are defined in the `jitterImageColorAndWarp` helper function at the end of this example.

```
augmentedTrainingData = transform(trainingData,@jitterImageColorAndWarp);
```

Read all the augmented data.

```
data = readall(augmentedTrainingData);
```

Display the augmented image and box label data.

```
rgb = cell(numObservations,1);
for k = 1:numObservations
    I = data{k,1};
    bbox = data{k,2};
    labels = data{k,3};
    rgb{k} = insertObjectAnnotation(I,'rectangle',bbox,labels,'LineWidth',8,'FontSize',40);
end
montage(rgb)
```

The second augmentation rescales the image and box label to a target size. These operations are defined in the `resizeImageAndLabel` helper function at the end of this example.

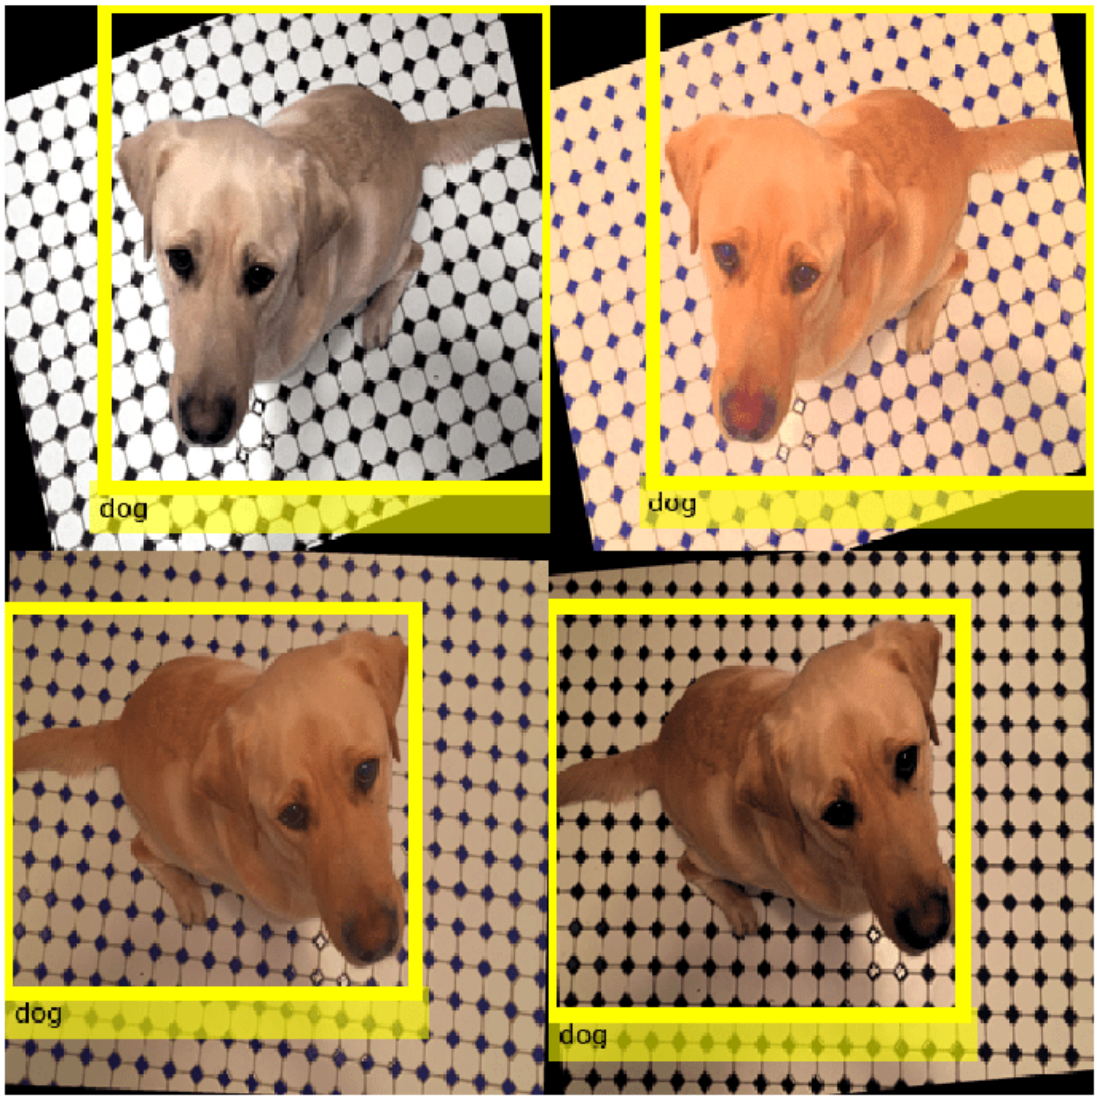
```
targetSize = [300 300];
preprocessedTrainingData = transform(augmentedTrainingData,...
    @(data)resizeImageAndLabel(data,targetSize));
```

Read all of the preprocessed data.

```
data = readall(preprocessedTrainingData);
```

Display the preprocessed image and box label data.

```
rgb = cell(numObservations,1);
for k = 1:numObservations
    I = data{k,1};
    bbox = data{k,2};
    labels = data{k,3};
    rgb{k} = insertObjectAnnotation(I,'rectangle',bbox,labels, ...
        'LineWidth',8,'FontSize',15);
end
montage(rgb)
```



Helper Functions for Augmentation

The `jitterImageColorAndWarp` helper function applies random color jitter to the image data, then applies an identical affine transformation to the image and box label data. The transformation consists of random horizontal reflection and rotation. The input `data` and output `out` are two-element cell arrays, where the first element is the image data and the second element is the box label data.

```
function out = jitterImageColorAndWarp(data)
% Unpack original data.
I = data{1};
boxes = data{2};
labels = data{3};
```

```
% Apply random color jitter.
I = jitterColorHSV(I,"Brightness",0.3,"Contrast",0.4,"Saturation",0.2);

% Define random affine transform.
tform = randomAffine2d("XReflection",true,'Rotation',[-30 30]);
rout = affineOutputView(size(I),tform);

% Transform image and bounding box labels.
augmentedImage = imwarp(I,tform,"OutputView",rout);
[augmentedBoxes, valid] = bboxwarp(boxes,tform,rout,'OverlapThreshold',0.4);
augmentedLabels = labels(valid);

% Return augmented data.
out = {augmentedImage,augmentedBoxes,augmentedLabels};
end
```

The `resizeImageAndLabel` helper function calculates the scale factor for the image to match a target size, then resizes the image using `imresize` and the box label using `bboxresize`. The input and output data are two-element cell arrays, where the first element is the image data and the second element is the box label data.

```
function data = resizeImageAndLabel(data,targetSize)
scale = targetSize./size(data{1},[1 2]);
data{1} = imresize(data{1},targetSize);
data{2} = bboxresize(data{2},scale);
end
```

Prepare Datastore for Image-to-Image Regression

This example shows how to prepare a datastore for training an image-to-image regression network using the `transform` and `combine` functions of `ImageDatastore`.

This example shows how to preprocess data using a pipeline suitable for training a denoising network. This example then uses the preprocessed noise data to train a simple convolutional autoencoder network to remove image noise.

Prepare Data Using Preprocessing Pipeline

This example uses a salt and pepper noise model in which a fraction of input image pixels are set to either `0` or `1` (black and white, respectively). Noisy images act as the network input. Pristine images act as the expected network response. The network learns to detect and remove the salt and pepper noise.

Load the pristine images in the digit data set as an `imageDatastore`. The datastore contains 10,000 synthetic images of digits from 0 to 9. The images are generated by applying random transformations to digit images created with different fonts. Each digit image is 28-by-28 pixels. The datastore contains an equal number of images per category.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet', ...
    'nndemos','nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

Specify a large read size to minimize the cost of file I/O.

```
imds.ReadSize = 500;
```

Set the seed of the global random number generator to aid in the reproducibility of results.

```
rng(0)
```

Use the `shuffle` function to shuffle the digit data prior to training.

```
imds = shuffle(imds);
```

Use the `splitEachLabel` function to divide `imds` into three image datastores containing pristine images for training, validation, and testing.

```
[imdsTrain,imdsVal,imdsTest] = splitEachLabel(imds,0.95,0.025);
```

Use the `transform` function to create noisy versions of each input image, which will serve as the network input. The `transform` function reads data from an underlying datastore and processes the data using the operations defined in the helper function `addNoise` (defined at the end of this example). The output of the `transform` function is a `TransformedDatastore`.

```
dsTrainNoisy = transform(imdsTrain,@addNoise);
dsValNoisy = transform(imdsVal,@addNoise);
dsTestNoisy = transform(imdsTest,@addNoise);
```

Use the `combine` function to combine the noisy images and pristine images into a single datastore that feeds data to `trainNetwork`. This combined datastore reads batches of data into a two-column cell array as expected by `trainNetwork`. The output of the `combine` function is a `CombinedDatastore`.

```
dsTrain = combine(dsTrainNoisy,imdsTrain);
dsVal = combine(dsValNoisy,imdsVal);
dsTest = combine(dsTestNoisy,imdsTest);
```

Use the `transform` function to perform additional preprocessing operations that are common to both the input and response datastores. The `commonPreprocessing` helper function (defined at the end of this example) resizes input and response images to 32-by-32 pixels to match the input size of the network, and normalizes the data in each image to the range [0, 1].

```
dsTrain = transform(dsTrain,@commonPreprocessing);
dsVal = transform(dsVal,@commonPreprocessing);
dsTest = transform(dsTest,@commonPreprocessing);
```

Finally, use the `transform` function to add randomized augmentation to the training set. The `augmentImages` helper function (defined at the end of this example) applies randomized 90 degree rotations to the data. Identical rotations are applied to the network input and corresponding expected responses.

```
dsTrain = transform(dsTrain,@augmentImages);
```

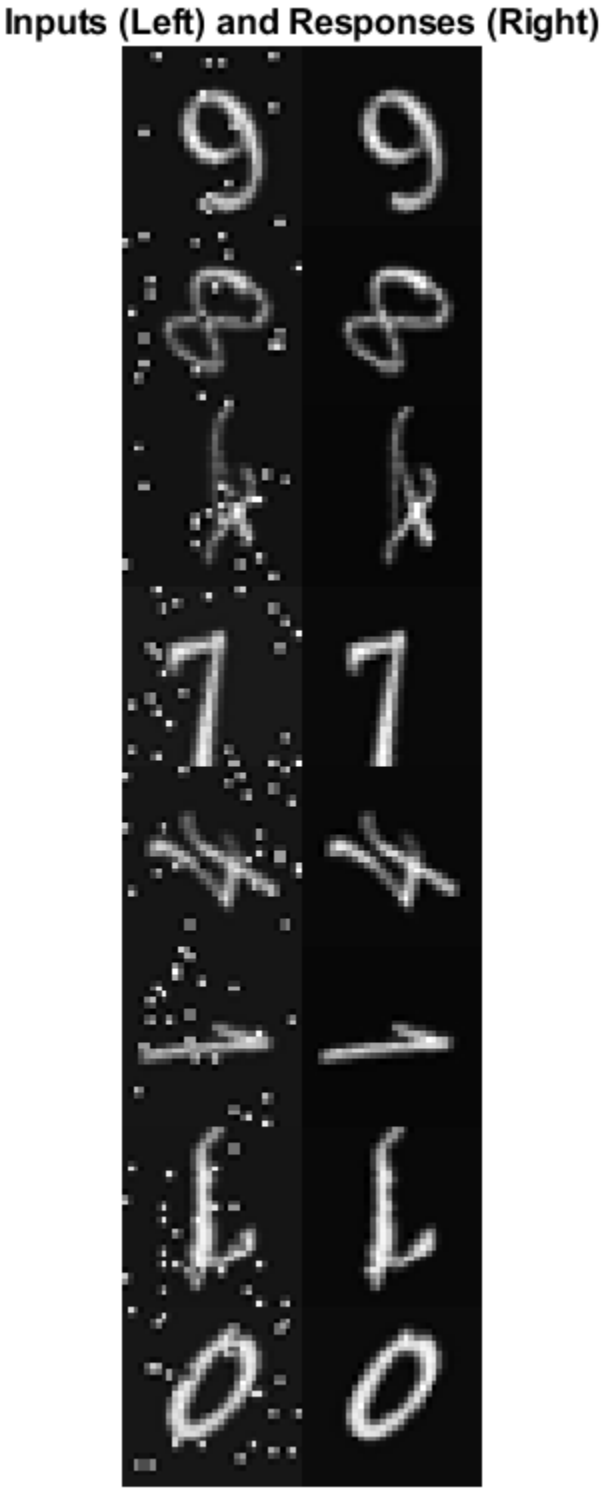
Augmentation reduces overfitting and adds robustness to the presence of rotations in the trained network. Randomized augmentation is not needed for the validation or test data sets.

Preview Preprocessed Data

Since there are several preprocessing operations necessary to prepare the training data, preview the preprocessed data to confirm it looks correct prior to training. Use the `preview` function to preview the data.

Visualize examples of paired noisy and pristine images using the `montage` (Image Processing Toolbox) function. The training data looks correct. Salt and pepper noise appears in the input images in the left column. Other than the addition of noise, the input image and response image are the same. Randomized 90 degree rotation is applied to both input and response images in the same way.

```
exampleData = preview(dsTrain);
inputs = exampleData(:,1);
responses = exampleData(:,2);
minibatch = cat(2,inputs,responses);
montage(minibatch','Size',[8 2])
title('Inputs (Left) and Responses (Right)')
```



Inputs (Left) and Responses (Right)

Define Convolutional Autoencoder Network

Convolutional autoencoders are a common architecture for denoising images. Convolutional autoencoders consist of two stages: an encoder and a decoder. The encoder compresses the original input image into a latent representation that is smaller in width and height, but deeper in the sense that there are many feature maps per spatial location than the original input image. The compressed latent representation loses some amount of spatial resolution in its ability to recover high frequency features in the original image, but it also learns to not include noisy artifacts in the encoding of the original image. The decoder repeatedly upsamples the encoded signal to move it back to its original width, height, and number of channels. Since the encoder removes noise, the decoded final image has fewer noise artifacts.

This example defines the convolutional autoencoder network using layers from Deep Learning Toolbox™, including:

- `imageInputLayer` - Image input layer
- `convolution2dLayer` - Convolution layer for convolutional neural networks
- `reluLayer` - Rectified linear unit layer
- `maxPooling2dLayer` - 2-D max pooling layer
- `transposedConv2dLayer` - Transposed convolution layer
- `clippedReluLayer` - Clipped rectified linear unit layer
- `regressionLayer` - Regression output layer

Create the image input layer. To simplify the padding concerns related to downsampling and upsampling by factors of two, choose a 32-by-32 input size because 32 is cleanly divisible by 2, 4, and 8.

```
imageLayer = imageInputLayer([32,32,1]);
```

Create the encoding layers. Downsampling in the encoder is achieved by max pooling with a pool size of 2 and a stride of 2.

```
encodingLayers = [ ...
    convolution2dLayer(3,16,'Padding','same'), ...
    reluLayer, ...
    maxPooling2dLayer(2,'Padding','same','Stride',2), ...
    convolution2dLayer(3,8,'Padding','same'), ...
    reluLayer, ...
    maxPooling2dLayer(2,'Padding','same','Stride',2), ...
    convolution2dLayer(3,8,'Padding','same'), ...
    reluLayer, ...
    maxPooling2dLayer(2,'Padding','same','Stride',2)];
```

Create the decoding layers. The decoder upsamples the encoded signal using a transposed convolution layer. Create the transposed convolution layer with the correct upsampling factor by using the `createUpsampleTransponseConvLayer` helper function. This function is defined at the end of this example.

The network uses a `clippedReluLayer` as the final activation layer to force outputs to be in the range [0, 1].

```
decodingLayers = [ ...
    createUpsampleTransponseConvLayer(2,8), ...
    reluLayer, ...
```

```
    createUpsampleTransponseConvLayer(2,8), ...
    reluLayer, ...
    createUpsampleTransponseConvLayer(2,16), ...
    reluLayer, ...
    convolution2dLayer(3,1,'Padding','same'), ...
    clippedReluLayer(1.0), ...
    regressionLayer];
```

Concatenate the image input layer, the encoding layers, and the decoding layers to form the convolutional autoencoder network architecture.

```
layers = [imageLayer,encodingLayers,decodingLayers];
```

Define Training Options

Train the network using the Adam optimizer. Specify the hyperparameter settings by using the `trainingOptions` function. Train for 100 epochs.

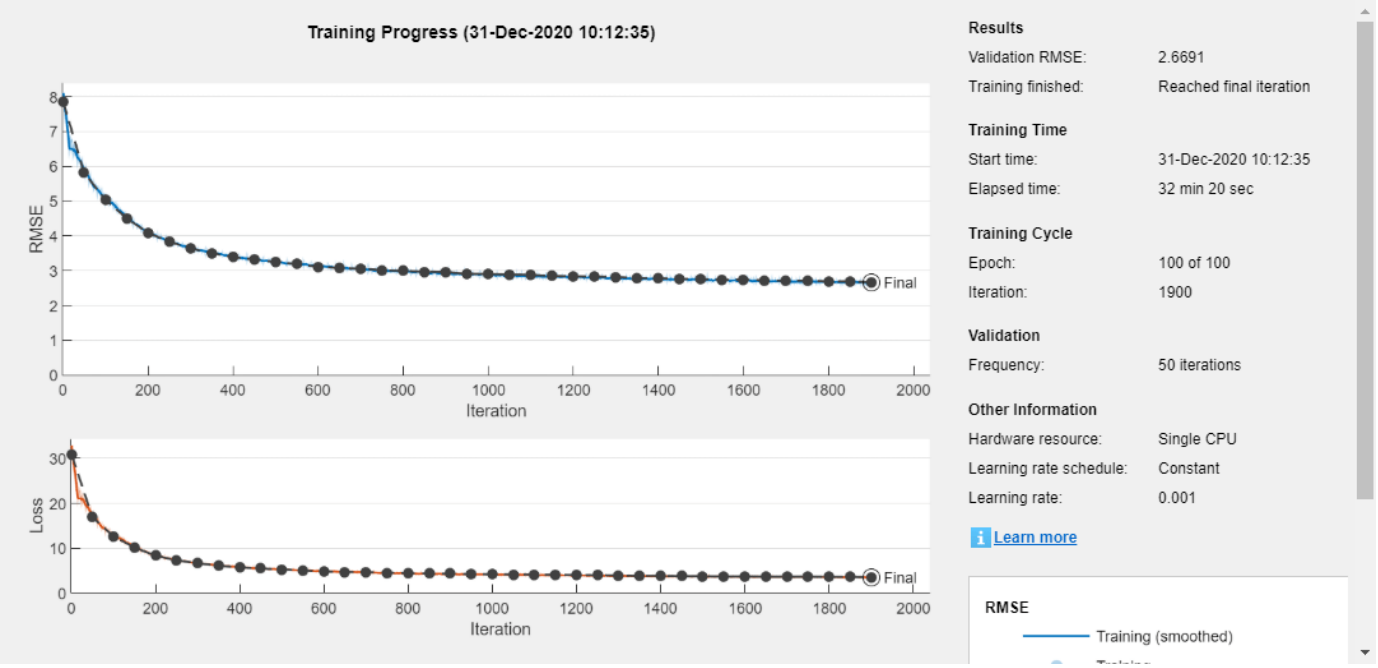
```
options = trainingOptions('adam', ...
    'MaxEpochs',100, ...
    'MiniBatchSize',imds.ReadSize, ...
    'ValidationData',dsVal, ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the Network

Now that the data source and training options are configured, train the convolutional autoencoder network using the `trainNetwork` function.

Train on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a CUDA® enabled NVIDIA® GPU. For more information, see “GPU Support by Release” (Parallel Computing Toolbox). Training takes about 25 minutes on an NVIDIA Titan XP.

```
net = trainNetwork(dsTrain,layers,options);
```



```
modelDateTime = string(datetime('now','Format',"yyyy-MM-dd-HH-mm-ss"));
save(strcat("trainedImageToImageRegressionNet-",modelDateTime,".mat"),'net');
```

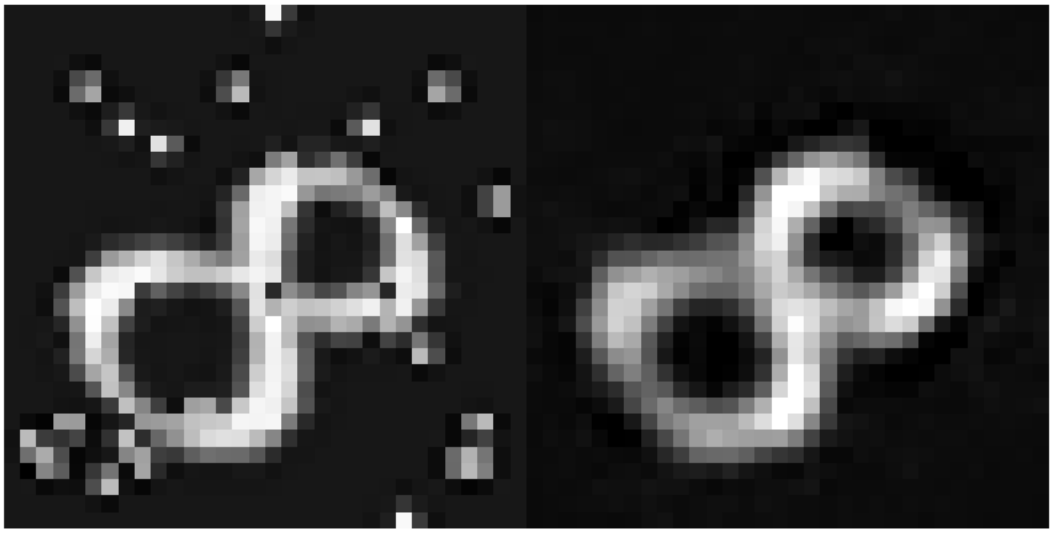
Evaluate the Performance of the Denoising Network

Obtain output images from the test set by using the `predict` function.

```
ypred = predict(net,dsTest);
```

Visualize a sample input image and the associated prediction output from the network to get a sense of how well denoising is working. As expected, the output image from the network has removed most of the noise artifacts from the input image. The denoised image is slightly blurry as a result of the encoding and decoding process.

```
inputImageExamples = preview(dsTest);
montage({inputImageExamples{1},ypred(:,:,:,1)});
```



Assess the performance of the network by analyzing the peak signal-to-noise ratio (PSNR).

```
ref = inputImageExamples{1,2};
originalNoisyImage = inputImageExamples{1,1};
psnrNoisy = psnr(originalNoisyImage,ref)
```

```
psnrNoisy = single
    17.8455
```

```
psnrDenoised = psnr(ypred(:,:,:,1),ref)
```

```
psnrDenoised = single
    21.8439
```

The PSNR of the output image is higher than the noisy input image, as expected.

Supporting Functions

The `addNoise` helper function adds salt and pepper noise to images by using the `imnoise` (Image Processing Toolbox) function. The `addNoise` function requires the format of the input data to be a cell array of image data, which matches the format of data returned by the `read` function of `ImageDatastore`.

```
function dataOut = addNoise(data)

    dataOut = data;
    for idx = 1:size(data,1)
       dataOut{idx} = imnoise(data{idx},'salt & pepper');
    end

end
```

The `commonPreprocessing` helper function defines the preprocessing that is common to the training, validation, and test sets. The helper function performs these preprocessing steps.

1. Convert the image data to data type `single`.
2. Resize image data to match the size of the input layer by using the `imresize` function.
3. Normalize data to the range [0, 1] by using the `rescale` function.

The helper function requires the format of the input data to be a two-column cell array of image data, which matches the format of data returned by the `read` function of `CombinedDatastore`.

```
function dataOut = commonPreprocessing(data)

    dataOut = cell(size(data));
    for col = 1:size(data,2)
        for idx = 1:size(data,1)
            temp = single(data{idx,col});
            temp = imresize(temp,[32,32]);
            temp = rescale(temp);
            dataOut{idx,col} = temp;
        end
    end
end
```

The `augmentImages` helper function adds randomized 90 degree rotations to the data by using the `rot90` function. Identical rotations are applied to the network input and corresponding expected responses. The function requires the format of the input data to be a two-column cell array of image data, which matches the format of data returned by the `read` function of `CombinedDatastore`.

```
function dataOut = augmentImages(data)

    dataOut = cell(size(data));
    for idx = 1:size(data,1)
        rot90Val = randi(4,1,1)-1;
        dataOut(idx,:) = {rot90(data{idx,1},rot90Val),rot90(data{idx,2},rot90Val)};
    end
end
```

The `createUpsampleTransposeConvLayer` helper function defines a transposed convolution layer that upsamples the layer input by the specified factor.

```
function out = createUpsampleTransponseConvLayer(factor,numFilters)

    filterSize = 2*factor - mod(factor,2);
    cropping = (factor-mod(factor,2))/2;
    numChannels = 1;

    out = transposedConv2dLayer(filterSize,numFilters, ...
        'NumChannels',numChannels,'Stride',factor,'Cropping',cropping);
end
```

Train Network Using Out-of-Memory Sequence Data

This example shows how to train a deep learning network on out-of-memory sequence data by transforming and combining datastores.

A transformed datastore transforms or processes data read from an underlying datastore. You can use a transformed datastore as a source of training, validation, test, and prediction data sets for deep learning applications. Use transformed datastores to read out-of-memory data or to perform specific preprocessing operations when reading batches of data. When you have separate datastores containing predictors and labels, you can combine them so you can input the data into a deep learning network.

When training the network, the software creates mini-batches of sequences of the same length by padding, truncating, or splitting the input data. For in-memory data, the `trainingOptions` function provides options to pad and truncate input sequences, however, for out-of-memory data, you must pad and truncate the sequences manually.

Load Training Data

Load the Japanese Vowels data set as described in [1] and [2]. The zip file `japaneseVowels.zip` contains sequences of varying length. The sequences are divided into two folders, `Train` and `Test`, which contain training sequences and test sequences, respectively. In each of these folders, the sequences are divided into subfolders, which are numbered from 1 to 9. The names of these subfolders are the label names. A MAT file represents each sequence. Each sequence is a matrix with 12 rows, with one row for each feature, and a varying number of columns, with one column for each time step. The number of rows is the sequence dimension and the number of columns is the sequence length.

Unzip the sequence data.

```
filename = "japaneseVowels.zip";
outputFolder = fullfile(tempdir,"japaneseVowels");
unzip(filename,outputFolder);
```

For the training predictors, create a file datastore and specify the read function to be the `load` function. The `load` function, loads the data from the MAT-file into a structure array. To read files from the subfolders in the training folder, set the `'IncludeSubfolders'` option to `true`.

```
folderTrain = fullfile(outputFolder,"Train");
fdsPredictorTrain = fileDatastore(folderTrain, ...
    'ReadFcn',@load, ...
    'IncludeSubfolders',true);
```

Preview the datastore. The returned struct contains a single sequence from the first file.

```
preview(fdsPredictorTrain)
```

```
ans = struct with fields:
    X: [12×20 double]
```

For the labels, create a file datastore and specify the read function to be the `readLabel` function, defined at the end of the example. The `readLabel` function extracts the label from the subfolder name.

```
classNames = string(1:9);
fdsLabelTrain = fileDatastore(folderTrain, ...
```

```
    'ReadFcn',@(filename) readLabel(filename,classNames), ...
    'IncludeSubfolders',true);
```

Preview the datastore. The output corresponds to the label of the first file.

```
preview(fdsLabelTrain)
```

```
ans = categorical
     1
```

Transform and Combine Datastores

To input the sequence data from the datastore of predictors to a deep learning network, the mini-batches of the sequences must have the same length. Transform the datastore using the `padSequence` function, defined at the end of the datastore, that pads or truncates the sequences to have length 20.

```
sequenceLength = 20;
tdsTrain = transform(fdsPredictorTrain,@(data) padSequence(data,sequenceLength));
```

Preview the transformed datastore. The output corresponds to the padded sequence from the first file.

```
X = preview(tdsTrain)
```

```
X = 1×1 cell array
    {12×20 double}
```

To input both the predictors and labels from both datastores into a deep learning network, combine them using the `combine` function.

```
cdsTrain = combine(tdsTrain,fdsLabelTrain);
```

Preview the combined datastore. The datastore returns a 1-by-2 cell array. The first element corresponds to the predictors. The second element corresponds to the label.

```
preview(cdsTrain)
```

```
ans = 1×2 cell array
    {12×20 double}    {[1]}
```

Define LSTM Network Architecture

Define the LSTM network architecture. Specify the number of features of the input data as the input size. Specify an LSTM layer with 100 hidden units and to output the last element of the sequence. Finally, specify a fully connected layer with output size equal to the number of classes, followed by a softmax layer and a classification layer.

```
numFeatures = 12;
numClasses = numel(classNames);
numHiddenUnits = 100;

layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last')
```

```
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify the training options. Set the solver to `'adam'` and `'GradientThreshold'` to 2. Set the mini-batch size to 27 and set the maximum number of epochs to 75. The datastores do not support shuffling, so set `'Shuffle'` to `'never'`.

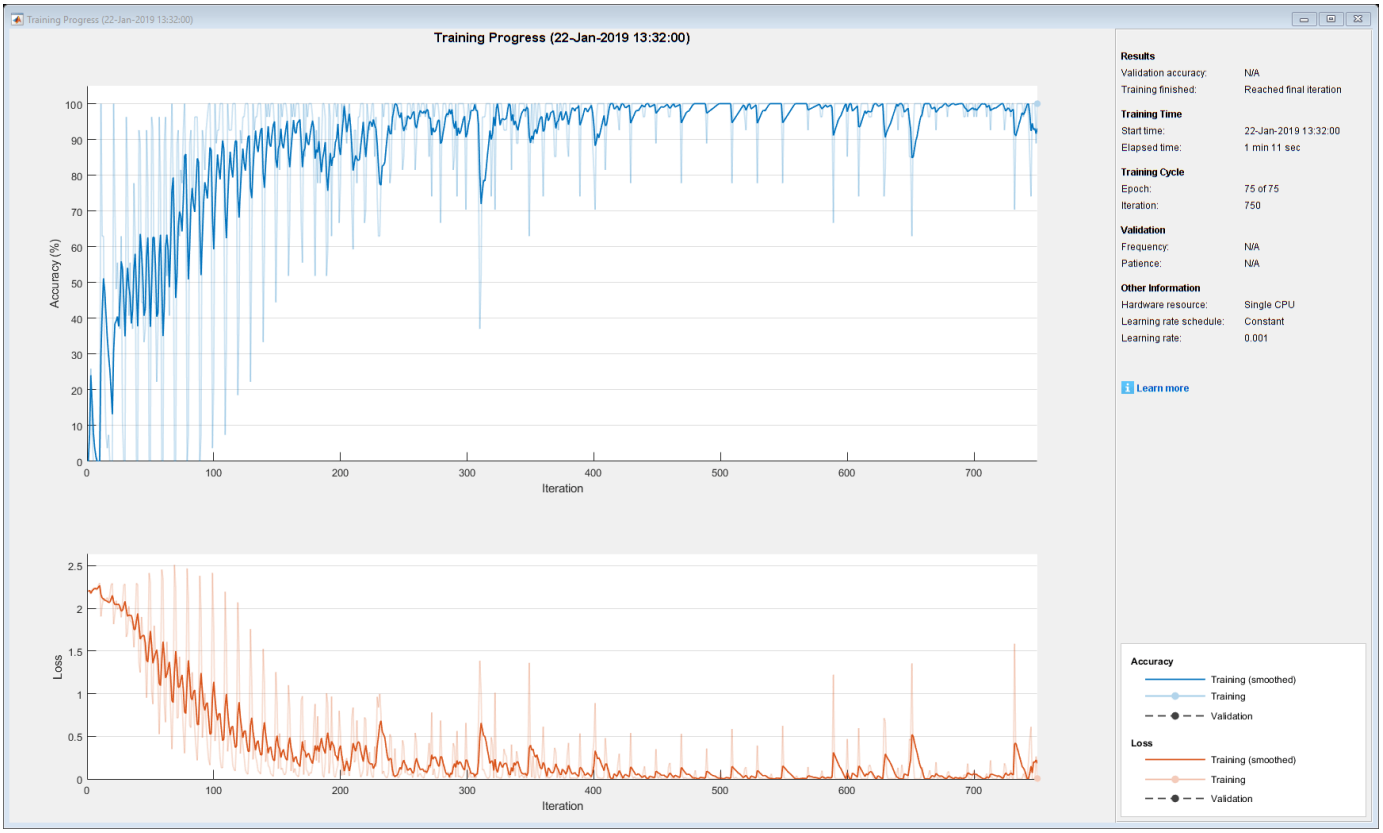
Because the mini-batches are small with short sequences, the CPU is better suited for training. Set `'ExecutionEnvironment'` to `'cpu'`. To train on a GPU, if available, set `'ExecutionEnvironment'` to `'auto'` (the default value).

```
miniBatchSize = 27;

options = trainingOptions('adam', ...
    'ExecutionEnvironment','cpu', ...
    'MaxEpochs',75, ...
    'MiniBatchSize',miniBatchSize, ...
    'GradientThreshold',2, ...
    'Shuffle','never',...
    'Verbose',0, ...
    'Plots','training-progress');
```

Train the LSTM network with the specified training options.

```
net = trainNetwork(cdsTrain,layers,options);
```



Test the Network

Create a transformed datastore containing the held-out test data using the same steps as for the training data.

```
folderTest = fullfile(outputFolder,"Test");

fdsPredictorTest = fileDatastore(folderTest, ...
    'ReadFcn',@load, ...
    'IncludeSubfolders',true);
tdsTest = transform(fdsPredictorTest,@(data) padSequence(data,sequenceLength));
```

Make predictions on the test data using the trained network.

```
YPred = classify(net,tdsTest,'MiniBatchSize',miniBatchSize);
```

Calculate the classification accuracy on the test data. To get the labels of the test set, create a file datastore with the read function `readLabel` and specify to include subfolders. Specify that the outputs are vertically concatenateable by setting the `'UniformRead'` option to `true`.

```
fdsLabelTest = fileDatastore(folderTest, ...
    'ReadFcn',@(filename) readLabel(filename,classNames), ...
    'IncludeSubfolders',true, ...
    'UniformRead',true);
YTest = readall(fdsLabelTest);

accuracy = mean(YPred == YTest)
```

```
accuracy = 0.9351
```

Functions

The `readLabel` function extracts the label from the specified filename over the categories in `classNames`.

```
function label = readLabel(filename,classNames)

filepath = fileparts(filename);
[~,label] = fileparts(filepath);

label = categorical(string(label),classNames);

end
```

The `padSequence` function pads or truncates the sequence in `data.X` to have the specified sequence length and returns the result in a 1-by-1 cell.

```
function sequence = padSequence(data,sequenceLength)

sequence = data.X;
[C,S] = size(sequence);

if S < sequenceLength
    padding = zeros(C,sequenceLength-S);
    sequence = [sequence padding];
else
    sequence = sequence(:,1:sequenceLength);
end
```

```
sequence = {sequence};

end
```

Train Network Using Custom Mini-Batch Datastore for Sequence Data

This example shows how to train a deep learning network on out-of-memory sequence data using a custom mini-batch datastore.

A mini-batch datastore is an implementation of a datastore with support for reading data in batches. Use mini-batch datastores to read out-of-memory data or to perform specific preprocessing operations when reading batches of data. You can use a mini-batch datastore as a source of training, validation, test, and prediction data sets for deep learning applications.

This example uses the custom mini-batch datastore `sequenceDatastore.m`. You can adapt this datastore to your data by customizing the datastore functions. For an example showing how to create your own custom mini-batch datastore, see “Develop Custom Mini-Batch Datastore” on page 19-36.

Load Training Data

Load the Japanese Vowels data set as described in [1] and [2]. The zip file `japaneseVowels.zip` contains sequences of varying length. The sequences are divided into two folders, `Train` and `Test`, which contain training sequences and test sequences, respectively. In each of these folders, the sequences are divided into subfolders, which are numbered from `1` to `9`. The names of these subfolders are the label names. A MAT file represents each sequence. Each sequence is a matrix with 12 rows, with one row for each feature, and a varying number of columns, with one column for each time step. The number of rows is the sequence dimension and the number of columns is the sequence length.

Unzip the sequence data.

```
filename = "japaneseVowels.zip";
outputFolder = fullfile(tempdir,"japaneseVowels");
unzip(filename,outputFolder);
```

Create Custom Mini-Batch Datastore

Create a custom mini-batch datastore. The mini-batch datastore `sequenceDatastore` reads data from a folder and gets the labels from the subfolder names. To use this datastore, first save the file `sequenceDatastore.m` to the path.

Create a datastore containing the sequence data using `sequenceDatastore`.

```
folderTrain = fullfile(outputFolder,"Train");
dsTrain = sequenceDatastore(folderTrain)
```

```
dsTrain =
  sequenceDatastore with properties:

           Datastore: [1×1 matlab.io.datastore.FileDatastore]
              Labels: [270×1 categorical]
          NumClasses: 9
    SequenceDimension: 12
        MiniBatchSize: 128
      NumObservations: 270
```

Define LSTM Network Architecture

Define the LSTM network architecture. Specify the sequence dimension of the input data as the input size. Specify an LSTM layer with 100 hidden units and to output the last element of the sequence. Finally, specify a fully connected layer with output size equal to the number of classes, followed by a softmax layer and a classification layer.

```
inputSize = dsTrain.SequenceDimension;
numClasses = dsTrain.NumClasses;
numHiddenUnits = 100;
layers = [
    sequenceInputLayer(inputSize)
    lstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify the training options. Specify `'adam'` as the solver and `'GradientThreshold'` as 1. Set the mini-batch size to 27 and set the maximum number of epochs to 75. To ensure that the datastore creates mini-batches of the size that the `trainNetwork` function expects, also set the mini-batch size of the datastore to the same value.

Because the mini-batches are small with short sequences, the CPU is better suited for training. Set `'ExecutionEnvironment'` to `'cpu'`. To train on a GPU, if available, set `'ExecutionEnvironment'` to `'auto'` (the default value).

```
miniBatchSize = 27;
options = trainingOptions('adam', ...
    'ExecutionEnvironment','cpu', ...
    'MaxEpochs',75, ...
    'MiniBatchSize',miniBatchSize, ...
    'GradientThreshold',1, ...
    'Verbose',0, ...
    'Plots','training-progress');
dsTrain.MiniBatchSize = miniBatchSize;
```

Train the LSTM network with the specified training options.

```
net = trainNetwork(dsTrain,layers,options);
```

Test the Network

Create a sequence datastore from the test data.

```
folderTest = fullfile(outputFolder,"Test");
dsTest = sequenceDatastore(folderTest);
```

Classify the test data. Specify the same mini-batch size as for the training data. To ensure that the datastore creates mini-batches of the size that the `classify` function expects, also set the mini-batch size of the datastore to the same value.

```
dsTest.MiniBatchSize = miniBatchSize;
YPred = classify(net,dsTest,'MiniBatchSize',miniBatchSize);
```

Calculate the classification accuracy of the predictions.

```
YTest = dsTest.Labels;
acc = sum(YPred == YTest)./numel(YTest)
```

```
acc = 0.9432
```

Classify Out-of-Memory Text Data Using Deep Learning

This example shows how to classify out-of-memory text data with a deep learning network using a transformed datastore.

A transformed datastore transforms or processes data read from an underlying datastore. You can use a transformed datastore as a source of training, validation, test, and prediction data sets for deep learning applications. Use transformed datastores to read out-of-memory data or to perform specific preprocessing operations when reading batches of data.

When training the network, the software creates mini-batches of sequences of the same length by padding, truncating, or splitting the input data. The `trainingOptions` function provides options to pad and truncate input sequences, however, these options are not well suited for sequences of word vectors. Furthermore, this function does not support padding data in a custom datastore. Instead, you must pad and truncate the sequences manually. If you *left-pad* and truncate the sequences of word vectors, then the training might improve.

The “Classify Text Data Using Deep Learning” (Text Analytics Toolbox) example manually truncates and pads all the documents to the same length. This process adds lots of padding to very short documents and discards lots of data from very long documents.

Alternatively, to prevent adding too much padding or discarding too much data, create a transformed datastore that inputs mini-batches into the network. The datastore created in this example converts mini-batches of documents to sequences or word indices and left-pads each mini-batch to the length of the longest document in the mini-batch.

Load Pretrained Word Embedding

The datastore requires a word embedding to convert documents to sequences of vectors. Load a pretrained word embedding using `fastTextWordEmbedding`. This function requires Text Analytics Toolbox™ Model *for fastText English 16 Billion Token Word Embedding* support package. If this support package is not installed, then the function provides a download link.

```
emb = fastTextWordEmbedding;
```

Load Data

Create a tabular text datastore from the data in `factoryReports.csv`. Specify to read the data from the `"Description"` and `"Category"` columns only.

```
filenameTrain = "factoryReports.csv";
textName = "Description";
labelName = "Category";
ttdsTrain = tabularTextDatastore(filenameTrain,'SelectedVariableNames',[textName labelName]);
```

View a preview of the datastore.

```
preview(ttdsTrain)
```

```
ans=8×2 table
                                Description                                                Category
    ____________________________________________________________________________    ____________________

    {'Items are occasionally getting stuck in the scanner spools.'        }    {'Mechanical Failu
    {'Loud rattling and banging sounds are coming from assembler pistons.'}    {'Mechanical Failu
    {'There are cuts to the power when starting the plant.'               }    {'Electronic Failu
```

```
    {'Fried capacitors in the assembler.'                                  }    {'Electronic Failu
    {'Mixer tripped the fuses.'                                            }    {'Electronic Failu
    {'Burst pipe in the constructing agent is spraying coolant.'           }    {'Leak'
    {'A fuse is blown in the mixer.'                                       }    {'Electronic Failu
    {'Things continue to tumble off of the belt.'                          }    {'Mechanical Failu
```

Transform Datastore

Create a custom transform function that converts data read from the datastore to a table containing the predictors and the responses. The `transformText` function takes the data read from a `tabularTextDatastore` object and returns a table of predictors and responses. The predictors are *C*-by-*S* arrays of word vectors given by the word embedding `emb`, where *C* is the embedding dimension and *S* is the sequence length. The responses are categorical labels over the classes.

To get the class names, read the labels from the training data using the `readLabels` function, listed and the end of the example, and find the unique class names.

```
labels = readLabels(ttdsTrain,labelName);
classNames = unique(labels);
numObservations = numel(labels);
```

Because tabular text datastores can read multiple rows of data in a single read, you can process a full mini-batch of data in the transform function. To ensure that the transform function processes a full mini-batch of data, set the read size of the tabular text datastore to the mini-batch size that will be used for training.

```
miniBatchSize = 64;
ttdsTrain.ReadSize = miniBatchSize;
```

To convert the output of the tabular text data to sequences for training, transform the datastore using the `transform` function.

```
tdsTrain = transform(ttdsTrain, @(data) transformText(data,emb,classNames))
```

```
tdsTrain =
  TransformedDatastore with properties:

       UnderlyingDatastore: [1×1 matlab.io.datastore.TabularTextDatastore]
    SupportedOutputFormats: ["txt"    "csv"    "xlsx"    "xls"    "parquet"    "parq"    "png"
                Transforms: {@(data)transformText(data,emb,classNames)}
               IncludeInfo: 0
```

Preview of the transformed datastore. The predictors are *C*-by-*S* arrays, where *S* is the sequence length and *C* is the number of features (the embedding dimension). The responses are the categorical labels.

```
preview(tdsTrain)
```

```
ans=8×2 table
      predictors           responses
    _______________    ________________

    {300×11 single}    Mechanical Failure
    {300×11 single}    Mechanical Failure
    {300×11 single}    Electronic Failure
    {300×11 single}    Electronic Failure
```

```
    {300×11 single}    Electronic Failure
    {300×11 single}    Leak
    {300×11 single}    Electronic Failure
    {300×11 single}    Mechanical Failure
```

Create and Train LSTM Network

Define the LSTM network architecture. To input sequence data into the network, include a sequence input layer and set the input size to the embedding dimension. Next, include an LSTM layer with 180 hidden units. To use the LSTM layer for a sequence-to-label classification problem, set the output mode to `'last'`. Finally, add a fully connected layer with output size equal to the number of classes, a softmax layer, and a classification layer.

```
numFeatures = emb.Dimension;
numHiddenUnits = 180;
numClasses = numel(classNames);
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify the training options. Specify the solver to be `'adam'` and the gradient threshold to be 2. The datastore does not support shuffling, so set `'Shuffle'`, to `'never'`. Validate the network once per epoch. To monitor the training progress, set the `'Plots'` option to `'training-progress'`. To suppress verbose output, set `'Verbose'` to `false`.

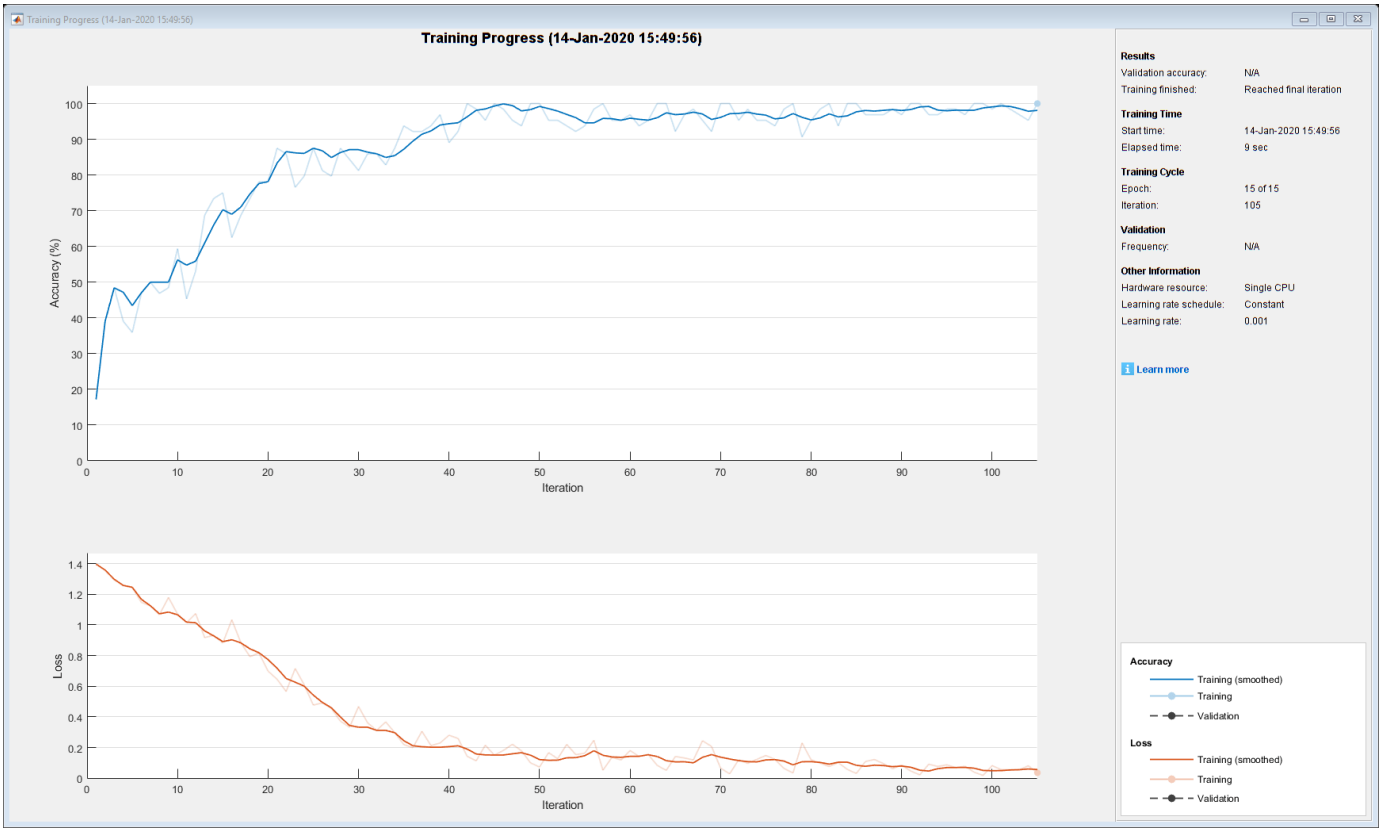
By default, `trainNetwork` uses a GPU if one is available. To specify the execution environment manually, use the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`. Training on a CPU can take significantly longer than training on a GPU. Training using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
numIterationsPerEpoch = floor(numObservations / miniBatchSize);

options = trainingOptions('adam', ...
    'MaxEpochs',15, ...
    'MiniBatchSize',miniBatchSize, ...
    'GradientThreshold',2, ...
    'Shuffle','never', ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the LSTM network using the `trainNetwork` function.

```
net = trainNetwork(tdsTrain,layers,options);
```



Predict Using New Data

Classify the event type of three new reports. Create a string array containing the new reports.

```
reportsNew = [ ...
    "Coolant is pooling underneath sorter."
    "Sorter blows fuses at start up."
    "There are some very loud rattling sounds coming from the assembler."];
```

Preprocess the text data using the preprocessing steps as the training documents.

```
documentsNew = preprocessText(reportsNew);
```

Convert the text data to sequences of embedding vectors using `doc2sequence`.

```
XNew = doc2sequence(emb,documentsNew);
```

Classify the new sequences using the trained LSTM network.

```
labelsNew = classify(net,XNew)
```

```
labelsNew = 3×1 categorical
     Leak
     Electronic Failure
     Mechanical Failure
```

Transform Text Function

The `transformText` function takes the data read from a `tabularTextDatastore` object and returns a table of predictors and responses. The predictors are *C*-by-*S* arrays of word vectors given by the word embedding `emb`, where *C* is the embedding dimension and *S* is the sequence length. The responses are categorical labels over the classes in `classNames`.

```
function dataTransformed = transformText(data,emb,classNames)

% Preprocess documents.
textData = data{:,1};
documents = preprocessText(textData);

% Convert to sequences.
predictors = doc2sequence(emb,documents);

% Read labels.
labels = data{:,2};
responses = categorical(labels,classNames);

% Convert data to table.
dataTransformed = table(predictors,responses);

end
```

Preprocessing Function

The function `preprocessText` performs these steps:

1. Tokenize the text using `tokenizedDocument`.
2. Convert the text to lowercase using `lower`.
3. Erase the punctuation using `erasePunctuation`.

```
function documents = preprocessText(textData)

documents = tokenizedDocument(textData);
documents = lower(documents);
documents = erasePunctuation(documents);

end
```

Read Labels Function

The `readLabels` function creates a copy of the `tabularTextDatastore` object `ttds` and reads the labels from the `labelName` column.

```
function labels = readLabels(ttds,labelName)

ttdsNew = copy(ttds);
ttdsNew.SelectedVariableNames = labelName;
tbl = readall(ttdsNew);
labels = tbl.(labelName);
```

```
end
```

Classify Out-of-Memory Text Data Using Custom Mini-Batch Datastore

This example shows how to classify out-of-memory text data with a deep learning network using a custom mini-batch datastore.

A mini-batch datastore is an implementation of a datastore with support for reading data in batches. You can use a mini-batch datastore as a source of training, validation, test, and prediction data sets for deep learning applications. Use mini-batch datastores to read out-of-memory data or to perform specific preprocessing operations when reading batches of data.

When training the network, the software creates mini-batches of sequences of the same length by padding, truncating, or splitting the input data. The `trainingOptions` function provides options to pad and truncate input sequences, however, these options are not well suited for sequences of word vectors. Furthermore, this function does not support padding data in a custom datastore. Instead, you must pad and truncate the sequences manually. If you *left-pad* and truncate the sequences of word vectors, then the training might improve.

The “Classify Text Data Using Deep Learning” (Text Analytics Toolbox) example manually truncates and pads all the documents to the same length. This process adds lots of padding to very short documents and discards lots of data from very long documents.

Alternatively, to prevent adding too much padding or discarding too much data, create a custom mini-batch datastore that inputs mini-batches into the network. The custom mini-batch datastore `textDatastore.m` converts mini-batches of documents to sequences or word indices and left-pads each mini-batch to the length of the longest document in the mini-batch. For sorted data, this datastore can help reduce the amount of padding added to the data since documents are not padded to a fixed length. Similarly, the datastore does not discard any data from the documents.

This example uses the custom mini-batch datastore `textDatastore`, attached to this example as a supporting file. To access this file, open the example as a live script. You can adapt this datastore to your data by customizing the functions. For an example showing how to create your own custom mini-batch datastore, see “Develop Custom Mini-Batch Datastore” on page 19-36.

Load Pretrained Word Embedding

The datastore `textDatastore` requires a word embedding to convert documents to sequences of vectors. Load a pretrained word embedding using `fastTextWordEmbedding`. This function requires Text Analytics Toolbox™ Model *for fastText English 16 Billion Token Word Embedding* support package. If this support package is not installed, then the function provides a download link.

```
emb = fastTextWordEmbedding;
```

Create Mini-Batch Datastore of Documents

Create a datastore that contains the data for training. The custom mini-batch datastore `textDatastore` reads predictors and labels from a CSV file. For the predictors, the datastore converts the documents into sequences of word indices and for the responses, the datastore returns a categorical label for each document. For more information about creating custom mini-batch datastores, see “Develop Custom Mini-Batch Datastore” on page 19-36.

For the training data, specify the CSV file `"factoryReports.csv"` and that the text and labels are in the columns `"Description"` and `"Category"` respectively.

```
filenameTrain = "factoryReports.csv";
textName = "Description";
labelName = "Category";
dsTrain = textDatastore(filenameTrain,textName,labelName,emb)
```

```
dsTrain =
  textDatastore with properties:

            ClassNames: ["Electronic Failure"    "Leak"    "Mechanical Failure"    "Software Fai
             Datastore: [1×1 matlab.io.datastore.TransformedDatastore]
    EmbeddingDimension: 300
             LabelName: "Category"
         MiniBatchSize: 128
            NumClasses: 4
       NumObservations: 480
```

Create and Train LSTM Network

Define the LSTM network architecture. To input sequence data into the network, include a sequence input layer and set the input size to the embedding dimension. Next, include an LSTM layer with 180 hidden units. To use the LSTM layer for a sequence-to-label classification problem, set the output mode to `'last'`. Finally, add a fully connected layer with output size equal to the number of classes, a softmax layer, and a classification layer.

```
numFeatures = dsTrain.EmbeddingDimension;
numHiddenUnits = 180;
numClasses = dsTrain.NumClasses;

layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify the training options. Specify the solver to be `'adam'` and the gradient threshold to be 2. The datastore `textDatastore.m` does not support shuffling, so set `'Shuffle'`, to `'never'`. For an example showing how to implement a datastore with support for shuffling, see “Develop Custom Mini-Batch Datastore” on page 19-36. To monitor the training progress, set the `'Plots'` option to `'training-progress'`. To suppress verbose output, set `'Verbose'` to `false`.

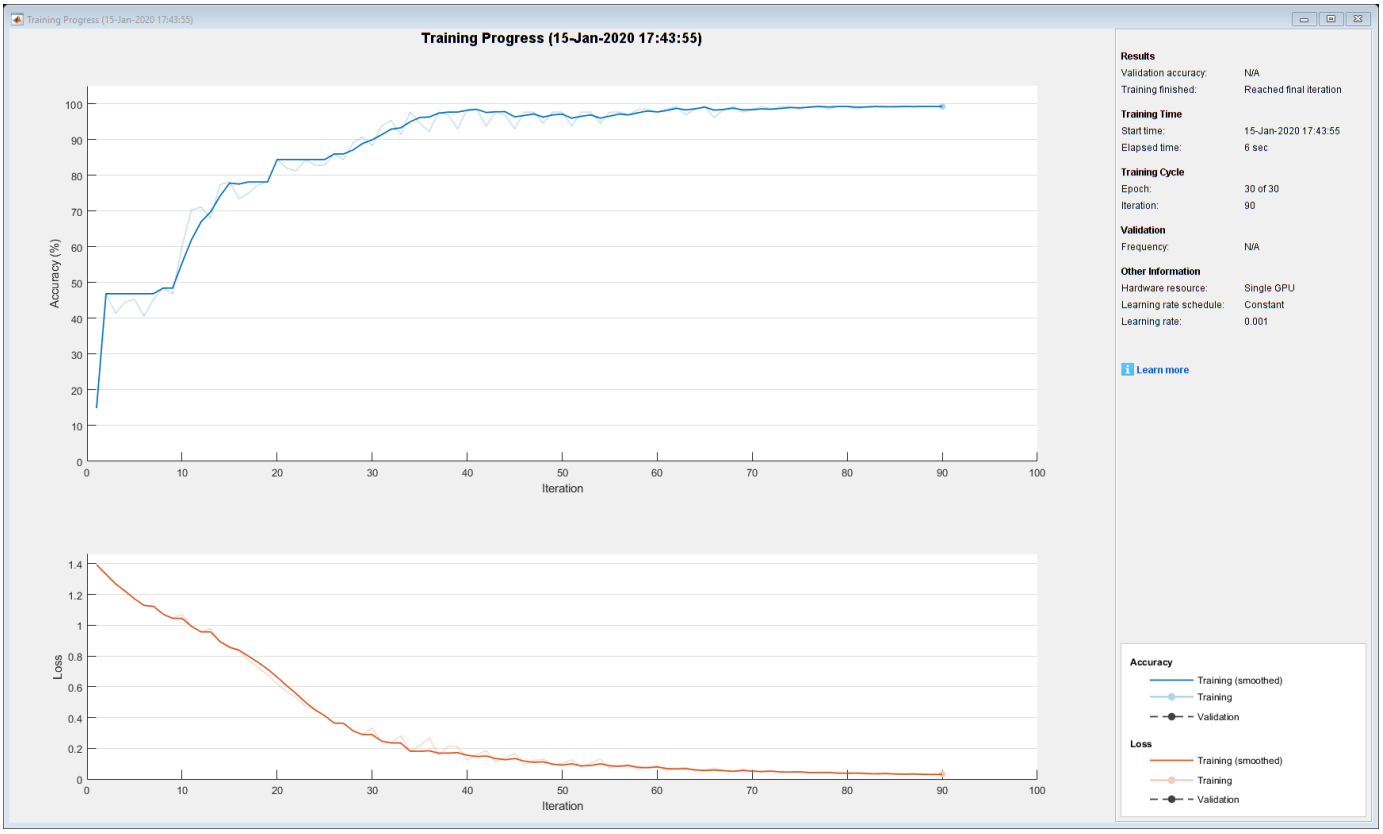
By default, `trainNetwork` uses a GPU if one is available. To specify the execution environment manually, use the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`. Training on a CPU can take significantly longer than training on a GPU. Training using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
miniBatchSize = 128;
numObservations = dsTrain.NumObservations;
numIterationsPerEpoch = floor(numObservations / miniBatchSize);

options = trainingOptions('adam', ...
    'MiniBatchSize',miniBatchSize, ...
    'GradientThreshold',2, ...
    'Shuffle','never', ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the LSTM network using the `trainNetwork` function.

```
net = trainNetwork(dsTrain,layers,options);
```



Predict Using New Data

Classify the event type of three new reports. Create a string array containing the new reports.

```
reportsNew = [
    "Coolant is pooling underneath sorter."
    "Sorter blows fuses at start up."
    "There are some very loud rattling sounds coming from the assembler."];
```

Preprocess the text data using the preprocessing steps as the datastore `textDatastore`.

```
documents = tokenizedDocument(reportsNew);
documents = lower(documents);
documents = erasePunctuation(documents);
predictors = doc2sequence(emb,documents);
```

Classify the new sequences using the trained LSTM network.

```
labelsNew = classify(net,predictors)
```

```
labelsNew = 3×1 categorical
     Leak
     Electronic Failure
```

```
Mechanical Failure
```

Data Sets for Deep Learning

Use these data sets to get started with deep learning applications.

Image Data Sets

Data Set	Description	Task

Digits	The Digits data set consists of 10,000 synthetic grayscale images of handwritten digits. Each image is 28-by-28 pixels and has an associated label denoting which digit the image represents (0–9). Each image has been rotated by a certain angle. When loading the images as in-memory numeric arrays, you can also load the rotation angle of the image.
	
	Load the Digits data as in-memory numeric arrays using the `digitTrain4DArrayData` and `digitTest4DArrayData` functions.
	
	`[XTrain,YTrain,anglesTrain] = digitTrain4DArrayData;`
	`[XTest,YTest,anglesTest] = digitTest4DArrayData;`
	
	For examples showing how to process this data for deep learning, see “Monitor Deep Learning Training Progress” on page 5-115 and “Train Convolutional Neural Network for Regression” on page 3-53.
		Image classification and image regression

	Load the Digits data as an image datastore using the `imageDatastore` function and specify the folder containing the image data.
	
	`dataFolder = fullfile(toolboxdir('nnet'),'nndemos','nndatasets','DigitDataset');`
	`imds = imageDatastore(dataFolder, ...`
	`    'IncludeSubfolders',true,'LabelSource','foldernames');`
	
	For an example showing how to process this data for deep learning, see “Create Simple Deep Learning Network for Classification” on page 3-47.
		Image classification

Data Set	Description	Task

MNIST
 (Representative example)
	The MNIST data set consists of 70,000 handwritten digits split into training and test partitions of 60,000 and 10,000 images, respectively. Each image is 28-by-28 pixels and has an associated label denoting which digit the image represents (0–9).
	
	Download the MNIST files from http://yann.lecun.com/exdb/mnist/ and load the data set into the workspace. To load the data from the files as MATLAB arrays, place the files in the working directory, then use the helper functions `processImagesMNIST` and `processLabelsMNIST`, which are used in the example "Train Variational Autoencoder (VAE) to Generate Images" on page 3-167.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','nnet','main'));`
	`filenameImagesTrain = 'train-images-idx3-ubyte.gz';`
	`filenameLabelsTrain = 'train-labels-idx1-ubyte.gz';`
	`filenameImagesTest = 't10k-images-idx3-ubyte.gz';`
	`filenameLabelsTest = 't10k-labels-idx1-ubyte.gz';`
	
	`XTrain = processImagesMNIST(filenameImagesTrain);`
	`YTrain = processLabelsMNIST(filenameLabelsTrain);`
	`XTest = processImagesMNIST(filenameImagesTest);`
	`YTest = processLabelsMNIST(filenameLabelsTest);`
	
	For an example showing how to process this data for deep learning, see "Train Variational Autoencoder (VAE) to Generate Images" on page 3-167.
	
	To restore the path, use the `path` function.
	
	`path(oldpath);`
		Image classification

Data Set	Description	Task

Omniglot	The Omniglot data set contains character sets for 50 alphabets, divided into 30 sets for training and 20 sets for testing [1]. Each alphabet contains a number of characters, from 14 for Ojibwe (Canadian Aboriginal syllabics) to 55 for Tifinagh. Finally, each character has 20 handwritten observations.
	
	Download and extract the Omniglot data set from https://github.com/brendenlake/omniglot. Set `downloadFolder` to the location of the data.
	
	`downloadFolder = tempdir;`
	
	`url = "https://github.com/brendenlake/omniglot/raw/master/python";`
	`urlTrain = url + "/images_background.zip";`
	`urlTest = url + "/images_evaluation.zip";`
	
	`filenameTrain = fullfile(downloadFolder,"images_background.zip");`
	`filenameTest = fullfile(downloadFolder,"images_evaluation.zip");`
	
	`dataFolderTrain = fullfile(downloadFolder,"images_background");`
	`dataFolderTest = fullfile(downloadFolder,"images_evaluation");`
	
	`if ~exist(dataFolderTrain,"dir")`
	`  fprintf("Downloading Omniglot training data set (4.5 MB)... ")`
	`  websave(filenameTrain,urlTrain);`
	`  unzip(filenameTrain,downloadFolder);`
	`  fprintf("Done.\n")`
	`end`
	
	`if ~exist(dataFolderTest,"dir")`
	`  fprintf("Downloading Omniglot test data (3.2 MB)... ")`
	`  websave(filenameTest,urlTest);`
	`  unzip(filenameTest,downloadFolder);`
	`  fprintf("Done.\n")`
	`end`
	
	To load the training and test data as image datastores, use the `imageDatastore` function. Specify the labels manually by extracting the labels from the file names and setting the `Labels` property.
	
	`imdsTrain = imageDatastore(dataFolderTrain, ...`
	`  'IncludeSubfolders',true, ...`
	`  'LabelSource','none');`
	
	`files = imdsTrain.Files;`
	`parts = split(files,filesep);`
	`labels = join(parts(:,(end-2):(end-1)),'_');`
	`imdsTrain.Labels = categorical(labels);`
	
	`imdsTest = imageDatastore(dataFolderTest, ...`
	`  'IncludeSubfolders',true, ...`
	`  'LabelSource','none');`
	
	`files = imdsTest.Files;`
	`parts = split(files,filesep);`
	`labels = join(parts(:,(end-2):(end-1)),'_');`
	`imdsTest.Labels = categorical(labels);`
		Image similarity

Data Set	Description	Task
	For an example showing how to process this data for deep learning, see “Train a Siamese Network to Compare Images” on page 3-128.	

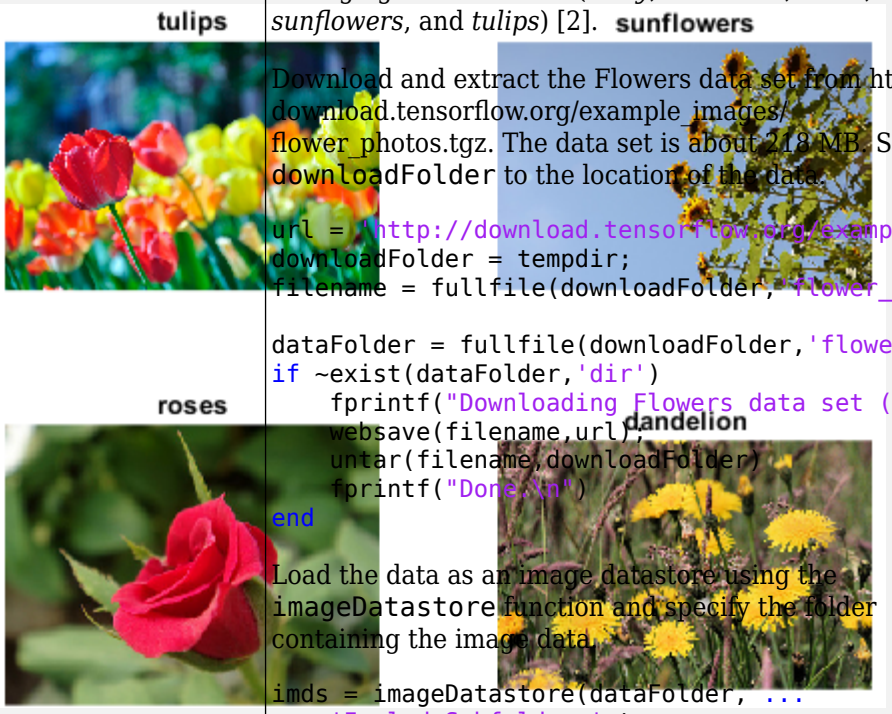
Flowers
  	


Image credits: [3] [4] [5] [6]
	The Flowers data set contains 3670 images of flowers belonging to five classes (*daisy*, *dandelion*, *roses*, *sunflowers*, and *tulips*) [2].
	
	Download and extract the Flowers data set from http://download.tensorflow.org/example_images/flower_photos.tgz. The data set is about 218 MB. Set `downloadFolder` to the location of the data.
	
	`url = 'http://download.tensorflow.org/example_images/flower_photos.tgz';`
	`downloadFolder = tempdir;`
	`filename = fullfile(downloadFolder,'flower_dataset.tgz');`
	
	`dataFolder = fullfile(downloadFolder,'flower_photos');`
	`if ~exist(dataFolder,'dir')`
	`  fprintf("Downloading Flowers data set (218 MB)... ")`
	`  websave(filename,url);`
	`  untar(filename,downloadFolder)`
	`  fprintf("Done.\n")`
	`end`
	
	Load the data as an image datastore using the `imageDatastore` function and specify the folder containing the image data.
	
	`imds = imageDatastore(dataFolder, ...`
	`  'IncludeSubfolders',true, ...`
	`  'LabelSource','foldernames');`
	
	For an example showing how to process this data for deep learning, see “Train Generative Adversarial Network (GAN)” on page 3-76.
		Image classification

Data Set	Description	Task

Example Food Images	The Example Food Images data set contains 978 photographs of food in nine classes (*caesar_salad*, *caprese_salad*, *french_fries*, *greek_salad*, *hamburger*, *hot_dog*, *pizza*, *sashimi*, and *sushi*).
	 	 
	Download the Example Food Images data set using the `downloadSupportFile` function and extract the images using the `unzip` function. This data set is about 77 MB.
	`fprintf('Downloading Example Food Image data set (77 MB)... ')`
	`filename = matlab.internal.examples.downloadSupportFile('nnet', ...`
	`    'data/ExampleFoodImageDataset.zip');`
	`fprintf("Done.\n")`
	`filepath = fileparts(filename);`
	`dataFolder = fullfile(filepath,'ExampleFoodImageDataset');`
	`unzip(filename,dataFolder);`
	For an example showing how to process this data for deep learning, see “View Network Behavior Using tsne” on page 5-129.
	 
	 
		Image classification

Data Set	Description	Task

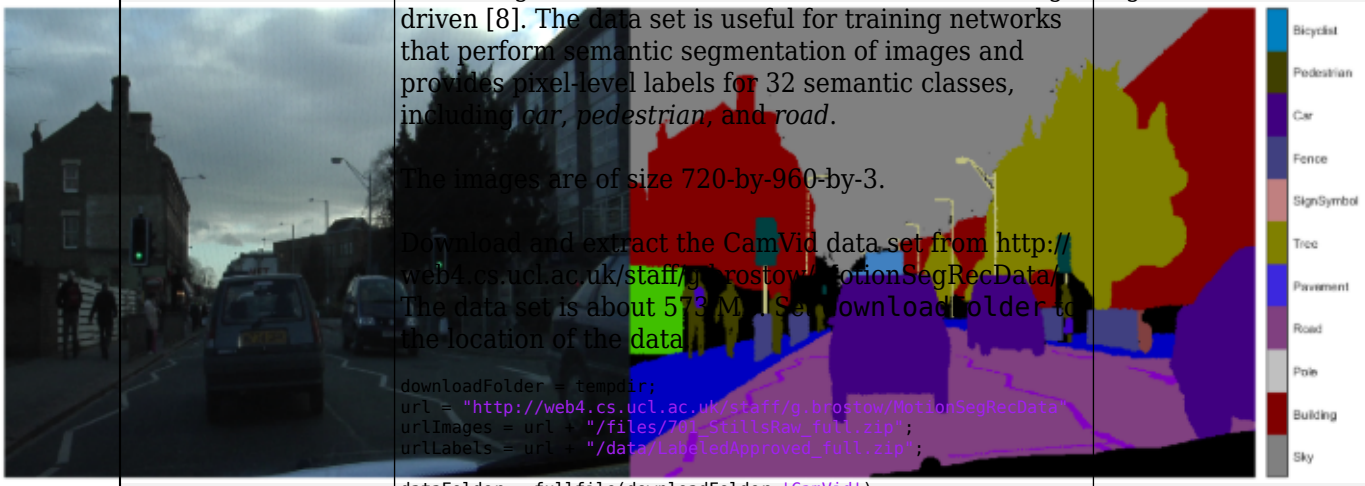
CIFAR-10
 
 	
(Representative example)
	The CIFAR-10 data set contains 60,000 color images of size 32-by-32 pixels, belonging to 10 classes (*airplane*, *automobile*, *bird*, *cat*, *deer*, *dog*, *frog*, *horse*, *ship*, and *truck*) [7]. There are 6,000 images per class.
	
	The data set is split into a training set with 50,000 images and a test set with 10,000 images. This data set is one of the most widely used data sets for testing new image classification models.
	
	Download and extract the CIFAR-10 data set from https://www.cs.toronto.edu/%7Ekriz/cifar-10-matlab.tar.gz. The data set is about 175 MB. Set `downloadFolder` to the location of the data.
	
	`url = 'https://www.cs.toronto.edu/~kriz/cifar-10-matlab.tar.gz';`
	`downloadFolder = tempdir;`
	`filename = fullfile(downloadFolder,'cifar-10-matlab.tar.gz');`
	
	`dataFolder = fullfile(downloadFolder,'cifar-10-batches-mat');`
	`if ~exist(dataFolder,'dir')`
	`  fprintf("Downloading CIFAR-10 dataset (175 MB)... ");`
	`  websave(filename,url);`
	`  untar(filename,downloadFolder);`
	`  fprintf("Done.\n")`
	`end`
	
	Convert the data to numeric arrays using the helper function `loadCIFARData`, which is used in the example “Train Residual Network for Image Classification” on page 3-13.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','nnet','main'));`
	`[XTrain,YTrain,XValidation,YValidation] = loadCIFARData(downloadFolder);`
	
	For an example showing how to process this data for deep learning, see “Train Residual Network for Image Classification” on page 3-13.
	
	To restore the path, use the `path` function.
	
	`path(oldpath);`
		Image classification

Data Set	Description	Task

MathWorks Merch    	The MathWorks Merch data set is a small data set containing 75 images of MathWorks merchandise, belonging to five different classes (*cap*, *cube*, *playing cards*, *screwdriver*, and *torch*). You can use this data set to try out transfer learning and image classification quickly.
	
	The images are of size 227-by-227-by-3.
	
	Extract the MathWorks Merch data set.
	
	`filename = 'MerchData.zip';`
	
	`dataFolder = fullfile(tempdir,'MerchData');`
	`if ~exist(dataFolder,'dir')`
	`  unzip(filename,tempdir);`
	`end`
	
	Load the data as an image datastore using the `imageDatastore` function and specify the folder containing the image data.
	
	`imds = imageDatastore(dataFolder, ...`
	`  'IncludeSubfolders',true,'LabelSource','foldernames');`
	
	For examples showing how to process this data for deep learning, see “Get Started with Transfer Learning” and “Train Deep Learning Network to Classify New Images” on page 3-6.
		Image classification

Data Set	Description	Task

CamVid	The CamVid data set is a collection of images containing street-level views obtained from cars being driven [8]. The data set is useful for training networks that perform semantic segmentation of images and provides pixel-level labels for 32 semantic classes, including *car*, *pedestrian*, and *road*.
	
	The images are of size 720-by-960-by-3.
	
	Download and extract the CamVid data set from http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData/. The data set is about 573 MB. Set `downloadFolder` to the location of the data.
	
	`downloadFolder = tempdir;`
	`url = "http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData";`
	`urlImages = url + "/files/701_StillsRaw_full.zip";`
	`urlLabels = url + "/data/LabeledApproved_full.zip";`
	`dataFolder = fullfile(downloadFolder,'CamVid');`
	`dataFolderImages = fullfile(dataFolder,'images');`
	`dataFolderLabels = fullfile(dataFolder,'labels');`
	
	`filenameLabels = fullfile(dataFolder,'labels.zip');`
	`filenameImages = fullfile(dataFolder,'images.zip');`
	
	`if ~exist(filenameLabels, 'file') || ~exist(imagesZip,'file')`
	`  mkdir(dataFolder)`
	
	`  fprintf("Downloading CamVid data set images (557 MB)... ");`
	`  websave(filenameImages, urlImages);`
	`  unzip(filenameImages, dataFolderImages);`
	`  fprintf("Done.\n")`
	
	`  fprintf("Downloading CamVid data set labels (16 MB)... ");`
	`  websave(filenameLabels, urlLabels);`
	`  unzip(filenameLabels, dataFolderLabels);`
	`  fprintf("Done.\n")`
	`end`
	
	Load the data as a pixel label datastore using the `pixelLabelDatastore` function and specify the folder containing the label data, the classes, and the label IDs. To make training easier, group some of the original classes to reduce the number of classes from 32 to 11. To get the label IDs, use the helper function `camvidPixelLabelIDs`, which is used in the example “Semantic Segmentation Using Deep Learning” on page 8-126.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','deeplearning_shared','main'));`
	`imds = imageDatastore(dataFolderImages,'IncludeSubfolders',true);`
	
	`classes = ["Sky" "Building" "Pole" "Road" "Pavement" "Tree" ...`
	`  "SignSymbol" "Fence" "Car" "Pedestrian" "Bicyclist"];`
	
	`labelIDs = camvidPixelLabelIDs;`
	
	`pxds = pixelLabelDatastore(dataFolderLabels,classes,labelIDs);`
	
	For an example showing how to process this data for deep learning, see “Semantic Segmentation Using Deep Learning” on page 8-126.
		Semantic segmentation



Data Set	Description	Task
	To restore the path, use the `path` function. `path(oldpath);`	

Vehicle
 	
 	The Vehicle data set consists of 295 images containing one or two labeled instances of a vehicle. This small data set is useful for exploring the YOLO-v2 training procedure, but in practice, more labeled images are needed to train a robust detector.
	
	The images are of size 720-by-960-by-3.
	
	Extract the Vehicle data set. Set `dataFolder` to the location of the data.
	
	`filename = 'vehicleDatasetImages.zip';`
	
	`dataFolder = fullfile(tempdir,'vehicleImages');`
	`if ~exist(dataFolder,'dir')`
	`  unzip(filename,tempdir);`
	`end`
	
	Load the data set as a table of file names and bounding boxes from the extracted MAT file and convert the file names to absolute file paths.
	
	`data = load('vehicleDatasetGroundTruth.mat');`
	`vehicleDataset = data.vehicleDataset;`
	
	`vehicleDataset.imageFilename = fullfile(tempdir,vehicleDataset.imageFilename);`
	
	Create an image datastore containing the images and a box label datastore containing the bounding boxes using the `imageDatastore` and `boxLabelDatastore` functions, respectively. Combine the resulting datastores using the `combine` function.
	
	`filenamesImages = vehicleDataset.imageFilename;`
	`tblBoxes = vehicleDataset(:,'vehicle');`
	
	`imds = imageDatastore(filenamesImages);`
	`blds = boxLabelDatastore(tblBoxes);`
	
	`cds = combine(imds,blds);`
	
	For an example showing how to process this data for deep learning, see “Object Detection Using YOLO v2 Deep Learning” on page 8-115.
		Object detection

Data Set	Description	Task

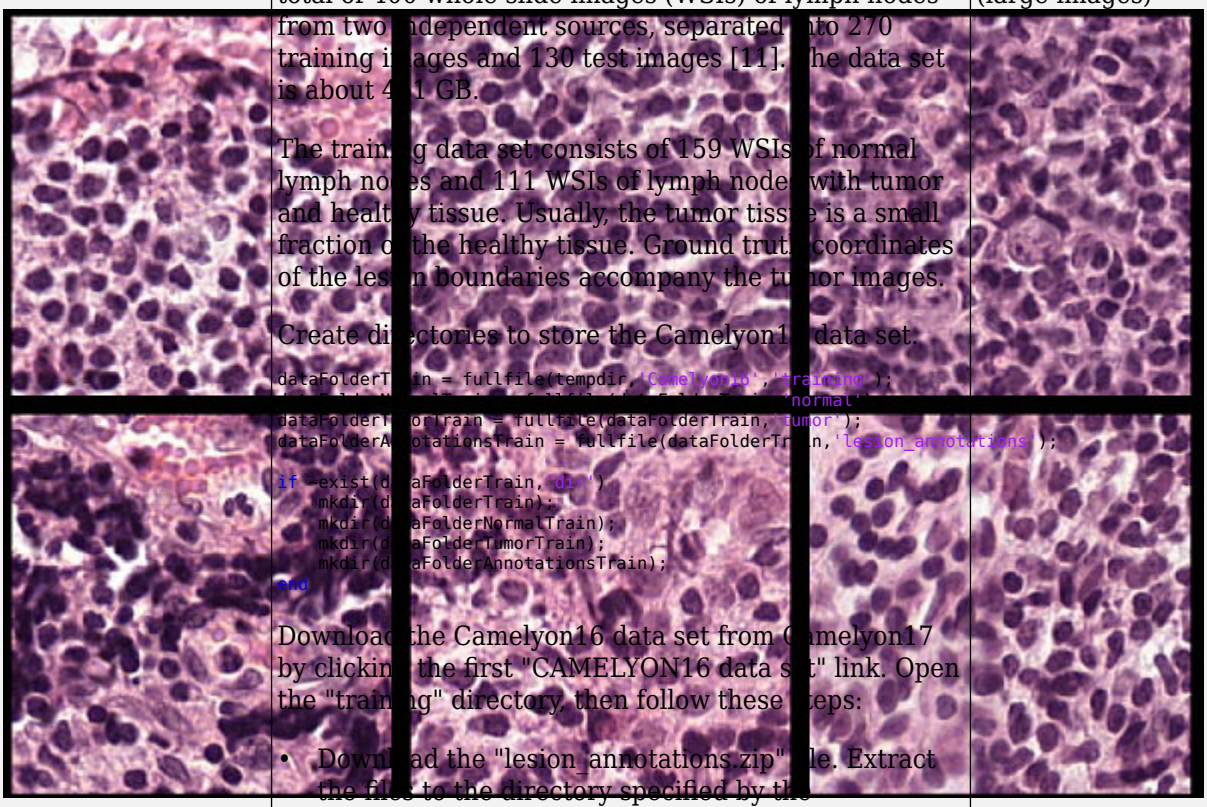
RIT-18	The RIT-18 data set contains image data captured by a drone over Hamlin Beach State Park in New York state [9]. The data contains labeled training, validation, and test sets, with 18 object class labels including *road markings*, *tree*, and *building*. The data set is about 3 GB.
	
	Download the RIT-18 data set from https://www.cis.rit.edu/%7Ermk6217/rit18_data.mat. Set `downloadFolder` to the location of the data.
	
	`downloadFolder = tempdir;`
	`url = 'http://www.cis.rit.edu/~rmk6217/rit18_data.mat';`
	`filename = fullfile(downloadFolder,'rit18_data.mat');`
	
	`if ~exist(filename,'file')`
	`  fprintf("Downloading Hamlin Beach data set (3 GB)... ");`
	`  websave(filename,url);`
	`  fprintf("Done.\n")`
	`end`
	
	For an example showing how to process this data for deep learning, see "Semantic Segmentation of Multispectral Images Using Deep Learning" on page 8-154.
		Semantic segmentation

Data Set	Description	Task

BraTS 	The BraTS data set contains MRI scans of brain tumors, namely gliomas, which are the most common primary brain malignancies [10].
	
	The data set contains 750 4-D volumes, each representing a stack of 3-D images. Each 4-D volume is of size 240-by-240-by-155-by-4, where the first three dimensions correspond to the height, width, and depth of a 3-D volumetric image. The fourth dimension corresponds to different scan modalities. The data set is divided into 484 training volumes with voxel labels and 266 test volumes. The data set is about 7 GB.
	
	Create a directory to store the BraTS data set.
	
	`dataFolder = fullfile(tempdir,'BraTS');`
	
	`if ~exist(dataFolder,'dir')`
	`  mkdir(dataFolder);`
	`end`
	
	Download the BraTS data from Medical Segmentation Decathlon by clicking the "Download Data" link. Download the "Task01_BrainTumour.tar" file.
	
	Extract the TAR file into the directory specified by the `dataFolder` variable. If the extraction is successful, then `dataFolder` contains a directory named `Task01_BrainTumour` that has three subdirectories: `imagesTr`, `imagesTs`, and `labelsTr`.
	
	For an example showing how to process this data for deep learning, see “3-D Brain Tumor Segmentation Using Deep Learning” on page 8-171.
		Semantic segmentation

Data Set	Description	Task

Camelyon16	The data from the Camelyon16 challenge contains a total of 400 whole-slide images (WSIs) of lymph nodes from two independent sources, separated into 270 training images and 130 test images [11]. The data set is about 4.1 GB.
	
	The training data set consists of 159 WSIs of normal lymph nodes and 111 WSIs of lymph nodes with tumor and healthy tissue. Usually, the tumor tissue is a small fraction of the healthy tissue. Ground truth coordinates of the lesion boundaries accompany the tumor images.
	
	Create directories to store the Camelyon16 data set:
	
	`dataFolderTrain = fullfile(tempdir,'Camelyon16','training');`
	`dataFolderNormalTrain = fullfile(dataFolderTrain,'normal');`
	`dataFolderTumorTrain = fullfile(dataFolderTrain,'tumor');`
	`dataFolderAnnotationsTrain = fullfile(dataFolderTrain,'lesion_annotations');`
	
	`if ~exist(dataFolderTrain,'dir')`
	`  mkdir(dataFolderTrain);`
	`  mkdir(dataFolderNormalTrain);`
	`  mkdir(dataFolderTumorTrain);`
	`  mkdir(dataFolderAnnotationsTrain);`
	`end`
	
	Download the Camelyon16 data set from Camelyon17 by clicking the first "CAMELYON16 data set" link. Open the "training" directory, then follow these steps:
	
	• Download the "lesion_annotations.zip" file. Extract the files to the directory specified by the `dataFolderAnnotationsTrain` variable.
	• Open the "normal" directory. Download the images to the directory specified by the `dataFolderNormalTrain` variable.
	• Open the "tumor" directory. Download the images to the directory specified by the `dataFolderTumorTrain` variable.
	
	For an example showing how to process this data for deep learning, see “Preprocess Multiresolution Images for Training Classification Network” (Image Processing Toolbox).
		Image classification (large images)



Data Set	Description	Task

Low Dose CT Grand Challenge	The Low Dose CT Grand Challenge includes pairs of regular-dose CT images and simulated low-dose CT images for 99 head scans (labeled N for neuro), 100 chest scans (labeled C for chest), and 100 abdomen scans (labeled L for liver) [12] [13]. The full data set is about 1.2 TB.
	
	Create a directory to store the chest files from the Low Dose CT Grand Challenge data set.
	
	`dataDir = fullfile(tempdir,"LDCT","LDCT-and-Projection-data");`
	`if ~exist(dataDir,'dir')`
	`    mkdir(dataDir);`
	`end`
	
	To download the data, go to The Cancer Imaging Archive website. Download the chest files from the "Images (DICOM, 952 GB)" data set using the NBIA Data Retriever. Specify the `dataDir` variable as the location of the downloaded data. When the data is downloaded successfully, `dataDir` contains 50 subfolders with names such as "C002" and "C004", ending with "C296".
	
	For an example showing how to process this data for deep learning, see “Unsupervised Medical Image Denoising Using CycleGAN” on page 9-130.
		Image-to-image regression

Data Set	Description	Task

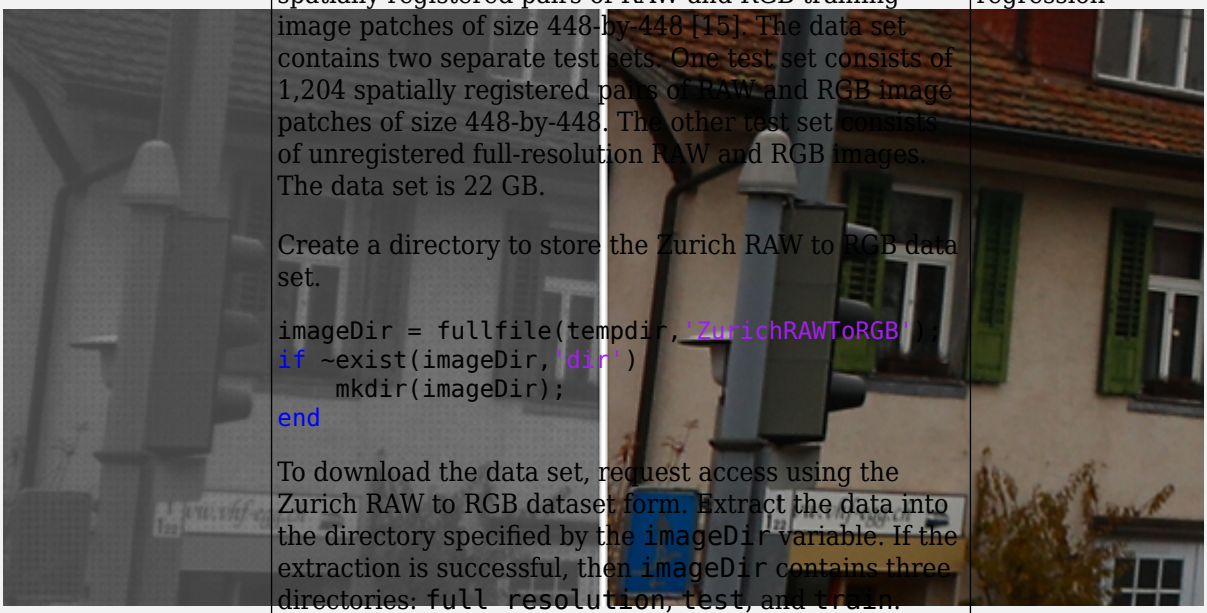
Common Objects in Context (COCO)
 
 (Representative example)
	The COCO 2014 train images data set consists of 82,783 images. The annotations data contains at least five captions corresponding to each image.
	
	Create directories to store the COCO data set.
	
	`dataFolder = fullfile(tempdir,"coco");`
	`if ~exist(dataFolder,'dir')`
	`  mkdir(dataFolder);`
	`end`
	
	Download and extract the COCO 2014 train images and captions from https://cocodataset.org/#download by clicking the "2014 Train images" and "2014 Train/Val annotations" links, respectively. Save the data in the folder specified by `dataFolder`.
	
	Extract the captions from the file `captions_train2014.json` using the `jsondecode` function.
	
	`filename = fullfile(dataFolder,"annotations_trainval2014","annotations", ...`
	`  "captions_train2014.json");`
	`str = fileread(filename);`
	`data = jsondecode(str);`
	
	The `annotations` field of the structure contains the data required for image captioning.
	
	For an example showing how to process this data for deep learning, see “Image Captioning Using Attention” on page 4-198.
		Image captioning

Data Set	Description	Task

IAPR TC-12
 (Representative example)
	The IAPR TC-12 Benchmark consists of 20,000 still natural images [14]. The data set includes photos of people, animals, cities, and more. The data file is about 1.8 GB.
	
	Download the IAPR TC-12 data set.
	
	`dataDir = fullfile(tempdir,'iaprtc12');`
	`url = 'http://www-i6.informatik.rwth-aachen.de/imageclef/resources/iaprtc12.t`
	
	`if ~exist(dataDir,'dir')`
	`    fprintf('Downloading IAPR TC-12 data set (1.8 GB)...\n');`
	`    try`
	`        untar(url,dataDir);`
	`    catch`
	`        % On some Windows machines, the untar command throws an error for .tg`
	`        % files. Rename to .tg and try again.`
	`        fileName = fullfile(tempdir,'iaprtc12.tg');`
	`        websave(fileName,url);`
	`        untar(fileName,dataDir);`
	`    end`
	`    fprintf('Done.\n\n');`
	`end`
	
	Load the data as an image datastore using the `imageDatastore` function. Specify the folder containing the image data and the image file extensions.
	
	`imageDir = fullfile(dataDir,'images')`
	`exts = {'.jpg','.bmp','.png'};`
	`imds = imageDatastore(imageDir, ...`
	`    'IncludeSubfolders',true,'FileExtensions',exts);`
	
	For an example showing how to process this data for deep learning, see “Single Image Super-Resolution Using Deep Learning” on page 9-8.
		Image-to-image regression

Data Set	Description	Task

Zurich RAW to RGB	The Zurich RAW to RGB data set contains 48,043 spatially registered pairs of RAW and RGB training image patches of size 448-by-448 [15]. The data set contains two separate test sets. One test set consists of 1,204 spatially registered pairs of RAW and RGB image patches of size 448-by-448. The other test set consists of unregistered full-resolution RAW and RGB images. The data set is 22 GB.
	
	Create a directory to store the Zurich RAW to RGB data set.
	
	`imageDir = fullfile(tempdir,'ZurichRAWToRGB');`
	`if ~exist(imageDir,'dir')`
	`    mkdir(imageDir);`
	`end`
	
	To download the data set, request access using the Zurich RAW to RGB dataset form. Extract the data into the directory specified by the `imageDir` variable. If the extraction is successful, then `imageDir` contains three directories: `full_resolution`, `test`, and `train`.
	
	For an example showing how to process this data for deep learning, see “Develop RAW Camera Processing Pipeline Using Deep Learning” on page 9-51.
		Image-to-image regression



Data Set	Description	Task

See-In-The-Dark (SID)	The See-In-The-Dark (SID) data set provides registered pairs of RAW images of the same scene [16]. In each pair, one image has a short exposure time and is
	 	er image has a longer
	exposed. The size of the Sony
	data set is 25 GB.
	
	the Sony camera data from
	
	`dataDir = fullfile(tempdir,"SID");`
	`if ~exist(dataDir,"dir")`
	`  mkdir(dataDir)`
	`end`
	
	go to this link: https://storage.googleapis.com/isl-datasets/SID/Sony.zip. Extract the data into the directory specified by the `dataDir` variable. When extracted successfully, `dataDir` contains the directory `Sony` with two subdirectories: `long` and `short`. The files in the `long` subdirectory have a long exposure and are well-exposed. The files in the `short` subdirectory have a short exposure and are quite underexposed and dark.
	
	The data set also provides text files that describe how to partition the files into training, validation, and test data sets. Move the files "Sony_train_list.txt", "Sony_val_list.txt", and "Sony_test_list.txt" to the directory specified by the `dataDir` variable.
	
	For an example showing how to process this data for deep learning, see “Recover Images from Extreme Low-Light Conditions Using Deep Learning” on page 9-73.
		Image-to-image regression

Data Set	Description	Task

LIVE In the Wild
 
	The LIVE In the Wild data set consists of 1,162 photos captured by mobile devices, with seven additional training images [17]. Each image is rated by an average of 175 individuals on a scale of [1, 100]. The data set provides the mean and standard deviation of the subjective scores for each image.
	
	Create a directory to store the LIVE In the Wild data set.
	
	`imageDir = fullfile(tempdir,"LIVEInTheWild");`
	`if ~exist(imageDir,'dir')`
	`    mkdir(imageDir);`
	`end`
	
	Download the data set by following the instructions outlined in LIVE In the Wild Image Quality Challenge Database. Extract the data into the directory specified by the `imageDir` variable. When extracted successfully, `imageDir` contains two directories: `Data` and `Images`.
	
	For an example showing how to process this data for deep learning, see “Quantify Image Quality Using Neural Image Assessment” on page 9-108.
		Image classification

Concrete Crack Images for Classification
 	The Concrete Crack Images for Classification data set contains images of two classes: "Negative" images without cracks present in the road and "Positive" images with cracks [18]. The data set provides 20,000 images of each class. The size of the data set is 235 MB.
	
	Create a directory to store the data set.
	
	`dataDir = fullfile(tempdir,"ConcreteCracks");`
	`if ~exist(dataDir,"dir")`
	`    mkdir(dataDir);`
	`end`
	
	To download the data set, go to this link: Concrete Crack Images for Classification. Extract the ZIP file to obtain a RAR file, then extract the contents of the RAR file into the directory specified by the `dataDir` variable. If the extraction is successful, then `dataDir` contains two subdirectories: `Negative` and `Positive`.
	
	For an example showing how to process this data for deep learning, see “Detect Image Anomalies Using Explainable One-Class Classification Neural Network” on page 9-157.
		Image classification

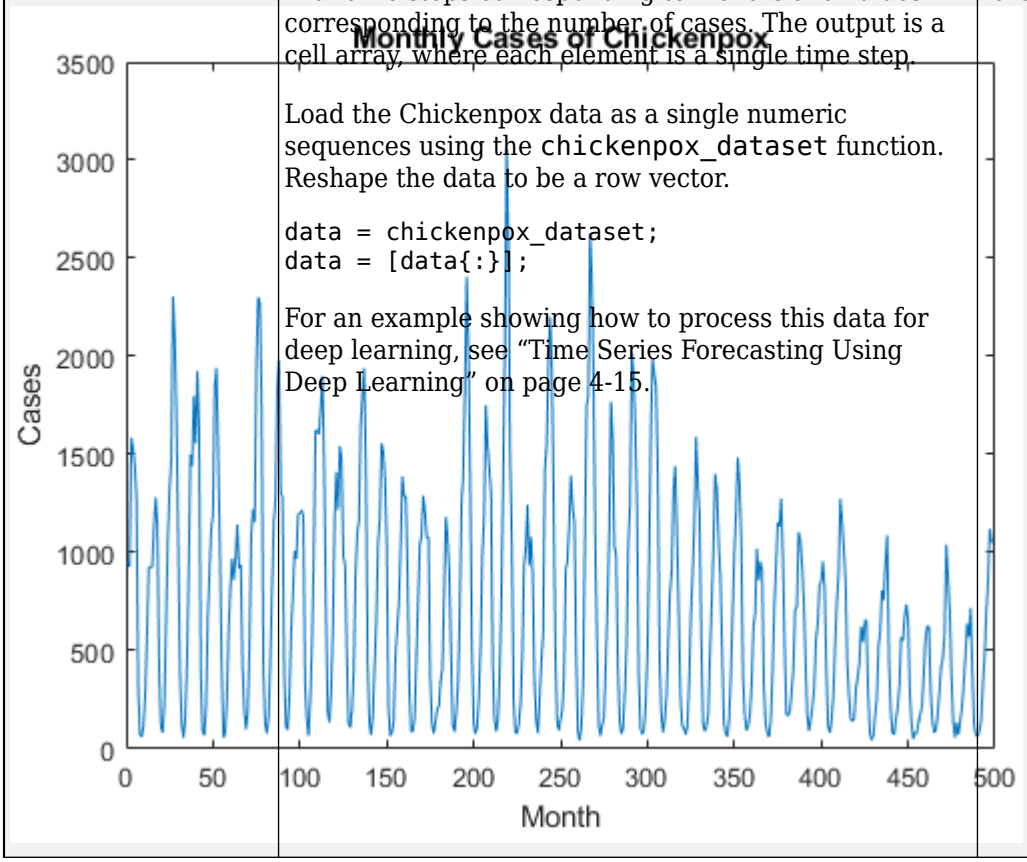
Time Series and Signal Data Sets

Data	Description	Task

Japanese Vowels	The Japanese Vowels data set contains preprocessed sequences representing utterances of Japanese vowels from different speakers [19] [20].
	 	`XTrain` and `XTest` are cell arrays containing sequences of dimension 12 of varying length. `YTrain` and `YTest` are categorical vectors of labels 1 to 9, that correspond to the nine speakers. The entries in `XTrain` are matrices with 12 rows (one row for each feature) and varying numbers of columns (one column for each time step). `XTest` is a cell array containing 370 sequences of dimension 12 of varying length.
	
	Load the Japanese Vowels data set as in-memory cell arrays containing numeric sequences using the `japaneseVowelsTrainData` and `japaneseVowelsTestData` functions.
	
	`[XTrain,YTrain] = japaneseVowelsTrainData;`
	`[XTest,YTest] = japaneseVowelsTestData;`
	
	For an example showing how to process this data for deep learning, see “Sequence Classification Using Deep Learning” on page 4-2.
		Sequence-to-label classification

Data	Description	Task

Chickenpox	The Chickenpox data set contains a single time series, with time steps corresponding to months and values corresponding to the number of cases. The output is a cell array, where each element is a single time step.
	
	Load the Chickenpox data as a single numeric sequences using the `chickenpox_dataset` function. Reshape the data to be a row vector.
	
	`data = chickenpox_dataset;`
	`data = [data{:}];`
	
	For an example showing how to process this data for deep learning, see “Time Series Forecasting Using Deep Learning” on page 4-15.
		Time-series forecasting



Data	Description	Task

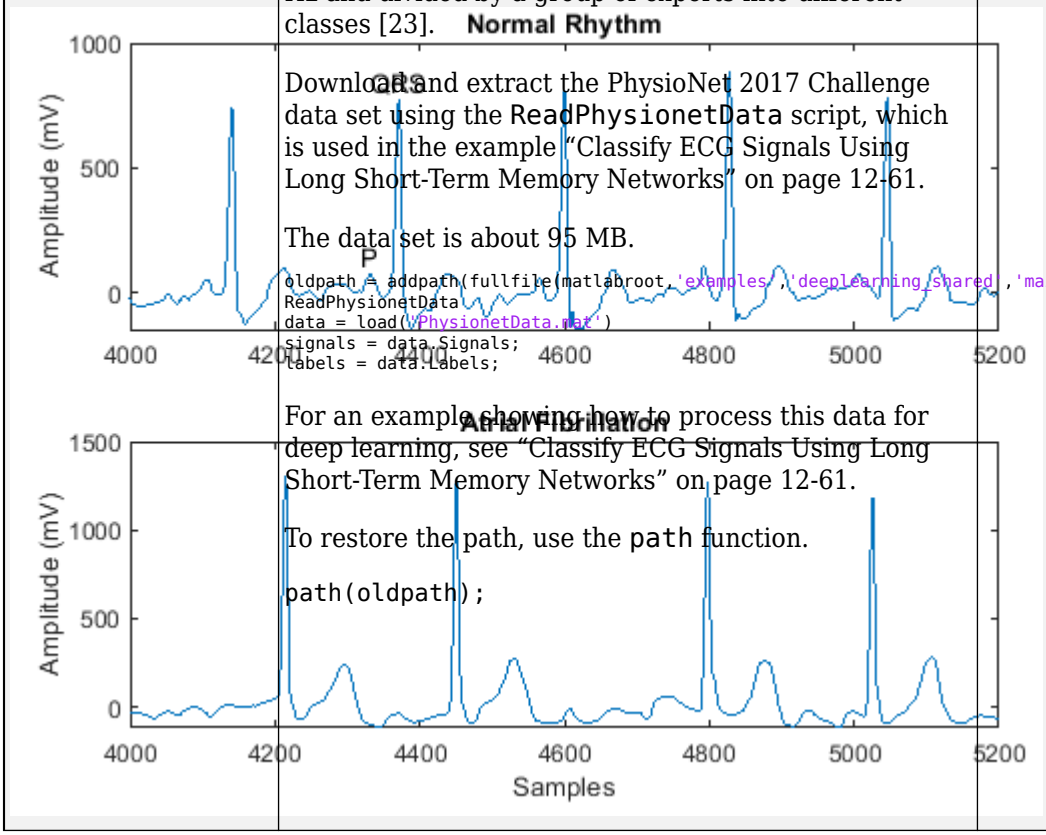
Human Activity 	The Human Activity data set contains seven time series of sensor data obtained from a smartphone worn on the body. Each sequence has three features and varies in length. The three features correspond to accelerometer readings in three different directions.
	
	Load the Human Activity data set.
	
	`dataTrain = load('HumanActivityTrain');`
	`dataTest = load('HumanActivityTest');`
	
	`XTrain = dataTrain.XTrain;`
	`YTrain = dataTrain.YTrain;`
	`XTest = dataTest.XTest;`
	`YTest = dataTest.YTest;`
	
	For an example showing how to process this data for deep learning, see “Sequence-to-Sequence Classification Using Deep Learning” on page 4-42.
		Sequence-to-sequence classification

Data	Description	Task

Turbofan Engine Degradation Simulation	Each time series of the Turbofan Engine Degradation Simulation data set represents a different engine [21]. Each engine starts with unknown degrees of initial wear and manufacturing variation. The engine is operating normally at the start of each time series, and develops a fault at some point during the series. In the training set, the fault grows in magnitude until system failure.
	
	 	
	The data contains a ZIP-compressed text files with 26 columns of numbers, separated by spaces. Each row is a snapshot of data taken during a single operational cycle, and each column is a different variable. The columns correspond to the following:
	
	• Column 1 – Unit number
	• Column 2 – Time in cycles
	• Columns 3–5 – Operational settings
	• Columns 6–26 – Sensor measurements 1–21
	
	Create a directory to store the Turbofan Engine Degradation Simulation data set.
	
	`dataFolder = fullfile(tempdir,"turbofan");`
	`if ~exist(dataFolder,'dir')`
	`  mkdir(dataFolder);`
	`end`
	
	Download and extract the Turbofan Engine Degradation Simulation Data Set from https://ti.arc.nasa.gov/tech/dash/groups/pcoe/prognostic-data-repository/.
	
	Unzip the data from the file `CMAPSSData.zip`.
	
	`filename = "CMAPSSData.zip";`
	`unzip(filename,dataFolder)`
	
	Load the training and test data using the helper functions `processTurboFanDataTrain` and `processTurboFanDataTest`, respectively. These functions are used in the example “Sequence-to-Sequence Regression Using Deep Learning” on page 4-47.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','nnet','main'));`
	`filenamePredictors = fullfile(dataFolder,"train_FD001.txt");`
	`[XTrain,YTrain] = processTurboFanDataTrain(filenamePredictors);`
	
	`filenamePredictors = fullfile(dataFolder,"test_FD001.txt");`
	`filenameResponses = fullfile(dataFolder,"RUL_FD001.txt");`
	`[XTest,YTest] = processTurboFanDataTest(filenamePredictors,filenameResponses);`
		Sequence-to-sequence regression, predictive maintenance

Data	Description	Task
	For an example showing how to process this data for deep learning, see “Sequence-to-Sequence Regression Using Deep Learning” on page 4-47. To restore the path, use the `path` function. `path(oldpath);`	

PhysioNet 2017 Challenge	The PhysioNet 2017 Challenge data set consists of a set of electrocardiogram (ECG) recordings sampled at 300 Hz and divided by a group of experts into different classes [23].
	
	Download and extract the PhysioNet 2017 Challenge data set using the `ReadPhysionetData` script, which is used in the example “Classify ECG Signals Using Long Short-Term Memory Networks” on page 12-61.
	
	The data set is about 95 MB.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','deeplearning_shared','main'));`
	`ReadPhysionetData`
	`data = load('PhysionetData.mat')`
	`signals = data.Signals;`
	`labels = data.Labels;`
	
	For an example showing how to process this data for deep learning, see “Classify ECG Signals Using Long Short-Term Memory Networks” on page 12-61.
	
	To restore the path, use the `path` function.
	
	`path(oldpath);`
		Sequence-to-label classification

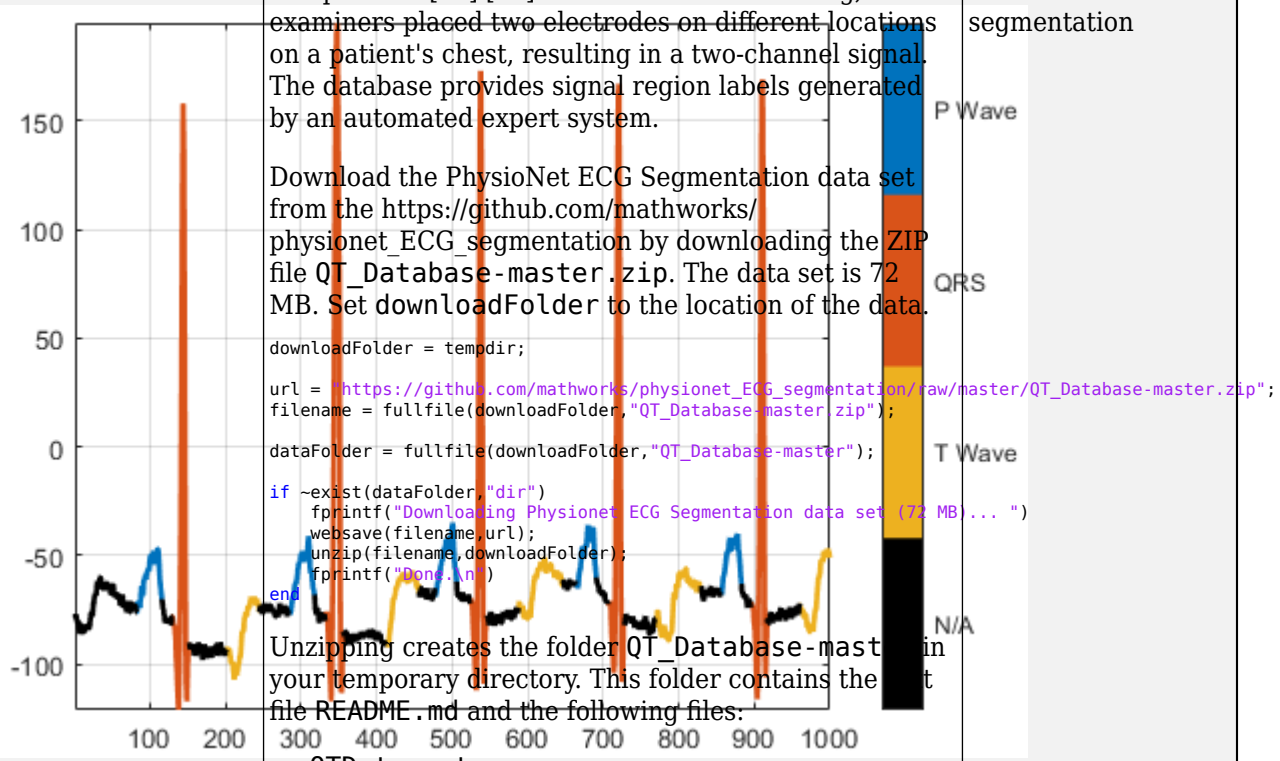


Data	Description	Task

Tennessee Eastman Process (TEP) simulation	This data set consists of MAT files converted from the Tennessee Eastman Process (TEP) simulation data [22].
	
	Download the Tennessee Eastman Process (TEP) simulation data set from the MathWorks support files site (see disclaimer). The data set has four components: fault-free training, fault-free testing, faulty training, and faulty testing. Download each file separately.
	
	The data set is 1.7 GB.
	
	 	`fprintf("Downloading TEP faulty training data (613 MB)... ")`
	`filenameFaultyTrain = matlab.internal.examples.downloadSupportFile('predmaint', ...`
	`'chemical-process-fault-detection-data/faultytraining.mat');`
	`fprintf("Done.\n")`
	
	`fprintf("Downloading TEP faulty testing data (1 GB)... ")`
	`filenameFaultyTest = matlab.internal.examples.downloadSupportFile('predmaint', ...`
	`'chemical-process-fault-detection-data/faultytesting.mat');`
	`fprintf("Done.\n")`
	
	`fprintf("Downloading TEP fault-free training data (36 MB)... ")`
	`filenameFaultFreeTrain = matlab.internal.examples.downloadSupportFile('predmaint', ...`
	`'chemical-process-fault-detection-data/faultfreetraining.mat');`
	`fprintf("Done.\n")`
	
	`fprintf("Downloading TEP fault-free testing data (69 MB)... ")`
	`filenameFaultFreeTest = matlab.internal.examples.downloadSupportFile('predmaint', ...`
	`'chemical-process-fault-detection-data/faultfreetesting.mat');`
	`fprintf("Done.\n")`
	
	Load the downloaded files into the MATLAB workspace.
	
	`load(filenameFaultyTrain);`
	`load(filenameFaultyTest);`
	`load(filenameFaultFreeTrain);`
	`load(filenameFaultFreeTest);`
	
	For an example showing how to process this data for deep learning, see “Chemical Process Fault Detection Using Deep Learning” on page 16-2.
		Sequence-to-label classification

Data	Description	Task

PhysioNet ECG Segmentation	The PhysioNet ECG Segmentation data set consists of roughly 15 minutes of ECG recordings from a total of 105 patients [23] [24]. To obtain each recording, the examiners placed two electrodes on different locations on a patient's chest, resulting in a two-channel signal. The database provides signal region labels generated by an automated expert system.
	
	Download the PhysioNet ECG Segmentation data set from the https://github.com/mathworks/physionet_ECG_segmentation by downloading the ZIP file `QT_Database-master.zip`. The data set is 72 MB. Set `downloadFolder` to the location of the data.
	
	`downloadFolder = tempdir;`
	
	`url = "https://github.com/mathworks/physionet_ECG_segmentation/raw/master/QT_Database-master.zip";`
	`filename = fullfile(downloadFolder,"QT_Database-master.zip");`
	
	`dataFolder = fullfile(downloadFolder,"QT_Database-master");`
	
	`if ~exist(dataFolder,"dir")`
	`  fprintf("Downloading Physionet ECG Segmentation data set (72 MB)... ")`
	`  websave(filename,url);`
	`  unzip(filename,downloadFolder);`
	`  fprintf("Done.\n")`
	`end`
	
	Unzipping creates the folder `QT_Database-master` in your temporary directory. This folder contains the text file `README.md` and the following files:
	
	• `QTData.mat`
	• `Modified_physionet_data.txt`
	• `License.txt`
	
	`QTData.mat` contains the PhysioNet ECG Segmentation data. The file `Modified_physionet_data.txt` provides the source attributions for the data and a description of the operations applied to each raw ECG recording. Load the PhysioNet ECG Segmentation data from the MAT file.
	
	`load(fullfile(dataFolder,'QTData.mat'))`
	
	For an example showing how to process this data for deep learning, see “Waveform Segmentation Using Deep Learning” on page 12-41.
		Sequence-to-label classification, waveform segmentation



Data	Description	Task

Synthetic pedestrian, car, and bicyclist backscattering	Generate a synthetic pedestrian, car, and bicyclist backscattering data set using the helper functions `helperBackScatterSignals` and `helperDopplerSignatures`, which are used in the example "Pedestrian and Bicyclist Classification Using Deep Learning" (Radar Toolbox).
	
	 	The helper function `helperBackScatterSignals` generates a specified number of pedestrian, bicyclist, and car radar returns. For each realization, the return signals have dimensions *N*fast-by-*N*slow, where *N*fast is the number of *fast-time* samples and *N*slow is the number of *slow-time* samples.
	
	The helper function `helperDopplerSignatures` computes the short-time Fourier transform (STFT) of a radar return to generate the micro-Doppler signature. To obtain the micro-Doppler signatures, use the helper functions to apply the STFT and a preprocessing method to each signal.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','phased','main'));`
	`numPed = 1; % Number of pedestrian realizations`
	`numBic = 1; % Number of bicyclist realizations`
	`numCar = 1; % Number of car realizations`
	`[xPedRec,xBicRec,xCarRec,Tsamp] = helperBackScatterSignals(numPed,numBic,numCar);`
	
	`[SPed,T,F] = helperDopplerSignatures(xPedRec,Tsamp);`
	`[SBic,~,~] = helperDopplerSignatures(xBicRec,Tsamp);`
	`[SCar,~,~] = helperDopplerSignatures(xCarRec,Tsamp);`
	
	For an example showing how to process this data for deep learning, see "Pedestrian and Bicyclist Classification Using Deep Learning" (Radar Toolbox).
	
	To restore the path, use the `path` function.
	
	`path(oldpath);`
		Sequence-to-label classification

Data	Description	Task

Generated waveforms 	Generate rectangular, linear FM, and phase coded waveforms using the helper function `helperGenerateRadarWaveforms`, which is used in the example “Radar and Communications Waveform Classification Using Deep Learning” (Radar Toolbox).
	
	The helper function `helperGenerateRadarWaveforms` generates 3000 signals with a sample rate of 100 MHz for each modulation type using `phased.RectangularWaveform` for rectangular pulses, `phased.LinearFMWaveform` for linear FM, and `phased.PhaseCodedWaveform` for phase-coded pulses with Barker code.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','phased','main'));`
	`[wav, modType] = helperGenerateRadarWaveforms;`
	
	For an example showing how to process this data for deep learning, see “Radar and Communications Waveform Classification Using Deep Learning” (Radar Toolbox).
	
	To restore the path, use the `path` function.
	
	`path(oldpath);`
		Sequence-to-label classification

Video Data Sets

Data	Description	Task

HMDB: a large human motion database
 (Representative example)
	The HMBD51 data set contains about 2 GB of video data for 7000 clips from 51 classes, such as *drink*, *run*, and *pushup*.
	
	Download and extract the HMBD51 data set from HMDB: a large human motion database. The data set is about 2 GB.
	
	After you extract the RAR files, get the file names and the labels of the videos by using the helper function `hmdb51Files`, which used in the example "Classify Videos Using Deep Learning" on page 4-54. Set `dataFolder` to the location of the data.
	
	`oldpath = addpath(fullfile(matlabroot,'examples','nnet','main'));`
	`dataFolder = fullfile(tempdir,"hmdb51_org");`
	`[files,labels] = hmdb51Files(dataFolder);`
	
	For an example showing how to process this data for deep learning, see "Classify Videos Using Deep Learning" on page 4-54.
	
	To restore the path, use the `path` function.
	
	`path(oldpath);`
		Video classification

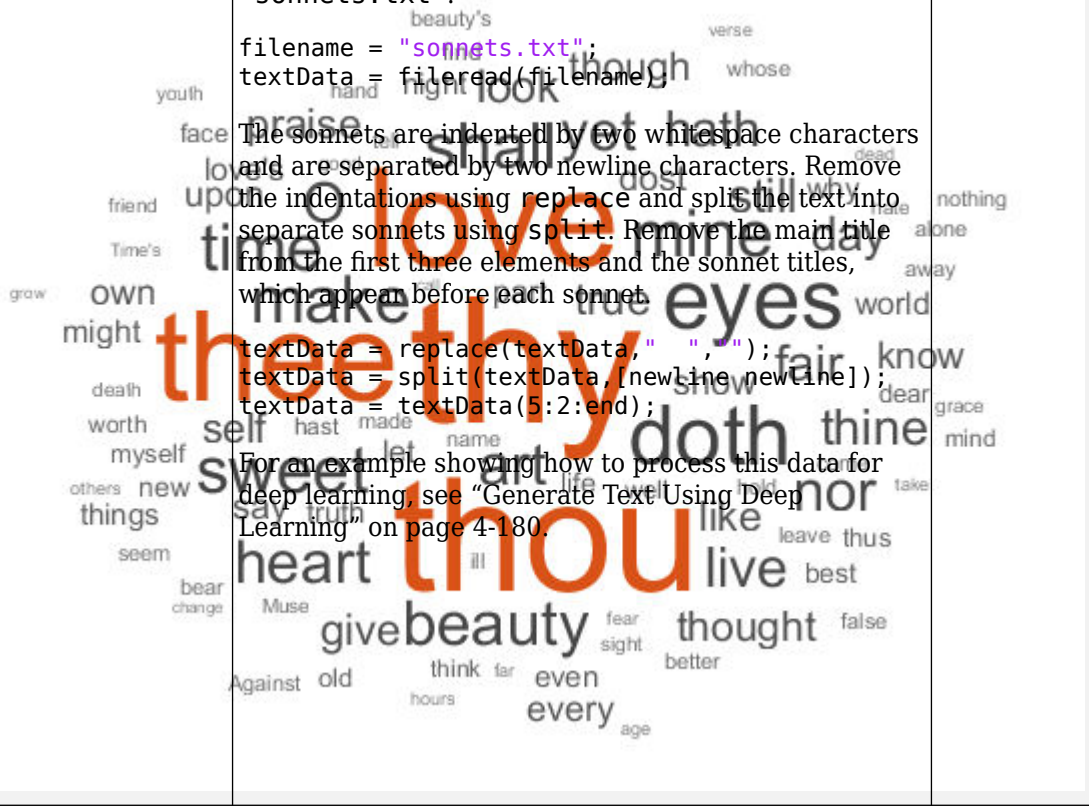
Text Data Sets

Data	Description	Task

Factory Reports	The Factory Reports data set is a table containing approximately 500 reports with various attributes including a plain text description in the variable `Description` and a categorical label in the variable `Category`.
	 	Read the Factory Reports data from the file `"factoryReports.csv"`. Extract the text data and the labels from the `Description` and `Category` columns, respectively.
	`filename = "factoryReports.csv";`
	`data = readtable(filename,'TextType','string');`
	`textData = data.Description;`
	`labels = data.Category;`
	For an example showing how to process this data for deep learning, see “Classify Text Data Using Deep Learning” on page 4-89.
		Text classification, topic modeling

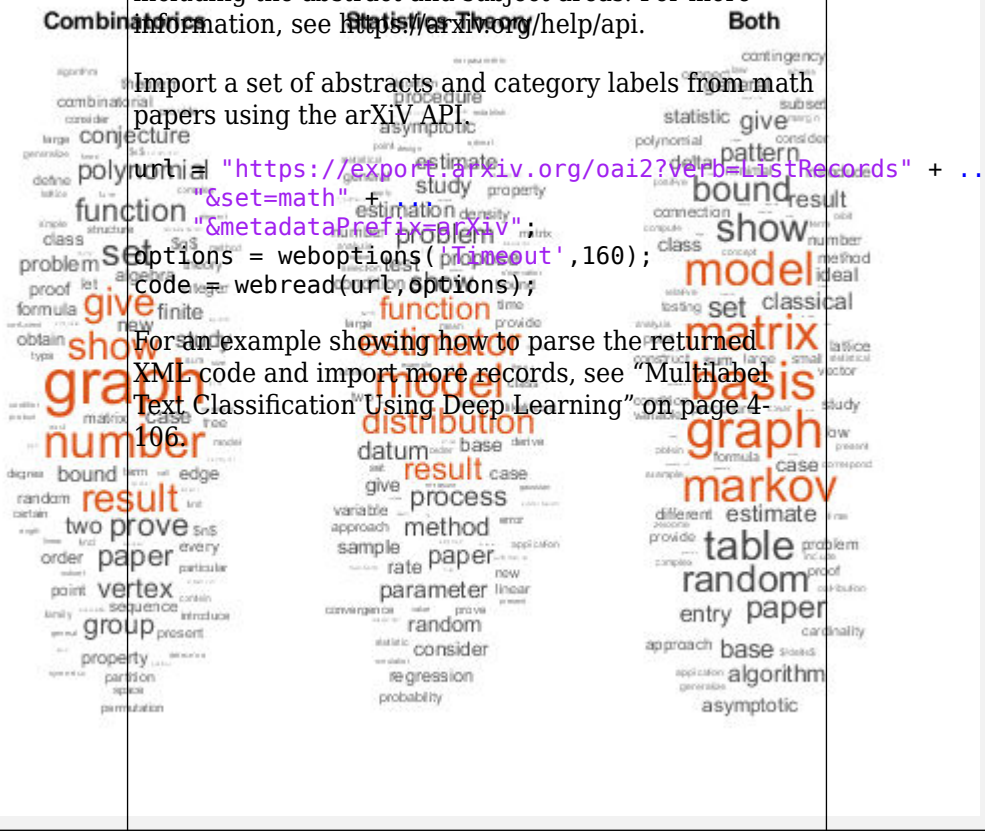
Data	Description	Task

Shakespeare's Sonnets	The file `sonnets.txt` contains all of Shakespeare's sonnets in a single text file.
	
	Read the Shakespeare's Sonnets data from the file `"sonnets.txt"`.
	
	`filename = "sonnets.txt";`
	`textData = fileread(filename);`
	
	The sonnets are indented by two whitespace characters and are separated by two newline characters. Remove the indentations using `replace` and split the text into separate sonnets using `split`. Remove the main title from the first three elements and the sonnet titles, which appear before each sonnet.
	
	`textData = replace(textData,"  ","");`
	`textData = split(textData,[newline newline]);`
	`textData = textData(5:2:end);`
	
	For an example showing how to process this data for deep learning, see "Generate Text Using Deep Learning" on page 4-180.
		Topic modeling, text generation



Data	Description	Task

ArXiv Metadata	The ArXiv API allows you to access the metadata of scientific e-prints submitted to https://arxiv.org including the abstract and subject areas. For more information, see https://arxiv.org/help/api.
	
	Import a set of abstracts and category labels from math papers using the arXiV API.
	
	`url = "https://export.arxiv.org/oai2?verb=ListRecords" + ... "&set=math" + ... "&metadataPrefix=arXiv";`
	`options = weboptions('Timeout',160);`
	`code = webread(url,options);`
	
	For an example showing how to parse the returned XML code and import more records, see “Multilabel Text Classification Using Deep Learning” on page 4-106.
		Text classification, topic modeling



Data	Description	Task

Books from Project Gutenberg	You can download many books from Project Gutenberg. For example, download the text from Alice's Adventures in Wonderland by Lewis Carroll from https://www.gutenberg.org/files/11/11-h/11-h.htm using the `webread` function.
	
	`url = "https://www.gutenberg.org/files/11/11-h/11-h.htm";`
	`code = webread(url);`
	
	The HTML code contains the relevant text inside `<p>` (paragraph) elements. Extract the relevant text by parsing the HTML code using the `htmlTree` function and then finding all the elements with the element name `"p"`.
	
	`tree = htmlTree(code);`
	`selector = "p";`
	`subtrees = findElement(tree,selector);`
	
	Extract the text data from the HTML subtrees using the `extractHTMLText` function and remove the empty elements.
	
	`textData = extractHTMLText(subtrees);`
	`textData(textData == "") = [];`
	
	For an example showing how to process this data for deep learning, see "Word-By-Word Text Generation Using Deep Learning" on page 4-192.
		Topic modeling, text generation

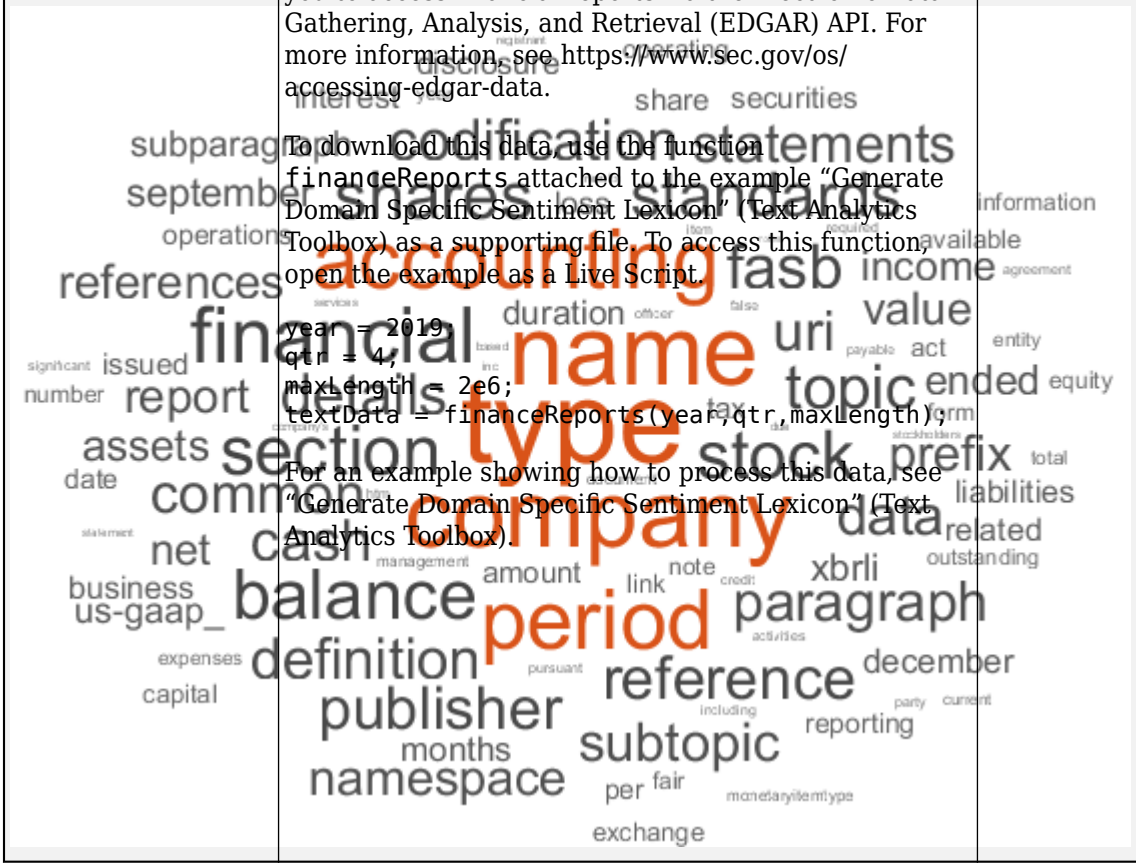
Data	Description	Task

Weekend updates	The file `weekendUpdates.xlsx` contains example social media status updates containing the hashtags "#weekend" and "#vacation". This data set requires Text Analytics Toolbox.
	
	Extract the text data from the file `weekendUpdates.xlsx` using the `readtable` function and extract the text data from the variable `TextData`.
	
	`filename = "weekendUpdates.xlsx";`
	`tbl = readtable(filename,'TextType','string');`
	`textData = tbl.TextData;`
	
	For an example showing how to process this data, see "Analyze Sentiment in Text" (Text Analytics Toolbox).
		Sentiment analysis

Roman Numerals	The CSV file `"romanNumerals.csv"` contains the decimal numbers 1–1000 in the first column and the corresponding Roman numerals in the second column.
	
	Load the decimal-Roman numeral pairs from the CSV file `"romanNumerals.csv"`.
	
	`filename = fullfile("romanNumerals.csv");`
	`options = detectImportOptions(filename, ...`
	`    'TextType','string', ...`
	`    'ReadVariableNames',false);`
	`options.VariableNames = ["Source" "Target"];`
	`options.VariableTypes = ["string" "string"];`
	
	`data = readtable(filename,options);`
	
	For an example showing how to process this data for deep learning, see "Sequence-to-Sequence Translation Using Attention" on page 4-164.
		Sequence-to-sequence translation

Data	Description	Task

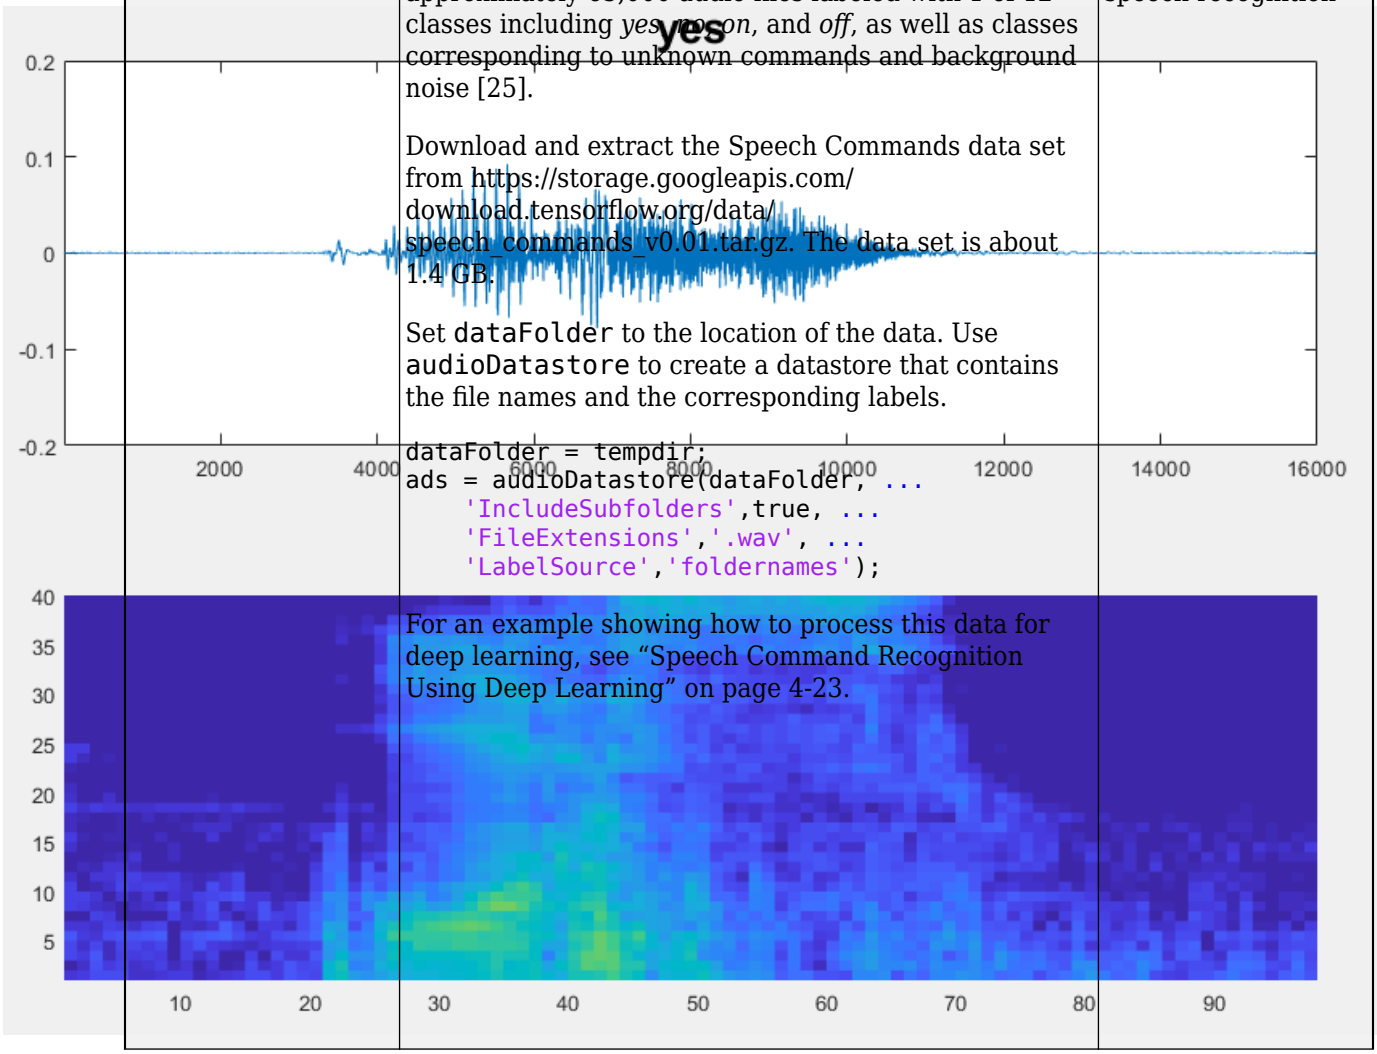
Finance Reports	The Securities and Exchange Commission (SEC) allows you to access financial reports via the Electronic Data Gathering, Analysis, and Retrieval (EDGAR) API. For more information, see https://www.sec.gov/os/accessing-edgar-data.
	
	To download this data, use the function `financeReports` attached to the example "Generate Domain Specific Sentiment Lexicon" (Text Analytics Toolbox) as a supporting file. To access this function, open the example as a Live Script.
	
	`year = 2019;`
	`qtr = 4;`
	`maxLength = 2e6;`
	`textData = financeReports(year,qtr,maxLength);`
	
	For an example showing how to process this data, see "Generate Domain Specific Sentiment Lexicon" (Text Analytics Toolbox).
		Sentiment analysis



Audio Data Sets

Data	Description	Task

Speech Commands	The Speech Commands data set consists of approximately 65,000 audio files labeled with 1 of 12 classes including *yes*, *no*, *on*, and *off*, as well as classes corresponding to unknown commands and background noise [25].
	
	Download and extract the Speech Commands data set from https://storage.googleapis.com/download.tensorflow.org/data/speech_commands_v0.01.tar.gz. The data set is about 1.4 GB.
	
	Set `dataFolder` to the location of the data. Use `audioDatastore` to create a datastore that contains the file names and the corresponding labels.
	
	`dataFolder = tempdir;`
	`ads = audioDatastore(dataFolder, ...`
	`    'IncludeSubfolders',true, ...`
	`    'FileExtensions','.wav', ...`
	`    'LabelSource','foldernames');`
	
	For an example showing how to process this data for deep learning, see “Speech Command Recognition Using Deep Learning” on page 4-23.
		Audio classification, speech recognition

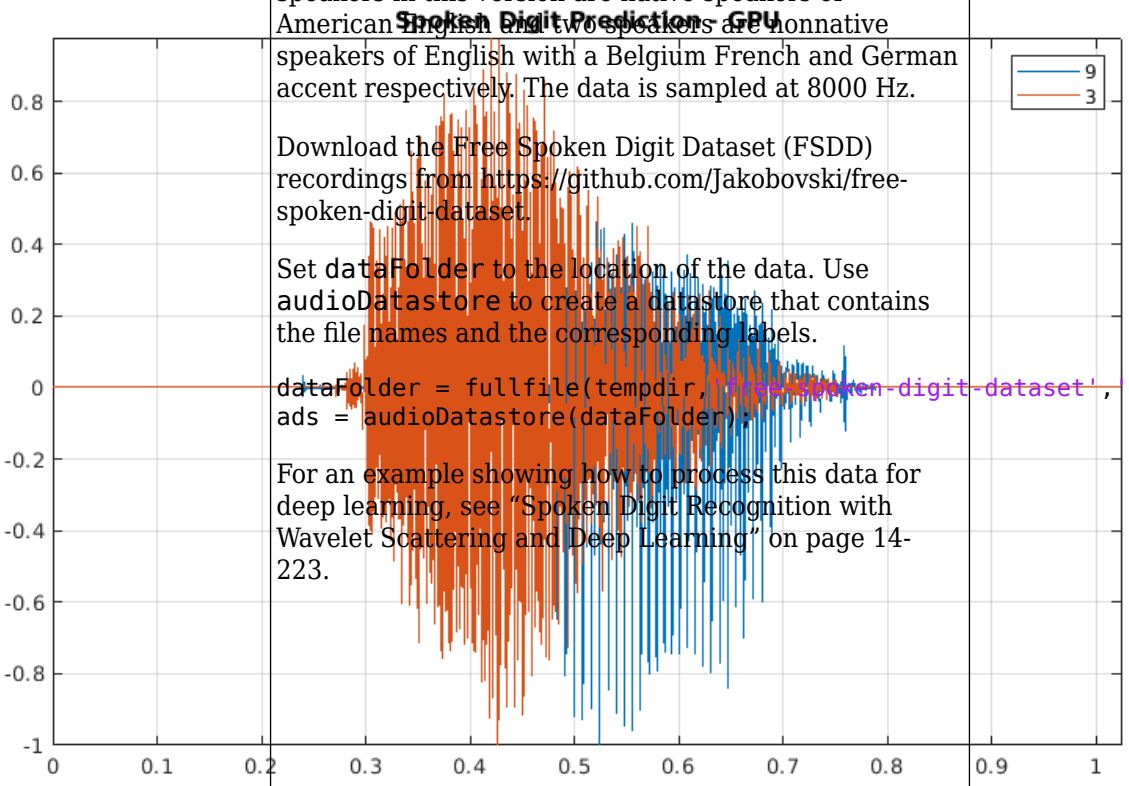


Data	Description	Task

Mozilla Common Voice	The Mozilla Common Voice data set consists of audio recordings of speech and corresponding text files. The data also includes demographic metadata such as age and accent.
	 	Download and extract the Mozilla Common Voice data set data set from https://voice.mozilla.org/. The data set is an open data set, which means that it can grow over time. As of October 2019, the data set is about 28 GB. Set `dataFolder` to the location of the data. Use `audioDatastore` to create a datastore that contains the file names and the corresponding labels.
	`dataFolder = tempdir;`
	`ads = audioDatastore(fullfile(dataFolder,"clips"));`
		Audio classification, speech recognition.

Data	Description	Task

Free Spoken Digit Dataset	The Free Spoken Digit Dataset, as of January 29, 2019, consists of 2000 recordings of the English digits 0 through 9 obtained from four speakers. Two of the speakers in this version are native speakers of American English and two speakers are nonnative speakers of English with a Belgium French and German accent respectively. The data is sampled at 8000 Hz.
	
	Download the Free Spoken Digit Dataset (FSDD) recordings from https://github.com/Jakobovski/free-spoken-digit-dataset.
	
	Set `dataFolder` to the location of the data. Use `audioDatastore` to create a datastore that contains the file names and the corresponding labels.
	
	`dataFolder = fullfile(tempdir,'free-spoken-digit-dataset','recordings');`
	`ads = audioDatastore(dataFolder);`
	
	For an example showing how to process this data for deep learning, see "Spoken Digit Recognition with Wavelet Scattering and Deep Learning" on page 14-223.
		Audio classification, speech recognition.



Data	Description	Task

Berlin Database of Emotional Speech	The Berlin Database of Emotional Speech contains 535 utterances spoken by 10 actors intended to convey one of the following emotions: anger, boredom, disgust, anxiety/fear, happiness, sadness, or neutral [26]. The emotions are text independent.
	
	The file names are codes indicating the speaker ID, text spoken, emotion, and version. The website contains a key for interpreting the code and additional information about the speakers such as age.
	
	Download the Berlin Database of Emotional Speech from http://emodb.bilderbar.info/index-1280.html. The data set is about 40 MB.
	
	Set `dataFolder` to the location of the data. Use `audioDatastore` to create a datastore that contains the file names and the corresponding labels.
	
	`dataFolder = tempdir;`
	`ads = audioDatastore(fullfile(dataFolder,"wav"));`
	
	For an example showing how to process this data for deep learning, see “Speech Emotion Recognition” on page 14-211.

Choose an App to Label Ground Truth Data

You can use Computer Vision Toolbox, Automated Driving Toolbox, Lidar Toolbox™, Audio Toolbox, and Signal Processing Toolbox apps to label ground truth data. Use this labeled data to validate or train algorithms such as image classifiers, object detectors, semantic segmentation networks, instance segmentation networks, and deep learning applications. The choice of labeling app depends on several factors, including the supported data sources, labels, and types of automation.

One key consideration is the type of data that you want to label.

- If your data is an image collection, use the **Image Labeler** app. An image collection is an unordered set of images that can vary in size. For example, you can use the app to label images of books for training a classifier. The **Image Labeler** can also handle very large images (at least one dimension >8K).
- If your data is a single video or image sequence, use the **Video Labeler** app. An image sequence is an ordered set of images that resembles a video. For example, you can use this app to label a video or image sequence of cars driving on a highway for training an object detector.
- If your data includes multiple time-overlapped signals, such as videos, image sequences, or lidar signals, use the **Ground Truth Labeler** app. For example, you can label data for a single scene captured by multiple sensors mounted on a vehicle.
- If your data is only a lidar signal, use the **Lidar Labeler**. For example, you can use this app to label data captured from a point cloud sensor.
- If your data consists of single-channel or multichannel one-dimensional signals, use the **Signal Labeler**. For example, you can label biomedical, speech, communications, or vibration data. To perform audio-specific tasks, such as speech detection, speech-to-text transcription, and recording new audio, use the **Audio Labeler** app.

This table summarizes the key features of the labeling apps.

Labeling App	Data Sources	Label Support	Automation	Additional Features
Image Labeler	• Image collections • Very large images (at least one dimension >8K)	• Rectangle regions of interest (ROIs) • Projected cuboid (ROIs) • Line ROIs • Pixel ROIs • Polygon ROIs • Sublabels • Attributes • Scenes	• Built-in automation algorithms • Custom automation algorithms • Blocked image automation algorithms	• View visual summary of labeled data

Labeling App	Data Sources	Label Support	Automation	Additional Features
Video Labeler	• Videos • Image sequences • Custom image data sources	• Rectangle ROIs • Projected cuboid (ROIs) • Line ROIs • Pixel ROIs • Polygon ROIs • Sublabels • Attributes • Scenes	• Built-in automation algorithms • Custom automation algorithms • Temporal automation algorithms	• View visual summary of labeled data
Ground Truth Labeler	• Videos • Image sequences • Custom image data sources • Point cloud sequences (PCD or PLY files) • Velodyne® lidar files • Rosbags (requires ROS Toolbox)	• Rectangle ROIs • Projected cuboid (ROIs) • Cuboid ROIs • Line ROIs • Pixel ROIs • Polygon ROIs • Sublabels • Attributes • Scenes	• Built-in automation algorithms, including vehicle and lane detection algorithms and a point cloud temporal interpolation algorithm • Custom automation algorithms • Temporal automation algorithms • Multisignal automation	• View visual summary of labeled data • Connect external tool to app for displaying time-synchronized signals, such as lidar or CAN bus data • Customize loading interface to support additional data sources

Labeling App	Data Sources	Label Support	Automation	Additional Features
Lidar Labeler	• Point cloud sequences (PCD or PLY files) • Velodyne lidar files • LAS/LAZ file sequences • Rosbags (requires ROS Toolbox)	• Cuboid ROIs • Attributes • Scenes	• Built-in automation algorithms, including a lidar object tracker and point cloud temporal interpolator • Custom automation algorithms • Temporal automation algorithms	• View the cuboid labels in top, side, and front views • Save and reuse custom camera views • Connect to external tool to display time-synchronized signals for ease of labeling, such as videos, to use as a reference while labeling
Signal Labeler	• Numeric arrays, MATLAB timetables, and `labeledSignalSet` objects in the MATLAB workspace • MAT-files and CSV files • Audio files (WAVE, OGG, FLAC, AU, AIFF, AIFC, MP3, MPEG-4 AAC)	• Time-based ROIs • Time-based points • Attributes • Sublabels	• Built-in peak labeling • Custom automation algorithms	• Expand, collapse, and browse details of labeled data • View signal spectra and spectrograms • Label ROIs and points using the spectrogram • Label signals in bulk • Use Label Viewer to view and compare labels
Audio Labeler	• Audio files (WAVE, OGG, FLAC, AU, AIFF, AIFC, MP3, MPEG-4 AAC) • `labeledSignalSet` objects in the MATLAB workspace or in MAT-files	• Time-based ROIs • File-level labels	• Speech detection • Speech-to-text transcription (requires Audio Toolbox extended functionality for speech2text)	• Audio playback • Audio recording • Inspect audio file information

Deep Learning Code Generation

Code Generation for Deep Learning Networks

This example shows how to perform code generation for an image classification application that uses deep learning. It uses the `codegen` command to generate a MEX function that runs prediction by using image classification networks such as MobileNet-v2, ResNet, and GoogLeNet.

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA® enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

`mobilenetv2_predict` Entry-Point Function

MobileNet-v2 is a convolutional neural network that is trained on more than a million images from the ImageNet database. The network is 155 layers deep and can classify images into 1000 object categories, such as keyboard, mouse, pencil, and many animals. The network has an image input size of 224-by-224. Use the `analyzeNetwork` function to display an interactive visualization of the deep learning network architecture.

```
net = mobilenetv2();
analyzeNetwork(net);
```

The `mobilenetv2_predict.m` entry-point function takes an image input and runs prediction on the image using the pretrained MobileNet-v2 convolutional neural network. The function uses a persistent object *mynet* to load the series network object and reuses the persistent object for prediction on subsequent calls.

```
type('mobilenetv2_predict.m')
```

```
% Copyright 2017-2019 The MathWorks, Inc.

function out = mobilenetv2_predict(in)
```

```
%#codegen

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('mobilenetv2','mobilenetv2');
end

% pass in input
out = mynet.predict(in);
```

Run MEX Code Generation

To generate CUDA code for the `mobilenetv2_predict` entry-point function, create a GPU code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command and specify an input size of [224,224,3]. This value corresponds to the input layer size of the MobileNet-v2 network.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg mobilenetv2_predict -args {ones(224,224,3)} -report

Code generation successful: View report
```

Generated Code Description

The series network is generated as a C++ class containing an array of 155 layer classes and functions to set up, call predict, and clean up the network.

```
class b_mobilenetv2_0
{
   ....
   public:
     b_mobilenetv2_0();
     void setup();
     void predict();
     void cleanup();
     ~b_mobilenetv2_0();
};
```

The `setup()` method of the class sets up handles and allocates memory for each layer of the network object. The `predict()` method performs prediction for each of the 155 layers in the network.

The entry-point function `mobilenetv2_predict()` in the generated code file `mobilenetv2_predict.cu` constructs a static object of *b_mobilenetv2* class type and invokes setup and predict on this network object.

```
static b_mobilenetv2_0 mynet;
static boolean_T mynet_not_empty;

/* Function Definitions */
void mobilenetv2_predict(const real_T in[150528], real32_T out[1000])
{
  if (!mynet_not_empty) {
    DeepLearningNetwork_setup(&mynet);
```

```
    mynet_not_empty = true;
  }

   /*  pass in input    */
   DeepLearningNetwork_predict(&mynet, in, out);
 }
```

Binary files are exported for layers with parameters such as fully connected and convolution layers in the network. For instance, files cnn_mobilenetv2_conv*_w and cnn_mobilenetv2_conv*_b correspond to weights and bias parameters for the convolution layers in the network. To see a list of the generated files, use:

```
dir(fullfile(pwd, 'codegen', 'mex', 'mobilenetv2_predict'))
```

Run Generated MEX

Load an input image.

```
im = imread('peppers.png');
imshow(im);
```

Call `mobilenetv2_predict_mex` on the input image.

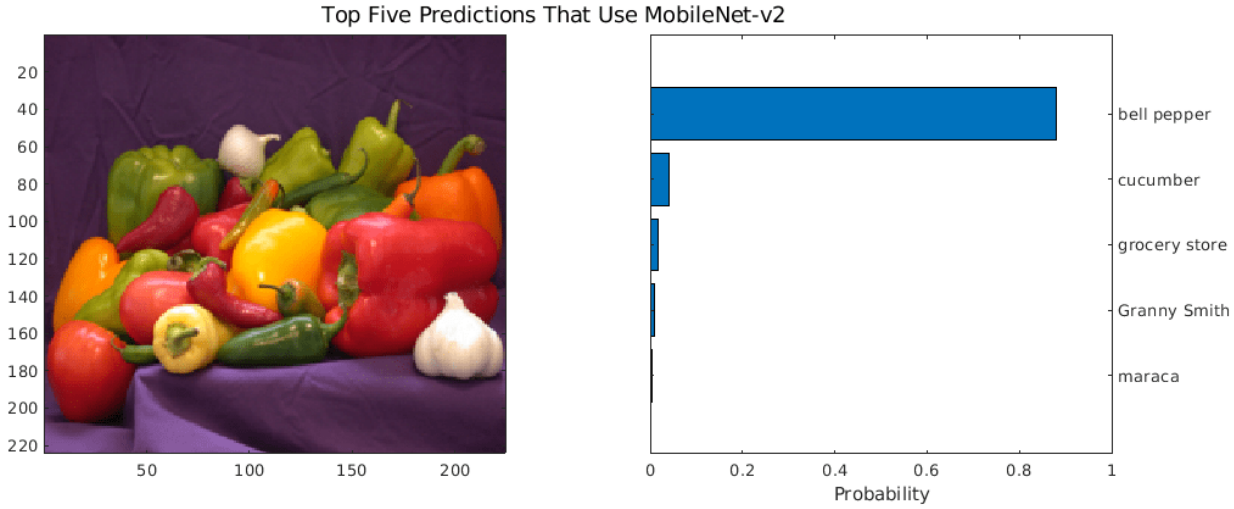
```
im = imresize(im, [224,224]);
predict_scores = mobilenetv2_predict_mex(double(im));
```

Get the top five prediction scores and their labels.

```
[scores,indx] = sort(predict_scores, 'descend');
classNames = net.Layers(end).ClassNames;
classNamesTop = classNames(indx(1:5));

h = figure;
h.Position(3) = 2*h.Position(3);
ax1 = subplot(1,2,1);
ax2 = subplot(1,2,2);

image(ax1,im);
barh(ax2,scores(5:-1:1))
xlabel(ax2,'Probability')
yticklabels(ax2,classNamesTop(5:-1:1))
ax2.YAxisLocation = 'right';
sgtitle('Top Five Predictions That Use MobileNet-v2')
```



Clear the static network object that was loaded in memory.

```
clear mex;
```

Classification of Images by Using ResNet-50 network

You can also use the DAG network ResNet-50 for image classification. A pretrained ResNet-50 model for MATLAB is available in the ResNet-50 support package of Deep Learning Toolbox. To download and install the support package, use the Add-On Explorer. To learn more about finding and installing add-ons, see “Get and Manage Add-Ons”.

```
net = resnet50;
disp(net)
```

```
  DAGNetwork with properties:

         Layers: [177×1 nnet.cnn.layer.Layer]
    Connections: [192×2 table]
     InputNames: {'input_1'}
    OutputNames: {'ClassificationLayer_fc1000'}
```

Run MEX Code Generation

To generate CUDA code for the `resnet_predict.m` entry-point function,create a GPU code configuration object for a MEX target and set the target language to C++. This entry-point function calls the `resnet50` function to load the network and perform prediction on the input image.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg resnet_predict -args {ones(224,224,3)} -report

Code generation successful: View report
```

Call `resnet_predict_mex` on the input image.

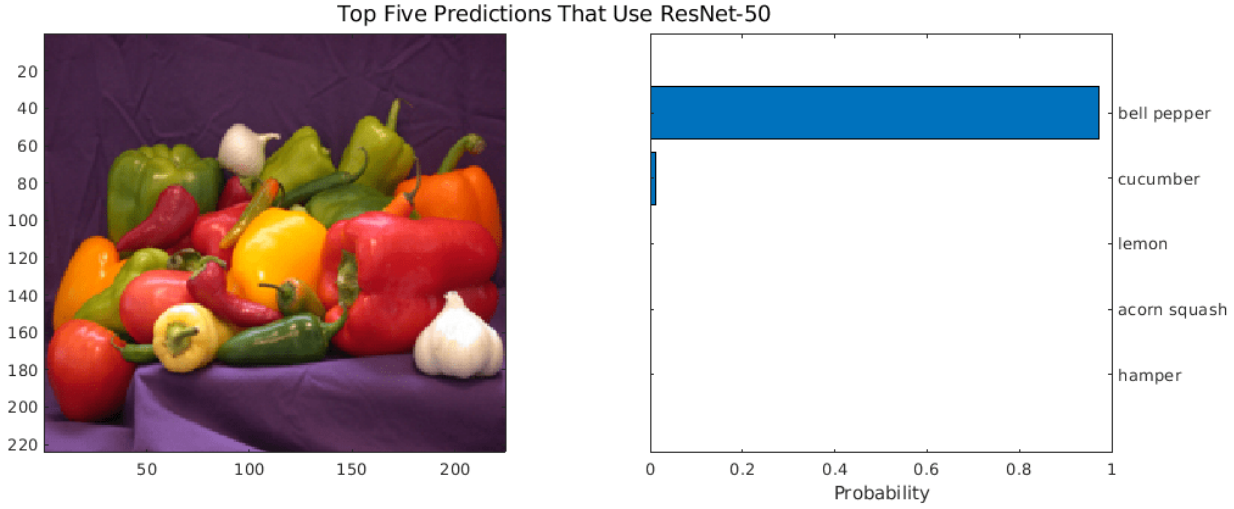
```
predict_scores = resnet_predict_mex(double(im));
```

Get the top five prediction scores and their labels.

```
[scores,indx] = sort(predict_scores, 'descend');
classNames = net.Layers(end).ClassNames;
classNamesTop = classNames(indx(1:5));

h = figure;
h.Position(3) = 2*h.Position(3);
ax1 = subplot(1,2,1);
ax2 = subplot(1,2,2);

image(ax1,im);
barh(ax2,scores(5:-1:1))
xlabel(ax2,'Probability')
yticklabels(ax2,classNamesTop(5:-1:1))
ax2.YAxisLocation = 'right';
sgtitle('Top Five Predictions That Use ResNet-50')
```



Clear the static network object that was loaded in memory.

```
clear mex;
```

Classification of Images by Using GoogLeNet (Inception) network

A pretrained GoogLeNet model for MATLAB is available in the GoogLeNet support package of Deep Learning Toolbox. To download and install the support package, use the Add-On Explorer. To learn more about finding and installing add-ons, see “Get and Manage Add-Ons”.

```
net = googlenet;
disp(net)
```

```
  DAGNetwork with properties:

         Layers: [144×1 nnet.cnn.layer.Layer]
    Connections: [170×2 table]
     InputNames: {'data'}
    OutputNames: {'output'}
```

Run MEX Code Generation

Generate CUDA code for the `googlenet_predict.m` entry-point function. This entry-point function calls the `googlenet` function to load the network and perform prediction on the input image. To generate code for this entry-point function, create a GPU configuration object for MEX target.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg googlenet_predict -args {ones(224,224,3)} -report
```

```
Code generation successful: View report
```

Call `googlenet_predict_mex` on the input image.

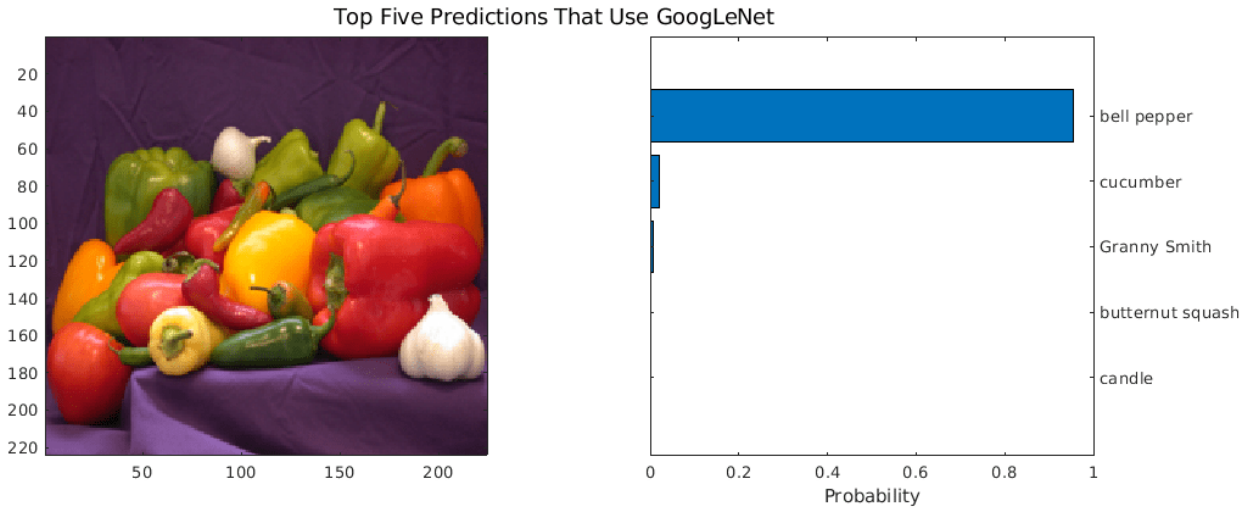
```
im = imresize(im, [224,224]);
predict_scores = googlenet_predict_mex(double(im));
```

Get the top five prediction scores and their labels.

```
[scores,indx] = sort(predict_scores, 'descend');
classNames = net.Layers(end).ClassNames;
classNamesTop = classNames(indx(1:5));

h = figure;
h.Position(3) = 2*h.Position(3);
ax1 = subplot(1,2,1);
ax2 = subplot(1,2,2);

image(ax1,im);
barh(ax2,scores(5:-1:1))
xlabel(ax2,'Probability')
yticklabels(ax2,classNamesTop(5:-1:1))
ax2.YAxisLocation = 'right';
sgtitle('Top Five Predictions That Use GoogLeNet')
```



Clear the static network object that was loaded in memory.

```
clear mex;
```

Code Generation for Semantic Segmentation Network

This example shows code generation for an image segmentation application that uses deep learning. It uses the `codegen` command to generate a MEX function that performs prediction on a DAG Network object for SegNet [1], a deep learning network for image segmentation.

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA® enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Segmentation Network

SegNet [1] is a type of convolutional neural network (CNN) designed for semantic image segmentation. It is a deep encoder-decoder multi-class pixel-wise segmentation network trained on the CamVid [2] dataset and imported into MATLAB® for inference. The SegNet [1] is trained to segment pixels belonging to 11 classes that include Sky, Building, Pole, Road, Pavement, Tree, SignSymbol, Fence, Car, Pedestrian, and Bicyclist.

For information regarding training a semantic segmentation network in MATLAB by using the CamVid [2] dataset, see “Semantic Segmentation Using Deep Learning” (Computer Vision Toolbox).

The `segnet_predict` Entry-Point Function

The `segnet_predict.m` entry-point function takes an image input and performs prediction on the image by using the deep learning network saved in the `SegNet.mat` file. The function loads the network object from the `SegNet.mat` file into a persistent variable *mynet* and reuses the persistent variable on subsequent prediction calls.

```
type('segnet_predict.m')
```

```
function out = segnet_predict(in)
%#codegen
% Copyright 2018-2021 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('SegNet.mat');
end

% pass in input
out = predict(mynet,in);
```

Get Pretrained SegNet DAG Network Object

```
net = getSegNet();
```

The DAG network contains 91 layers including convolution, batch normalization, pooling, unpooling, and the pixel classification output layers. Use the `analyzeNetwork` function to display an interactive visualization of the deep learning network architecture.

```
analyzeNetwork(net);
```

Run MEX Code Generation

To generate CUDA code for the `segnet_predict.m` entry-point function, create a GPU code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command specifying an input size of [360,480,3]. This value corresponds to the input layer size of `SegNet`.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg segnet_predict -args {ones(360,480,3,'uint8')} -report

Code generation successful: View report
```

Run Generated MEX

Load and display an input image. Call `segnet_predict_mex` on the input image.

```
im = imread('gpucoder_segnet_image.png');
imshow(im);
```

```
predict_scores = segnet_predict_mex(im);
```

The *predict_scores* variable is a three-dimensional matrix that has 11 channels corresponding to the pixel-wise prediction scores for every class. Compute the channel by using the maximum prediction score to get pixel-wise labels.

```
[~,argmax] = max(predict_scores,[],3);
```

Overlay the segmented labels on the input image and display the segmented region.

```
classes = [
    "Sky"
    "Building"
    "Pole"
    "Road"
    "Pavement"
    "Tree"
    "SignSymbol"
    "Fence"
    "Car"
    "Pedestrian"
    "Bicyclist"
    ];

cmap = camvidColorMap();
```

```
SegmentedImage = labeloverlay(im,argmax,'ColorMap',cmap);
figure
imshow(SegmentedImage);
pixelLabelColorbar(cmap,classes);
```

Lane Detection Optimized with GPU Coder

This example shows how to generate CUDA® code from a deep learning network, represented by a `SeriesNetwork` object. In this example, the series network is a convolutional neural network that can detect and output lane marker boundaries from an image.

Prerequisites

- CUDA enabled NVIDIA® GPU.
- NVIDIA CUDA toolkit and driver.
- NVIDIA cuDNN library.
- OpenCV libraries for video read and image display operations.
- Environment variables for the compilers and libraries. For information on the supported versions of the compilers and libraries, see “Third-Party Hardware” (GPU Coder). For setting up the environment variables, see “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Get Pretrained SeriesNetwork

```
[laneNet, coeffMeans, coeffStds] = getLaneDetectionNetworkGPU();
```

This network takes an image as an input and outputs two lane boundaries that correspond to the left and right lanes of the ego vehicle. Each lane boundary is represented by the parabolic equation: $y = ax^2 + bx + c$, where y is the lateral offset and x is the longitudinal distance from the vehicle. The network outputs the three parameters a, b, and c per lane. The network architecture is similar to `AlexNet` except that the last few layers are replaced by a smaller fully connected layer and regression output layer. To view the network architecture, use the `analyzeNetwork` function.

```
analyzeNetwork(laneNet)
```

Examine Main Entry-Point Function

```
type detect_lane.m
```

```
function [laneFound, ltPts, rtPts] = detect_lane(frame, laneCoeffMeans, laneCoeffStds)
% From the networks output, compute left and right lane points in the image
% coordinates. The camera coordinates are described by the caltech mono
% camera model.

%#codegen

% A persistent object mynet is used to load the series network object. At
% the first call to this function, the persistent object is constructed and
% setup. When the function is called subsequent times, the same object is
% reused to call predict on inputs, thus avoiding reconstructing and
```

```
% reloading the network object.
persistent lanenet;

if isempty(lanenet)
    lanenet = coder.loadDeepLearningNetwork('laneNet.mat', 'lanenet');
end

lanecoeffsNetworkOutput = lanenet.predict(permute(frame, [2 1 3]));

% Recover original coeffs by reversing the normalization steps

params = lanecoeffsNetworkOutput .* laneCoeffStds + laneCoeffMeans;

isRightLaneFound = abs(params(6)) > 0.5; %c should be more than 0.5 for it to be a right lane
isLeftLaneFound =  abs(params(3)) > 0.5;

vehicleXPoints = 3:30; %meters, ahead of the sensor
ltPts = coder.nullcopy(zeros(28,2,'single'));
rtPts = coder.nullcopy(zeros(28,2,'single'));

if isRightLaneFound && isLeftLaneFound
    rtBoundary = params(4:6);
    rt_y = computeBoundaryModel(rtBoundary, vehicleXPoints);
    ltBoundary = params(1:3);
    lt_y = computeBoundaryModel(ltBoundary, vehicleXPoints);

    % Visualize lane boundaries of the ego vehicle
    tform = get_tformToImage;
    % map vehicle to image coordinates
    ltPts =  tform.transformPointsInverse([vehicleXPoints', lt_y']);
    rtPts =  tform.transformPointsInverse([vehicleXPoints', rt_y']);
    laneFound = true;
else
    laneFound = false;
end

end

     PrincipalPoint(1), PrincipalPoint(2), 1];
end
```

Generate Code for Network and Post-Processing Code

The network computes parameters a, b, and c that describe the parabolic equation for the left and right lane boundaries.

From these parameters, compute the x and y coordinates corresponding to the lane positions. The coordinates must be mapped to image coordinates. The function `detect_lane.m` performs all these computations. Generate CUDA code for this function by creating a GPU code configuration object for a `'lib'` target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command.

```
cfg = coder.gpuConfig('lib');
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
cfg.GenerateReport = true;
cfg.TargetLang = 'C++';
inputs = {ones(227,227,3,'single'),ones(1,6,'double'),ones(1,6,'double')};
codegen -args inputs -config cfg detect_lane

Code generation successful: View report
```

Generated Code Description

The series network is generated as a C++ class containing an array of 23 layer classes.

```
class c_lanenet {
 public:
  int32_T batchSize; int32_T numLayers; real32_T *inputData; real32_T
  *outputData; MWCNNLayer *layers[23];
 public:
  c_lanenet(void); void setup(void); void predict(void); void
  cleanup(void); ~c_lanenet(void);
};
```

The `setup()` method of the class sets up handles and allocates memory for each layer object. The `predict()` method invokes prediction for each of the 23 layers in the network.

The cnn_lanenet_conv*_w and cnn_lanenet_conv*_b files are the binary weights and bias file for convolution layer in the network. The cnn_lanenet_fc*_w and cnn_lanenet_fc*_b files are the binary weights and bias file for fully connected layer in the network.

```
codegendir = fullfile('codegen', 'lib', 'detect_lane');
dir(codegendir)
```

Generate Additional Files for Post-Processing the Output

Export mean and std values from the trained network for use during execution.

```
codegendir = fullfile(pwd, 'codegen', 'lib','detect_lane');
fid = fopen(fullfile(codegendir,'mean.bin'), 'w');
A = [coeffMeans coeffStds];
fwrite(fid, A, 'double');
fclose(fid);
```

Main File

Compile the network code by using a main file. The main file uses the OpenCV `VideoCapture` method to read frames from the input video. Each frame is processed and classified until no more frames are read. Before displaying the output for each frame, the outputs are post-processed by using the `detect_lane` function generated in `detect_lane.cu`.

```
type main_lanenet.cu
```

Code Generation for a Sequence-to-Sequence LSTM Network

This example demonstrates how to generate CUDA® code for a long short-term memory (LSTM) network. The example generates a MEX application that makes predictions at each step of an input timeseries. Two methods are demonstrated: a method using a standard LSTM network, and a method leveraging the stateful behavior of the same LSTM network. This example uses accelerometer sensor data from a smartphone carried on the body and makes predictions on the activity of the wearer. User movements are classified into one of five categories, namely dancing, running, sitting, standing, and walking. The example uses a pretrained LSTM network. For more information on training, see the "Sequence Classification Using Deep Learning" on page 4-2 example from Deep Learning Toolbox™.

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see "Third-Party Hardware" (GPU Coder) and "Setting Up the Prerequisite Products" (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

The `lstmnet_predict` Entry-Point Function

A sequence-to-sequence LSTM network enables you to make different predictions for each individual time step of a data sequence. The `lstmnet_predict.m` entry-point function takes an input sequence and passes it to a trained LSTM network for prediction. Specifically, the function uses the LSTM network trained in the *Sequence to Sequence Classification Using Deep Learning* example. The function loads the network object from the `lstmnet_predict.mat` file into a persistent variable and reuses the persistent object on subsequent prediction calls.

To display an interactive visualization of the network architecture and information about the network layers, use the `analyzeNetwork` function.

```
type('lstmnet_predict.m')
```

```
function out = lstmnet_predict(in) %#codegen
```

```
% Copyright 2019-2021 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('lstmnet.mat');
end

% pass in input
out = predict(mynet,in);
```

Generate CUDA MEX

To generate CUDA MEX for the `lstmnet_predict.m` entry-point function, create a GPU configuration object and specify the target to be MEX. Set the target language to C++. Create a deep learning configuration object that specifies the target library as cuDNN. Attach this deep learning configuration object to the GPU configuration object.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
```

At compile time, GPU Coder™ must know the data types of all the inputs to the entry-point function. Specify the type and size of the input argument to the `codegen` (MATLAB Coder) command by using the `coder.typeof` (MATLAB Coder) function. For this example, the input is of double data type with a feature dimension value of three and a variable sequence length. Specifying the sequence length as variable-sized enables us to perform prediction on an input sequence of any length.

```
matrixInput = coder.typeof(double(0),[3 Inf],[false true]);
```

Run the codegen command.

```
codegen -config cfg lstmnet_predict -args {matrixInput} -report
```

```
Code generation successful: View report
```

Run Generated MEX on Test Data

Load the `HumanActivityValidate` MAT-file. This MAT-file stores the variable `XValidate` that contains sample timeseries of sensor readings on which you can test the generated code. Call `lstmnet_predict_mex` on the first observation.

```
load HumanActivityValidate
YPred1 = lstmnet_predict_mex(XValidate{1});
```

`YPred1` is a 5-by-53888 numeric matrix containing the probabilities of the five classes for each of the 53888 time steps. For each time step, find the predicted class by calculating the index of the maximum probability.

```
[~, maxIndex] = max(YPred1, [], 1);
```

Associate the indices of max probability to the corresponding label. Display the first ten labels. From the results, you can see that the network predicted the human to be sitting for the first ten time steps.

```
labels = categorical({'Dancing', 'Running', 'Sitting', 'Standing', 'Walking'});
predictedLabels1 = labels(maxIndex);
disp(predictedLabels1(1:10)')
```

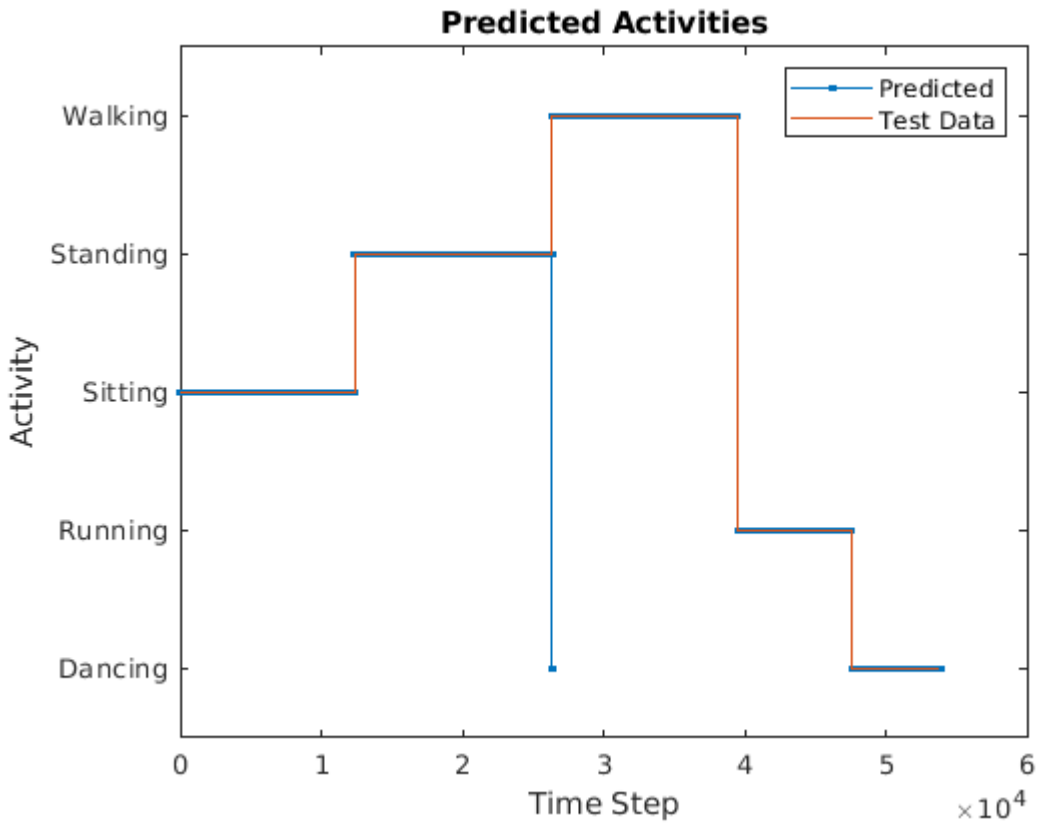
```
Sitting
Sitting
Sitting
Sitting
Sitting
Sitting
Sitting
Sitting
Sitting
Sitting
```

Compare Predictions with Test Data

Use a plot to compare the MEX output data with the test data.

```
figure
plot(predictedLabels1,'.-');
hold on
plot(YValidate{1});
hold off

xlabel("Time Step")
ylabel("Activity")
title("Predicted Activities")
legend(["Predicted" "Test Data"])
```



Call Generated MEX on an Observation with a Different Sequence Length

Call `lstmnet_predict_mex` on the second observation with a different sequence length. In this example, `XValidate{2}` has a sequence length of 64480 whereas `XValidate{1}` had a sequence length of 53888. The generated code handles prediction correctly because we specified the sequence length dimension to be variable-size.

```
YPred2 = lstmnet_predict_mex(XValidate{2});
[~, maxIndex] = max(YPred2, [], 1);
predictedLabels2 = labels(maxIndex);
disp(predictedLabels2(1:10)')
```

```
     Sitting
     Sitting
     Sitting
     Sitting
     Sitting
     Sitting
     Sitting
     Sitting
     Sitting
     Sitting
```

Generate MEX that takes in Multiple Observations

If you want to perform prediction on many observations at once, you can group the observations together in a cell array and pass the cell array for prediction. The cell array must be a column cell array, and each cell must contain one observation. Each observation must have the same feature dimension, but the sequence lengths may vary. In this example, `XValidate` contains five observations. To generate a MEX that can take `XValidate` as input, specify the input type to be a 5-by-1 cell array. Further, specify that each cell be of the same type as `matrixInput`, the type you specified for the single observation in the previous `codegen` command.

```
matrixInput = coder.typeof(double(0),[3 Inf],[false true]);
cellInput = coder.typeof({matrixInput}, [5 1]);

codegen -config cfg lstmnet_predict -args {cellInput} -report

Code generation successful: View report

YPred3 = lstmnet_predict_mex(XValidate);
```

The output is a 5-by-1 cell array of predictions for the five observations passed in.

```
disp(YPred3)
```

```
    {5×53888 single}
    {5×64480 single}
    {5×53696 single}
    {5×56416 single}
    {5×50688 single}
```

Generate MEX with Stateful LSTM

Instead of passing the entire timeseries to predict in one step, we can run prediction on an input by streaming in one timestep at a time, making use of the function `predictAndUpdateState` This

function takes in an input, produces an output prediction, and updates the internal state of the network so that future predictions take this initial input into account.

The entry-point function `lstmnet_predict_and_update.m` takes in a single-timestep input and processes the input using the `predictAndUpdateState` function. `predictAndUpdateState` outputs a prediction for the input timestep and updates the network so that subsequent inputs are treated as subsequent timesteps of the same sample. After passing in all timesteps one at a time, the resulting output is the same as if all timesteps were passed in as a single input.

```
type('lstmnet_predict_and_update.m')
```

```
function out = lstmnet_predict_and_update(in) %#codegen

% Copyright 2019-2021 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('lstmnet.mat');
end

% pass in input
[mynet, out] = predictAndUpdateState(mynet,in);
```

Run codegen on this new design file. Since we are taking in a single timestep each call, we specify `matrixInput` to have a fixed sequence dimension of 1 instead of a variable sequence length.

```
matrixInput = coder.typeof(double(0),[3 1]);
codegen -config cfg lstmnet_predict_and_update -args {matrixInput} -report
```

```
Code generation successful: View report
```

Run the generated MEX on the first validation sample's first timestep.

```
firstSample = XValidate{1};
firstTimestep = firstSample(:,1);
YPredStateful = lstmnet_predict_and_update_mex(firstTimestep);
[~, maxIndex] = max(YPredStateful, [], 1);
predictedLabelsStateful1 = labels(maxIndex)
```

```
predictedLabelsStateful1 = categorical
     Sitting
```

Compare the output label with the ground truth.

```
YValidate{1}(1)
```

```
ans = categorical
     Sitting
```

Deep Learning Prediction on ARM Mali GPU

This example shows how to use the `cnncodegen` function to generate code for an image classification application that uses deep learning on ARM® Mali GPUs. The example uses the `MobileNet-v2` DAG network to perform image classification. The generated code takes advantage of the ARM Compute library for computer vision and machine learning.

Prerequisites

- ARM Mali GPU based hardware. For example, HiKey960 is one of the target platforms that contains a Mali GPU.
- ARM Compute Library on the target ARM hardware built for the Mali GPU.
- Open source Computer Vision Library (OpenCV v2.4.9) on the target ARM hardware.
- Environment variables for the compilers and libraries. Ensure that the `ARM_COMPUTE` and the `LD_LIBRARY_PATH` variables are set on the target platform. For information on the supported versions of the compilers and libraries, see “Third-Party Hardware” (GPU Coder). For setting up the environment variables, see “Setting Up the Prerequisite Products” (GPU Coder).

Get Pretrained DAGNetwork

Load the pretrained `MobileNet-v2` network available in the `Deep Learning Toolbox Model for MobileNet-v2 Network`.

```
net = mobilenetv2
```

```
net =
  DAGNetwork with properties:

         Layers: [154×1 nnet.cnn.layer.Layer]
    Connections: [163×2 table]
     InputNames: {'input_1'}
    OutputNames: {'ClassificationLayer_Logits'}
```

The network contains 155 layers including convolution, batch normalization, softmax, and the classification output layers. The `analyzeNetwork()` function displays an interactive plot of the network architecture and a table containing information about the network layers.

```
analyzeNetwork(net);
```

Generate Code

For deep learning on ARM targets, you generate code on the host development computer. To build and run the executable program, move the generated code to the ARM target platform. The target platform must have an ARM Mali GPU. For example, HiKey960 is one of the target platforms on which you can execute the code generated in this example.

Call the `cnncodegen` function, specifying the target library as `arm-compute-mali`.

```
cnncodegen(net,'targetlib','arm-compute-mali');
```

Copy Generated Files to the Target

Move the generated codegen folder and other required files from the host development computer to the target platform by using your preferred SCP (Secure Copy Protocol) or Secure Shell File Transfer Protocol (SSH) client.

For example, on the Linux® platform, to transfer the files to the HiKey960, use the scp command with the format:

```
system('sshpass -p [password] scp (sourcefile) [username]@[targetname]:~/');
```

```
system('sshpass -p password scp main_mobilenet_arm_generic.cpp username@targetname:~/');
system('sshpass -p password scp peppers_mobilenet.png username@targetname:~/');
system('sshpass -p password scp makefile_mobilenet_arm_generic.mk username@targetname:~/');
system('sshpass -p password scp synsetWords.txt username@targetname:~/');
system('sshpass -p password scp -r codegen username@targetname:~/');
```

On the Windows® platform, you can use the `pscp` tool that comes with a PuTTY installation. For example:

```
system('pscp -pw password-r codegen username@targetname:/home/username');
```

PSCP utilities must be either on your PATH or in your current folder.

Build Executable

To build the library on the target platform, use the generated makefile `cnnbuild_rtw.mk`.

For example, to build the library on the HiKey960:

```
system('sshpass -p password ssh username@targetname' ...
' "make -C /home/username/codegen -f cnnbuild_rtw.mk"');
```

On the Windows platform, you can use the `putty` command with `-ssh` argument to log in and run the make command. For example:

```
system('putty -ssh username@targetname -pw password');
```

To build and run the executable on the target platform, use the command with the format: `make -C /home/$(username)` and `./execfile -f makefile_mobilenet_arm_generic.mk`

For example, on the HiKey960:

```
make -C /home/usrname arm_mobilenet -f makefile_mobilenet_arm_generic.mk
```

Run the executable on the ARM platform specifying an input image file.

```
./mobilenet_exe peppers_mobilenet.png
```

The top five predictions for the input image file are:

```
Top 5 Predictions:
------------------------------
88.976% bell pepper
4.907% cucumber
1.390% grocery store
0.512% Granny Smith
0.256% lemon
```

Code Generation for Object Detection by Using YOLO v2

This example shows how to generate CUDA® MEX for a you only look once (YOLO) v2 object detector. A YOLO v2 object detection network is composed of two subnetworks. A feature extraction network followed by a detection network. This example generates code for the network trained in the *Object Detection Using YOLO v2 Deep Learning* example from Computer Vision Toolbox™. For more information, see "Object Detection Using YOLO v2 Deep Learning" (Computer Vision Toolbox). You can modify this example to generate CUDA® MEX for the network imported in the *Import Pretrained ONNX YOLO v2 Object Detector* example from Computer Vision Toolbox™. For more information, see "Import Pretrained ONNX YOLO v2 Object Detector" (Computer Vision Toolbox).

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA® enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see "Third-Party Hardware" (GPU Coder) and "Setting Up the Prerequisite Products" (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Get Pretrained DAGNetwork

This example uses the `yolov2ResNet50VehicleExample` MAT-file containing the pretrained network. The file is approximately 98MB in size. Download the file from the MathWorks website.

```
matFile = matlab.internal.examples.downloadSupportFile('vision/data','yolov2ResNet50VehicleExamp
vehicleDetector = load(matFile);
net = vehicleDetector.detector.Network
```

```
net =
  DAGNetwork with properties:

         Layers: [150×1 nnet.cnn.layer.Layer]
    Connections: [162×2 table]
     InputNames: {'input_1'}
```

```
    OutputNames: {'yolov2OutputLayer'}
```

The DAG network contains 150 layers including convolution, ReLU, and batch normalization layers and the YOLO v2 transform and YOLO v2 output layers. To display an interactive visualization of the deep learning network architecture, use the `analyzeNetwork` function.

```
analyzeNetwork(net);
```

The `yolov2_detect` Entry-Point Function

The `yolov2_detect.m` entry-point function takes an image input and runs the detector on the image using the deep learning network saved in the `yolov2ResNet50VehicleExample.mat` file. The function loads the network object from the `yolov2ResNet50VehicleExample.mat` file into a persistent variable *yolov2Obj* and reuses the persistent object on subsequent detection calls.

```
type('yolov2_detect.m')
```

```
function outImg = yolov2_detect(in,matFile)

%   Copyright 2018-2021 The MathWorks, Inc.

persistent yolov2Obj;

if isempty(yolov2Obj)
    yolov2Obj = coder.loadDeepLearningNetwork(matFile);
end

% Call to detect method
[bboxes,~,labels] = yolov2Obj.detect(in,'Threshold',0.5);

% Convert categorical labels to cell array of charactor vectors
labels = cellstr(labels);

% Annotate detections in the image.
outImg = insertObjectAnnotation(in,'rectangle',bboxes,labels);
```

Run MEX Code Generation

To generate CUDA code for the entry-point function, create a GPU code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command specifying an input size of 224-by-224-by-3. This value corresponds to the input layer size of YOLOv2.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
cfg.GenerateReport = true;
inputArgs = {ones(224,224,3,'uint8'),coder.Constant(matFile)};

codegen -config cfg yolov2_detect -args inputArgs
```

```
Code generation successful: View report
```

Run Generated MEX

Set up the video file reader and read the input video. Create a video player to display the video and the output detections.

```
videoFile = 'highway_lanechange.mp4';
videoFreader = vision.VideoFileReader(videoFile,'VideoOutputDataType','uint8');
depVideoPlayer = vision.DeployableVideoPlayer('Size','Custom','CustomSize',[640 480]);
```

Read the video input frame-by-frame and detect the vehicles in the video using the detector.

```
cont = ~isDone(videoFreader);
while cont
    I = step(videoFreader);
    in = imresize(I,[224,224]);
    out = yolov2_detect_mex(in,matFile);
    step(depVideoPlayer, out);
    % Exit the loop if the video player figure window is closed
    cont = ~isDone(videoFreader) && isOpen(depVideoPlayer);
end
```

Code Generation For Object Detection Using YOLO v3 Deep Learning

This example shows how to generate CUDA® MEX for a you only look once (YOLO) v3 object detector with custom layers. YOLO v3 improves upon YOLO v2 by adding detection at multiple scales to help detect smaller objects. Moreover, the loss function used for training is separated into mean squared error for bounding box regression and binary cross-entropy for object classification to help improve detection accuracy. The YOLO v3 network used in this example was trained from the *Object Detection Using YOLO v3 Deep Learning* example in the Computer Vision Toolbox (TM). For more information, see “Object Detection Using YOLO v3 Deep Learning” (Computer Vision Toolbox).

Third-Party Prerequisites

Required

- CUDA enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA CUDA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

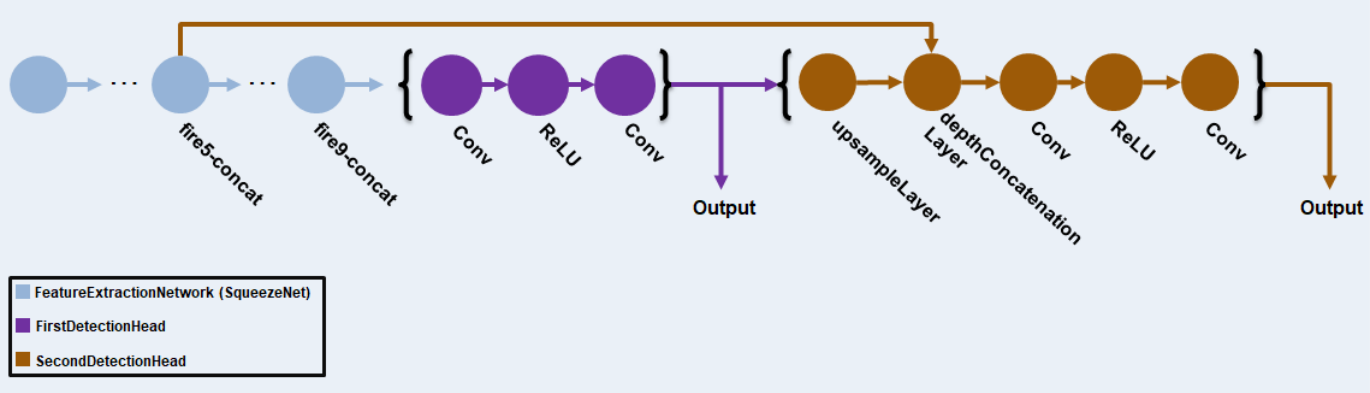
To verify that the compilers and libraries for running this example are set up correctly, use the `coder.checkGpuInstall` (GPU Coder) function.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

YOLO v3 Network

The YOLO v3 network in this example is based on `squeezenet`, and uses the feature extraction network in SqueezeNet with the addition of two detection heads at the end. The second detection head is twice the size of the first detection head, so it is better able to detect small objects. Note that any number of detection heads of different sizes can be specified based on the size of the objects to be detected. The YOLO v3 network uses anchor boxes estimated using training data to have better initial priors corresponding to the type of data set and to help the network learn to predict the boxes accurately. For information about anchor boxes, see “Anchor Boxes for Object Detection” (Computer Vision Toolbox).

The YOLO v3 network in this example is illustrated in the following diagram.



Each detection head predicts the bounding box coordinates (x, y, width, height), object confidence, and class probabilities for the respective anchor box masks. Therefore, for each detection head, the number of output filters in the last convolution layer is the number of anchor box mask times the number of prediction elements per anchor box. The detection heads comprise the output layer of the network.

Pretrained YOLO v3 Network

This example uses the `yolov3SqueezeNetVehicleExample_21a.zip` file containing the pretrained YOLO v3 network. This file is approximately 9MB in size. Download the file from the MathWorks website, then unzip the file.

```
fileName = matlab.internal.examples.downloadSupportFile('vision/data/','yolov3SqueezeNetVehicleEx
unzip(fileName);
```

The YOLO v3 network used in this example was trained using the steps described in “Object Detection Using YOLO v3 Deep Learning” (Computer Vision Toolbox).

```
matFile = 'yolov3SqueezeNetVehicleExample_21a.mat';
pretrained = load(matFile);
net = pretrained.net;
```

YOLO v3 network uses a `resize2dLayer` (Image Processing Toolbox) to resize the 2-D input image by replicating the neighboring pixel values by a scaling factor of 2. The resize2DLayer is implemented as a custom layer supported for code generation. For more information, see “Define Custom Deep Learning Layer for Code Generation” on page 18-142.

Note: You can also use the pretrained detector network availabe through the Computer Vision Toolbox™ Model for YOLO v3 Object Detection support package.

To use this pretrained network, you must first install the Computer Vision Toolbox Model for YOLO v3 Object Detection from the Add-On Explorer. For more information about installing add-ons, see “Get and Manage Add-Ons”.

Then, save the network from the `yolov3ObjectDetector` object to a MAT-file and proceed. For example,

```
detector = yolov3ObjectDetector('darknet53-coco');
net = detector.Network;
matFile = 'pretrainedYOLOv3Detector.mat';
save(matFile,'net');
```

The `yolov3Detect` Entry-Point Function

The `yolov3Detect` entry-point function takes an input image and passes it to a trained network for prediction through the `yolov3Predict` function. The `yolov3Predict` function loads the network object from the MAT-file into a persistent variable and reuses the persistent object for subsequent prediction calls. Specifically, the function uses the `dlnetwork` representation of the network trained in the “Object Detection Using YOLO v3 Deep Learning” (Computer Vision Toolbox) example. The predictions from the YOLO v3 grid cell coordinates obtained from the `yolov3Predict` calls are then converted to bounding box coordinates by using the supporting functions `generateTiledAnchors` and `applyAnchorBoxOffsets`.

```
type('yolov3Detect.m')
```

```
function [bboxes,scores,labelsIndex] = yolov3Detect(matFile, im,...
    networkInputSize, networkOutputs, confidenceThreshold,...
    overlapThreshold, classes)
% The yolov3Detect function detects the bounding boxes, scores, and
% labelsIndex in an image.
%#codegen

%   Copyright 2020-2021 The MathWorks, Inc.

%% Preprocess Data
% This example applies all the preprocessing transforms to the data set
% applied during training, except data augmentation. Because the example
% uses a pretrained YOLO v3 network, the input data must be representative
% of the original data and left unmodified for unbiased evaluation.

% Specifically the following preprocessing operations are applied to the
% input data.
%     1. Resize the images to the network input size, as the images are
%     bigger than networkInputSize. 2. Scale the image pixels in the range
%     [0 1]. 3. Convert the resized and rescaled image to a dlarray object.

im = dlarray(preprocessData(im, networkInputSize), "SSCB");
imageSize = size(im,[1,2]);

%% Define Anchor Boxes
% Specify the anchor boxes estimated on the basis of the preprocessed
% training data used when training the YOLO v3 network. These anchor box
% values are same as mentioned in "Object Detection Using YOLO v3 Deep
% Learning" example. For details on estimating anchor boxes, see "Anchor
% Boxes for Object Detection".

anchors = [
    41    34;
   163   130;
    98    93;
   144   125;
    33    24;
    69    66];

% Specify anchorBoxMasks to select anchor boxes to use in both the
% detection heads of the YOLO v3 network. anchorBoxMasks is a cell array of
% size M-by-1, where M denotes the number of detection heads. Each
% detection head consists of a 1-by-N array of row index of anchors in
% anchorBoxes, where N is the number of anchor boxes to use. Select anchor
```

```
% boxes for each detection head based on size-use larger anchor boxes at
% lower scale and smaller anchor boxes at higher scale. To do so, sort the
% anchor boxes with the larger anchor boxes first and assign the first
% three to the first detection head and the next three to the second
% detection head.

area = anchors(:, 1).*anchors(:, 2);
[~, idx] = sort(area, 'descend');
anchors = anchors(idx, :);
anchorBoxMasks = {[1,2,3],[4,5,6]};

%% Predict on Yolov3
% Predict and filter the detections based on confidence threshold.
predictions = yolov3Predict(matFile,im,networkOutputs,anchorBoxMasks);

%% Generate Detections
% indices corresponding to x,y,w,h predictions for bounding boxes
anchorIndex = 2:5;
tiledAnchors = generateTiledAnchors(predictions,anchors,anchorBoxMasks,...
    anchorIndex);
predictions = applyAnchorBoxOffsets(tiledAnchors, predictions,...
    networkInputSize, anchorIndex);
[bboxes,scores,labelsIndex] = generateYOLOv3DetectionsForCodegen(predictions,...
    confidenceThreshold, overlapThreshold, imageSize, classes);

end

function YPredCell = yolov3Predict(matFile,im,networkOutputs,anchorBoxMask)
% Predict the output of network and extract the confidence, x, y,
% width, height, and class.

% load the deep learning network for prediction
persistent net;

if isempty(net)
    net = coder.loadDeepLearningNetwork(matFile);
end

YPredictions = cell(coder.const(networkOutputs), 1);
[YPredictions{:}] = predict(net, im);
YPredCell = extractPredictions(YPredictions, anchorBoxMask);

% Apply activation to the predicted cell array.
YPredCell = applyActivations(YPredCell);
end
```

Evaluate the Entry-Point Function for Object Detection

Follow these steps to evaluate the entry-point function on an image from the test data.

- Specify the confidence threshold as 0.5 to keep only detections with confidence scores above this value.
- Specify the overlap threshold as 0.5 to remove overlapping detections.
- Read an image from the input data.
- Use the entry-point function `yolov3Detect` to get the predicted bounding boxes, confidence scores, and class labels.

- Display the image with bounding boxes and confidence scores.

Define the desired thresholds.

```
confidenceThreshold = 0.5;
overlapThreshold = 0.5;
```

Specify the network input size of the trained network and the number of network outputs.

```
networkInputSize = [227 227 3];
networkOutputs = numel(net.OutputNames);
```

Read the example image data obtained from the labeled data set from the “Object Detection Using YOLO v3 Deep Learning” (Computer Vision Toolbox) example. This image contains one instance of an object of type vehicle.

```
I = imread('vehicleImage.jpg');
```

Specify the class names.

```
classNames = {'vehicle'};
```

Invoke the detect method on YOLO v3 network and display the results.

```
[bboxes,scores,labelsIndex] = yolov3Detect(matFile,I,...
networkInputSize,networkOutputs,confidenceThreshold,overlapThreshold,classNames);
labels = classNames(labelsIndex);

% Display the detections on the image
IAnnotated = insertObjectAnnotation(I,'rectangle',bboxes,strcat(labels,{' - '},num2str(scores)));
figure
imshow(IAnnotated)
```

Generate CUDA MEX

To generate CUDA® code for the `yolov3Detect` entry-point function, create a GPU code configuration object for a MEX target and set the target language to C++. Use the

`coder.DeepLearningConfig` (GPU Coder) function to create a CuDNN deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig(TargetLibrary='cudnn');

args = {coder.Constant(matFile),I,coder.Constant(networkInputSize),...
coder.Constant(networkOutputs),confidenceThreshold,...
overlapThreshold,classNames};

codegen -config cfg yolov3Detect -args args -report

Code generation successful: View report
```

To generate CUDA® code for TensorRT target create and use a TensorRT deep learning configuration object instead of the CuDNN configuration object. Similarly, to generate code for MKLDNN target, create a CPU code configuration object and use MKLDNN deep learning configuration object as its `DeepLearningConfig` property.

Run the Generated MEX

Call the generated CUDA MEX with the same image input `I` as before and display the results.

```
[bboxes,scores,labelsIndex] = yolov3Detect_mex(matFile,I,...
networkInputSize,networkOutputs,confidenceThreshold,...
overlapThreshold,classNames);
labels = classNames(labelsIndex);

figure;
IAnnotated = insertObjectAnnotation(I,'rectangle',bboxes,strcat(labels,{' - '},num2str(scores)));
imshow(IAnnotated);
```

Utility Functions

The utillity functions listed below are based on the ones used in “Object Detection Using YOLO v3 Deep Learning” (Computer Vision Toolbox) example and modified to make the utility functions suitable for code generation.

```
type('applyActivations.m')
```

```
function YPredCell = applyActivations(YPredCell)    %#codegen

%   Copyright 2020-2021 The MathWorks, Inc.

numCells = size(YPredCell, 1);
for iCell = 1:numCells
    for idx = 1:3
        YPredCell{iCell, idx} = sigmoidActivation(YPredCell{iCell,idx});
    end
end
for iCell = 1:numCells
    for idx = 4:5
        YPredCell{iCell, idx} = exp(YPredCell{iCell, idx});
    end
end
for iCell = 1:numCells
    YPredCell{iCell, 6} = sigmoidActivation(YPredCell{iCell, 6});
end
end

function out = sigmoidActivation(x)
out = 1./(1+exp(-x));
end
```

```
type('extractPredictions.m')
```

```
function predictions = extractPredictions(YPredictions, anchorBoxMask)
%#codegen

%   Copyright 2020-2021 The MathWorks, Inc.

numPredictionHeads = size(YPredictions, 1);
predictions = cell(numPredictionHeads,6);
for ii = 1:numPredictionHeads
    % Get the required info on feature size.
    numChannelsPred = size(YPredictions{ii},3);
    numAnchors = size(anchorBoxMask{ii},2);
    numPredElemsPerAnchors = numChannelsPred/numAnchors;
    allIds = (1:numChannelsPred);

    stride = numPredElemsPerAnchors;
    endIdx = numChannelsPred;

    YPredictionsData = extractdata(YPredictions{ii});

    % X positions.
    startIdx = 1;

Deep Learning Prediction by Using NVIDIA TensorRT

This example shows code generation for a deep learning application by using the NVIDIA TensorRT™ library. It uses the `codegen` command to generate a MEX file to perform prediction with a ResNet-50 image classification network by using TensorRT. A second example demonstrates usage of `codegen` command to generate a MEX file that performs 8-bit integer prediction by using TensorRT for a logo classification network.

Third-Party Prerequisites

Required

This example generates CUDA® MEX and has the following third-party requirements.

- CUDA enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN and TensorRT library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'tensorrt';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

The `resnet_predict` Entry-Point Function

This example uses the DAG network ResNet-50 to show image classification by using TensorRT. A pretrained ResNet-50 model for MATLAB® is available in the ResNet-50 support package of Deep Learning Toolbox. To download and install the support package, use the Add-On Explorer.

The `resnet_predict.m` function loads the ResNet-50 network into a persistent network object and reuses the persistent object on subsequent prediction calls.

```
type('resnet_predict.m')
```

```
% Copyright 2020 The MathWorks, Inc.

function out = resnet_predict(in)
%#codegen

% A persistent object mynet is used to load the series network object. At
% the first call to this function, the persistent object is constructed and
% setup. When the function is called subsequent times, the same object is
```

```
% reused to call predict on inputs, avoiding reconstructing and reloading
% the network object.

persistent mynet;

if isempty(mynet)
    % Call the function resnet50 that returns a DAG network
    % for ResNet-50 model.
    mynet = coder.loadDeepLearningNetwork('resnet50','resnet');
end

% pass in input
out = mynet.predict(in);
```

Run MEX Code Generation

To generate CUDA code for the `resnet_predict` entry-point function, create a GPU code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `TensorRT` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command specifying an input size of [224,224,3]. This value corresponds to the input layer size of ResNet-50 network.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('tensorrt');
codegen -config cfg resnet_predict -args {ones(224,224,3)} -report

Code generation successful: View report
```

Perform Prediction on Test Image

```
im = imread('peppers.png');
im = imresize(im, [224,224]);
predict_scores = resnet_predict_mex(double(im));
%
% get top 5 probability scores and their labels
[val,indx] = sort(predict_scores, 'descend');
scores = val(1:5)*100;
net = resnet50;
classnames = net.Layers(end).ClassNames;
labels = classnames(indx(1:5));
```

Clear the static network object that was loaded in memory.

```
clear mex;
```

Generate TensorRT Code for INT8 Prediction

Generate TensorRT code that runs inference in int8 precision. Use a pretrained logo classification network to classify logos in images. Download the pretrained `LogoNet` network and save it as a `logonet.mat` file. The network was developed in MATLAB. This network can recognize 32 logos under various lighting conditions and camera angles. The network is pretrained in single precision floating-point format.

```
net = getLogonet();
```

Code generation by using the NVIDIA TensorRT Library with inference computation in 8-bit integer precision supports these additional networks:

- Object detector networks such as YOLOv2 and SSD.
- Regression and semantic segmentation networks.

TensorRT requires a calibration data set to calibrate a network that is trained in floating-point to compute inference in 8-bit integer precision. Set the data type to int8 and the path to the calibration data set by using the `DeepLearningConfig`. `logos_dataset` is a subfolder containing images grouped by their corresponding classification labels. For int8 support, GPU compute capability must be 6.1 or higher.

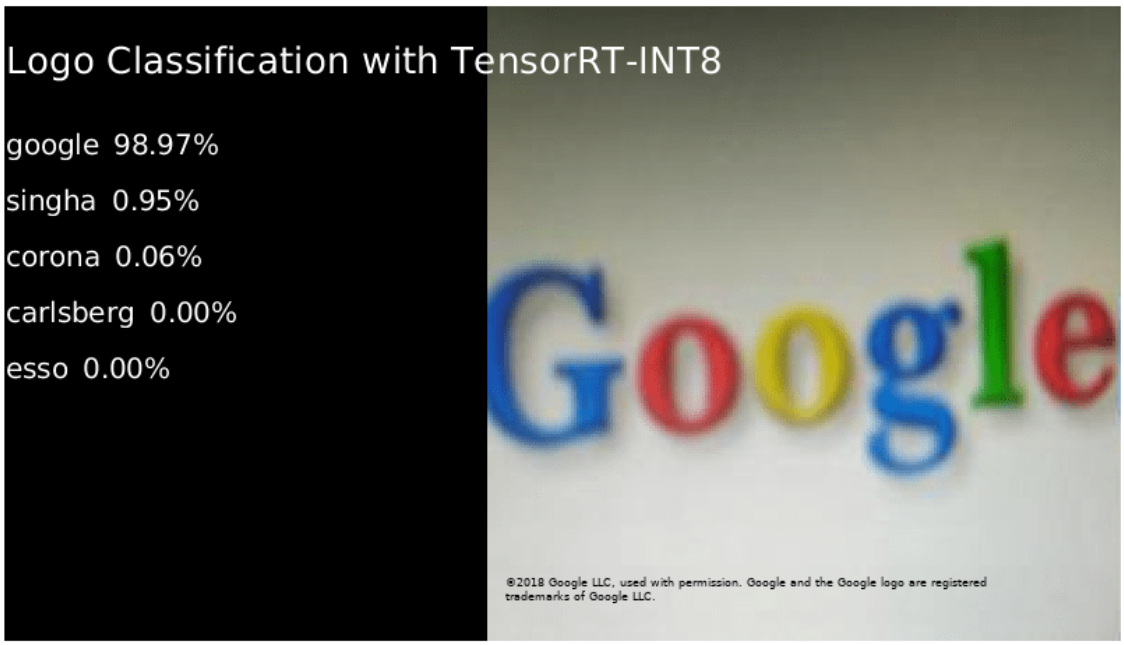
Note: For semantic segmentation networks, the calibration data images must be of a format supported by the `imread` function.

```
unzip('logos_dataset.zip');
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.GpuConfig.ComputeCapability = '6.1';
cfg.DeepLearningConfig = coder.DeepLearningConfig('tensorrt');
cfg.DeepLearningConfig.DataType = 'int8';
cfg.DeepLearningConfig.DataPath = 'logos_dataset';
cfg.DeepLearningConfig.NumCalibrationBatches = 50;
codegen -config cfg logonet_predict -args {ones(227,227,3,'int8')} -report
```

```
Code generation successful: View report
```

Run INT8 Prediction on Test Image

```
im = imread('gpucoder_tensorrt_test.png');
im = imresize(im, [227,227]);
predict_scores = logonet_predict_mex(int8(im));
%
% get top 5 probability scores and their labels
[val,indx] = sort(predict_scores, 'descend');
scores = val(1:5)*100;
classnames = net.Layers(end).ClassNames;
labels = classnames(indx(1:5));
```

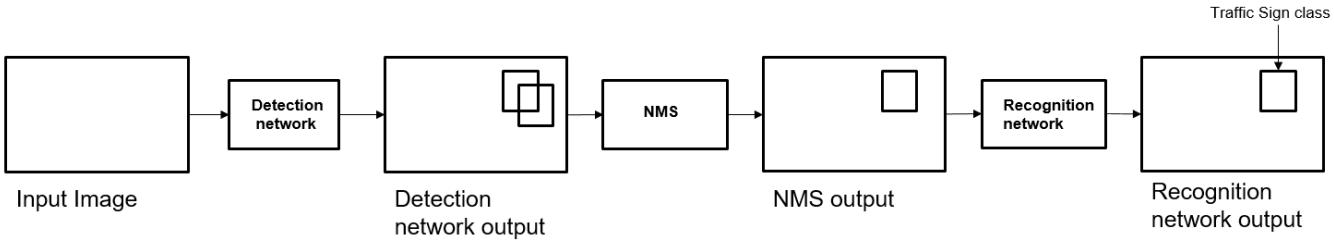


Clear the static network object that was loaded in memory.

```
clear mex;
```

Traffic Sign Detection and Recognition

This example shows how to generate CUDA® MEX code for a traffic sign detection and recognition application that uses deep learning. Traffic sign detection and recognition is an important application for driver assistance systems, aiding and providing information to the driver about road signs.



In this traffic sign detection and recognition example you perform three steps - detection, Non-Maximal Suppression (NMS), and recognition. First, the example detects the traffic signs on an input image by using an object detection network that is a variant of the You Only Look Once (YOLO) network. Then, overlapping detections are suppressed by using the NMS algorithm. Finally, the recognition network classifies the detected traffic signs.

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA® enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Detection and Recognition Networks

The detection network is trained in the Darknet framework and imported into MATLAB® for inference. Because the size of the traffic sign is relatively small with respect to that of the image and the number of training samples per class are fewer in the training data, all the traffic signs are considered as a single class for training the detection network.

The detection network divides the input image into a 7-by-7 grid. Each grid cell detects a traffic sign if the center of the traffic sign falls within the grid cell. Each cell predicts two bounding boxes and confidence scores for these bounding boxes. Confidence scores indicate whether the box contains an object or not. Each cell predicts on probability for finding the traffic sign in the grid cell. The final score is product of the preceding scores. You apply a threshold of 0.2 on this final score to select the detections.

The recognition network is trained on the same images by using MATLAB.

The trainRecognitionnet.m helper script shows the recognition network training.

Get the Pretrained SeriesNetwork

Download the detection and recognition networks.

```
getTsdr();
```

The detection network contains 58 layers including convolution, leaky ReLU, and fully connected layers.

```
load('yolo_tsr.mat');
yolo
```

```
yolo =
  SeriesNetwork with properties:

         Layers: [58×1 nnet.cnn.layer.Layer]
     InputNames: {'input'}
    OutputNames: {'classoutput'}
```

To view the network architecture, use the `analyzeNetwork` function.

```
analyzeNetwork(yolo)
```

The recognition network contains 14 layers including convolution, fully connected, and the classification output layers.

```
load('RecognitionNet.mat');
convnet
```

```
convnet =
  SeriesNetwork with properties:

         Layers: [14×1 nnet.cnn.layer.Layer]
     InputNames: {'imageinput'}
    OutputNames: {'classoutput'}
```

The `tsdr_predict` Entry-Point Function

The `tsdr_predict.m` entry-point function takes an image input and detects the traffic signs in the image by using the detection network. The function suppresses the overlapping detections (NMS) by using `selectStrongestBbox` and recognizes the traffic sign by using the recognition network. The function loads the network objects from `yolo_tsr.mat` into a persistent variable *detectionnet* and the `RecognitionNet.mat` into a persistent variable *recognitionnet*. The function reuses the persistent objects on subsequent calls.

```
type('tsdr_predict.m')
```

```
function [selectedBbox,idx] = tsdr_predict(img)
%#codegen

```

Generate CUDA MEX for the `tsdr_predict` Function

Create a GPU configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. To generate CUDA MEX, use the `codegen` command and specify the input to be of size [480,704,3]. This value corresponds to the input image size of the `tsdr_predict` function.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg tsdr_predict -args {ones(480,704,3,'uint8')} -report
```

```
Code generation successful: View report
```

To generate code by using TensorRT, pass `coder.DeepLearningConfig('tensorrt')` as an option to the coder configuration object instead of `'cudnn'`.

Run Generated MEX

Load an input image.

```
im = imread('stop.jpg');
imshow(im);
```

Call `tsdr_predict_mex` on the input image.

```
im = imresize(im, [480,704]);
[bboxes,classes] = tsdr_predict_mex(im);
```

Map the class numbers to traffic sign names in the class dictionary.

```
classNames = {...
    'addedLane','slow','dip','speedLimit25','speedLimit35','speedLimit40',...
    'speedLimit45','speedLimit50','speedLimit55','speedLimit65',...
    'speedLimitUrdbl','doNotPass','intersection','keepRight','laneEnds',...
    'merge','noLeftTurn','noRightTurn','stop','pedestrianCrossing',...
    'stopAhead','rampSpeedAdvisory20','rampSpeedAdvisory45',...
    'truckSpeedLimit55','rampSpeedAdvisory50','turnLeft',...
    'rampSpeedAdvisoryUrdbl','turnRight','rightLaneMustTurn','yield',...
    'yieldAhead','school','schoolSpeedLimit25','zoneAhead45','signalAhead'};

classRec = classNames(classes);
```

Display the detected traffic signs.

```
outputImage = insertShape(im,'Rectangle',bboxes,'LineWidth',3);

for i = 1:size(bboxes,1)
    outputImage = insertText(outputImage,[bboxes(i,1)+ ...
        bboxes(i,3) bboxes(i,2)-20],classRec{i},'FontSize',20,...
        'TextColor','red');
end

imshow(outputImage);
```

Traffic Sign Detection and Recognition on a Video

The included helper file `tsdr_testVideo.m` grabs frames from the test video, performs traffic sign detection and recognition, and plots the results on each frame of the test video.

```
type tsdr_testVideo

Logo Recognition Network

This example shows code generation for a logo classification application that uses deep learning. It uses the `codegen` command to generate a MEX function that performs prediction on a `SeriesNetwork` object called LogoNet.

Third-Party Prerequisites

Required

This example generates CUDA® MEX and has the following third-party requirements.

- CUDA enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

The Logo Recognition Network

Logos assist users in brand identification and recognition. Many companies incorporate their logos in advertising, documentation materials, and promotions. The logo recognition network (logonet) was developed in MATLAB® and can recognize 32 logos under various lighting conditions and camera motions. Because this network focuses only on recognition, you can use it in applications where localization is not required.

Training the Network

The network is trained in MATLAB by using training data that contains around 200 images for each logo. Because the number of images for training the network is small, data augmentation increases the number of training samples. Four types of data augmentation are used: contrast normalization, Gaussian blur, random flipping, and shearing. This data augmentation helps in recognizing logos in images captured by different lighting conditions and camera motions. The input size for logonet is 227-by-227-by-3. Standard SGDM trains by using a learning rate of 0.0001 for 40 epochs with a mini-batch size of 45. The trainLogonet.m helper script demonstrates the data augmentation on a sample image, architecture of the logonet, and training options.

Get Pretrained SeriesNetwork

Download the logonet network and save it to `LogoNet.mat`.

```
getLogonet();
```

The saved network contains 22 layers including convolution, fully connected, and the classification output layers.

```
load('LogoNet.mat');
convnet
```

```
convnet = SeriesNetwork with properties:
         Layers: [22×1 nnet.cnn.layer.Layer]
     InputNames: {'imageinput'}
    OutputNames: {'classoutput'}
```

To view the network architecture, use the `analyzeNetwork` function.

```
analyzeNetwork(convnet)
```

The `logonet_predict` Entry-Point Function

The `logonet_predict.m` entry-point function takes an image input and performs prediction on the image using the deep learning network saved in the `LogoNet.mat` file. The function loads the network object from `LogoNet.mat` into a persistent variable *logonet* and reuses the persistent variable on subsequent prediction calls.

```
type('logonet_predict.m')
```

```
function out = logonet_predict(in)
%#codegen

% Copyright 2017-2020 The MathWorks, Inc.

persistent logonet;

if isempty(logonet)

    logonet = coder.loadDeepLearningNetwork('LogoNet.mat','logonet');
end

out = logonet.predict(in);

end
```

Generate CUDA MEX for the `logonet_predict` Function

Create a GPU configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. To generate CUDA MEX, use the `codegen` command and specify the input to be of size [227,227,3]. This value corresponds to the input layer size of the logonet network.

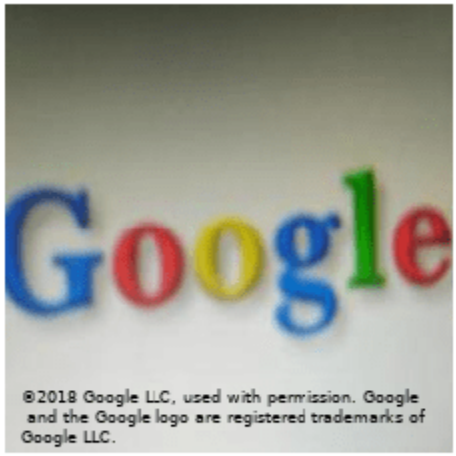
```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg logonet_predict -args {ones(227,227,3,'uint8')} -report
```

```
Code generation successful: View report
```

Run Generated MEX

Load an input image. Call `logonet_predict_mex` on the input image.

```
im = imread('test.png');
imshow(im);
```



```
im = imresize(im, [227,227]);
predict_scores = logonet_predict_mex(im);
```

Map the top five prediction scores to words in the Wordnet dictionary synset (logos).

```
synsetOut = {'adidas', 'aldi', 'apple', 'becks', 'bmw', 'carlsberg', ...
    'chimay', 'cocacola', 'corona', 'dhl', 'erdinger', 'esso', 'fedex',...
    'ferrari', 'ford', 'fosters', 'google', 'guinness', 'heineken', 'hp',...
    'milka', 'nvidia', 'paulaner', 'pepsi', 'rittersport', 'shell',...
    'singha', 'starbucks', 'stellaartois', 'texaco', 'tsingtao', 'ups'};

[val,indx] = sort(predict_scores, 'descend');
scores = val(1:5)*100;
top5labels = synsetOut(indx(1:5));
```

Display the top five classification labels.

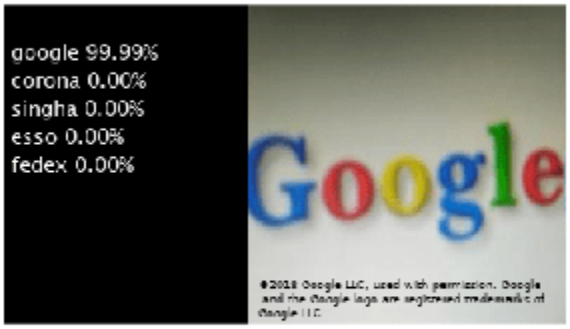
```
outputImage = zeros(227,400,3, 'uint8');
for k = 1:3
    outputImage(:,174:end,k) = im(:,:,k);
end

scol = 1;
srow = 20;

for k = 1:5
    outputImage = insertText(outputImage, [scol, srow],...
```

```
        [top5labels{k},' ',num2str(scores(k),'%2.2f'),'%'],...
        'TextColor', 'w','FontSize',15, 'BoxColor', 'black');
    srow = srow + 20;
end

 imshow(outputImage);
```



Clear the static network object that was loaded in memory.

```
clear mex;
```

Code Generation for Denoising Deep Neural Network

This example shows how to generate CUDA® MEX from MATLAB® code and denoise grayscale images by using the denoising convolutional neural network (DnCNN [1]). You can use the denoising network to estimate noise in a noisy image, and then remove it to obtain a denoised image.

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA® enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

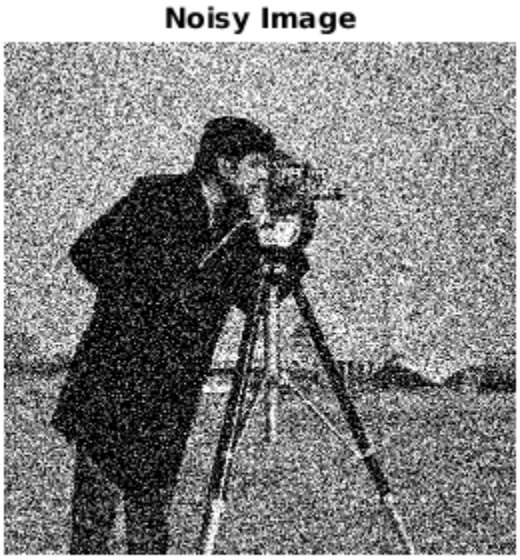
Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Load Noisy Image

Load a noisy grayscale image into the workspace and display the image.

```
noisyI = imread('noisy_cameraman.png');
figure
imshow(noisyI);
title('Noisy Image');
```



Get Pretrained Denoising Network

Call the `getDenoisingNetwork` helper function to get a pretrained image denoising deep neural network.

```
net = getDenoisingNetwork;
```

The `getDenoisingNetwork` function returns a pretrained DnCNN [1] that you can use to detect additive white Gaussian noise (AWGN) that has unknown levels. The network is a feed-forward denoising convolutional network that implements a residual learning technique to predict a residual image. In other words, DnCNN [1] computes the difference between a noisy image and the latent clean image.

The network contains 59 layers including convolution, batch normalization, and regression output layers. To display an interactive visualization of the deep learning network architecture, use the `analyzeNetwork` function.

```
analyzeNetwork(net);
```

The `denoisenet_predict` Function

The `denoisenet_predict` entry-point function takes a noisy image input and returns a denoised image by using a pretrained denoising network.

The function loads the network object returned by `getDenoisingNetwork` into a persistent variable *mynet* and reuses the persistent object on subsequent prediction calls.

```
type denoisenet_predict
```

```
function I = denoisenet_predict(in)
%#codegen
% Copyright 2018-2021 The MathWorks, Inc.
```

```
persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('getDenoisingNetwork', 'DnCNN');
end

% The activations methods extracts the output from the last layer. The
% 'OutputAs' 'channels' name-value pair argument is used inorder to call
% activations on an image whose input dimensions are greater than or equal
% to the network's imageInputLayer.InputSize.

res = mynet.activations(in, 59,'OutputAs','channels');

% Once the noise is estimated, we subtract the noise from the original
% image to obtain a denoised image.

I = in - res;
```

Here, the `activations` method is called with the layer numeric index as 59 to extract the activations from the final layer of the network. The `'OutputAs' 'channels'` name-value pair argument computes activations on images larger than the `imageInputLayer.InputSize` of the network.

The `activations` method returns an estimate of the noise in the input image by using the pretrained denoising image.

Once the noise is estimated, subtract the noise from the original image to obtain a denoised image.

Run MEX Code Generation

To generate CUDA code for the `denoisenet_predict.m` entry-point function, create a GPU code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command specifying an input size of [256,256]. This value corresponds to the size of the noisy image that you intend to denoise.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg denoisenet_predict -args {ones(256,256,'single')} -report

Code generation successful: View report
```

Run Generated MEX

The DnCNN [1] is trained on input images having an input range [0,1]. Call the `im2single` (Image Processing Toolbox) function on `noisyI` to rescale the values from [0,255] to [0,1].

Call `denoisenet_predict_predict` on the rescaled input image.

```
denoisedI = denoisenet_predict_mex(im2single(noisyI));
```

View Denoised Image

```
figure
imshowpair(noisyI,denoisedI,'montage');
title('Noisy Image (left) and Denoised Image (right)');
```

Train and Deploy Fully Convolutional Networks for Semantic Segmentation

This example shows how to train and deploy a fully convolutional semantic segmentation network on an NVIDIA® GPU by using GPU Coder™.

A semantic segmentation network classifies every pixel in an image, resulting in an image that is segmented by class. Applications for semantic segmentation include road segmentation for autonomous driving and cancer cell segmentation for medical diagnosis. To learn more, see “Getting Started with Semantic Segmentation Using Deep Learning” (Computer Vision Toolbox).

To illustrate the training procedure, this example trains FCN-8s [1], one type of convolutional neural network (CNN) designed for semantic image segmentation. Other types of networks for semantic segmentation include fully convolutional networks, such as SegNet and U-Net. You can apply this training procedure to those networks too.

This example uses the CamVid dataset [2] from the University of Cambridge for training. This data set is a collection of images containing street-level views obtained while driving. The data set provides pixel-level labels for 32 semantic classes including car, pedestrian, and road.

Third-party Prerequisites

Required

- CUDA® enabled NVIDIA GPU and compatible driver.

Optional

- NVIDIA CUDA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For information on the supported versions of the compilers and libraries, see “Third-Party Hardware” (GPU Coder). For setting up the environment variables, see “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Setup

This example creates the fully convolutional semantic segmentation network with weights initialized from the VGG-16 network. The vgg16 function checks for the existence of the Deep Learning Toolbox Model for VGG-16 Network support package and returns a pretrained VGG-16 model.

```
vgg16();
```

Download a pretrained version of FCN. This pretrained model enables you to run the entire example without waiting for the training to complete. The doTraining flag controls whether the example uses the trained network of the example or the pretrained FCN network for code generation.

```
doTraining = false;
if ~doTraining
    pretrainedURL = 'https://www.mathworks.com/supportfiles/gpucoder/cnn_models/fcn/FCN8sCamVid.m
    disp('Downloading pretrained FCN (448 MB)...');
    websave('FCN8sCamVid.mat',pretrainedURL);
end
```

```
Downloading pretrained FCN (448 MB)...
```

Download CamVid Dataset

Download the CamVid dataset from these URLs.

```
imageURL = 'http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData/files/701_StillsRaw_full.zi
labelURL = 'http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData/data/LabeledApproved_full.z

outputFolder = fullfile(pwd,'CamVid');

if ~exist(outputFolder, 'dir')

    mkdir(outputFolder)
    labelsZip = fullfile(outputFolder,'labels.zip');
    imagesZip = fullfile(outputFolder,'images.zip');

    disp('Downloading 16 MB CamVid dataset labels...');
    websave(labelsZip, labelURL);
    unzip(labelsZip, fullfile(outputFolder,'labels'));

    disp('Downloading 557 MB CamVid dataset images...');
    websave(imagesZip, imageURL);
    unzip(imagesZip, fullfile(outputFolder,'images'));
end
```

The data download time depends on your Internet connection. The example execution does not proceed until the download operation is complete. Alternatively, use your web browser to first download the data set to your local disk. Then, use the outputFolder variable to point to the location of the downloaded file.

Load CamVid Images

Use `imageDatastore` to load CamVid images. The imageDatastore enables you to efficiently load a large collection of images onto a disk.

```
imgDir = fullfile(outputFolder,'images','701_StillsRaw_full');
imds = imageDatastore(imgDir);
```

Display one of the images.

```
I = readimage(imds,25);
I = histeq(I);
imshow(I)
```

Load CamVid Pixel-Labeled Images

Use `pixelLabelDatastore` (Computer Vision Toolbox) to load CamVid pixel label image data. A pixelLabelDatastore encapsulates the pixel label data and the label ID to a class name mapping.

Following the training method described in the SegNet paper [3], group the 32 original classes in CamVid to 11 classes. Specify these classes.

```
classes = [
    "Sky"
    "Building"
    "Pole"
    "Road"
    "Pavement"
    "Tree"
    "SignSymbol"
    "Fence"
    "Car"
    "Pedestrian"
    "Bicyclist"
    ];
```

To reduce 32 classes into 11 classes, multiple classes from the original data set are grouped together. For example, "Car" is a combination of "Car", "SUVPickupTruck", "Truck_Bus", "Train", and "OtherMoving". Return the grouped label IDs by using the camvidPixelLabelIDs supporting function.

```
labelIDs = camvidPixelLabelIDs();
```

Use the classes and label IDs to create the pixelLabelDatastore.

```
labelDir = fullfile(outputFolder,'labels');
pxds = pixelLabelDatastore(labelDir,classes,labelIDs);
```

Read and display one of the pixel-labeled images by overlaying it on top of an image.

```
C = readimage(pxds,25);
cmap = camvidColorMap;
B = labeloverlay(I,C,'ColorMap',cmap);
imshow(B)
pixelLabelColorbar(cmap,classes);
```

Areas with no color overlay do not have pixel labels and are not used during training.

Analyze Data Set Statistics

To see the distribution of class labels in the CamVid dataset, use `countEachLabel` (Computer Vision Toolbox). This function counts the number of pixels by class label.

```
tbl = countEachLabel(pxds)
```

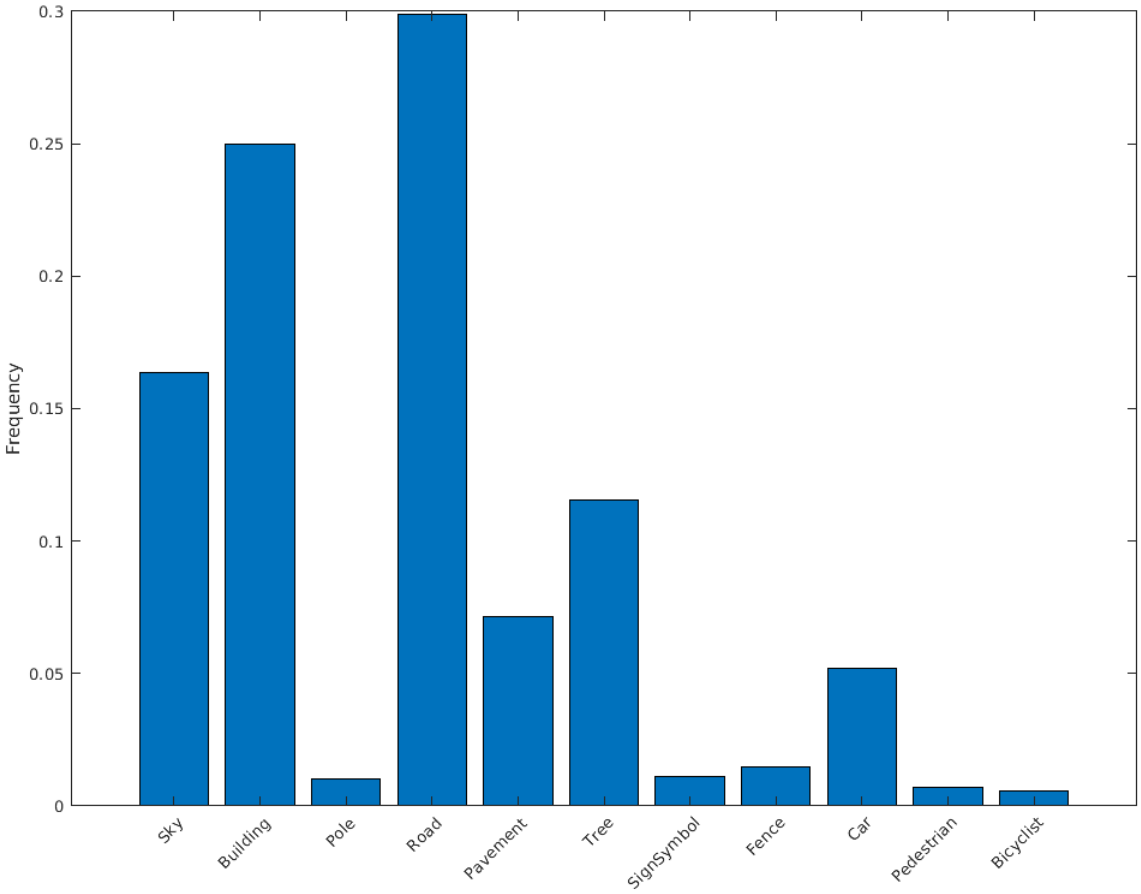
```
tbl=11×3 table
         Name          PixelCount    ImagePixelCount
    _______________    __________    _______________

    {'Sky'       }    7.6801e+07      4.8315e+08
    {'Building'  }    1.1737e+08      4.8315e+08
    {'Pole'      }    4.7987e+06      4.8315e+08
    {'Road'      }    1.4054e+08      4.8453e+08
    {'Pavement'  }    3.3614e+07      4.7209e+08
    {'Tree'      }    5.4259e+07       4.479e+08
    {'SignSymbol'}    5.2242e+06      4.6863e+08
    {'Fence'     }    6.9211e+06       2.516e+08
    {'Car'       }    2.4437e+07      4.8315e+08
    {'Pedestrian'}    3.4029e+06      4.4444e+08
    {'Bicyclist' }    2.5912e+06      2.6196e+08
```

Visualize the pixel counts by class.

```
frequency = tbl.PixelCount/sum(tbl.PixelCount);

bar(1:numel(classes),frequency)
xticks(1:numel(classes))
xticklabels(tbl.Name)
xtickangle(45)
ylabel('Frequency')
```



Ideally, all classes have an equal number of observations. The classes in CamVid are imbalanced, which is a common issue in automotive data sets of street scenes. Such scenes have more sky, building, and road pixels than pedestrian and bicyclist pixels because sky, buildings, and roads cover more area in the image. If not handled correctly, this imbalance can be detrimental to the learning process because the learning is biased in favor of the dominant classes. Later on in this example, you use class weighting to handle this issue.

Resize CamVid Data

The images in the CamVid data set are 720-by-960. To reduce training time and memory usage, resize the images and pixel label images to 360-by-480 by using the resizeCamVidImages and resizeCamVidPixelLabels supporting functions.

```
imageFolder = fullfile(outputFolder,'imagesResized',filesep);
imds = resizeCamVidImages(imds,imageFolder);

labelFolder = fullfile(outputFolder,'labelsResized',filesep);
pxds = resizeCamVidPixelLabels(pxds,labelFolder);
```

Prepare Training and Test Sets

SegNet is trained by using 60% of the images from the dataset. The rest of the images are used for testing. The following code randomly splits the image and pixel label data into a training set and a test set.

```
[imdsTrain,imdsTest,pxdsTrain,pxdsTest] = partitionCamVidData(imds,pxds);
```

The 60/40 split results in the following number of training and test images:

```
numTrainingImages = numel(imdsTrain.Files)
```

```
numTrainingImages = 421
```

```
numTestingImages = numel(imdsTest.Files)
```

```
numTestingImages = 280
```

Create Network

Use `fcnLayers` (Computer Vision Toolbox) to create fully convolutional network layers initialized by using VGG-16 weights. The `fcnLayers` function performs the network transformations to transfer the weights from VGG-16 and adds the additional layers required for semantic segmentation. The output of the `fcnLayers` function is a LayerGraph object representing FCN. A LayerGraph object encapsulates the network layers and the connections between the layers.

```
imageSize = [360 480];
numClasses = numel(classes);
lgraph = fcnLayers(imageSize,numClasses);
```

The image size is selected based on the size of the images in the dataset. The number of classes is selected based on the classes in CamVid.

Balance Classes by Using Class Weighting

The classes in CamVid are not balanced. To improve training, you can use the pixel label counts computed earlier by the `countEachLabel` (Computer Vision Toolbox) function and calculate the median frequency class weights [3].

```
imageFreq = tbl.PixelCount ./ tbl.ImagePixelCount;
classWeights = median(imageFreq) ./ imageFreq;
```

Specify the class weights by using a `pixelClassificationLayer` (Computer Vision Toolbox).

```
pxLayer = pixelClassificationLayer('Name','labels','Classes',tbl.Name,'ClassWeights',classWeights
```

```
pxLayer =
  PixelClassificationLayer with properties:

           Name: 'labels'
        Classes: [11×1 categorical]
    ClassWeights: [11×1 double]
      OutputSize: 'auto'

   Hyperparameters
    LossFunction: 'crossentropyex'
```

Update the SegNet network that has the new pixelClassificationLayer by removing the current pixelClassificationLayer and adding the new layer. The current pixelClassificationLayer is named 'pixelLabels'. Remove it by using the `removeLayers` function, add the new one by using the `addLayers` function, and connect the new layer to the rest of the network by using the `connectLayers` function.

```
lgraph = removeLayers(lgraph,'pixelLabels');
lgraph = addLayers(lgraph, pxLayer);
lgraph = connectLayers(lgraph,'softmax','labels');
```

Select Training Options

The optimization algorithm for training is Adam, which is derived from *adaptive moment estimation*. Use the `trainingOptions` function to specify the hyperparameters used for Adam.

```
options = trainingOptions('adam', ...
    'InitialLearnRate',1e-3, ...
    'MaxEpochs',100, ...
    'MiniBatchSize',4, ...
    'Shuffle','every-epoch', ...
    'CheckpointPath', tempdir, ...
    'VerboseFrequency',2);
```

A 'MiniBatchSize' of four reduces memory usage while training. You can increase or decrease this value based on the amount of GPU memory in your system.

'CheckpointPath' is set to a temporary location. This name-value pair enables the saving of network checkpoints at the end of every training epoch. If training is interrupted due to a system failure or power outage, you can resume training from the saved checkpoint. Make sure that the location specified by 'CheckpointPath' has enough space to store the network checkpoints.

Data Augmentation

Data augmentation is used to improve network accuracy by randomly transforming the original data during training. By using data augmentation, you can add more variety to the training data without increasing the number of labeled training samples. To apply the same random transformation to both image and pixel label data use datastore combine and transform. First, combine `imdsTrain` and `pxdsTrain`.

```
dsTrain = combine(imdsTrain, pxdsTrain);
```

Next, use datastore transform to apply the desired data augmentation defined in the supporting function `augmentImageAndLabel`. Here, random left/right reflection and random X/Y translation of +/- 10 pixels is used for data augmentation.

```
xTrans = [-10 10];
yTrans = [-10 10];
dsTrain = transform(dsTrain, @(data)augmentImageAndLabel(data,xTrans,yTrans));
```

Note that data augmentation is not applied to the test and validation data. Ideally, test and validation data should be representative of the original data and is left unmodified for unbiased evaluation.

Start Training

Start training using `trainNetwork` if the `doTraining` flag is true. Otherwise, load a pretrained network.

The training was verified on an NVIDIA™ Titan Xp with 12 GB of GPU memory. If your GPU has less memory, you might run out of memory. If you do not have enough memory in your system, try lowering the `MiniBatchSize` property in `trainingOptions` to 1. Training this network takes about 5 hours or longer depending on your GPU hardware.

```
doTraining = false;
if doTraining
    [net, info] = trainNetwork(dsTrain,lgraph,options);
    save('FCN8sCamVid.mat','net');
end
```

Save the DAG network object as a MAT-file named `FCN8sCamVid.mat`. This MAT-file is used during code generation.

Perform MEX Code-generation

The fcn_predict.m function takes an image input and performs prediction on the image by using the deep learning network saved in `FCN8sCamVid.mat` file. The function loads the network object from `FCN8sCamVid.mat` into a persistent variable *mynet* and reuses the persistent object on subsequent prediction calls.

```
type('fcn_predict.m')
```

```
function out = fcn_predict(in)
%#codegen
% Copyright 2018-2019 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('FCN8sCamVid.mat');
end

% pass in input
out = predict(mynet,in);
```

Generate a GPU Configuration object for MEX target setting target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a cuDNN deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` (MATLAB Coder) command specifying an input size [360, 480, 3]. This size corresponds to the input layer of FCN.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg fcn_predict -args {ones(360,480,3,'uint8')} -report
```

```
Code generation successful: View report
```

Run Generated MEX

Load and display an input image.

```
im = imread('testImage.png');
imshow(im);
```

Run prediction by calling `fcn_predict_mex` on the input image.

```
predict_scores = fcn_predict_mex(im);
```

The `predict_scores` variable is a three-dimensional matrix having 11 channels corresponding to the pixel-wise prediction scores for every class. Compute the channel by using the maximum prediction score to get pixel-wise labels.

```
[~,argmax] = max(predict_scores,[],3);
```

Overlay the segmented labels on the input image and display the segmented region.

```
classes = [
    "Sky"
    "Building"
    "Pole"
    "Road"
    "Pavement"
    "Tree"
    "SignSymbol"
    "Fence"
    "Car"
    "Pedestrian"
    "Bicyclist"
    ];
```

```
cmap = camvidColorMap();
SegmentedImage = labeloverlay(im,argmax,'ColorMap',cmap);
figure
imshow(SegmentedImage);
pixelLabelColorbar(cmap,classes);
```

Cleanup

Clear the static network object that was loaded in memory.

```
clear mex;
```

Supporting Functions

```
function data = augmentImageAndLabel(data, xTrans, yTrans)
% Augment images and pixel label images using random reflection and
% translation.

for i = 1:size(data,1)

    tform = randomAffine2d(...
        'XReflection',true,...
        'XTranslation', xTrans, ...
        'YTranslation', yTrans);
```

```
    % Center the view at the center of image in the output space while
    % allowing translation to move the output image out of view.
    rout = affineOutputView(size(data{i,1}), tform, 'BoundsStyle', 'centerOutput');

    % Warp the image and pixel labels using the same transform.
    data{i,1} = imwarp(data{i,1}, tform, 'OutputView', rout);
    data{i,2} = imwarp(data{i,2}, tform, 'OutputView', rout);

end
end
```

Code Generation for Semantic Segmentation Network That Uses U-net

This example shows code generation for an image segmentation application that uses deep learning. It uses the `codegen` command to generate a MEX function that performs prediction on a DAG Network object for U-Net, a deep learning network for image segmentation.

For a similar example covering segmentation of images by using U-Net without the `codegen` command, see “Semantic Segmentation of Multispectral Images Using Deep Learning” (Image Processing Toolbox).

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA® enabled NVIDIA® GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Segmentation Network

U-Net [1] is a type of convolutional neural network (CNN) designed for semantic image segmentation. In U-Net, the initial series of convolutional layers are interspersed with max pooling layers, successively decreasing the resolution of the input image. These layers are followed by a series of convolutional layers interspersed with upsampling operators, successively increasing the resolution of the input image. Combining these two series paths forms a U-shaped graph. The network was originally trained for and used to perform prediction on biomedical image segmentation applications. This example demonstrates the ability of the network to track changes in forest cover over time. Environmental agencies track deforestation to assess and qualify the environmental and ecological health of a region.

Deep-learning-based semantic segmentation can yield a precise measurement of vegetation cover from high-resolution aerial photographs. One challenge is differentiating classes that have similar

visual characteristics, such as trying to classify a green pixel as grass, shrubbery, or tree. To increase classification accuracy, some data sets contain multispectral images that provide additional information about each pixel. For example, the Hamlin Beach State Park data set supplements the color images with near-infrared channels that provide a clearer separation of the classes.

This example uses the Hamlin Beach State Park Data [2] along with a pretrained U-Net network in order to correctly classify each pixel.

The U-Net used is trained to segment pixels belonging to 18 classes which includes:

```
0. Other Class/Image Border      7. Picnic Table         14. Grass
1. Road Markings                 8. Black Wood Panel     15. Sand
2. Tree                          9. White Wood Panel     16. Water (Lake)
3. Building                     10. Orange Landing Pad   17. Water (Pond)
4. Vehicle (Car, Truck, or Bus) 11. Water Buoy           18. Asphalt (Parking Lot/Walkway)
5. Person                       12. Rocks
6. Lifeguard Chair              13. Other Vegetation
```

The `segmentImageUnet` Entry-Point Function

The `segmentImageUnet.m` entry-point function performs patchwise semantic segmentation on the input image by using the multispectralUnet network found in the `multispectralUnet.mat` file. The function loads the network object from the `multispectralUnet.mat` file into a persistent variable *mynet* and reuses the persistent variable on subsequent prediction calls.

```
type('segmentImageUnet.m')
```

```
%  OUT = segmentImageUnet(IM, PATCHSIZE) returns a semantically segmented
%  image, segmented using the network multispectralUnet. The segmentation
%  is performed over each patch of size PATCHSIZE.
%
% Copyright 2019-2021 The MathWorks, Inc.
function out = segmentImageUnet(im, patchSize)

%#codegen

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('trainedUnet/multispectralUnet.mat');
end

[height, width, nChannel] = size(im);
patch = coder.nullcopy(zeros([patchSize, nChannel-1]));

% pad image to have dimensions as multiples of patchSize
padSize = zeros(1,2);
padSize(1) = patchSize(1) - mod(height, patchSize(1));
padSize(2) = patchSize(2) - mod(width, patchSize(2));

im_pad = padarray (im, padSize, 0, 'post');
[height_pad, width_pad, ~] = size(im_pad);

out = zeros([size(im_pad,1), size(im_pad,2)], 'uint8');

for i = 1:patchSize(1):height_pad
    for j =1:patchSize(2):width_pad
        for p = 1:nChannel-1
```

```
            patch(:,:,p) = squeeze( im_pad( i:i+patchSize(1)-1,...
                                            j:j+patchSize(2)-1,...
                                            p));
        end

        % pass in input
        segmentedLabels = activations(mynet, patch, 'Segmentation-Layer');

        % Takes the max of each channel (6 total at this point)
        [~,L] = max(segmentedLabels,[],3);
        patch_seg = uint8(L);

        % populate section of output
        out(i:i+patchSize(1)-1, j:j+patchSize(2)-1) = patch_seg;

    end
end

% Remove the padding
out = out(1:height, 1:width);
```

Get Pretrained U-Net DAG Network Object

```
trainedUnet_url = 'https://www.mathworks.com/supportfiles/vision/data/multispectralUnet.mat';
downloadTrainedUnet(trainedUnet_url,pwd);
```

```
Downloading Pretrained U-net for Hamlin Beach dataset...
This will take several minutes to download...
done.
```

```
ld = load("trainedUnet/multispectralUnet.mat");
net = ld.net;
```

The DAG network contains 58 layers including convolution, max pooling, depth concatenation, and the pixel classification output layers. To display an interactive visualization of the deep learning network architecture, use the `analyzeNetwork` function. analyzeNetwork(net);

Prepare Data

Download the Hamlin Beach State Park data.

```
if ~exist(fullfile(pwd,'data'),'dir')
    url = 'http://www.cis.rit.edu/~rmk6217/rit18_data.mat';
    downloadHamlinBeachMSIData(url,pwd+"/data/");
end
```

```
Downloading Hamlin Beach dataset...
This will take several minutes to download...
done.
```

Load and examine the data in MATLAB.

```
load(fullfile(pwd,'data','rit18_data','rit18_data.mat'));

% Examine data
whos test_data
```

```
  Name           Size                         Bytes  Class     Attributes

  test_data      7x12446x7654            1333663576  uint16
```

The image has seven channels. The RGB color channels are the fourth, fifth, and sixth image channels. The first three channels correspond to the near-infrared bands and highlight different components of the image based on their heat signatures. Channel 7 is a mask that indicates the valid segmentation region.

The multispectral image data is arranged as numChannels-by-width-by-height arrays. In MATLAB, multichannel images are arranged as width-by-height-by-numChannels arrays. To reshape the data so that the channels are in the third dimension, use the helper function, `switchChannelsToThirdPlane`.

```
test_data  = switchChannelsToThirdPlane(test_data);

% Confirm data has the correct structure (channels last).
whos test_data
```

```
  Name               Size                         Bytes  Class     Attributes

  test_data      12446x7654x7            1333663576  uint16
```

Run MEX Code Generation

To generate CUDA code for `segmentImageUnet.m` entry-point function, create a GPU Configuration object for a MEX target setting the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command specifying an input size of [12446,7654,7] and a patch size of [1024,1024]. These values correspond to the entire test_data size. The smaller patch sizes speed up inference. To see how the patches are calculated, see the `segmentImageUnet.m` entry-point function.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
inputArgs = {ones(size(test_data),'uint16'),coder.Constant([1024 1024])};
codegen -config cfg segmentImageUnet -args inputArgs -report
```

```
Code generation successful: View report
```

Run Generated MEX to Predict Results for test_data

This `segmentImageUnet` function takes in the data to test (test_data) and a vector containing the dimensions of the patch size to use. Take patches of the image, predict the pixels in a particular patch, then combine all the patches together. Due to the size of test_data (12446x7654x7), it is easier to process such a large image in patches.

```
segmentedImage = segmentImageUnet_mex(test_data,[1024 1024]);
```

To extract only the valid portion of the segmentation, multiply the segmented image by the mask channel of the test data.

```
segmentedImage = uint8(test_data(:,:,7)~=0) .* segmentedImage;
```

Because the output of the semantic segmentation is noisy, remove the noise and stray pixels by using the `medfilt2` function.

```
segmentedImage = medfilt2(segmentedImage,[5,5]);
```

Display U-Net Segmented test_data

The following line of code creates a vector of the class names.

```
classNames = [ "RoadMarkings","Tree","Building","Vehicle","Person", ...
               "LifeguardChair","PicnicTable","BlackWoodPanel",...
               "WhiteWoodPanel","OrangeLandingPad","Buoy","Rocks",...
               "LowLevelVegetation","Grass_Lawn","Sand_Beach",...
               "Water_Lake","Water_Pond","Asphalt"];
```

Overlay the labels on the segmented RGB test image and add a color bar to the segmentation image.

```
cmap = jet(numel(classNames));
B = labeloverlay(imadjust(test_data(:,:,4:6),[0 0.6],[0.1 0.9],0.55),...
    segmentedImage,'Transparency',0.8,'Colormap',cmap);
figure
imshow(B)

N = numel(classNames);
ticks = 1/(N*2):1/N:1;
colorbar('TickLabels',cellstr(classNames),'Ticks',ticks,'TickLength',0,...
    'TickLabelInterpreter','none');
colormap(cmap)
title('Segmented Image');
```

Code Generation for Deep Learning on ARM Targets

This example shows how to generate and deploy code for prediction on an ARM®-based device without using a hardware support package.

When you generate code for prediction using the ARM Compute Library and a hardware support package, `codegen` generates code on the host computer, copies the generated files to the target hardware, and builds the executable on the target hardware. Without a hardware support package, `codegen` generates code on the host computer. You must run commands to copy the files and build the executable program on the target hardware.

This example uses the `packNGo` function to package all relevant files into a compressed zip file. Use this example to learn how to deploy the generated code on ARM Neon targets that do not have a hardware support package by using `packNGo`.

Prerequisites

- ARM processor that supports the NEON extension
- ARM Compute Library (on the target ARM hardware)
- Open Source Computer Vision Library(Open CV)
- Environment variables for the compilers and libraries
- MATLAB® Coder™
- The support package MATLAB Coder Interface for Deep Learning
- Deep Learning Toolbox™

The ARM Compute library version that this example uses might not be the latest version that code generation supports. For supported versions of libraries and for information about setting up environment variables, see “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder).

This example is not supported for MATLAB Online.

squeezenet_predict Function

This example uses the DAG network SqueezeNet to show image classification with the ARM Compute Library. A pretrained SqueezeNet for MATLAB is available in the Deep Learning Toolbox. The `squeezenet_predict` function loads the SqueezeNet network into a persistent network object. On subsequent calls to the function, the persistent object is reused.

```
type squeezenet_predict
```

```
% Copyright 2018 The MathWorks, Inc.

function out = squeezenet_predict(in)
%#codegen

% A persistent object mynet is used to load the DAG network object.
% At the first call to this function, the persistent object is constructed and
% set up. When the function is called subsequent times, the same object is reused
% to call predict on inputs, avoiding reconstructing and reloading the
% network object.

persistent mynet;
```

```
if isempty(mynet)
       mynet = coder.loadDeepLearningNetwork('squeezenet','squeezenet');
end

out = mynet.predict(in);
```

Set Up a Code Generation Configuration Object for a Static Library

When you generate code targeting an ARM-based device and do not use a hardware support package, create a configuration object for a library. Do not create a configuration object for an executable program.

Set up the configuration object for generation of C++ code and generation of code only.

```
cfg = coder.config('lib');
cfg.TargetLang = 'C++';
cfg.GenCodeOnly = true;
```

Set Up a Configuration Object for Deep Learning Code Generation

Create a `coder.ARMNEONConfig` object. Specify the library version and the architecture of the target ARM processor. For example, suppose that the target board is a HiKey/Rock960 board with ARMv8 architecture and ARM Compute Library version 19.05.

```
dlcfg = coder.DeepLearningConfig('arm-compute');
dlcfg.ArmComputeVersion = '19.05';
dlcfg.ArmArchitecture = 'armv8';
```

Attach the Deep Learning Configuration Object to the Code Generation Configuration Object

Set the `DeepLearningConfig` property of the code generation configuration object to the deep learning configuration object.

```
cfg.DeepLearningConfig = dlcfg;
```

Generate Source C++ Code by Using codegen

```
codegen -config cfg squeezenet_predict -args {ones(227, 227, 3, 'single')} -d arm_compute
```

The code is generated in the arm_compute folder in the current working folder on the host computer.

Generate the Zip File using packNGo function

The packNGo function packages all relevant files in a compressed zip file.

```
zipFileName = 'arm_compute.zip';
bInfo = load(fullfile('arm_compute','buildInfo.mat'));
packNGo(bInfo.buildInfo, {'fileName', zipFileName,'minimalHeaders', false, 'ignoreFileMissing',t
```

The code is generated as zip file.

Copy the Generated Zip file to the Target Hardware

Copy the Zip file and extract into folder and remove the Zip file in the hardware

In the following commands, replace:

- `password` with your password
- `username` with your user name
- `targetname` with the name of your device
- `targetloc` with the destination folder for the files

Perform the steps below to copy and extract zip file from Linux.

```
if isunix, system(['sshpass -p password scp -r '  fullfile(pwd,zipFileName) ' username@targetname
if isunix, system('sshpass -p password ssh username@targetname "if [ -d targetloc/arm_compute ];
if isunix, system(['sshpass -p password ssh username@targetname "unzip targetloc/' zipFileName '
if isunix, system(['sshpass -p password ssh username@targetname "rm -rf  targetloc' zipFileName
```

Perform the steps below to copy and extract zip file from Windows.

```
if ispc, system(['pscp.exe -pw password -r '  fullfile(pwd,zipFileName) ' username@targetname:ta
if ispc, system('plink.exe -l username -pw password targetname "if [ -d targetloc/arm_compute ];
if ispc, system(['plink.exe -l username -pw password targetname "unzip targetloc/' zipFileName '
if ispc, system(['plink.exe -l username -pw password targetname "rm -rf  targetloc' zipFileName
```

Copy Example Files to the Target Hardware

Copy these supporting files from the host computer to the target hardware:

- Input image, `coffeemug.png`
- Makefile for generating the library, `squeezenet_predict_rtw.mk`
- Makefile for building the executable program, `makefile_squeezenet_arm_generic.mk`
- Synset dictionary, `synsetWords.txt`

In the following commands, replace:

- `password` with your password
- `username` with your user name
- `targetname` with the name of your device
- `targetloc` with the destination folder for the files

Perform the steps below to copy all the required files when running from Linux

```
if isunix, system('sshpass -p password scp squeezenet_predict_rtw.mk username@targetname:targetlo
if isunix, system('sshpass -p password scp coffeemug.png username@targetname:targetloc/arm_comput
if isunix, system('sshpass -p password scp makefile_squeezenet_arm_generic.mk username@targetname
if isunix, system('sshpass -p password scp synsetWords.txt username@targetname:targetloc/arm_comp
```

Perform the steps below to copy all the required files when running from Windows

```
if ispc, system('pscp.exe -pw password squeezenet_predict_rtw.mk username@targetname:targetloc/a
if ispc, system('pscp.exe -pw password coffeemug.png username@targetname:targetloc/arm_compute/'
if ispc, system('pscp.exe -pw password makefile_squeezenet_arm_generic.mk username@targetname:ta
if ispc, system('pscp.exe -pw password synsetWords.txt username@targetname:targetloc/arm_compute/
```

Build the Library on the Target Hardware

To build the library on the target hardware, execute the generated makefile on the ARM hardware.

Make sure that you set the environment variables ARM_COMPUTELIB and LD_LIBRARY_PATH on the target hardware. See “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder).

ARM_ARCH variable is used in Makefile to pass compiler flags based on Arm Architecture. ARM_VER variable is used in Makefile to compile the code based on Arm Compute Version. Replace the hardware credentials and paths in similar to above steps.

Perform the below steps to build the library from Linux.

```
if isunix, system('sshpass -p password scp main_squeezenet_arm_generic.cpp username@targetname:ta
if isunix, system(['sshpass -p password ssh username@targetname "make -C targetloc/arm_compute/ -
```

Perform the below steps to build the library from windows.

```
if ispc, system('pscp.exe -pw password main_squeezenet_arm_generic.cpp username@targetname:targe
if ispc, system(['plink.exe -l username -pw password targetname "make -C targetloc/arm_compute/ -
```

Create Executable from the Library on the Target Hardware

Build the library with the source main wrapper file to create the executable. `main_squeezenet_arm_generic.cpp` is the C++ main wrapper file which invokes squeezenet_predict function to create the executable.

Run the below command to create the executable from Linux.

```
if isunix, system('sshpass -p password ssh username@targetname "make -C targetloc/arm_compute/ -f
```

Run the below command to create the executable from Windows.

```
if ispc, system('plink.exe -l username -pw password targetname "make -C targetloc/arm_compute/ -f
```

Run the Executable on the Target Hardware

Run the executable from Linux using below command.

```
if isunix, system('sshpass -p password ssh username@targetname "cd targetloc/arm_compute/; ./sque
```

Run the executable from Windows using below command.

```
if ispc, system('plink.exe -l username -pw password targetname "cd targetloc/arm_compute/; ./sque
```

```
Top 5 Predictions:
------------------------------
88.299% coffee mug
7.309% cup
1.098% candle
0.634% paper towel
0.591% water jug
```

MathWorks

Deep Learning Prediction with ARM Compute Using codegen

This example shows how to use `codegen` to generate code for a Logo classification application that uses deep learning on ARM® processors. The logo classification application uses the `LogoNet` series network to perform logo recognition from images. The generated code takes advantage of the ARM Compute library for computer vision and machine learning.

Prerequisites

- ARM processor that supports the NEON extension
- Open Source Computer Vision Library (OpenCV) v3.1
- Environment variables for ARM Compute and OpenCV libraries
- MATLAB® Coder™ for C++ code generation
- The support package MATLAB Coder Interface for Deep Learning
- Deep Learning Toolbox™ for using the `SeriesNetwork` object

The ARM Compute library version that this example uses might not be the latest version that code generation supports. For supported versions of libraries and for information about setting up environment variables, see “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder).

This example is supported on Linux® and Windows® platforms and not supported for MATLAB Online.

Get the Pretrained SeriesNetwork

Download the pretrained `LogoNet` network and save it as `logonet.mat`, if it does not exist. The network was developed in MATLAB® and its architecture is similar to that of AlexNet. This network can recognize 32 logos under various lighting conditions and camera angles.

```
net = getLogonet();
```

The network contains 22 layers including convolution, fully connected, and the classification output layers.

```
net.Layers
```

```
ans =

  22×1 Layer array with layers:

```

Set Environment Variables

On the ARM target hardware, make sure that ARM_COMPUTELIB is set and that LD_LIBRARY_PATH contains the path to the ARM Compute Library folder.

See “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder).

logonet_predict Function

The `logonet_predict.m` entry-point function takes an image input and performs prediction on the image using the deep learning network saved in the `LogoNet` MAT-file. The function loads the network object from `LogoNet.mat` into a persistent network variable *logonet*. On subsequent calls to the function, the persistent object is reused.

```
type logonet_predict
```

```
function out = logonet_predict(in)
%#codegen

% Copyright 2017-2020 The MathWorks, Inc.

persistent logonet;

if isempty(logonet)

    logonet = coder.loadDeepLearningNetwork('LogoNet.mat','logonet');
end

out = logonet.predict(in);

end
```

Set Up a Code Generation Configuration Object for a Static Library

When you generate code targeting an ARM-based device and do not use a hardware support package, create a configuration object for a library. Do not create a configuration object for an executable program.

Set up the configuration object for generation of C++ code and generation of code only.

```
cfg = coder.config('lib');
cfg.TargetLang = 'C++';
cfg.GenCodeOnly = true;
```

Set Up a Configuration Object for Deep Learning Code Generation

Create a `coder.ARMNEONConfig` object. Specify the library version and the architecture of the target ARM processor. For example, suppose that the target board is a HiKey/Rock960 board with ARMv8 architecture and ARM Compute Library version 19.05.

```
dlcfg = coder.DeepLearningConfig('arm-compute');
dlcfg.ArmComputeVersion = '19.05';
dlcfg.ArmArchitecture = 'armv8';
```

Attach the Deep Learning Configuration Object to the Code Generation Configuration Object

Set the `DeepLearningConfig` property of the code generation configuration object to the deep learning configuration object.

```
cfg.DeepLearningConfig = dlcfg;
```

Generate Source C++ Code by Using codegen

```
codegen -config cfg logonet_predict -args {ones(227, 227, 3, 'single')} -d arm_compute
```

The code is generated in the `arm_compute` folder in the current working folder on the host computer.

Generate the Zip File Using the packNGo function

The packNGo function packages all relevant files in a compressed zip file.

```
zipFileName = 'arm_compute.zip';
bInfo = load(fullfile('arm_compute','buildInfo.mat'));
packNGo(bInfo.buildInfo, {'fileName', zipFileName,'minimalHeaders', false, 'ignoreFileMissing',t
```

Copy the Generated Zip File to the Target Hardware

Copy the Zip file and extract into a folder. Remove the Zip file from the target hardware.

In the following commands, replace:

- `password` with your password
- `username` with your user name
- `targetname` with the name of your device
- `targetloc` with the destination folder for the files

Run these commands to copy and extract zip file from Linux.

```
if isunix, system(['sshpass -p password scp -r '  fullfile(pwd,zipFileName) ' username@targetname
if isunix, system('sshpass -p password ssh username@targetname "if [ -d targetloc/arm_compute ];
if isunix, system(['sshpass -p password ssh username@targetname "unzip targetloc/' zipFileName '
if isunix, system(['sshpass -p password ssh username@targetname "rm -rf  targetloc' zipFileName
```

Run these commands to copy and extract zip file from Windows.

```
if ispc, system(['pscp.exe -pw password -r '  fullfile(pwd,zipFileName) ' username@targetname:ta
if ispc, system('plink.exe -l username -pw password targetname "if [ -d targetloc/arm_compute ];
if ispc, system(['plink.exe -l username -pw password targetname "unzip targetloc/' zipFileName '
if ispc, system(['plink.exe -l username -pw password targetname "rm -rf  targetloc' zipFileName
```

Copy Example Files to the Target Hardware

Copy these supporting files from the host computer to the target hardware:

- Input image, `coderdemo_google.png`
- Makefile for generating the library, `logonet_predict_rtw.mk`
- Makefile for building the executable program, `makefile_arm_logo.mk`
- Synset dictionary, `synsetWordsLogoDet.txt`

In the following commands, replace:

- `password` with your password
- `username` with your user name
- `targetname` with the name of your device
- `targetloc` with the destination folder for the files

Perform the steps below to copy all the required files when running from Linux

```
if isunix, system('sshpass -p password scp logonet_predict_rtw.mk username@targetname:targetloc/a
if isunix, system('sshpass -p password scp coderdemo_google.png username@targetname:targetloc/arm
if isunix, system('sshpass -p password scp makefile_arm_logo.mk username@targetname:targetloc/arm
if isunix, system('sshpass -p password scp synsetWordsLogoDet.txt username@targetname:targetloc/a
```

Perform the steps below to copy all the required files when running from Windows

```
if ispc, system('pscp.exe -pw password logonet_predict_rtw.mk username@targetname:targetloc/arm_c
if ispc, system('pscp.exe -pw password coderdemo_google.png username@targetname:targetloc/arm_com
if ispc, system('pscp.exe -pw password makefile_arm_logo.mk username@targetname:targetloc/arm_com
if ispc, system('pscp.exe -pw password synsetWordsLogoDet.txt username@targetname:targetloc/arm_c
```

Build the Library on the Target Hardware

To build the library on the target hardware, execute the generated makefile on the ARM hardware.

Make sure that you set the environment variables ARM_COMPUTELIB and LD_LIBRARY_PATH on the target hardware. See “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder). The ARM_ARCH variable is used in the Makefile to pass compiler flags based on Arm Architecture. ARM_VER variable is used in the Makefile to compile the code based on Arm Compute Version. Replace the hardware credentials and paths in these commands similar to previous section.

Perform the below steps to build the library from Linux.

```
if isunix, system('sshpass -p password scp main_arm_logo.cpp username@targetname:targetloc/arm_co
if isunix, system(['sshpass -p password ssh username@targetname "make -C targetloc/arm_compute/ 
```

Perform the below steps to build the library from windows.

```
if ispc, system('pscp.exe -pw password main_arm_logo.cpp username@targetname:targetloc/arm_comput
if ispc, system(['plink.exe -l username -pw password targetname "make -C targetloc/arm_compute/ 
```

Create Executable from the Library on the Target Hardware

Build the library with the source main wrapper file to create the executable. `main_arm_logo.cpp` is the C++ main wrapper file which invokes the `logonet_predict` function.

Run the below command to create the executable from Linux.

```
if isunix, system('sshpass -p password ssh username@targetname "make -C targetloc/arm_compute/ -f
```

Run the below command to create the executable from Windows.

```
if ispc, system('plink.exe -l username -pw password targetname "make -C targetloc/arm_compute/ -f
```

Run the Executable on the Target Hardware

Run the executable from Linux using below command.

```
if isunix, system('sshpass -p password ssh username@targetname "cd targetloc/arm_compute/; ./logo
```

Run the executable from Windows using below command.

```
if ispc, system('plink.exe -l username -pw password targetname "cd targetloc/arm_compute/; ./logo
```

```
Top 5 Predictions:

0.003% corona
0.003% singha
0.001% esso
0.000% fedex
```

Deep Learning Code Generation on Intel Targets for Different Batch Sizes

This example shows how to use the `codegen` command to generate code for an image classification application that uses deep learning on Intel® processors. The generated code uses the Intel Math Kernel Library for Deep Neural Networks (MKL-DNN). This example consists of two parts:

- The first part shows how to generate a MEX function that accepts a batch of images as input.
- The second part shows how to generate an executable that accepts a batch of images as input.

Prerequisites

- Intel processor with support for Intel Advanced Vector Extensions 2 (Intel AVX2) instructions
- Intel Math Kernel Library for Deep Neural Networks (MKL-DNN)
- Environment variables for the compilers and libraries. For information on the supported versions of compilers, see Supported Compilers. For setting up the environment variables, see “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder).

This example is supported on Linux® , Windows® and Mac® platforms and not supported for MATLAB Online.

Download input video File

Download a sample video file.

```
if ~exist('./object_class.avi', 'file')
    url = 'https://www.mathworks.com/supportfiles/gpucoder/media/object_class.avi.zip';
    websave('object_class.avi.zip',url);
    unzip('object_class.avi.zip');
end
```

Define the `resnet_predict` Function

This example uses the DAG network ResNet-50 to show image classification on Intel desktops. A pretrained ResNet-50 model for MATLAB is available as part of the support package Deep Learning Toolbox Model for ResNet-50 Network.

The `resnet_predict` function loads the ResNet-50 network into a persistent network object and then performs prediction on the input. Subsequent calls to the function reuse the persistent network object.

```
type resnet_predict
```

```
% Copyright 2020 The MathWorks, Inc.

function out = resnet_predict(in)
%#codegen

% A persistent object mynet is used to load the series network object.
% At the first call to this function, the persistent object is constructed and
% setup. When the function is called subsequent times, the same object is reused
% to call predict on inputs, avoiding reconstructing and reloading the
% network object.
```

```
persistent mynet;

if isempty(mynet)
    % Call the function resnet50 that returns a DAG network
    % for ResNet-50 model.
    mynet = coder.loadDeepLearningNetwork('resnet50','resnet');
end

% pass in input
out = mynet.predict(in);
```

Generate MEX for `resnet_predict`

To generate a MEX function for the `resnet_predict` function, use `codegen` with a deep learning configuration object for the MKL-DNN library. Attach the deep learning configuration object to the MEX code generation configuration object that you pass to `codegen`. Run the `codegen` command and specify the input as a 4D matrix of size [224,224,3,|batchSize|]. This value corresponds to the input layer size of the ResNet-50 network.

```
    batchSize = 5;
    cfg = coder.config('mex');
    cfg.TargetLang = 'C++';
    cfg.DeepLearningConfig = coder.DeepLearningConfig('mkldnn');
    codegen -config cfg resnet_predict -args {ones(224,224,3,batchSize,'single')} -report

Code generation successful: To view the report, open('codegen\mex\resnet_predict\html\report.mlda
```

Perform Prediction on a Batch of Images

Presuming the Object_class.avi video file is already downloaded. Create the videoReader object and read five frames using videoReader read function.Since batchSize is set to 5 read 5 images .Resize the batch of input images to size needed by resnet50 size expected by ResNet50 network.

```
videoReader = VideoReader('Object_class.avi');
imBatch = read(videoReader,[1 5]);
imBatch = imresize(imBatch, [224,224]);
```

Call the generated `resnet_predict_mex` function which outputs classification results for the inputs that you provide.

```
predict_scores = resnet_predict_mex(single(imBatch));
```

Get top 5 probability scores and their labels for each image in the batch.

```
[val,indx] = sort(transpose(predict_scores), 'descend');
scores = val(1:5,:)*100;
net = resnet50;
classnames = net.Layers(end).ClassNames;
for i = 1:batchSize
    labels = classnames(indx(1:5,i));
    disp(['Top 5 predictions on image, ', num2str(i)]);
    for j=1:5
        disp([labels{j},' ',num2str(scores(j,i), '%2.2f'),'%'])
    end
end
```

For predictions on the first image, map the top five prediction scores to words in the `synset` dictionary.

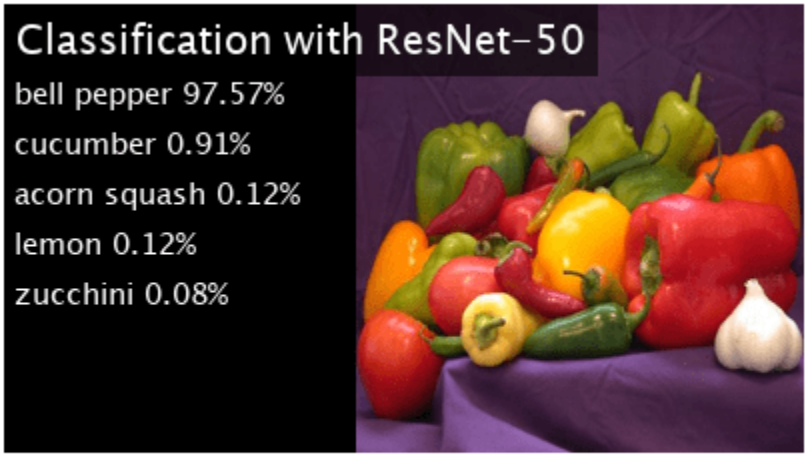
```
fid = fopen('synsetWords.txt');
synsetOut = textscan(fid,'%s', 'delimiter', '\n');
synsetOut = synsetOut{1};
fclose(fid);
[val,indx] = sort(transpose(predict_scores), 'descend');
scores = val(1:5,1)*100;
top5labels = synsetOut(indx(1:5,1));
```

Display the top five classification labels on the image.

```
outputImage = zeros(224,400,3, 'uint8');
for k = 1:3
    outputImage(:,177:end,k) = imBatch(:,:,k,1);
end

scol = 1;
srow = 1;
outputImage = insertText(outputImage, [scol, srow], 'Classification with ResNet-50', 'TextCol
srow = srow + 30;
for k = 1:5
    outputImage = insertText(outputImage, [scol, srow], [top5labels{k},' ',num2str(scores(k),
    srow = srow + 25;
end

imshow(outputImage);
```



Clear the persistent network object from memory.

```
clear mex;
```

Define the `resnet_predict_exe` Entry-Point Function

To generate an executable from MATLAB code, define a new entry-point function `resnet_predict_exe`. This function is similar to the previous entry-point function `resent_predict` but, in addition, includes code for preprocessing and postprocessing. The API that `resnet_predict_exe` uses is platform independent. This function accepts a video and the batch size as input arguments. These arguments are compile-time constants.

```
type resnet_predict_exe
```

```
% Copyright 2020 The MathWorks, Inc.

function resnet_predict_exe(inputVideo,batchSize)
%#codegen

    % A persistent object mynet is used to load the series network object.
    % At the first call to this function, the persistent object is constructed and
    % setup. When the function is called subsequent times, the same object is reused
    % to call predict on inputs, avoiding reconstructing and reloading the
    % network object.
    persistent mynet;

    if isempty(mynet)
        % Call the function resnet50 that returns a DAG network
        % for ResNet-50 model.
        mynet = coder.loadDeepLearningNetwork('resnet50','resnet');
    end

    % Create video reader and video player objects %
    videoReader = VideoReader(inputVideo);
    depVideoPlayer = vision.DeployableVideoPlayer;

    % Read the classification label names %
    synsetOut = readImageClassLabels('synsetWords.txt');

    i=1;
    % Read frames until end of video file %
    while ~(i+batchSize > (videoReader.NumFrames+1))
        % Read and resize batch of frames as specified by input argument%
        reSizedImagesBatch = readImageInputBatch(videoReader,batchSize,i);

        % run predict on resized input images %
        predict_scores = mynet.predict(reSizedImagesBatch);

        % overlay the prediction scores on images and display %
        overlayResultsOnImages(predict_scores,synsetOut,reSizedImagesBatch,batchSize,depVideoPlay

        i = i+ batchSize;
    end
    release(depVideoPlayer);
end

function synsetOut = readImageClassLabels(classLabelsFile)
% Read the classification label names from the file
%
```

```
% Inputs :
% classLabelsFile - supplied by user
%
% Outputs :
% synsetOut       - cell array filled with 1000 image class labels

    synsetOut = cell(1000,1);
    fid = fopen(classLabelsFile);
    for i = 1:1000
        synsetOut{i} = fgetl(fid);
    end
    fclose(fid);
end

function reSizedImagesBatch = readImageInputBatch(videoReader,batchSize,i)
% Read and resize batch of frames as specified by input argument%
%
% Inputs :
% videoReader - Object used for reading the images from video file
% batchSize   - Number of images in batch to process. Supplied by user

% batchSize       - Number of images in batch to process. Supplied by user
% depVideoPlayer  - Object for displaying results
%
% Outputs :
% Predicted results overlayed on input images

    % sort the predicted scores  %
    [val,indx] = sort(transpose(predict_scores), 'descend');

    for j = 1:batchSize
        scores = val(1:5,j)*100;
        outputImage = zeros(224,400,3, 'uint8');
        for k = 1:3
            outputImage(:,177:end,k) = reSizedImagesBatch(:,:,k,j);
        end

        % Overlay the results on image %
        scol = 1;
        srow = 1;
```

```
        outputImage = insertText(outputImage, [scol, srow], 'Classification with ResNet-50', 'Tex
        srow = srow + 30;
        for k = 1:5
            scoreStr = sprintf('%2.2f',scores(k));
            outputImage = insertText(outputImage, [scol, srow], [synsetOut{indx(k,j)},' ',scoreSt
            srow = srow + 25;
        end

        depVideoPlayer(outputImage);
    end
end
```

Structure of the `resnet_predict_exe` Function

The function `resnet_predict_exe` contains four subsections that perform these actions:

- Read the classification labels from supplied input text file
- Read the input batch of images and resize them as needed by the network
- Run inference on input image batch
- Overlay the results on the images

For more information each of these steps, see the subsequent sections.

The `readImageClassLabels` Function

This function accepts the `synsetWords.txt` file as an input argument. It reads the classification labels and populates a cell array.

```
function synsetOut = readImageClassLabels(classLabelsFile)
% Read the classification label names from the file
%
% Inputs :
% classLabelsFile - supplied by user
%
% Outputs :
% synsetOut       - cell array filled with 1000 image class labels

    synsetOut = cell(1000,1);
    fid = fopen(classLabelsFile);
    for i = 1:1000
        synsetOut{i} = fgetl(fid);
    end
    fclose(fid);
end
```

The `readImageInputBatch` Function

This function reads and resizes the images from the video input file that is passed to the function as an input argument. It reads the specified input images and resizes them to 224x224x3 which is the size the resnet50 network expects.

```
function reSizedImagesBatch = readImageInputBatch(videoReader,batchSize,i)
% Read and resize batch of frames as specified by input argument%
%
% Inputs :
```

```
% videoReader - Object used for reading the images from video file
% batchSize   - Number of images in batch to process. Supplied by user
% i           - index to track frames read from video file
%
% Outputs :
% reSizedImagesBatch - Batch of images resized to 224x224x3xbatchsize

    img = read(videoReader,[i (i+batchSize-1)]);
    reSizedImagesBatch = coder.nullcopy(ones(224,224,3,batchSize,'like',img));
    resizeTo  = coder.const([224,224]);
    reSizedImagesBatch(:,:,:,:) = imresize(img,resizeTo);
end
```

The `mynet.predict` Function

This function accepts the resized batch of images as input and returns the prediction results.

```
% run predict on resized input images %
predict_scores = mynet.predict(reSizedImagesBatch);
```

The `overlayResultsOnImages` Function

This function accepts the prediction results and sorts them in descending order. It overlays these results on the input images and displays them.

```
function overlayResultsOnImages(predict_scores,synsetOut,reSizedImagesBatch,batchSize,depV
% Read and resize batch of frames as specified by input argument%
%
% Inputs :
% predict_scores  - classification results for given network
% synsetOut       - cell array filled with 1000 image class labels
% reSizedImagesBatch - Batch of images resized to 224x224x3xbatchsize
% batchSize       - Number of images in batch to process. Supplied by user
% depVideoPlayer  - Object for displaying results
%
% Outputs :
% Predicted results overlayed on input images

    % sort the predicted scores  %
    [val,indx] = sort(transpose(predict_scores), 'descend');

    for j = 1:batchSize
        scores = val(1:5,j)*100;
        outputImage = zeros(224,400,3, 'uint8');
        for k = 1:3
            outputImage(:,177:end,k) = reSizedImagesBatch(:,:,k,j);
        end

        % Overlay the results on image %
        scol = 1;
        srow = 1;
        outputImage = insertText(outputImage, [scol, srow], 'Classification with ResNet-50
        srow = srow + 30;
        for k = 1:5
            scoreStr = sprintf('%2.2f',scores(k));
            outputImage = insertText(outputImage, [scol, srow], [synsetOut{indx(k,j)},' '
            srow = srow + 25;
        end
```

```
            depVideoPlayer(outputImage);
        end
    end
```

Build and Run Executable

Create a code configuration object for generating an executable. Attach a deep learning configuration object to it. Set the `batchSize` and `inputVideoFile` variables.

If you do not intend to create a custom C++ main function and use the generated example C++ main instead, set the `GenerateExampleMain` parameter to `'GenerateCodeAndCompile'`. Also, disable cfg.EnableOpenMP to make sure there are no openmp library dependencies when you run your executable from the desktop terminal.

```
cfg = coder.config('exe');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('mkldnn');
batchSize = 5;
inputVideoFile = 'object_class.avi';
cfg.GenerateExampleMain = 'GenerateCodeAndCompile';
cfg.EnableOpenMP = 0;
```

Run the `codegen` command to build the executable. Run the generated executable resnet_predict_exe either at the MATLAB command line or at the desktop terminal.

```
codegen -config cfg resnet_predict_exe -args {coder.Constant(inputVideoFile), coder.Consta
system('./resnet_predict_exe')
```

Generate C++ Code for Object Detection Using YOLO v2 and Intel MKL-DNN

This example shows how to generate C++ code for the YOLO v2 Object detection network on an Intel® processor. The generated code uses the Intel Math Kernel Library for Deep Neural Networks (MKL-DNN).

For more information, see "Object Detection Using YOLO v2 Deep Learning" (Computer Vision Toolbox).

Prerequisites

- Intel Math Kernel Library for Deep Neural Networks (MKL-DNN)
- Refer MKLDNN CPU Support to know the list of processors that supports MKL-DNN library
- MATLAB® Coder™ for C++ code generation
- MATLAB Coder Interface for Deep Learning support package
- Deep Learning Toolbox™ for using the `DAGNetwork` object
- Computer Vision Toolbox™ for video I/O operations

For more information on the supported versions of the compilers and libraries, see "Third-Party Hardware and Software" (MATLAB Coder).

This example is supported on Linux®, Windows®, and macOS platforms and not supported for MATLAB Online.

Get the Pretrained `DAGNetwork` Object

The DAG network contains 150 layers including convolution, ReLU, and batch normalization layers and the YOLO v2 transform and YOLO v2 output layers.

```
net = getYOLOv2();
```

```
Downloading pretrained detector (98 MB)...
```

Use the command `net.Layers` to see all the layers of the network.

```
net.Layers
```

Code Generation for `yolov2_detection` Function

The `yolov2_detection` function attached with the example takes an image input and runs the detector on the image using the network saved in `yolov2ResNet50VehicleExample.mat`. The function loads the network object from `yolov2ResNet50VehicleExample.mat` into a persistent variable `yolov2Obj`. Subsequent calls to the function reuse the persistent object for detection.

```
type('yolov2_detection.m')
```

```
function outImg = yolov2_detection(in)

%   Copyright 2018-2019 The MathWorks, Inc.

% A persistent object yolov2Obj is used to load the YOLOv2ObjectDetector object.
% At the first call to this function, the persistent object is constructed and
```

```
% set up. Subsequent calls to the function reuse the same object to call detection
% on inputs, thus avoiding having to reconstruct and reload the
% network object.
persistent yolov2Obj;

if isempty(yolov2Obj)
    yolov2Obj = coder.loadDeepLearningNetwork('yolov2ResNet50VehicleExample.mat');
end

% pass in input
[bboxes,~,labels] = yolov2Obj.detect(in,'Threshold',0.5);
outImg = in;

% convert categorical labels to cell array of character vectors
labels = cellstr(labels);

if ~(isempty(bboxes) && isempty(labels))
% Annotate detections in the image.
    outImg = insertObjectAnnotation(in,'rectangle',bboxes,labels);
end
```

To generate code, create a code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` function to create a MKL-DNN deep learning configuration object. Assign this object to the `DeepLearningConfig` property of the code configuration object. Specify the input size as an argument to the `codegen` command. In this example, the input layer size of the YOLO v2 network is `[224,224,3]`.

```
cfg = coder.config('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('mkldnn');
codegen -config cfg yolov2_detection -args {ones(224,224,3,'uint8')} -report

Code generation successful: To view the report, open('codegen/mex/yolov2_detection/html/report.m
```

Run the Generated MEX Function on Example Input

Set up a video file reader and read the example input video `highway_lanechange.mp4`. Create a video player to display the video and the output detections.

```
videoFile = 'highway_lanechange.mp4';
videoFreader = vision.VideoFileReader(videoFile,'VideoOutputDataType','uint8');
depVideoPlayer = vision.DeployableVideoPlayer('Size','Custom','CustomSize',[640 480]);
```

Read the video input frame by frame and detect the vehicles in the video by using the detector.

```
cont = ~isDone(videoFreader);
while cont
    I = step(videoFreader);
    in = imresize(I,[224,224]);
    out = yolov2_detection_mex(in);
    depVideoPlayer(out);
    cont = ~isDone(videoFreader) && isOpen(depVideoPlayer); % Exit the loop if the video player
end
```

Code Generation and Deployment of MobileNet-v2 Network to Raspberry Pi

This example shows how to generate and deploy C++ code that uses the MobileNet-v2 pretrained network for object prediction.

Prerequisites

- ARM processor that supports the NEON extension
- ARM Compute Library (on the target ARM hardware)
- Open Source Computer Vision Library(OpenCV) v2.4 (on the target ARM hardware)
- Environment variables for the compilers and libraries
- MATLAB® Coder™
- MATLAB Coder Interface for Deep Learning Libraries support package
- Deep Learning Toolbox™
- Deep Learning Toolbox Model for MobileNet-v2 Network support package
- Image Processing Toolbox™
- MATLAB Support Package for Raspberry Pi Hardware

The ARM Compute library version that this example uses might not be the latest version that code generation supports. For supported versions of libraries and for information about setting up environment variables, see “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder).

This example is not supported for MATLAB online.

This example uses the DAG network MobileNet-v2 to perform image classification with the ARM® Compute Library. The pretrained MobileNet-v2 network for MATLAB is available in the Deep Learning Toolbox Model for MobileNet-v2 Network support package.

When you generate code that uses the ARM Compute Library and a hardware support package, `codegen` generates code on the host computer, copies the generated files to the target hardware, and builds the executable on the target hardware.

Configure Code Generation for the `mobilenet_predict` Function

The `mobilenet_predict` function calls the predict method of the MobileNet-v2 network object on an input image and returns the prediction score output. The function calls `coder.updateBuildInfo` to specify linking options for the generated makefile.

```
type mobilenet_predict
```

```
function out = mobilenet_predict(in)

persistent net;
opencv_linkflags = '`pkg-config --cflags --libs opencv`';
coder.updateBuildInfo('addLinkFlags',opencv_linkflags);
if isempty(net)
    net = coder.loadDeepLearningNetwork('mobilenetv2', 'mobilenet');
end
```

```
out = net.predict(in);

end
```

Create a C++ code generation configuration object.

```
cfg = coder.config('exe');
cfg.TargetLang = 'C++';
```

Specify Use of the ARM Compute Library. The ARM Compute Library provides optimized functionality for the Raspberry Pi hardware. To generate code that uses the ARM Compute Library, create a `coder.ARMNEONConfig` object. Specify the version of the ARM Compute Library installed on your Raspberry Pi and the architecture of the Raspberry Pi. Attach the deep learning configuration object to the code generation configuration object.

```
dlcfg = coder.DeepLearningConfig('arm-compute');
supportedVersions = dlcfg.getARMComputeSupportedVersions;
dlcfg.ArmArchitecture = 'armv7';
dlcfg.ArmComputeVersion = '19.05';
cfg.DeepLearningConfig = dlcfg;
```

Create a Connection to the Raspberry Pi

Use the MATLAB Support Package for Raspberry Pi Hardware function `raspi` to create a connection to the Raspberry Pi. In this code, replace:

- `raspiname` with the host name of your Raspberry Pi
- `username` with your user name
- `password` with your password

```
r = raspi('raspiname','username','password');
```

Configure Code Generation Hardware Parameters for Raspberry Pi

Create a `coder.Hardware` object for the Raspberry Pi and attach it to the code generation configuration object.

```
hw = coder.hardware('Raspberry Pi');
cfg.Hardware = hw;
```

Specify a build folder on the Raspberry Pi:

```
buildDir = '~/remoteBuildDir';
cfg.Hardware.BuildDir = buildDir;
```

Provide a C++ Main File

Specify the main file `main_mobilenet.cpp` in the code generation configuration object. The file calls the generated C++ code for the `mobilenet_predict` function. The file reads the input image, passes the data to the generated function calls, retrieves the predictions on the image, and prints the prediction scores to a file.

```
cfg.CustomSource = 'main_mobilenet.cpp';
```

Generate the Executable Program on the Raspberry Pi

Generate C++ code. When you use `codegen` with the MATLAB Support Package for Raspberry PI Hardware, the executable is built on the Raspberry Pi.

For code generation, you must set the “Environment Variables” (MATLAB Coder) `ARM_COMPUTELIB` and `LD_LIBRARY_PATH` on the Raspberry Pi.

```
codegen -config cfg mobilenet_predict -args {ones(224, 224, 3,'single')} -report
```

Fetch the Generated Executable Folder

To test the generated code on the Raspberry Pi, copy the input image to the generated code folder. You can find this folder manually or by using the `raspi.utils.getRemoteBuildDirectory` API. This function lists the folders of the binary files that are generated by using `codegen`. Assuming that the binary is found in only one folder, enter:

```
applicationDirPaths = raspi.utils.getRemoteBuildDirectory('applicationName','mobilenet_predict');
targetDirPath = applicationDirPaths{1}.directory;
```

Copy Example Files to the Raspberry Pi

To copy files required to run the executable program, use `putFile`.

```
r.putFile('peppers_raspi_mobilenet.png',targetDirPath);
```

Run the Executable Program on the Raspberry Pi

Run the executable program on the Raspberry Pi from MATLAB and direct the output back to MATLAB.

```
exeName = 'mobilenet_predict.elf';
argsforexe = ' peppers_raspi_mobilenet.png '; % Provide the input image;
command = ['cd ' targetDirPath ';sudo ./' exeName argsforexe];
output = system(r,command);
```

Get the Prediction Scores for the 1000 Output Classes of the Network

```
outputfile = [targetDirPath, '/output.txt'];
r.getFile(outputfile);
```

Map the Prediction Scores to Labels and Display Output

Map the top five prediction scores to the corresponding labels in the trained network, and display the output.

```
type mapPredictedScores_mobilenet
```

```
%% Map the Prediction Scores to Labels and Display Output
net = mobilenetv2;
ClassNames = net.Layers(end).ClassNames;

%% Read the classification
fid = fopen('output.txt') ;
S = textscan(fid,'%s');
fclose(fid) ;
S = S{1} ;
predict_scores = cellfun(@(x)str2double(x), S);

%% Remove NaN values that were strings
predict_scores(isnan(predict_scores))=[];
[val,indx] = sort(predict_scores, 'descend');
scores = val(1:5)*100;
```

```
top5labels = ClassNames(indx(1:5));

%% Display classification labels on the image
im = imread('peppers_raspi_mobilenet.png');
im = imresize(im, [224 224]);
outputImage = zeros(224,400,3, 'uint8');
for k = 1:3
    outputImage(:,177:end,k) = im(:,:,k);
end
scol = 1;
srow = 1;
outputImage = insertText(outputImage, [scol, srow], 'Classification with MobileNetv2', 'TextColo
srow = srow + 30;
for k = 1:5
    outputImage = insertText(outputImage, [scol, srow], [top5labels{k},' ',num2str(scores(k), '%
    srow = srow + 25;
end
imshow(outputImage);
```

Code Generation for Semantic Segmentation Application on Intel CPUs That Uses U-Net

This example demonstrates code generation for an image segmentation application that uses deep learning. It uses the `codegen` command to generate a MEX function that performs prediction by using the deep learning network U-Net for image segmentation.

For a similar example that demonstrates segmentation of images by using U-Net but does not use the `codegen` command, see "Semantic Segmentation of Multispectral Images Using Deep Learning" (Image Processing Toolbox).

Third-Party Prerequisites

- Xeon processor with support for Intel Advanced Vector Extensions 2 (Intel AVX2) instructions

This example is supported on Linux®, Windows®, and macOS platforms.

This example uses the Intel MKL-DNN library that ships with MATLAB and generates a MEX function for semantic segmentation.

This example is not supported in MATLAB Online.

Overview of U-Net

U-Net [1] is a type of convolutional neural network (CNN)that is designed for semantic image segmentation. In U-Net, the initial series of convolutional layers are interspersed with max pooling layers, successively decreasing the resolution of the input image. These layers are followed by a series of convolutional layers interspersed with upsampling operators, successively increasing the resolution of the input image. The combination of these two series paths forms a U-shaped graph. The network was originally trained to perform prediction for biomedical image segmentation applications. This example demonstrates the ability of the network to track changes in forest cover over time. Environmental agencies track deforestation to assess and qualify the environmental and ecological health of a region.

Deep-learning-based semantic segmentation can yield a precise measurement of vegetation cover from high-resolution aerial photographs. One of the challenges is differentiating classes that have similar visual characteristics, such as trying to classify a green pixel as grass, shrubbery, or tree. To increase classification accuracy, some data sets contain multispectral images that provide additional information about each pixel. For example, the Hamlin Beach State Park data set supplements the color images with near-infrared channels that provide a clearer separation of the classes.

This example uses the Hamlin Beach State Park Data [2] along with a pretrained U-Net network in order to correctly classify each pixel.

The U-Net this example uses is trained to segment pixels belonging to 18 classes which includes:

```
0. Other Class/Image Border      7. Picnic Table         14. Grass
1. Road Markings                 8. Black Wood Panel     15. Sand
2. Tree                          9. White Wood Panel     16. Water (Lake)
3. Building                     10. Orange Landing Pad   17. Water (Pond)
4. Vehicle (Car, Truck, or Bus) 11. Water Buoy           18. Asphalt (Parking Lot/Walkway)
5. Person                       12. Rocks
6. Lifeguard Chair              13. Other Vegetation
```

Get Pretrained U-Net DAG Network Object

```
trainedUnet_url = 'https://www.mathworks.com/supportfiles/vision/data/multispectralUnet.mat';
downloadTrainedUnet(trainedUnet_url,pwd);
```

```
Downloading Pre-trained U-net for Hamlin Beach dataset...
This will take several minutes to download...
done.
```

```
ld = load("trainedUnet/multispectralUnet.mat");
net = ld.net;
```

The DAG network contains 58 layers including convolution, max pooling, depth concatenation, and pixel classification output layers. To display an interactive visualization of the deep learning network architecture, use the `analyzeNetwork` function.

```
%   analyzeNetwork(net);
```

The `segmentImageUnet` Entry-Point Function

The segmentImageUnet.m entry-point function performs semantic segmentation on the input image for each patch of a fixed size by using the multispectralUnet network contained in the `multispectralUnet.mat` file. This function loads the network object from the `multispectralUnet.mat` file into a persistent variable `mynet`. The function reuses this persistent variable in subsequent prediction calls.

```
type('segmentImageUnet.m')
```

```
%  OUT = segmentImageUnet(IM, PATCHSIZE) returns a semantically segmented
%  image, segmented using the network multispectralUnet. The segmentation
%  is performed over each patch of size PATCHSIZE.
%
% Copyright 2019-2020 The MathWorks, Inc.
function out = segmentImageUnet(im, patchSize)

%#codegen

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('trainedUnet/multispectralUnet.mat');
end

[height, width, nChannel] = size(im);
patch = coder.nullcopy(zeros([patchSize, nChannel-1]));

% pad image to have dimensions as multiples of patchSize
padSize = zeros(1,2);
padSize(1) = patchSize(1) - mod(height, patchSize(1));
padSize(2) = patchSize(2) - mod(width, patchSize(2));

im_pad = padarray (im, padSize, 0, 'post');
[height_pad, width_pad, ~] = size(im_pad);

out = zeros([size(im_pad,1), size(im_pad,2)], 'uint8');
```

```
for i = 1:patchSize(1):height_pad
    for j =1:patchSize(2):width_pad
        for p = 1:nChannel-1
            patch(:,:,p) = squeeze( im_pad( i:i+patchSize(1)-1,...
                                            j:j+patchSize(2)-1,...
                                            p));
        end

        % pass in input
        segmentedLabels = activations(mynet, patch, 'Segmentation-Layer');

        % Takes the max of each channel (6 total at this point)
        [~,L] = max(segmentedLabels,[],3);
        patch_seg = uint8(L);

        % populate section of output
        out(i:i+patchSize(1)-1, j:j+patchSize(2)-1) = patch_seg;

    end
end

% Remove the padding
out = out(1:height, 1:width);
```

Prepare Data

Download the Hamlin Beach State Park data.

```
if ~exist(fullfile(pwd,'data'),'dir')
    url = 'http://www.cis.rit.edu/~rmk6217/rit18_data.mat';
    downloadHamlinBeachMSIData(url,pwd+"/data/");
end
```

```
Downloading Hamlin Beach dataset...
This will take several minutes to download...
done.
```

Load and examine the data in MATLAB.

```
load(fullfile(pwd,'data','rit18_data','rit18_data.mat'));

% Examine data
whos test_data
```

```
  Name           Size                         Bytes  Class     Attributes

  test_data      7x12446x7654            1333663576  uint16
```

The image has seven channels. The RGB color channels are the fourth, fifth, and sixth image channels. The first three channels correspond to the near-infrared bands and highlight different components of the image based on their heat signatures. Channel 7 is a mask that indicates the valid segmentation region.

The multispectral image data is arranged as numChannels-by-width-by-height arrays. In MATLAB, multichannel images are arranged as width-by-height-by-numChannels arrays. To reshape the data so that the channels are in the third dimension, use the helper function, `switchChannelsToThirdPlane`.

```
test_data  = switchChannelsToThirdPlane(test_data);
```

Confirm data has the correct structure (channels last).

```
whos test_data
```

```
  Name               Size                     Bytes  Class     Attributes

  test_data      12446x7654x7            1333663576  uint16
```

This example uses a cropped version of the full Hamlin Beach State Park dataset that the `test_data` variable contains. Crop the height and width of `test_data` to create the variable `input_data` that this example uses.

```
test_datacropRGB = imcrop(test_data(:,:,1:3),[2600, 3000, 2000, 2000]);
test_datacropInfrared = imcrop(test_data(:,:,4:6),[2600, 3000, 2000, 2000]);
test_datacropMask = imcrop(test_data(:,:,7),[2600, 3000, 2000, 2000]);
input_data(:,:,1:3) = test_datacropRGB;
input_data(:,:,4:6) = test_datacropInfrared;
input_data(:,:,7) = test_datacropMask;
```

Examine the input_data variable.

```
whos('input_data');
```

```
  Name               Size                       Bytes  Class     Attributes

  input_data      2001x2001x7                56056014  uint16
```

Generate MEX

To generate a MEX function for the segmentImageUnet.m entry-point function, create a code configuration object `cfg` for MEX code generation. Set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create an MKL-DNN deep learning configuration object and assign it to the `DeepLearningConfig` property of `cfg`. Run the `codegen` command specifying an input size of [12446,7654,7] and a patch size of [1024,1024]. These values correspond to the size of the entire `input_data` variable. The smaller patch sizes speed up inference. To see how the patches are calculated, see the `segmentImageUnet` entry-point function.

```
cfg = coder.config('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('mkldnn');
codegen -config cfg segmentImageUnet -args {ones(size(input_data),'uint16'),coder.Constant([1024
```

```
Code generation successful: To view the report, open('codegen\mex\segmentImageUnet\html\report.m
```

Run Generated MEX to Predict Results for `input_data`

The `segmentImageUnet` function accepts `input_data` and a vector containing the dimensions of the patch size as inputs. The function divides the image into patches, predicts the pixels in a particular patch, and finally combines all the patches. Because of the large size of `input_data` (12446x7654x7), it is easier to process the image in patches.

```
segmentedImage = segmentImageUnet_mex(input_data,[1024 1024]);
```

To extract only the valid portion of the segmentation, multiply the segmented image by the mask channel of the test data.

```
segmentedImage = uint8(input_data(:,:,7)~=0) .* segmentedImage;
```

Remove the noise and stray pixels by using the `medfilt2` function.

```
segmentedImage = medfilt2(segmentedImage,[5,5]);
```

Display U-Net Segmented input_data

This line of code creates a vector of the class names:

```
classNames = net.Layers(end).Classes;
```

Overlay the labels on the segmented RGB test image and add a color bar to the segmentation image.

```
% Display input data

figure(1);
imshow(histeq(input_data(:,:,1:3)));
title('Input Image');
cmap = jet(numel(classNames));
segmentedImageOut = labeloverlay(imadjust(input_data(:,:,4:6),[0 0.6],[0.1 0.9],0.55),segmentedI

% Display segmented data

figure(2);
imshow(segmentedImageOut);
title('Segmented Image Output');
N = numel(classNames);
ticks = 1/(N*2):1/N:1;
colorbar('TickLabels',cellstr(classNames),'Ticks',ticks,'TickLength',0,'TickLabelInterpreter','n
colormap(cmap)
title('Segmented Image using Mkldnn');
segmentedImageOverlay = labeloverlay(imadjust(input_data(:,:,4:6),[0 0.6],[0.1 0.9],0.55),segmen
figure(3);
imshow(segmentedImageOverlay);
title('Segmented Overlay Image');
```

Code Generation for Semantic Segmentation Application on ARM® Neon targets That Uses U-Net

This example shows how to generate code for an image segmentation application that uses deep learning. It uses the `codegen` command to generate a static library that performs prediction on a DAG Network object for U-Net. U-Net is a deep learning network for image segmentation.

For a similar example that uses U-Net for image segmentation but does not use the `codegen` command, see "Semantic Segmentation of Multispectral Images Using Deep Learning" (Image Processing Toolbox).

Prerequisites

- ARM processor that supports the NEON extension and has a RAM of at least 3GB
- ARM Compute Library (on the target ARM hardware)
- Environment variables for the compilers and libraries
- MATLAB® Coder™
- MATLAB Coder Interface for Deep Learning Libraries support package
- Deep Learning Toolbox™

The ARM Compute library version that this example uses might not be the latest version that code generation supports. For information about supported versions of libraries and about environment variables, see "Prerequisites for Deep Learning with MATLAB Coder" (MATLAB Coder).

This example is not supported in MATLAB Online.

Overview of U-Net

U-Net [1] is a type of convolutional neural network (CNN) designed for semantic image segmentation. In U-Net, the initial series of convolutional layers are interspersed with max pooling layers, successively decreasing the resolution of the input image. These layers are followed by a series of convolutional layers interspersed with upsampling operators, successively increasing the resolution of the input image. The combination of these two series paths forms a U-shaped graph. The U-Net network was originally trained to perform prediction on biomedical image segmentation applications. This example demonstrates the ability of the network to track changes in forest cover over time. Environmental agencies track deforestation to assess and qualify the environmental and ecological health of a region.

Deep learning based semantic segmentation can yield a precise measurement of vegetation cover from high-resolution aerial photographs. One of the challenges of such computation is to differentiating classes that have similar visual characteristics, such as classifying a green pixel as grass, shrubbery, or tree. To increase classification accuracy, some data sets contain multispectral images that provide additional information about each pixel. For example, the Hamlin Beach State Park data set supplements the color images with near-infrared channels that provide a clearer separation of the classes.

This example uses the Hamlin Beach State Park Data [2] along with a pretrained U-Net network to correctly classify each pixel.

The U-Net that this example uses is trained to segment pixels belonging to a set of 18 classes which includes:

```
0. Other Class/Image Border      7. Picnic Table         14. Grass
1. Road Markings                 8. Black Wood Panel     15. Sand
2. Tree                          9. White Wood Panel     16. Water (Lake)
3. Building                     10. Orange Landing Pad   17. Water (Pond)
4. Vehicle (Car, Truck, or Bus) 11. Water Buoy           18. Asphalt (Parking Lot/Walkway)
5. Person                       12. Rocks
6. Lifeguard Chair              13. Other Vegetation
```

The `segmentationUnetARM` Entry-Point Function

The segmentationUnetARM.m entry-point function performs patchwise semantic segmentation on the input image by using the multispectralUnet network contained in the `multispectralUnet.mat` file. The function loads the network object from the `multispectralUnet.mat` file into a persistent variable `mynet` and reuses the persistent variable on subsequent prediction calls.

```
type('segmentationUnetARM.m')
```

```
%  OUT = segmentationUnetARM(IM) returns a semantically segmented
%  image, which is segmented using the network multispectralUnet. This segmentation
%  is performed on the input image patchwise on patches of size 256,256.
%
% Copyright 2019-2020 The MathWorks, Inc.
function out = segmentationUnetARM(im)

%#codegen

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('trainedUnet/multispectralUnet.mat');
end

% The input data has to be padded to the size compatible
% with the network Input Size. This input_data is padded inorder to
% perform semantic segmentation on each patch of size (Network Input Size)
[height, width, nChannel] = size(im);
patch = coder.nullcopy(zeros([256, 256, nChannel-1]));
%
padSize = zeros(1,2);
padSize(1) = 256 - mod(height, 256);
padSize(2) = 256 - mod(width, 256);
%
% Pad image must have have dimensions as multiples of network input dimensions
im_pad = padarray (im, padSize, 0, 'post');
[height_pad, width_pad, ~] = size(im_pad);
%
out = zeros([size(im_pad,1), size(im_pad,2)], 'uint8');

for i = 1:256:height_pad
    for j =1:256:width_pad
        for p = 1:nChannel -1
            patch(:,:,p) = squeeze( im( i:i+255,...
                                        j:j+255,...
                                        p));
        end

        % pass in input
        segmentedLabels = activations(mynet, patch, 'Segmentation-Layer');
```

```
        % Takes the max of each channel (6 total at this point)
        [~,L] = max(segmentedLabels,[],3);
        patch_seg = uint8(L);

        % populate section of output
        out(i:i+255, j:j+255) = patch_seg;

    end
end

% Remove the padding
out = out(1:height, 1:width);
```

Get Pretrained U-Net DAG Network Object

Download the `multispectralUnet.mat` file and load the U-Net DAG network object.

```
if ~exist('trainedUnet/multispectralUnet.mat','file')
    trainedUnet_url = 'https://www.mathworks.com/supportfiles/vision/data/multispectralUnet.mat'
    downloadUNet(trainedUnet_url,pwd);
end

ld = load("trainedUnet/multispectralUnet.mat");
net = ld.net;
```

The DAG network contains 58 layers that include convolution, max pooling, depth concatenation, and pixel classification output layers. To display an interactive visualization of the deep learning network architecture, use the `analyzeNetwork` function.

```
analyzeNetwork(net);
```

Prepare Input Data

Download the Hamlin Beach State Park data.

```
if ~exist(fullfile(pwd,'data'),'dir')
    url = 'http://www.cis.rit.edu/~rmk6217/rit18_data.mat';
    downloadHamlinBeachMSIData(url,pwd+"/data/");
end
```

Load and examine the data in MATLAB.

```
load(fullfile(pwd,'data','rit18_data','rit18_data.mat'));
```

Examine data

```
whos test_data
```

The image has seven channels. The RGB color channels are the fourth, fifth, and sixth image channels. The first three channels correspond to the near-infrared bands and highlight different components of the image based on their heat signatures. Channel 7 is a mask that indicates the valid segmentation region.

The multispectral image data is arranged as numChannels-by-width-by-height arrays. In MATLAB, multichannel images are arranged as width-by-height-by-numChannels arrays. To reshape the data so that the channels are in the third dimension, use the helper function, `switchChannelsToThirdPlane`.

```
test_data = switchChannelsToThirdPlane(test_data);
```

Confirm data has the correct structure (channels last).

```
whos test_data
```

This example uses a cropped version of the full Hamlin Beach State Park dataset that the `test_data` variable contains. Crop the height and width of `test_data` to create the variable `input_data` that this example uses.

```
test_datacropRGB = imcrop(test_data(:,:,1:3),[2600, 3000, 2000, 2000]);
test_datacropInfrared = imcrop(test_data(:,:,4:6),[2600, 3000, 2000, 2000]);
test_datacropMask = imcrop(test_data(:,:,7),[2600, 3000, 2000, 2000]);

input_data(:,:,1:3) = test_datacropRGB;
input_data(:,:,4:6) = test_datacropInfrared;
input_data(:,:,7) = test_datacropMask;
```

Examine the `input_data` variable.

```
whos('input_data');
```

Write the input data into a text file that is passed as input to the generated executable.

```
WriteInputDatatoTxt(input_data);
[height, width, channels] = size(input_data);
```

Set Up a Code Generation Configuration Object for a Static Library

To generate code that targets an ARM-based device, create a configuration object for a library. Do not create a configuration object for an executable program. Set up the configuration object for generation of C++ source code only.

```
cfg = coder.config('lib');
cfg.TargetLang = 'C++';
cfg.GenCodeOnly = true;
```

Set Up a Configuration Object for Deep Learning Code Generation

Create a `coder.ARMNEONConfig` object. Specify the library version and the architecture of the target ARM processor. For example, suppose that the target board is a HiKey/Rock960 board with ARMv8 architecture and ARM Compute Library version 19.05.

```
dlcfg = coder.DeepLearningConfig('arm-compute');
dlcfg.ArmComputeVersion = '19.05';
dlcfg.ArmArchitecture = 'armv8';
```

Assign the `DeepLearningConfig` property of the code generation configuration object `cfg` to the deep learning configuration object `dlcfg`.

```
cfg.DeepLearningConfig = dlcfg;
```

Generate C++ Source Code by Using codegen

```
codegen -config cfg segmentationUnetARM -args {ones(size(input_data),'uint16')} -d unet_predict
```

The code gets generated in the `unet_predict` folder that is located in the current working directory on the host computer.

Generate Zip File by Using packNGo

The `packNGo` function packages all relevant files into a compressed zip file.

```
zipFileName = 'unet_predict.zip';
bInfo = load(fullfile('unet_predict','buildInfo.mat'));
packNGo(bInfo.buildInfo, {'fileName', zipFileName,'minimalHeaders', false, 'ignoreFileMissing',t
```

The name of the generated zip file is `unet_predict.zip`.

Copy Generated Zip file to the Target Hardware

Copy the zip file into the target hardware board. Extract the contents of the zip file into a folder and delete the zip file from the hardware.

In the following commands, replace:

- `password` with your password
- `username` with your user name
- `targetname` with the name of your device
- `targetDir` with the destination folder for the files

On the Linux® platform, to transfer and extract the zip file on the target hardware, run these commands:

```
if isunix, system(['sshpass -p password scp -r '  fullfile(pwd,zipFileName) ' username@targetname
if isunix, system('sshpass -p password ssh username@targetname "if [ -d targetDir/unet_predict ]
if isunix, system(['sshpass -p password ssh username@targetname "unzip targetDir/' zipFileName '
if isunix, system(['sshpass -p password ssh username@targetname "rm -rf  targetDir/' zipFileName
```

On the Windows® platform, to transfer and extract the zip file on the target hardware, run these commands:

```
if ispc, system(['pscp.exe -pw password -r '  fullfile(pwd,zipFileName) ' username@targetname:ta
if ispc, system('plink.exe -l username -pw password targetname "if [ -d targetDir/unet_predict ]
if ispc, system(['plink.exe -l username -pw password targetname "unzip targetDir/' zipFileName '
if ispc, system(['plink.exe -l username -pw password targetname "rm -rf  targetDir/' zipFileName
```

Copy Supporting Files to the Target Hardware

Copy these files from the host computer to the target hardware:

- Input data, `input_data.txt`
- Makefile for creating the library, `unet_predict_rtw.mk`
- Makefile for building the executable program, `makefile_unet_arm_generic.mk`

In the following commands, replace:

- `password` with your password
- `username` with your user name
- `targetname` with the name of your device
- `targetDir` with the destination folder for the files

On the Linux® platform, to transfer the supporting files to the target hardware, run these commands:

```
if isunix, system('sshpass -p password scp unet_predict_rtw.mk username@targetname:targetDir/unet
if isunix, system('sshpass -p password scp input_data.txt username@targetname:targetDir/unet_pred
if isunix, system('sshpass -p password scp makefile_unet_arm_generic.mk username@targetname:targe
```

On the Windows® platform, to transfer the supporting files to the target hardware, run these commands:

```
if ispc, system('pscp.exe -pw password unet_predict_rtw.mk username@targetname:targetDir/unet_pre
if ispc, system('pscp.exe -pw password input_data.txt username@targetname:targetDir/unet_predict/
if ispc, system('pscp.exe -pw password makefile_unet_arm_generic.mk username@targetname:targetDir
```

Build the Library on the Target Hardware

To build the library on the target hardware, execute the generated makefile on the ARM hardware.

Make sure that you set the environment variables `ARM_COMPUTELIB` and `LD_LIBRARY_PATH` on the target hardware. See “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder). The `ARM_ARCH` variable is used in Makefile to pass compiler flags based on the ARM Architecture. The `ARM_VER` variable is used in Makefile to compile the code based on the version of the ARM Compute library.

On the Linux host platform, run this command to build the library:

```
if isunix, system(['sshpass -p password ssh username@targetname "make -C targetDir/unet_predict/
```

On the Windows host platform, run this command to build the library:

```
if ispc, system(['plink.exe -l username -pw password targetname "make -C targetDir/unet_predict/
```

Create Executable on the Target

In these commands, replace `targetDir` with the destination folder where the library is generated. The variables `height`, `width`, and `channels` represent the dimensions of the input data.

`main_unet_arm_generic.cpp` is the C++ main wrapper file which invokes the segmentationUnetARM function and passes the input image to it. Build the library with the wrapper file to create the executable.

On the Linux host platform, to create the executable, run these commands:

```
if isunix, system('sshpass -p password scp main_unet_arm_generic.cpp username@targetname:targetDi
if isunix, system(['sshpass -p password ssh username@targetname "make -C targetDir/unet_predict/
```

On the Windows host platform, to create the executable, run these commands:

```
if ispc, system('pscp.exe -pw password main_unet_arm_generic.cpp username@targetname:targetDir/un
if ispc, system(['plink.exe -l username -pw password targetname "make -C targetDir/unet_predict/
```

Run the Executable on the Target Hardware

Run the Executable on the target hardware with the input image file `input_data.txt`.

On the Linux host platform, run this command:

```
if isunix, system('sshpass -p password ssh username@targetname "cd targetDir/unet_predict/; ./une
```

On the Windows host platform, run this command:

```
if ispc, system('plink.exe -l username -pw password targetname "cd targetDir/unet_predict/; ./une
```

The `unet` executable accepts the input data. Because of the large size of `input_data` (2001x2001x7), it is easier to process the input image in patches. The executable splits the input image into multiple patches, each corresponding to network input size. The executable performs prediction on the pixels in one particular patch at a time and then combines all the patches together.

Transfer the Output from Target Hardware to MATLAB

Copy the generated output file `output_data.txt` back to the current MATLAB session. On the Linux platform, run:

```
if isunix, system('sshpass -p password scp username@targetname:targetDir/unet_predict/output_data
```

To perform the same action on the Windows platform, run:

```
if ispc, system('pscp.exe -pw password username@targetname:targetDir/unet_predict/output_data.tx
```

Store the output data in the variable `segmentedImage`:

```
segmentedImage = uint8(importdata('output_data.txt'));
segmentedImage = reshape(segmentedImage,[height,width]);
```

To extract only the valid portion of the segmented image, multiply it by the mask channel of the input data.

```
segmentedImage = uint8(input_data(:,:,7)~=0) .* segmentedImage;
```

Remove the noise and stray pixels by using the `medfilt2` function.

```
segmentedImageCodegen = medfilt2(segmentedImage,[5,5]);
```

Display U-Net Segmented data

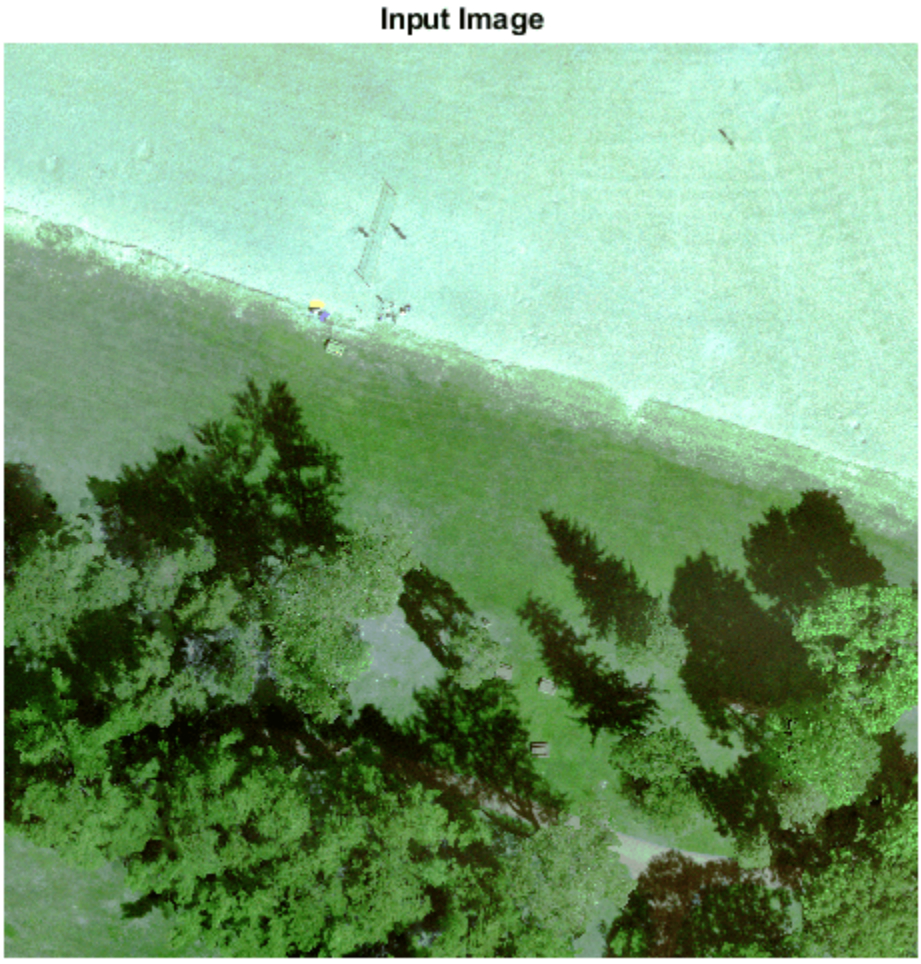
This line of code creates a vector of the class names.

```
classNames = net.Layers(end).Classes;
disp(classNames);
```

Overlay the labels on the segmented RGB test image and add a color bar to the segmented image.

Display input data

```
figure(1);
imshow(histeq(input_data(:,:,1:3)));
title('Input Image');
```



```
cmap = jet(numel(classNames));
segmentedImageOut = labeloverlay(imadjust(input_data(:,:,4:6),[0 0.6],[0.1 0.9],0.55),segmentedI
figure(2);
imshow(segmentedImageOut);
```

Display segmented data

```
title('Segmented Image using Codegen on ARM');
N = numel(classNames);
ticks = 1/(N*2):1/N:1;
colorbar('TickLabels',cellstr(classNames),'Ticks',ticks,'TickLength',0,'TickLabelInterpreter','n
colormap(cmap)
```

Display segmented overlay Image

```
segmentedImageOverlay = labeloverlay(imadjust(input_data(:,:,4:6),[0 0.6],[0.1 0.9],0.55),segmen
figure(3);
imshow(segmentedImageOverlay);
title('Segmented Overlayed Image');
```

Code Generation for LSTM Network on Raspberry Pi

This example shows how to generate code for a pretrained long short-term memory (LSTM) network that uses the ARM® Compute Library and deploy the code on a Raspberry Pi™ target. In this example, the LSTM network predicts the Remaining Useful Life (RUL) of a machine. The network takes as input time series data sets that represent various sensors in the engine. The network returns the Remaining Useful Life of an engine, measured in cycles, as its output.

This example uses the Turbofan Engine Degradation Simulation Data Set as described in [1]. This data set contains 100 training observations and 100 test observations. The training data contains simulated time series data for 100 engines. Each sequence has 17 features, varies in length, and corresponds to a full run to failure (RTF) instance. The test data contains 100 partial sequences and corresponding values of the Remaining Useful Life at the end of each sequence.

This example uses a pretrained LSTM network. For more information on how to train an LSTM network, see the example “Sequence Classification Using Deep Learning” on page 4-2.

This example demonstrates two different approaches for performing prediction by using an LSTM network:

- The first approach uses a standard LSTM network and runs inference on a set of time series data.
- The second approach leverages the stateful behavior of the same LSTM network. In this method, you pass a single timestep of data at a time, and have the network update its state at each time step.

This example uses the PIL based workflow to generate a MEX function, which in turn calls the executable generated in the target hardware from MATLAB.

Notes:

- The code lines in this example are commented out. Uncomment them before you run the example.
- The ARM Compute library version that this example uses might not be the latest version that code generation supports. For information on the supported versions of the compilers and libraries, see “Third-Party Hardware and Software” (MATLAB Coder).
- This example is not supported in MATLAB Online.

Prerequisites

- MATLAB® Coder™
- Embedded Coder®
- Deep Learning Toolbox™
- MATLAB Coder Interface for Deep Learning Libraries. To install this support package, use the Add-On Explorer.
- MATLAB Support Package for Raspberry Pi Hardware. To install this support package, use the Add-On Explorer.
- Raspberry Pi hardware
- ARM Compute Library (on the target ARM hardware)
- Environment variables for the compilers and libraries. For setting up the environment variables, see “Environment Variables” (MATLAB Coder).

Set Up a Code Generation Configuration Object for a Static Library

To generate a PIL MEX function for a specified entry-point function, create a code configuration object for a static library and set the verification mode to 'PIL'. Set the target language to C++.

```
% cfg = coder.config('lib', 'ecoder', true);
% cfg.VerificationMode = 'PIL';
% cfg.TargetLang = 'C++';
```

Set Up a Configuration Object for Deep Learning Code Generation

Create a `coder.ARMNEONConfig` object. Specify the Compute Library version. For this example, suppose that the ARM Compute Library in the Raspberry Pi hardware is version 19.05.

```
% dlcfg = coder.DeepLearningConfig('arm-compute');
% dlcfg.ArmComputeVersion = '19.05';
```

Set the `DeepLearningConfig` property of the code generation configuration object to the deep learning configuration object.

```
% cfg.DeepLearningConfig = dlcfg;
```

Create a Connection to the Raspberry Pi

Use the MATLAB Support Package for Raspberry Pi Support Package function, `raspi`, to create a connection to the Raspberry Pi. In the following code, replace:

- `raspiname` with the name of your Raspberry Pi
- `username` with your user name
- `password` with your password

```
% r = raspi('raspiname','username','password');
```

Configure Code Generation Hardware Parameters for Raspberry Pi

Create a `coder.Hardware` object for Raspberry Pi and attach it to the code generation configuration object.

```
% hw = coder.hardware('Raspberry Pi');
% cfg.Hardware = hw;
```

First Approach: Generate PIL MEX Function for LSTM Network

In this approach, you generate code for the entry-point function `rul_lstmnet_predict`.

The rul_lstmnet_predict.m entry-point function takes an entire time series data set as an input and passes it to the network for prediction. Specifically, the function uses the LSTM network that is trained in the example “Sequence Classification Using Deep Learning” on page 4-2. The function loads the network object from the `rul_lstmnet.mat` file into a persistent variable and reuses this persistent object in subsequent prediction calls. A sequence-to-sequence LSTM network enables you to make different predictions for each individual time step of a data sequence.

To display an interactive visualization of the network architecture and information about the network layers, use the `analyzeNetwork` function.

```
type('rul_lstmnet_predict.m')
```

```
function out =  rul_lstmnet_predict(in) %#codegen

% Copyright 2019 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('rul_lstmnet.mat');
end

out = mynet.predict(in);
```

To generate code by using the `codegen` (MATLAB Coder) command, use the `coder.typeof` (MATLAB Coder) function to specify the type and size of the input argument to the entry-point function. In this example, the input is of double data type with a feature dimension value of 17 and a variable sequence length. Specify the sequence length as variable-size to perform prediction on an input sequence of any length.

```
% matrixInput = coder.typeof(double(0),[17 Inf],[false true]);
```

Run the codegen command to generate a PIL based mex function `rul_lstmnet_predict_pil` on the host platform.

```
% codegen -config cfg rul_lstmnet_predict -args {matrixInput} -report
```

Run Generated PIL MEX Function on Test Data

Load the MAT-file `RULTestData`. This MAT-file stores the variables `XTest` and `YTest` that contain sample timeseries of sensor readings on which you can test the generated code. This test data is taken from the example “Sequence Classification Using Deep Learning” on page 4-2 after data pre-processing.

```
load RULTestData;
```

The `XTest` variable contains 100 input observations. Each observation has 17 features with varying sequence length.

```
XTest(1:5)
```

```
ans=5×1 cell array
    {17×31  double}
    {17×49  double}
    {17×126 double}
    {17×106 double}
    {17×98  double}
```

The `YTest` variable contains 100 output observations that correspond to the `XTest` input variable. Each output observation is a Remaining Useful Life (RUI) value, measured in cycles, for each time step data in entire sequence.

```
YTest(1:5)
```

```
ans=5×1 cell array
    {[
    {[
    {[150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150 150
```

```
    {[                                                                  150 150 150 150 150 150
    {[                                                                                          ]
```

Run the generated MEX function `rul_lstmnet_predict_pil` on a random test data set.

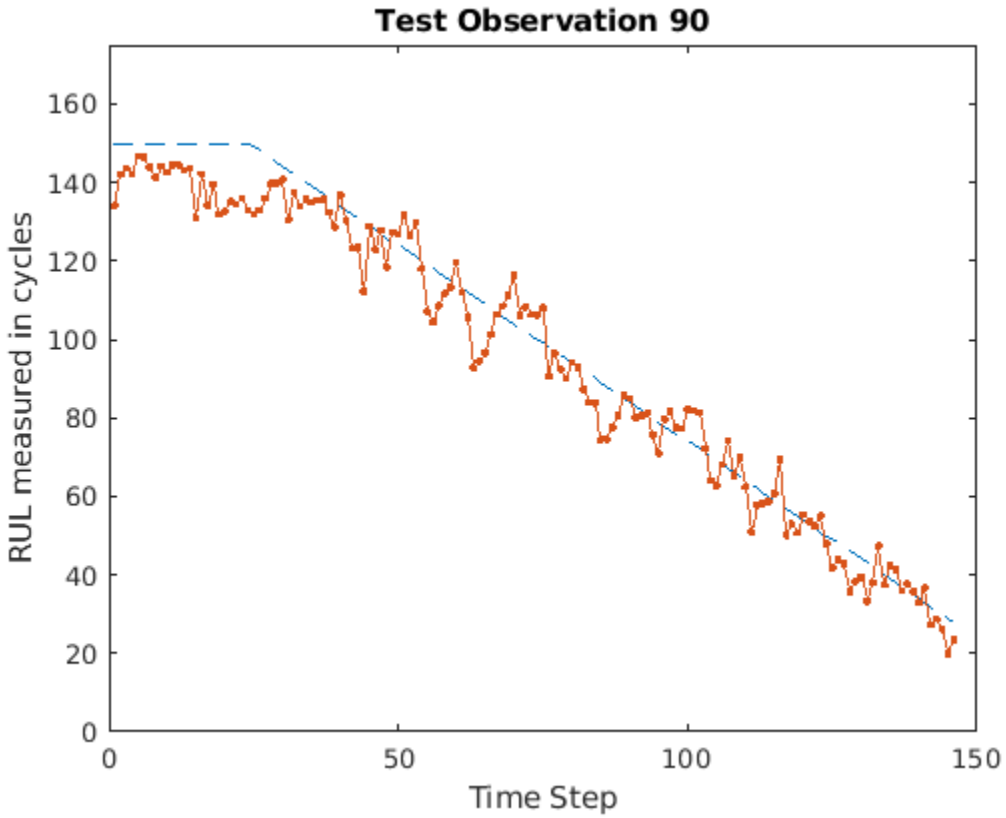
```
% idx = randperm(numel(XTest), 1);
% inputData = XTest{idx};

% YPred1 = rul_lstmnet_predict_pil(inputData);
```

Compare Predictions with Test Data

Use a plot to compare the MEX output data with the test data.

```
% figure('Name', 'Standard LSTM', 'NumberTitle', 'off');
%
% plot(YTest{idx},'--')
% hold on
% plot(YPred1,'.-')
% hold off
%
% ylim([0 175])
% title("Test Observation " + idx)
% xlabel("Time Step")
% ylabel("RUL measured in cycles")
```



Clear PIL

```
% clear rul_lstmnet_predict_pil;
```

Second Approach: Generate PIL MEX Function for Stateful LSTM Network

Instead of passing the entire timeseries data all at once to `predict`, you can run prediction by streaming the input data segment-wise by using the `predictAndUpdateState` function.

The entry-point function rul_lstmnet_predict_and_update.m accepts a single-timestep input and processes it by using the `predictAndUpdateState` function. `predictAndUpdateState` returns a prediction for the input timestep and updates the network so that subsequent parts of the input are treated as subsequent timesteps of the same sample.

```
type('rul_lstmnet_predict_and_update.m')
```

```
function out = rul_lstmnet_predict_and_update(in) %#codegen

% Copyright 2019 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('rul_lstmnet.mat');
end

[mynet, out] = predictAndUpdateState(mynet, in);

end
```

Create the input type for the `codegen` command. Because `rul_lstmnet_predict_and_update` accepts a single timestep data in each call, specify the input type `matrixInput` to have a fixed sequence length of 1 instead of a variable sequence length.

```
% matrixInput = coder.typeof(double(0),[17 1]);
```

Run the `codegen` command to generate PIL based mex function `rul_lstmnet_predict_and_update_pil` on the host platform.

```
% codegen -config cfg rul_lstmnet_predict_and_update -args {matrixInput} -report
```

Run Generated PIL MEX Function on Test Data

```
% Run generated MEX function(|rul_lstmnet_predict_and_update_pil|) for each
% time step data in the inputData sequence.

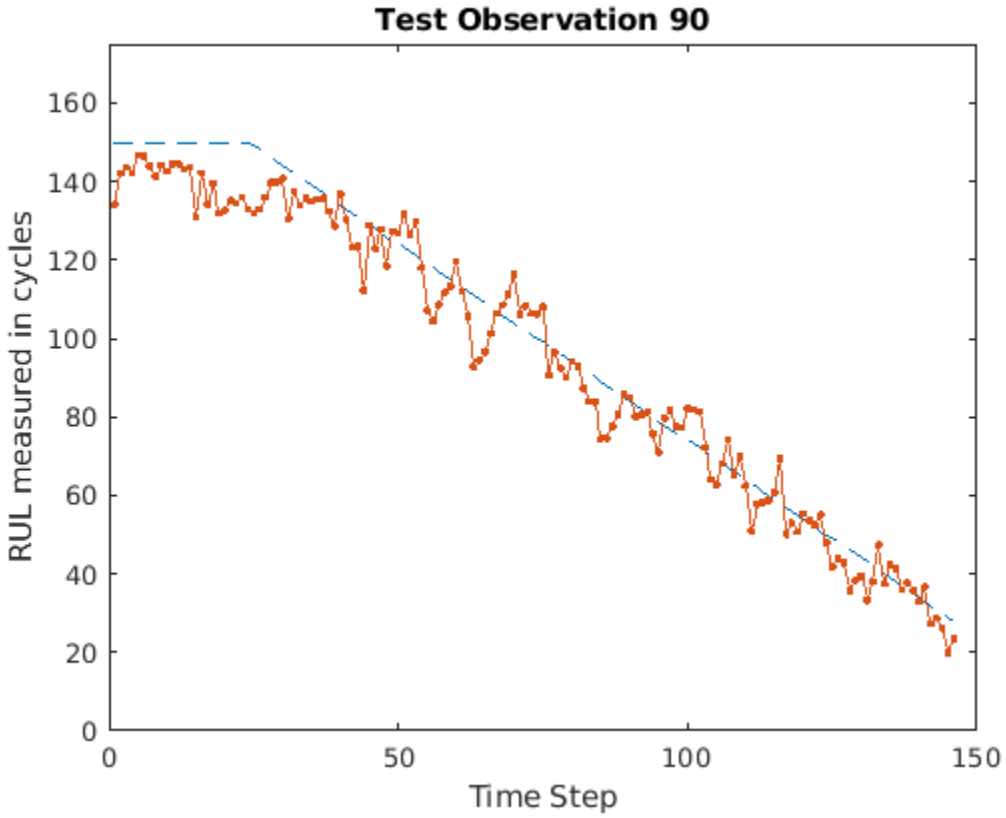
% sequenceLength = size(inputData,2);
% YPred2 = zeros(1, sequenceLength);
% for i=1:sequenceLength
%     inTimeStep = inputData(:,i);
%     YPred2(:, i) = rul_lstmnet_predict_and_update_pil(inTimeStep);
% end
```

After you pass all timesteps, one at a time, to the `rul_lstmnet_predict_and_update` function, the resulting output is the same as that in the first approach in which you passed all inputs at once.

Compare Predictions with Test Data

Use a plot to compare the MEX output data with the test data.

```
% figure('Name', 'Statefull LSTM', 'NumberTitle', 'off');
%
%
% plot(YTest{idx},'--')
% hold on
% plot(YPred2,'.-')
% hold off
%
% ylim([0 175])
% title("Test Observation " + idx)
% xlabel("Time Step")
% ylabel("RUL measured in cycles")
```



Clear PIL

```
% clear rul_lstmnet_predict_and_update_pil;
```

Code Generation for LSTM Network That Uses Intel MKL-DNN

This example shows how to generate code for a pretrained long short-term memory (LSTM) network that uses the Intel Math Kernel Library for Deep Neural Networks (MKL-DNN).This example generates a MEX function that makes predictions for each step of an input timeseries. The example demonstrates two approaches. The first approach uses a standard LSTM network. The second approach leverages the stateful behavior of the same LSTM network. This example uses textual descriptions of factory events that can be classified into one of these four categories: Electronic Failure, Leak, Mechanical Failure, and Software Failure. The example uses a pretrained LSTM network. For more information on training a network, see the “Classify Text Data Using Deep Learning” (Text Analytics Toolbox).

Third-Party Prerequisites

- Intel Math Kernel Library for Deep Neural Networks (MKL-DNN)
- For a list of processors that support the MKL-DNN library, see MKLDNN CPU Support
- For more information on the supported versions of the compilers and libraries, see “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder)

This example is supported on Mac®, Linux® and Windows® platforms and not supported for MATLAB Online.

Prepare Input

Load the `wordEncoding` MAT-file. This MAT-file stores the words encoded as numerical indices. This encoding was performed during the training of the network. For more information, see “Classify Text Data Using Deep Learning” (Text Analytics Toolbox).

```
load("wordEncoding.mat");
```

Create a string array containing the new reports to classify the event type.

```
reportsNew = [ ...
    "Coolant is pooling underneath sorter."
    "Sorter blows fuses at start up."
    "There are some very loud rattling sounds coming from the assembler."
    "At times mechanical arrangement software freezes."
    "Mixer output is stuck."];
```

Tokenize the input string by using the `preprocessText` function.

```
documentsNew = preprocessText(reportsNew);
```

Use the `doc2sequence` (Text Analytics Toolbox) function to convert documents to sequences.

```
XNew = doc2sequence(enc,documentsNew);
labels = categorical({'Electronic Failure', 'Leak', 'Mechanical Failure', 'Software Failure'});
```

The `lstm_predict` Entry-Point Function

A sequence-to-sequence LSTM network enables you to make different predictions for each individual time step of a data sequence. The `lstm_predict.m` entry-point function takes an input sequence and passes it to a trained LSTM network for prediction. Specifically, the function uses the LSTM network that is trained in the example “Classify Text Data Using Deep Learning” (Text Analytics Toolbox). The function loads the network object from the `textClassifierNetwork.mat` file into a

persistent variable and then performs prediction. On subsequent calls, the function reuses the persistent object.

```
type('lstm_predict.m')
```

```
function out = lstm_predict(in)
%#codegen

%   Copyright 2020 The MathWorks, Inc.

    persistent mynet;

    if isempty(mynet)
        mynet = coder.loadDeepLearningNetwork('textClassifierNetwork.mat');
    end

    out = predict(mynet, in);
end
```

To display an interactive visualization of the network architecture and information about the network layers, use the `analyzeNetwork` function.

Generate MEX

To generate code, create a code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` function to create a MKL-DNN deep learning configuration object. Assign it to the `DeepLearningConfig` property of the code configuration object.

```
cfg = coder.config('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('mkldnn');
```

Use the `coder.typeof` (MATLAB Coder) function to specify the type and size of the input argument to the entry-point function. In this example, the input is of double data type with a feature dimension value of 1 and a variable sequence length.

```
matrixInput = coder.typeof(double(0),[1 Inf],[false true]);
```

Generate a MEX function by running the `codegen` (MATLAB Coder) command.

```
codegen -config cfg lstm_predict -args {matrixInput} -report
```

```
Code generation successful: View report
```

Run Generated MEX

Call `lstm_predict_mex` on the first observation.

```
YPred1 = lstm_predict_mex(XNew{1});
```

`YPred1` contains the probabilities for the four classes. Find the predicted class by calculating the index of the maximum probability.

```
[~, maxIndex] = max(YPred1);
```

Associate the indices of max probability to the corresponding label. Display the classification. From the results, you can see that the network predicted the first event to be a Leak.

```
predictedLabels1 = labels(maxIndex);
disp(predictedLabels1)
```

```
     Leak
```

Generate MEX that Accepts Multiple Observations

If you want to perform prediction on many observations at once, you can group the observations together in a cell array and pass the cell array for prediction. The cell array must be a column cell array, and each cell must contain one observation. The sequence lengths of the inputs might vary. In this example, `XNew` contains five observations. To generate a MEX function that can accept `XNew` as input, specify the input type to be a 5-by-1 cell array. Specify that each cell be of the same type as `matrixInput`.

```
matrixInput = coder.typeof(double(0),[1 Inf],[false true]);
cellInput = coder.typeof({matrixInput}, [5 1]);
codegen -config cfg lstm_predict -args {cellInput} -report
```

```
Code generation successful: View report
```

Run the generated MEX function with `XNew` as input.

```
YPred2 = lstm_predict_mex(XNew);
```

`YPred2` is 5-by-4 cell array. Find the indices that have maximum probability for each of the five inputs and classify them.

```
[~, maxIndex] = max(YPred2, [], 2);
predictedLabels2 = labels(maxIndex);
disp(predictedLabels2)
```

```
     Leak      Mechanical Failure      Mechanical Failure      Software Failure      Electronic F
```

Generate MEX with Stateful LSTM

Instead of passing the entire timeseries to `predict` in a single step, you can run prediction on an input by streaming in one timestep at a time and using the function `predictAndUpdateState`. This function accepts an input, produces an output prediction, and updates the internal state of the network so that future predictions take this initial input into account.

The entry-point function `lstm_predict_and_update.m` accepts a single-timestep input and processes the input using the `predictAndUpdateState` function. The `predictAndUpdateState` function returns a prediction for the input timestep and updates the network so that subsequent inputs are treated as subsequent timesteps of the same sample. After passing in all timesteps, one at a time, the resulting output is identical to the case where all timesteps were passed in as a single input.

```
type('lstm_predict_and_update.m')
```

```
function out = lstm_predict_and_update(in)
%#codegen

%   Copyright 2020 The MathWorks, Inc.

    persistent mynet;

    if isempty(mynet)
        mynet = coder.loadDeepLearningNetwork('textClassifierNetwork.mat');
```

```
    end

    [mynet, out] = predictAndUpdateState(mynet,in);
end
```

Generate code for `lstm_predict_and_update`. Because this function accepts a single timestep at each call, specify `matrixInput` to have a fixed sequence dimension of 1 instead of a variable sequence length.

```
matrixInput = coder.typeof(double(0),[1 1]);
codegen -config cfg lstm_predict_and_update -args {matrixInput} -report
```

```
Code generation successful: View report
```

Run the generated MEX on the first observation.

```
sequenceLength = size(XNew{1},2);
for i=1:sequenceLength
    inTimeStep = XNew{1}(:,i);
    YPred3 = lstm_predict_and_update_mex(inTimeStep);
end
clear mex;
```

Find the index that has the highest probability and map it to the labels.

```
[~, maxIndex] = max(YPred3);
predictedLabels3 = labels(maxIndex);
disp(predictedLabels3)
```

```
     Leak
```

Cross Compile Deep Learning Code for ARM Neon Targets

This example shows how to cross-compile the generated deep learning code to create a library or an executable, and then deploy the library or executable on an ARM® target such as Hikey 960 or Rock 960. This example uses the `codegen` command.

Cross compiling the deep learning code for ARM® targets involves these steps:

- Configure the installed cross-compiler toolchain to perform compilation on the host MATLAB®. The compilation happens when you run the `codegen` command in MATLAB in the host computer.
- Use the `codegen` command to build the generated code and create a library or an executable on the host computer.
- Copy the generated library or executable and other supporting files to the target hardware. If you generate a library on the host computer, compile the copied makefile on the target to create an executable.
- Run the generated executable on the target ARM hardware.

You can use this workflow for any ARM Neon target that supportes the Neon|SIMD instruction set. This example is supported only for host Linux® platforms.

Prerequisites

- ARM processor that supports the Neon|SIMD extension
- ARM Compute Library (on the host computer)
- MATLAB® Coder™
- The support package MATLAB Coder Interface for Deep Learning
- Deep Learning Toolbox™
- The support package Deep Learning Toolbox Model for Inception-v3 Network
- Image Processing Toolbox™
- For deployment on armv7 (32 bit Arm Architecture) target, GNU/GCC `g++-arm-linux-gnueabihf` toolchain
- For deployment on armv8 (64 bit Arm Architecture) target, GNU/GCC `g++-aarch64-linux-gnu` toolchain
- Environment variables for the cross compilers and libraries

For information about how to install the cross-compiler toolchain and set up the associated environment variable, see “Cross-Compile Deep Learning Code That Uses ARM Compute Library” (MATLAB Coder).

The ARM Compute library version that this example uses might not be the latest version that code generation supports. For information about supported versions of libraries and about environment variables, see “Prerequisites for Deep Learning with MATLAB Coder” (MATLAB Coder).

The code lines in this example are commented out. Uncomment them before you run the example.

This example in not supported in MATLAB Online.

The `inception_predict_arm` Entry-Point Function

This example uses the Inception-V3 image classification network. A pretrained Inception-V3 network for MATLAB is available in the support package Deep Learning Toolbox Model for Inception-V3

Network. The `inception_predict_arm` entry-point function loads the Inception-V3 network into a persistent network object. On subsequent calls to the function, the persistent object is reused.

```
type inception_predict_arm
```

```
function out = inception_predict_arm(in)

persistent net;
if isempty(net)
    net = coder.loadDeepLearningNetwork('inceptionv3','inceptionv3');
end

out = net.predict(in);

end
```

Set up a Deep Learning Configuration Object

Create a `coder.ARMNEONConfig` object. Specify the version of the ARM Compute library.

```
dlcfg = coder.DeepLearningConfig('arm-compute');
dlcfg.ArmComputeVersion = '19.05';
```

For classifying the input image `peppers.png`, convert the image to a text file.

```
% generateImagetoTxt('peppers.png');
```

First Approach: Create Static Library for Entry-Point Function on Host

In this approach, you first cross-compile the generated code to create a static library on the host computer. You then transfer the generated static library, the ARM Compute library files, the makefile, and other supporting files to the target hardware. You run the makefile on the target hardware to generate the executable. Finally, you run the executable on the target hardware.

Set Up a Code Generation Configuration Object

Create a code generation configuration object for a static library. Specify the target language as C++.

```
cfg = coder.config('lib');
cfg.TargetLang = 'C++';
```

Attach the deep learning configuration object to the code generation configuration object.

```
cfg.DeepLearningConfig = dlcfg;
```

Configure the Cross-Compiler Toolchain

Configure the cross-compiler toolchain based on the ARM Architecture of the target device.

```
%   cfg.Toolchain =  'Linaro AArch64 Linux v6.3.1';% When the Arm Architecture is armv8
```

```
%   cfg.Toolchain =  'Linaro AArch32 Linux v6.3.1';% When the Arm Architecture is armv7
```

Generate Static Library on Host Computer by Using codegen

Use the `codegen` command to generate code for the entry-point function, build the generated code, and create static library for the target ARM architecture.

```
% codegen -config cfg inception_predict_arm -args {ones(299,299,3,'single')} -d arm_compute_cc_li
```

Copy the Generated Cross-Compiled Static Library to Target hardware

Copy the static library, the bin files, and the header files from the generated folder `arm_compute_cc_lib` to the target ARM hardware. In this code line and other code lines that follow, replace:

- password with your password
- username with your username
- hostname with the name of your device
- targetDir with the destination folder for the files

```
% system('sshpass -p password scp -r arm_compute_cc_lib/*.bin arm_compute_cc_lib/*.lib arm_comput
```

Copy the ARM Compute Library Files to Target Hardware

The executable uses the ARM Compute library files during runtime. The target board does not need header files while generating the executable and running the executable. Copy the library to the desired path.

```
% system(['sshpass -p password scp -r ' fullfile(getenv('ARM_COMPUTELIB'),'lib') ' username@hostn
```

Copy Supporting Files to Target Hardware

Copy these files to the target ARM hardware:

- Makefile `Makefile_Inceptionv3` to generate executable from static library.
- Input Image `inputimage.txt` that you want to classify.
- The text file `synsetWords.txt` that contains the ClassNames returned by `net.Layers(end).Classes`
- The main wrapper file `main_inception_arm.cpp` that calls the code generated for the `inception_predict_arm` function.

```
% system('sshpass -p password scp synsetWords.txt ./Makefile_Inceptionv3 ./inputimage.txt ./main_
```

Create the Executable on the Target

Compile the makefile on the target to generate the executable from the static library. This makefile links the static library with the main wrapper file `main_inception_arm.cpp` and generates the executable.

```
% system('sshpass -p password ssh username@hostname "make -C targetDir -f Makefile_Inceptionv3 ar
```

Run the Executable on the Target

Run the generated executable on the target. Make sure to export LD_LIBRARY_PATH that points to the ARM Compute library files while running executable.

```
% system('sshpass -p password ssh username@hostname "export LD_LIBRARY_PATH=targetDir/lib; cd tar
```

Second Approach: Create Executable for Entry-Point function on Host

In this approach, you first cross-compile the generated code to create an executable on the host computer. You then transfer the generated executable, the ARM Compute library files, and other supporting files to the target hardware. Finally, you run the executable on the target hardware.

Set Up a Code Generation Configuration Object

Create a code generation configuration object for an generating an executable. Set the target language as C++.

```
cfg = coder.config('exe');
cfg.TargetLang = 'C++';
```

Attach the deep learning configuration object to the code generation configuration object.

```
cfg.DeepLearningConfig = dlcfg;
```

Declare the main wrapper file `main_inception_arm.cpp` as the custom source file.

```
cfg.CustomSource = 'main_inception_arm.cpp';
```

Configure the Cross-Compiler Toolchain

Configure the cross-compiler toolchain based on the ARM Architecture of the target device.

```
%   cfg.Toolchain =  'Linaro AArch64 Linux v6.3.1'; % When the Arm Architecture is armv8,

%   cfg.Toolchain =  'Linaro AArch32 Linux v6.3.1';% When the Arm Architecture is armv7,
```

Generate Executable on the Host Computer by Using codegen

Use the `codegen` command to generate code for the entry-point function, build the generated code, and create an executablle for the target ARM architecture.

```
% codegen -config cfg inception_predict_arm -args {ones(299,299,3,'single')} -d arm_compute_cc_ex
```

Copy the Generated Executable to the Target Hardware

Copy the generated executable and the bin files to the target ARM hardware. In this code line and other code lines that follow, replace:

- password with your password
- username with your username
- hostname with the name of your device
- `targetDir` with the destination folder for the files

```
% system('sshpass -p password scp -r arm_compute_cc_exe/*.bin username@hostname:targetDir/');
% system('sshpass -p password scp inception_predict_arm.elf username@hostname:targetDir/');
```

Copy the ARM Compute Library Files to the Target Hardware

The executable uses the ARM Compute library files during runtime. It does not use header files at runtime. Copy the library files to the desired path.

```
% system(['sshpass -p password scp -r ' fullfile(getenv('ARM_COMPUTELIB'),'lib') ' username@hostn
```

Copy Supporting Files to the Target Hardware

Copy these files to the target ARM hardware:

- Input Image `inputimage.txt` that you want to classify.

- The text file `synsetWords.txt` that contains the ClassNames returned by `net.Layers(end).Classes`
- The main wrapper file `main_inception_arm.cpp` that calls the code generated for the `inception_predict_arm` function.

```
% system('sshpass -p password scp synsetWords.txt ./inputimage.txt ./main_inception_arm.cpp user
```

Run the Executable on the Target Hardware

Run the generated executable on the target. Make sure to export LD_LIBRARY_PATH that points to the ARM Compute library files while running executable.

```
% system('sshpass -p password ssh username@hostname "export LD_LIBRARY_PATH=targetDir/lib; cd ta
```

Transfer the Output Data from Target to MATLAB

Copy the generated output back to the current MATLAB session on the host computer.

```
% system('sshpass -p password scp username@hostname:targetDir/out.txt ./');
```

Map Prediction Scores to Labels

Map the top five prediction scores to corresponding labels in the trained network.

```
% outputImage = mapPredictionScores;

% Display the overlayed Image with Classification Scores.

% imshow(outputImage);
```

Generate Generic C/C++ Code for Sequence-to-Sequence Regression That Uses Deep Learning

This example demonstrates how to generate plain C/C++ code that does not depend on any third-party deep learning libraries for a long short-term memory (LSTM) network. You generate a MEX function that accepts time series data representing various sensors in an engine. The MEX function then makes predictions for each step of the input timeseries to predict the remaining useful life (RUL) of the engine measured in cycles.

This example uses the Turbofan Engine Degradation Simulation Data Set as described in [1] and a pretrained LSTM network to predict the remaining useful life of an engine. The network was trained on simulated time series sequence data for 100 engines and corresponding values of the remaining useful life at the end of each sequence. Each sequence in this training data has a different length and corresponds to a full run to failure (RTF) instance. For more information on training the network, see the example “Sequence-to-Sequence Regression Using Deep Learning” on page 4-47

Define Entry-Point Function `rulPredict`

The `rulPredict` entry-point function takes an input sequence and passes it to a trained sequence-to-sequence LSTM network for prediction. The function loads the network object from the `rulNetwork.mat` file into a persistent variable and reuses the persistent object on subsequent prediction calls. The LSTM network makes predictions on the partial sequence one time step at a time. At each time step, the network predicts using the value at this time step, and the network state calculated from the previous time steps only. The network updates its state between each prediction. The `predict` function returns a sequence of these predictions. The last element of the prediction corresponds to the predicted RUL for the partial sequence.

To display an interactive visualization of the network architecture and information about the network layers, use the `analyzeNetwork` function.

```
type rulPredict.m
```

```
function out = rulPredict(in)
%#codegen

% Copyright 2020 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('rulNetwork.mat');
end

% pass in input to predict method
% To prevent the function from adding padding to the data, specify the mini-batch size 1.
out = predict(mynet,in,'MiniBatchSize',1);
```

Run `rulPredict` on Test Data

Load the `TurboFanRULValidate` MAT-file. This MAT-file stores the variable `XValidate` that contains sample timeseries data for sensor readings the you use to test the entry-point function in MATLAB. Make predictions on the test data by calling the `rulPredict` method.

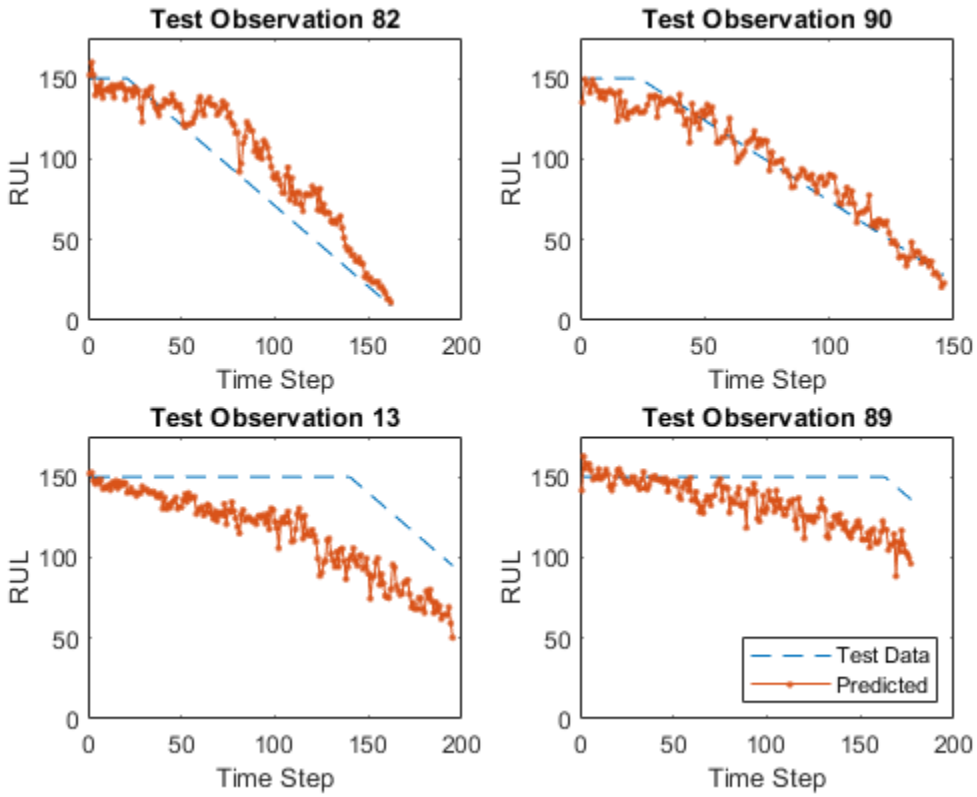
```
load TurboFanRULValidate.mat
YPred = rulPredict(XValidate);
```

Visualize some of the predictions in a plot.

```
idx = randperm(numel(YPred),4);
figure
for i = 1:numel(idx)
    subplot(2,2,i)

    plot(YValidate{idx(i)},'--')
    hold on
    plot(YPred{idx(i)},'.-')
    hold off

    ylim([0 175])
    title("Test Observation " + idx(i))
    xlabel("Time Step")
    ylabel("RUL")
end
legend(["Test Data" "Predicted"],'Location','southeast')
```



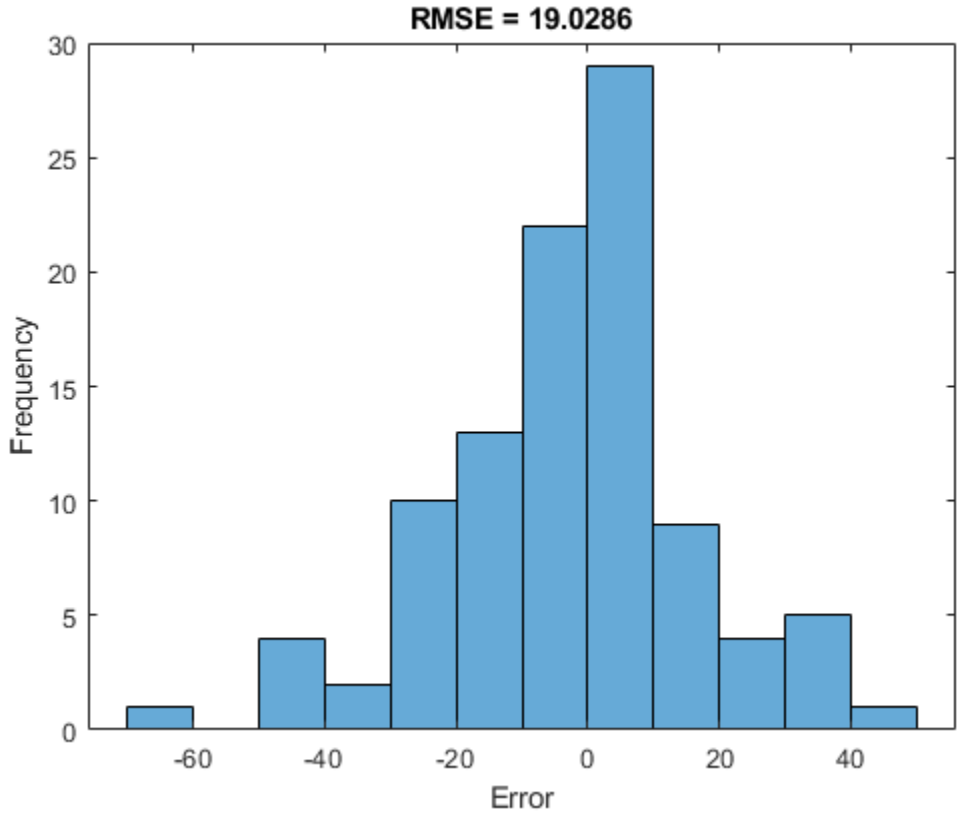
For a given partial sequence, the predicted current RUL is the last element of the predicted sequences. Calculate the root-mean-square error (RMSE) of the predictions, and visualize the prediction error in a histogram.

```
YValidateLast = zeros(1, numel(YValidate));
YPredLast = zeros(1, numel(YValidate));
for i = 1:numel(YValidate)
    YValidateLast(i) = YValidate{i}(end);
    YPredLast(i) = YPred{i}(end);
```

```
end
figure
rmse = sqrt(mean((YPredLast - YValidateLast).^2))
```

```
rmse = 19.0286
```

```
histogram(YPredLast - YValidateLast)
title("RMSE = " + rmse)
ylabel("Frequency")
xlabel("Error")
```



Generate MEX function for `rulPredict`

To generate a MEX function for the `rulPredict` entry-point function, create a code generation configuration object `cfg` for MEX code generation. Create a deep learning configuration object that specifies that no target library is required and attach this deep learning configuration object to `cfg`.

```
cfg = coder.config('mex');
cfg.DeepLearningConfig = coder.DeepLearningConfig('TargetLibrary','none');
```

By default, the target language is set to C. If you want to generate C++ code, explicitly set the target language to C++.

Use the `coder.typeof` function to create the input type for the entry-point function `rulPredict` that you use with the `-args` option in the `codegen` command.

The data `XValidate` contains 100 observations where each observation is of double data type with a feature dimension value of 17 and a variable sequence length. In order to perform prediction on

several such observations in a single function call, you can group the observations together in a cell array and pass the cell array for prediction. The cell array must be a column cell array, and each cell must contain one observation. Each observation must have the same feature dimension, but the sequence lengths might vary as is the case for `XValidate`. Specifying the sequence length as variable-size enables us to perform prediction on an input sequence of any length.

```
matrixInput = coder.typeof(0, [17 Inf],[false true]); % input type for a single observation
cellInput = coder.typeof({matrixInput}, [100 1]); % input type for multiple observations
```

Run the codegen command. Specify the input type to be `cellInput`.

```
codegen -config cfg rulPredict -args {cellInput} -report
```

```
Code generation successful: To view the report, open('codegen\mex\rulPredict\html\report.mldatx')
```

By default for MEX code generation, the generated code calls into BLAS library for matrix operations and uses OpenMP library (if the compiler supports OpenMP) so that the any parallelizable for loops in the MEX can run on multiple threads leading to better execution performance. While OpenMP is enabled by default for standalone code generation, you will have to provide a custom BLAS callback to indicate to MATLAB Coder ™ that you want to generate BLAS calls for matrix operations following the steps mentioned in “Speed Up Matrix Operations in Generated Standalone Code by Using BLAS Calls” (MATLAB Coder).

Run Generated MEX Function on Test Data

Make predictions on the test data by calling the generated MEX function `rulPredict_mex`.

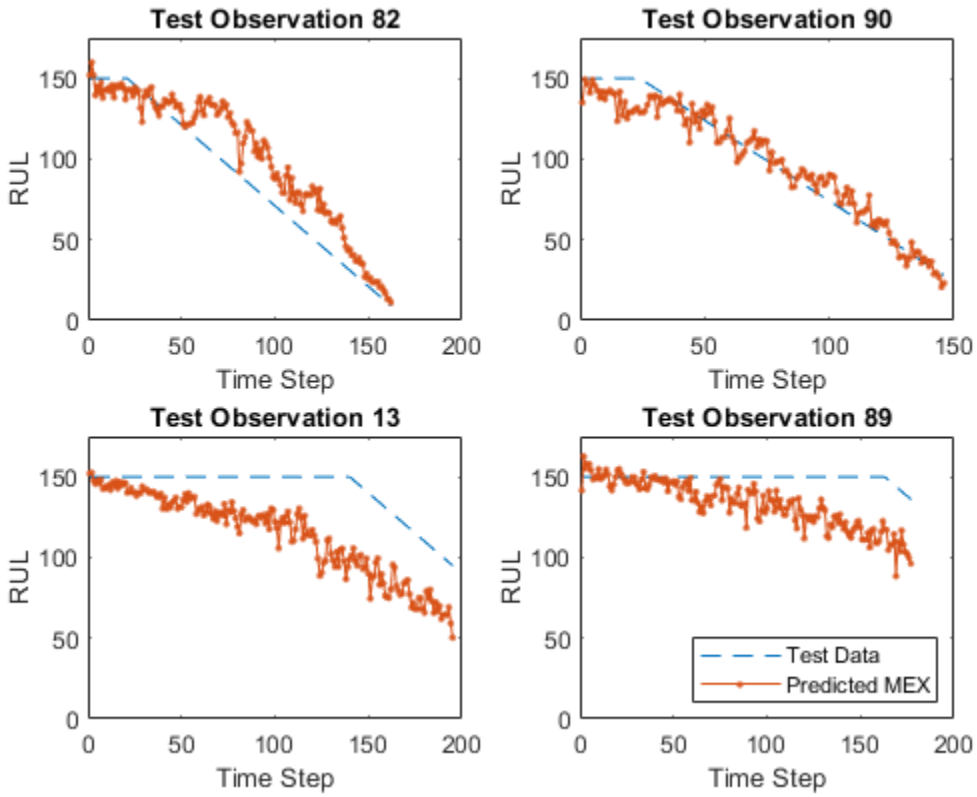
```
YPredMex = rulPredict_mex(XValidate);
```

You can visualize the same predictions as before in a plot.

```
figure
for i = 1:numel(idx)
    subplot(2,2,i)

    plot(YValidate{idx(i)},'--')
    hold on
    plot(YPredMex{idx(i)},'.-')
    hold off

    ylim([0 175])
    title("Test Observation " + idx(i))
    xlabel("Time Step")
    ylabel("RUL")
end
legend(["Test Data" "Predicted MEX"],'Location','southeast')
```

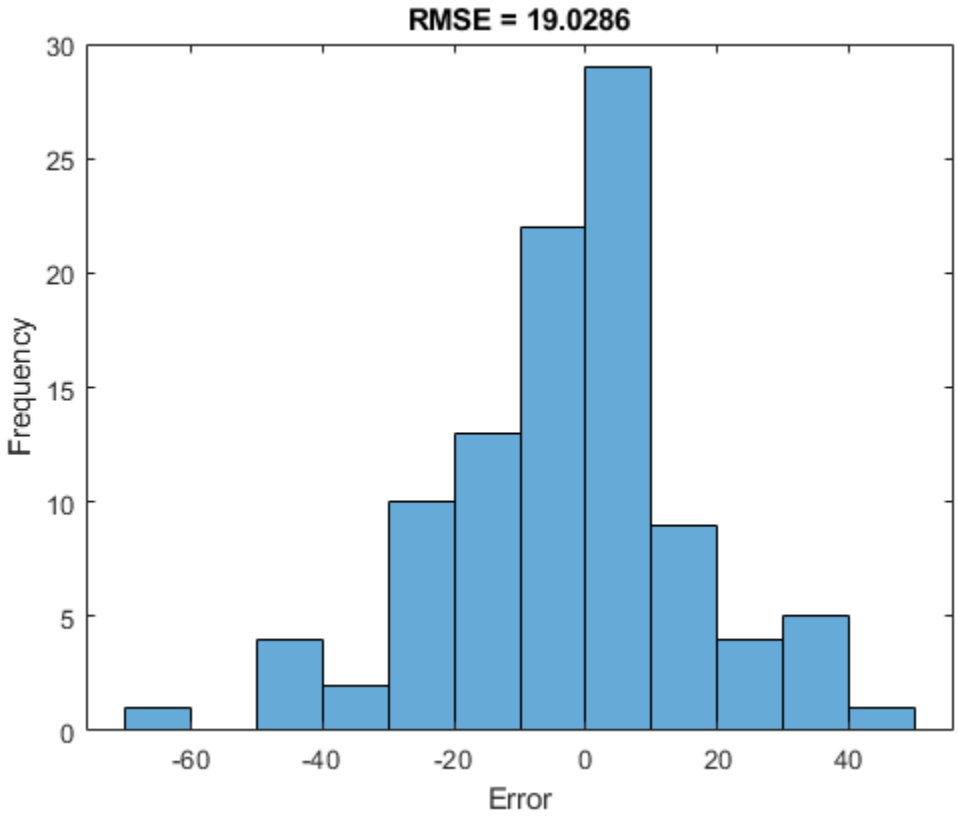


Calculate the root-mean-square error (RMSE) of the predictions, and visualize the prediction error in a histogram.

```
YPredLastMex = zeros(1, numel(YValidate));
for i = 1:numel(YValidate)
    YPredLastMex(i) = YPredMex{i}(end);
end
figure
rmse = sqrt(mean((YPredLastMex - YValidateLast).^2))
```

```
rmse = 19.0286
```

```
histogram(YPredLastMex - YValidateLast)
title("RMSE = " + rmse)
ylabel("Frequency")
xlabel("Error")
```



Generate MEX function with Stateful LSTM

Instead of passing the entire timeseries to predict in one step, you can make predictions one time step at a time by using `predictAndUpdateState`. This is useful when you have the values of the time steps arriving in a stream. The `predictAndUpdateState` function takes in an input, produces an output prediction, and updates the internal state of the network so that future predictions take this initial input into account. Usually, it is faster to make predictions on full sequences when compared to making predictions one time step at a time.

The entry-point function `rulPredictAndUpdate` takes in a single-timestep input and processes the input using the `predictAndUpdateState` function. `predictAndUpdateState` outputs a prediction for the input timestep and updates the network so that subsequent inputs are treated as subsequent timesteps of the same sample. After passing in all timesteps one at a time, the resulting output is the same as if all timesteps were passed in as a single input.

```
type rulPredictAndUpdate.m
```

```
function out = rulPredictAndUpdate(in)
%#codegen

% Copyright 2020 The MathWorks, Inc.

persistent mynet;

if isempty(mynet)
    mynet = coder.loadDeepLearningNetwork('rulNetwork.mat');
end
```

```
% pass in input to predictAndUpdateState method
[mynet, out] = predictAndUpdateState(mynet, in);
```

Run codegen on this new entry-point function. Since we are taking in a single timestep each call, we specify `matrixInput` to have a fixed sequence dimension of 1 instead of a variable sequence length.

```
matrixInput = coder.typeof(double(0),[17 1]);
codegen -config cfg rulPredictAndUpdate -args {matrixInput} -report
```

```
Code generation successful: To view the report, open('codegen\mex\rulPredictAndUpdate\html\report
```

Make predictions on the test data by calling the `rulPredictAndUpdate` function in MATLAB and the generated MEX function `rulPredictAndUpdate_mex`.

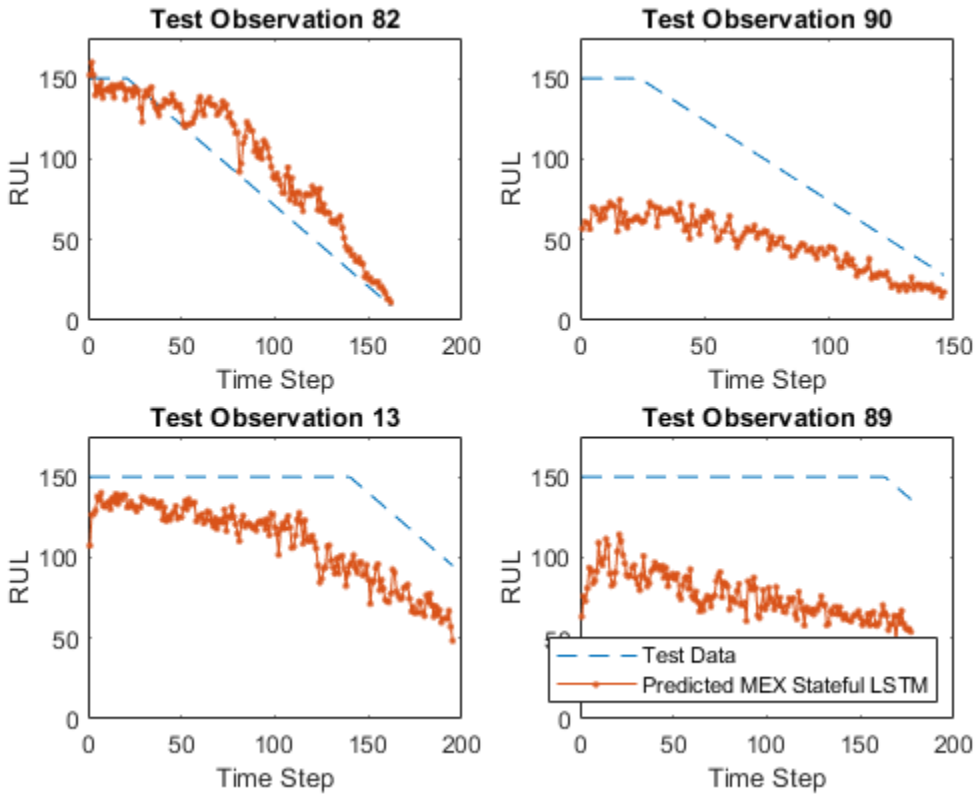
```
YPredStatefulMex = cell(numel(idx), 1);
for iSample = 1:numel(idx)
    sample = XValidate{idx(iSample)};
    numTimeStepsTest = size(sample, 2);
    for iStep = 1:numTimeStepsTest
        YPredStatefulMex{iSample}(1, iStep) = rulPredictAndUpdate_mex(sample(:, iStep));
    end
end
```

Once again you can visualize the predictions for stateful MEX as before in a plot.

```
figure
for i = 1:numel(idx)
    subplot(2,2,i)

    plot(YValidate{idx(i)},'--')
    hold on
    plot(YPredStatefulMex{i},'.-')
    hold off

    ylim([0 175])
    title("Test Observation " + idx(i))
    xlabel("Time Step")
    ylabel("RUL")
end
legend(["Test Data" "Predicted MEX Stateful LSTM"],'Location','southeast')
```



Finally you can also visualize the results for the two different MEX functions along with the MATLAB prediction in a plot for any particular sample.

```
figure()
sampleIdx = idx(1);
plot(YValidate{sampleIdx},'--')
hold on
plot(YPred{sampleIdx},'o-')
plot(YPredMex{sampleIdx},'^-')
plot(YPredStatefulMex{1},'x-')
hold off

ylim([0 175])
title("Test Observation " + idx(i))
xlabel("Time Step")
ylabel("RUL")
legend(["Test Data" "Predicted in MATLAB" "Predicted MEX" "Predicted MEX with Stateful LSTM"],'Lo
```

More About

- “Generate Generic C/C++ Code for Deep Learning Networks” (MATLAB Coder)

Quantize Residual Network Trained for Image Classification and Generate CUDA Code

This example shows how to quantize the learnable parameters in the convolution layers of a deep learning neural network that has residual connections and has been trained for image classification with CIFAR-10 data.

Neural networks use memory to store input data, parameters (weights), and activations from each layer as the input propagates through the network. Most neural networks that you create and train using Deep Learning Toolbox™ use single-precision floating point data types. Even small networks require a considerable amount of memory and hardware to perform these floating-point arithmetic operations. These restrictions can inhibit deployment of deep learning models to devices that have low computational power and less memory resources. By using a lower precision to store the weights and activations, you can reduce the memory requirements of the network.

In this example, you use the Deep Learning Toolbox in tandem with the Deep Learning Toolbox Model Quantization Library support package to reduce the memory footprint of a deep neural network by quantizing the weights, biases, and activations of convolution layers to 8-bit scaled integer data types.

The network in this example has been trained for image classification with CIFAR-10 data.

Residual connections are a popular element in convolutional neural network architectures. A residual network is a type of DAG network that has residual (or shortcut) connections that bypass the main network layers. Residual connections enable the parameter gradients to propagate more easily from the output layer to the earlier layers of the network, which makes it possible to train deeper networks. This increased network depth can result in higher accuracies on more difficult tasks. For information on the network architecture and training, see Train Residual Network for Image Classification.

To run this example, you must have the products required to quantize and deploy a deep learning network to a GPU environment. For information on these products, see Quantization Workflow Prerequisites.

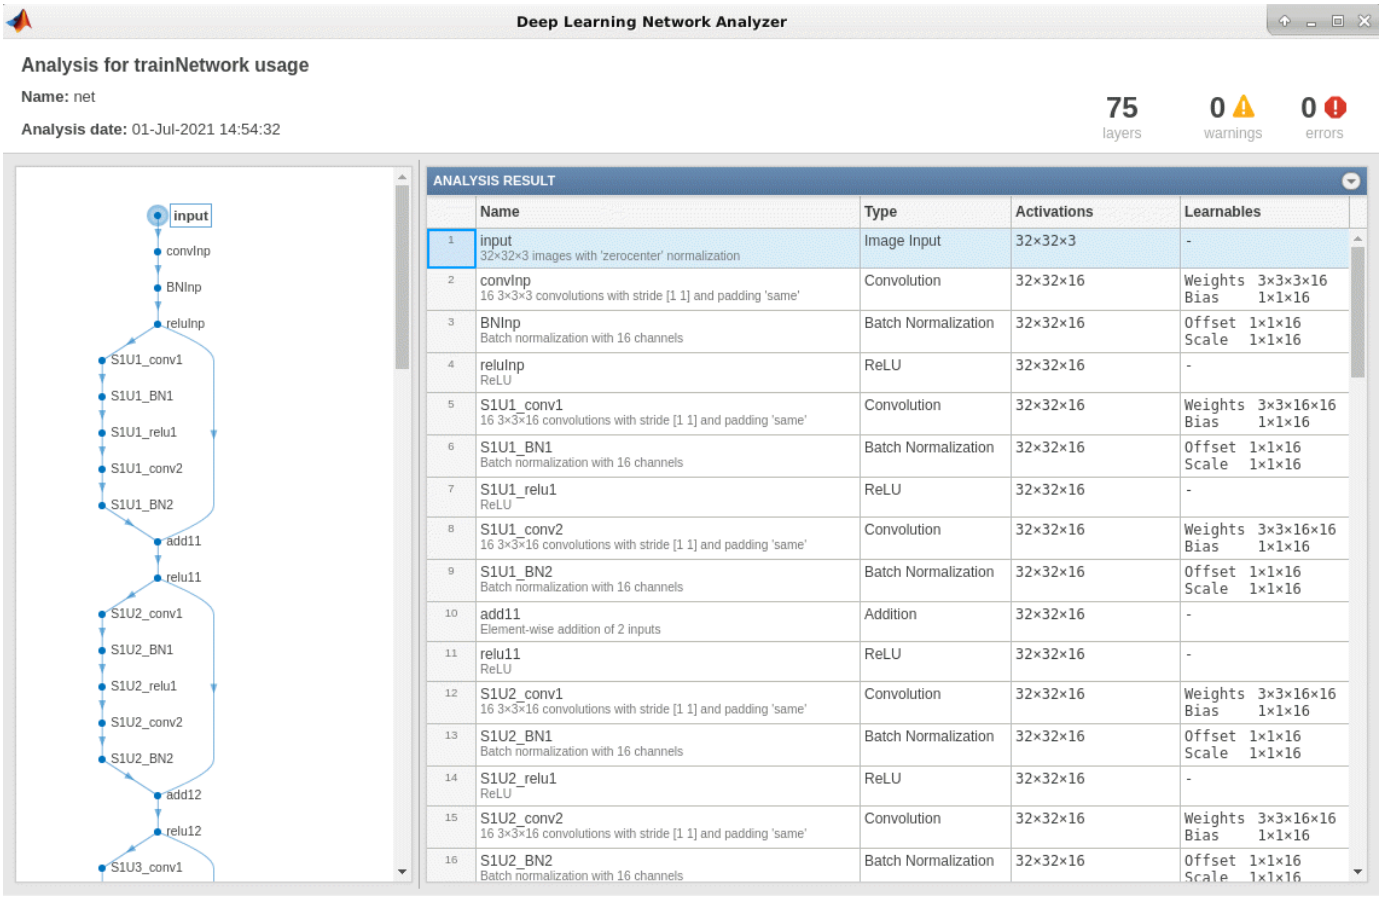
Load Pretrained Network

Load the pretrained network. For information on creating and training a network with residual connections for image classification yourself, see Train Residual Network for Image Classification.

```
load('CIFARNet-20-16.mat','trainedNet');
net = trainedNet;
```

You can use `analyzeNetwork` to analyze the deep learning network architecture.

```
analyzeNetwork(net)
```



Load Data

Download the CIFAR-10 data set [1] by executing the code below. The data set contains 60,000 images. Each image is 32-by-32 in size and has three color channels (RGB). The size of the data set is 175 MB. Depending on your internet connection, the download process can take some time.

```
datadir = tempdir;
downloadCIFARData(datadir);
```

```
Downloading CIFAR-10 dataset (175 MB). This can take a while...done.
```

Prepare Data for Calibration and Validation

Load the CIFAR-10 training and test images as 4-D arrays. The training set contains 50,000 images and the test set contains 10,000 images. Use the CIFAR-10 test images for network validation.

```
[XTrain,YTrain,XValidation,YValidation] = loadCIFARData(datadir);
```

You can display a random sample of the training images using the following code.

```
figure;
idx = randperm(size(XTrain,4),20);
im = imtile(XTrain(:,:,:,idx),'ThumbnailSize',[96,96]);
imshow(im)
```

Create an `augmentedImageDatastore` object to use for calibration and validation. Use 200 random images for calibration and 50 random images for validation.

```
inputSize = net.Layers(1).InputSize;

augimdsTrain = augmentedImageDatastore(inputSize,XTrain,YTrain);
augimdsCalibration = shuffle(augimdsTrain).subset(1:200);

augimdsValidation = augmentedImageDatastore(inputSize,XValidation,YValidation);
augimdsValidation = shuffle(augimdsValidation).subset(1:50);
```

Quantize the Network for GPU Deployment Using the Deep Network Quantizer App

This example uses a GPU execution environment. To learn about the products required to quantize and deploy the deep learning network to a GPU environment, see Quantization Workflow Prerequisites.

In the MATLAB® Command Window, open the Deep Network Quantizer app.

```
deepNetworkQuantizer
```

Select **New > Quantize a network**. The app automatically verifies your execution environment.

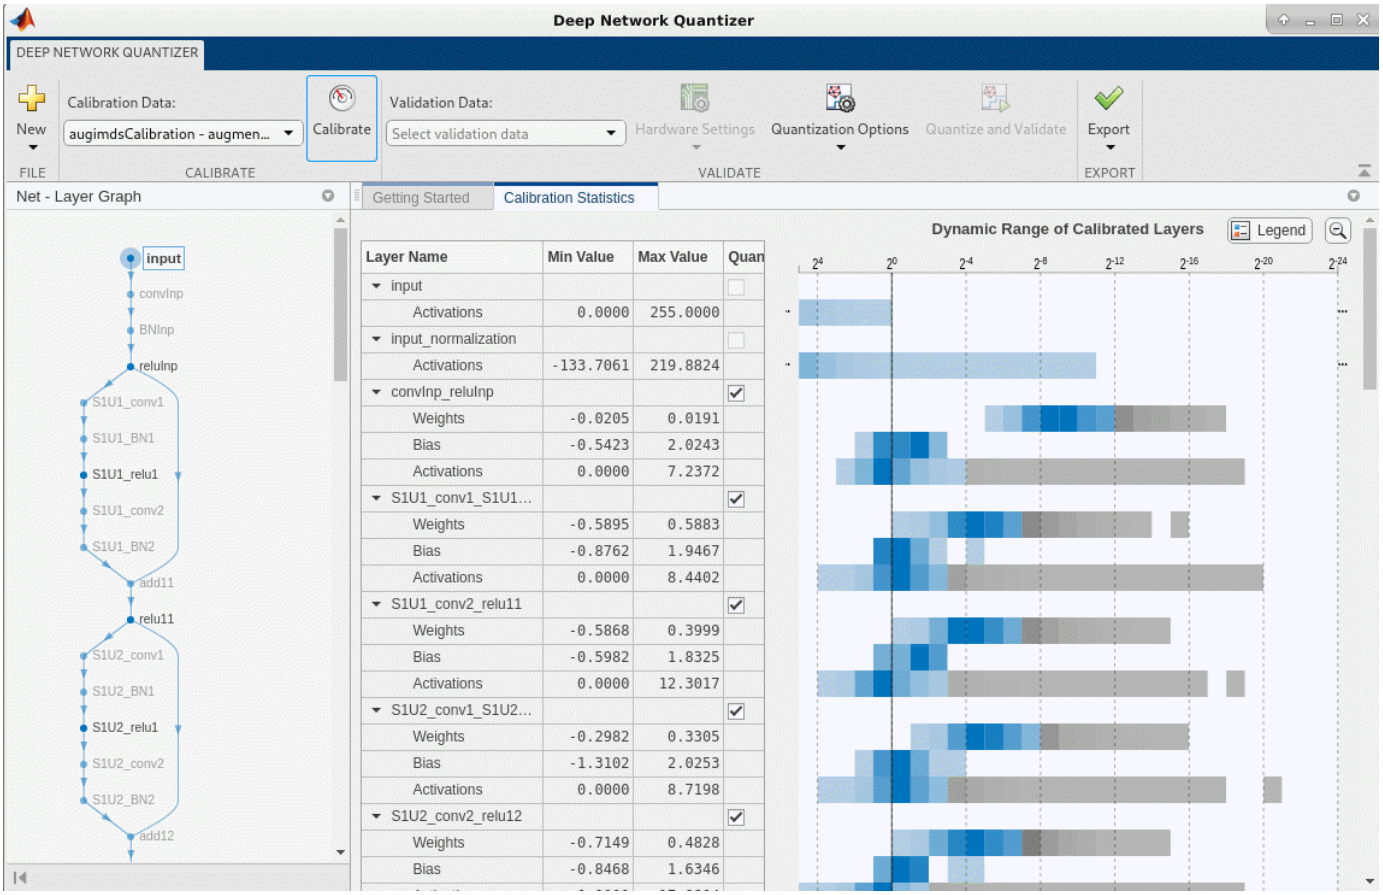
In the dialog, select the execution environment and the network to quantize from the base workspace. For this example, select a GPU execution environment and the DAG network `net`.

In the **Calibrate** section of the toolstrip, under **Calibration Data**, select the `augmentedImageDatastore` object from the base workspace containing the calibration data `augimdsCalibration`.

Click **Calibrate**.

Deep Network Quantizer uses the calibration data to exercise the network and collect range information for the learnable parameters in the network layers.

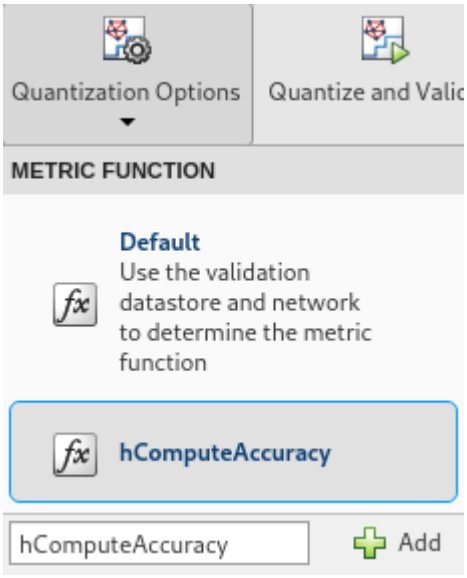
When the calibration is complete, the app displays a table containing the weights and biases in the convolution, as well as fully connected layers of the network and the dynamic ranges of the activations in all layers of the network with their minimum and maximum values during the calibration. To the right of the table, the app displays histograms of the dynamic ranges of the parameters. The gray regions of the histograms indicate data that cannot be represented by the quantized representation. For more information on how to interpret these histograms, see Quantization of Deep Neural Networks.



In the **Quantize Layer** column of the table, indicate whether to quantize the learnable parameters in the layer. Layers that are not convolution layers cannot be quantized, and therefore cannot be selected. Layers that are not quantized remain in single precision after quantization.

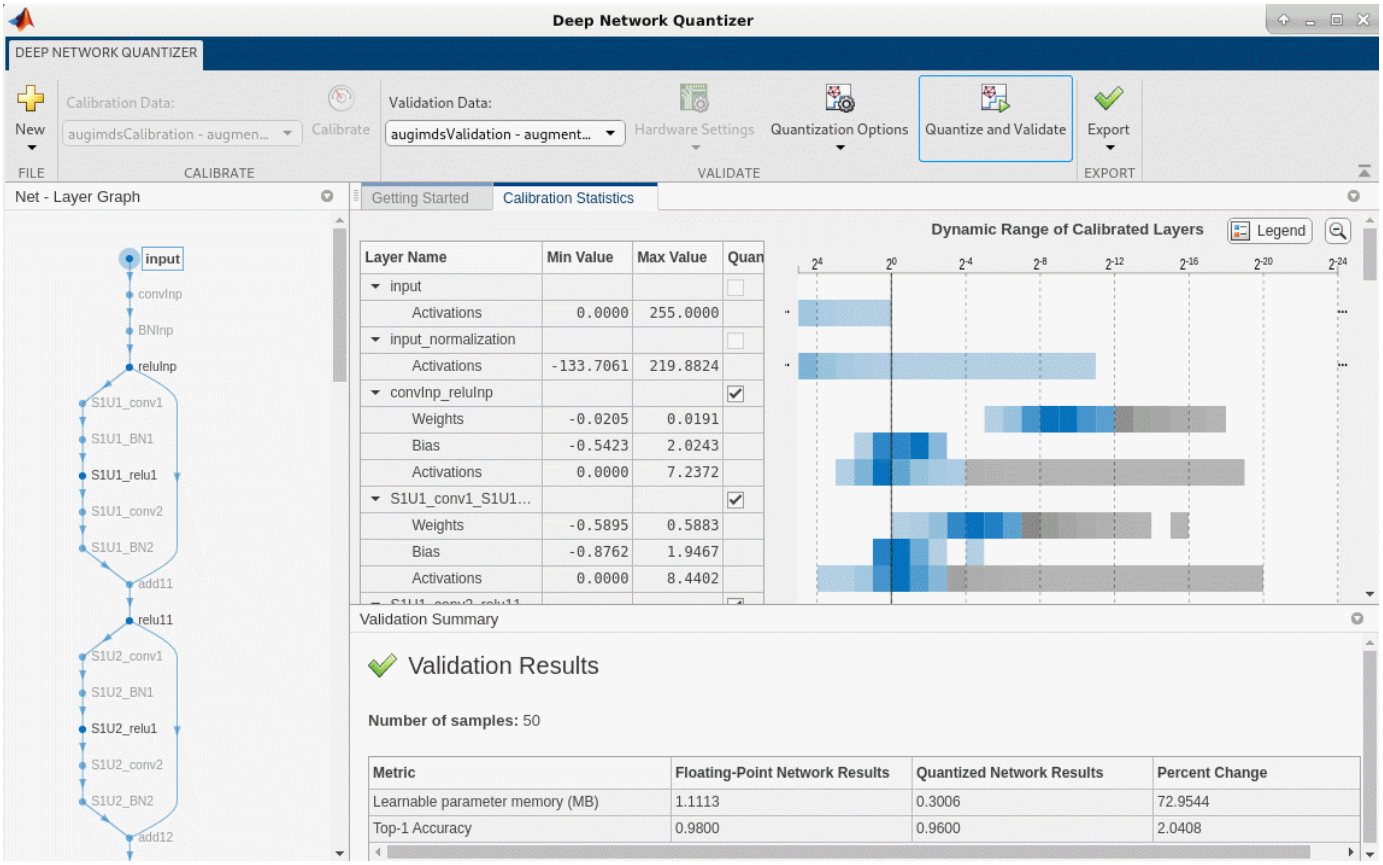
In the **Validate** section of the toolstrip, under **Validation Data**, select the `augmentedImageDatastore` object from the base workspace containing the validation data, `augimdsValidation`.

In the **Validate** section of the toolstrip, under **Quantization Options**, select the metric function to use for validation. The app determines a default metric function to use for validation based on the type of network that you quantize. You can also add additional custom metric functions to use for validation. For this example, enter the name of the custom metric function `hComputeAccuracy`. Select **Add** to add `hComputeAccuracy` to the list of metric functions available in the app. Select `hComputeAccuracy` as the metric function to use for validation. This custom metric function compares the predicted label to the ground truth and returns the top-1 accuracy. The custom metric function must be on the path.



Click **Quantize and Validate**.

The app quantizes the network and displays a summary of the validation results. For this set of calibration and validation images, quantization of the network results in a 2% decrease in accuracy with a 73% reduction in learnable parameter memory for the set of 50 validation images.



After quantizing and validating the network, you can export the quantized network or generate code. To export the quantized network, select **Export > Export Quantizer** to create a `dlquantizer` object in the base workspace. To open the GPU Coder app and generate GPU code from the quantized neural network, select **Export > Generate Code**. To learn how to generate CUDA code for a quantized deep convolutional neural network using GPU Coder, see Code Generation for Quantized Deep Learning Networks.

Validate the Performance of the Quantized Network Using Multiple Metric Functions

You can use multiple metric functions to evaluate the performance of the quantized network simultaneously by using the `dlquantizer` function.

To begin, load the pretrained network and data, and prepare the data for calibration and validation, as described above.

Create a `dlquantizer` object. Specify the network to quantize and the execution environment to use. Use the `calibrate` function to exercise the network with sample inputs from `augimdsCalibration` and collect range information.

```
dq = dlquantizer(net,'ExecutionEnvironment','GPU');
calResults = calibrate(dq,augimdsCalibration)
```

```
calResults=72×5 table

    {'S1U2_conv2_relu12_Bias'       }      {'relu12'    }            "Bias"                 -0.84
    {'S1U3_conv1_S1U3_relu1_Weights'}      {'S1U3_relu1'}            "Weights"              -0.10
    {'S1U3_conv1_S1U3_relu1_Bias'   }      {'S1U3_relu1'}            "Bias"                  -1.3
    {'S1U3_conv2_relu13_Weights'    }      {'relu13'    }            "Weights"              -0.47
    {'S1U3_conv2_relu13_Bias'       }      {'relu13'    }            "Bias"                  -1.0
    {'S2U1_conv1_S2U1_relu1_Weights'}      {'S2U1_relu1'}            "Weights"              -0.14
    {'S2U1_conv1_S2U1_relu1_Bias'   }      {'S2U1_relu1'}            "Bias"                  -1.8
      ⋮
```

Specify the metric functions in a `dlquantizationOptions` object. Use the `validate` function to quantize the learnable parameters in the convolution layers of the network and exercise the network. The `validate` function uses the metric functions defined in the `dlquantizationOptions` object to compare the results of the network before and after quantization. For this example, use the top-1 accuracy and top-5 accuracy metrics are used to evaluate the performance of the network.

```
dqOpts = dlquantizationOptions('MetricFcn',...
    {@(x)hComputeAccuracy(x,net,augimdsValidation), ...
    @(x)hComputeTop_5(x,net,augimdsValidation)});

validationResults = validate(dq,augimdsValidation,dqOpts)
```

```
validationResults = struct with fields:
       NumSamples: 50
    MetricResults: [1×2 struct]
       Statistics: [2×2 table]
```

Examine the `MetricResults.Result` field of the validation output to see the performance of the quantized network as measured by each metric function used.

```
validationResults.MetricResults.Result
```

```
ans=2×2 table
    NetworkImplementation    MetricOutput
    _____________________    ____________

     {'Floating-Point'}          0.98
     {'Quantized'     }          0.96

ans=2×2 table
    NetworkImplementation    MetricOutput
    _____________________    ____________

     {'Floating-Point'}           1
     {'Quantized'     }           1
```

```
validationResults.Statistics
```

```
ans=2×2 table
    NetworkImplementation    LearnableParameterMemory(bytes)
    _____________________    _______________________________

     {'Floating-Point'}               1.1113e+06
     {'Quantized'     }               3.0057e+05
```

To visualize the calibration statistics, first save the `dlquantizer` object `dq.`

```
save('dlquantObj.mat','dq')
```

Then import the `dlquantizer` object `dq` in the Deep Network Quantizer app by selecting **New > Import `dlquantizer` object**.

Generate CUDA Code

Generate CUDA® code for a quantized deep convolutional neural network.

Create Entry-Point Function

Write an entry-point function in MATLAB® that:

1. Uses the `coder.loadDeepLearningNetwork` function to load a deep learning model and to construct and set up a CNN class. For more information, see Load Pretrained Networks for Code Generation.
2. Calls `predict` (Deep Learning Toolbox) to predict the responses.

```
type('mynet_predict.m');
```

```
function out = mynet_predict(netFile, im)
    persistent net;
    if isempty(net)
        net = coder.loadDeepLearningNetwork(netFile);
    end
    out = net.predict(im);
end
```

A persistent object `mynet` loads the `DAGNetwork` object. The first call to the entry-point function constructs and sets up the persistent object. Subsequent calls to the function reuse the same object to call `predict` on inputs, avoiding reconstructing and reloading the network object.

Code Generation by Using codegen

To configure build settings such as the output file name, location, and type, you create coder configuration objects. To create the objects, use the `coder.gpuConfig` function. For example, when generating CUDA MEX using the codegen command, use `cfg = coder.gpuConfig('mex')`.

To specify code generation parameters for cuDNN, set the `DeepLearningConfig` property to a `coder.CuDNNConfig` object that you create by using `coder.DeepLearningConfig`.

Specify the location of the MAT file containing the calibration data.

Specify the precision of the inference computations in supported layers by using the `DataType` property. For 8-bit integers, use `'int8'`. Int8 precision requires a CUDA GPU with compute capability of 6.1, 6.3, or higher. Use the `ComputeCapability` property of the `gpuConfig` object to set the appropriate compute capability value.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
cfg.DeepLearningConfig.DataType = 'int8';
cfg.DeepLearningConfig.CalibrationResultFile = 'dlquantObj.mat';
netFile = 'mynet.mat';
save(netFile,'net');
```

Run the `codegen` command. The `codegen` command generates CUDA code from the `mynet_predict.m` entry-point function.

```
codegen -config cfg mynet_predict -args {coder.Constant(netFile), ones(inputSize, 'single')} -re
```

When code generation is successful, you can view the resulting code generation report by clicking View Report in the MATLAB Command Window. The report is displayed in the Report Viewer window. If the code generator detects errors or warnings during code generation, the report describes the issues and provides links to the problematic MATLAB code. See Code Generation Reports.

```
Code generation successful: View report
```

Quantize Object Detectors and Generate CUDA® Code

This example shows how to generate CUDA® code for an SSD vehicle detector and a YOLO v2 vehicle detector that performs inference computations in 8-bit integers.

Deep learning is a powerful machine learning technique in which you train a network to learn image features and perform detection tasks. There are several techniques for object detection using deep learning, such as Faster R-CNN, You Only Look Once (YOLO v2), and SSD. For more information, see Object Detection Using YOLO v2 Deep Learning and Object Detection Using SSD Deep Learning.

Neural network architectures used for deep learning applications contain many processing layers, including convolutional layers. Deep learning models typically work on large sets of labeled data. Performing inference on these models is computationally intensive, consuming significant amounts of memory. Neural networks use memory to store input data, parameters (weights), and activations from each layer as the input propagates through the network. Deep neural networks trained in MATLAB use single-precision floating point data types. Even networks that are small in size require a considerable amount of memory and hardware to perform these floating-point arithmetic operations. These restrictions can inhibit deployment of deep learning models to devices that have low computational power and smaller memory resources. By using a lower precision to store the weights and activations, you can reduce the memory requirements of the network.

You can use Deep Learning Toolbox in tandem with the Deep Learning Toolbox Model Quantization Library support package to reduce the memory footprint of a deep neural network by quantizing the weights, biases, and activations of convolution layers to 8-bit scaled integer data types. Then, you can use GPU Coder™ to generate CUDA code for the quantized network.

Download Pretrained Network

Download a pretrained object detector to avoid having to wait for training to complete.

```
detectorType = YOLOV2
```

```
detectorType = 2
```

```
switch detectorType
    case 1
        if ~exist('ssdResNet50VehicleExample_20a.mat','file')
            disp('Downloading pretrained detector...');
            pretrainedURL = 'https://www.mathworks.com/supportfiles/vision/data/ssdResNet50Vehic
            websave('ssdResNet50VehicleExample_20a.mat',pretrainedURL);
        end
    case 2
        if ~exist('yolov2ResNet50VehicleExample_19b.mat','file')
            disp('Downloading pretrained detector...');
            pretrainedURL = 'https://www.mathworks.com/supportfiles/vision/data/yolov2ResNet50Vel
            websave('yolov2ResNet50VehicleExample_19b.mat',pretrainedURL);
        end
end
```

```
Downloading pretrained detector...
```

Load Data

This example uses a small vehicle data set that contains 295 images. Many of these images come from the Caltech Cars 1999 and 2001 data sets, used with permission and available at the Caltech

Computational Vision website, created by Pietro Perona. Each image contains one or two labeled instances of a vehicle. A small data set is useful for exploring the training procedure, but in practice, more labeled images are needed to train a robust detector. Extract the vehicle images and load the vehicle ground truth data.

```
unzip vehicleDatasetImages.zip
data = load('vehicleDatasetGroundTruth.mat');
vehicleDataset = data.vehicleDataset;
```

Prepare Data for Training, Calibration, and Validation

The training data is stored in a table. The first column contains the path to the image files. The remaining columns contain the ROI labels for vehicles. Display the first few rows of the data.

```
vehicleDataset(1:4,:)
```

```
ans=4×2 table
              imageFilename                    vehicle
    ____________________________________    _______________

    {'vehicleImages/image_00001.jpg'}    {[220 136 35 28]}
    {'vehicleImages/image_00002.jpg'}    {[175 126 61 45]}
    {'vehicleImages/image_00003.jpg'}    {[108 120 45 33]}
    {'vehicleImages/image_00004.jpg'}    {[124 112 38 36]}
```

Split the data set into training, validation, and test sets. Select 60% of the data for training, 10% for calibration, and the remainder for validating the trained detector.

```
rng(0);
shuffledIndices = randperm(height(vehicleDataset));
idx = floor(0.6 * length(shuffledIndices) );

trainingIdx = 1:idx;
trainingDataTbl = vehicleDataset(shuffledIndices(trainingIdx),:);

calibrationIdx = idx+1 : idx + 1 + floor(0.1 * length(shuffledIndices) );
calibrationDataTbl = vehicleDataset(shuffledIndices(calibrationIdx),:);

validationIdx = calibrationIdx(end)+1 : length(shuffledIndices);
validationDataTbl = vehicleDataset(shuffledIndices(validationIdx),:);
```

Use `imageDatastore` and `boxLabelDatastore` to create datastores for loading the image and label data during training and evaluation.

```
imdsTrain = imageDatastore(trainingDataTbl{:,'imageFilename'});
bldsTrain = boxLabelDatastore(trainingDataTbl(:,'vehicle'));

imdsCalibration = imageDatastore(calibrationDataTbl{:,'imageFilename'});
bldsCalibration = boxLabelDatastore(calibrationDataTbl(:,'vehicle'));

imdsValidation = imageDatastore(validationDataTbl{:,'imageFilename'});
bldsValidation = boxLabelDatastore(validationDataTbl(:,'vehicle'));
```

Combine the image and box label datastores.

```
trainingData = combine(imdsTrain,bldsTrain);
calibrationData = combine(imdsCalibration,bldsCalibration);
validationData = combine(imdsValidation,bldsValidation);
```

Display one of the training images and box labels.

```
data = read(calibrationData);
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```

Define Network Parameters

To reduce the computational cost of running the example, specify a network input size that corresponds to the minimum size required to run the network.

```
inputSize = [];
switch detectorType
    case 1
        inputSize = [300 300 3]; % Minimum size for SSD
    case 2
        inputSize = [224 224 3]; % Minimum size for YOLO v2
end
```

Define the number of object classes to detect.

```
numClasses = width(vehicleDataset)-1;
```

Data Augmentation

Data augmentation is used to improve network accuracy by randomly transforming the original data during training. By using data augmentation, you can add more variety to the training data without actually having to increase the number of labeled training samples.

Use transformations to augment the training data by:

- Randomly flipping the image and associated box labels horizontally.
- Randomly scaling the image and associated box labels.
- Jitter the image color.

Note that data augmentation is not applied to the test data. Ideally, test data is representative of the original data and left unmodified for unbiased evaluation.

```
augmentedCalibrationData = transform(calibrationData,@augmentVehicleData);
```

Visualize augmented training data by reading the same image multiple times.

```
augmentedData = cell(4,1);
for k = 1:4
    data = read(augmentedCalibrationData);
    augmentedData{k} = insertShape(data{1},'Rectangle',data{2});
    reset(augmentedCalibrationData);
end

figure
montage(augmentedData,'BorderSize',10)
```

Preprocess Calibration Data

Preprocess the augmented calibration data to prepare for calibration of the network.

```
preprocessedCalibrationData = transform(augmentedCalibrationData,@(data)preprocessVehicleData(da
```

Read the preprocessed calibration data.

```
data = read(preprocessedCalibrationData);
```

Display the image and bounding boxes.

```
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```

Load and Test Pretrained Detector

Load the pretrained detector.

```
switch detectorType
    case 1
        % Load pretrained SSD detector for the example.
        pretrained = load('ssdResNet50VehicleExample_20a.mat');
        detector = pretrained.detector;
    case 2
        % Load pretrained YOLO v2 detector for the example.
        pretrained = load('yolov2ResNet50VehicleExample_19b.mat');
        detector = pretrained.detector;
end
```

As a quick test, run the detector on one test image.

```
data = read(calibrationData);
I = data{1,1};
```

```
I = imresize(I,inputSize(1:2));
[bboxes,scores] = detect(detector,I, 'Threshold', 0.4);
```

Display the results.

```
I = insertObjectAnnotation(I,'rectangle',bboxes,scores);
figure
imshow(I)
```

Validate Floating-Point Network

Evaluate the trained object detector on a large set of images to measure the performance. Computer Vision Toolbox™ provides functions to measure common object detector metrics, such as average precision (`evaluateDetectionPrecision`) and log-average miss rates (`evaluateDetectionMissRate`). For this example, use the average precision metric to evaluate performance. The average precision provides a single number that incorporates the ability of the detector to make correct classifications (`precision`) and the ability of the detector to find all relevant objects (`recall`).

Apply the same preprocessing transform to the test data as for the training data. Note that data augmentation is not applied to the test data. Ideally, test data is representative of the original data and left unmodified for unbiased evaluation.

```
preprocessedValidationData = transform(validationData,@(data)preprocessVehicleData(data,inputSize
```

Run the detector on all the test images.

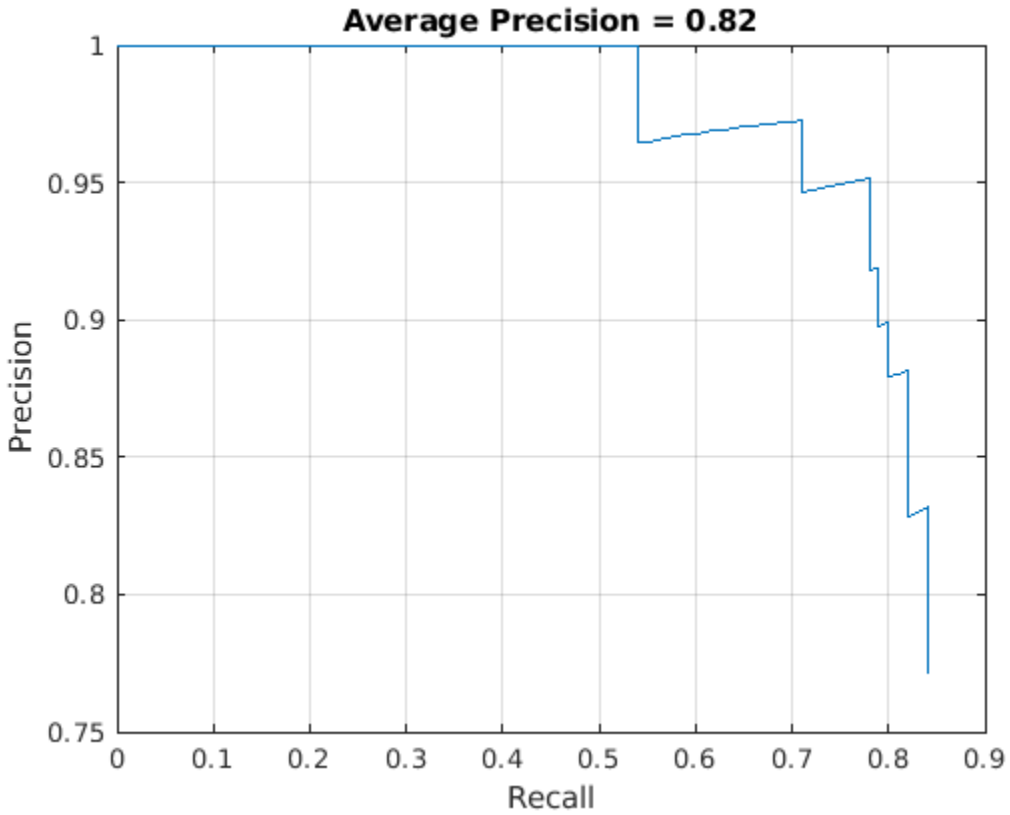
```
detectionResults = detect(detector, preprocessedValidationData,'Threshold',0.4);
```

Evaluate the object detector using average precision metric.

```
[ap,recall,precision] = evaluateDetectionPrecision(detectionResults,preprocessedValidationData);
```

The precision/recall (PR) curve highlights how precise a detector is at varying levels of recall. Ideally, the precision is 1 at all recall levels. Using more data can help improve the average precision, but might require more training time. Plot the PR curve.

```
figure
plot(recall,precision)
xlabel('Recall')
ylabel('Precision')
grid on
title(sprintf('Average Precision = %.2f',ap))
```



Quantize Network

Create a `dlquantizer` object and specify the detector to quantize. By default, the execution environment is set to GPU. To learn about the products required to quantize and deploy the detector to a GPU environment, see Quantization Workflow Prerequisites.

```
quantObj = dlquantizer(detector)
```

```
quantObj =
  dlquantizer with properties:

          NetworkObject: [1×1 yolov2ObjectDetector]
    ExecutionEnvironment: 'GPU'
```

Specify the metric function in a `dlquantizationOptions` object.

```
quantOpts = dlquantizationOptions;
quantOpts = dlquantizationOptions('MetricFcn', ...
    {@(x)hVerifyDetectionResults(x, detector.Network, preprocessedValidationData)});
```

Use the `calibrate` function to exercise the network with sample inputs and collect range information. The `calibrate` function exercises the network and collects the dynamic ranges of the weights and biases in the convolution and fully connected layers of the network, as well as the dynamic ranges of the activations in all layers of the network. The function returns a table. Each row of the table contains range information for a learnable parameter of the optimized network.

```
calResults = calibrate(quantObj,preprocessedCalibrationData)
```

```
calResults=147×5 table
                Optimized Layer Name                 Network Layer Name      Learnables / Activat
    ____________________________________________    ____________________    ____________________

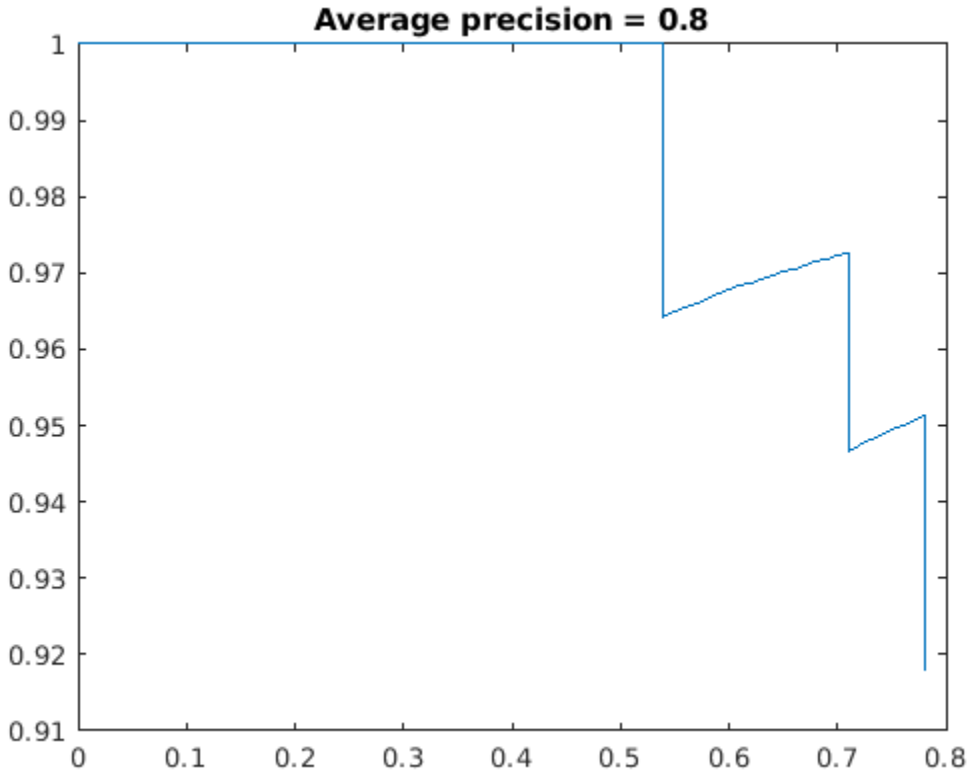
    {'conv1_activation_1_relu_Bias'            }    {'activation_1_relu'}          "Bias"
    {'res2a_branch2a_activation_2_relu_Weights'}    {'activation_2_relu'}          "Weights"
    {'res2a_branch2a_activation_2_relu_Bias'   }    {'activation_2_relu'}          "Bias"
    {'res2a_branch2b_activation_3_relu_Weights'}    {'activation_3_relu'}          "Weights"
    {'res2a_branch2b_activation_3_relu_Bias'   }    {'activation_3_relu'}          "Bias"
    {'res2a_branch1_Weights'                   }    {'bn2a_branch1'     }          "Weights"
    {'res2a_branch1_Bias'                      }    {'bn2a_branch1'     }          "Bias"
    {'res2a_branch2c_activation_4_relu_Weights'}    {'activation_4_relu'}          "Weights"
    {'res2a_branch2c_activation_4_relu_Bias'   }    {'activation_4_relu'}          "Bias"
    {'res2b_branch2a_activation_5_relu_Weights'}    {'activation_5_relu'}          "Weights"
    {'res2b_branch2a_activation_5_relu_Bias'   }    {'activation_5_relu'}          "Bias"
    {'res2b_branch2b_activation_6_relu_Weights'}    {'activation_6_relu'}          "Weights"
    {'res2b_branch2b_activation_6_relu_Bias'   }    {'activation_6_relu'}          "Bias"
    {'res2b_branch2c_activation_7_relu_Weights'}    {'activation_7_relu'}          "Weights"
    {'res2b_branch2c_activation_7_relu_Bias'   }    {'activation_7_relu'}          "Bias"
      ⋮
```

Use the `validate` function to quantize the learnable parameters in the convolution layers of the network and exercise the network. The function uses the metric function defined in the `dlquantizationOptions` object to compare the results of the network before and after quantization.

Examine the `MetricResults.Result` field of the validation output to see the performance of the quantized network. The first row in the results table contains the information for the original, floating-point implementation. The second row contains the information for the quantized implementation. The output of the metric function is displayed in the `MetricOutput` column.

```
valResults = validate(quantObj,preprocessedValidationData,quantOpts)
```



Average precision = 0.8
1
0.99

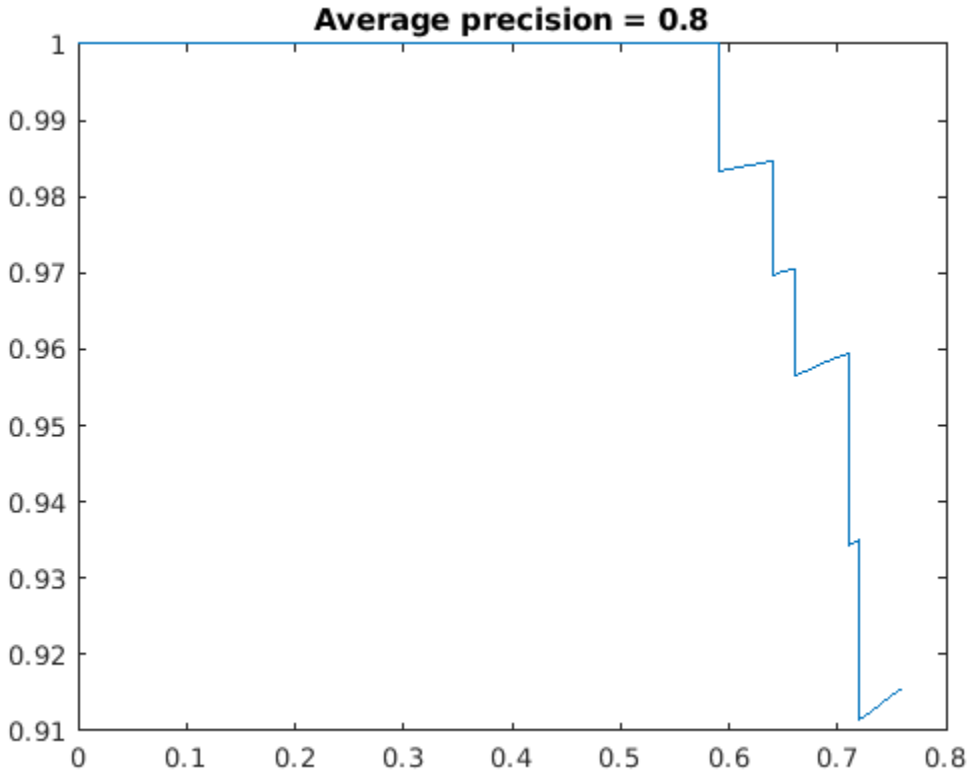
0.94
0.93
0.92
0.91
0
0.1
0.2
0.3
0.4
0.5
0.6
0.7
0.8



```
valResults = struct with fields:
       NumSamples: 88
    MetricResults: [1×1 struct]
       Statistics: [2×2 table]
```

```
valResults.MetricResults.Result
```

```
ans=2×2 table
    NetworkImplementation    MetricOutput
    _____________________    ____________

     {'Floating-Point'}        0.77119
     {'Quantized'     }        0.75244
```

The metrics show that quantization reduces the required memory by approximately 75% and the network accuracy by approximately 3%.

To visualize the calibration statistics, use the Deep Network Quantizer app. First, save the `dlquantizer` object.

```
save('dlquantObj.mat','quantObj')
```

In the MATLAB® Command Window, open the Deep Network Quantizer app.

```
deepNetworkQuantizer
```

Then import the `dlquantizer` object `dq` in the Deep Network Quantizer app by selecting **New > Import `dlquantizer` object**.

Generate CUDA Code

After you train and evaluate the detector, you can generate code for the `ssdObjectDetector` or `yolov2ObjectDetector` using GPU Coder™. For more details, see “Code Generation for Object Detection by Using Single Shot Multibox Detector” (Computer Vision Toolbox) and “Code Generation for Object Detection by Using YOLO v2” (GPU Coder).

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';

% Check compute capability of GPU
gpuInfo = gpuDevice;
cc = gpuInfo.ComputeCapability;

% Create deep learning code generation configuration object
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');

% INT8 precision requires a CUDA GPU with minimum compute capability of
% 6.1, 6.3, or higher
cfg.GpuConfig.ComputeCapability = cc;
cfg.DeepLearningConfig.DataType = 'int8';
cfg.DeepLearningConfig.CalibrationResultFile = 'dlquantObj.mat';
```

Run the `codegen` command to generate CUDA code.

```
codegen -config cfg mynet_detect -args {coder.Constant(detectorType), ones(inputSize, 'single')}
```

When code generation is successful, you can view the resulting code generation report by clicking View Report in the MATLAB Command Window. The report is displayed in the Report Viewer window. If the code generator detects errors or warnings during code generation, the report describes the issues and provides links to the problematic MATLAB code. See Code Generation Reports.

Parameter Pruning and Quantization of Image Classification Network

This example shows how to prune the parameters of a trained neural network using two parameter score metrics: The magnitude score [1] and Synaptic Flow score [2].

In many applications where transfer learning is used to retrain an image classification network for a new task or when a new network is trained from scratch, the optimal network architecture is not known and teh network might be overparameterized. An overparameterized network has redundant connections.. Structured pruning, also known as sparsification, is a compression technique that aims to identify redundant, unnecessary connections you can remove without affecting the network accuracy. When you use pruning in combination with network quantization, you can reduce the inference speed and memory footprint of the network making it easier to deploy.

This example shows how to:

- Perform post-training, iterative, unstructured pruning without the need for training data
- Evaluate the performance of two different pruning algorithms
- Investigate the layer-wise sparsity induced after pruning
- Evaluate the impact of pruning on classification accuracy
- Evaluate the impact of quantization on the clasification accuracy of the pruned network

This example uses a simple convolutional neural network to classify handwritten digits from 0 to 9. For more information on setting up the data used for training and validation, see Create Simple Deep Learning Network for Classification.

Load Pretrained Network and Data

Load the training and validation data. Train a convolutional neural network for the classification task.

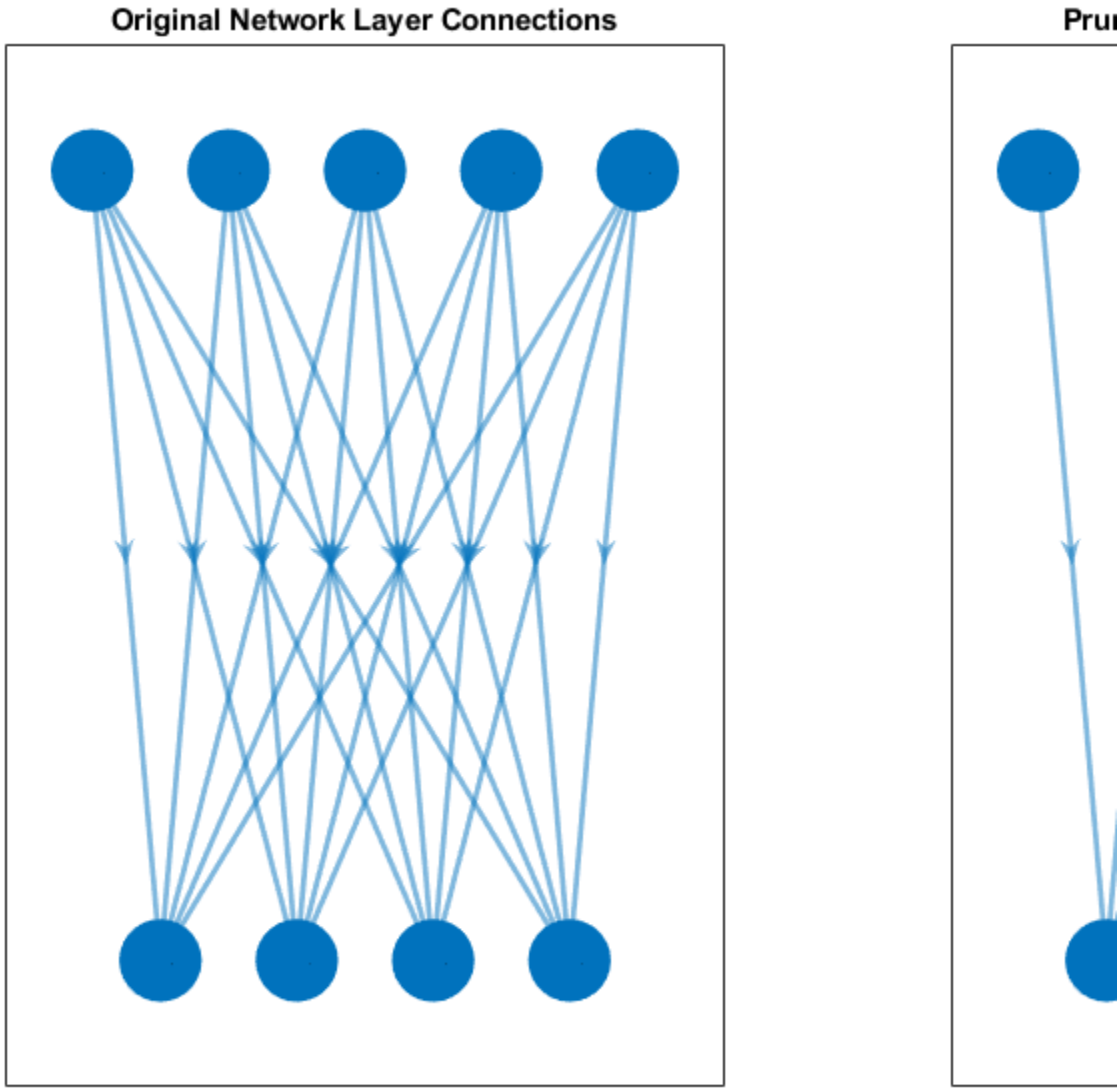
```
[imdsTrain, imdsValidation] = loadDigitDataset;
net = trainDigitDataNetwork(imdsTrain, imdsValidation);
trueLabels = imdsValidation.Labels;
classes = categories(trueLabels);
```

Create a `minibatchqueue` object containing the validation data. SetexecutionEnvironment to auto to evaluate the network on a GPU, if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see GPU Support by Release (Parallel Computing Toolbox).

```
executionEnvironment = auto;
miniBatchSize = 128;
imdsValidation.ReadSize = miniBatchSize;
mbqValidation = minibatchqueue(imdsValidation,1,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFormat','SSCB',...
    'MiniBatchFcn',@preprocessMiniBatch,...
    'OutputEnvironment',executionEnvironment);
```

Neural Network Pruning

The goal of neural network pruning is to identify and remove unimportant connections to reduce the size of the network without affecting network accuracy. In the following figure, on the left, the network has connections that map each neuron to the neuron of the next layer. After pruning, the network has fewer connections than the original network.

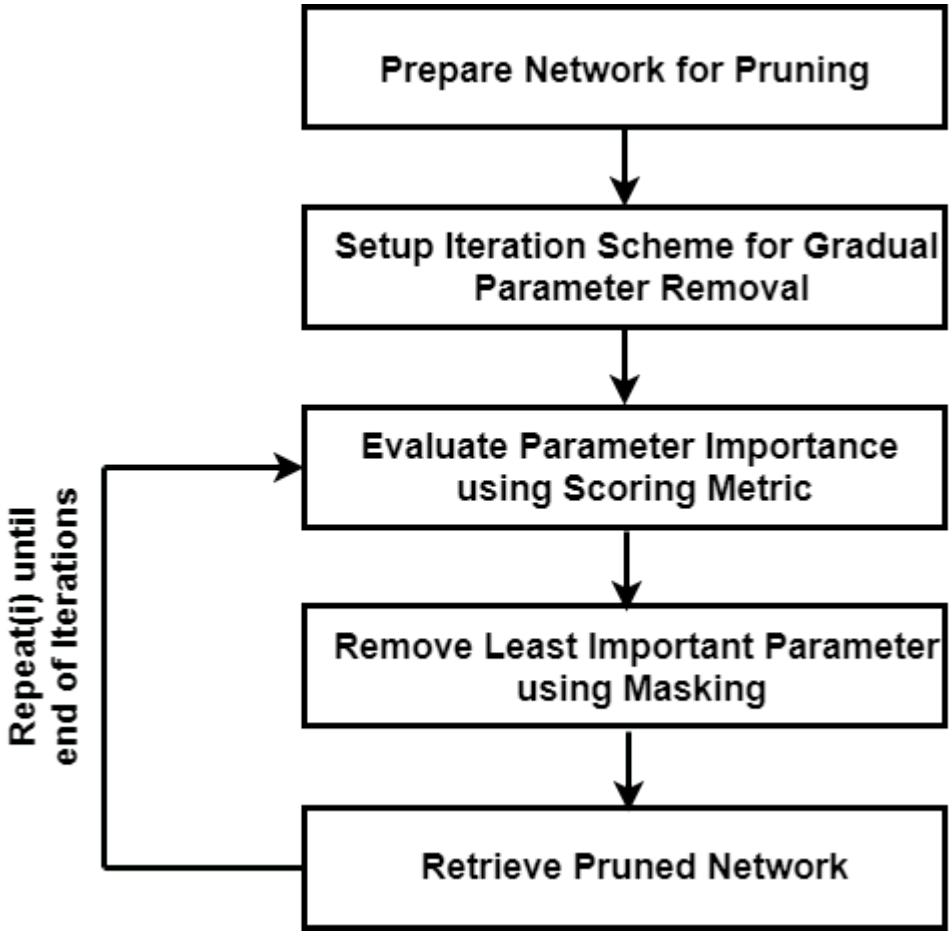


A pruning algorithm assigns a score to each parameter in the network. The score ranks the importance of each connection in the network. You can use one of two pruning approaches to achieve a target sparsity:

- One-shot pruning - Remove a specified percentage of connections based on their score in one step. This method is prone to layer collapse when you specify a high sparsity value.
- Iterative pruning - Achieve the target sparsity in a series of iterative steps. You can use this method when evaluated scores are sensitive to network structure. Scores are reevaluated at every iteration, so using a series of steps allows the network to move toward sparsity incrementally.

This example uses the iterative pruning method to achieve a target sparsity.

Iterative Pruning



Convert to `dlnetwork` Object

In this example, you use the Synaptic Flow algorithm, which requires that you create a custom cost function and evaluate the gradients with respect to the cost function to calculate the parameter score. To create a custom cost function, first convert the pretrained network to a `dlnetwork`.

Convert the network to a layer graph and remove the layers used for classification using `removeLayers`.

```
lgraph = layerGraph(net.Layers);
lgraph = removeLayers(lgraph,["softmax","classoutput"]);
dlnet = dlnetwork(lgraph);
```

Use `analyzeNetwork` to analyze the network architecture and learnable parameters.

```
analyzeNetwork(dlnet)
```

Evaluate the accuracy of the network before pruning.

```
accuracyOriginalNet = evaluateAccuracy(dlnet,mbqValidation,classes,trueLabels)
```

```
accuracyOriginalNet = 0.9900
```

The layers with learnable parameters are the 3 convolution layers and one fully connected layer. The network initially consists of total 21578 learnable parameters.

```
numTotalParams = sum(cellfun(@numel,dlnet.Learnables.Value))
```

```
numTotalParams = 21578
```

```
numNonZeroPerParam = cellfun(@(w)nnz(extractdata(w)),dlnet.Learnables.Value)
```

```
numNonZeroPerParam = 8×1

          72
           8
        1152
          16
        4608
          32
       15680
          10
```

Sparsity is defined as the percentage of parameters in the network with a value of zero. Check the sparsity of the network.

```
initialSparsity = 1-sum(numNonZeroPerParam)/numTotalParams
```

```
initialSparsity = 0
```

Before pruning, the network has a sparsity of zero.

Create Iteration Scheme

To define an iterative pruning scheme, specify the target sparsity and number of iterations. For this example, use linearly spaced iterations to achieve the target sparsity.

```
numIterations = 10;
targetSparsity = 0.90;
iterationScheme = linspace(0,targetSparsity,numIterations);
```

Pruning Loop

For each iteration, the custom pruning loop in this example performs the following steps:

- Calculate the score for each connection.
- Rank the scores for all connections in the network based on the selected pruning algorithm.
- Determine the threshold for removing connections with the lowest scores.
- Create the pruning mask using the threshold.
- Apply the pruning mask to learnable parameters of the network.

Network Mask

Instead of setting entries in the weight arrays directly to zero, the pruning algorithm creates a binary mask for each learnable parameter that specifies whether a connection is pruned. The mask allows you to explore the behavior of the pruned network and try different pruning schemes without changing the underlying network structure.

For example, consider the following weights.

```
testWeight = [10.4 5.6 0.8 9];
```

Create a binary mask for each parameter in testWeight.

```
testMask = [1 0 1 0];
```

Apply the mask to `testWeight` to get the pruned weights.

```
testWeightsPruned = testWeight.*testMask
```

```
testWeightsPruned = 1×4

   10.4000         0    0.8000         0
```

In iterative pruning, you create a binary mask for each iteration that contains pruning information. Applying the mask to the weights array does not change either the size of the array or the structure of the neural network. Therefore, the pruning step does not directly result in any speedup during inference or compression of the network size on disk.

Initialize a plot that compares the accuracy of the pruned network to the original network.

```
figure
plot(100*iterationScheme([1,end]),100*accuracyOriginalNet*[1 1],'*-b','LineWidth',2,"Color","b")
ylim([0 100])
xlim(100*iterationScheme([1,end]))
xlabel("Sparsity (%)")
ylabel("Accuracy (%)")
legend("Original Accuracy","Location","southwest")
title("Pruning Accuracy")
grid on
```

Magnitude Pruning

Magnitude pruning [1] assigns a score to each parameter equal to its absolute value. It is assumed that the absolute value of a parameter corresponds to its relative importance to the accuracy of the trained network.

Initialize the mask. For the first iteration, you do not prune any parameters and the sparsity is 0%.

```
pruningMaskMagnitude = cell(1,numIterations);
pruningMaskMagnitude{1} = dlupdate(@(p)true(size(p)), dlnet.Learnables);
```

Below is an implementation of magnitude pruning. The network is pruned to various different target sparsities in a loop to provide the flexibility to choose a pruned network based on its accuracy.

```
lineAccuracyPruningMagnitude = animatedline('Color','g','Marker','o','LineWidth',1.5);
legend("Original Accuracy","Magnitude Pruning Accuracy","Location","southwest")
```

```
% Compute magnitude scores
scoresMagnitude = calculateMagnitudeScore(dlnet);

for idx = 1:numel(iterationScheme)

    prunedNetMagnitude = dlnet;

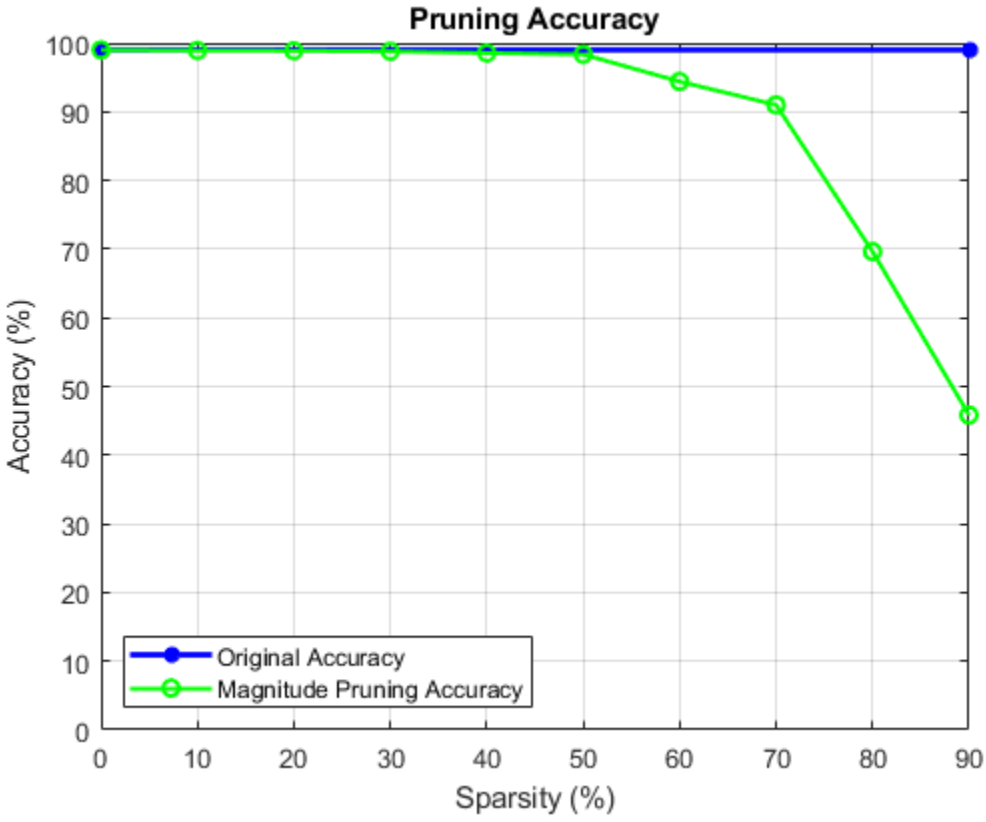
    % Update the pruning mask
    pruningMaskMagnitude{idx} = calculateMask(scoresMagnitude,iterationScheme(idx));

    % Check the number of zero entries in the pruning mask
    numPrunedParams = sum(cellfun(@(m)nnz(~extractdata(m)),pruningMaskMagnitude{idx}.Value));
    sparsity = numPrunedParams/numTotalParams;

    % Apply pruning mask to network parameters
    prunedNetMagnitude.Learnables = dlupdate(@(W,M)W.*M, prunedNetMagnitude.Learnables, pruningMa

    % Compute validation accuracy on pruned network
    accuracyMagnitude = evaluateAccuracy(prunedNetMagnitude,mbqValidation,classes,trueLabels);

    % Display the pruning progress
    addpoints(lineAccuracyPruningMagnitude,100*sparsity,100*accuracyMagnitude)
    drawnow
end
```



SynFlow Pruning

Synaptic flow conservation (SynFlow) [2] scores are used for pruning. You can use this method to prune networks that use linear activation functions such as ReLU.

Initialize the mask. For the first iteration, no parameters are pruned and the sparsity is 0%.

```
pruningMaskSynFlow = cell(1,numIterations);
pruningMaskSynFlow{1} = dlupdate(@(p)true(size(p)),dlnet.Learnables);
```

The input data you use to compute the scores is a single image containing ones. If you are using a GPU, convert the data to a `gpuArray`.

```
dlX = dlarray(ones(net.Layers(1).InputSize),'SSC');
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlX = gpuArray(dlX);
end
```

The below loop implements iterative synaptic flow score for pruning [2] where a custom cost function evaluates the SynFlow score for each parameter used for network pruning.

```
lineAccuracyPruningSynflow = animatedline('Color','r','Marker','o','LineWidth',1.5);
legend("Original Accuracy","Magnitude Pruning Accuracy","Synaptic Flow Accuracy","Location","sou

prunedNetSynFlow = dlnet;

% Iteratively increase sparsity
for idx = 1:numel(iterationScheme)
    % Compute SynFlow scores
    scoresSynFlow = calculateSynFlowScore(prunedNetSynFlow,dlX);

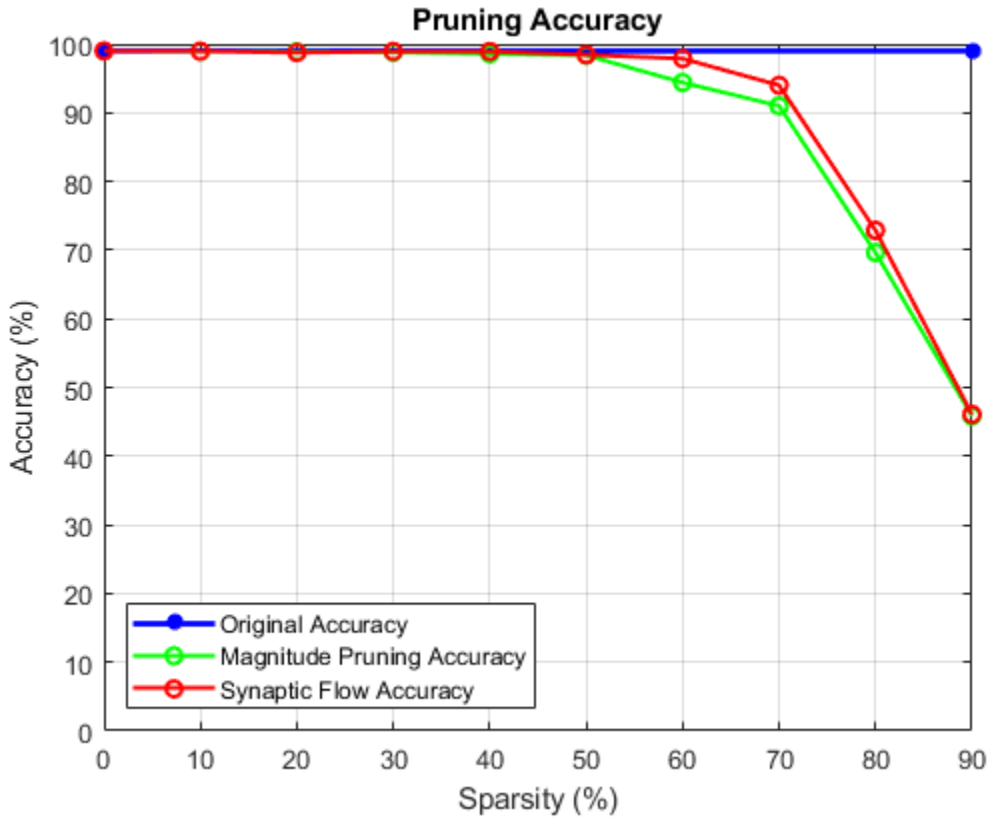
    % Update the pruning mask
    pruningMaskSynFlow{idx} = calculateMask(scoresSynFlow,iterationScheme(idx));

    % Check the number of zero entries in the pruning mask
    numPrunedParams = sum(cellfun(@(m)nnz(~extractdata(m)),pruningMaskSynFlow{idx}.Value));
    sparsity = numPrunedParams/numTotalParams;

    % Apply pruning mask to network parameters
    prunedNetSynFlow.Learnables = dlupdate(@(W,M)W.*M, prunedNetSynFlow.Learnables, pruningMaskSy

    % Compute validation accuracy on pruned network
    accuracySynFlow = evaluateAccuracy(prunedNetSynFlow,mbqValidation,classes,trueLabels);

    % Display the pruning progress
    addpoints(lineAccuracyPruningSynflow,100*sparsity,100*accuracySynFlow)
    drawnow
end
```



Investigate Structure of Pruned Network

Choosing how much to prune a network is a trade-off between accuracy and sparsity. Use the sparsity versus accuracy plot to select the iteration with the desired sparsity level and acceptable accuracy.

```
pruningMethod = "SynFlow";
selectedIteration = 8;

prunedDLNet = createPrunedNet(dlnet,selectedIteration,pruningMaskSynFlow,pruningMaskMagnitude,pru

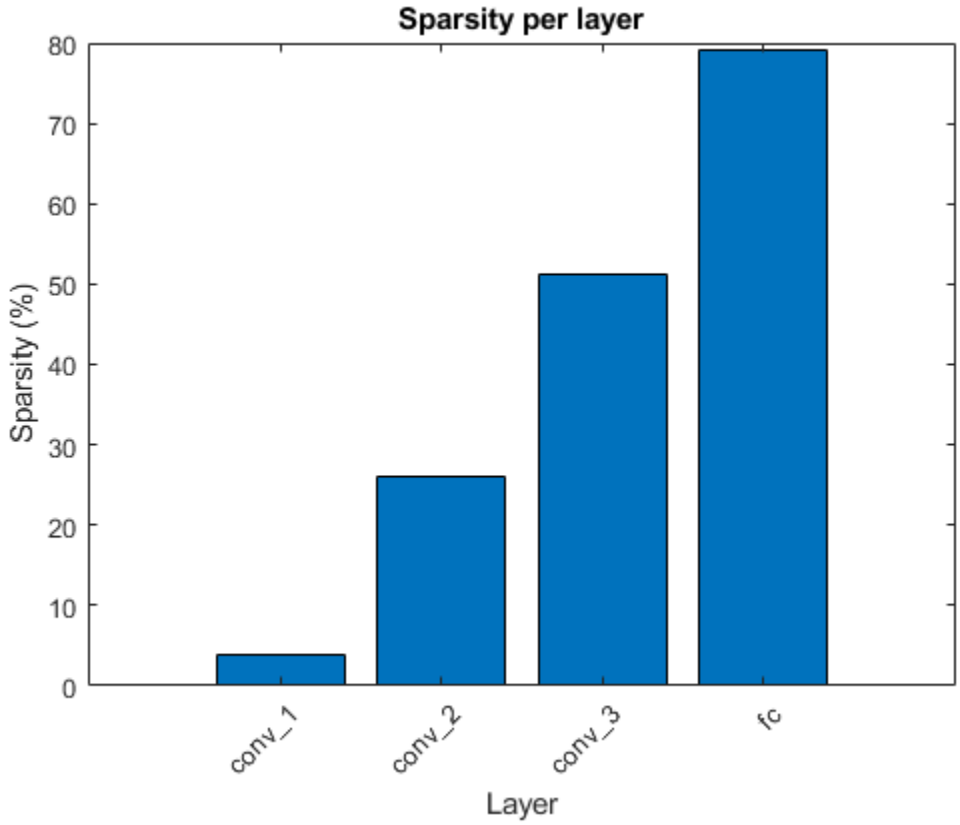
[sparsityPerLayer,prunedChannelsPerLayer,numOutChannelsPerLayer,layerNames] = pruningStatistics(p
```

Earlier convolution layers are typically pruned less since they contain more relevant information about the core low-level structure of the image (e.g. edges and corners) which are essential for interpreting the image.

Plot the sparsity per layer for the selected pruning method and iteration.

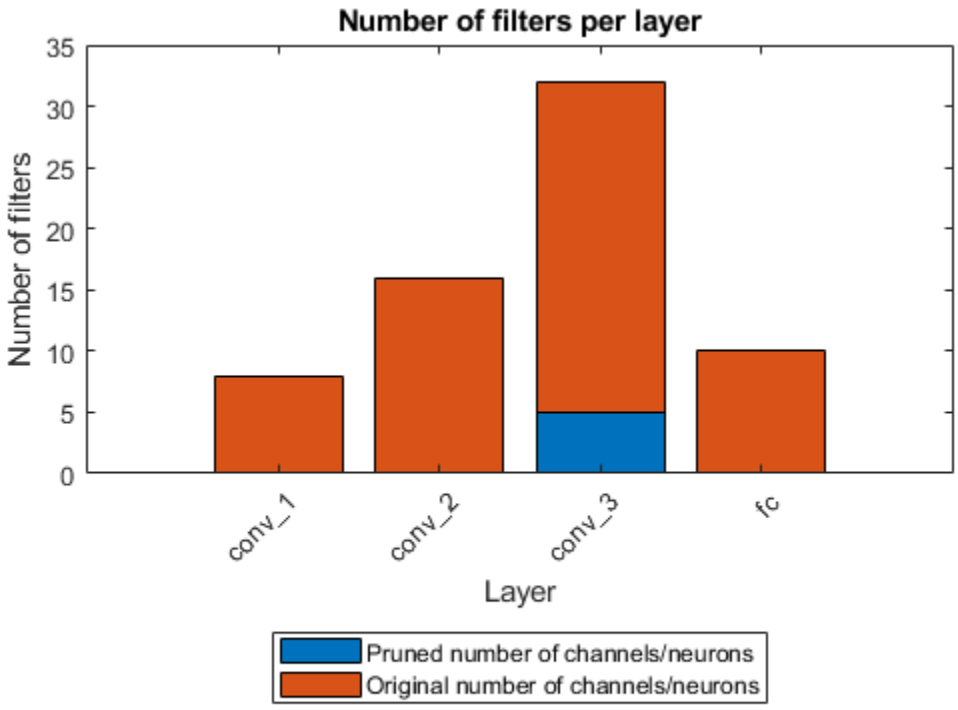
```
figure
bar(sparsityPerLayer*100)
title("Sparsity per layer")
xlabel("Layer")
ylabel("Sparsity (%)")
xticks(1:numel(sparsityPerLayer))
xticklabels(layerNames)
```

```
xtickangle(45)
set(gca,'TickLabelInterpreter','none')
```



The pruning algorithm prunes single connections when you specify a low target sparsity. When you specify a high target sparsity, the pruning algorithm can prune whole filters and neurons in convolutional or fully connected layers, allowing you to significantly reduce the structural size of the network.

```
figure
bar([prunedChannelsPerLayer,numOutChannelsPerLayer-prunedChannelsPerLayer],"stacked")
xlabel("Layer")
ylabel("Number of filters")
title("Number of filters per layer")
xticks(1:(numel(layerNames)))
xticklabels(layerNames)
xtickangle(45)
legend("Pruned number of channels/neurons" , "Original number of channels/neurons","Location","so
set(gca,'TickLabelInterpreter','none')
```



Evaluate Network Accuracy

Compare the accuracy of the network before and after pruning.

```
YPredOriginal = modelPredictions(dlnet,mbqValidation,classes);
accOriginal = mean(YPredOriginal == trueLabels)
```

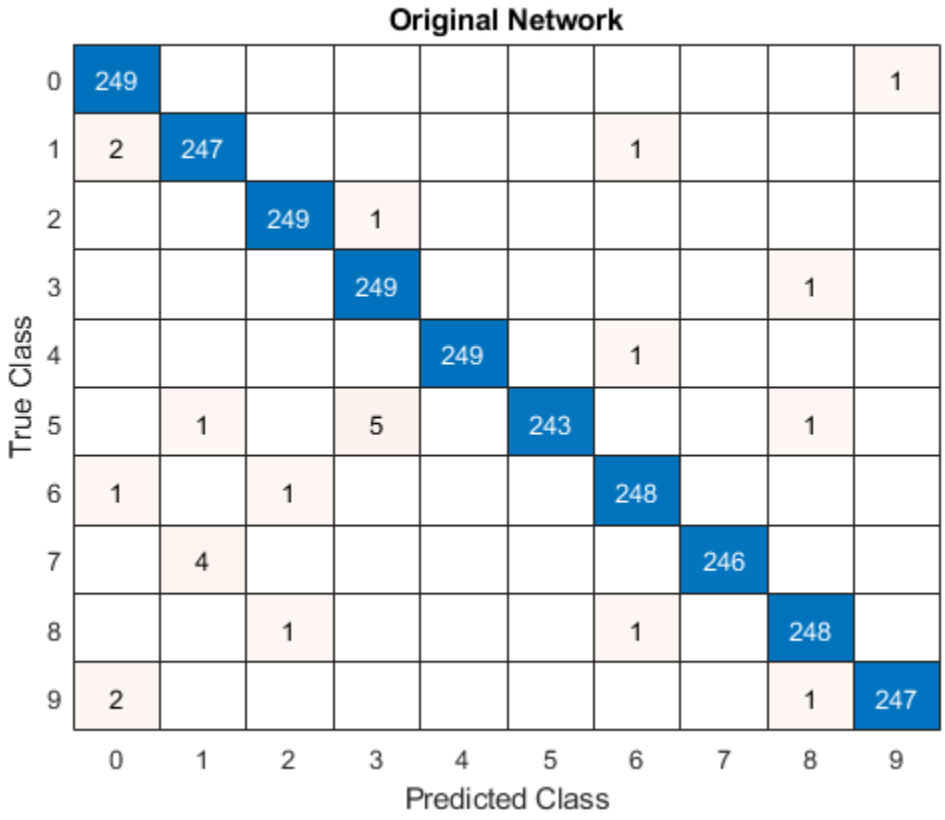
```
accOriginal = 0.9900
```

```
YPredPruned = modelPredictions(prunedDLNet,mbqValidation,classes);
accPruned = mean(YPredPruned == trueLabels)
```

```
accPruned = 0.9400
```

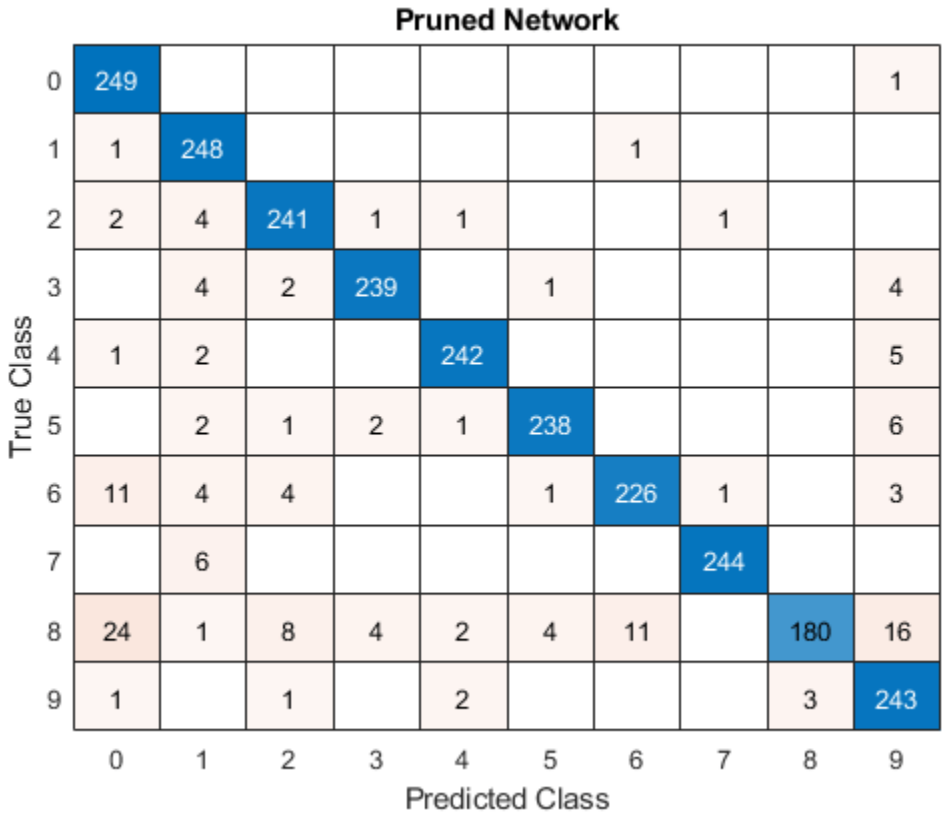
Create a confusion matrix chart to explore the true class labels to the predicted class labels for the original and pruned network.

```
figure
confusionchart(trueLabels,YPredOriginal);
title("Original Network")
```



The validation set of the digits data contains 250 images for each class, so if a network predicts the class of each image perfectly, all scores on the diagonal equal 250 and no values are outside of the diagonal.

```
confusionchart(trueLabels,YPredPruned);
title("Pruned Network")
```



When pruning a network, compare the confusion chart of the original network and the pruned network to check how the accuracy for each class labels changes for the selected sparsity level. If all numbers on the diagonal decrease roughly equally, no bias is present. However, if the decreases are not equal, you might need to choose a pruned network from an earlier iteration by reducing the value of the variable selectedIteration.

Quantize Pruned Network

Deep neural networks trained in MATLAB use single-precision floating point data types. Even networks that are small in size require a considerable amount of memory and hardware to perform floating-point arithmetic operations. These restrictions can inhibit deployment of deep learning models that have low computational power and less memory resources. By using a lower precision to store the weights and activations, you can reduce the memory requirements of the network. You can use Deep Learning Toolbox in tandem with the Deep Learning Model Quantization Library support package to reduce the memory footprint of a deep neural network by quantizing the weights, biases, and activations of the convolution layers to 8-bit scaled integer data types.

Pruning a network impacts the range statistics of parameters and activations at each layer, so the accuracy of the quantized network can change. To explore this difference, quantize the pruned network and use the quantized network to perform inference.

Split the data into calibration and validation data sets.

```
calibrationDataStore = splitEachLabel(imdsTrain,0.1,'randomize');
validationDataStore = imdsValidation;
```

Create a `dlquantizer` object and specify the pruned network as the network to quantize.

```
prunedNet  = assembleNetwork([prunedDLNet.Layers ; net.Layers(end-1:end)]);

quantObjPrunedNetwork = dlquantizer(prunedNet,'ExecutionEnvironment','GPU');
```

Use the `calibrate` function to exercise the network with the calibration data and collect range statistics for the weights, biases, and activations at each layer.

```
calResults = calibrate(quantObjPrunedNetwork, calibrationDataStore)
```

```
calResults=18×5 table

```

Mini Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses a mini-batch of predictors by extracting the image data from the input cell array and concatenate into a numeric array. For grayscale input, concatenating the data over the fourth dimension adds a third dimension to each image to use as a singleton channel dimension.

```
function X = preprocessMiniBatch(XCell)
% Extract image data from cell and concatenate.
X = cat(4,XCell{:});
end
```

Model Accuracy Function

Evaluate the classification accuracy of the `dlnetwork`. Accuracy is the percentage of labels correctly classified by the network.

```
function accuracy = evaluateAccuracy(dlnet,mbqValidation,classes,trueLabels)
YPred = modelPredictions(dlnet,mbqValidation,classes);
accuracy = mean(YPred == trueLabels);
end
```

SynFlow Score Function

The `calculateSynFlowScore` function calculates Synaptic Flow (SynFlow) scores. Synaptic saliency [2] is described as the class of gradient-based scores defined by the product of gradient of loss multiplied by the parameter value:

$$\text{synFlowScore} = \frac{d(\text{loss})}{d\theta} * \theta$$

The SynFlow score is a synaptic saliency score that uses the sum of all network outputs as a loss function:

$$\text{loss} = \sum f(\text{abs}(\theta), X)$$

f is the function represented by the neural network

θ are the parameters of the network

X is the input array to the network

To compute parameter gradients with respect to this loss function, use `dlfeval` and a model gradients function.

```
function score = calculateSynFlowScore(dlnet,dlX)
dlnet.Learnables = dlupdate(@abs, dlnet.Learnables);
gradients = dlfeval(@modelGradients,dlnet,dlX);
score = dlupdate(@(g,w)g.*w, gradients, dlnet.Learnables);
end
```

Model Gradients for SynFlow Score

```
function gradients = modelGradients(dlNet,inputArray)
% Evaluate the gradients on a given input to the dlnetwork
dlYPred = predict(dlNet,inputArray);
pseudoloss = sum(dlYPred,'all');
```

```
gradients = dlgradient(pseudoloss,dlNet.Learnables);
end
```

Magnitude Score Function

The `calculateMagnitudeScore` function returns the magnitude score, defined as the element-wise absolute value of the parameters.

```
function score = calculateMagnitudeScore(dlnet)
score = dlupdate(@abs, dlnet.Learnables);
end
```

Mask Generation Function

The `calculateMask` function returns a binary mask for the network parameters based on the given scores and the target sparsity.

```
function mask = calculateMask(scoresMagnitude,sparsity)
% Compute a binary mask based on the parameter-wise scores such that the mask contains a percenta

% Flatten the cell array of scores into one long score vector
flattenedScores = cell2mat(cellfun(@(S)extractdata(gather(S(:))),scoresMagnitude.Value,'UniformOu
% Rank the scores and determine the threshold for removing connections for the
% given sparsity
flattenedScores = sort(flattenedScores);
k = round(sparsity*numel(flattenedScores));
if k==0
    thresh = 0;
else
    thresh = flattenedScores(k);
end
% Create a binary mask
mask = dlupdate( @(S)S>thresh, scoresMagnitude);
end
```

Model Predictions Function

The `modelPredictions` function takes as input a `dlnetwork` object dlnet, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in the minibatchqueue object. The function uses the `onehotdecode` function to find the predicted class with the highest score.

```
function predictions = modelPredictions(dlnet,mbq,classes)
predictions = [];
while hasdata(mbq)
    dlXTest = next(mbq);
    dlYPred = softmax(predict(dlnet,dlXTest));
    YPred = onehotdecode(dlYPred,classes,1)';
    predictions = [predictions; YPred];
end
reset(mbq)
end
```

Apply Pruning Function

The `createPrunedNet` function returns the pruned dlnetwork for the specified pruning algorithm and iteration.

```
function prunedNet = createPrunedNet(dlnet,selectedIteration,pruningMaskSynFlow,pruningMaskMagni
switch pruningMethod
    case "Magnitude"
        prunedNet = dlupdate(@(W,M)W.*M, dlnet, pruningMaskMagnitude{selectedIteration});
    case "SynFlow"
        prunedNet = dlupdate(@(W,M)W.*M, dlnet, pruningMaskSynFlow{selectedIteration});
end
end
```

Pruning Statistics Function

The `pruningStatistics` function extracts detailed layer-level pruning statistics such the layer-level sparsity and the number of filters or neurons being pruned.

sparsityPerLayer - `percentage of parameters pruned in each layer`

prunedChannelsPerLayer - number of channels/neurons in each layer that can be removed as a result of pruning

numOutChannelsPerLayer - number of channels/neurons in each layer

```
function [sparsityPerLayer,prunedChannelsPerLayer,numOutChannelsPerLayer,layerNames] = pruningSta

layerNames = unique(dlnet.Learnables.Layer,'stable');
numLayers = numel(layerNames);
layerIDs = zeros(numLayers,1);
for idx = 1:numel(layerNames)
    layerIDs(idx) = find(layerNames(idx)=={dlnet.Layers.Name});
end

sparsityPerLayer = zeros(numLayers,1);
prunedChannelsPerLayer = zeros(numLayers,1);
numOutChannelsPerLayer = zeros(numLayers,1);

numParams = zeros(numLayers,1);
numPrunedParams = zeros(numLayers,1);
for idx = 1:numLayers
    layer = dlnet.Layers(layerIDs(idx));

    % Calculate the sparsity
    paramIDs = strcmp(dlnet.Learnables.Layer,layerNames(idx));
    paramValue = dlnet.Learnables.Value(paramIDs);
    for p = 1:numel(paramValue)
        numParams(idx) = numParams(idx) + numel(paramValue{p});
        numPrunedParams(idx) = numPrunedParams(idx) + nnz(extractdata(paramValue{p})==0);
    end

    % Calculate channel statistics
    sparsityPerLayer(idx) = numPrunedParams(idx)/numParams(idx);
    switch class(layer)
        case "nnet.cnn.layer.FullyConnectedLayer"
            numOutChannelsPerLayer(idx) = layer.OutputSize;
            prunedChannelsPerLayer(idx) = nnz(all(layer.Weights==0,2)&layer.Bias(:)==0);
        case "nnet.cnn.layer.Convolution2DLayer"
            numOutChannelsPerLayer(idx) = layer.NumFilters;
            prunedChannelsPerLayer(idx) = nnz(reshape(all(layer.Weights==0,[1,2,3]),[],1)&layer.B
        case "nnet.cnn.layer.GroupedConvolution2DLayer"
            numOutChannelsPerLayer(idx) = layer.NumGroups*layer.NumFiltersPerGroup;
```

```
            prunedChannelsPerLayer(idx) = nnz(reshape(all(layer.Weights==0,[1,2,3]),[],1)&layer.B
        otherwise
            error("Unknown layer: "+class(layer))
    end
end
end
```

Load Digits Data set Function

The `loadDigitDataset` function loads the Digits data set and splits the data into training and validation data.

```
function [imdsTrain, imdsValidation] = loadDigitDataset()
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet','nndemos', ...
    'nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true,'LabelSource','foldernames');
[imdsTrain, imdsValidation] = splitEachLabel(imds,0.75,"randomized");
end
```

Train Digit Recognition Network Function

The `trainDigitDataNetwork` function trains a convolutional neural network to classify digits in grayscale images.

```
function net = trainDigitDataNetwork(imdsTrain,imdsValidation)
layers = [
    imageInputLayer([28 28 1],"Normalization","rescale-zero-one")
    convolution2dLayer(3,8,'Padding','same')
    reluLayer
    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,16,'Padding','same')
    reluLayer
    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,32,'Padding','same')
    reluLayer

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer];

% Specify the training options
options = trainingOptions('sgdm', ...
    'InitialLearnRate',0.01, ...
    'MaxEpochs',10, ...
    'Shuffle','every-epoch', ...
    'ValidationData',imdsValidation, ...
    'ValidationFrequency',30, ...
    'Verbose',false, ...
    'Plots','none',"ExecutionEnvironment","auto");

% Train network
net = trainNetwork(imdsTrain,layers,options);
end
```

Quantization of Deep Neural Networks

In digital hardware, numbers are stored in binary words. A binary word is a fixed-length sequence of bits (1's and 0's). The data type defines how hardware components or software functions interpret this sequence of 1's and 0's. Numbers are represented as either scaled integer (usually referred to as fixed-point) or floating-point data types.

Most pretrained neural networks and neural networks trained using Deep Learning Toolbox use single-precision floating point data types. Even small trained neural networks require a considerable amount of memory, and require hardware that can perform floating-point arithmetic. These restrictions can inhibit deployment of deep learning capabilities to low-power microcontrollers and FPGAs.

Using the Deep Learning Toolbox Model Quantization Library support package, you can quantize a network to use 8-bit scaled integer data types.

To learn about the products required to quantize and deploy the deep learning network to a GPU, FPGA, or CPU environment, see “Quantization Workflow Prerequisites” on page 20-193.

Precision and Range

Scaled 8-bit integer data types have limited precision and range when compared to single-precision floating point data types. There are several numerical considerations when casting a number from a larger floating-point data type to a smaller data type of fixed length.

- Precision loss: Precision loss is a rounding error. When precision loss occurs, the value is rounded to the nearest number that is representable by the data type. In the case of a tie it rounds:
  - Positive numbers to the closest representable value in the direction of positive infinity.
  - Negative numbers to the closest representable value in the direction of negative infinity.

  In MATLAB you can perform this type of rounding using the `round` function.
- Underflow: Underflow is a type of precision loss. Underflows occur when the value is smaller than the smallest value representable by the data type. When this occurs, the value saturates to zero.
- Overflow: When a value is larger than the largest value that a data type can represent, an overflow occurs. When an overflow occurs, the value saturates to the largest value representable by the data type.

Histograms of Dynamic Ranges

Use the **Deep Network Quantizer** app to collect and visualize the dynamic ranges of the weights and biases of the convolution layers and fully connected layers of a network, and the activations of all layers in the network. The app assigns a scaled 8-bit integer data type for the weights, biases, and activations of the convolution layers of the network. The app displays a histogram of the dynamic range for each of these parameters. The following steps describe how these histograms are produced.

1 Consider the following values logged for a parameter while exercising a network.

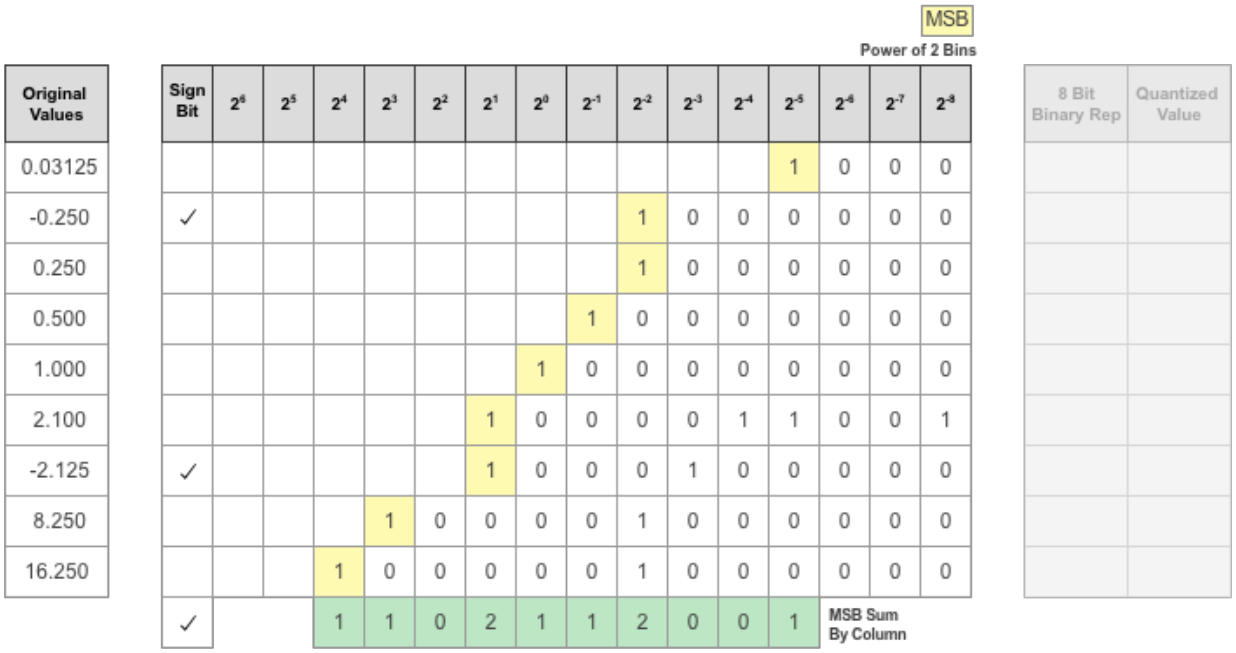
Original Values	Power of 2 Bins																8 Bit Binary Rep	Quantized Value
	Sign Bit	2^6	2^5	2^4	2^3	2^2	2^1	2^0	2^{-1}	2^{-2}	2^{-3}	2^{-4}	2^{-5}	2^{-6}	2^{-7}	2^{-8}		
0.03125																		
-0.250																		
0.250																		
0.500																		
1.000																		
2.100																		
-2.125																		
8.250																		
16.250																		

2 Find the ideal binary representation of each logged value of the parameter.

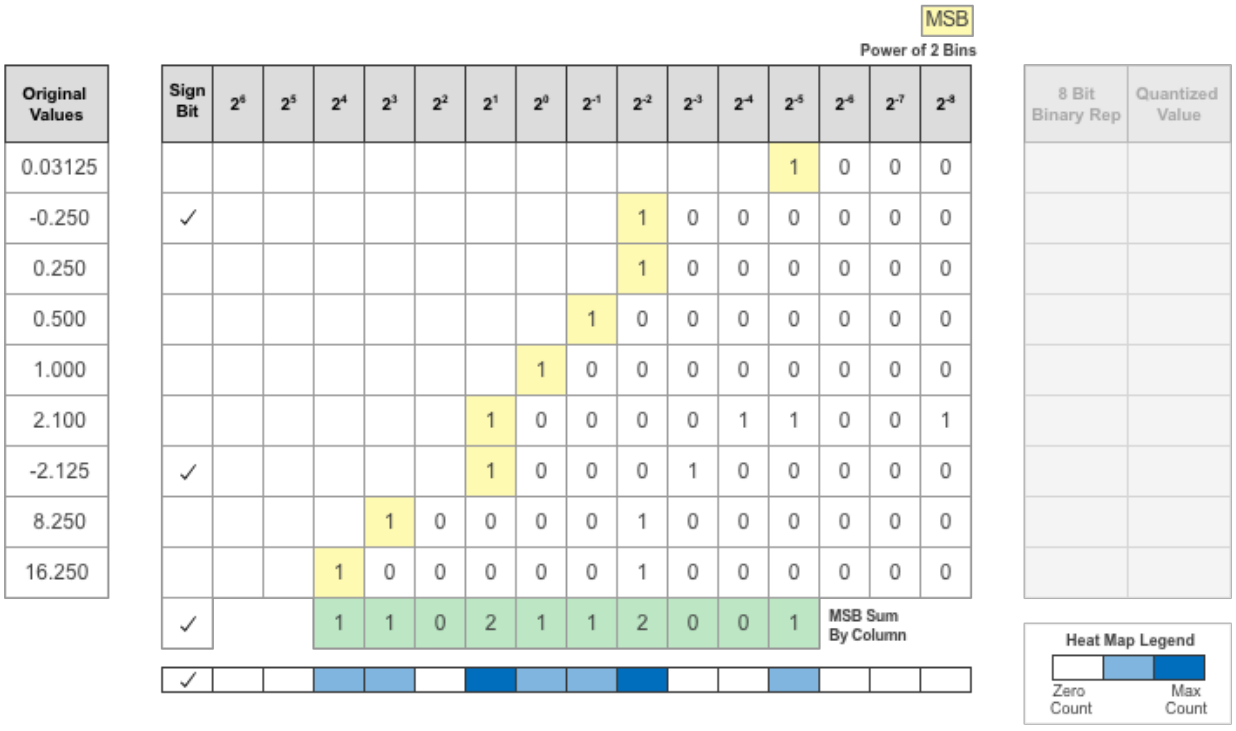
The most significant bit (MSB) is the left-most bit of the binary word. This bit contributes most to the value of the number. The MSB for each value is highlighted in yellow.

													MSB					
													Power of 2 Bins					
Original Values	Sign Bit	2^6	2^5	2^4	2^3	2^2	2^1	2^0	2^{-1}	2^{-2}	2^{-3}	2^{-4}	2^{-5}	2^{-6}	2^{-7}	2^{-8}	8 Bit Binary Rep	Quantized Value
0.03125													1	0	0	0		
-0.250	✓									1	0	0	0	0	0	0		
0.250										1	0	0	0	0	0	0		
0.500									1	0	0	0	0	0	0	0		
1.000								1	0	0	0	0	0	0	0	0		
2.100							1	0	0	0	0	1	1	0	0	1		
-2.125	✓						1	0	0	0	1	0	0	0	0	0		
8.250					1	0	0	0	0	1	0	0	0	0	0	0		
16.250				1	0	0	0	0	0	1	0	0	0	0	0	0		

3 By aligning the binary words, you can see the distribution of bits used by the logged values of a parameter. The sum of MSB's in each column, highlighted in green, give an aggregate view of the logged values.

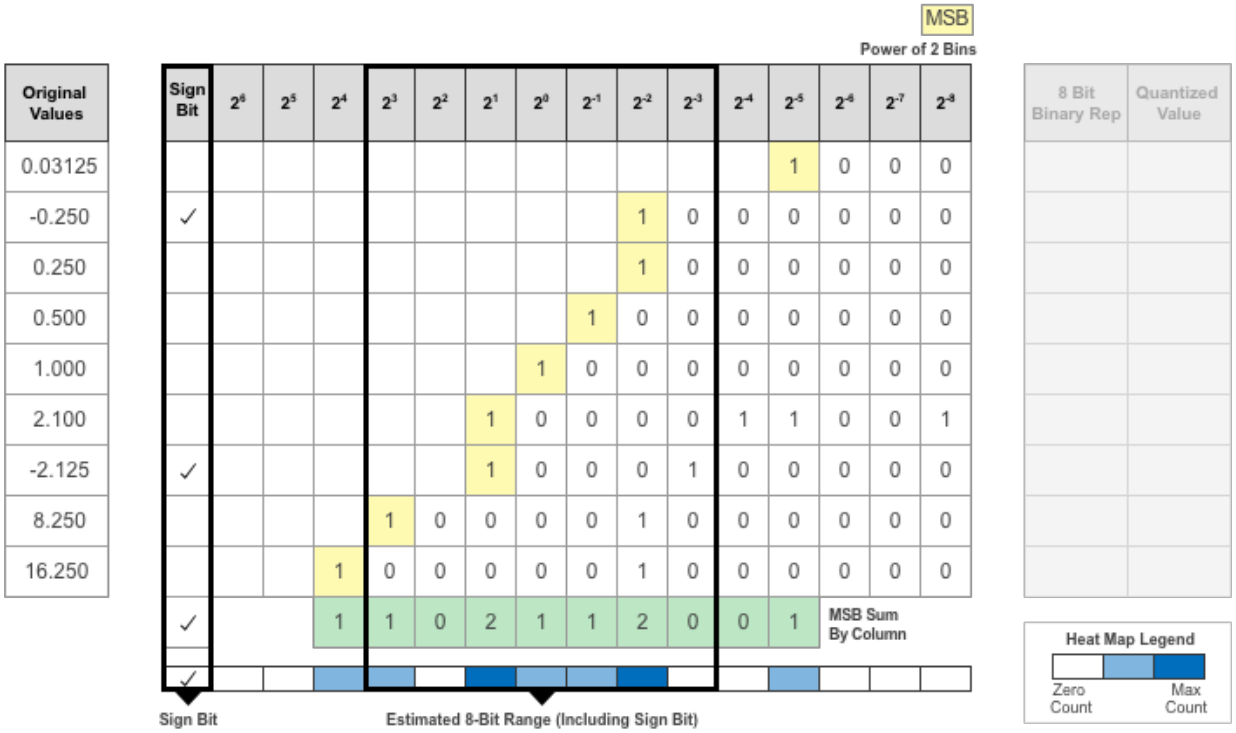


4 The MSB counts of each bit location are displayed as a heat map. In this heat map, darker blue regions correspond to a larger number of MSB's in the bit location.

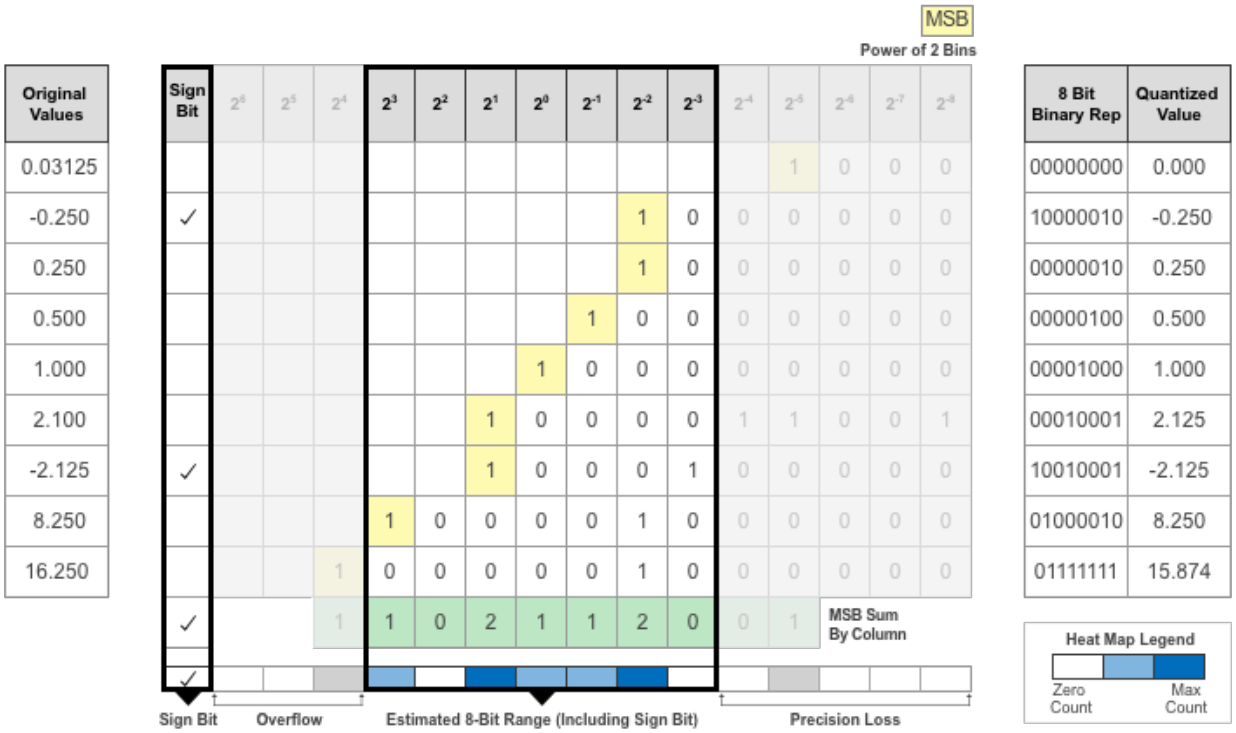


5 The **Deep Network Quantizer** app assigns a data type that can avoid overflow, cover the range, and allow underflow. An additional sign bit is required to represent the signedness of the value.

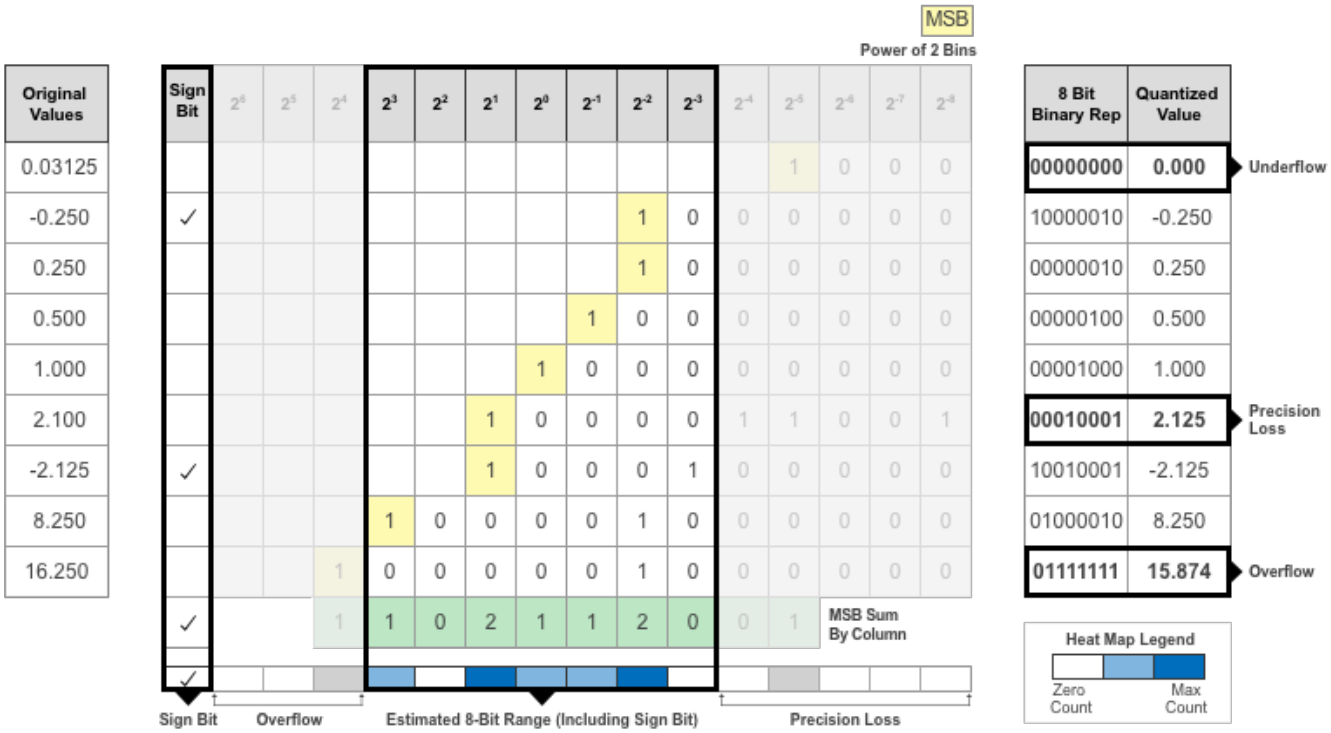
The figure below shows an example of a data type that represents bits from 2^3 to 2^{-3}, including the sign bit.



6 After assigning the data type, any bits outside of that data type are removed. Due to the assignment of a smaller data type of fixed length, precision loss, overflow, and underflow can occur for values that are not representable by the data type.



In this example, the value 0.03125, suffers from an underflow, so the quantized value is 0. The value 2.1 suffers some precision loss, so the quantized value is 2.125. The value 16.250 is larger than the largest representable value of the data type, so this value overflows and the quantized value saturates to 15.874.



7 The **Deep Network Quantizer** app displays this heat map histogram for each learnable parameter in the convolution layers and fully connected layers of the network. The gray regions of the histogram show the bits that cannot be represented by the data type.

Neural Network Design Book

The developers of the Deep Learning Toolbox software have written a textbook, *Neural Network Design* (Hagan, Demuth, and Beale, ISBN 0-9717321-0-8). The book presents the theory of neural networks, discusses their design and application, and makes considerable use of the MATLAB environment and Deep Learning Toolbox software. Example programs from the book are used in various sections of this documentation. (You can find all the book example programs in the Deep Learning Toolbox software by typing `nnd`.)

Obtain this book from John Stovall at (303) 492-3648, or by email at `John.Stovall@colorado.edu`.

The *Neural Network Design* textbook includes:

- An Instructor's Manual for those who adopt the book for a class
- Transparency Masters for class use

If you are teaching a class and want an Instructor's Manual (with solutions to the book exercises), contact John Stovall at (303) 492-3648, or by email at `John.Stovall@colorado.edu`

To look at sample chapters of the book and to obtain Transparency Masters, go directly to the Neural Network Design page at:

`https://hagan.okstate.edu/nnd.html`

From this link, you can obtain sample book chapters in PDF format and you can download the Transparency Masters by clicking **Transparency Masters (3.6MB)**.

You can get the Transparency Masters in PowerPoint or PDF format.

Neural Network Objects, Data, and Training Styles

Workflow for Neural Network Design

The work flow for the neural network design process has seven primary steps. Referenced topics discuss the basic ideas behind steps 2, 3, and 5.

1. Collect data
2. Create the network — “Create Neural Network Object” on page 21-13
3. Configure the network — “Configure Shallow Neural Network Inputs and Outputs” on page 21-16
4. Initialize the weights and biases
5. Train the network — “Neural Network Training Concepts” on page 21-22
6. Validate the network
7. Use the network

Data collection in step 1 generally occurs outside the framework of Deep Learning Toolbox software, but it is discussed in general terms in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2. Details of the other steps and discussions of steps 4, 6, and 7, are discussed in topics specific to the type of network.

The Deep Learning Toolbox software uses the network object to store all of the information that defines a neural network. This topic describes the basic components of a neural network and shows how they are created and stored in the network object.

After a neural network has been created, it needs to be configured and then trained. Configuration involves arranging the network so that it is compatible with the problem you want to solve, as defined by sample data. After the network has been configured, the adjustable network parameters (called weights and biases) need to be tuned, so that the network performance is optimized. This tuning process is referred to as training the network. Configuration and training require that the network be provided with example data. This topic shows how to format the data for presentation to the network. It also explains network configuration and the two forms of network training: incremental training and batch training.

Four Levels of Neural Network Design

There are four different levels at which the neural network software can be used. The first level is represented by the GUIs that are described in “Get Started with Deep Learning Toolbox”. These provide a quick way to access the power of the toolbox for many problems of function fitting, pattern recognition, clustering and time series analysis.

The second level of toolbox use is through basic command-line operations. The command-line functions use simple argument lists with intelligent default settings for function parameters. (You can override all of the default settings, for increased functionality.) This topic, and the ones that follow, concentrate on command-line operations.

The GUIs described in Getting Started can automatically generate MATLAB code files with the command-line implementation of the GUI operations. This provides a nice introduction to the use of the command-line functionality.

A third level of toolbox use is customization of the toolbox. This advanced capability allows you to create your own custom neural networks, while still having access to the full functionality of the toolbox.

The fourth level of toolbox usage is the ability to modify any of the code files contained in the toolbox. Every computational component is written in MATLAB code and is fully accessible.

The first level of toolbox use (through the GUIs) is described in Getting Started which also introduces command-line operations. The following topics will discuss the command-line operations in more detail. The customization of the toolbox is described in “Define Shallow Neural Network Architectures”.

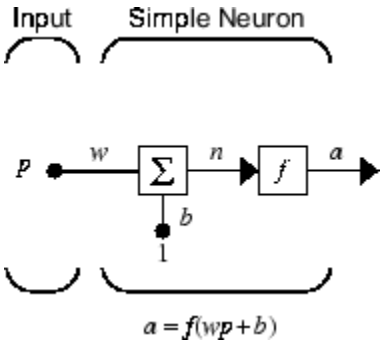
Neuron Model

In this section...

Simple Neuron

The fundamental building block for neural networks is the single-input neuron, such as this example.



There are three distinct functional operations that take place in this example neuron. First, the scalar input p is multiplied by the scalar weight w to form the product wp, again a scalar. Second, the weighted input wp is added to the scalar bias b to form the net input n. (In this case, you can view the bias as shifting the function f to the left by an amount b. The bias is much like a weight, except that it has a constant input of 1.) Finally, the net input is passed through the transfer function f, which produces the scalar output a. The names given to these three processes are: the weight function, the net input function and the transfer function.

For many types of neural networks, the weight function is a product of a weight times the input, but other weight functions (e.g., the distance between the weight and the input, $|w - p|$) are sometimes used. (For a list of weight functions, type `help nnweight`.) The most common net input function is the summation of the weighted inputs with the bias, but other operations, such as multiplication, can be used. (For a list of net input functions, type `help nnnetinput`.) “Introduction to Radial Basis Neural Networks” on page 25-2 discusses how distance can be used as the weight function and multiplication can be used as the net input function. There are also many types of transfer functions. Examples of various transfer functions are in “Transfer Functions” on page 21-5. (For a list of transfer functions, type `help nntransfer`.)

Note that w and b are both *adjustable* scalar parameters of the neuron. The central idea of neural networks is that such parameters can be adjusted so that the network exhibits some desired or interesting behavior. Thus, you can train the network to do a particular job by adjusting the weight or bias parameters.

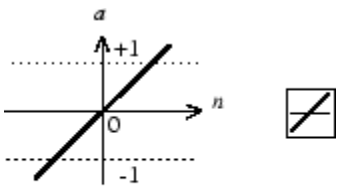
All the neurons in the Deep Learning Toolbox software have provision for a bias, and a bias is used in many of the examples and is assumed in most of this toolbox. However, you can omit a bias in a neuron if you want.

Transfer Functions

Many transfer functions are included in the Deep Learning Toolbox software.

Two of the most commonly used functions are shown below.

The following figure illustrates the linear transfer function.

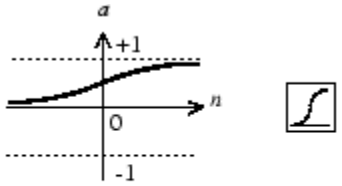


$a = purelin(n)$

Linear Transfer Function

Neurons of this type are used in the final layer of multilayer networks that are used as function approximators. This is shown in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

The sigmoid transfer function shown below takes the input, which can have any value between plus and minus infinity, and squashes the output into the range 0 to 1.



$a = logsig(n)$

Log-Sigmoid Transfer Function

This transfer function is commonly used in the hidden layers of multilayer networks, in part because it is differentiable.

The symbol in the square to the right of each transfer function graph shown above represents the associated transfer function. These icons replace the general *f* in the network diagram blocks to show the particular transfer function being used.

For a complete list of transfer functions, type `help nntransfer`. You can also specify your own transfer functions.

You can experiment with a simple neuron and various transfer functions by running the example program `nnd2n1`.

Neuron with Vector Input

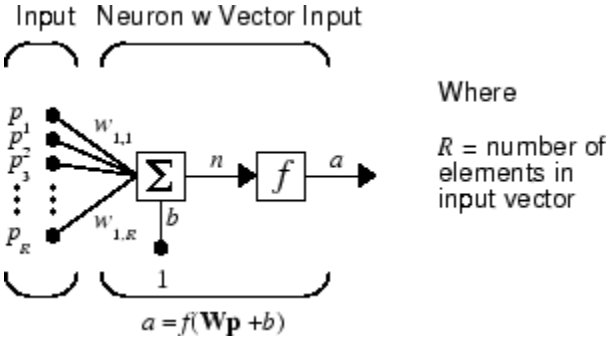
The simple neuron can be extended to handle inputs that are vectors. A neuron with a single *R*-element input vector is shown below. Here the individual input elements

$$p_1, p_2, \ldots p_R$$

are multiplied by weights

$$w_{1,1}, w_{1,2}, \ldots w_{1,R}$$

and the weighted values are fed to the summing junction. Their sum is simply **Wp**, the dot product of the (single row) matrix **W** and the vector **p**. (There are other weight functions, in addition to the dot product, such as the distance between the row of the weight matrix and the input vector, as in “Introduction to Radial Basis Neural Networks” on page 25-2.)



The neuron has a bias b, which is summed with the weighted inputs to form the net input n. (In addition to the summation, other net input functions can be used, such as the multiplication that is used in “Introduction to Radial Basis Neural Networks” on page 25-2.) The net input n is the argument of the transfer function f.

$$n = w_{1,1}p_1 + w_{1,2}p_2 + \ldots + w_{1,R}p_R + b$$

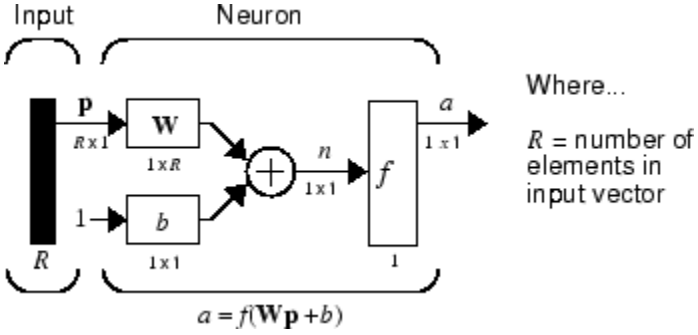
This expression can, of course, be written in MATLAB code as

```
n = W*p + b
```

However, you will seldom be writing code at this level, for such code is already built into functions to define and simulate entire networks.

Abbreviated Notation

The figure of a single neuron shown above contains a lot of detail. When you consider networks with many neurons, and perhaps layers of many neurons, there is so much detail that the main thoughts tend to be lost. Thus, the authors have devised an abbreviated notation for an individual neuron. This notation, which is used later in circuits of multiple neurons, is shown here.



Here the input vector **p** is represented by the solid dark vertical bar at the left. The dimensions of **p** are shown below the symbol **p** in the figure as $R \times 1$. (Note that a capital letter, such as R in the

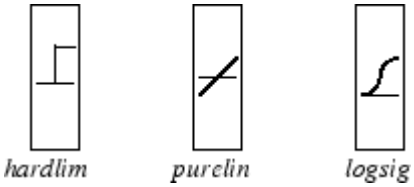
previous sentence, is used when referring to the *size* of a vector.) Thus, **p** is a vector of *R* input elements. These inputs postmultiply the single-row, *R*-column matrix **W**. As before, a constant 1 enters the neuron as an input and is multiplied by a scalar bias *b*. The net input to the transfer function *f* is *n*, the sum of the bias *b* and the product **Wp**. This sum is passed to the transfer function *f* to get the neuron's output *a*, which in this case is a scalar. Note that if there were more than one neuron, the network output would be a vector.

A *layer* of a network is defined in the previous figure. A layer includes the weights, the multiplication and summing operations (here realized as a vector product **Wp**), the bias *b*, and the transfer function *f*. The array of inputs, vector **p**, is not included in or called a layer.

As with the “Simple Neuron” on page 21-4, there are three operations that take place in the layer: the weight function (matrix multiplication, or dot product, in this case), the net input function (summation, in this case), and the transfer function.

Each time this abbreviated network notation is used, the sizes of the matrices are shown just below their matrix variable names. This notation will allow you to understand the architectures and follow the matrix mathematics associated with them.

As discussed in “Transfer Functions” on page 21-5, when a specific transfer function is to be used in a figure, the symbol for that transfer function replaces the *f* shown above. Here are some examples.



You can experiment with a two-element neuron by running the example program nnd2n2.

- “Workflow for Neural Network Design” on page 21-2

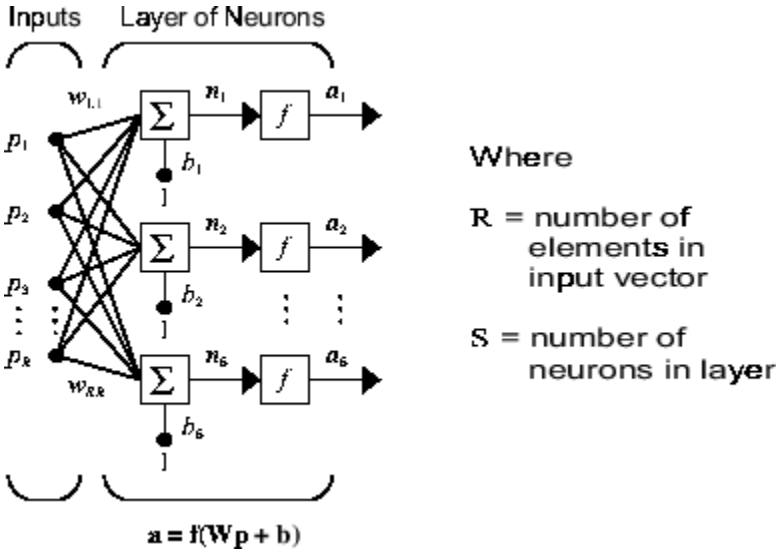
Neural Network Architectures

In this section...

Two or more of the neurons shown earlier can be combined in a layer, and a particular network could contain one or more such layers. First consider a single layer of neurons.

One Layer of Neurons

A one-layer network with R input elements and S neurons follows.



In this network, each element of the input vector **p** is connected to each neuron input through the weight matrix **W**. The ith neuron has a summer that gathers its weighted inputs and bias to form its own scalar output $n(i)$. The various $n(i)$ taken together form an S-element net input vector **n**. Finally, the neuron layer outputs form a column vector **a**. The expression for **a** is shown at the bottom of the figure.

Note that it is common for the number of inputs to a layer to be different from the number of neurons (i.e., R is not necessarily equal to S). A layer is not constrained to have the number of its inputs equal to the number of its neurons.

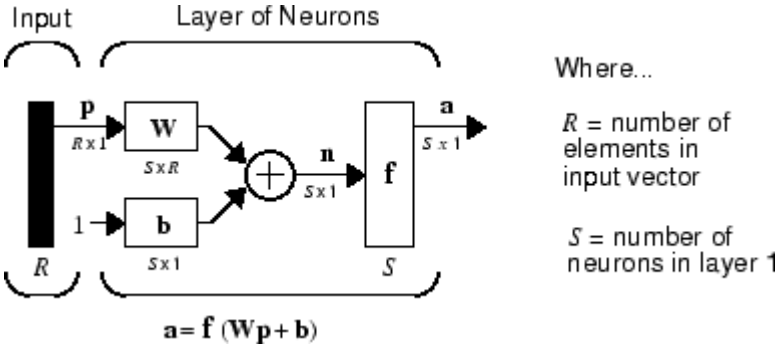
You can create a single (composite) layer of neurons having different transfer functions simply by putting two of the networks shown earlier in parallel. Both networks would have the same inputs, and each network would create some of the outputs.

The input vector elements enter the network through the weight matrix **W**.

$$\mathbf{W} = \begin{bmatrix} w_{1,1} & w_{1,2} & \cdots & w_{1,R} \\ w_{2,1} & w_{2,2} & \cdots & w_{2,R} \\ & & & \\ w_{S,1} & w_{S,2} & \cdots & w_{S,R} \end{bmatrix}$$

Note that the row indices on the elements of matrix **W** indicate the destination neuron of the weight, and the column indices indicate which source is the input for that weight. Thus, the indices in $w_{1,2}$ say that the strength of the signal *from* the second input element *to* the first (and only) neuron is $w_{1,2}$.

The S neuron R-input one-layer network also can be drawn in abbreviated notation.

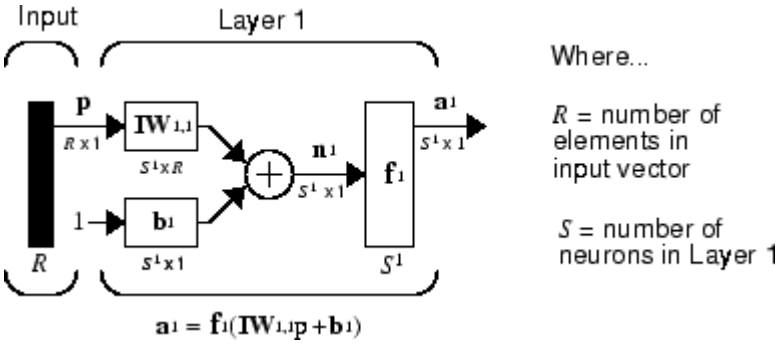


Here **p** is an R-length input vector, **W** is an $S \times R$ matrix, **a** and **b** are S-length vectors. As defined previously, the neuron layer includes the weight matrix, the multiplication operations, the bias vector **b**, the summer, and the transfer function blocks.

Inputs and Layers

To describe networks having multiple layers, the notation must be extended. Specifically, it needs to make a distinction between weight matrices that are connected to inputs and weight matrices that are connected between layers. It also needs to identify the source and destination for the weight matrices.

We will call weight matrices connected to inputs *input weights;* we will call weight matrices connected to layer outputs *layer weights.* Further, superscripts are used to identify the source (second index) and the destination (first index) for the various weights and other elements of the network. To illustrate, the one-layer multiple input network shown earlier is redrawn in abbreviated form here.

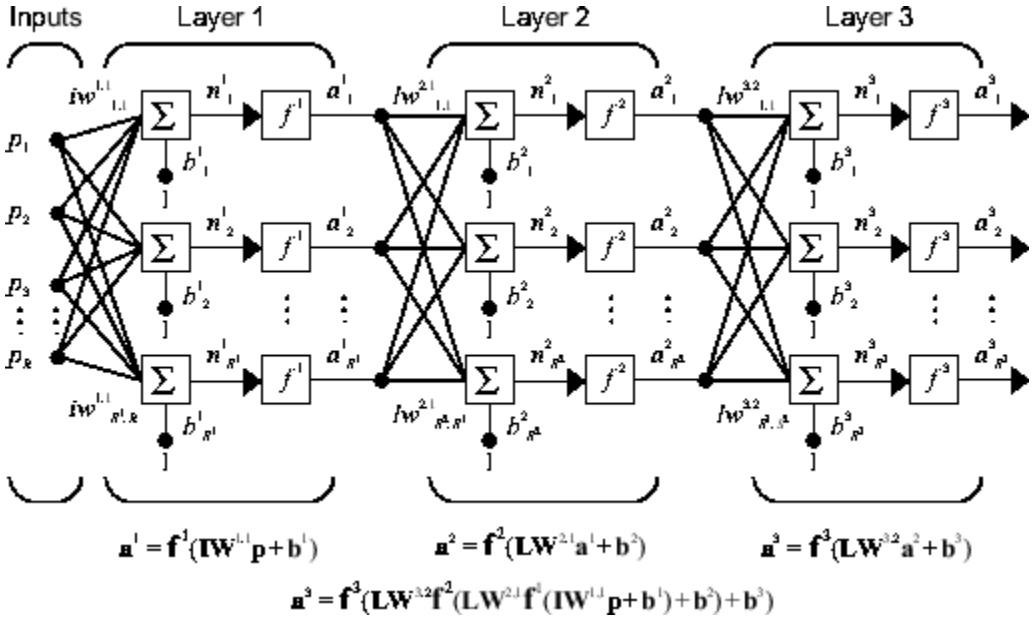


As you can see, the weight matrix connected to the input vector **p** is labeled as an input weight matrix ($\mathbf{IW}^{1,1}$) having a source 1 (second index) and a destination 1 (first index). Elements of layer 1, such as its bias, net input, and output have a superscript 1 to say that they are associated with the first layer.

“Multiple Layers of Neurons” on page 21-10 uses layer weight (**LW**) matrices as well as input weight (**IW**) matrices.

Multiple Layers of Neurons

A network can have several layers. Each layer has a weight matrix **W**, a bias vector **b**, and an output vector **a**. To distinguish between the weight matrices, output vectors, etc., for each of these layers in the figures, the number of the layer is appended as a superscript to the variable of interest. You can see the use of this layer notation in the three-layer network shown next, and in the equations at the bottom of the figure.



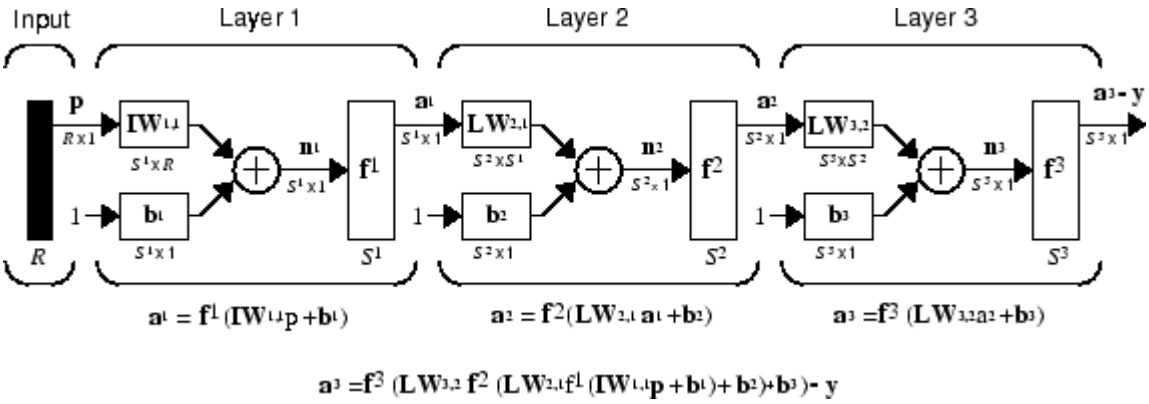
The network shown above has R^1 inputs, S^1 neurons in the first layer, S^2 neurons in the second layer, etc. It is common for different layers to have different numbers of neurons. A constant input 1 is fed to the bias for each neuron.

Note that the outputs of each intermediate layer are the inputs to the following layer. Thus layer 2 can be analyzed as a one-layer network with S^1 inputs, S^2 neurons, and an $S^2 \times S^1$ weight matrix $\mathbf{W}^2$. The input to layer 2 is $\mathbf{a}^1$; the output is $\mathbf{a}^2$. Now that all the vectors and matrices of layer 2 have been identified, it can be treated as a single-layer network on its own. This approach can be taken with any layer of the network.

The layers of a multilayer network play different roles. A layer that produces the network output is called an *output layer*. All other layers are called *hidden layers*. The three-layer network shown earlier has one output layer (layer 3) and two hidden layers (layer 1 and layer 2). Some authors refer to the inputs as a fourth layer. This toolbox does not use that designation.

The architecture of a multilayer network with a single input vector can be specified with the notation $R - S^1 - S^2 - \ldots - S^M$, where the number of elements of the input vector and the number of neurons in each layer are specified.

The same three-layer network can also be drawn using abbreviated notation.



Multiple-layer networks are quite powerful. For instance, a network of two layers, where the first layer is sigmoid and the second layer is linear, can be trained to approximate any function (with a finite number of discontinuities) arbitrarily well. This kind of two-layer network is used extensively in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

Here it is assumed that the output of the third layer, $\mathbf{a}^3$, is the network output of interest, and this output is labeled as $\mathbf{y}$. This notation is used to specify the output of multilayer networks.

Input and Output Processing Functions

Network inputs might have associated processing functions. Processing functions transform user input data to a form that is easier or more efficient for a network.

For instance, `mapminmax` transforms input data so that all values fall into the interval [−1, 1]. This can speed up learning for many networks. `removeconstantrows` removes the rows of the input vector that correspond to input elements that always have the same value, because these input elements are not providing any useful information to the network. The third common processing function is `fixunknowns`, which recodes unknown data (represented in the user's data with `NaN` values) into a numerical form for the network. `fixunknowns` preserves information about which values are known and which are unknown.

Similarly, network outputs can also have associated processing functions. Output processing functions are used to transform user-provided target vectors for network use. Then, network outputs are reverse-processed using the same functions to produce output data with the same characteristics as the original user-provided targets.

Both `mapminmax` and `removeconstantrows` are often associated with network outputs. However, `fixunknowns` is not. Unknown values in targets (represented by `NaN` values) do not need to be altered for network use.

Processing functions are described in more detail in “Choose Neural Network Input-Output Processing Functions” on page 22-7.

Create Neural Network Object

This topic is part of the design workflow described in “Workflow for Neural Network Design” on page 21-2.

The easiest way to create a neural network is to use one of the network creation functions. To investigate how this is done, you can create a simple, two-layer feedforward network, using the command `feedforwardnet`:

```
net = feedforwardnet

net =

Neural Network

              name: 'Feed-Forward Neural Network'
          userdata: (your custom info)

       unconfigure: Unconfigure inputs & outputs

    evaluate:       outputs = net(inputs)
```

This display is an overview of the network object, which is used to store all of the information that defines a neural network. There is a lot of detail here, but there are a few key sections that can help you to see how the network object is organized.

The dimensions section stores the overall structure of the network. Here you can see that there is one input to the network (although the one input can be a vector containing many elements), one network output, and two layers.

The connections section stores the connections between components of the network. For example, there is a bias connected to each layer, the input is connected to layer 1, and the output comes from layer 2. You can also see that layer 1 is connected to layer 2. (The rows of `net.layerConnect` represent the destination layer, and the columns represent the source layer. A one in this matrix indicates a connection, and a zero indicates no connection. For this example, there is a single one in element 2,1 of the matrix.)

The key subobjects of the network object are `inputs`, `layers`, `outputs`, `biases`, `inputWeights`, and `layerWeights`. View the `layers` subobject for the first layer with the command

```
net.layers{1}
```

```

               size: 10
        topologyFcn: (none)
        transferFcn: 'tansig'
     transferParam: (none)
          userdata: (your custom info)
```

The number of neurons in a layer is given by its `size` property. In this case, the layer has 10 neurons, which is the default size for the `feedforwardnet` command. The net input function is `netsum` (summation) and the transfer function is the `tansig`. If you wanted to change the transfer function to `logsig`, for example, you could execute the command:

```
net.layers{1}.transferFcn = 'logsig';
```

To view the `layerWeights` subobject for the weight between layer 1 and layer 2, use the command:

```
net.layerWeights{2,1}
```

```
Neural Network Weight

            delays: 0
           initFcn: (none)
        initConfig: .inputSize
             learn: true
          learnFcn: 'learngdm'
        learnParam: .lr, .mc
              size: [0 10]
         weightFcn: 'dotprod'
       weightParam: (none)
          userdata: (your custom info)
```

The weight function is `dotprod`, which represents standard matrix multiplication (dot product). Note that the size of this layer weight is 0-by-10. The reason that we have zero rows is because the network has not yet been configured for a particular data set. The number of output neurons is equal to the number of rows in your target vector. During the configuration process, you will provide the network with example inputs and targets, and then the number of output neurons can be assigned.

This gives you some idea of how the network object is organized. For many applications, you will not need to be concerned about making changes directly to the network object, since that is taken care of by the network creation functions. It is usually only when you want to override the system defaults that it is necessary to access the network object directly. Other topics will show how this is done for particular networks and training methods.

To investigate the network object in more detail, you might find that the object listings, such as the one shown above, contain links to help on each subobject. Click the links, and you can selectively investigate those parts of the object that are of interest to you.

Configure Shallow Neural Network Inputs and Outputs

This topic is part of the design workflow described in “Workflow for Neural Network Design” on page 21-2.

After a neural network has been created, it must be configured. The configuration step consists of examining input and target data, setting the network's input and output sizes to match the data, and choosing settings for processing inputs and outputs that will enable best network performance. The configuration step is normally done automatically, when the training function is called. However, it can be done manually, by using the configuration function. For example, to configure the network you created previously to approximate a sine function, issue the following commands:

```
p = -2:.1:2;
t = sin(pi*p/2);
net1 = configure(net,p,t);
```

You have provided the network with an example set of inputs and targets (desired network outputs). With this information, the `configure` function can set the network input and output sizes to match the data.

After the configuration, if you look again at the weight between layer 1 and layer 2, you can see that the dimension of the weight is 1 by 20. This is because the target for this network is a scalar.

```
net1.layerWeights{2,1}

    Neural Network Weight

            delays: 0
           initFcn: (none)
        initConfig: .inputSize
             learn: true
          learnFcn: 'learngdm'
        learnParam: .lr, .mc
              size: [1 10]
         weightFcn: 'dotprod'
       weightParam: (none)
          userdata: (your custom info)
```

In addition to setting the appropriate dimensions for the weights, the configuration step also defines the settings for the processing of inputs and outputs. The input processing can be located in the `inputs` subobject:

```
net1.inputs{1}

    Neural Network Input

              name: 'Input'
    feedbackOutput: []
       processFcns: {'removeconstantrows', mapminmax}
     processParams: {1x2 cell array of 2 params}
   processSettings: {1x2 cell array of 2 settings}
     processedRange: [1x2 double]
      processedSize: 1
              range: [1x2 double]
               size: 1
          userdata: (your custom info)
```

Before the input is applied to the network, it will be processed by two functions: `removeconstantrows` and `mapminmax`. These are discussed fully in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2 so we won't address the particulars here. These processing functions may have some processing parameters, which are contained in the subobject `net1.inputs{1}.processParam`. These have default values that you can override. The processing functions can also have configuration settings that are dependent on the sample data. These are contained in `net1.inputs{1}.processSettings` and are set during the configuration process. For example, the `mapminmax` processing function normalizes the data so that all inputs fall in the range [−1, 1]. Its configuration settings include the minimum and maximum values in the sample data, which it needs to perform the correct normalization. This will be discussed in much more depth in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

As a general rule, we use the term “parameter,” as in process parameters, training parameters, etc., to denote constants that have default values that are assigned by the software when the network is created (and which you can override). We use the term “configuration setting,” as in process configuration setting, to denote constants that are assigned by the software from an analysis of sample data. These settings do not have default values, and should not generally be overridden.

For more information, see also “Understanding Shallow Network Data Structures” on page 21-18.

Understanding Shallow Network Data Structures

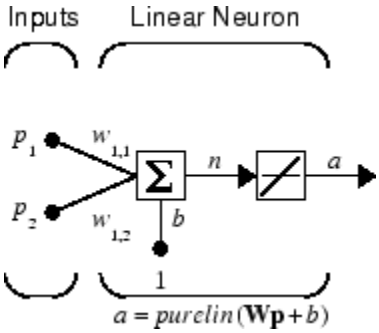
In this section...

This topic discusses how the format of input data structures affects the simulation of networks. It starts with static networks, and then continues with dynamic networks. The following section describes how the format of the data structures affects network training.

There are two basic types of input vectors: those that occur *concurrently* (at the same time, or in no particular time sequence), and those that occur *sequentially* in time. For concurrent vectors, the order is not important, and if there were a number of networks running in parallel, you could present one input vector to each of the networks. For sequential vectors, the order in which the vectors appear is important.

Simulation with Concurrent Inputs in a Static Network

The simplest situation for simulating a network occurs when the network to be simulated is static (has no feedback or delays). In this case, you need not be concerned about whether or not the input vectors occur in a particular time sequence, so you can treat the inputs as concurrent. In addition, the problem is made even simpler by assuming that the network has only one input vector. Use the following network as an example.



To set up this linear feedforward network, use the following commands:

```
net = linearlayer;
net.inputs{1}.size = 2;
net.layers{1}.dimensions = 1;
```

For simplicity, assign the weight matrix and bias to be **W** = [1 2] and b = [0].

The commands for these assignments are

```
net.IW{1,1} = [1 2];
net.b{1} = 0;
```

Suppose that the network simulation data set consists of Q = 4 concurrent vectors:

$$\mathbf{p}_1 = \begin{bmatrix}1\\2\end{bmatrix}, \mathbf{p}_2 = \begin{bmatrix}2\\1\end{bmatrix}, \mathbf{p}_3 = \begin{bmatrix}2\\3\end{bmatrix}, \mathbf{p}_4 = \begin{bmatrix}3\\1\end{bmatrix}$$

Concurrent vectors are presented to the network as a single matrix:

```
P = [1 2 2 3; 2 1 3 1];
```

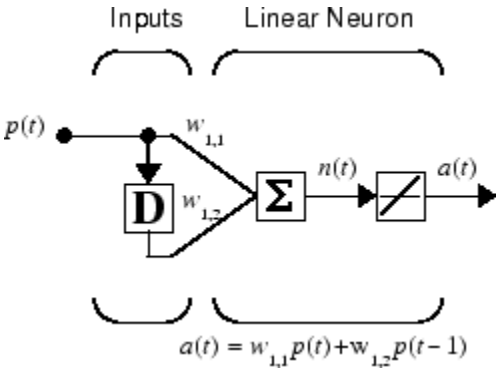
You can now simulate the network:

```
A = net(P)
A =
     5     4     8     5
```

A single matrix of concurrent vectors is presented to the network, and the network produces a single matrix of concurrent vectors as output. The result would be the same if there were four networks operating in parallel and each network received one of the input vectors and produced one of the outputs. The ordering of the input vectors is not important, because they do not interact with each other.

Simulation with Sequential Inputs in a Dynamic Network

When a network contains delays, the input to the network would normally be a sequence of input vectors that occur in a certain time order. To illustrate this case, the next figure shows a simple network that contains one delay.



The following commands create this network:

```
net = linearlayer([0 1]);
net.inputs{1}.size = 1;
net.layers{1}.dimensions = 1;
net.biasConnect = 0;
```

Assign the weight matrix to be **W** = [1 2].

The command is:

```
net.IW{1,1} = [1 2];
```

Suppose that the input sequence is:

$$\mathbf{p}_1 = [1], \mathbf{p}_2 = [2], \mathbf{p}_3 = [3], \mathbf{p}_4 = [4]$$

Sequential inputs are presented to the network as elements of a cell array:

```
P = {1 2 3 4};
```

You can now simulate the network:

```
A = net(P)
A =
    [1]    [4]    [7]    [10]
```

You input a cell array containing a sequence of inputs, and the network produces a cell array containing a sequence of outputs. The order of the inputs is important when they are presented as a sequence. In this case, the current output is obtained by multiplying the current input by 1 and the preceding input by 2 and summing the result. If you were to change the order of the inputs, the numbers obtained in the output would change.

Simulation with Concurrent Inputs in a Dynamic Network

If you were to apply the same inputs as a set of concurrent inputs instead of a sequence of inputs, you would obtain a completely different response. (However, it is not clear why you would want to do this with a dynamic network.) It would be as if each input were applied concurrently to a separate parallel network. For the previous example, “Simulation with Sequential Inputs in a Dynamic Network” on page 21-19, if you use a concurrent set of inputs you have

$$\mathbf{p}_1 = [1], \mathbf{p}_2 = [2], \mathbf{p}_3 = [3], \mathbf{p}_4 = [4]$$

which can be created with the following code:

```
P = [1 2 3 4];
```

When you simulate with concurrent inputs, you obtain

```
A = net(P)
A =
     1     2     3     4
```

The result is the same as if you had concurrently applied each one of the inputs to a separate network and computed one output. Note that because you did not assign any initial conditions to the network delays, they were assumed to be 0. For this case the output is simply 1 times the input, because the weight that multiplies the current input is 1.

In certain special cases, you might want to simulate the network response to several different sequences at the same time. In this case, you would want to present the network with a concurrent set of sequences. For example, suppose you wanted to present the following two sequences to the network:

$$\mathbf{p}_1(1) = [1], \mathbf{p}_1(2) = [2], \mathbf{p}_1(3) = [3], \mathbf{p}_1(4) = [4]$$
$$\mathbf{p}_2(1) = [4], \mathbf{p}_2(2) = [3], \mathbf{p}_2(3) = [2], \mathbf{p}_2(4) = [1]$$

The input P should be a cell array, where each element of the array contains the two elements of the two sequences that occur at the same time:

```
P = {[1 4] [2 3] [3 2] [4 1]};
```

You can now simulate the network:

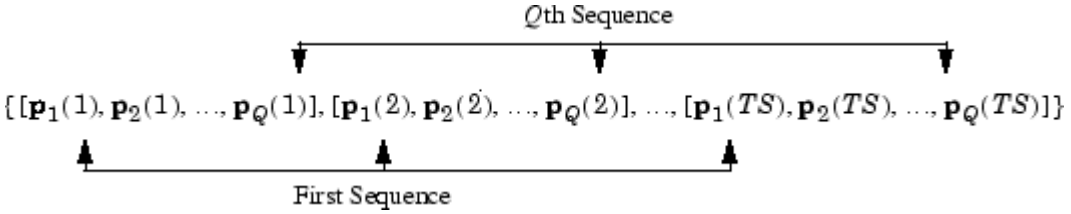
```
A = net(P);
```

The resulting network output would be

```
A = {[1 4] [4 11] [7 8] [10 5]}
```

As you can see, the first column of each matrix makes up the output sequence produced by the first input sequence, which was the one used in an earlier example. The second column of each matrix makes up the output sequence produced by the second input sequence. There is no interaction between the two concurrent sequences. It is as if they were each applied to separate networks running in parallel.

The following diagram shows the general format for the network input P when there are *Q* concurrent sequences of *TS* time steps. It covers all cases where there is a single input vector. Each element of the cell array is a matrix of concurrent vectors that correspond to the same point in time for each sequence. If there are multiple input vectors, there will be multiple rows of matrices in the cell array.



In this topic, you apply sequential and concurrent inputs to dynamic networks. In “Simulation with Concurrent Inputs in a Static Network” on page 21-18, you applied concurrent inputs to static networks. It is also possible to apply sequential inputs to static networks. It does not change the simulated response of the network, but it can affect the way in which the network is trained. This will become clear in “Neural Network Training Concepts” on page 21-22.

See also “Configure Shallow Neural Network Inputs and Outputs” on page 21-16.

Neural Network Training Concepts

In this section...

This topic is part of the design workflow described in “Workflow for Neural Network Design” on page 21-2.

This topic describes two different styles of training. In *incremental* training the weights and biases of the network are updated each time an input is presented to the network. In *batch* training the weights and biases are only updated after all the inputs are presented. The batch training methods are generally more efficient in the MATLAB environment, and they are emphasized in the Deep Learning Toolbox software, but there some applications where incremental training can be useful, so that paradigm is implemented as well.

Incremental Training with adapt

Incremental training can be applied to both static and dynamic networks, although it is more commonly used with dynamic networks, such as adaptive filters. This section illustrates how incremental training is performed on both static and dynamic networks.

Incremental Training of Static Networks

Consider again the static network used for the first example. You want to train it incrementally, so that the weights and biases are updated after each input is presented. In this case you use the function `adapt`, and the inputs and targets are presented as sequences.

Suppose you want to train the network to create the linear function:

$$t = 2p_1 + p_2$$

Then for the previous inputs,

$$\mathbf{p}_1 = \begin{bmatrix}1\\2\end{bmatrix}, \mathbf{p}_2 = \begin{bmatrix}2\\1\end{bmatrix}, \mathbf{p}_3 = \begin{bmatrix}2\\3\end{bmatrix}, \mathbf{p}_4 = \begin{bmatrix}3\\1\end{bmatrix}$$

the targets would be

$$\mathbf{t}_1 = [4], \mathbf{t}_2 = [5], \mathbf{t}_3 = [7], \mathbf{t}_4 = [7]$$

For incremental training, you present the inputs and targets as sequences:

```
P = {[1;2] [2;1] [2;3] [3;1]};
T = {4 5 7 7};
```

First, set up the network with zero initial weights and biases. Also, set the initial learning rate to zero to show the effect of incremental training.

```
net = linearlayer(0,0);
net = configure(net,P,T);
```

```
net.IW{1,1} = [0 0];
net.b{1} = 0;
```

Recall from “Simulation with Concurrent Inputs in a Static Network” on page 21-18 that, for a static network, the simulation of the network produces the same outputs whether the inputs are presented as a matrix of concurrent vectors or as a cell array of sequential vectors. However, this is not true when training the network. When you use the `adapt` function, if the inputs are presented as a cell array of sequential vectors, then the weights are updated as each input is presented (incremental mode). As shown in the next section, if the inputs are presented as a matrix of concurrent vectors, then the weights are updated only after all inputs are presented (batch mode).

You are now ready to train the network incrementally.

```
[net,a,e,pf] = adapt(net,P,T);
```

The network outputs remain zero, because the learning rate is zero, and the weights are not updated. The errors are equal to the targets:

```
a = [0]    [0]    [0]    [0]
e = [4]    [5]    [7]    [7]
```

If you now set the learning rate to 0.1 you can see how the network is adjusted as each input is presented:

```
net.inputWeights{1,1}.learnParam.lr = 0.1;
net.biases{1,1}.learnParam.lr = 0.1;
[net,a,e,pf] = adapt(net,P,T);
a = [0]    [2]    [6]    [5.8]
e = [4]    [3]    [1]    [1.2]
```

The first output is the same as it was with zero learning rate, because no update is made until the first input is presented. The second output is different, because the weights have been updated. The weights continue to be modified as each error is computed. If the network is capable and the learning rate is set correctly, the error is eventually driven to zero.

Incremental Training with Dynamic Networks

You can also train dynamic networks incrementally. In fact, this would be the most common situation.

To train the network incrementally, present the inputs and targets as elements of cell arrays. Here are the initial input `Pi` and the inputs `P` and targets `T` as elements of cell arrays.

```
Pi = {1};
P = {2 3 4};
T = {3 5 7};
```

Take the linear network with one delay at the input, as used in a previous example. Initialize the weights to zero and set the learning rate to 0.1.

```
net = linearlayer([0 1],0.1);
net = configure(net,P,T);
net.IW{1,1} = [0 0];
net.biasConnect = 0;
```

You want to train the network to create the current output by summing the current and the previous inputs. This is the same input sequence you used in the previous example with the exception that you

assign the first term in the sequence as the initial condition for the delay. You can now sequentially train the network using `adapt`.

```
[net,a,e,pf] = adapt(net,P,T,Pi);
a = [0] [2.4] [7.98]
e = [3] [2.6] [-0.98]
```

The first output is zero, because the weights have not yet been updated. The weights change at each subsequent time step.

Batch Training

Batch training, in which weights and biases are only updated after all the inputs and targets are presented, can be applied to both static and dynamic networks. Both types of networks are discussed in this section.

Batch Training with Static Networks

Batch training can be done using either `adapt` or `train`, although `train` is generally the best option, because it typically has access to more efficient training algorithms. Incremental training is usually done with `adapt`; batch training is usually done with `train`.

For batch training of a static network with `adapt`, the input vectors must be placed in one matrix of concurrent vectors.

```
P = [1 2 2 3; 2 1 3 1];
T = [4 5 7 7];
```

Begin with the static network used in previous examples. The learning rate is set to 0.01.

```
net = linearlayer(0,0.01);
net = configure(net,P,T);
net.IW{1,1} = [0 0];
net.b{1} = 0;
```

When you call `adapt`, it invokes `trains` (the default adaption function for the linear network) and `learnwh` (the default learning function for the weights and biases). `trains` uses Widrow-Hoff learning.

```
[net,a,e,pf] = adapt(net,P,T);
a = 0 0 0 0
e = 4 5 7 7
```

Note that the outputs of the network are all zero, because the weights are not updated until all the training set has been presented. If you display the weights, you find

```
net.IW{1,1}
  ans = 0.4900 0.4100
net.b{1}
  ans =
    0.2300
```

This is different from the result after one pass of `adapt` with incremental updating.

Now perform the same batch training using `train`. Because the Widrow-Hoff rule can be used in incremental or batch mode, it can be invoked by `adapt` or `train`. (There are several algorithms that

can only be used in batch mode (e.g., Levenberg-Marquardt), so these algorithms can only be invoked by `train`.)

For this case, the input vectors can be in a matrix of concurrent vectors or in a cell array of sequential vectors. Because the network is static and because `train` always operates in batch mode, `train` converts any cell array of sequential vectors to a matrix of concurrent vectors. Concurrent mode operation is used whenever possible because it has a more efficient implementation in MATLAB code:

```
P = [1 2 2 3; 2 1 3 1];
T = [4 5 7 7];
```

The network is set up in the same way.

```
net = linearlayer(0,0.01);
net = configure(net,P,T);
net.IW{1,1} = [0 0];
net.b{1} = 0;
```

Now you are ready to train the network. Train it for only one epoch, because you used only one pass of `adapt`. The default training function for the linear network is `trainb`, and the default learning function for the weights and biases is `learnwh`, so you should get the same results obtained using `adapt` in the previous example, where the default adaption function was `trains`.

```
net.trainParam.epochs = 1;
net = train(net,P,T);
```

If you display the weights after one epoch of training, you find

```
net.IW{1,1}
  ans = 0.4900 0.4100
net.b{1}
  ans =
    0.2300
```

This is the same result as the batch mode training in `adapt`. With static networks, the `adapt` function can implement incremental or batch training, depending on the format of the input data. If the data is presented as a matrix of concurrent vectors, batch training occurs. If the data is presented as a sequence, incremental training occurs. This is not true for `train`, which always performs batch training, regardless of the format of the input.

Batch Training with Dynamic Networks

Training static networks is relatively straightforward. If you use `train` the network is trained in batch mode and the inputs are converted to concurrent vectors (columns of a matrix), even if they are originally passed as a sequence (elements of a cell array). If you use `adapt`, the format of the input determines the method of training. If the inputs are passed as a sequence, then the network is trained in incremental mode. If the inputs are passed as concurrent vectors, then batch mode training is used.

With dynamic networks, batch mode training is typically done with `train` only, especially if only one training sequence exists. To illustrate this, consider again the linear network with a delay. Use a learning rate of 0.02 for the training. (When using a gradient descent algorithm, you typically use a smaller learning rate for batch mode training than incremental training, because all the individual gradients are summed before determining the step change to the weights.)

```
net = linearlayer([0 1],0.02);
net.inputs{1}.size = 1;
net.layers{1}.dimensions = 1;
net.IW{1,1} = [0 0];
net.biasConnect = 0;
net.trainParam.epochs = 1;
Pi = {1};
P = {2 3 4};
T = {3 5 6};
```

You want to train the network with the same sequence used for the incremental training earlier, but this time you want to update the weights only after all the inputs are applied (batch mode). The network is simulated in sequential mode, because the input is a sequence, but the weights are updated in batch mode.

```
net = train(net,P,T,Pi);
```

The weights after one epoch of training are

```
net.IW{1,1}
ans = 0.9000    0.6200
```

These are different weights than you would obtain using incremental training, where the weights would be updated three times during one pass through the training set. For batch training the weights are only updated once in each epoch.

Training Feedback

The `showWindow` parameter allows you to specify whether a training window is visible when you train. The training window appears by default. Two other parameters, `showCommandLine` and `show`, determine whether command-line output is generated and the number of epochs between command-line feedback during training. For instance, this code turns off the training window and gives you training status information every 35 epochs when the network is later trained with `train`:

```
net.trainParam.showWindow = false;
net.trainParam.showCommandLine = true;
net.trainParam.show= 35;
```

Sometimes it is convenient to disable all training displays. To do that, turn off both the training window and command-line feedback:

```
net.trainParam.showWindow = false;
net.trainParam.showCommandLine = false;
```

The training window appears automatically when you train.

Multilayer Shallow Neural Networks and Backpropagation Training

Multilayer Shallow Neural Networks and Backpropagation Training

The shallow multilayer feedforward neural network can be used for both function fitting and pattern recognition problems. With the addition of a tapped delay line, it can also be used for prediction problems, as discussed in “Design Time Series Time-Delay Neural Networks” on page 23-10. This topic shows how you can use a multilayer network. It also illustrates the basic procedures for designing any neural network.

Note The training functions described in this topic are not limited to multilayer networks. They can be used to train arbitrary architectures (even custom networks), as long as their components are differentiable.

The work flow for the general neural network design process has seven primary steps:

1. Collect data
2. Create the network
3. Configure the network
4. Initialize the weights and biases
5. Train the network
6. Validate the network (post-training analysis)
7. Use the network

Step 1 might happen outside the framework of Deep Learning Toolbox software, but this step is critical to the success of the design process.

Details of this workflow are discussed in these sections:

- “Multilayer Shallow Neural Network Architecture” on page 22-3
- “Prepare Data for Multilayer Shallow Neural Networks” on page 22-6
- “Create, Configure, and Initialize Multilayer Shallow Neural Networks” on page 22-11
- “Train and Apply Multilayer Shallow Neural Networks” on page 22-13
- “Analyze Shallow Neural Network Performance After Training” on page 22-18
- “Use the Network” on page 22-17
- “Limitations and Cautions” on page 22-22

Optional workflow steps are discussed in these sections:

- “Choose Neural Network Input-Output Processing Functions” on page 22-7
- “Divide Data for Optimal Neural Network Training” on page 22-9
- “Shallow Neural Networks with Parallel and GPU Computing” on page 28-2

For time series, dynamic modeling, and prediction, see this section:

- “How Dynamic Neural Networks Work” on page 23-3

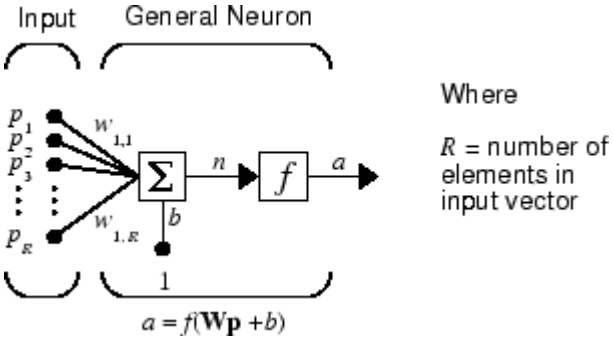
Multilayer Shallow Neural Network Architecture

In this section...

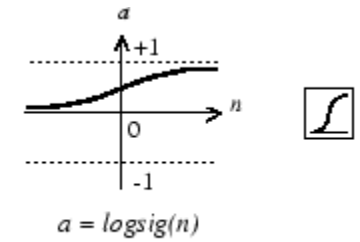
This topic presents part of a typical multilayer shallow network workflow. For more information and other steps, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

Neuron Model (logsig, tansig, purelin)

An elementary neuron with *R* inputs is shown below. Each input is weighted with an appropriate *w*. The sum of the weighted inputs and the bias forms the input to the transfer function *f*. Neurons can use any differentiable transfer function *f* to generate their output.



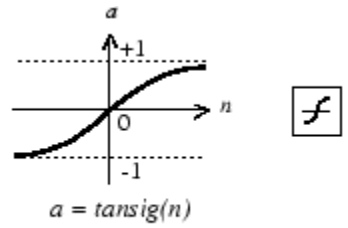
Multilayer networks often use the log-sigmoid transfer function `logsig`.



Log-Sigmoid Transfer Function

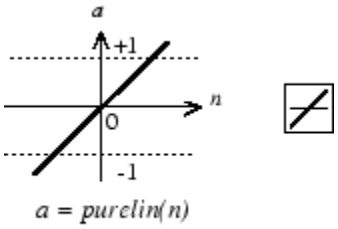
The function `logsig` generates outputs between 0 and 1 as the neuron's net input goes from negative to positive infinity.

Alternatively, multilayer networks can use the tan-sigmoid transfer function `tansig`.



Tan-Sigmoid Transfer Function

Sigmoid output neurons are often used for pattern recognition problems, while linear output neurons are used for function fitting problems. The linear transfer function `purelin` is shown below.

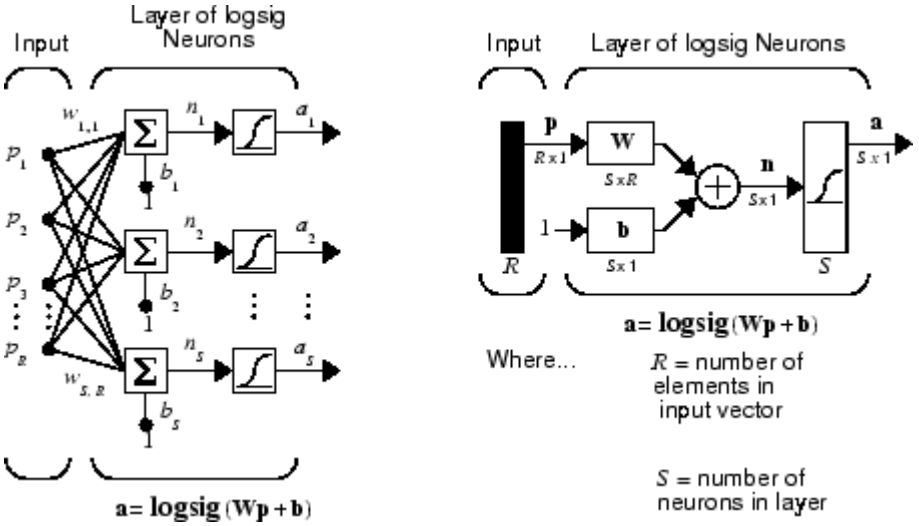


Linear Transfer Function

The three transfer functions described here are the most commonly used transfer functions for multilayer networks, but other differentiable transfer functions can be created and used if desired.

Feedforward Neural Network

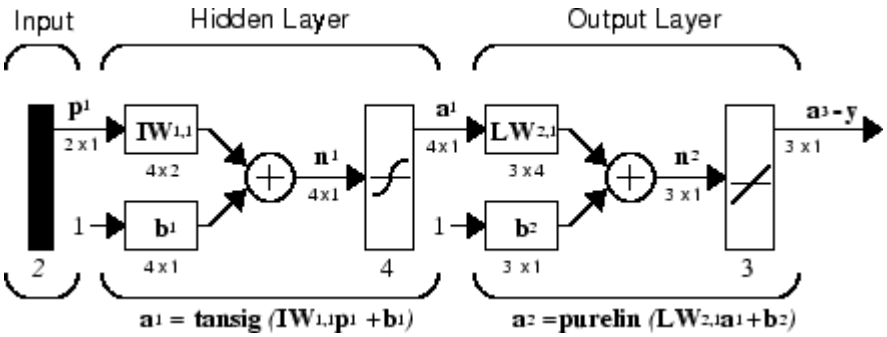
A single-layer network of S `logsig` neurons having R inputs is shown below in full detail on the left and with a layer diagram on the right.



Feedforward networks often have one or more hidden layers of sigmoid neurons followed by an output layer of linear neurons. Multiple layers of neurons with nonlinear transfer functions allow the network to learn nonlinear relationships between input and output vectors. The linear output layer is most often used for function fitting (or nonlinear regression) problems.

On the other hand, if you want to constrain the outputs of a network (such as between 0 and 1), then the output layer should use a sigmoid transfer function (such as `logsig`). This is the case when the network is used for pattern recognition problems (in which a decision is being made by the network).

For multiple-layer networks the layer number determines the superscript on the weight matrix. The appropriate notation is used in the two-layer `tansig`/`purelin` network shown next.



This network can be used as a general function approximator. It can approximate any function with a finite number of discontinuities arbitrarily well, given sufficient neurons in the hidden layer.

Now that the architecture of the multilayer network has been defined, the design process is described in the following sections.

Prepare Data for Multilayer Shallow Neural Networks

Tip To learn how to prepare image data for deep learning networks, see “Preprocess Images for Deep Learning” on page 19-16.

This topic presents part of a typical multilayer network workflow. For more information and other steps, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

Before beginning the network design process, you first collect and prepare sample data. It is generally difficult to incorporate prior knowledge into a neural network, therefore the network can only be as accurate as the data that are used to train the network.

It is important that the data cover the range of inputs for which the network will be used. Multilayer networks can be trained to generalize well within the range of inputs for which they have been trained. However, they do not have the ability to accurately extrapolate beyond this range, so it is important that the training data span the full range of the input space.

After the data have been collected, there are two steps that need to be performed before the data are used to train the network: the data need to be preprocessed, and they need to be divided into subsets.

Choose Neural Network Input-Output Processing Functions

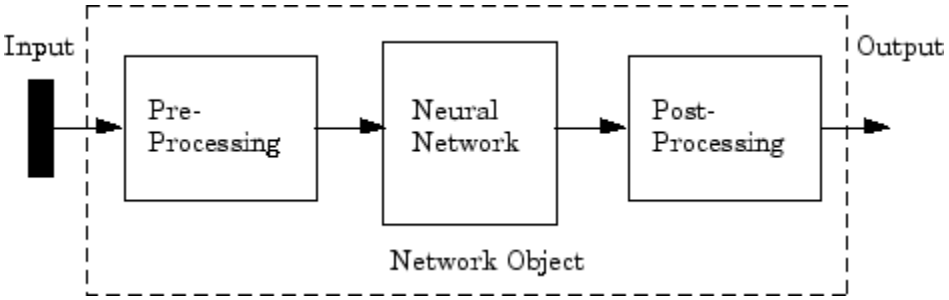
This topic presents part of a typical multilayer network workflow. For more information and other steps, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

Neural network training can be more efficient if you perform certain preprocessing steps on the network inputs and targets. This section describes several preprocessing routines that you can use. (The most common of these are provided automatically when you create a network, and they become part of the network object, so that whenever the network is used, the data coming into the network is preprocessed in the same way.)

For example, in multilayer networks, sigmoid transfer functions are generally used in the hidden layers. These functions become essentially saturated when the net input is greater than three (exp $(-3) \cong 0.05$). If this happens at the beginning of the training process, the gradients will be very small, and the network training will be very slow. In the first layer of the network, the net input is a product of the input times the weight plus the bias. If the input is very large, then the weight must be very small in order to prevent the transfer function from becoming saturated. It is standard practice to normalize the inputs before applying them to the network.

Generally, the normalization step is applied to both the input vectors and the target vectors in the data set. In this way, the network output always falls into a normalized range. The network output can then be reverse transformed back into the units of the original target data when the network is put to use in the field.

It is easiest to think of the neural network as having a preprocessing block that appears between the input and the first layer of the network and a postprocessing block that appears between the last layer of the network and the output, as shown in the following figure.



Most of the network creation functions in the toolbox, including the multilayer network creation functions, such as `feedforwardnet`, automatically assign processing functions to your network inputs and outputs. These functions transform the input and target values you provide into values that are better suited for network training.

You can override the default input and output processing functions by adjusting network properties after you create the network.

To see a cell array list of processing functions assigned to the input of a network, access this property:

```
net.inputs{1}.processFcns
```

where the index 1 refers to the first input vector. (There is only one input vector for the feedforward network.) To view the processing functions returned by the output of a two-layer network, access this network property:

```
net.outputs{2}.processFcns
```

where the index 2 refers to the output vector coming from the second layer. (For the feedforward network, there is only one output vector, and it comes from the final layer.) You can use these properties to change the processing functions that you want your network to apply to the inputs and outputs. However, the defaults usually provide excellent performance.

Several processing functions have parameters that customize their operation. You can access or change the parameters of the `i`th input processing function for the network input as follows:

```
net.inputs{1}.processParams{i}
```

You can access or change the parameters of the `i`th output processing function for the network output associated with the second layer, as follows:

```
net.outputs{2}.processParams{i}
```

For multilayer network creation functions, such as `feedforwardnet`, the default input processing functions are `removeconstantrows` and `mapminmax`. For outputs, the default processing functions are also `removeconstantrows` and `mapminmax`.

The following table lists the most common preprocessing and postprocessing functions. In most cases, you will not need to use them directly, since the preprocessing steps become part of the network object. When you simulate or train the network, the preprocessing and postprocessing will be done automatically.

Function	Algorithm
`mapminmax`	Normalize inputs/targets to fall in the range [−1, 1]
`mapstd`	Normalize inputs/targets to have zero mean and unity variance
`processpca`	Extract principal components from the input vector
`fixunknowns`	Process unknown inputs
`removeconstantrows`	Remove inputs/targets that are constant

Representing Unknown or Don't-Care Targets

Unknown or “don't care” targets can be represented with `NaN` values. We do not want unknown target values to have an impact on training, but if a network has several outputs, some elements of any target vector may be known while others are unknown. One solution would be to remove the partially unknown target vector and its associated input vector from the training set, but that involves the loss of the good target values. A better solution is to represent those unknown targets with `NaN` values. All the performance functions of the toolbox will ignore those targets for purposes of calculating performance and derivatives of performance.

Divide Data for Optimal Neural Network Training

This topic presents part of a typical multilayer network workflow. For more information and other steps, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

When training multilayer networks, the general practice is to first divide the data into three subsets. The first subset is the training set, which is used for computing the gradient and updating the network weights and biases. The second subset is the validation set. The error on the validation set is monitored during the training process. The validation error normally decreases during the initial phase of training, as does the training set error. However, when the network begins to overfit the data, the error on the validation set typically begins to rise. The network weights and biases are saved at the minimum of the validation set error. This technique is discussed in more detail in “Improve Shallow Neural Network Generalization and Avoid Overfitting” on page 28-25.

The test set error is not used during training, but it is used to compare different models. It is also useful to plot the test set error during the training process. If the error on the test set reaches a minimum at a significantly different iteration number than the validation set error, this might indicate a poor division of the data set.

There are four functions provided for dividing data into training, validation and test sets. They are `dividerand` (the default), `divideblock`, `divideint`, and `divideind`. The data division is normally performed automatically when you train the network.

Function	Algorithm
`dividerand`	Divide the data randomly (default)
`divideblock`	Divide the data into contiguous blocks
`divideint`	Divide the data using an interleaved selection
`divideind`	Divide the data by index

You can access or change the division function for your network with this property:

```
net.divideFcn
```

Each of the division functions takes parameters that customize its behavior. These values are stored and can be changed with the following network property:

```
net.divideParam
```

The divide function is accessed automatically whenever the network is trained, and is used to divide the data into training, validation and testing subsets. If `net.divideFcn` is set to `'dividerand'` (the default), then the data is randomly divided into the three subsets using the division parameters `net.divideParam.trainRatio`, `net.divideParam.valRatio`, and `net.divideParam.testRatio`. The fraction of data that is placed in the training set is `trainRatio/(trainRatio+valRatio+testRatio)`, with a similar formula for the other two sets. The default ratios for training, testing and validation are 0.7, 0.15 and 0.15, respectively.

If `net.divideFcn` is set to `'divideblock'`, then the data is divided into three subsets using three contiguous blocks of the original data set (training taking the first block, validation the second and testing the third). The fraction of the original data that goes into each subset is determined by the same three division parameters used for `dividerand`.

If `net.divideFcn` is set to `'divideint'`, then the data is divided by an interleaved method, as in dealing a deck of cards. It is done so that different percentages of data go into the three subsets. The

fraction of the original data that goes into each subset is determined by the same three division parameters used for `dividerand`.

When `net.divideFcn` is set to `'divideind'`, the data is divided by index. The indices for the three subsets are defined by the division parameters `net.divideParam.trainInd`, `net.divideParam.valInd` and `net.divideParam.testInd`. The default assignment for these indices is the null array, so you must set the indices when using this option.

Create, Configure, and Initialize Multilayer Shallow Neural Networks

In this section...

This topic presents part of a typical multilayer shallow network workflow. For more information and other steps, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

After the data has been collected, the next step in training a network is to create the network object. The function `feedforwardnet` creates a multilayer feedforward network. If this function is invoked with no input arguments, then a default network object is created that has not been configured. The resulting network can then be configured with the `configure` command.

As an example, the file `bodyfat_dataset.mat` contains a predefined set of input and target vectors. The input vectors define data regarding physical attributes of people and the target values define percentage body fat of the people. Load the data using the following command:

```
load bodyfat_dataset
```

Loading this file creates two variables. The input matrix `bodyfatInputs` consists of 252 column vectors of 13 physical attribute variables for 252 different people. The target matrix `bodyfatTargets` consists of the corresponding 252 body fat percentages.

The next step is to create the network. The following call to `feedforwardnet` creates a two-layer network with 10 neurons in the hidden layer. (During the configuration step, the number of neurons in the output layer is set to one, which is the number of elements in each vector of targets.)

```
net = feedforwardnet;
net = configure(net, bodyfatInputs, bodyfatTargets);
```

Optional arguments can be provided to `feedforwardnet`. For instance, the first argument is an array containing the number of neurons in each hidden layer. (The default setting is 10, which means one hidden layer with 10 neurons. One hidden layer generally produces excellent results, but you may want to try two hidden layers, if the results with one are not adequate. Increasing the number of neurons in the hidden layer increases the power of the network, but requires more computation and is more likely to produce overfitting.) The second argument contains the name of the training function to be used. If no arguments are supplied, the default number of layers is 2, the default number of neurons in the hidden layer is 10, and the default training function is `trainlm`. The default transfer function for hidden layers is `tansig` and the default for the output layer is `purelin`.

The `configure` command configures the network object and also initializes the weights and biases of the network; therefore the network is ready for training. There are times when you might want to reinitialize the weights, or to perform a custom initialization. “Initializing Weights (init)” on page 22-12 explains the details of the initialization process. You can also skip the configuration step and go directly to training the network. The `train` command will automatically configure the network and initialize the weights.

Other Related Architectures

While two-layer feedforward networks can potentially learn virtually any input-output relationship, feedforward networks with more layers might learn complex relationships more quickly. For most

problems, it is best to start with two layers, and then increase to three layers, if the performance with two layers is not satisfactory.

The function `cascadeforwardnet` creates cascade-forward networks. These are similar to feedforward networks, but include a weight connection from the input to each layer, and from each layer to the successive layers. For example, a three-layer network has connections from layer 1 to layer 2, layer 2 to layer 3, and layer 1 to layer 3. The three-layer network also has connections from the input to all three layers. The additional connections might improve the speed at which the network learns the desired relationship.

The function `patternnet` creates a network that is very similar to `feedforwardnet`, except that it uses the `tansig` transfer function in the last layer. This network is generally used for pattern recognition. Other networks can learn dynamic or time-series relationships.

Initializing Weights (init)

Before training a feedforward network, you must initialize the weights and biases. The `configure` command automatically initializes the weights, but you might want to reinitialize them. You do this with the `init` command. This function takes a network object as input and returns a network object with all weights and biases initialized. Here is how a network is initialized (or reinitialized):

```
net = init(net);
```

Train and Apply Multilayer Shallow Neural Networks

In this section...

Tip To train a deep learning network, use `trainNetwork`.

This topic presents part of a typical multilayer shallow network workflow. For more information and other steps, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

When the network weights and biases are initialized, the network is ready for training. The multilayer feedforward network can be trained for function approximation (nonlinear regression) or pattern recognition. The training process requires a set of examples of proper network behavior—network inputs `p` and target outputs `t`.

The process of training a neural network involves tuning the values of the weights and biases of the network to optimize network performance, as defined by the network performance function `net.performFcn`. The default performance function for feedforward networks is mean square error `mse`—the average squared error between the network outputs `a` and the target outputs `t`. It is defined as follows:

$$F = mse = \frac{1}{N}\sum_{i=1}^{N}(e_i)^2 = \frac{1}{N}\sum_{i=1}^{N}(t_i - a_i)^2$$

(Individual squared errors can also be weighted. See “Train Neural Networks with Error Weights” on page 23-32.) There are two different ways in which training can be implemented: incremental mode and batch mode. In incremental mode, the gradient is computed and the weights are updated after each input is applied to the network. In batch mode, all the inputs in the training set are applied to the network before the weights are updated. This topic describes batch mode training with the `train` command. Incremental training with the `adapt` command is discussed in “Incremental Training with adapt” on page 21-22. For most problems, when using the Deep Learning Toolbox software, batch training is significantly faster and produces smaller errors than incremental training.

For training multilayer feedforward networks, any standard numerical optimization algorithm can be used to optimize the performance function, but there are a few key ones that have shown excellent performance for neural network training. These optimization methods use either the gradient of the network performance with respect to the network weights, or the Jacobian of the network errors with respect to the weights.

The gradient and the Jacobian are calculated using a technique called the *backpropagation* algorithm, which involves performing computations backward through the network. The backpropagation computation is derived using the chain rule of calculus and is described in Chapters 11 (for the gradient) and 12 (for the Jacobian) of [HDB96 on page 32-2].

Training Algorithms

As an illustration of how the training works, consider the simplest optimization algorithm — gradient descent. It updates the network weights and biases in the direction in which the performance

function decreases most rapidly, the negative of the gradient. One iteration of this algorithm can be written as

$$\mathbf{x}_{k+1} = \mathbf{x}_k - \alpha_k \mathbf{g}_k$$

where $\boldsymbol{x}_k$ is a vector of current weights and biases, $\boldsymbol{g}_k$ is the current gradient, and α_k is the learning rate. This equation is iterated until the network converges.

A list of the training algorithms that are available in the Deep Learning Toolbox software and that use gradient- or Jacobian-based methods, is shown in the following table.

For a detailed description of several of these techniques, see also Hagan, M.T., H.B. Demuth, and M.H. Beale, Neural Network Design, Boston, MA: PWS Publishing, 1996, Chapters 11 and 12.

Function	Algorithm
`trainlm`	Levenberg-Marquardt
`trainbr`	Bayesian Regularization
`trainbfg`	BFGS Quasi-Newton
`trainrp`	Resilient Backpropagation
`trainscg`	Scaled Conjugate Gradient
`traincgb`	Conjugate Gradient with Powell/Beale Restarts
`traincgf`	Fletcher-Powell Conjugate Gradient
`traincgp`	Polak-Ribiére Conjugate Gradient
`trainoss`	One Step Secant
`traingdx`	Variable Learning Rate Gradient Descent
`traingdm`	Gradient Descent with Momentum
`traingd`	Gradient Descent

The fastest training function is generally `trainlm`, and it is the default training function for `feedforwardnet`. The quasi-Newton method, `trainbfg`, is also quite fast. Both of these methods tend to be less efficient for large networks (with thousands of weights), since they require more memory and more computation time for these cases. Also, `trainlm` performs better on function fitting (nonlinear regression) problems than on pattern recognition problems.

When training large networks, and when training pattern recognition networks, `trainscg` and `trainrp` are good choices. Their memory requirements are relatively small, and yet they are much faster than standard gradient descent algorithms.

See “Choose a Multilayer Neural Network Training Function” on page 28-14 for a full comparison of the performances of the training algorithms shown in the table above.

As a note on terminology, the term “backpropagation” is sometimes used to refer specifically to the gradient descent algorithm, when applied to neural network training. That terminology is not used here, since the process of computing the gradient and Jacobian by performing calculations backward through the network is applied in all of the training functions listed above. It is clearer to use the name of the specific optimization algorithm that is being used, rather than to use the term backpropagation alone.

Also, the multilayer network is sometimes referred to as a backpropagation network. However, the backpropagation technique that is used to compute gradients and Jacobians in a multilayer network

can also be applied to many different network architectures. In fact, the gradients and Jacobians for any network that has differentiable transfer functions, weight functions and net input functions can be computed using the Deep Learning Toolbox software through a backpropagation process. You can even create your own custom networks and then train them using any of the training functions in the table above. The gradients and Jacobians will be automatically computed for you.

Training Example

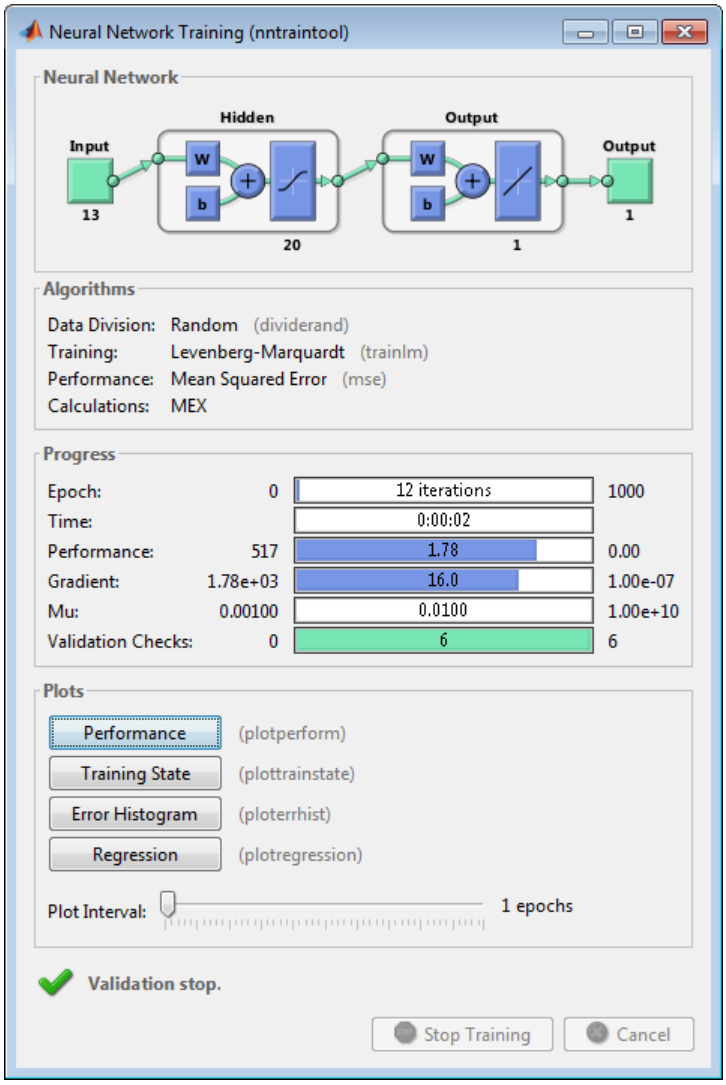
To illustrate the training process, execute the following commands:

```
load bodyfat_dataset
net = feedforwardnet(20);
[net,tr] = train(net,bodyfatInputs,bodyfatTargets);
```

Notice that you did not need to issue the `configure` command, because the configuration is done automatically by the `train` function. The training window will appear during training, as shown in the following figure. (If you do not want to have this window displayed during training, you can set the parameter `net.trainParam.showWindow` to `false`. If you want training information displayed in the command line, you can set the parameter `net.trainParam.showCommandLine` to `true`.)

This window shows that the data has been divided using the `dividerand` function, and the Levenberg-Marquardt (`trainlm`) training method has been used with the mean square error performance function. Recall that these are the default settings for `feedforwardnet`.

During training, the progress is constantly updated in the training window. Of most interest are the performance, the magnitude of the gradient of performance and the number of validation checks. The magnitude of the gradient and the number of validation checks are used to terminate the training. The gradient will become very small as the training reaches a minimum of the performance. If the magnitude of the gradient is less than 1e-5, the training will stop. This limit can be adjusted by setting the parameter `net.trainParam.min_grad`. The number of validation checks represents the number of successive iterations that the validation performance fails to decrease. If this number reaches 6 (the default value), the training will stop. In this run, you can see that the training did stop because of the number of validation checks. You can change this criterion by setting the parameter `net.trainParam.max_fail`. (Note that your results may be different than those shown in the following figure, because of the random setting of the initial weights and biases.)



There are other criteria that can be used to stop network training. They are listed in the following table.

Parameter	Stopping Criteria
`min_grad`	Minimum Gradient Magnitude
`max_fail`	Maximum Number of Validation Increases
`time`	Maximum Training Time
`goal`	Minimum Performance Value
`epochs`	Maximum Number of Training Epochs (Iterations)

The training will also stop if you click the **Stop Training** button in the training window. You might want to do this if the performance function fails to decrease significantly over many iterations. It is always possible to continue the training by reissuing the `train` command shown above. It will continue to train the network from the completion of the previous run.

From the training window, you can access four plots: performance, training state, error histogram, and regression. The performance plot shows the value of the performance function versus the iteration number. It plots training, validation, and test performances. The training state plot shows the progress of other training variables, such as the gradient magnitude, the number of validation checks, etc. The error histogram plot shows the distribution of the network errors. The regression plot shows a regression between network outputs and network targets. You can use the histogram and regression plots to validate network performance, as is discussed in “Analyze Shallow Neural Network Performance After Training” on page 22-18.

Use the Network

After the network is trained and validated, the network object can be used to calculate the network response to any input. For example, if you want to find the network response to the fifth input vector in the building data set, you can use the following

```
a = net(bodyfatInputs(:,5))
```

```
a =

   27.3740
```

If you try this command, your output might be different, depending on the state of your random number generator when the network was initialized. Below, the network object is called to calculate the outputs for a concurrent set of all the input vectors in the body fat data set. This is the batch mode form of simulation, in which all the input vectors are placed in one matrix. This is much more efficient than presenting the vectors one at a time.

```
a = net(bodyfatInputs);
```

Each time a neural network is trained, can result in a different solution due to different initial weight and bias values and different divisions of data into training, validation, and test sets. As a result, different neural networks trained on the same problem can give different outputs for the same input. To ensure that a neural network of good accuracy has been found, retrain several times.

There are several other techniques for improving upon initial solutions if higher accuracy is desired. For more information, see “Improve Shallow Neural Network Generalization and Avoid Overfitting” on page 28-25.

Analyze Shallow Neural Network Performance After Training

This topic presents part of a typical shallow neural network workflow. For more information and other steps, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2. To learn about how to monitor deep learning training progress, see “Monitor Deep Learning Training Progress” on page 5-115.

When the training in “Train and Apply Multilayer Shallow Neural Networks” on page 22-13 is complete, you can check the network performance and determine if any changes need to be made to the training process, the network architecture, or the data sets. First check the training record, `tr`, which was the second argument returned from the training function.

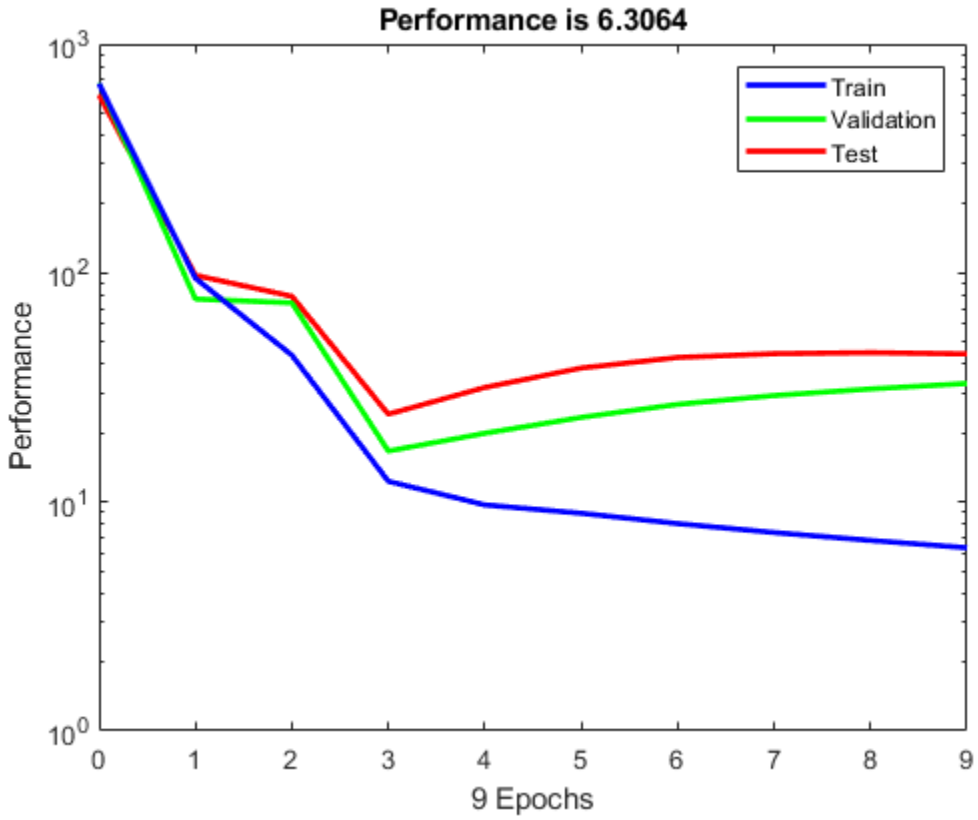
```
tr
```

```
tr = struct with fields:
        trainFcn: 'trainlm'
      trainParam: [1x1 struct]
      performFcn: 'mse'
    performParam: [1x1 struct]
        derivFcn: 'defaultderiv'
       divideFcn: 'dividerand'
      divideMode: 'sample'
     divideParam: [1x1 struct]
        trainInd: [2 3 5 6 9 10 11 13 14 15 18 19 20 22 23 24 25 29 30 ... ]
          valInd: [1 8 17 21 27 28 34 43 63 71 72 74 75 83 106 124 125 ... ]
         testInd: [4 7 12 16 26 32 37 42 53 60 61 67 69 78 82 87 89 104 ... ]
            stop: 'Training finished: Met validation criterion'
      num_epochs: 9
       trainMask: {[NaN 1 1 NaN 1 1 NaN NaN 1 1 1 NaN 1 1 1 NaN NaN 1 1 ... ]}
         valMask: {[1 NaN NaN NaN NaN NaN NaN 1 NaN NaN NaN NaN NaN NaN ... ]}
        testMask: {[NaN NaN NaN 1 NaN NaN 1 NaN NaN NaN NaN 1 NaN NaN ... ]}
      best_epoch: 3
            goal: 0
          states: {1x8 cell}
           epoch: [0 1 2 3 4 5 6 7 8 9]
            time: [0.0600 0.1350 0.1610 0.2010 0.2220 0.2410 0.2580 ... ]
            perf: [672.2031 94.8128 43.7489 12.3078 9.7063 8.9212 8.0412 ... ]
           vperf: [675.3788 76.9621 74.0752 16.6857 19.9424 23.4096 ... ]
           tperf: [599.2224 97.7009 79.1240 24.1796 31.6290 38.4484 ... ]
              mu: [1.0000e-03 0.0100 0.0100 0.1000 0.1000 0.1000 0.1000 ... ]
        gradient: [2.4114e+03 867.8889 301.7333 142.1049 12.4011 85.0504 ... ]
        val_fail: [0 0 0 0 1 2 3 4 5 6]
       best_perf: 12.3078
      best_vperf: 16.6857
      best_tperf: 24.1796
```

This structure contains all of the information concerning the training of the network. For example, `tr.trainInd`, `tr.valInd` and `tr.testInd` contain the indices of the data points that were used in the training, validation and test sets, respectively. If you want to retrain the network using the same division of data, you can set `net.divideFcn` to `'divideInd'`, `net.divideParam.trainInd` to `tr.trainInd`, `net.divideParam.valInd` to `tr.valInd`, `net.divideParam.testInd` to `tr.testInd`.

The `tr` structure also keeps track of several variables during the course of training, such as the value of the performance function, the magnitude of the gradient, etc. You can use the training record to plot the performance progress by using the `plotperf` command:

```
plotperf(tr)
```

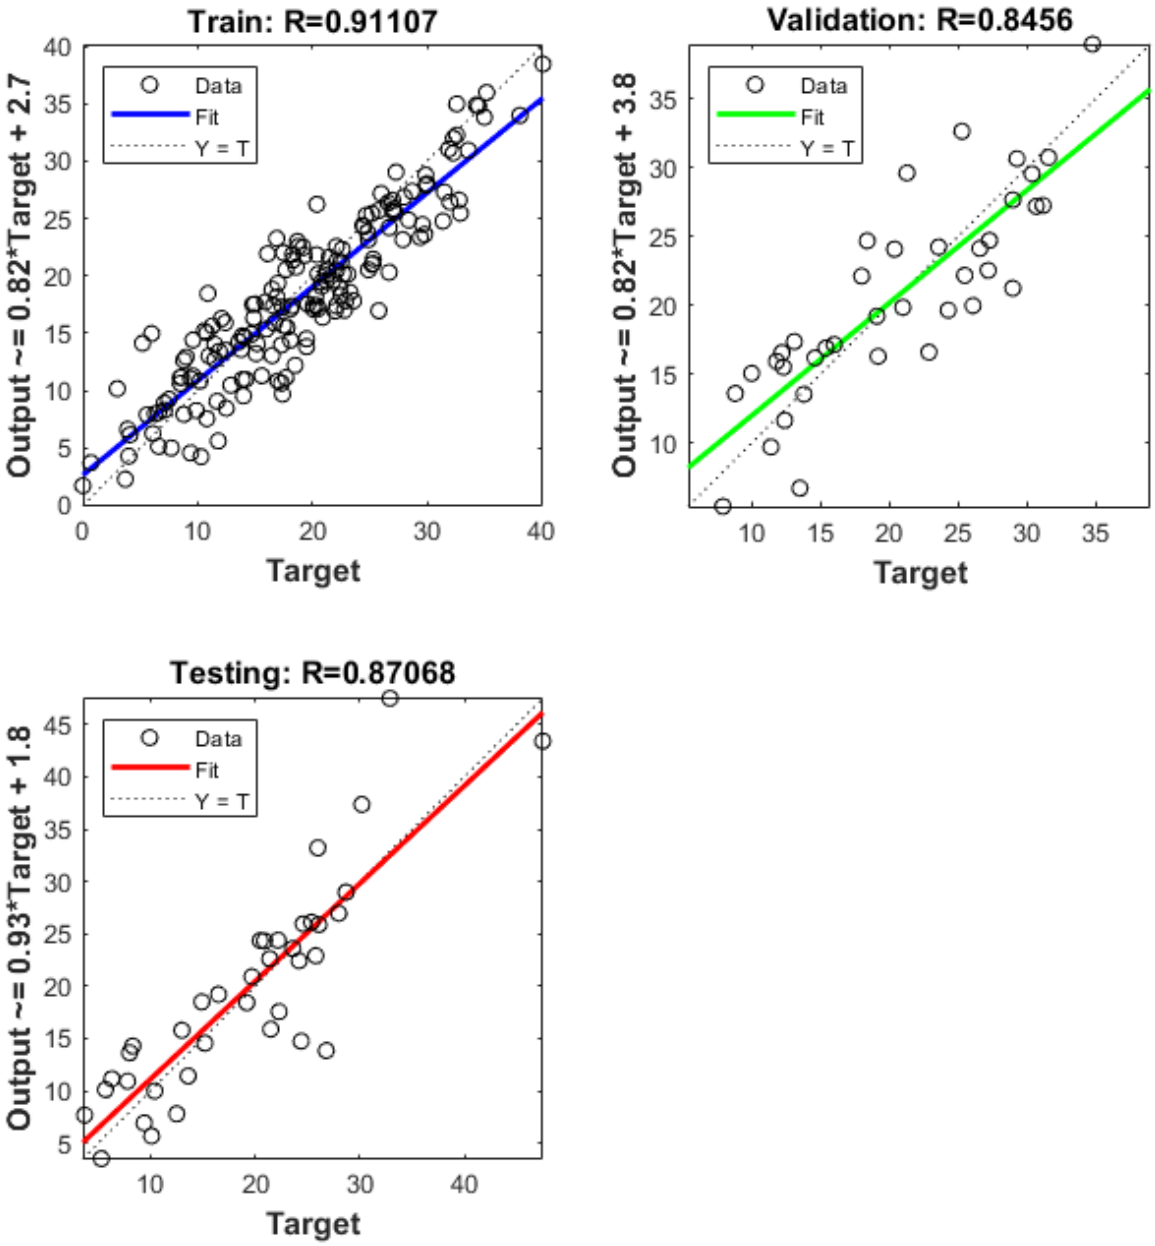


The property `tr.best_epoch` indicates the iteration at which the validation performance reached a minimum. The training continued for 6 more iterations before the training stopped.

This figure does not indicate any major problems with the training. The validation and test curves are very similar. If the test curve had increased significantly before the validation curve increased, then it is possible that some overfitting might have occurred.

The next step in validating the network is to create a regression plot, which shows the relationship between the outputs of the network and the targets. If the training were perfect, the network outputs and the targets would be exactly equal, but the relationship is rarely perfect in practice. For the body fat example, we can create a regression plot with the following commands. The first command calculates the trained network response to all of the inputs in the data set. The following six commands extract the outputs and targets that belong to the training, validation and test subsets. The final command creates three regression plots for training, testing and validation.

```
bodyfatOutputs = net(bodyfatInputs);
trOut = bodyfatOutputs(tr.trainInd);
vOut = bodyfatOutputs(tr.valInd);
tsOut = bodyfatOutputs(tr.testInd);
trTarg = bodyfatTargets(tr.trainInd);
vTarg = bodyfatTargets(tr.valInd);
tsTarg = bodyfatTargets(tr.testInd);
plotregression(trTarg, trOut, 'Train', vTarg, vOut, 'Validation', tsTarg, tsOut, 'Testing')
```



The three plots represent the training, validation, and testing data. The dashed line in each plot represents the perfect result – outputs = targets. The solid line represents the best fit linear regression line between outputs and targets. The R value is an indication of the relationship between the outputs and targets. If R = 1, this indicates that there is an exact linear relationship between outputs and targets. If R is close to zero, then there is no linear relationship between outputs and targets.

For this example, the training data indicates a good fit. The validation and test results also show large R values. The scatter plot is helpful in showing that certain data points have poor fits. For example, there is a data point in the test set whose network output is close to 35, while the corresponding target value is about 12. The next step would be to investigate this data point to determine if it represents extrapolation (i.e., is it outside of the training data set). If so, then it should be included in the training set, and additional data should be collected to be used in the test set.

Improving Results

If the network is not sufficiently accurate, you can try initializing the network and the training again. Each time your initialize a feedforward network, the network parameters are different and might produce different solutions.

```
net = init(net);
net = train(net, bodyfatInputs, bodyfatTargets);
```

As a second approach, you can increase the number of hidden neurons above 20. Larger numbers of neurons in the hidden layer give the network more flexibility because the network has more parameters it can optimize. (Increase the layer size gradually. If you make the hidden layer too large, you might cause the problem to be under-characterized and the network must optimize more parameters than there are data vectors to constrain these parameters.)

A third option is to try a different training function. Bayesian regularization training with `trainbr`, for example, can sometimes produce better generalization capability than using early stopping.

Finally, try using additional training data. Providing additional data for the network is more likely to produce a network that generalizes well to new data.

Limitations and Cautions

You would normally use Levenberg-Marquardt training for small and medium size networks, if you have enough memory available. If memory is a problem, then there are a variety of other fast algorithms available. For large networks you will probably want to use `trainscg` or `trainrp`.

Multilayer networks are capable of performing just about any linear or nonlinear computation, and they can approximate any reasonable function arbitrarily well. However, while the network being trained might theoretically be capable of performing correctly, backpropagation and its variations might not always find a solution. See page 12-8 of [HDB96 on page 32-2] for a discussion of convergence to local minimum points.

The error surface of a nonlinear network is more complex than the error surface of a linear network. To understand this complexity, see the figures on pages 12-5 to 12-7 of [HDB96 on page 32-2], which show three different error surfaces for a multilayer network. The problem is that nonlinear transfer functions in multilayer networks introduce many local minima in the error surface. As gradient descent is performed on the error surface, depending on the initial starting conditions, it is possible for the network solution to become trapped in one of these local minima. Settling in a local minimum can be good or bad depending on how close the local minimum is to the global minimum and how low an error is required. In any case, be cautioned that although a multilayer backpropagation network with enough neurons can implement just about any function, backpropagation does not always find the correct weights for the optimum solution. You might want to reinitialize the network and retrain several times to guarantee that you have the best solution.

Networks are also sensitive to the number of neurons in their hidden layers. Too few neurons can lead to underfitting. Too many neurons can contribute to overfitting, in which all training points are well fitted, but the fitting curve oscillates wildly between these points. Ways of dealing with various of these issues are discussed in “Improve Shallow Neural Network Generalization and Avoid Overfitting” on page 28-25. This topic is also discussed starting on page 11-21 of [HDB96 on page 32-2].

For more information about the workflow with multilayer networks, see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.

Dynamic Neural Networks

Introduction to Dynamic Neural Networks

Neural networks can be classified into dynamic and static categories. Static (feedforward) networks have no feedback elements and contain no delays; the output is calculated directly from the input through feedforward connections. In dynamic networks, the output depends not only on the current input to the network, but also on the current or previous inputs, outputs, or states of the network.

Details of this workflow are discussed in the following sections:

- “Design Time Series Time-Delay Neural Networks” on page 23-10
- “Prepare Input and Layer Delay States” on page 23-13
- “Design Time Series Distributed Delay Neural Networks” on page 23-14
- “Design Time Series NARX Feedback Neural Networks” on page 23-16
- “Design Layer-Recurrent Neural Networks” on page 23-22

Optional workflow steps are discussed in these sections:

- “Choose Neural Network Input-Output Processing Functions” on page 22-7
- “Divide Data for Optimal Neural Network Training” on page 22-9
- “Train Neural Networks with Error Weights” on page 23-32

How Dynamic Neural Networks Work

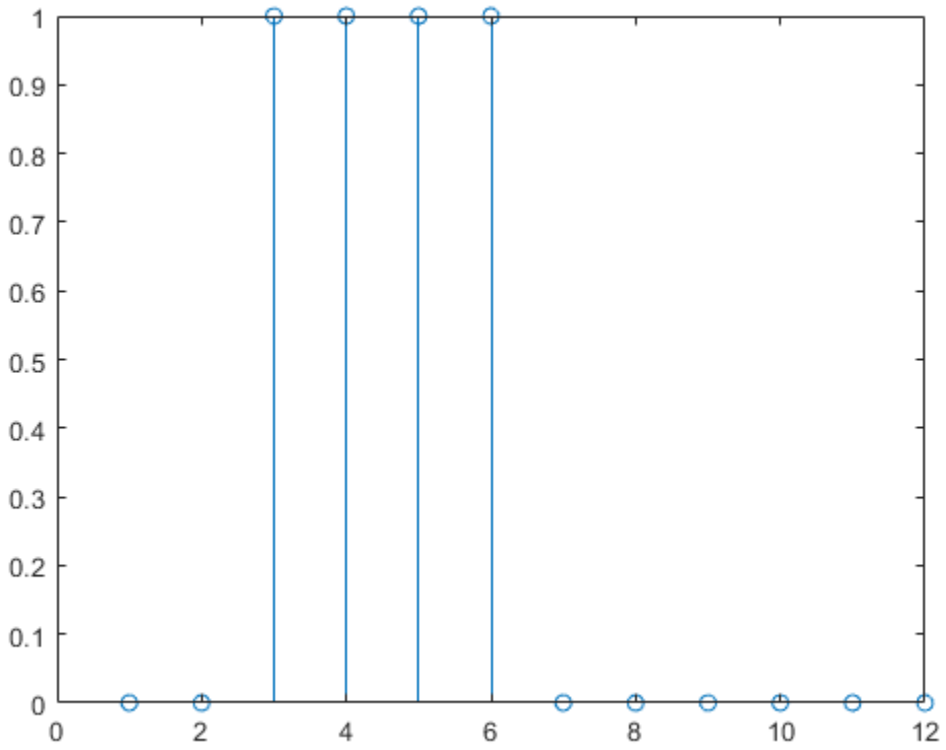
In this section...

Feedforward and Recurrent Neural Networks

Dynamic networks can be divided into two categories: those that have only feedforward connections, and those that have feedback, or recurrent, connections. To understand the differences between static, feedforward-dynamic, and recurrent-dynamic networks, create some networks and see how they respond to an input sequence. (First, you might want to review “Simulation with Sequential Inputs in a Dynamic Network” on page 21-19.)

The following commands create a pulse input sequence and plot it:

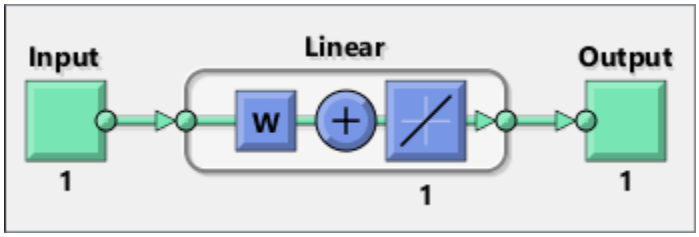
```
p = {0 0 1 1 1 1 0 0 0 0 0 0};
stem(cell2mat(p))
```



Now create a static network and find the network response to the pulse sequence. The following commands create a simple linear network with one layer, one neuron, no bias, and a weight of 2:

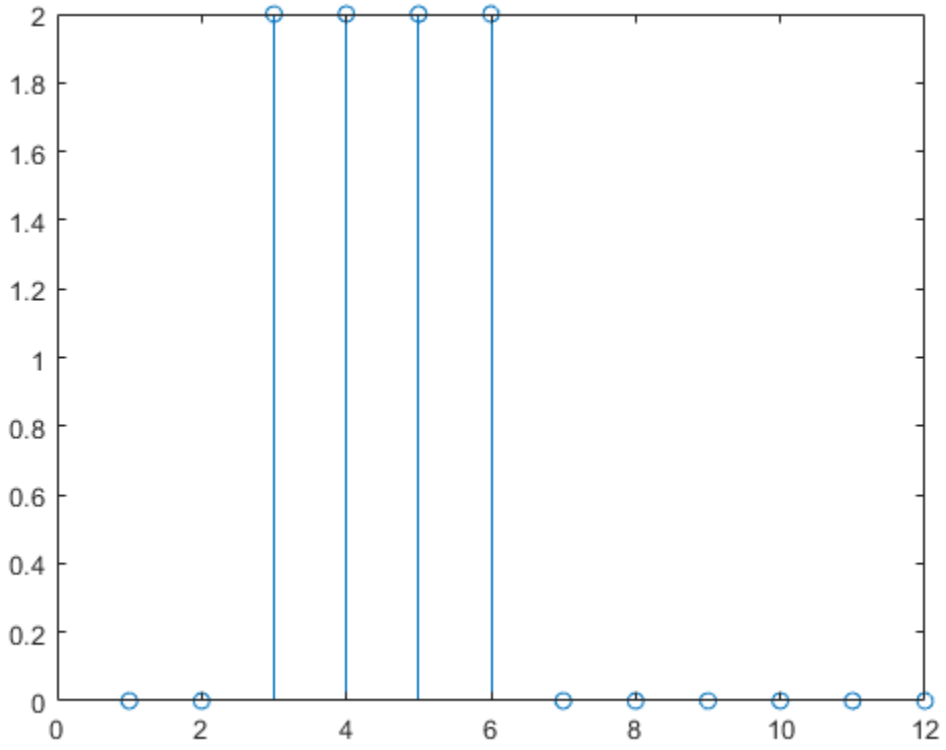
```
net = linearlayer;
net.inputs{1}.size = 1;
net.layers{1}.dimensions = 1;
net.biasConnect = 0;
net.IW{1,1} = 2;

view(net)
```



You can now simulate the network response to the pulse input and plot it:

```
a = net(p);
stem(cell2mat(a))
```

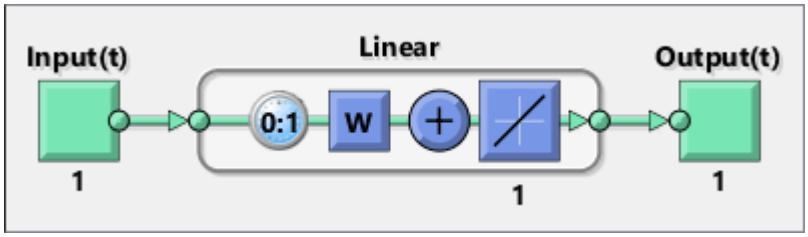


Note that the response of the static network lasts just as long as the input pulse. The response of the static network at any time point depends only on the value of the input sequence at that same time point.

Now create a dynamic network, but one that does not have any feedback connections (a nonrecurrent network). You can use the same network used in “Simulation with Concurrent Inputs in a Dynamic Network” on page 21-20, which was a linear network with a tapped delay line on the input:

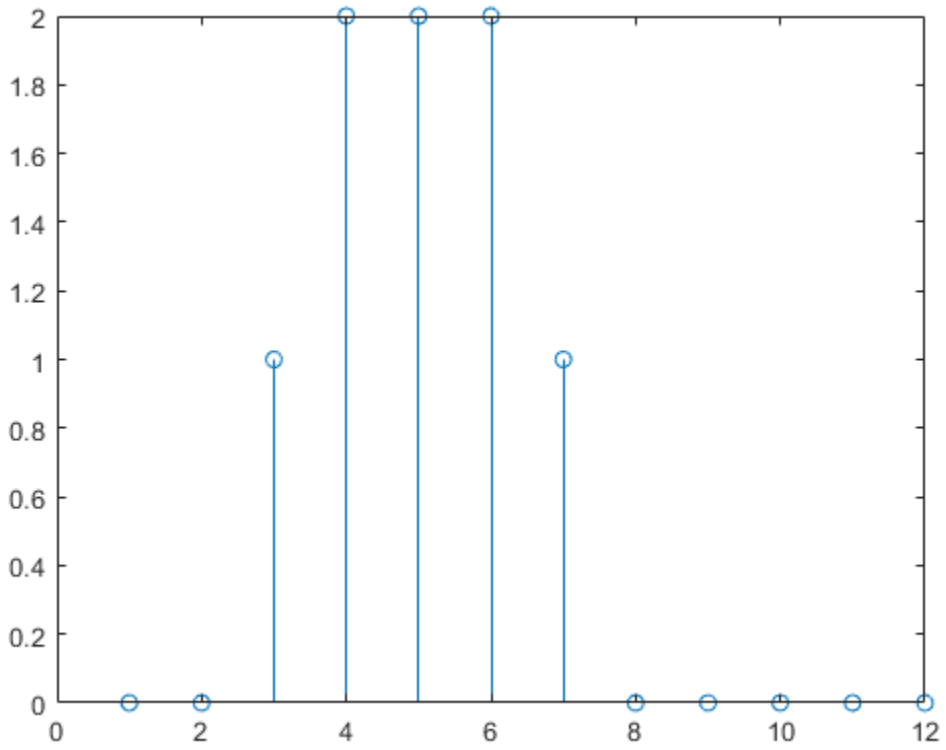
```
net = linearlayer([0 1]);
net.inputs{1}.size = 1;
net.layers{1}.dimensions = 1;
net.biasConnect = 0;
net.IW{1,1} = [1 1];

view(net)
```



You can again simulate the network response to the pulse input and plot it:

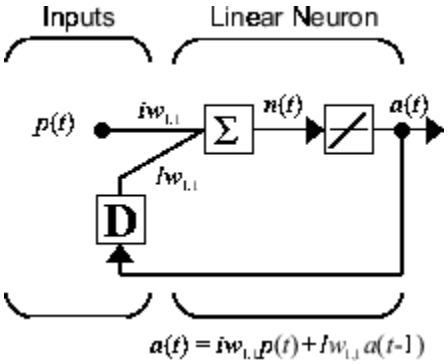
```
a = net(p);
stem(cell2mat(a))
```



The response of the dynamic network lasts longer than the input pulse. The dynamic network has memory. Its response at any given time depends not only on the current input, but also on the history

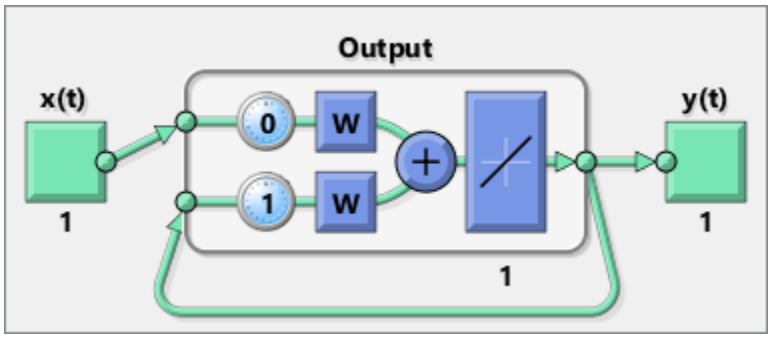
of the input sequence. If the network does not have any feedback connections, then only a finite amount of history will affect the response. In this figure you can see that the response to the pulse lasts one time step beyond the pulse duration. That is because the tapped delay line on the input has a maximum delay of 1.

Now consider a simple recurrent-dynamic network, shown in the following figure.



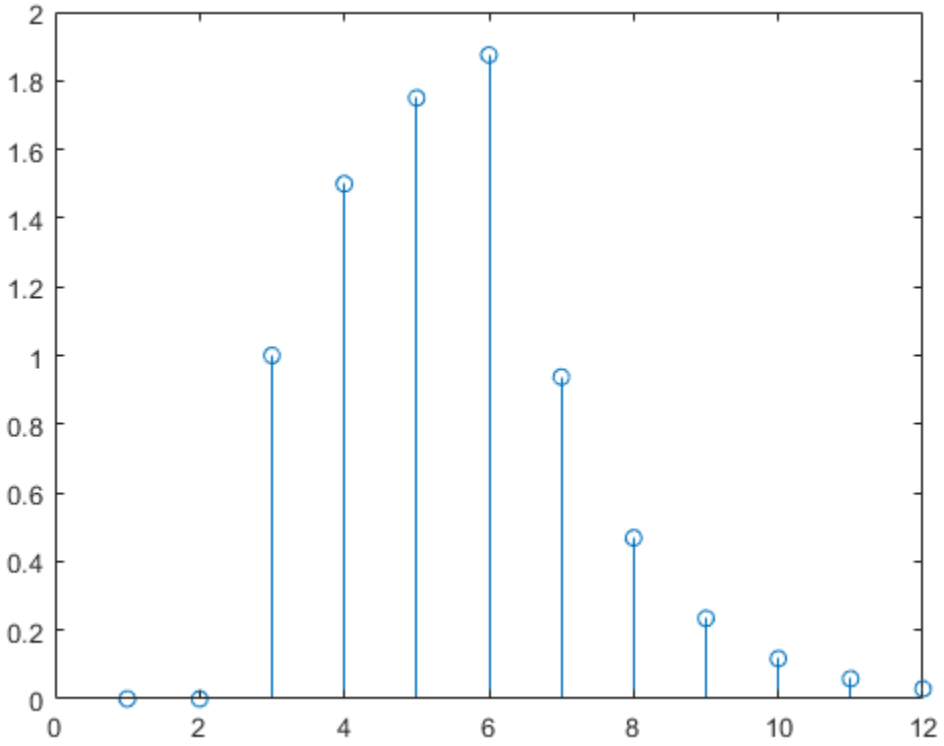
You can create the network, view it and simulate it with the following commands. The `narxnet` command is discussed in “Design Time Series NARX Feedback Neural Networks” on page 23-16.

```
net = narxnet(0,1,[],'closed');
net.inputs{1}.size = 1;
net.layers{1}.dimensions = 1;
net.biasConnect = 0;
net.LW{1} = .5;
net.IW{1} = 1;
view(net)
```



The following commands plot the network response.

```
a = net(p);
stem(cell2mat(a))
```



Notice that recurrent-dynamic networks typically have a longer response than feedforward-dynamic networks. For linear networks, feedforward-dynamic networks are called finite impulse response (FIR), because the response to an impulse input will become zero after a finite amount of time. Linear recurrent-dynamic networks are called infinite impulse response (IIR), because the response to an impulse can decay to zero (for a stable network), but it will never become exactly equal to zero. An impulse response for a nonlinear network cannot be defined, but the ideas of finite and infinite responses do carry over.

Applications of Dynamic Networks

Dynamic networks are generally more powerful than static networks (although somewhat more difficult to train). Because dynamic networks have memory, they can be trained to learn sequential or time-varying patterns. This has applications in such disparate areas as prediction in financial markets [RoJa96 on page 32-2], channel equalization in communication systems [FeTs03 on page 32-2], phase detection in power systems [KaGr96 on page 32-2], sorting [JaRa04 on page 32-2], fault detection [ChDa99 on page 32-2], speech recognition [Robin94 on page 32-2], and even the prediction of protein structure in genetics [GiPr02 on page 32-2]. You can find a discussion of many more dynamic network applications in [MeJa00 on page 32-2].

One principal application of dynamic neural networks is in control systems. This application is discussed in detail in “Neural Network Control Systems”. Dynamic networks are also well suited for filtering. You will see the use of some linear dynamic networks for filtering in and some of those ideas are extended in this topic, using nonlinear dynamic networks.

Dynamic Network Structures

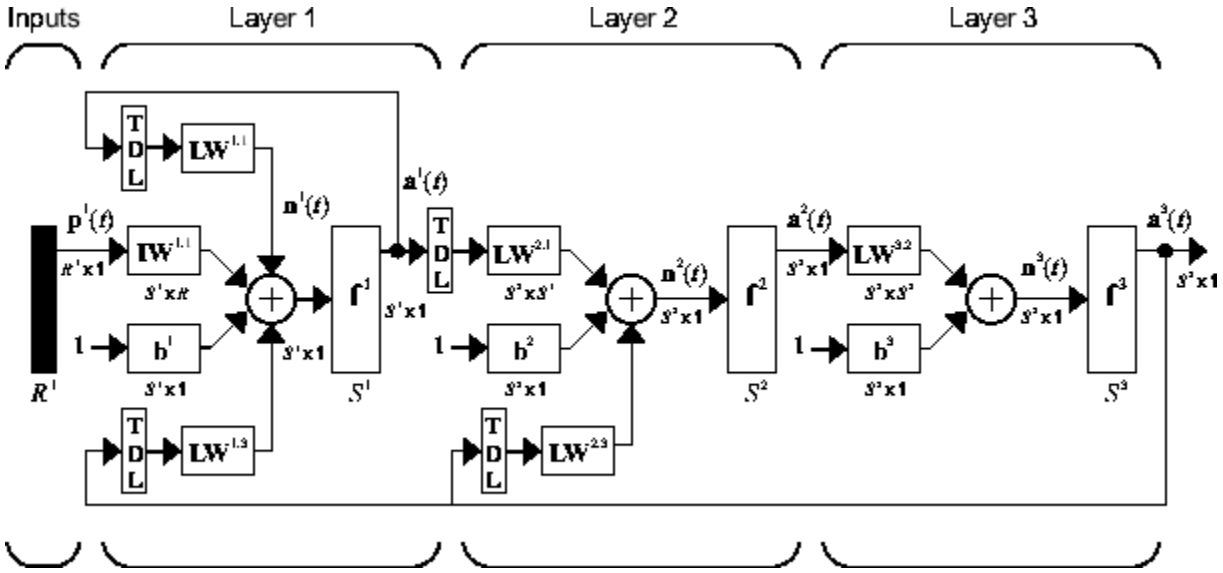
The Deep Learning Toolbox software is designed to train a class of network called the Layered Digital Dynamic Network (LDDN). Any network that can be arranged in the form of an LDDN can be trained with the toolbox. Here is a basic description of the LDDN.

Each layer in the LDDN is made up of the following parts:

- Set of weight matrices that come into that layer (which can connect from other layers or from external inputs), associated weight function rule used to combine the weight matrix with its input (normally standard matrix multiplication, `dotprod`), and associated tapped delay line
- Bias vector
- Net input function rule that is used to combine the outputs of the various weight functions with the bias to produce the net input (normally a summing junction, `netprod`)
- Transfer function

The network has inputs that are connected to special weights, called input weights, and denoted by $\mathbf{IW}^{i,j}$ (`net.IW{i,j}` in the code), where *j* denotes the number of the input vector that enters the weight, and *i* denotes the number of the layer to which the weight is connected. The weights connecting one layer to another are called layer weights and are denoted by $\mathbf{LW}^{i,j}$ (`net.LW{i,j}` in the code), where *j* denotes the number of the layer coming into the weight and *i* denotes the number of the layer at the output of the weight.

The following figure is an example of a three-layer LDDN. The first layer has three weights associated with it: one input weight, a layer weight from layer 1, and a layer weight from layer 3. The two layer weights have tapped delay lines associated with them.

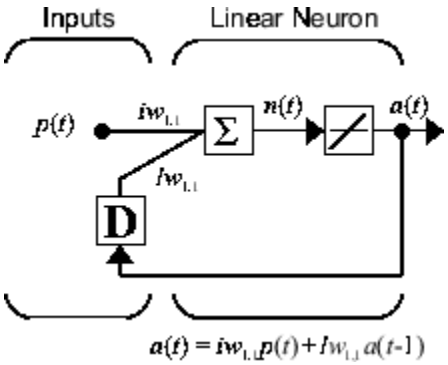


The Deep Learning Toolbox software can be used to train any LDDN, so long as the weight functions, net input functions, and transfer functions have derivatives. Most well-known dynamic network architectures can be represented in LDDN form. In the remainder of this topic you will see how to use some simple commands to create and train several very powerful dynamic networks. Other LDDN networks not covered in this topic can be created using the generic network command, as explained in “Define Shallow Neural Network Architectures”.

Dynamic Network Training

Dynamic networks are trained in the Deep Learning Toolbox software using the same gradient-based algorithms that were described in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2. You can select from any of the training functions that were presented in that topic. Examples are provided in the following sections.

Although dynamic networks can be trained using the same gradient-based algorithms that are used for static networks, the performance of the algorithms on dynamic networks can be quite different, and the gradient must be computed in a more complex way. Consider again the simple recurrent network shown in this figure.

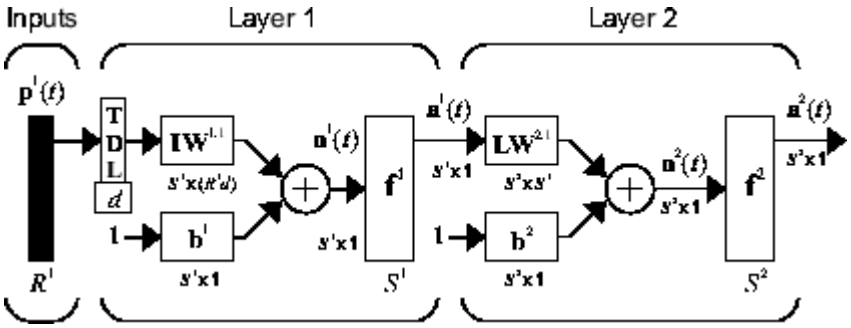


The weights have two different effects on the network output. The first is the direct effect, because a change in the weight causes an immediate change in the output at the current time step. (This first effect can be computed using standard backpropagation.) The second is an indirect effect, because some of the inputs to the layer, such as $a(t - 1)$, are also functions of the weights. To account for this indirect effect, you must use dynamic backpropagation to compute the gradients, which is more computationally intensive. (See [DeHa01a on page 32-2], [DeHa01b on page 32-2] and [DeHa07 on page 32-2].) Expect dynamic backpropagation to take more time to train, in part for this reason. In addition, the error surfaces for dynamic networks can be more complex than those for static networks. Training is more likely to be trapped in local minima. This suggests that you might need to train the network several times to achieve an optimal result. See [DHH01 on page 32-2] and [HDH09 on page 32-2] for some discussion on the training of dynamic networks.

The remaining sections of this topic show how to create, train, and apply certain dynamic networks to modeling, detection, and forecasting problems. Some of the networks require dynamic backpropagation for computing the gradients and others do not. As a user, you do not need to decide whether or not dynamic backpropagation is needed. This is determined automatically by the software, which also decides on the best form of dynamic backpropagation to use. You just need to create the network and then invoke the standard `train` command.

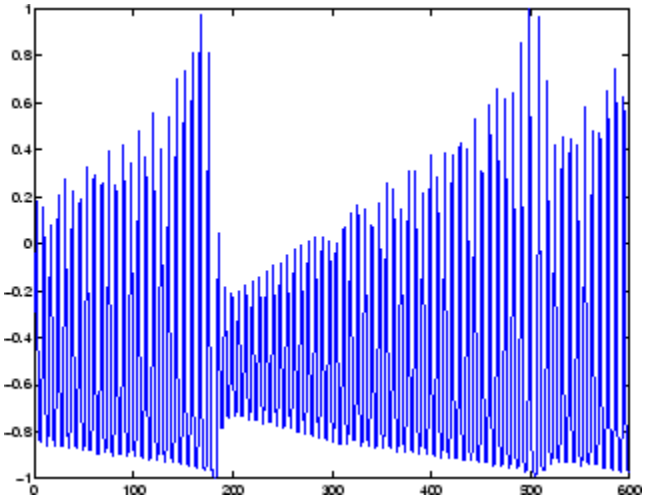
Design Time Series Time-Delay Neural Networks

Begin with the most straightforward dynamic network, which consists of a feedforward network with a tapped delay line at the input. This is called the focused time-delay neural network (FTDNN). This is part of a general class of dynamic networks, called focused networks, in which the dynamics appear only at the input layer of a static multilayer feedforward network. The following figure illustrates a two-layer FTDNN.



This network is well suited to time-series prediction. The following example the use of the FTDNN for predicting a classic time series.

The following figure is a plot of normalized intensity data recorded from a Far-Infrared-Laser in a chaotic state. This is a part of one of several sets of data used for the Santa Fe Time Series Competition [WeGe94 on page 32-2]. In the competition, the objective was to use the first 1000 points of the time series to predict the next 100 points. Because our objective is simply to illustrate how to use the FTDNN for prediction, the network is trained here to perform one-step-ahead predictions. (You can use the resulting network for multistep-ahead predictions by feeding the predictions back to the input of the network and continuing to iterate.)



The first step is to load the data, normalize it, and convert it to a time sequence (represented by a cell array):

```
y = laser_dataset;
y = y(1:600);
```

Now create the FTDNN network, using the `timedelaynet` command. This command is similar to the `feedforwardnet` command, with the additional input of the tapped delay line vector (the first input). For this example, use a tapped delay line with delays from 1 to 8, and use ten neurons in the hidden layer:

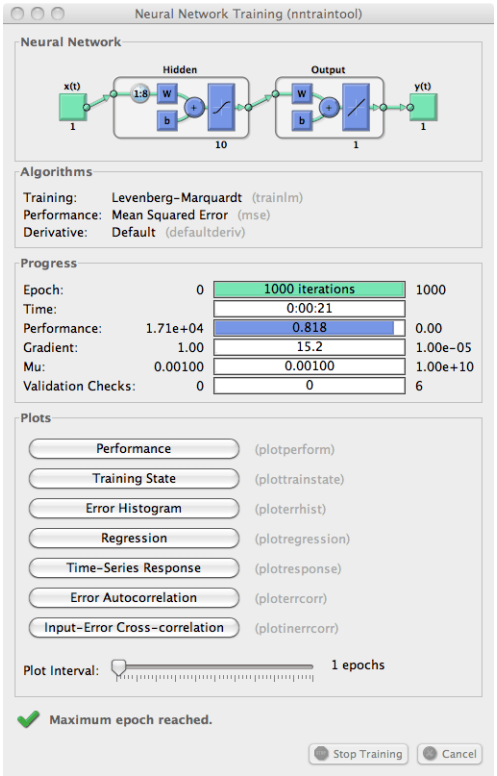
```
ftdnn_net = timedelaynet([1:8],10);
ftdnn_net.trainParam.epochs = 1000;
ftdnn_net.divideFcn = '';
```

Arrange the network inputs and targets for training. Because the network has a tapped delay line with a maximum delay of 8, begin by predicting the ninth value of the time series. You also need to load the tapped delay line with the eight initial values of the time series (contained in the variable `Pi`):

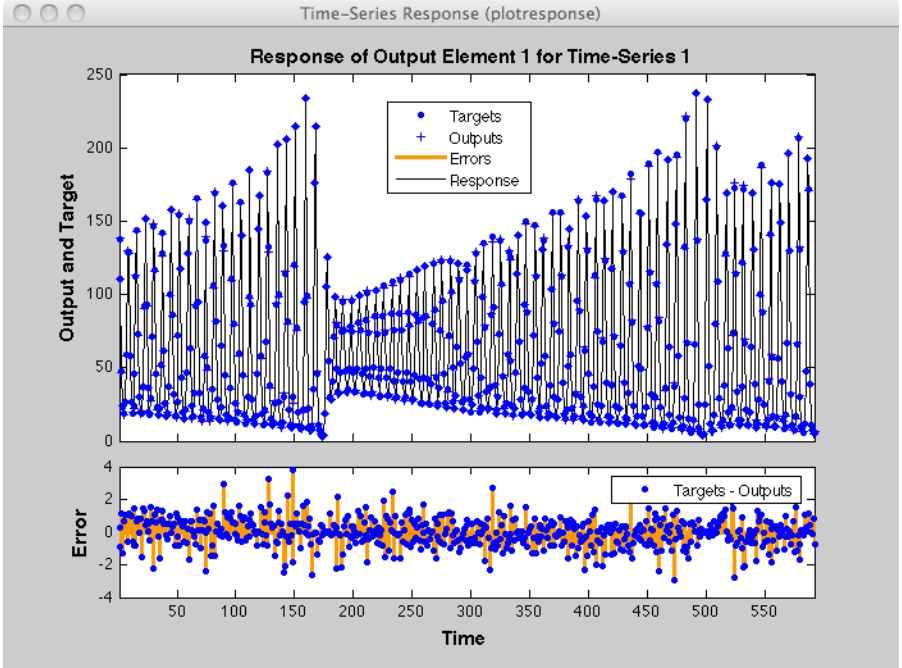
```
p = y(9:end);
t = y(9:end);
Pi=y(1:8);
ftdnn_net = train(ftdnn_net,p,t,Pi);
```

Notice that the input to the network is the same as the target. Because the network has a minimum delay of one time step, this means that you are performing a one-step-ahead prediction.

During training, the following training window appears.



Training stopped because the maximum epoch was reached. From this window, you can display the response of the network by clicking **Time-Series Response**. The following figure appears.



Now simulate the network and determine the prediction error.

```
yp = ftdnn_net(p,Pi);
e = gsubtract(yp,t);
rmse = sqrt(mse(e))

rmse =
    0.9740
```

(Note that `gsubtract` is a general subtraction function that can operate on cell arrays.) This result is much better than you could have obtained using a linear predictor. You can verify this with the following commands, which design a linear filter with the same tapped delay line input as the previous FTDNN.

```
lin_net = linearlayer([1:8]);
lin_net.trainFcn='trainlm';
[lin_net,tr] = train(lin_net,p,t,Pi);
lin_yp = lin_net(p,Pi);
lin_e = gsubtract(lin_yp,t);
lin_rmse = sqrt(mse(lin_e))

lin_rmse =
    21.1386
```

The `rms` error is 21.1386 for the linear predictor, but 0.9740 for the nonlinear FTDNN predictor.

One nice feature of the FTDNN is that it does not require dynamic backpropagation to compute the network gradient. This is because the tapped delay line appears only at the input of the network, and contains no feedback loops or adjustable parameters. For this reason, you will find that this network trains faster than other dynamic networks.

If you have an application for a dynamic network, try the linear network first (`linearlayer`) and then the FTDNN (`timedelaynet`). If neither network is satisfactory, try one of the more complex dynamic networks discussed in the remainder of this topic.

Each time a neural network is trained, can result in a different solution due to different initial weight and bias values and different divisions of data into training, validation, and test sets. As a result, different neural networks trained on the same problem can give different outputs for the same input. To ensure that a neural network of good accuracy has been found, retrain several times.

There are several other techniques for improving upon initial solutions if higher accuracy is desired. For more information, see “Improve Shallow Neural Network Generalization and Avoid Overfitting” on page 28-25.

Prepare Input and Layer Delay States

You will notice in the last section that for dynamic networks there is a significant amount of data preparation that is required before training or simulating the network. This is because the tapped delay lines in the network need to be filled with initial conditions, which requires that part of the original data set be removed and shifted. There is a toolbox function that facilitates the data preparation for dynamic (time series) networks - `preparets`. For example, the following lines:

```
p = y(9:end);
t = y(9:end);
Pi = y(1:8);
```

can be replaced with

```
[p,Pi,Ai,t] = preparets(ftdnn_net,y,y);
```

The `preparets` function uses the network object to determine how to fill the tapped delay lines with initial conditions, and how to shift the data to create the correct inputs and targets to use in training or simulating the network. The general form for invoking `preparets` is

```
[X,Xi,Ai,T,EW,shift] = preparets(net,inputs,targets,feedback,EW)
```

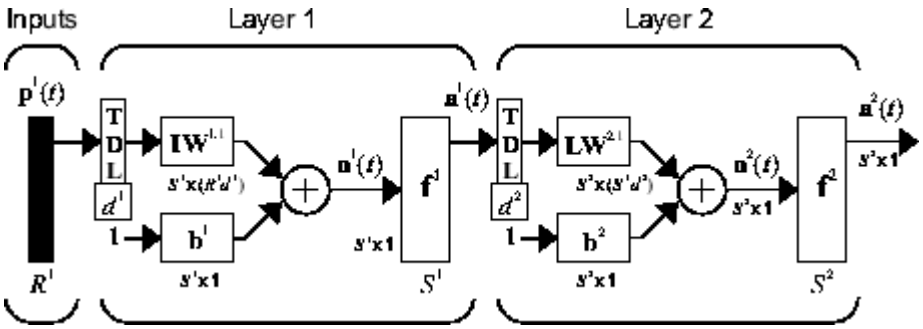
The input arguments for `preparets` are the network object (`net`), the external (non-feedback) input to the network (`inputs`), the non-feedback target (`targets`), the feedback target (`feedback`), and the error weights (`EW`) (see “Train Neural Networks with Error Weights” on page 23-32). The difference between external and feedback signals will become clearer when the NARX network is described in “Design Time Series NARX Feedback Neural Networks” on page 23-16. For the FTDNN network, there is no feedback signal.

The return arguments for `preparets` are the time shift between network inputs and outputs (`shift`), the network input for training and simulation (`X`), the initial inputs (`Xi`) for loading the tapped delay lines for input weights, the initial layer outputs (`Ai`) for loading the tapped delay lines for layer weights, the training targets (`T`), and the error weights (`EW`).

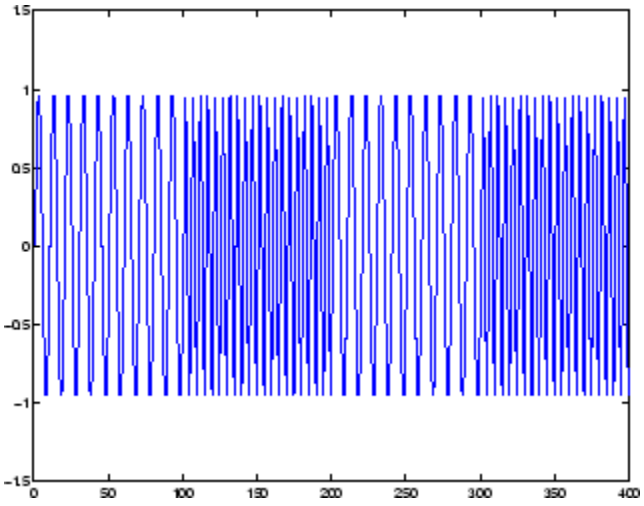
Using preparets eliminates the need to manually shift inputs and targets and load tapped delay lines. This is especially useful for more complex networks.

Design Time Series Distributed Delay Neural Networks

The FTDNN had the tapped delay line memory only at the input to the first layer of the static feedforward network. You can also distribute the tapped delay lines throughout the network. The distributed TDNN was first introduced in [WaHa89 on page 32-2] for phoneme recognition. The original architecture was very specialized for that particular problem. The following figure shows a general two-layer distributed TDNN.



This network can be used for a simplified problem that is similar to phoneme recognition. The network will attempt to recognize the frequency content of an input signal. The following figure shows a signal in which one of two frequencies is present at any given time.



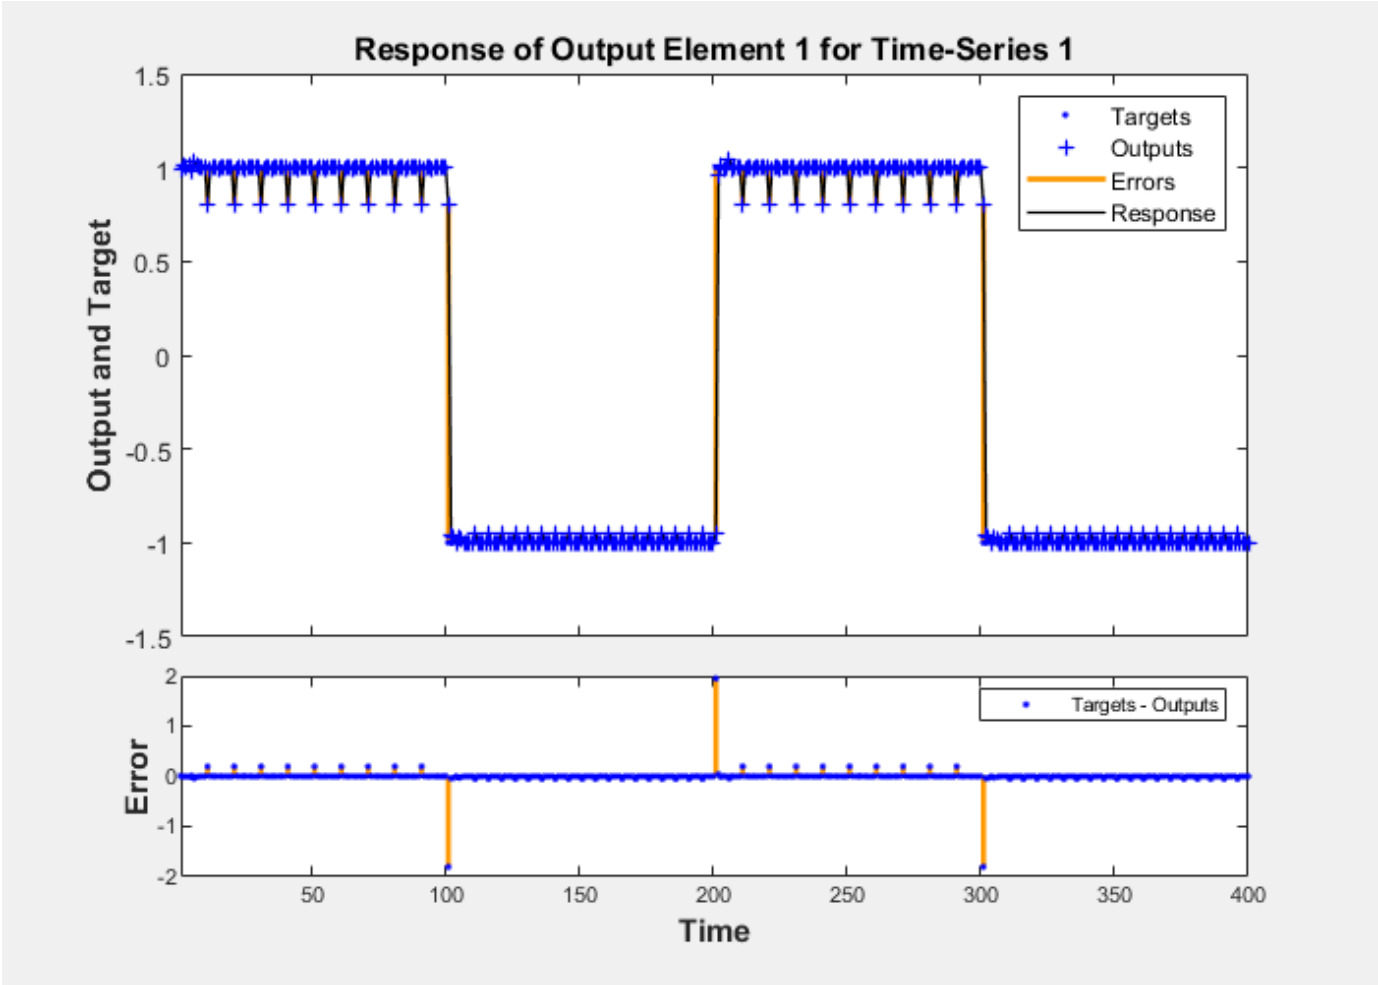
The following code creates this signal and a target network output. The target output is 1 when the input is at the low frequency and -1 when the input is at the high frequency.

```
time = 0:99;
y1 = sin(2*pi*time/10);
y2 = sin(2*pi*time/5);
y = [y1 y2 y1 y2];
t1 = ones(1,100);
t2 = -ones(1,100);
t = [t1 t2 t1 t2];
```

Now create the distributed TDNN network with the `distdelaynet` function. The only difference between the `distdelaynet` function and the `timedelaynet` function is that the first input argument is a cell array that contains the tapped delays to be used in each layer. In the next example,

delays of zero to four are used in layer 1 and zero to three are used in layer 2. (To add some variety, the training function `trainbr` is used in this example instead of the default, which is `trainlm`. You can use any training function discussed in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.)

```
d1 = 0:4;
d2 = 0:3;
p = con2seq(y);
t = con2seq(t);
dtdnn_net = distdelaynet({d1,d2},5);
dtdnn_net.trainFcn = 'trainbr';
dtdnn_net.divideFcn = '';
dtdnn_net.trainParam.epochs = 100;
dtdnn_net = train(dtdnn_net,p,t);
yp = sim(dtdnn_net,p);
plotresponse(t,yp)
```



The network is able to accurately distinguish the two “phonemes.”

You will notice that the training is generally slower for the distributed TDNN network than for the FTDNN. This is because the distributed TDNN must use dynamic backpropagation.

Design Time Series NARX Feedback Neural Networks

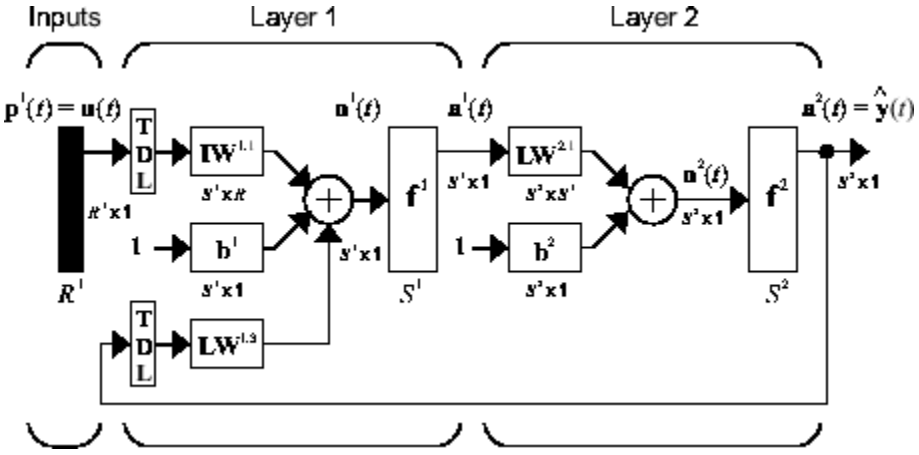
To see examples of using NARX networks being applied in open-loop form, closed-loop form and open/closed-loop multistep prediction see “Multistep Neural Network Prediction” on page 23-39.

All the specific dynamic networks discussed so far have either been focused networks, with the dynamics only at the input layer, or feedforward networks. The nonlinear autoregressive network with exogenous inputs (NARX) is a recurrent dynamic network, with feedback connections enclosing several layers of the network. The NARX model is based on the linear ARX model, which is commonly used in time-series modeling.

The defining equation for the NARX model is

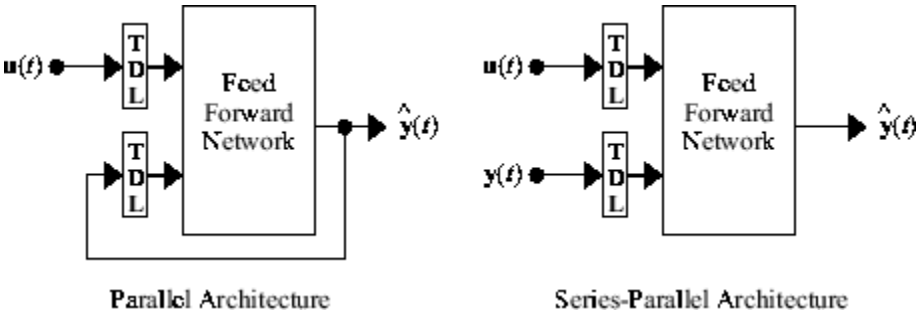
$$y(t) = f(y(t-1), y(t-2), \ldots, y(t-n_y), u(t-1), u(t-2), \ldots, u(t-n_u))$$

where the next value of the dependent output signal $y(t)$ is regressed on previous values of the output signal and previous values of an independent (exogenous) input signal. You can implement the NARX model by using a feedforward neural network to approximate the function f. A diagram of the resulting network is shown below, where a two-layer feedforward network is used for the approximation. This implementation also allows for a vector ARX model, where the input and output can be multidimensional.



There are many applications for the NARX network. It can be used as a predictor, to predict the next value of the input signal. It can also be used for nonlinear filtering, in which the target output is a noise-free version of the input signal. The use of the NARX network is shown in another important application, the modeling of nonlinear dynamic systems.

Before showing the training of the NARX network, an important configuration that is useful in training needs explanation. You can consider the output of the NARX network to be an estimate of the output of some nonlinear dynamic system that you are trying to model. The output is fed back to the input of the feedforward neural network as part of the standard NARX architecture, as shown in the left figure below. Because the true output is available during the training of the network, you could create a series-parallel architecture (see [NaPa91 on page 32-2]), in which the true output is used instead of feeding back the estimated output, as shown in the right figure below. This has two advantages. The first is that the input to the feedforward network is more accurate. The second is that the resulting network has a purely feedforward architecture, and static backpropagation can be used for training.

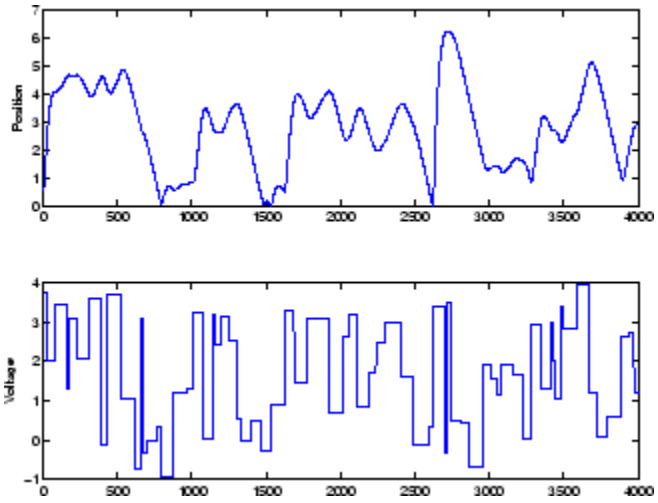


Parallel Architecture Series-Parallel Architecture

The following shows the use of the series-parallel architecture for training a NARX network to model a dynamic system.

The example of the NARX network is the magnetic levitation system described beginning in “Use the NARMA-L2 Controller Block” on page 24-15. The bottom graph in the following figure shows the voltage applied to the electromagnet, and the top graph shows the position of the permanent magnet. The data was collected at a sampling interval of 0.01 seconds to form two time series.

The goal is to develop a NARX model for this magnetic levitation system.



First, load the training data. Use tapped delay lines with two delays for both the input and the output, so training begins with the third data point. There are two inputs to the series-parallel network, the $u(t)$ sequence and the $y(t)$ sequence.

```
load magdata
y = con2seq(y);
u = con2seq(u);
```

Create the series-parallel NARX network using the function `narxnet`. Use 10 neurons in the hidden layer and use `trainlm` for the training function, and then prepare the data with `preparets`:

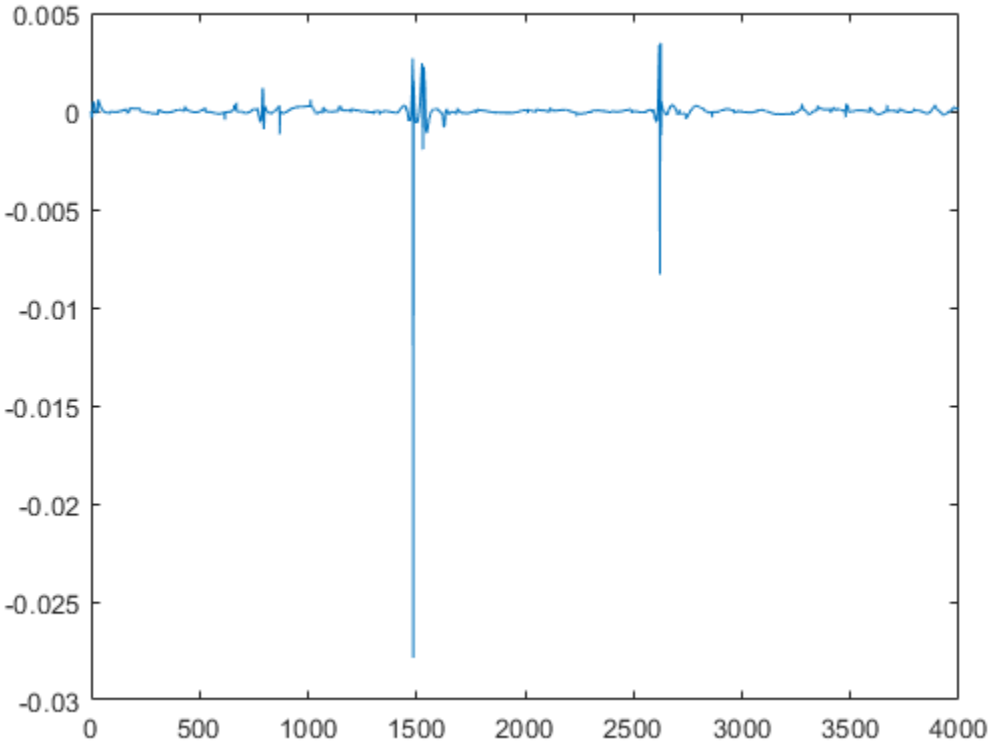
```
d1 = [1:2];
d2 = [1:2];
narx_net = narxnet(d1,d2,10);
narx_net.divideFcn = '';
narx_net.trainParam.min_grad = 1e-10;
[p,Pi,Ai,t] = preparets(narx_net,u,{},y);
```

(Notice that the y sequence is considered a feedback signal, which is an input that is also an output (target). Later, when you close the loop, the appropriate output will be connected to the appropriate input.) Now you are ready to train the network.

```
narx_net = train(narx_net,p,t,Pi);
```

You can now simulate the network and plot the resulting errors for the series-parallel implementation.

```
yp = sim(narx_net,p,Pi);
e = cell2mat(yp)-cell2mat(t);
plot(e)
```



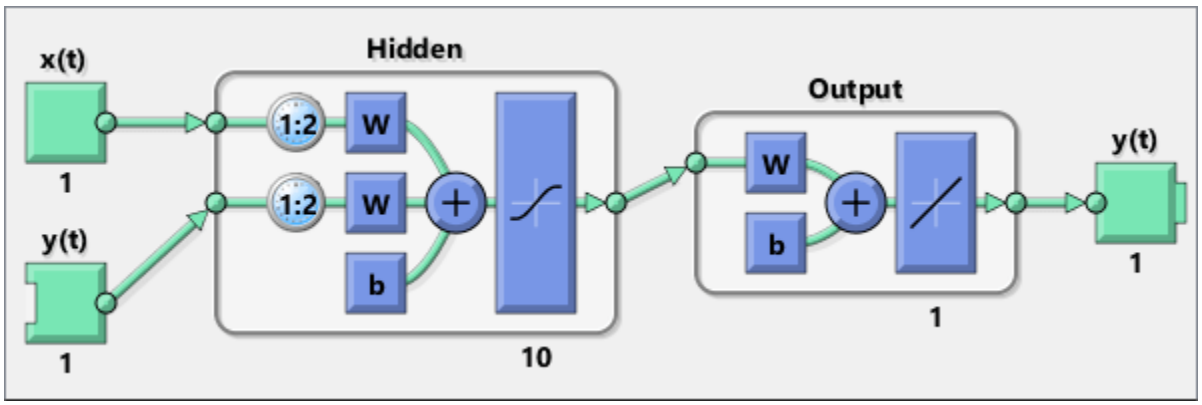
You can see that the errors are very small. However, because of the series-parallel configuration, these are errors for only a one-step-ahead prediction. A more stringent test would be to rearrange the network into the original parallel form (closed loop) and then to perform an iterated prediction over many time steps. Now the parallel operation is shown.

There is a toolbox function (`closeloop`) for converting NARX (and other) networks from the series-parallel configuration (open loop), which is useful for training, to the parallel configuration (closed loop), which is useful for multi-step-ahead prediction. The following command illustrates how to convert the network that you just trained to parallel form:

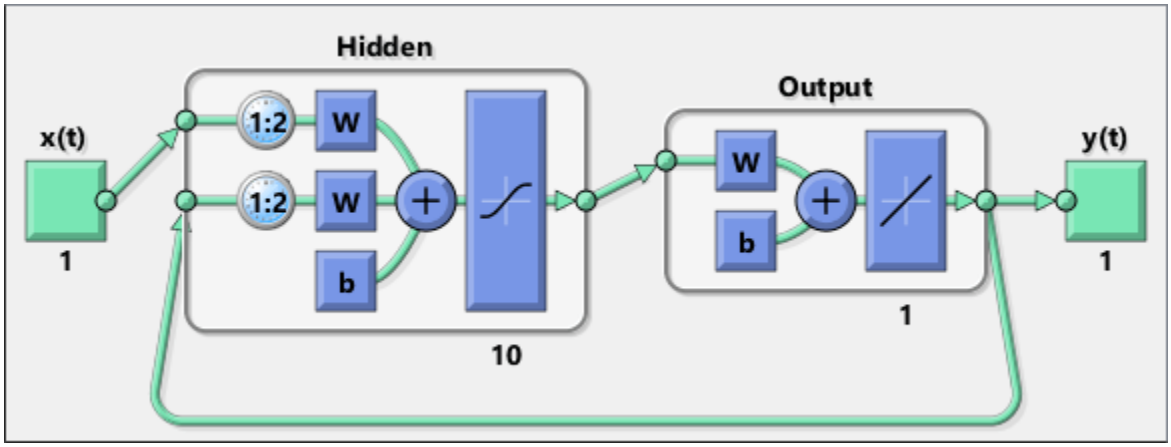
```
narx_net_closed = closeloop(narx_net);
```

To see the differences between the two networks, you can use the view command:

```
view(narx_net)
```



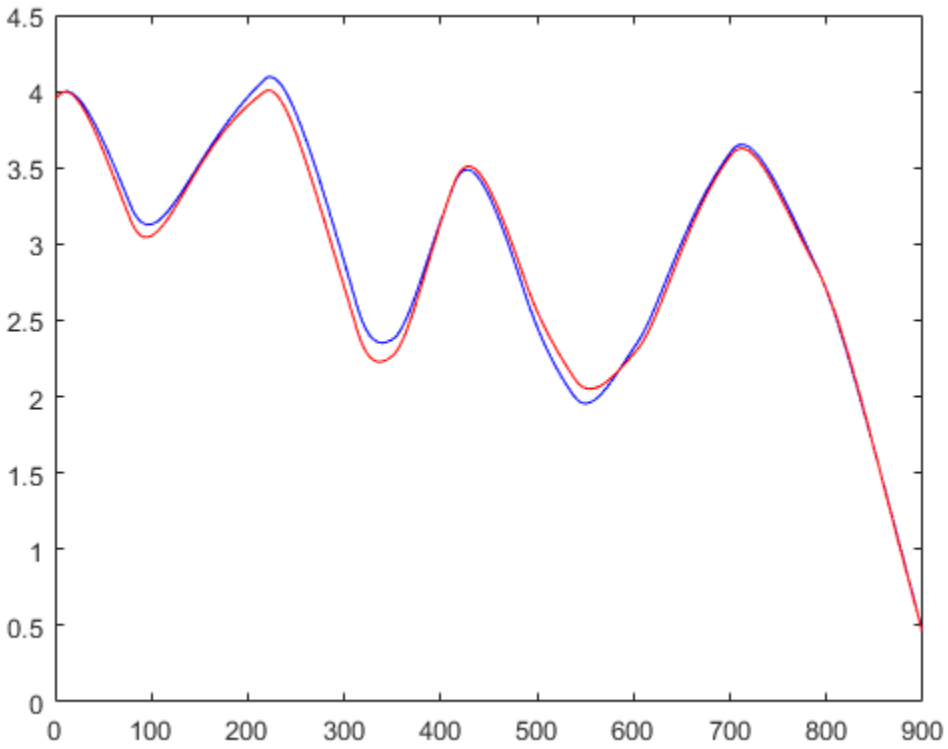
```
view(narx_net_closed)
```



All of the training is done in open loop (also called series-parallel architecture), including the validation and testing steps. The typical workflow is to fully create the network in open loop, and only when it has been trained (which includes validation and testing steps) is it transformed to closed loop for multistep-ahead prediction. Likewise, the R values in the GUI are computed based on the open-loop training results.

You can now use the closed-loop (parallel) configuration to perform an iterated prediction of 900 time steps. In this network you need to load the two initial inputs and the two initial outputs as initial conditions. You can use the `preparets` function to prepare the data. It will use the network structure to determine how to divide and shift the data appropriately.

```
y1 = y(1700:2600);
u1 = u(1700:2600);
[p1,Pi1,Ai1,t1] = preparets(narx_net_closed,u1,{},y1);
yp1 = narx_net_closed(p1,Pi1,Ai1);
TS = size(t1,2);
plot(1:TS,cell2mat(t1),'b',1:TS,cell2mat(yp1),'r')
```



The figure illustrates the iterated prediction. The blue line is the actual position of the magnet, and the red line is the position predicted by the NARX neural network. Even though the network is predicting 900 time steps ahead, the prediction is very accurate.

In order for the parallel response (iterated prediction) to be accurate, it is important that the network be trained so that the errors in the series-parallel configuration (one-step-ahead prediction) are very small.

You can also create a parallel (closed loop) NARX network, using the `narxnet` command with the fourth input argument set to `'closed'`, and train that network directly. Generally, the training takes longer, and the resulting performance is not as good as that obtained with series-parallel training.

Each time a neural network is trained, can result in a different solution due to different initial weight and bias values and different divisions of data into training, validation, and test sets. As a result, different neural networks trained on the same problem can give different outputs for the same input. To ensure that a neural network of good accuracy has been found, retrain several times.

There are several other techniques for improving upon initial solutions if higher accuracy is desired. For more information, see “Improve Shallow Neural Network Generalization and Avoid Overfitting” on page 28-25.

Multiple External Variables

The maglev example showed how to model a time series with a single external input value over time. But the NARX network will work for problems with multiple external input elements and predict

series with multiple elements. In these cases, the input and target consist of row cell arrays representing time, but with each cell element being an N-by-1 vector for the N elements of the input or target signal.

For example, here is a dataset which consists of 2-element external variables predicting a 1-element series.

```
[X,T] = ph_dataset;
```

The external inputs X are formatted as a row cell array of 2-element vectors, with each vector representing acid and base solution flow. The targets represent the resulting pH of the solution over time.

You can reformat your own multi-element series data from matrix form to neural network time-series form with the function `con2seq`.

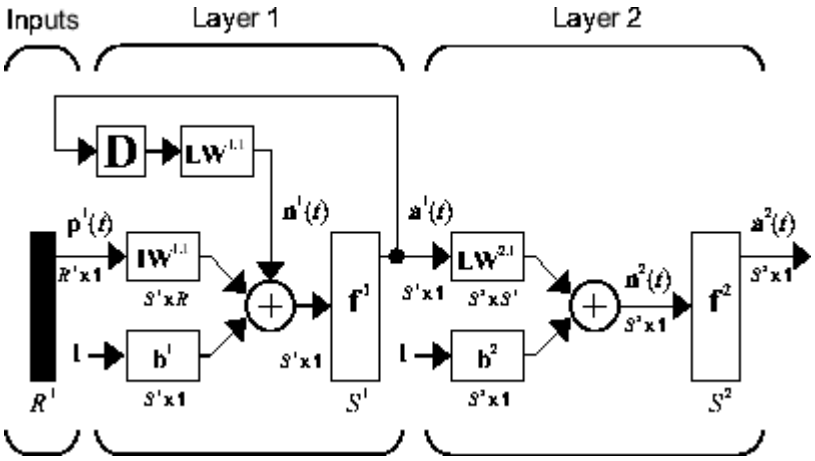
The process for training a network proceeds as it did above for the maglev problem.

```
net = narxnet(10);
[x,xi,ai,t] = preparets(net,X,{},T);
net = train(net,x,t,xi,ai);
y = net(x,xi,ai);
e = gsubtract(t,y);
```

To see examples of using NARX networks being applied in open-loop form, closed-loop form and open/closed-loop multistep prediction see “Multistep Neural Network Prediction” on page 23-39.

Design Layer-Recurrent Neural Networks

The next dynamic network to be introduced is the Layer-Recurrent Network (LRN). An earlier simplified version of this network was introduced by Elman [Elma90 on page 32-2]. In the LRN, there is a feedback loop, with a single delay, around each layer of the network except for the last layer. The original Elman network had only two layers, and used a `tansig` transfer function for the hidden layer and a `purelin` transfer function for the output layer. The original Elman network was trained using an approximation to the backpropagation algorithm. The `layrecnet` command generalizes the Elman network to have an arbitrary number of layers and to have arbitrary transfer functions in each layer. The toolbox trains the LRN using exact versions of the gradient-based algorithms discussed in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2. The following figure illustrates a two-layer LRN.

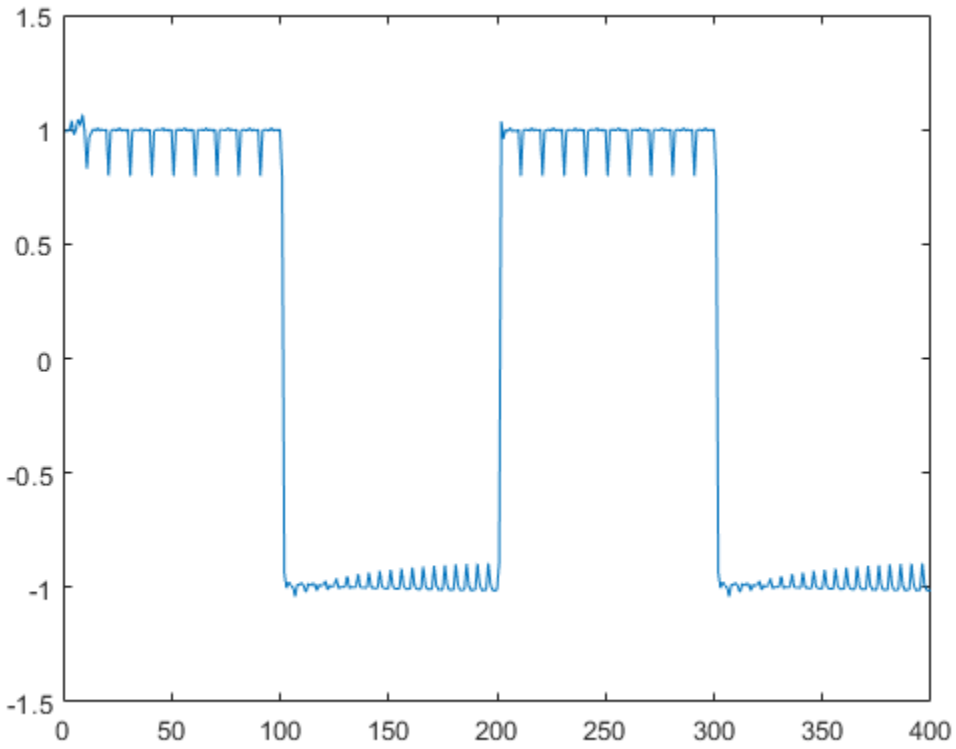


The LRN configurations are used in many filtering and modeling applications discussed already. To show its operation, this example uses the “phoneme” detection problem discussed in “Design Time Series Distributed Delay Neural Networks” on page 23-14. Here is the code to load the data and to create and train the network:

```
load phoneme
p = con2seq(y);
t = con2seq(t);
lrn_net = layrecnet(1,8);
lrn_net.trainFcn = 'trainbr';
lrn_net.trainParam.show = 5;
lrn_net.trainParam.epochs = 50;
lrn_net = train(lrn_net,p,t);
```

After training, you can plot the response using the following code:

```
y = lrn_net(p);
plot(cell2mat(y))
```



The plot shows that the network was able to detect the “phonemes.” The response is very similar to the one obtained using the TDNN.

Each time a neural network is trained, can result in a different solution due to different initial weight and bias values and different divisions of data into training, validation, and test sets. As a result, different neural networks trained on the same problem can give different outputs for the same input. To ensure that a neural network of good accuracy has been found, retrain several times.

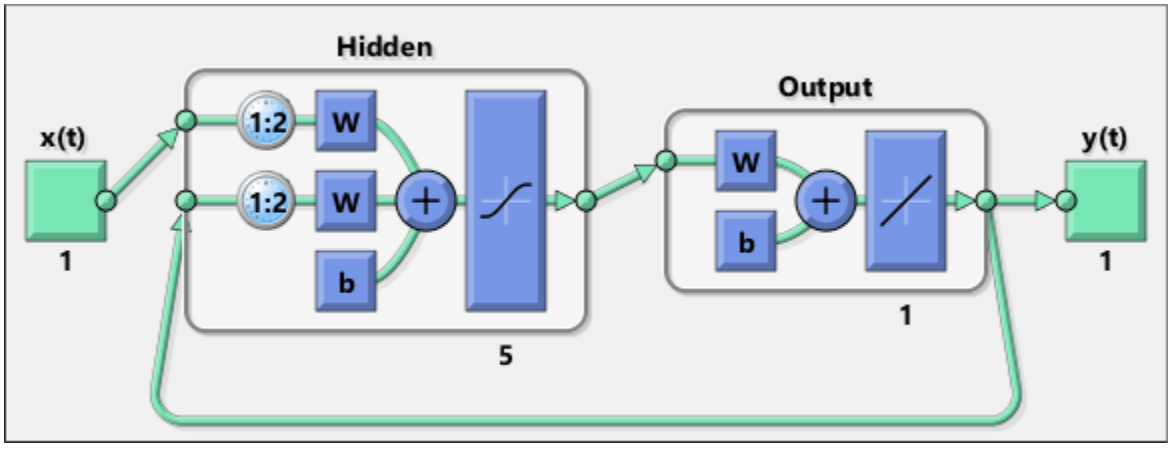
There are several other techniques for improving upon initial solutions if higher accuracy is desired. For more information, see “Improve Shallow Neural Network Generalization and Avoid Overfitting” on page 28-25.

Create Reference Model Controller with MATLAB Script

So far, this topic has described the training procedures for several specific dynamic network architectures. However, *any* network that can be created in the toolbox can be trained using the training functions described in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2 so long as the components of the network are differentiable. This section gives an example of how to create and train a custom architecture. The custom architecture you will use is the model reference adaptive control (MRAC) system that is described in detail in “Design Model-Reference Neural Controller in Simulink” on page 24-19.

As you can see in “Design Model-Reference Neural Controller in Simulink” on page 24-19, the model reference control architecture has two subnetworks. One subnetwork is the model of the plant that you want to control. The other subnetwork is the controller. You will begin by training a NARX network that will become the plant model subnetwork. For this example, you will use the robot arm to represent the plant, as described in “Design Model-Reference Neural Controller in Simulink” on page 24-19. The following code will load data collected from the robot arm and create and train a NARX network. For this simple problem, you do not need to preprocess the data, and all of the data can be used for training, so no data division is needed.

```
[u,y] = robotarm_dataset;
d1 = [1:2];
d2 = [1:2];
S1 = 5;
narx_net = narxnet(d1,d2,S1);
narx_net.divideFcn = '';
narx_net.inputs{1}.processFcns = {};
narx_net.inputs{2}.processFcns = {};
narx_net.outputs{2}.processFcns = {};
narx_net.trainParam.min_grad = 1e-10;
[p,Pi,Ai,t] = preparets(narx_net,u,{},y);
narx_net = train(narx_net,p,t,Pi);
narx_net_closed = closeloop(narx_net);
view(narx_net_closed)
```



The resulting network is shown in the figure.

Now that the NARX plant model is trained, you can create the total MRAC system and insert the NARX model inside. Begin with a feedforward network, and then add the feedback connections. Also, turn off learning in the plant model subnetwork, since it has already been trained. The next stage of training will train only the controller subnetwork.

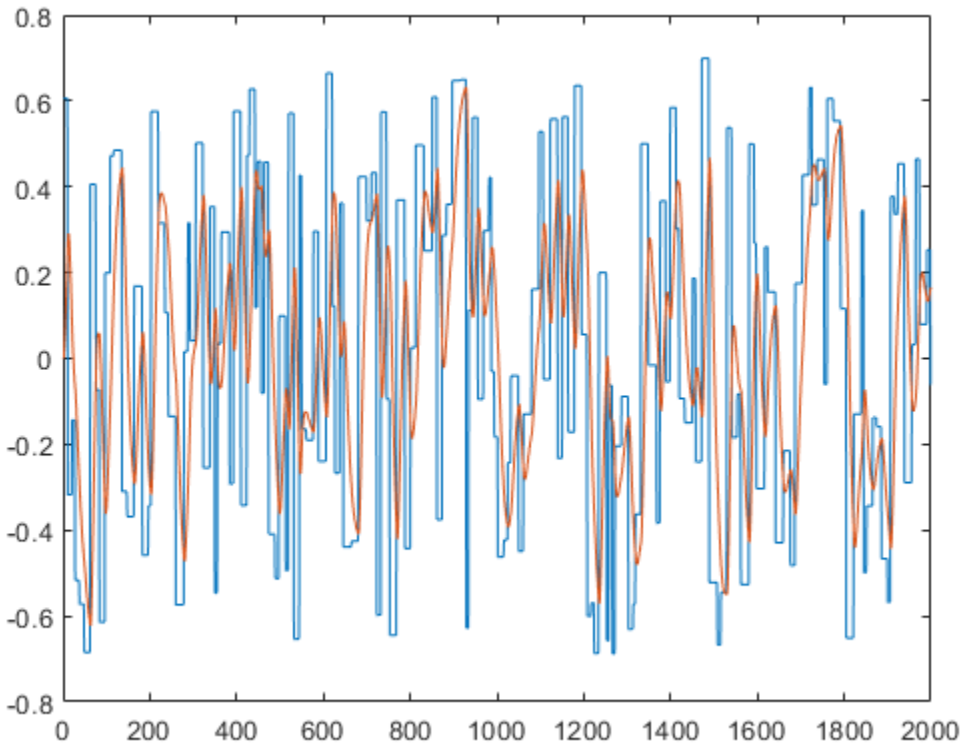
```
mrac_net = feedforwardnet([S1 1 S1]);
mrac_net.layerConnect = [0 1 0 1;1 0 0 0;0 1 0 1;0 0 1 0];
mrac_net.outputs{4}.feedbackMode = 'closed';
mrac_net.layers{2}.transferFcn = 'purelin';
mrac_net.layerWeights{3,4}.delays = 1:2;
mrac_net.layerWeights{3,2}.delays = 1:2;
mrac_net.layerWeights{3,2}.learn = 0;
mrac_net.layerWeights{3,4}.learn = 0;
mrac_net.layerWeights{4,3}.learn = 0;
mrac_net.biases{3}.learn = 0;
mrac_net.biases{4}.learn = 0;
```

The following code turns off data division and preprocessing, which are not needed for this example problem. It also sets the delays needed for certain layers and names the network.

```
mrac_net.divideFcn = '';
mrac_net.inputs{1}.processFcns = {};
mrac_net.outputs{4}.processFcns = {};
mrac_net.name = 'Model Reference Adaptive Control Network';
mrac_net.layerWeights{1,2}.delays = 1:2;
mrac_net.layerWeights{1,4}.delays = 1:2;
mrac_net.inputWeights{1}.delays = 1:2;
```

To configure the network, you need some sample training data. The following code loads and plots the training data, and configures the network:

```
[refin,refout] = refmodel_dataset;
ind = 1:length(refin);
plot(ind,cell2mat(refin),ind,cell2mat(refout))
mrac_net = configure(mrac_net,refin,refout);
```



You want the closed-loop MRAC system to respond in the same way as the reference model that was used to generate this data. (See “Use the Model Reference Controller Block” on page 24-20 for a description of the reference model.)

Now insert the weights from the trained plant model network into the appropriate location of the MRAC system.

```
mrac_net.LW{3,2} = narx_net_closed.IW{1};
mrac_net.LW{3,4} = narx_net_closed.LW{1,2};
mrac_net.b{3} = narx_net_closed.b{1};
mrac_net.LW{4,3} = narx_net_closed.LW{2,1};
mrac_net.b{4} = narx_net_closed.b{2};
```

You can set the output weights of the controller network to zero, which will give the plant an initial input of zero.

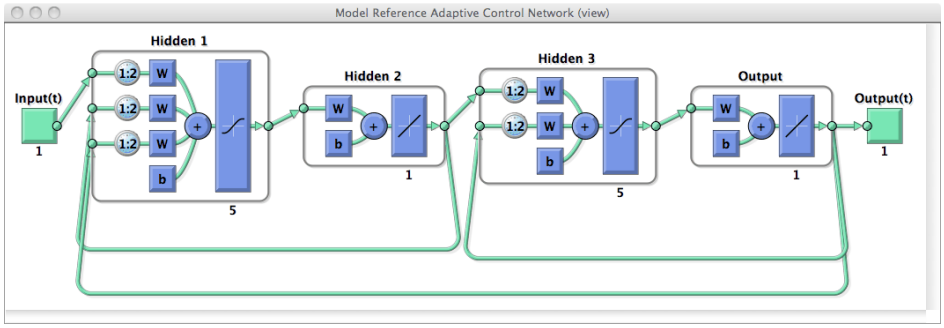
```
mrac_net.LW{2,1} = zeros(size(mrac_net.LW{2,1}));
mrac_net.b{2} = 0;
```

You can also associate any plots and training function that you desire to the network.

```
mrac_net.plotFcns = {'plotperform','plottrainstate',...
    'ploterrhist','plotregression','plotresponse'};
mrac_net.trainFcn = 'trainlm';
```

The final MRAC network can be viewed with the following command:

```
view(mrac_net)
```



Layer 3 and layer 4 (output) make up the plant model subnetwork. Layer 1 and layer 2 make up the controller.

You can now prepare the training data and train the network.

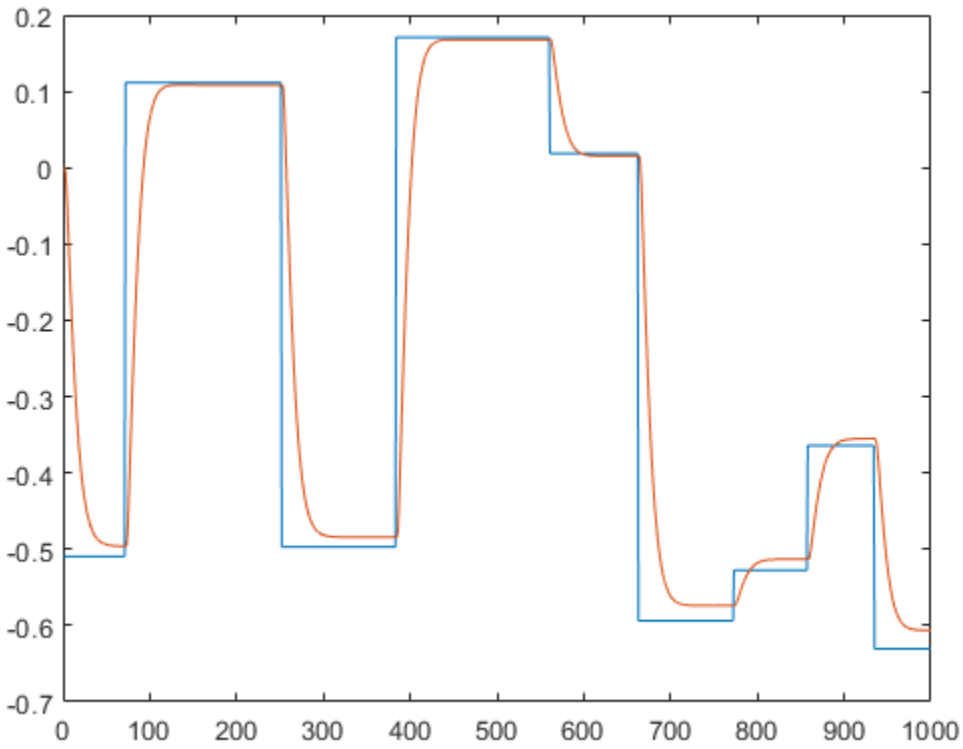
```
[x_tot,xi_tot,ai_tot,t_tot] = ...
            preparets(mrac_net,refin,{},refout);
mrac_net.trainParam.epochs = 50;
mrac_net.trainParam.min_grad = 1e-10;
[mrac_net,tr] = train(mrac_net,x_tot,t_tot,xi_tot,ai_tot);
```

Note Notice that you are using the `trainlm` training function here, but any of the training functions discussed in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2 could be used as well. Any network that you can create in the toolbox can be trained with any of those training functions. The only limitation is that all of the parts of the network must be differentiable.

You will find that the training of the MRAC system takes much longer that the training of the NARX plant model. This is because the network is recurrent and dynamic backpropagation must be used. This is determined automatically by the toolbox software and does not require any user intervention. There are several implementations of dynamic backpropagation (see [DeHa07 on page 32-2]), and the toolbox software automatically determines the most efficient one for the selected network architecture and training algorithm.

After the network has been trained, you can test the operation by applying a test input to the MRAC network. The following code creates a `skyline` input function, which is a series of steps of random height and width, and applies it to the trained MRAC network.

```
testin = skyline(1000,50,200,-.7,.7);
testinseq = con2seq(testin);
testoutseq = mrac_net(testinseq);
testout = cell2mat(testoutseq);
figure
plot([testin' testout'])
```



From the figure, you can see that the plant model output does follow the reference input with the correct critically damped response, even though the input sequence was not the same as the input sequence in the training data. The steady state response is not perfect for each step, but this could be improved with a larger training set and perhaps more hidden neurons.

The purpose of this example was to show that you can create your own custom dynamic network and train it using the standard toolbox training functions without any modifications. Any network that you can create in the toolbox can be trained with the standard training functions, as long as each component of the network has a defined derivative.

It should be noted that recurrent networks are generally more difficult to train than feedforward networks. See [HDH09 on page 32-2] for some discussion of these training difficulties.

Multiple Sequences with Dynamic Neural Networks

There are times when time-series data is not available in one long sequence, but rather as several shorter sequences. When dealing with static networks and concurrent batches of static data, you can simply append data sets together to form one large concurrent batch. However, you would not generally want to append time sequences together, since that would cause a discontinuity in the sequence. For these cases, you can create a concurrent set of sequences, as described in “Understanding Shallow Network Data Structures” on page 21-18.

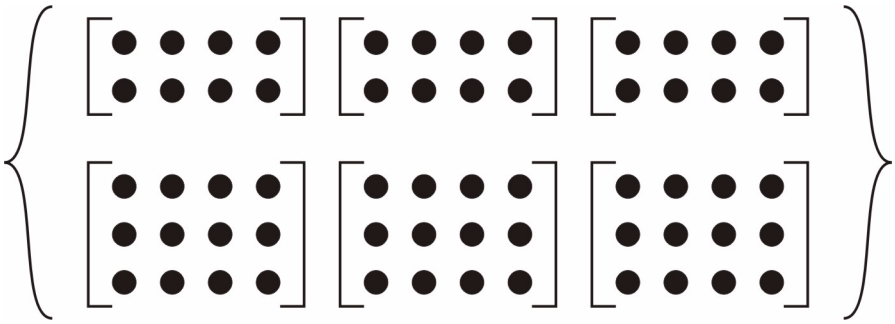
When training a network with a concurrent set of sequences, it is required that each sequence be of the same length. If this is not the case, then the shorter sequence inputs and targets should be padded with NaNs, in order to make all sequences the same length. The targets that are assigned values of NaN will be ignored during the calculation of network performance.

The following code illustrates the use of the function `catsamples` to combine several sequences together to form a concurrent set of sequences, while at the same time padding the shorter sequences.

```
load magmulseq
y_mul = catsamples(y1,y2,y3,'pad');
u_mul = catsamples(u1,u2,u3,'pad');
d1 = [1:2];
d2 = [1:2];
narx_net = narxnet(d1,d2,10);
narx_net.divideFcn = '';
narx_net.trainParam.min_grad = 1e-10;
[p,Pi,Ai,t] = preparets(narx_net,u_mul,{},y_mul);
narx_net = train(narx_net,p,t,Pi);
```

Neural Network Time-Series Utilities

There are other utility functions that are useful when manipulating neural network data, which can consist of time sequences, concurrent batches or combinations of both. It can also include multiple signals (as in multiple input, output or target vectors). The following diagram illustrates the structure of a general neural network data object. For this example there are three time steps of a batch of four samples (four sequences) of two signals. One signal has two elements, and the other signal has three elements.



The following table lists some of the more useful toolbox utility functions for neural network data. They allow you to do things like add, subtract, multiply, divide, etc. (Addition and subtraction of cell arrays do not have standard definitions, but for neural network data these operations are well defined and are implemented in the following functions.)

Function	Operation
`gadd`	Add neural network (nn) data.
`gdivide`	Divide nn data.
`getelements`	Select indicated elements from nn data.
`getsamples`	Select indicated samples from nn data.
`getsignals`	Select indicated signals from nn data.
`gettimesteps`	Select indicated time steps from nn data.
`gmultiply`	Multiply nn data.
`gnegate`	Take the negative of nn data.
`gsubtract`	Subtract nn data.
`nndata`	Create an nn data object of specified size, where values are assigned randomly or to a constant.
`nnsize`	Return number of elements, samples, time steps and signals in an nn data object.
`numelements`	Return the number of elements in nn data.
`numsamples`	Return the number of samples in nn data.
`numsignals`	Return the number of signals in nn data.
`numtimesteps`	Return the number of time steps in nn data.
`setelements`	Set specified elements of nn data.
`setsamples`	Set specified samples of nn data.

Function	Operation
`setsignals`	Set specified signals of nn data.
`settimesteps`	Set specified time steps of nn data.

There are also some useful plotting and analysis functions for dynamic networks that are listed in the following table. There are examples of using these functions in the “Get Started with Deep Learning Toolbox”.

Function	Operation
`ploterrcorr`	Plot the autocorrelation function of the error.
`plotinerrcorr`	Plot the crosscorrelation between the error and the input.
`plotresponse`	Plot network output and target versus time.

Train Neural Networks with Error Weights

In the default mean square error performance function (see “Train and Apply Multilayer Shallow Neural Networks” on page 22-13), each squared error contributes the same amount to the performance function as follows:

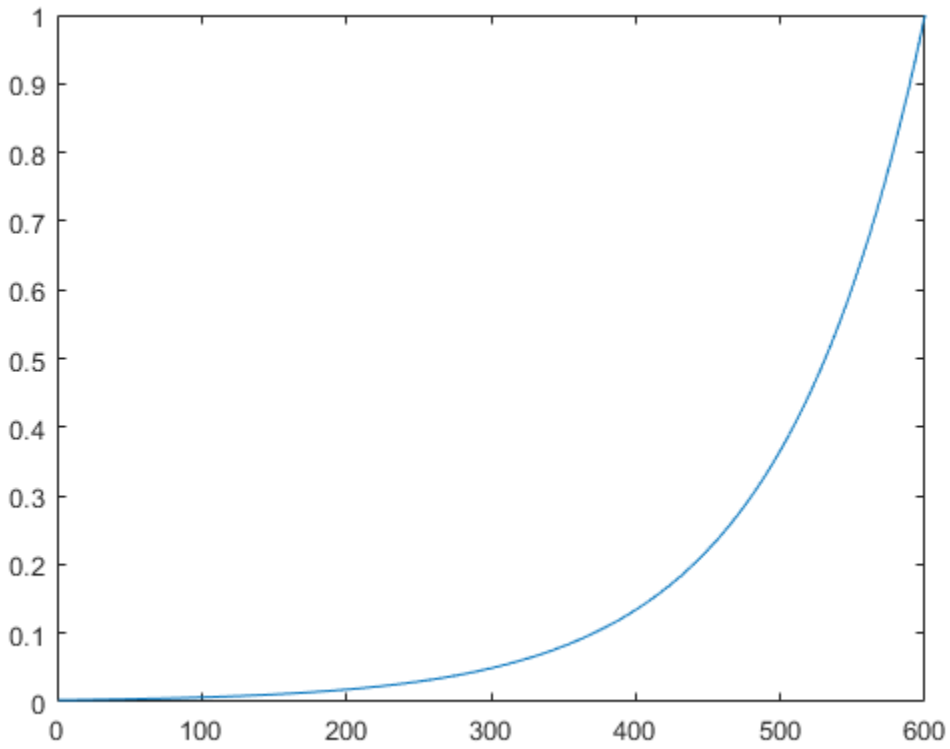
$$F = mse = \frac{1}{N}\sum_{i=1}^{N}(e_i)^2 = \frac{1}{N}\sum_{i=1}^{N}(t_i - a_i)^2$$

However, the toolbox allows you to weight each squared error individually as follows:

$$F = mse = \frac{1}{N}\sum_{i=1}^{N}w_i^e(e_i)^2 = \frac{1}{N}\sum_{i=1}^{N}w_i^e(t_i - a_i)^2$$

The error weighting object needs to have the same dimensions as the target data. In this way, errors can be weighted according to time step, sample number, signal number or element number. The following is an example of weighting the errors at the end of a time sequence more heavily than errors at the beginning of a time sequence. The error weighting object is passed as the last argument in the call to `train`.

```
y = laser_dataset;
y = y(1:600);
ind = 1:600;
ew = 0.99.^(600-ind);
figure
plot(ew)
```



```
ew = con2seq(ew);
ftdnn_net = timedelaynet([1:8],10);
ftdnn_net.trainParam.epochs = 1000;
ftdnn_net.divideFcn = '';
[p,Pi,Ai,t,ew1] = preparets(ftdnn_net,y,y,{},ew);
[ftdnn_net1,tr] = train(ftdnn_net,p,t,Pi,Ai,ew1);
```

The figure illustrates the error weighting for this example. There are 600 time steps in the training data, and the errors are weighted exponentially, with the last squared error having a weight of 1, and the squared error at the first time step having a weighting of 0.0024.

The response of the trained network is shown in the following figure. If you compare this response to the response of the network that was trained without exponential weighting on the squared errors, as shown in “Design Time Series Time-Delay Neural Networks” on page 23-10, you can see that the errors late in the sequence are smaller than the errors earlier in the sequence. The errors that occurred later are smaller because they contributed more to the weighted performance index than earlier errors.

Normalize Errors of Multiple Outputs

The most common performance function used to train neural networks is mean squared error (mse). However, with multiple outputs that have different ranges of values, training with mean squared error tends to optimize accuracy on the output element with the wider range of values relative to the output element with a smaller range.

For instance, here two target elements have very different ranges:

```
x = -1:0.01:1;
t1 = 100*sin(x);
t2 = 0.01*cos(x);
t = [t1; t2];
```

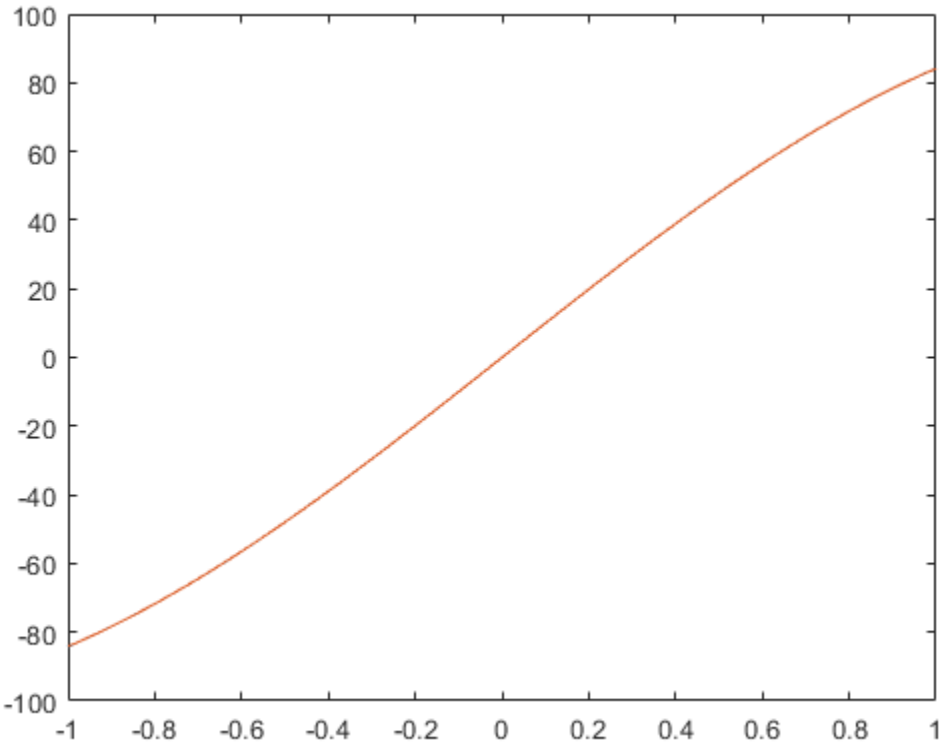
The range of `t1` is 200 (from a minimum of -100 to a maximum of 100), while the range of `t2` is only 0.02 (from -0.01 to 0.01). The range of `t1` is 10,000 times greater than the range of `t2`.

If you create and train a neural network on this to minimize mean squared error, training favors the relative accuracy of the first output element over the second.

```
net = feedforwardnet(5);
net1 = train(net,x,t);
y = net1(x);
```

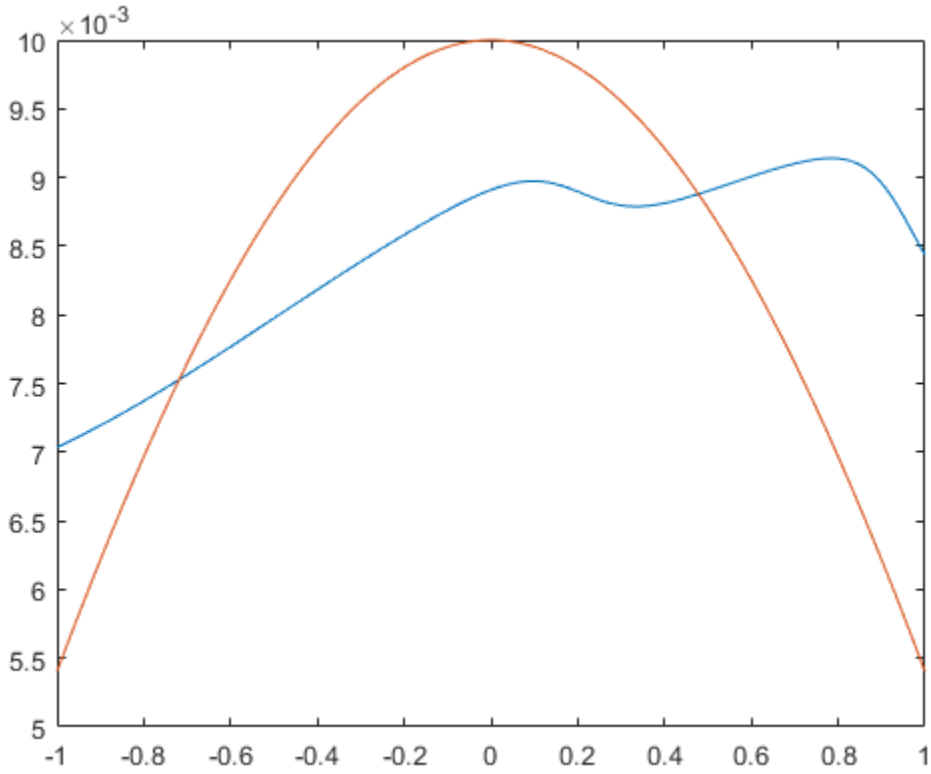
Here you can see that the network has learned to fit the first output element very well.

```
figure(1)
plot(x,y(1,:),x,t(1,:))
```



However, the second element's function is not fit nearly as well.

```
figure(2)
plot(x,y(2,:),x,t(2,:))
```

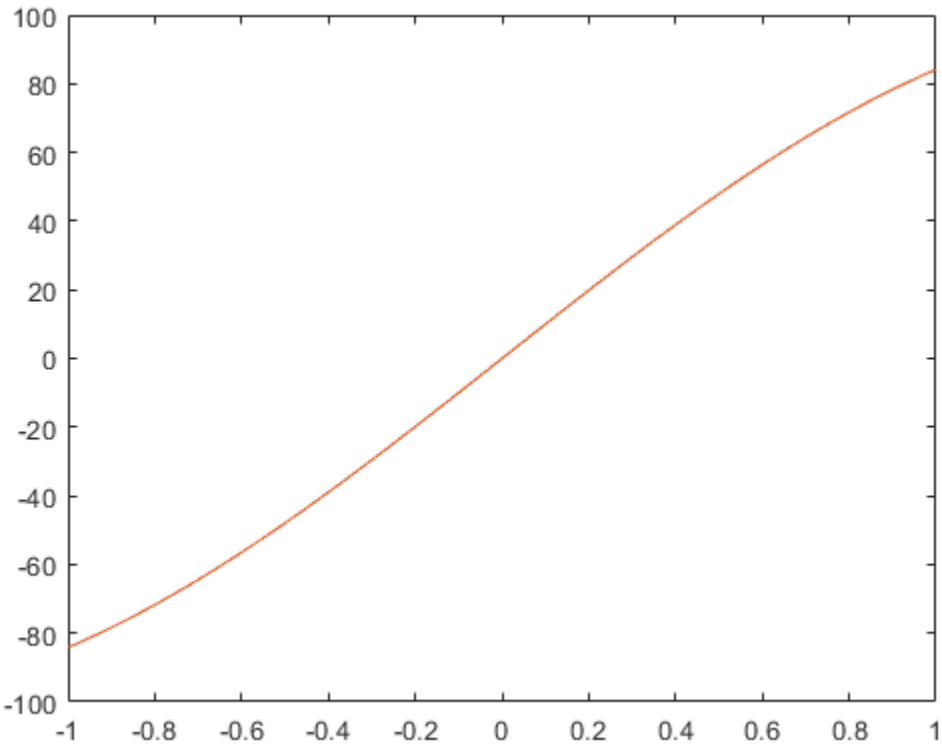


To fit both output elements equally well in a relative sense, set the `normalization` performance parameter to `'standard'`. This then calculates errors for performance measures as if each output element has a range of 2 (i.e., as if each output element's values range from -1 to 1, instead of their differing ranges).

```
net.performParam.normalization = 'standard';
net2 = train(net,x,t);
y = net2(x);
```

Now the two output elements both fit well.

```
figure(3)
plot(x,y(1,:),x,t(1,:))
```



```

Multistep Neural Network Prediction

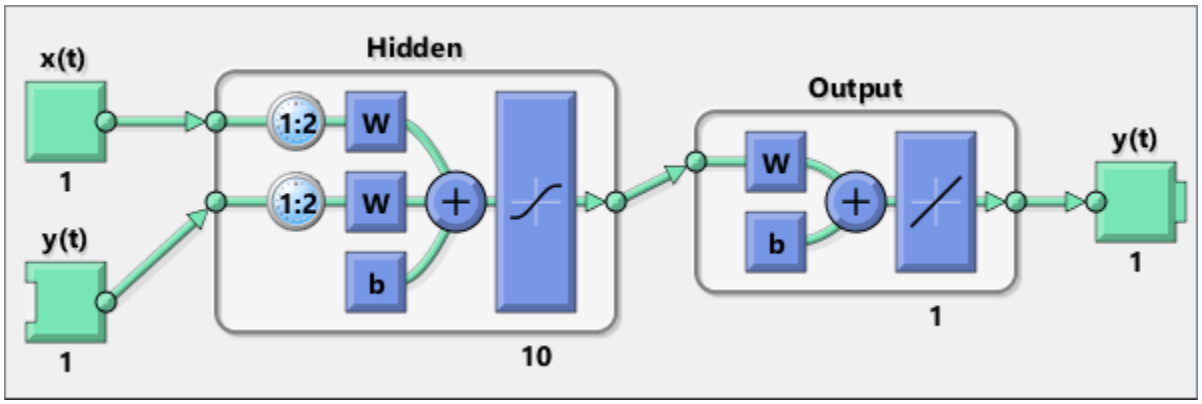
In this section...

Set Up in Open-Loop Mode

Dynamic networks with feedback, such as `narxnet` and `narnet` neural networks, can be transformed between open-loop and closed-loop modes with the functions `openloop` and `closeloop`. Closed-loop networks make multistep predictions. In other words they continue to predict when external feedback is missing, by using internal feedback.

Here a neural network is trained to model the magnetic levitation system and simulated in the default open-loop mode.

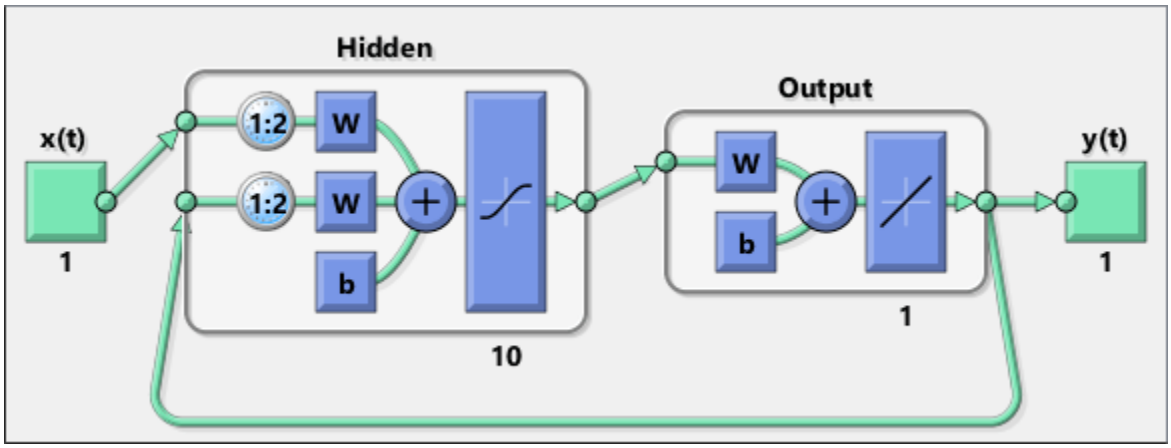
```
[X,T] = maglev_dataset;
net = narxnet(1:2,1:2,10);
[x,xi,ai,t] = preparets(net,X,{},T);
net = train(net,x,t,xi,ai);
y = net(x,xi,ai);
view(net)
```



Multistep Closed-Loop Prediction From Initial Conditions

A neural network can also be simulated only in closed-loop form, so that given an external input series and initial conditions, the neural network performs as many predictions as the input series has time steps.

```
netc = closeloop(net);
view(netc)
```



Here the training data is used to define the inputs `x`, and the initial input and layer delay states, `xi` and `ai`, but they can be defined to make multiple predictions for any input series and initial states.

```
[x,xi,ai,t] = preparets(netc,X,{},T);
yc = netc(x,xi,ai);
```

Multistep Closed-Loop Prediction Following Known Sequence

It can also be useful to simulate a trained neural network up the present with all the known values of a time-series in open-loop mode, then switch to closed-loop mode to continue the simulation for as many predictions into the future as are desired.

Just as `openloop` and `closeloop` can be used to transform between open- and closed-loop neural networks, they can convert the state of open- and closed-loop networks. Here are the full interfaces for these functions.

```
[open_net,open_xi,open_ai] = openloop(closed_net,closed_xi,closed_ai);
[closed_net,closed_xi,closed_ai] = closeloop(open_net,open_xi,open_ai);
```

Consider the case where you might have a record of the Maglev's behavior for 20 time steps, and you want to predict ahead for 20 more time steps.

First, define the first 20 steps of inputs and targets, representing the 20 time steps where the known output is defined by the targets `t`. With the next 20 time steps of the input are defined, use the network to predict the 20 outputs using each of its predictions feedback to help the network perform the next prediction.

```
x1 = x(1:20);
t1 = t(1:20);
x2 = x(21:40);
```

The open-loop neural network is then simulated on this data.

```
[x,xi,ai,t] = preparets(net,x1,{},t1);
[y1,xf,af] = net(x,xi,ai);
```

Now the final input and layer states returned by the network are converted to closed-loop form along with the network. The final input states `xf` and layer states `af` of the open-loop network become the initial input states `xi` and layer states `ai` of the closed-loop network.

```
[netc,xi,ai] = closeloop(net,xf,af);
```

Typically use `preparets` to define initial input and layer states. Since these have already been obtained from the end of the open-loop simulation, you do not need `preparets` to continue with the 20 step predictions of the closed-loop network.

```
[y2,xf,af] = netc(x2,xi,ai);
```

Note that you can set `x2` to different sequences of inputs to test different scenarios for however many time steps you would like to make predictions. For example, to predict the magnetic levitation system's behavior if 10 random inputs are used:

```
x2 = num2cell(rand(1,10));
[y2,xf,af] = netc(x2,xi,ai);
```

Following Closed-Loop Simulation with Open-Loop Simulation

If after simulating the network in closed-loop form, you can continue the simulation from there in open-loop form. Here the closed-loop state is converted back to open-loop state. (You do not have to convert the network back to open-loop form as you already have the original open-loop network.)

```
[~,xi,ai] = openloop(netc,xf,af);
```

Now you can define continuations of the external input and open-loop feedback, and simulate the open-loop network.

```
x3 = num2cell(rand(2,10));
y3 = net(x3,xi,ai);
```

In this way, you can switch simulation between open-loop and closed-loop manners. One application for this is making time-series predictions of a sensor, where the last sensor value is usually known, allowing open-loop prediction of the next step. But on some occasions the sensor reading is not available, or known to be erroneous, requiring a closed-loop prediction step. The predictions can alternate between open-loop and closed-loop form, depending on the availability of the last step's sensor reading.

Control Systems

Introduction to Neural Network Control Systems

Neural networks have been applied successfully in the identification and control of dynamic systems. The universal approximation capabilities of the multilayer perceptron make it a popular choice for modeling nonlinear systems and for implementing general-purpose nonlinear controllers [HaDe99 on page 32-2]. This topic introduces three popular neural network architectures for prediction and control that have been implemented in the Deep Learning Toolbox software, and presents brief descriptions of each of these architectures and shows how you can use them:

- Model Predictive Control
- NARMA-L2 (or Feedback Linearization) Control
- Model Reference Control

There are typically two steps involved when using neural networks for control:

1. System identification
2. Control design

In the system identification stage, you develop a neural network model of the plant that you want to control. In the control design stage, you use the neural network plant model to design (or train) the controller. In each of the three control architectures described in this topic, the system identification stage is identical. The control design stage, however, is different for each architecture:

- For model predictive control, the plant model is used to predict future behavior of the plant, and an optimization algorithm is used to select the control input that optimizes future performance.
- For NARMA-L2 control, the controller is simply a rearrangement of the plant model.
- For model reference control, the controller is a neural network that is trained to control a plant so that it follows a reference model. The neural network plant model is used to assist in the controller training.

The next three sections discuss model predictive control, NARMA-L2 control, and model reference control. Each section consists of a brief description of the control concept, followed by an example of the use of the appropriate Deep Learning Toolbox function. These three controllers are implemented as Simulink blocks, which are contained in the Deep Learning Toolbox blockset.

To assist you in determining the best controller for your application, the following list summarizes the key controller features. Each controller has its own strengths and weaknesses. No single controller is appropriate for every application.

- **Model Predictive Control** — This controller uses a neural network model to predict future plant responses to potential control signals. An optimization algorithm then computes the control signals that optimize future plant performance. The neural network plant model is trained offline, in batch form. (This is true for all three control architectures.) The controller, however, requires a significant amount of online computation, because an optimization algorithm is performed at each sample time to compute the optimal control input.
- **NARMA-L2 Control** — This controller requires the least computation of these three architectures. The controller is simply a rearrangement of the neural network plant model, which is trained offline, in batch form. The only online computation is a forward pass through the neural network controller. The drawback of this method is that the plant must either be in companion form, or be capable of approximation by a companion form model. (“Identification of the NARMA-L2 Model” on page 24-13 describes the companion form model.)

- **Model Reference Control** — The online computation of this controller, like NARMA-L2, is minimal. However, unlike NARMA-L2, the model reference architecture requires that a separate neural network controller be trained offline, in addition to the neural network plant model. The controller training is computationally expensive, because it requires the use of dynamic backpropagation [HaJe99 on page 32-2]. On the positive side, model reference control applies to a larger class of plant than does NARMA-L2 control.

Design Neural Network Predictive Controller in Simulink

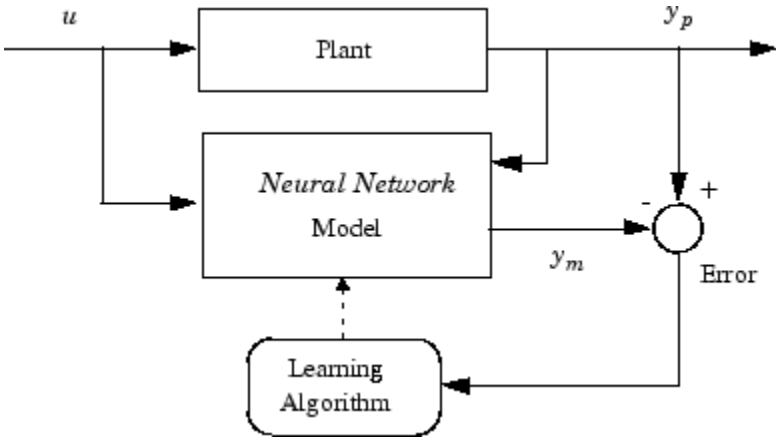
In this section...

The neural network predictive controller that is implemented in the Deep Learning Toolbox software uses a neural network model of a nonlinear plant to predict future plant performance. The controller then calculates the control input that will optimize plant performance over a specified future time horizon. The first step in model predictive control is to determine the neural network plant model (system identification). Next, the plant model is used by the controller to predict future performance. (See the Model Predictive Control Toolbox™ documentation for complete coverage of the application of various model predictive control strategies to linear systems.)

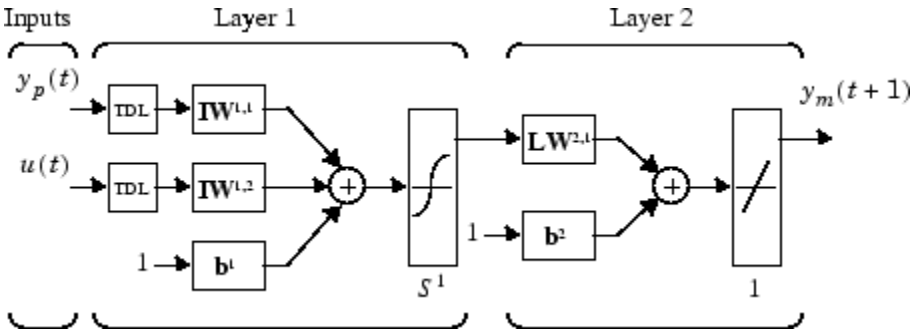
The following section describes the system identification process. This is followed by a description of the optimization process. Finally, it discusses how to use the model predictive controller block that is implemented in the Simulink environment.

System Identification

The first stage of model predictive control is to train a neural network to represent the forward dynamics of the plant. The prediction error between the plant output and the neural network output is used as the neural network training signal. The process is represented by the following figure:



The neural network plant model uses previous inputs and previous plant outputs to predict future values of the plant output. The structure of the neural network plant model is given in the following figure.



This network can be trained offline in batch mode, using data collected from the operation of the plant. You can use any of the training algorithms discussed in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2 for network training. This process is discussed in more detail in following sections.

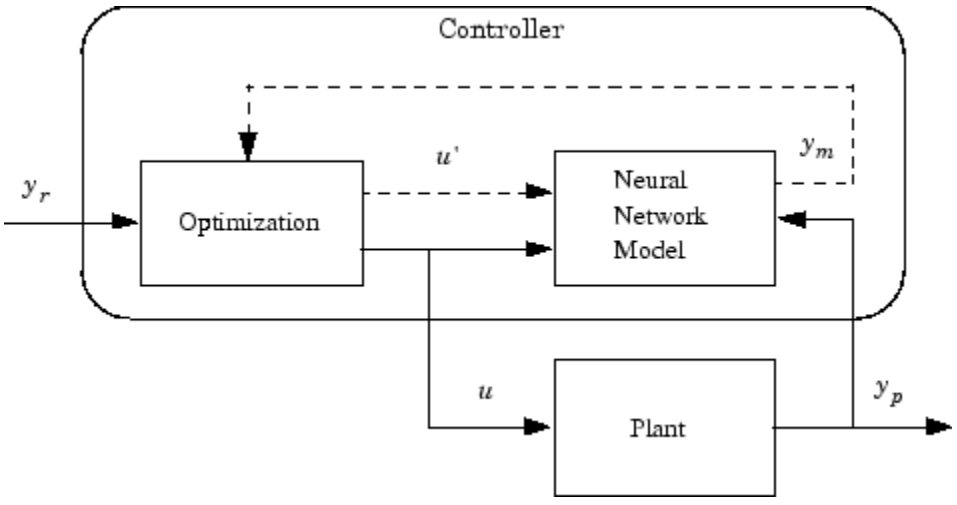
Predictive Control

The model predictive control method is based on the receding horizon technique [SoHa96 on page 32-2]. The neural network model predicts the plant response over a specified time horizon. The predictions are used by a numerical optimization program to determine the control signal that minimizes the following performance criterion over the specified horizon

$$J = \sum_{j=N_1}^{N_2} (y_r(t+j) - y_m(t+j))^2 + \rho \sum_{j=1}^{N_u} (u'(t+j-1) - u'(t+j-2))^2$$

where N_1, N_2, and N_u define the horizons over which the tracking error and the control increments are evaluated. The u' variable is the tentative control signal, y_r is the desired response, and y_m is the network model response. The ρ value determines the contribution that the sum of the squares of the control increments has on the performance index.

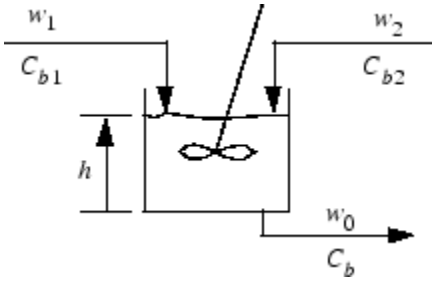
The following block diagram illustrates the model predictive control process. The controller consists of the neural network plant model and the optimization block. The optimization block determines the values of u' that minimize J, and then the optimal u is input to the plant. The controller block is implemented in Simulink, as described in the following section.



Use the Neural Network Predictive Controller Block

This section shows how the NN Predictive Controller block is used. The first step is to copy the NN Predictive Controller block from the Deep Learning Toolbox block library to the Simulink Editor. See the Simulink documentation if you are not sure how to do this. This step is skipped in the following example.

An example model is provided with the Deep Learning Toolbox software to show the use of the predictive controller. This example uses a catalytic Continuous Stirred Tank Reactor (CSTR). A diagram of the process is shown in the following figure.



The dynamic model of the system is

$$\frac{dh(t)}{dt} = w_1(t) + w_2(t) - 0.2\sqrt{h(t)}$$

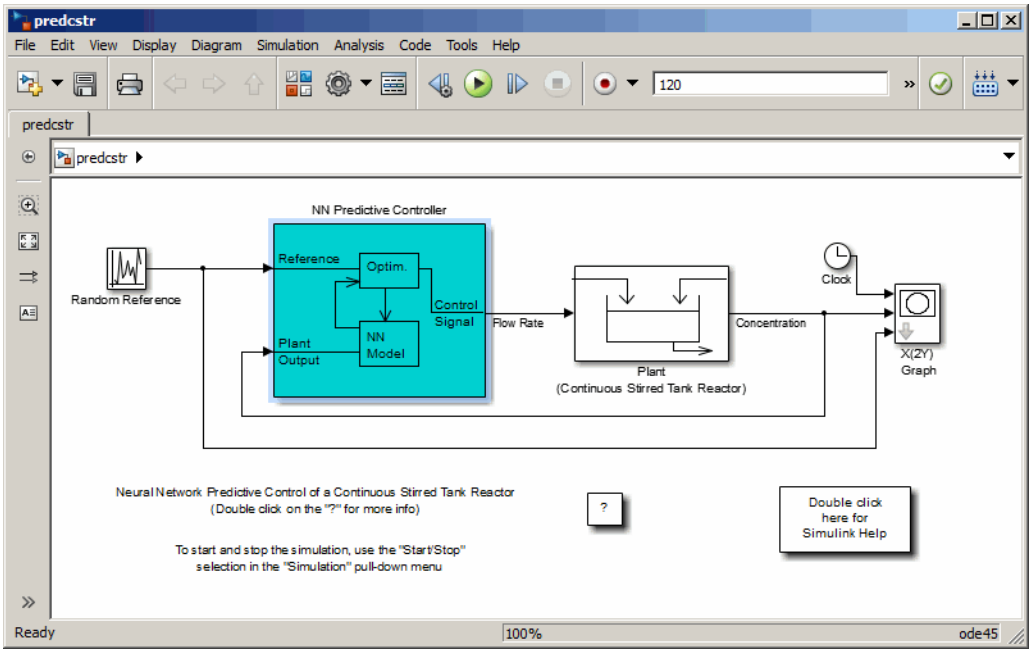
$$\frac{dC_b(t)}{dt} = (C_{b1} - C_b(t))\frac{w_1(t)}{h(t)} + (C_{b2} - C_b(t))\frac{w_2(t)}{h(t)} - \frac{k_1 C_b(t)}{(1 + k_2 C_b(t))^2}$$

where $h(t)$ is the liquid level, $C_b(t)$ is the product concentration at the output of the process, $w_1(t)$ is the flow rate of the concentrated feed C_{b1}, and $w_2(t)$ is the flow rate of the diluted feed C_{b2}. The input concentrations are set to $C_{b1} = 24.9$ and $C_{b2} = 0.1$. The constants associated with the rate of consumption are $k_1 = 1$ and $k_2 = 1$.

The objective of the controller is to maintain the product concentration by adjusting the flow $w_1(t)$. To simplify the example, set $w_2(t) = 0.1$. The level of the tank $h(t)$ is not controlled for this experiment.

To run this example:

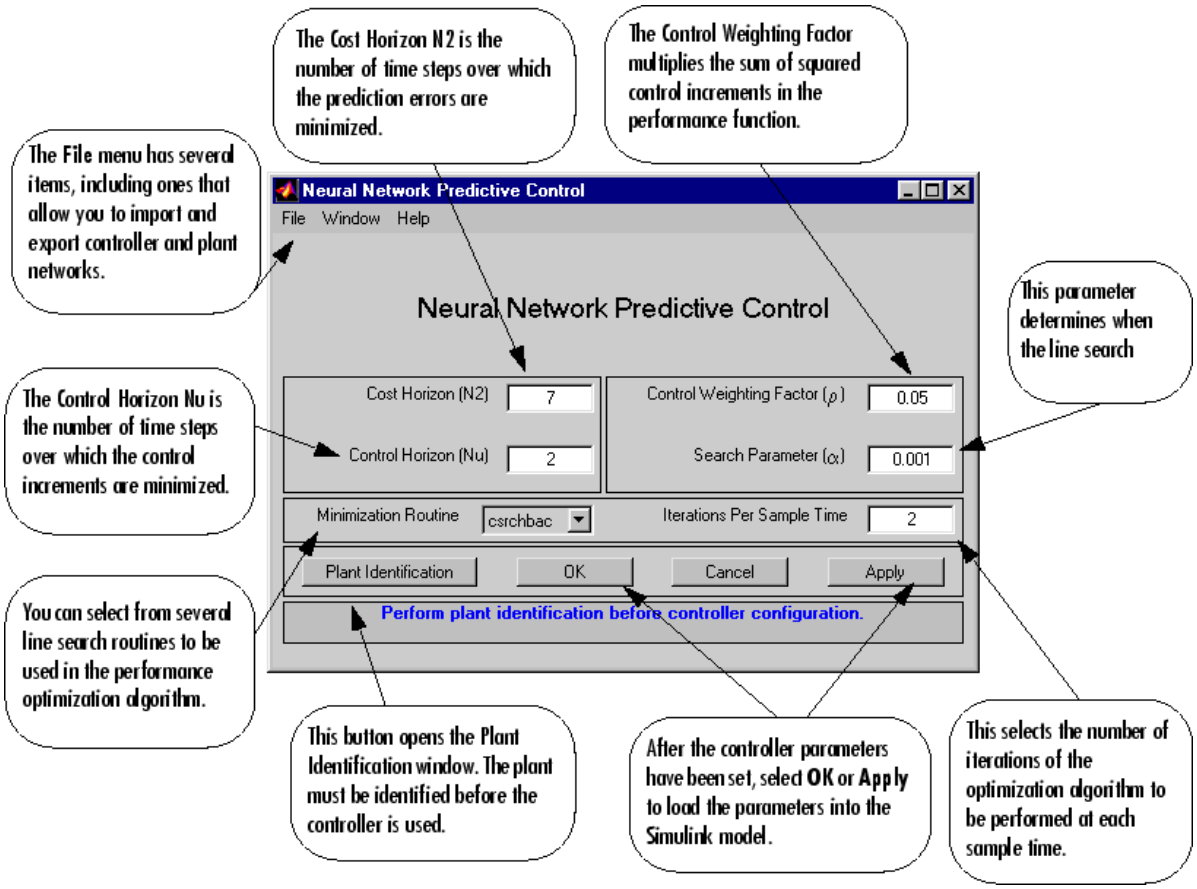
1. Start MATLAB.
2. Type `predcstr` in the MATLAB Command Window. This command opens the Simulink Editor with the following model.



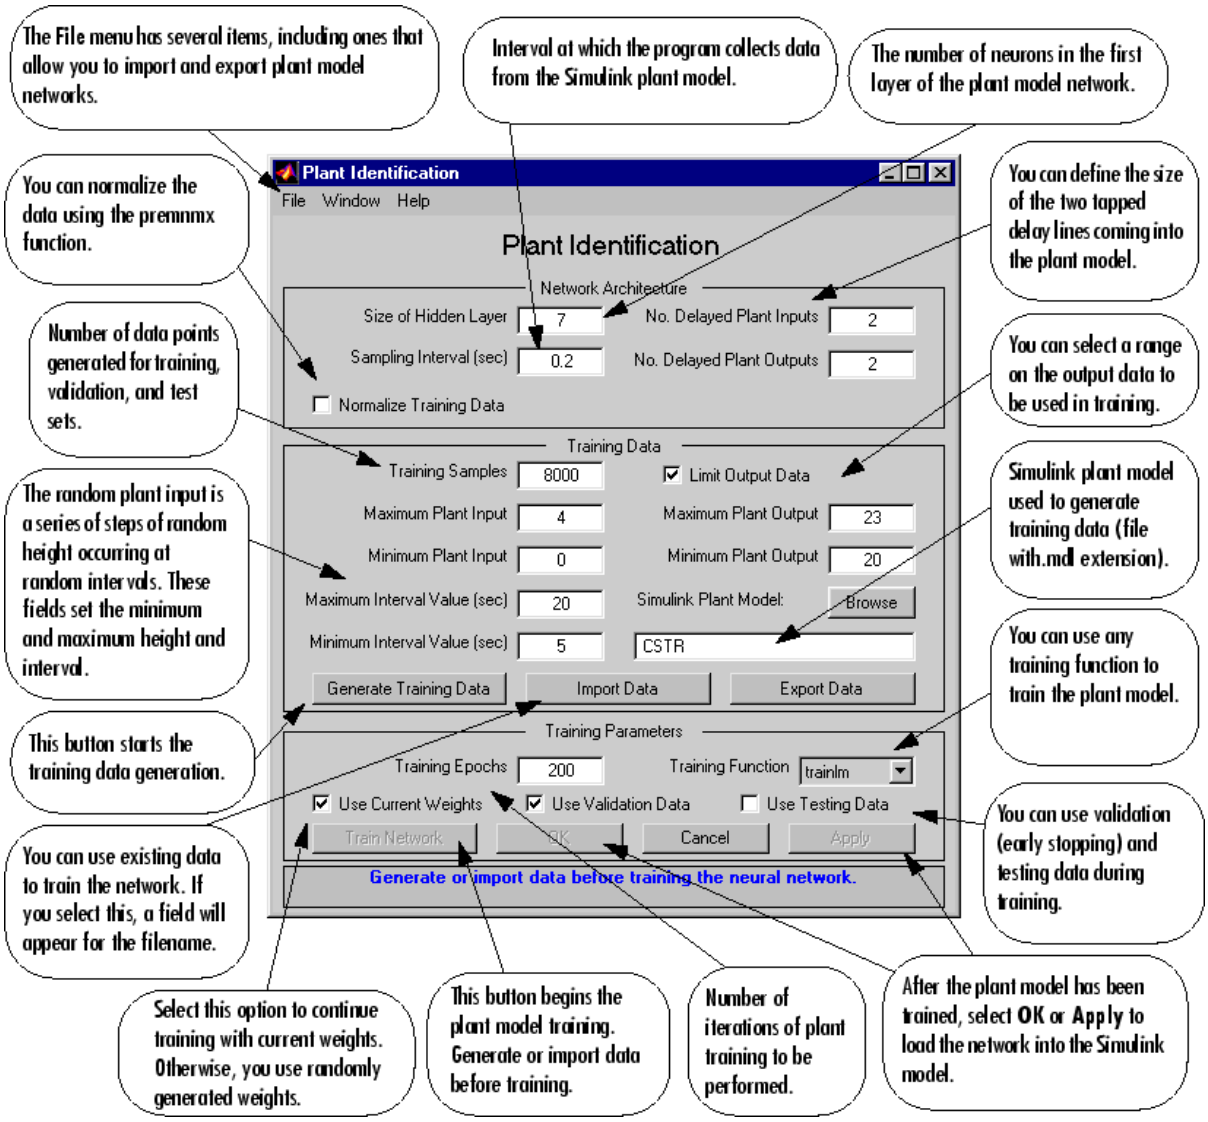
The Plant block contains the Simulink CSTR plant model. The NN Predictive Controller block signals are connected as follows:

- Control Signal is connected to the input of the Plant model.
- The Plant Output signal is connected to the Plant block output.
- The Reference is connected to the Random Reference signal.

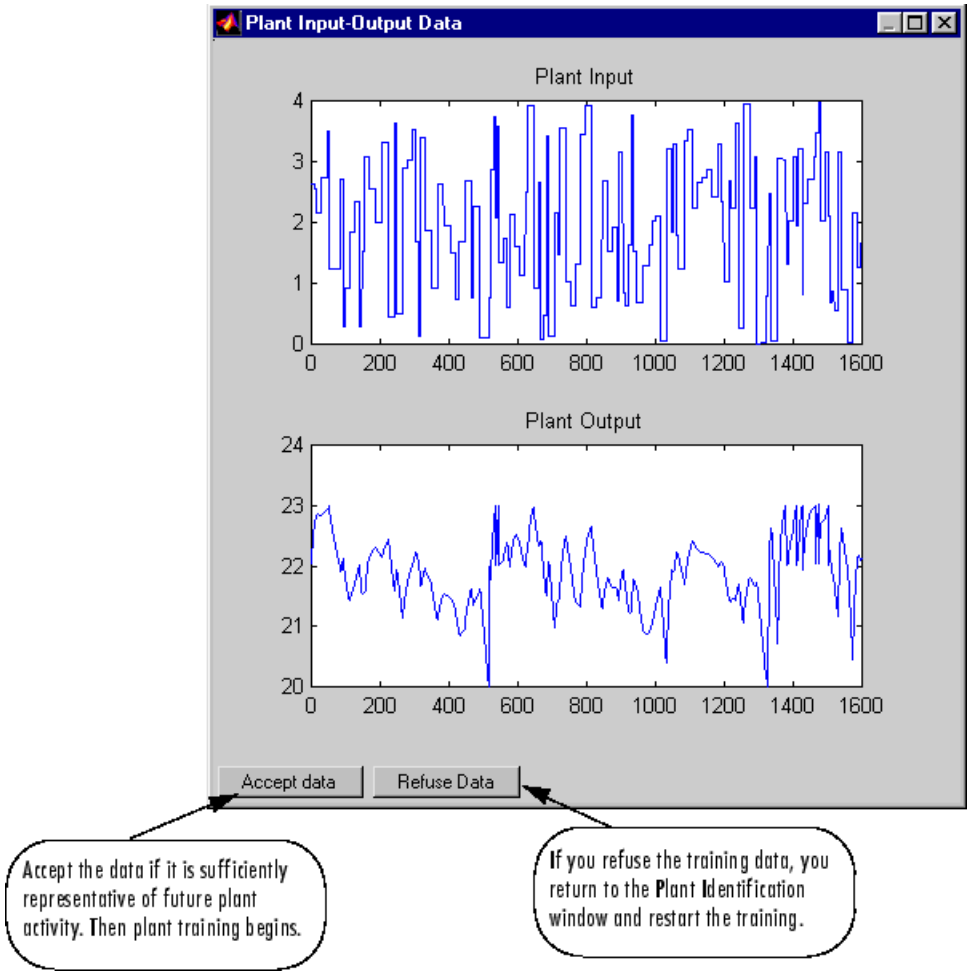
3 Double-click the NN Predictive Controller block. This opens the following window for designing the model predictive controller. This window enables you to change the controller horizons N_2 and N_u. (N_1 is fixed at 1.) The weighting parameter ρ, described earlier, is also defined in this window. The parameter α is used to control the optimization. It determines how much reduction in performance is required for a successful optimization step. You can select which linear minimization routine is used by the optimization algorithm, and you can decide how many iterations of the optimization algorithm are performed at each sample time. The linear minimization routines are slight modifications of those discussed in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2.



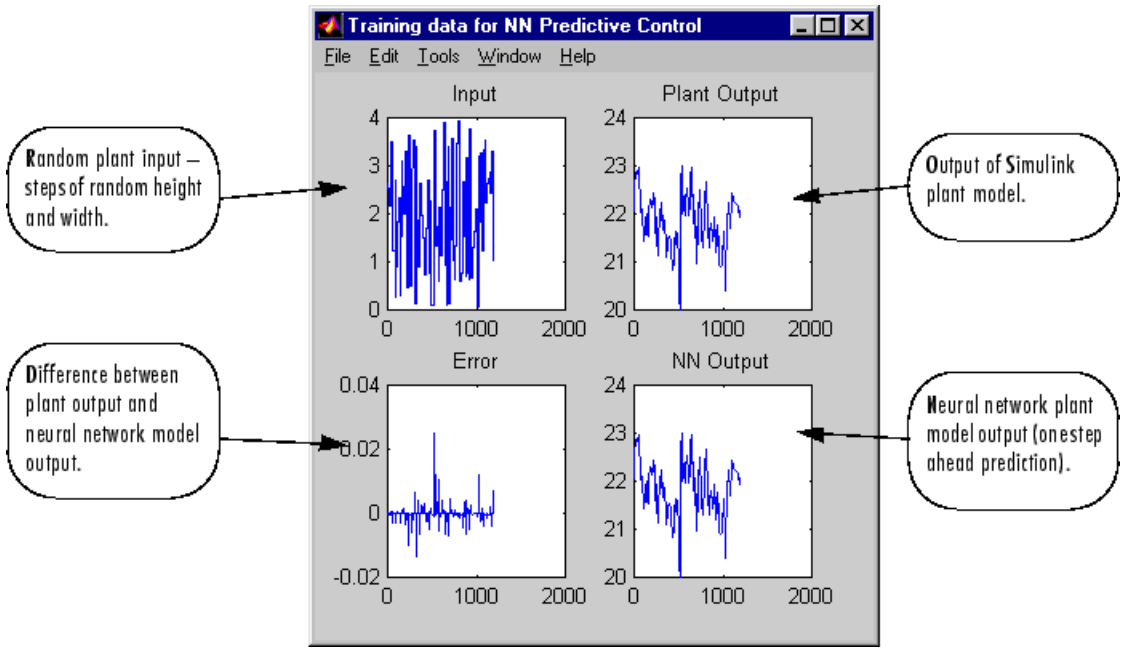
4 Select **Plant Identification**. This opens the following window. You must develop the neural network plant model before you can use the controller. The plant model predicts future plant outputs. The optimization algorithm uses these predictions to determine the control inputs that optimize future performance. The plant model neural network has one hidden layer, as shown earlier. You select the size of that layer, the number of delayed inputs and delayed outputs, and the training function in this window. You can select any of the training functions described in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2 to train the neural network plant model.



5 Click **Generate Training Data**. The program generates training data by applying a series of random step inputs to the Simulink plant model. The potential training data is then displayed in a figure similar to the following.



6 Click **Accept Data**, and then click **Train Network** in the Plant Identification window. Plant model training begins. The training proceeds according to the training algorithm (`trainlm` in this case) you selected. This is a straightforward application of batch training, as described in “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2. After the training is complete, the response of the resulting plant model is displayed, as in the following figure. (There are also separate plots for validation and testing data, if they exist.)



You can then continue training with the same data set by selecting **Train Network** again, you can **Erase Generated Data** and generate a new data set, or you can accept the current plant model and begin simulating the closed loop system. For this example, begin the simulation, as shown in the following steps.

7. Select **OK** in the Plant Identification window. This loads the trained neural network plant model into the NN Predictive Controller block.
8. Select **OK** in the Neural Network Predictive Control window. This loads the controller parameters into the NN Predictive Controller block.
9. Return to the Simulink Editor and start the simulation by choosing the menu option **Simulation > Run**. As the simulation runs, the plant output and the reference signal are displayed, as in the following figure.

Design NARMA-L2 Neural Controller in Simulink

In this section...

The neurocontroller described in this section is referred to by two different names: feedback linearization control and NARMA-L2 control. It is referred to as feedback linearization when the plant model has a particular form (companion form). It is referred to as NARMA-L2 control when the plant model can be approximated by the same form. The central idea of this type of control is to transform nonlinear system dynamics into linear dynamics by canceling the nonlinearities. This section begins by presenting the companion form system model and showing how you can use a neural network to identify this model. Then it describes how the identified neural network model can be used to develop a controller. This is followed by an example of how to use the NARMA-L2 Control block, which is contained in the Deep Learning Toolbox blockset.

Identification of the NARMA-L2 Model

As with model predictive control, the first step in using feedback linearization (or NARMA-L2) control is to identify the system to be controlled. You train a neural network to represent the forward dynamics of the system. The first step is to choose a model structure to use. One standard model that is used to represent general discrete-time nonlinear systems is the nonlinear autoregressive-moving average (NARMA) model:

$$y(k+d) = N[y(k), y(k-1), \ldots, y(k-n+1), u(k), u(k-1), \ldots, u(k-n+1)]$$

where $u(k)$ is the system input, and $y(k)$ is the system output. For the identification phase, you could train a neural network to approximate the nonlinear function N. This is the identification procedure used for the NN Predictive Controller.

If you want the system output to follow some reference trajectory $y(k+d) = y_r(k+d)$, the next step is to develop a nonlinear controller of the form:

$$u(k) = G[y(k), y(k-1), \ldots, y(k-n+1), y_r(k+d), u(k-1), \ldots, u(k-m+1)]$$

The problem with using this controller is that if you want to train a neural network to create the function G to minimize mean square error, you need to use dynamic backpropagation ([NaPa91 on page 32-2] or [HaJe99 on page 32-2]). This can be quite slow. One solution, proposed by Narendra and Mukhopadhyay [NaMu97 on page 32-2], is to use approximate models to represent the system. The controller used in this section is based on the NARMA-L2 approximate model:

$$\begin{aligned}\widehat{y}(k+d) = {} & f[y(k), y(k-1), \ldots, y(k-n+1), u(k-1), \ldots, u(k-m+1)] \\ & + g[y(k), y(k-1), \ldots, y(k-n+1), u(k-1), \ldots, u(k-m+1)] \cdot u(k)\end{aligned}$$

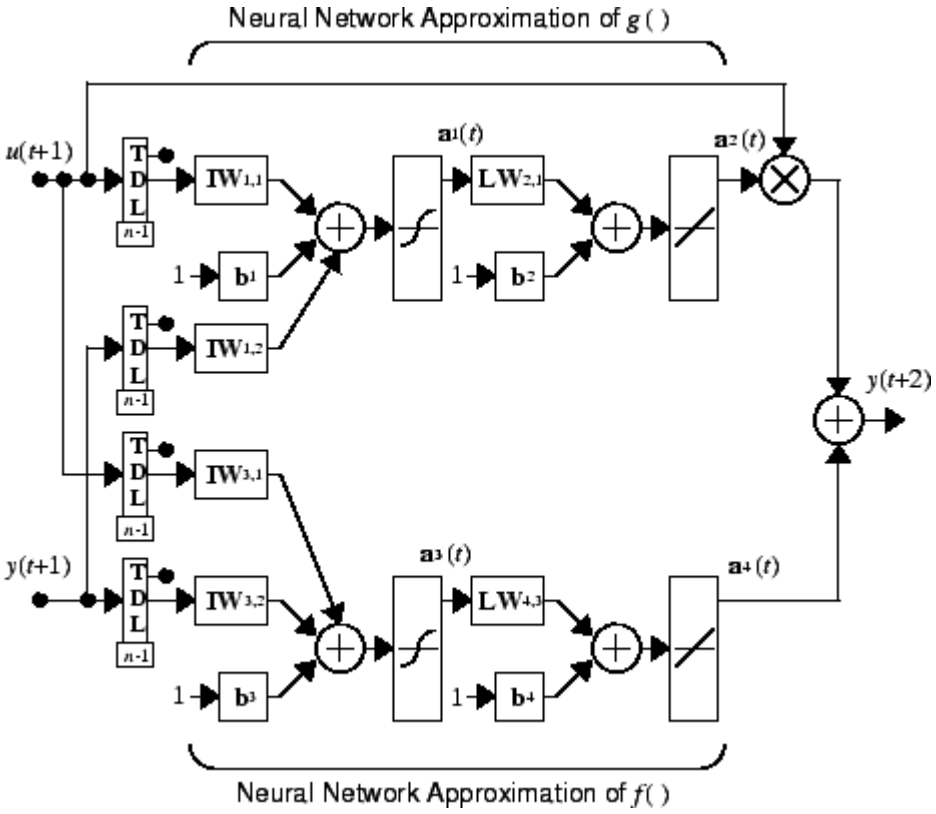
This model is in companion form, where the next controller input $u(k)$ is not contained inside the nonlinearity. The advantage of this form is that you can solve for the control input that causes the system output to follow the reference $y(k+d) = y_r(k+d)$. The resulting controller would have the form

$$u(k) = \frac{y_r(k+d) - f[y(k), y(k-1), \ldots, y(k-n+1), u(k-1), \ldots, u(k-n+1)]}{g[y(k), y(k-1), \ldots, y(k-n+1), u(k-1), \ldots, u(k-n+1)]}$$

Using this equation directly can cause realization problems, because you must determine the control input $u(k)$ based on the output at the same time, $y(k)$. So, instead, use the model

$$y(k+d) = f[y(k), y(k-1), \ldots, y(k-n+1), u(k), u(k-1), \ldots, u(k-n+1)] + g[y(k), \ldots, y(k-n+1), u(k), \ldots, u(k-n+1)] \cdot u(k+1)$$

where $d \geq 2$. The following figure shows the structure of a neural network representation.

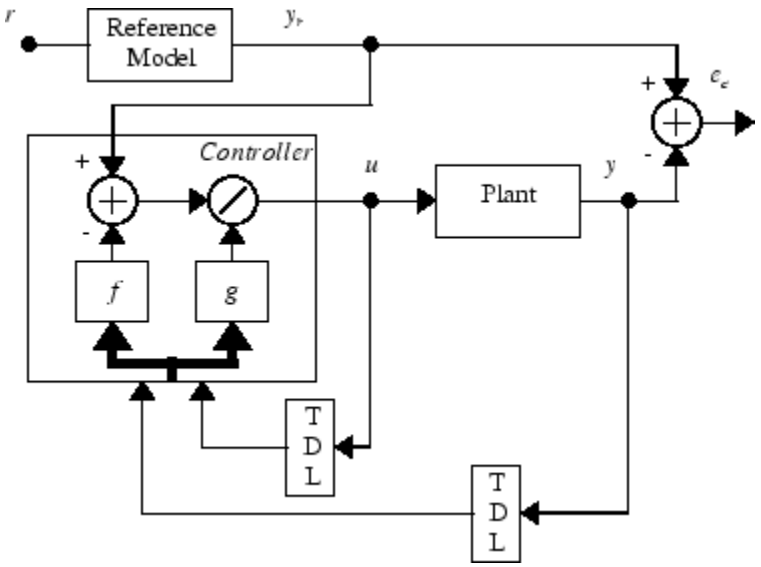


NARMA-L2 Controller

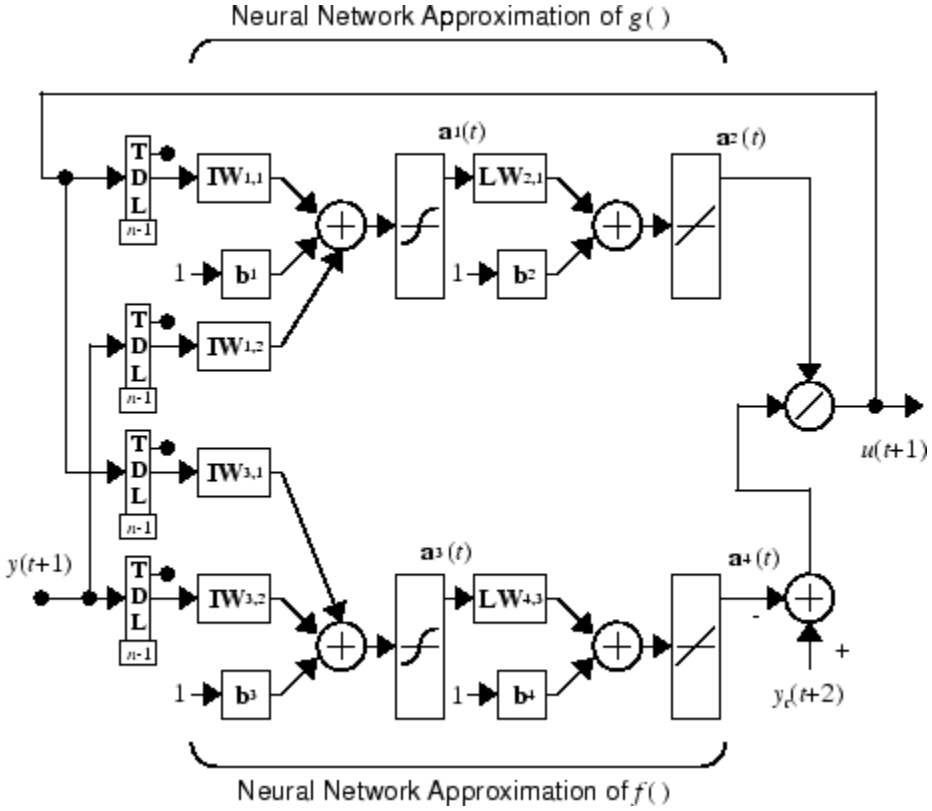
Using the NARMA-L2 model, you can obtain the controller

$$u(k+1) = \frac{y_r(k+d) - f[y(k), \ldots, y(k-n+1), u(k), \ldots, u(k-n+1)]}{g[y(k), \ldots, y(k-n+1), u(k), \ldots, u(k-n+1)]}$$

which is realizable for $d \geq 2$. The following figure is a block diagram of the NARMA-L2 controller.



This controller can be implemented with the previously identified NARMA-L2 plant model, as shown in the following figure.

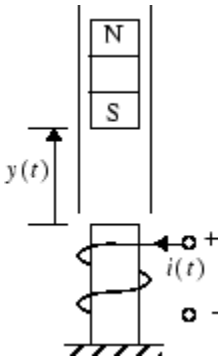


Use the NARMA-L2 Controller Block

This section shows how the NARMA-L2 controller is trained. The first step is to copy the NARMA-L2 Controller block from the Deep Learning Toolbox block library to the Simulink Editor. See the

Simulink documentation if you are not sure how to do this. This step is skipped in the following example.

An example model is provided with the Deep Learning Toolbox software to show the use of the NARMA-L2 controller. In this example, the objective is to control the position of a magnet suspended above an electromagnet, where the magnet is constrained so that it can only move in the vertical direction, as in the following figure.



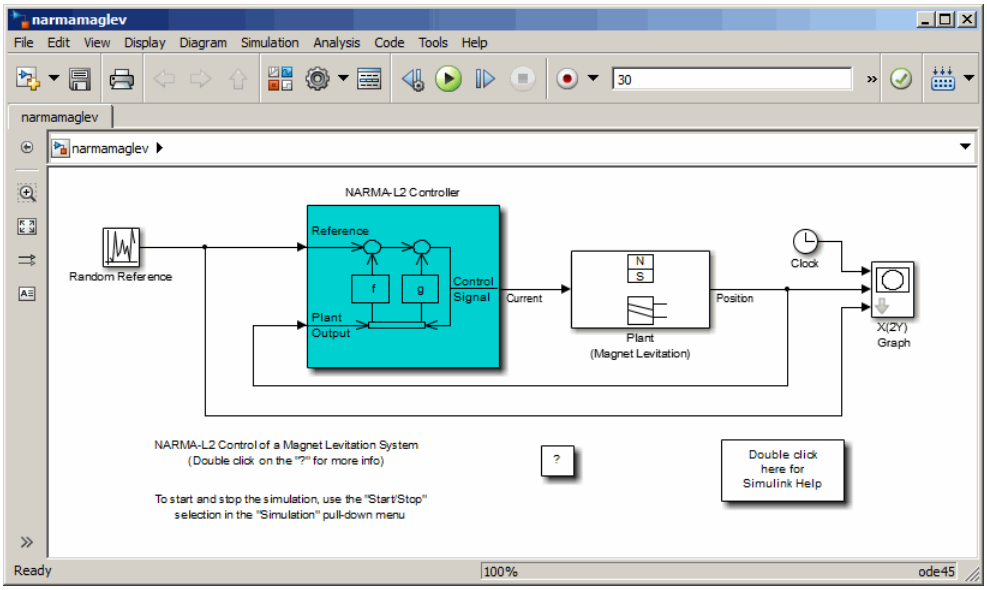
The equation of motion for this system is

$$\frac{d^2y(t)}{dt^2} = -g + \frac{\alpha}{M}\frac{i^2(t)}{y(t)} - \frac{\beta}{M}\frac{dy(t)}{dt}$$

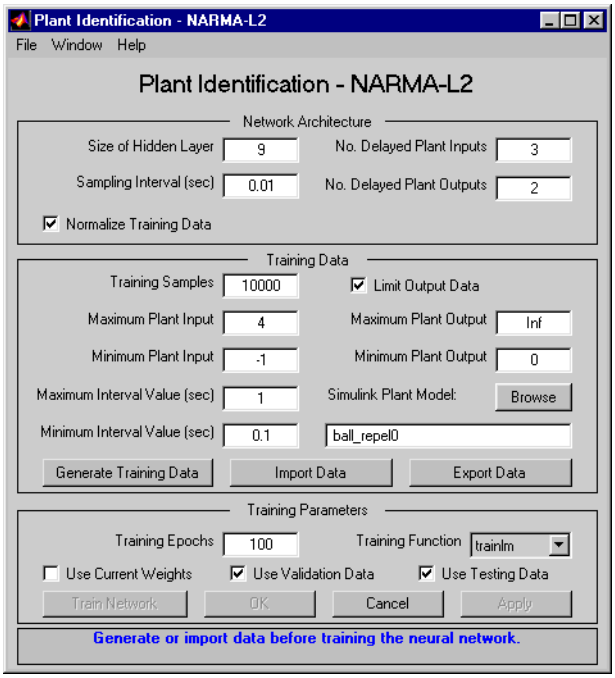
where $y(t)$ is the distance of the magnet above the electromagnet, $i(t)$ is the current flowing in the electromagnet, M is the mass of the magnet, and g is the gravitational constant. The parameter β is a viscous friction coefficient that is determined by the material in which the magnet moves, and α is a field strength constant that is determined by the number of turns of wire on the electromagnet and the strength of the magnet.

To run this example:

1. Start MATLAB.
2. Type `narmamaglev` in the MATLAB Command Window. This command opens the Simulink Editor with the following model. The NARMA-L2 Control block is already in the model.



3 Double-click the NARMA-L2 Controller block. This opens the following window. This window enables you to train the NARMA-L2 model. There is no separate window for the controller, because the controller is determined directly from the model, unlike the model predictive controller.



4 This window works the same as the other Plant Identification windows, so the training process is not repeated. Instead, simulate the NARMA-L2 controller.

5 Return to the Simulink Editor and start the simulation by choosing the menu option **Simulation > Run**. As the simulation runs, the plant output and the reference signal are displayed, as in the following figure.

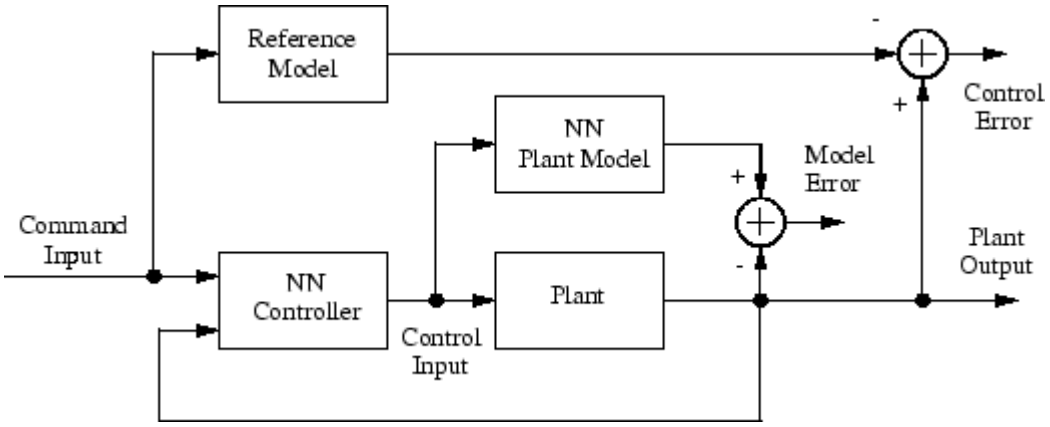
Design Model-Reference Neural Controller in Simulink

The neural model reference control architecture uses two neural networks: a controller network and a plant model network, as shown in the following figure. The plant model is identified first, and then the controller is trained so that the plant output follows the reference model output.



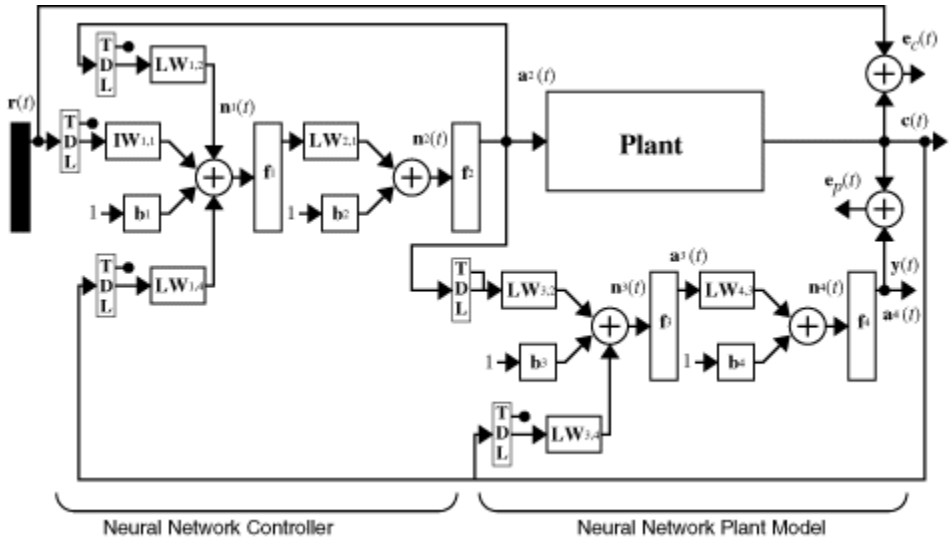
The following figure shows the details of the neural network plant model and the neural network controller as they are implemented in the Deep Learning Toolbox software. Each network has two layers, and you can select the number of neurons to use in the hidden layers. There are three sets of controller inputs:

- Delayed reference inputs
- Delayed controller outputs
- Delayed plant outputs

For each of these inputs, you can select the number of delayed values to use. Typically, the number of delays increases with the order of the plant. There are two sets of inputs to the neural network plant model:

- Delayed controller outputs
- Delayed plant outputs

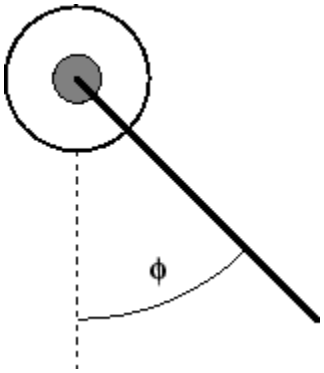
As with the controller, you can set the number of delays. The next section shows how you can set the parameters.



Use the Model Reference Controller Block

This section shows how the neural network controller is trained. The first step is to copy the Model Reference Control block from the Deep Learning Toolbox blockset to Simulink Editor. See the Simulink documentation if you are not sure how to do this. This step is skipped in the following example.

An example model is provided with the Deep Learning Toolbox software to show the use of the model reference controller. In this example, the objective is to control the movement of a simple, single-link robot arm, as shown in the following figure:



The equation of motion for the arm is

$$\frac{d^2\phi}{dt^2} = -10\sin\phi - 2\frac{d\phi}{dt} + u$$

where ϕ is the angle of the arm, and u is the torque supplied by the DC motor.

The objective is to train the controller so that the arm tracks the reference model

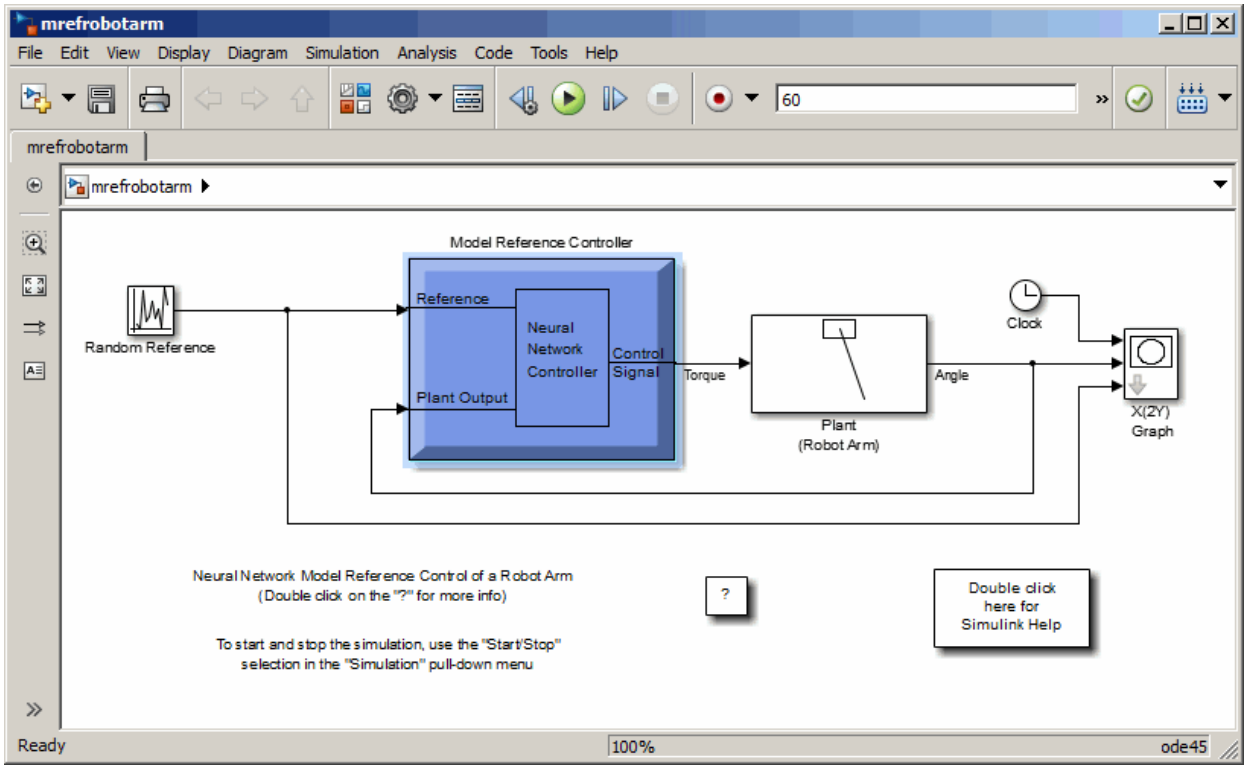
$$\frac{d^2y_r}{dt^2} = -9y_r - 6\frac{dy_r}{dt} + 9r$$

where y_r is the output of the reference model, and r is the input reference signal.

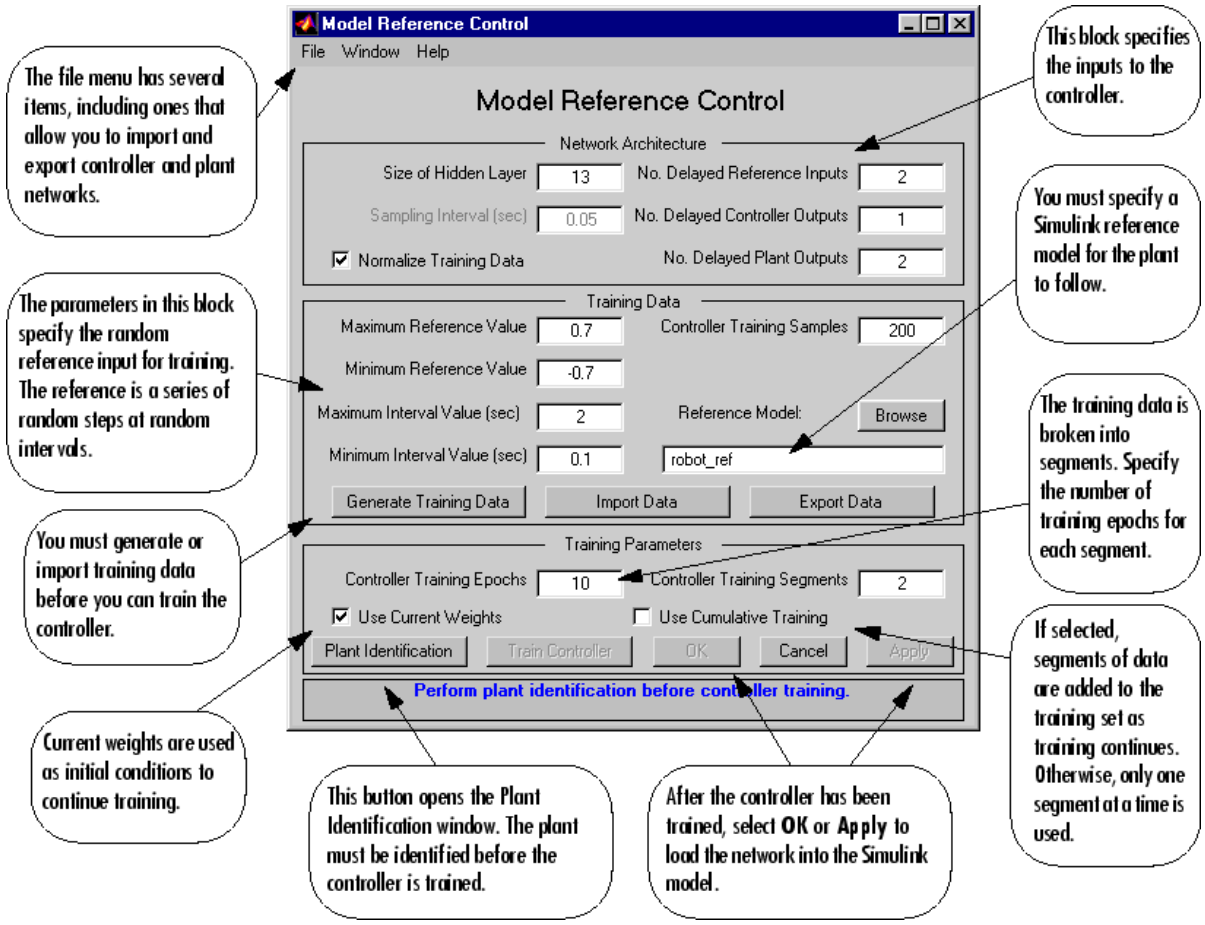
This example uses a neural network controller with a 5-13-1 architecture. The inputs to the controller consist of two delayed reference inputs, two delayed plant outputs, and one delayed controller output. A sampling interval of 0.05 seconds is used.

To run this example:

1. Start MATLAB.
2. Type `mrefrobotarm` in the MATLAB Command Window. This command opens the Simulink Editor with the Model Reference Control block already in the model.

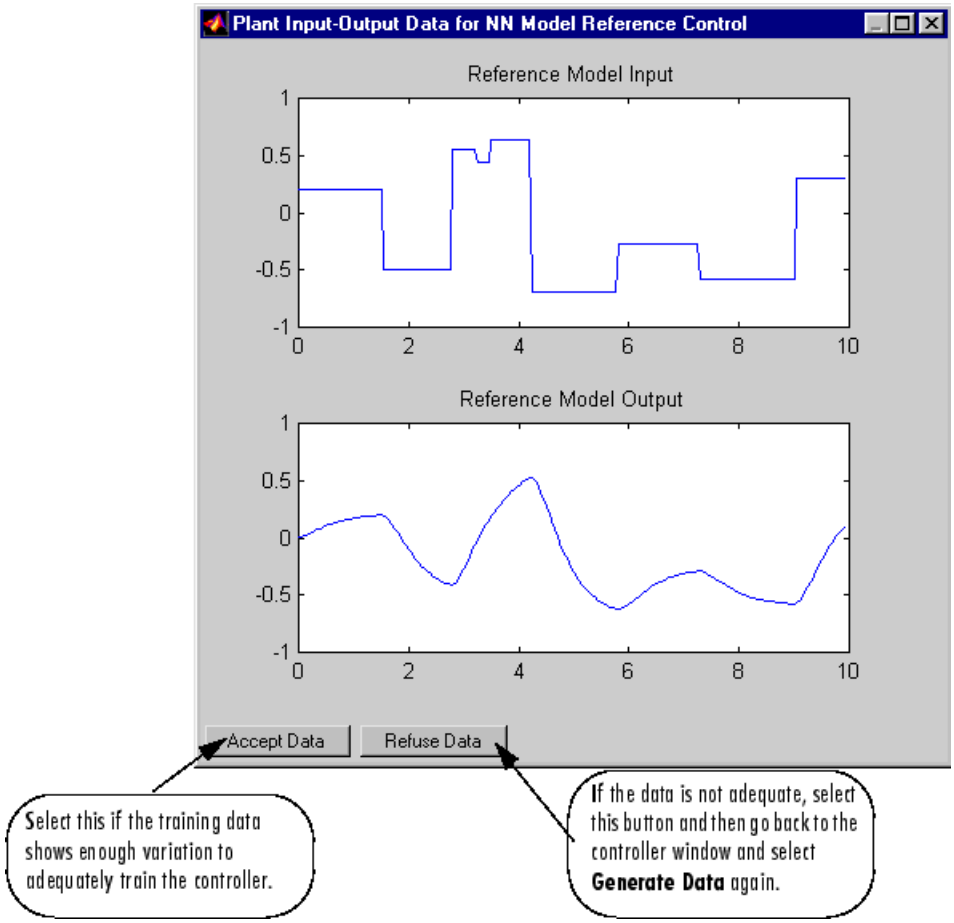


3. Double-click the Model Reference Control block. This opens the following window for training the model reference controller.

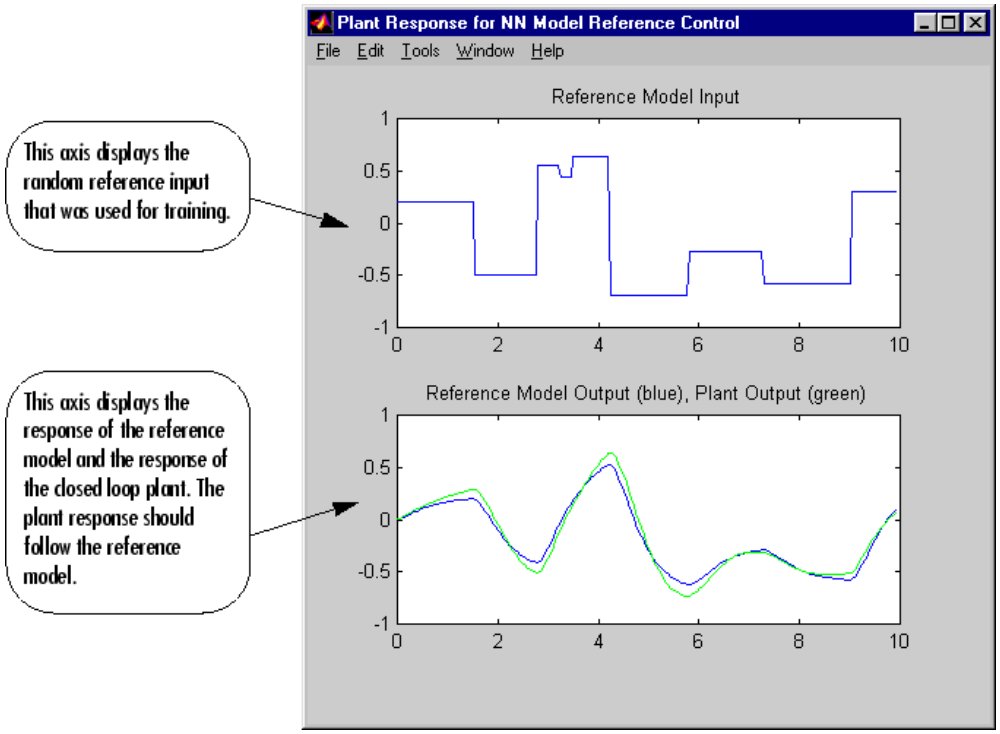


4 The next step would normally be to click **Plant Identification**, which opens the Plant Identification window. You would then train the plant model. Because the Plant Identification window is identical to the one used with the previous controllers, that process is omitted here.

5 Click **Generate Training Data**. The program starts generating the data for training the controller. After the data is generated, the following window appears.



6 Click **Accept Data**. Return to the Model Reference Control window and click **Train Controller**. The program presents one segment of data to the network and trains the network for a specified number of iterations (five in this case). This process continues, one segment at a time, until the entire training set has been presented to the network. Controller training can be significantly more time consuming than plant model training. This is because the controller must be trained using *dynamic* backpropagation (see [HaJe99 on page 32-2]). After the training is complete, the response of the resulting closed loop system is displayed, as in the following figure.



7 Go back to the Model Reference Control window. If the performance of the controller is not accurate, then you can select **Train Controller** again, which continues the controller training with the same data set. If you would like to use a new data set to continue training, select **Generate Data** or **Import Data** before you select **Train Controller**. (Be sure that **Use Current Weights** is selected if you want to continue training with the same weights.) It might also be necessary to retrain the plant model. If the plant model is not accurate, it can affect the controller training. For this example, the controller should be accurate enough, so select **OK**. This loads the controller weights into the Simulink model.

8 Return to the Simulink Editor and start the simulation by choosing the menu option **Simulation > Run**. As the simulation runs, the plant output and the reference signal are displayed, as in the following figure.

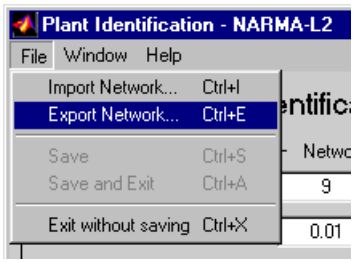
Import-Export Neural Network Simulink Control Systems

In this section...

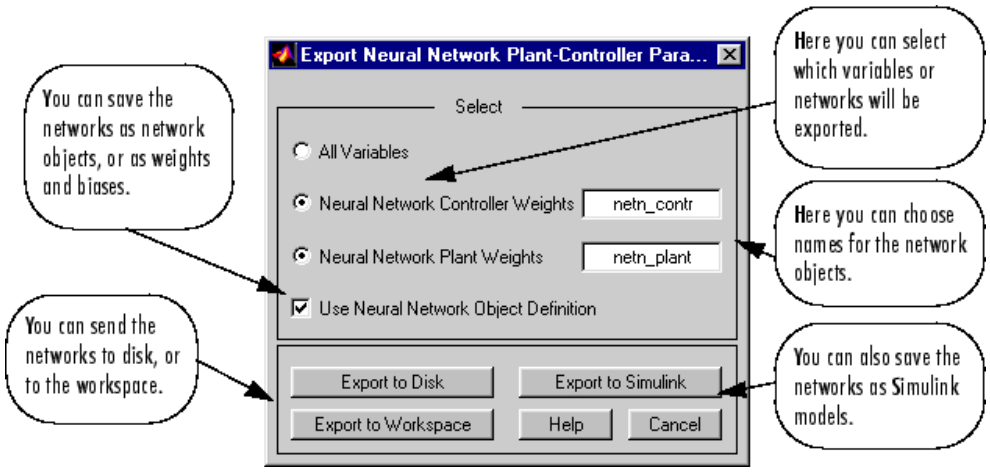
Import and Export Networks

The controller and plant model networks that you develop are stored within Simulink controller blocks. At some point you might want to transfer the networks into other applications, or you might want to transfer a network from one controller block to another. You can do this by using the **Import Network** and **Export Network** menu options. The following example leads you through the export and import processes. (The NARMA-L2 window is used for this example, but the same procedure applies to all the controllers.)

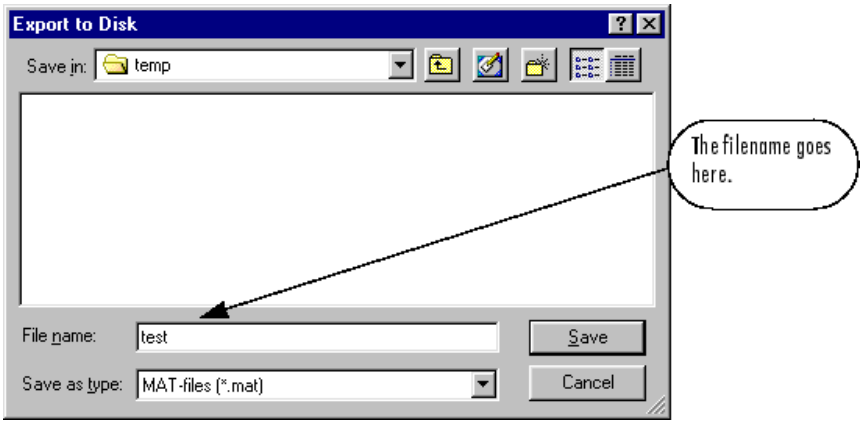
1. Repeat the first three steps of the NARMA-L2 example in “Use the NARMA-L2 Controller Block” on page 24-15. The NARMA-L2 Plant Identification window should now be open.
2. Select **File > Export Network**, as shown below.



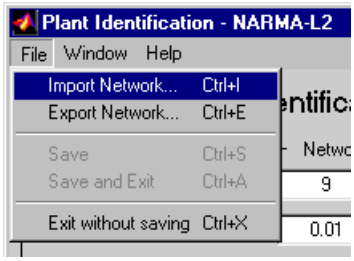
This opens the following window.



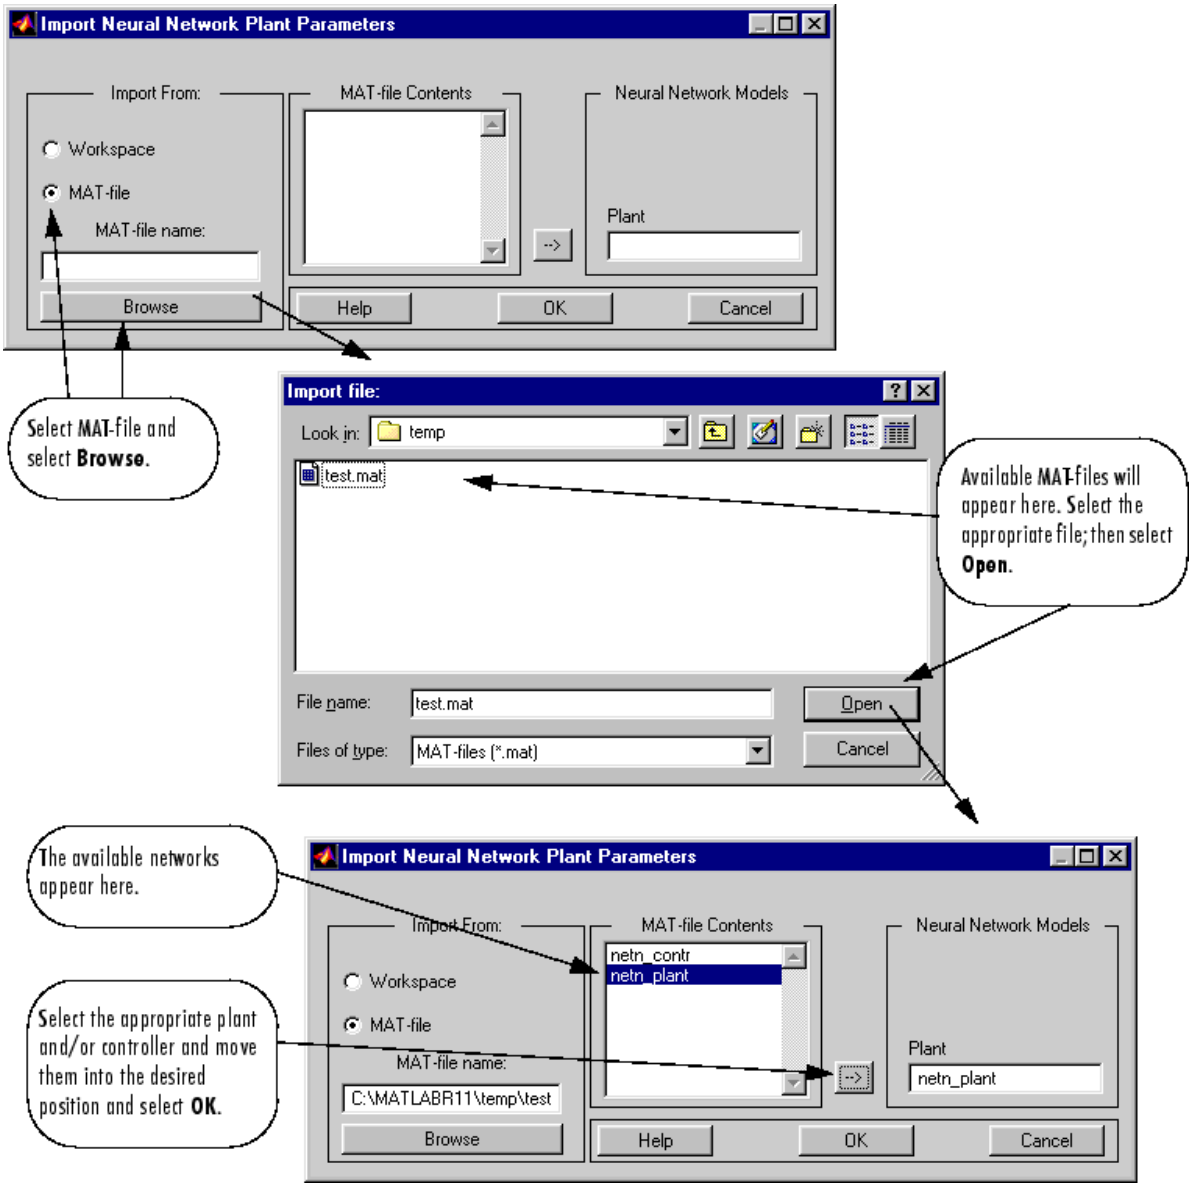
3. Select **Export to Disk**. The following window opens. Enter the file name `test` in the box, and select **Save**. This saves the controller and plant networks to disk.



4 Retrieve that data with the **Import** menu option. Select **File > Import Network**, as in the following figure.



This causes the following window to appear. Follow the steps indicated to retrieve the data that you previously exported. Once the data is retrieved, you can load it into the controller block by clicking **OK** or **Apply**. Notice that the window only has an entry for the plant model, even though you saved both the plant model and the controller. This is because the NARMA-L2 controller is derived directly from the plant model, so you do not need to import both networks.

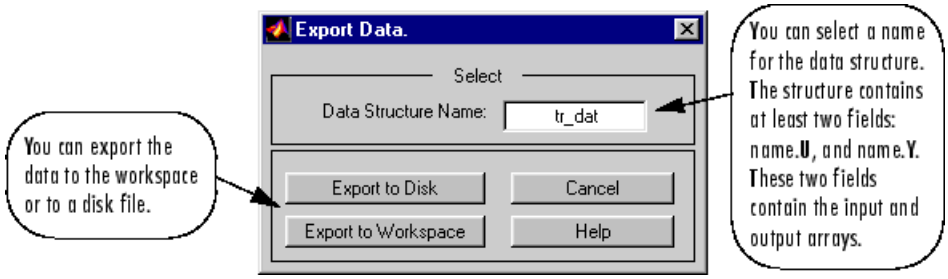


Import and Export Training Data

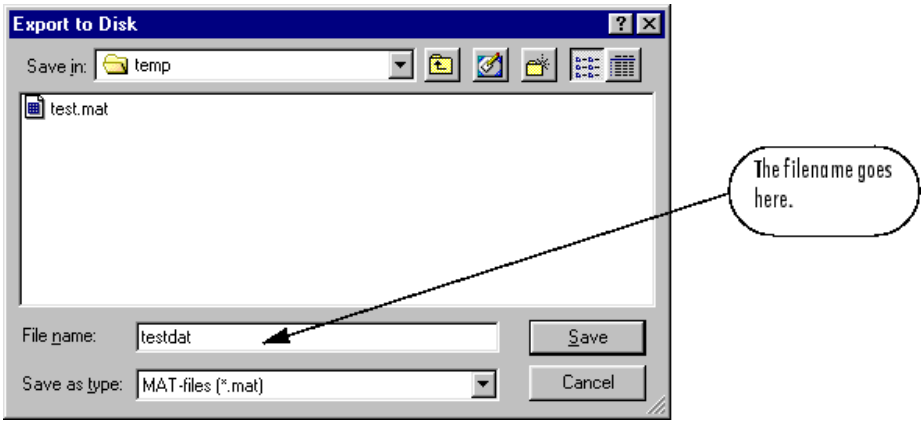
The data that you generate to train networks exists only in the corresponding plant identification or controller training window. You might want to save the training data to the workspace or to a disk file so that you can load it again at a later time. You might also want to combine data sets manually and then load them back into the training window. You can do this by using the **Import** and **Export** buttons. The following example leads you through the import and export processes. (The NN Predictive Control window is used for this example, but the same procedure applies to all the controllers.)

1 Repeat the first five steps of the NN Predictive Control example in “Use the Neural Network Predictive Controller Block” on page 24-6. Then select **Accept Data**. The Plant Identification window should then be open, and the **Import** and **Export** buttons should be active.

2 Click **Export** to open the following window.



3 Click **Export to Disk**. The following window opens. Enter the filename `testdat` in the box, and select **Save**. This saves the training data structure to disk.



4 Now retrieve the data with the import command. Click **Import** in the Plant Identification window to open the following window. Follow the steps indicated on the following page to retrieve the data that you previously exported. Once the data is imported, you can train the neural network plant model.

Radial Basis Neural Networks

Introduction to Radial Basis Neural Networks

Radial basis networks can require more neurons than standard feedforward backpropagation networks, but often they can be designed in a fraction of the time it takes to train standard feedforward networks. They work best when many training vectors are available.

You might want to consult the following paper on this subject: Chen, S., C.F.N. Cowan, and P.M. Grant, “Orthogonal Least Squares Learning Algorithm for Radial Basis Function Networks,” *IEEE Transactions on Neural Networks*, Vol. 2, No. 2, March 1991, pp. 302–309.

This topic discusses two variants of radial basis networks, generalized regression networks (GRNN) and probabilistic neural networks (PNN). You can read about them in P.D. Wasserman, *Advanced Methods in Neural Computing*, New York: Van Nostrand Reinhold, 1993, on pp. 155–61 and pp. 35–55, respectively.

Important Radial Basis Functions

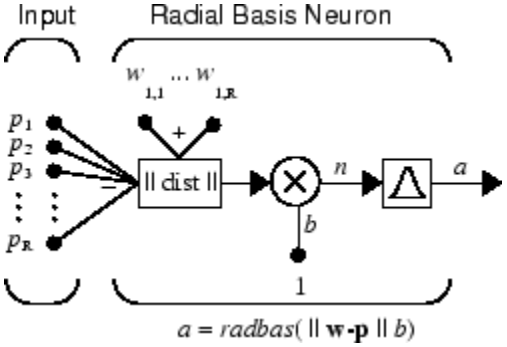
Radial basis networks can be designed with either `newrbe` or `newrb`. GRNNs and PNNs can be designed with `newgrnn` and `newpnn`, respectively.

Radial Basis Neural Networks

In this section...

Neuron Model

Here is a radial basis network with R inputs.

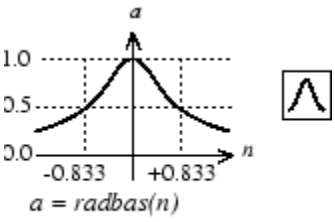


Notice that the expression for the net input of a `radbas` neuron is different from that of other neurons. Here the net input to the `radbas` transfer function is the vector distance between its weight vector **w** and the input vector **p**, multiplied by the bias b. (The `|| dist ||` box in this figure accepts the input vector **p** and the single row input weight matrix, and produces the dot product of the two.)

The transfer function for a radial basis neuron is

$$radbas(n) = e^{-n^2}$$

Here is a plot of the `radbas` transfer function.



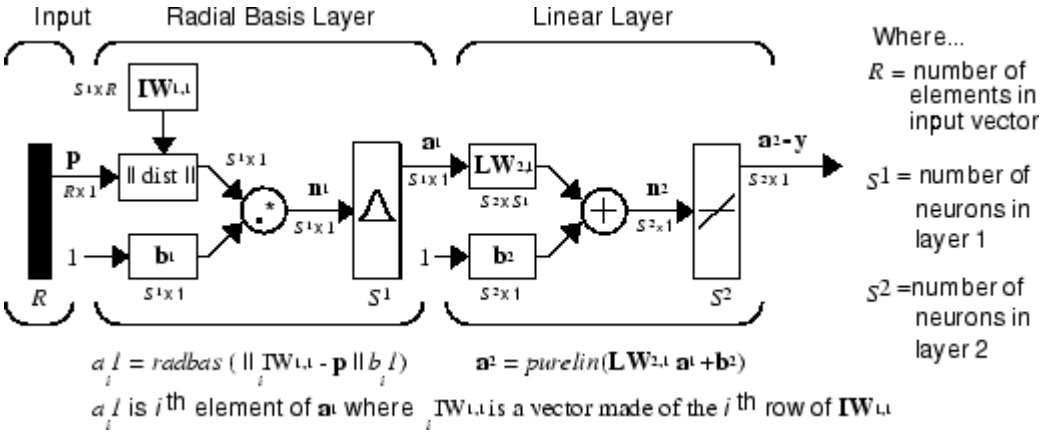
Radial Basis Function

The radial basis function has a maximum of 1 when its input is 0. As the distance between **w** and **p** decreases, the output increases. Thus, a radial basis neuron acts as a detector that produces 1 whenever the input **p** is identical to its weight vector **w**.

The bias *b* allows the sensitivity of the `radbas` neuron to be adjusted. For example, if a neuron had a bias of 0.1 it would output 0.5 for any input vector **p** at vector distance of 8.326 (0.8326/*b*) from its weight vector **w**.

Network Architecture

Radial basis networks consist of two layers: a hidden radial basis layer of S^1 neurons, and an output linear layer of S^2 neurons.



The `|| dist ||` box in this figure accepts the input vector **p** and the input weight matrix $\mathbf{IW}^{1,1}$, and produces a vector having S_1 elements. The elements are the distances between the input vector and vectors ${}_i\mathbf{IW}^{1,1}$ formed from the rows of the input weight matrix.

The bias vector $\mathbf{b}^1$ and the output of `|| dist ||` are combined with the MATLAB operation .* , which does element-by-element multiplication.

The output of the first layer for a feedforward network `net` can be obtained with the following code:

```
a{1} = radbas(netprod(dist(net.IW{1,1},p),net.b{1}))
```

Fortunately, you won't have to write such lines of code. All the details of designing this network are built into design functions `newrbe` and `newrb`, and you can obtain their outputs with `sim`.

You can understand how this network behaves by following an input vector **p** through the network to the output $\mathbf{a}^2$. If you present an input vector to such a network, each neuron in the radial basis layer will output a value according to how close the input vector is to each neuron's weight vector.

Thus, radial basis neurons with weight vectors quite different from the input vector **p** have outputs near zero. These small outputs have only a negligible effect on the linear output neurons.

In contrast, a radial basis neuron with a weight vector close to the input vector **p** produces a value near 1. If a neuron has an output of 1, its output weights in the second layer pass their values to the linear neurons in the second layer.

In fact, if only one radial basis neuron had an output of 1, and all others had outputs of 0s (or very close to 0), the output of the linear layer would be the active neuron's output weights. This would, however, be an extreme case. Typically several neurons are always firing, to varying degrees.

Now look in detail at how the first layer operates. Each neuron's weighted input is the distance between the input vector and its weight vector, calculated with `dist`. Each neuron's net input is the

element-by-element product of its weighted input with its bias, calculated with `netprod`. Each neuron's output is its net input passed through `radbas`. If a neuron's weight vector is equal to the input vector (transposed), its weighted input is 0, its net input is 0, and its output is 1. If a neuron's weight vector is a distance of `spread` from the input vector, its weighted input is `spread`, its net input is sqrt(−log(.5)) (or 0.8326), therefore its output is 0.5.

Exact Design (newrbe)

You can design radial basis networks with the function `newrbe`. This function can produce a network with zero error on training vectors. It is called in the following way:

```
net = newrbe(P,T,SPREAD)
```

The function `newrbe` takes matrices of input vectors `P` and target vectors `T`, and a spread constant `SPREAD` for the radial basis layer, and returns a network with weights and biases such that the outputs are exactly `T` when the inputs are `P`.

This function `newrbe` creates as many `radbas` neurons as there are input vectors in `P`, and sets the first-layer weights to `P'`. Thus, there is a layer of `radbas` neurons in which each neuron acts as a detector for a different input vector. If there are *Q* input vectors, then there will be *Q* neurons.

Each bias in the first layer is set to 0.8326/`SPREAD`. This gives radial basis functions that cross 0.5 at weighted inputs of +/− `SPREAD`. This determines the width of an area in the input space to which each neuron responds. If `SPREAD` is 4, then each `radbas` neuron will respond with 0.5 or more to any input vectors within a vector distance of 4 from their weight vector. `SPREAD` should be large enough that neurons respond strongly to overlapping regions of the input space.

The second-layer weights IW ^{2,1} (or in code, `IW{2,1}`) and biases b^2 (or in code, `b{2}`) are found by simulating the first-layer outputs a^1 (`A{1}`), and then solving the following linear expression:

```
[W{2,1} b{2}] * [A{1}; ones(1,Q)] = T
```

You know the inputs to the second layer (`A{1}`) and the target (`T`), and the layer is linear. You can use the following code to calculate the weights and biases of the second layer to minimize the sum-squared error.

```
Wb = T/[A{1}; ones(1,Q)]
```

Here `Wb` contains both weights and biases, with the biases in the last column. The sum-squared error is always 0, as explained below.

There is a problem with *C* constraints (input/target pairs) and each neuron has *C* +1 variables (the *C* weights from the *C* `radbas` neurons, and a bias). A linear problem with *C* constraints and more than *C* variables has an infinite number of zero error solutions.

Thus, `newrbe` creates a network with zero error on training vectors. The only condition required is to make sure that `SPREAD` is large enough that the active input regions of the `radbas` neurons overlap enough so that several `radbas` neurons always have fairly large outputs at any given moment. This makes the network function smoother and results in better generalization for new input vectors occurring between input vectors used in the design. (However, `SPREAD` should not be so large that each neuron is effectively responding in the same large area of the input space.)

The drawback to `newrbe` is that it produces a network with as many hidden neurons as there are input vectors. For this reason, `newrbe` does not return an acceptable solution when many input vectors are needed to properly define a network, as is typically the case.

More Efficient Design (newrb)

The function `newrb` iteratively creates a radial basis network one neuron at a time. Neurons are added to the network until the sum-squared error falls beneath an error goal or a maximum number of neurons has been reached. The call for this function is

```
net = newrb(P,T,GOAL,SPREAD)
```

The function `newrb` takes matrices of input and target vectors `P` and `T`, and design parameters `GOAL` and `SPREAD`, and returns the desired network.

The design method of `newrb` is similar to that of `newrbe`. The difference is that `newrb` creates neurons one at a time. At each iteration the input vector that results in lowering the network error the most is used to create a `radbas` neuron. The error of the new network is checked, and if low enough `newrb` is finished. Otherwise the next neuron is added. This procedure is repeated until the error goal is met or the maximum number of neurons is reached.

As with `newrbe`, it is important that the spread parameter be large enough that the `radbas` neurons respond to overlapping regions of the input space, but not so large that all the neurons respond in essentially the same manner.

Why not always use a radial basis network instead of a standard feedforward network? Radial basis networks, even when designed efficiently with `newrbe`, tend to have many times more neurons than a comparable feedforward network with `tansig` or `logsig` neurons in the hidden layer.

This is because sigmoid neurons can have outputs over a large region of the input space, while `radbas` neurons only respond to relatively small regions of the input space. The result is that the larger the input space (in terms of number of inputs, and the ranges those inputs vary over) the more `radbas` neurons required.

On the other hand, designing a radial basis network often takes much less time than training a sigmoid/linear network, and can sometimes result in fewer neurons' being used, as can be seen in the next example.

Examples

The example “Radial Basis Approximation” on page 31-114 shows how a radial basis network is used to fit a function. Here the problem is solved with only five neurons.

Examples “Radial Basis Underlapping Neurons” on page 31-118 and “Radial Basis Overlapping Neurons” on page 31-120 examine how the spread constant affects the design process for radial basis networks.

In “Radial Basis Underlapping Neurons” on page 31-118, a radial basis network is designed to solve the same problem as in “Radial Basis Approximation” on page 31-114. However, this time the spread constant used is 0.01. Thus, each radial basis neuron returns 0.5 or lower for any input vector with a distance of 0.01 or more from its weight vector.

Because the training inputs occur at intervals of 0.1, no two radial basis neurons have a strong output for any given input.

“Radial Basis Underlapping Neurons” on page 31-118 showed that having too small a spread constant can result in a solution that does not generalize from the input/target vectors used in the design. Example “Radial Basis Overlapping Neurons” on page 31-120 shows the opposite problem. If the

spread constant is large enough, the radial basis neurons will output large values (near 1.0) for all the inputs used to design the network.

If all the radial basis neurons always output 1, any information presented to the network becomes lost. No matter what the input, the second layer outputs 1's. The function `newrb` will attempt to find a network, but cannot because of numerical problems that arise in this situation.

The moral of the story is, choose a spread constant larger than the distance between adjacent input vectors, so as to get good generalization, but smaller than the distance across the whole input space.

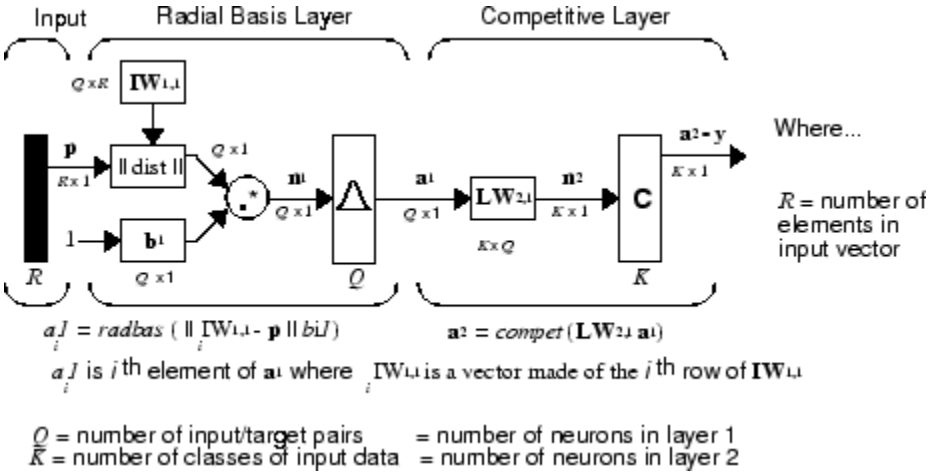
For this problem that would mean picking a spread constant greater than 0.1, the interval between inputs, and less than 2, the distance between the leftmost and rightmost inputs.

Probabilistic Neural Networks

In this section...

Probabilistic neural networks can be used for classification problems. When an input is presented, the first layer computes distances from the input vector to the training input vectors and produces a vector whose elements indicate how close the input is to a training input. The second layer sums these contributions for each class of inputs to produce as its net output a vector of probabilities. Finally, a *compete* transfer function on the output of the second layer picks the maximum of these probabilities, and produces a 1 for that class and a 0 for the other classes. The architecture for this system is shown below.

Network Architecture



It is assumed that there are Q input vector/target vector pairs. Each target vector has K elements. One of these elements is 1 and the rest are 0. Thus, each input vector is associated with one of K classes.

The first-layer input weights, $IW^{1,1}$ (`net.IW{1,1}`), are set to the transpose of the matrix formed from the Q training pairs, **P'**. When an input is presented, the `|| dist ||` box produces a vector whose elements indicate how close the input is to the vectors of the training set. These elements are multiplied, element by element, by the bias and sent to the `radbas` transfer function. An input vector close to a training vector is represented by a number close to 1 in the output vector $\mathbf{a}^1$. If an input is close to several training vectors of a single class, it is represented by several elements of $\mathbf{a}^1$ that are close to 1.

The second-layer weights, $LW^{1,2}$ (`net.LW{2,1}`), are set to the matrix **T** of target vectors. Each vector has a 1 only in the row associated with that particular class of input, and 0s elsewhere. (Use function `ind2vec` to create the proper vectors.) The multiplication $\mathbf{Ta}^1$ sums the elements of $\mathbf{a}^1$ due to each of the K input classes. Finally, the second-layer transfer function, `compet`, produces a 1 corresponding to the largest element of $\mathbf{n}^2$, and 0s elsewhere. Thus, the network classifies the input vector into a specific K class because that class has the maximum probability of being correct.

Design (newpnn)

You can use the function newpnn to create a PNN. For instance, suppose that seven input vectors and their corresponding targets are

```
P = [0 0;1 1;0 3;1 4;3 1;4 1;4 3]'
```

which yields

```
P =
     0     1     0     1     3     4     4
     0     1     3     4     1     1     3
Tc = [1 1 2 2 3 3 3]
```

which yields

```
Tc =
     1     1     2     2     3     3     3
```

You need a target matrix with 1s in the right places. You can get it with the function ind2vec. It gives a matrix with 0s except at the correct spots. So execute

```
T = ind2vec(Tc)
```

which gives

```
T =
   (1,1)        1
   (1,2)        1
   (2,3)        1
   (2,4)        1
   (3,5)        1
   (3,6)        1
   (3,7)        1
```

Now you can create a network and simulate it, using the input P to make sure that it does produce the correct classifications. Use the function vec2ind to convert the output Y into a row Yc to make the classifications clear.

```
net = newpnn(P,T);
Y = sim(net,P);
Yc = vec2ind(Y)
```

This produces

```
Yc =
     1     1     2     2     3     3     3
```

You might try classifying vectors other than those that were used to design the network. Try to classify the vectors shown below in P2.

```
P2 = [1 4;0 1;5 2]'
P2 =
     1     0     5
     4     1     2
```

Can you guess how these vectors will be classified? If you run the simulation and plot the vectors as before, you get

```
Yc =
     2     1     3
```

These results look good, for these test vectors were quite close to members of classes 2, 1, and 3, respectively. The network has managed to generalize its operation to properly classify vectors other than those used to design the network.

You might want to try “PNN Classification” on page 31-126. It shows how to design a PNN, and how the network can successfully classify a vector not used in the design.

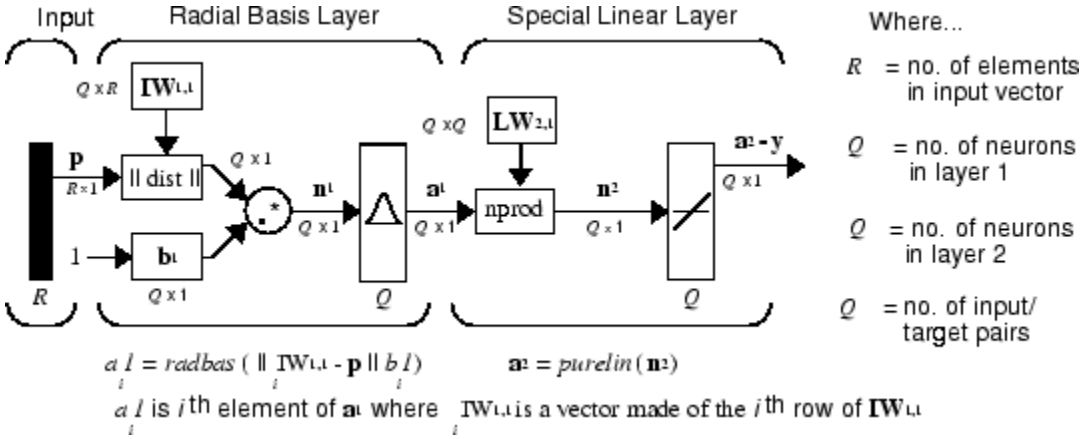
Generalized Regression Neural Networks

In this section...

Network Architecture

A generalized regression neural network (GRNN) is often used for function approximation. It has a radial basis layer and a special linear layer.

The architecture for the GRNN is shown below. It is similar to the radial basis network, but has a slightly different second layer.



Here the **nprod** box shown above (code function `normprod`) produces S^2 elements in vector $\mathbf{n}^2$. Each element is the dot product of a row of $LW^{2,1}$ and the input vector $\mathbf{a}^1$, all normalized by the sum of the elements of $\mathbf{a}^1$. For instance, suppose that

```
LW{2,1}= [1 -2;3 4;5 6];
a{1} = [0.7;0.3];
```

Then

```
aout = normprod(LW{2,1},a{1})
aout =
    0.1000
    3.3000
    5.3000
```

The first layer is just like that for `newrbe` networks. It has as many neurons as there are input/ target vectors in **P**. Specifically, the first-layer weights are set to **P'**. The bias $\mathbf{b}^1$ is set to a column vector of 0.8326/SPREAD. The user chooses SPREAD, the distance an input vector must be from a neuron's weight vector to be 0.5.

Again, the first layer operates just like the `newrbe` radial basis layer described previously. Each neuron's weighted input is the distance between the input vector and its weight vector, calculated with `dist`. Each neuron's net input is the product of its weighted input with its bias, calculated with `netprod`. Each neuron's output is its net input passed through `radbas`. If a neuron's weight vector is

equal to the input vector (transposed), its weighted input will be 0, its net input will be 0, and its output will be 1. If a neuron's weight vector is a distance of `spread` from the input vector, its weighted input will be `spread`, and its net input will be sqrt(−log(.5)) (or 0.8326). Therefore its output will be 0.5.

The second layer also has as many neurons as input/target vectors, but here `LW{2,1}` is set to `T`.

Suppose you have an input vector **p** close to $\mathbf{p}_i$, one of the input vectors among the input vector/target pairs used in designing layer 1 weights. This input **p** produces a layer 1 $\mathbf{a}^i$ output close to 1. This leads to a layer 2 output close to $\mathbf{t}_i$, one of the targets used to form layer 2 weights.

A larger `spread` leads to a large area around the input vector where layer 1 neurons will respond with significant outputs. Therefore if `spread` is small the radial basis function is very steep, so that the neuron with the weight vector closest to the input will have a much larger output than other neurons. The network tends to respond with the target vector associated with the nearest design input vector.

As `spread` becomes larger the radial basis function's slope becomes smoother and several neurons can respond to an input vector. The network then acts as if it is taking a weighted average between target vectors whose design input vectors are closest to the new input vector. As `spread` becomes larger more and more neurons contribute to the average, with the result that the network function becomes smoother.

Design (newgrnn)

You can use the function `newgrnn` to create a GRNN. For instance, suppose that three input and three target vectors are defined as

```
P = [4 5 6];
T = [1.5 3.6 6.7];
```

You can now obtain a GRNN with

```
net = newgrnn(P,T);
```

and simulate it with

```
P = 4.5;
v = sim(net,P);
```

You might want to try “GRNN Function Approximation” on page 31-122 as well.

Function	Description
`compet`	Competitive transfer function.
`dist`	Euclidean distance weight function.
`dotprod`	Dot product weight function.
`ind2vec`	Convert indices to vectors.
`negdist`	Negative Euclidean distance weight function.
`netprod`	Product net input function.
`newgrnn`	Design a generalized regression neural network.
`newpnn`	Design a probabilistic neural network.

Function	Description
`newrb`	Design a radial basis network.
`newrbe`	Design an exact radial basis network.
`normprod`	Normalized dot product weight function.
`radbas`	Radial basis transfer function.
`vec2ind`	Convert vectors to indices.

Self-Organizing and Learning Vector Quantization Networks

Introduction to Self-Organizing and LVQ

Self-organizing in networks is one of the most fascinating topics in the neural network field. Such networks can learn to detect regularities and correlations in their input and adapt their future responses to that input accordingly. The neurons of competitive networks learn to recognize groups of similar input vectors. Self-organizing maps learn to recognize groups of similar input vectors in such a way that neurons physically near each other in the neuron layer respond to similar input vectors. Self-organizing maps do not have target vectors, since their purpose is to divide the input vectors into clusters of similar vectors. There is no desired output for these types of networks.

Learning vector quantization (LVQ) is a method for training competitive layers in a supervised manner (with target outputs). A competitive layer automatically learns to classify input vectors. However, the classes that the competitive layer finds are dependent only on the distance between input vectors. If two input vectors are very similar, the competitive layer probably will put them in the same class. There is no mechanism in a strictly competitive layer design to say whether or not any two input vectors are in the same class or different classes.

LVQ networks, on the other hand, learn to classify input vectors into target classes chosen by the user.

You might consult the following reference: Kohonen, T., *Self-Organization and Associative Memory, 2nd Edition*, Berlin: Springer-Verlag, 1987.

Important Self-Organizing and LVQ Functions

You can create competitive layers and self-organizing maps with `competlayer` and `selforgmap`, respectively.

You can create an LVQ network with the function `lvqnet`.

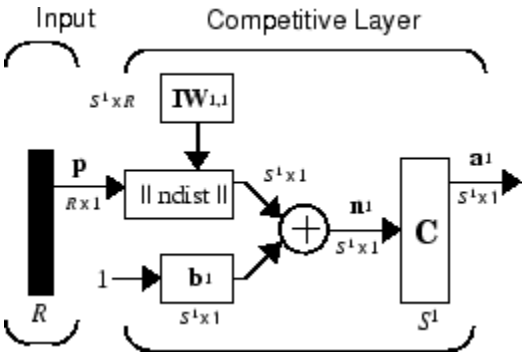
Cluster with a Competitive Neural Network

In this section...

The neurons in a competitive layer distribute themselves to recognize frequently presented input vectors.

Architecture

The architecture for a competitive network is shown below.



The ‖ `dist` ‖ box in this figure accepts the input vector **p** and the input weight matrix $\mathbf{IW}^{1,1}$, and produces a vector having S_1 elements. The elements are the negative of the distances between the input vector and vectors $_i\mathbf{IW}^{1,1}$ formed from the rows of the input weight matrix.

Compute the net input $\mathbf{n}^1$ of a competitive layer by finding the negative distance between input vector **p** and the weight vectors and adding the biases **b**. If all biases are zero, the maximum net input a neuron can have is 0. This occurs when the input vector **p** equals that neuron's weight vector.

The competitive transfer function accepts a net input vector for a layer and returns neuron outputs of 0 for all neurons except for the *winner*, the neuron associated with the most positive element of net input $\mathbf{n}^1$. The winner's output is 1. If all biases are 0, then the neuron whose weight vector is closest to the input vector has the *least* negative net input and, therefore, wins the competition to output a 1.

Reasons for using biases with competitive layers are introduced in “Bias Learning Rule (learncon)” on page 26-5.

Create a Competitive Neural Network

You can create a competitive neural network with the function `competlayer`. A simple example shows how this works.

Suppose you want to divide the following four two-element vectors into two classes.

```
p = [.1 .8 .1 .9; .2 .9 .1 .8]

p =
    0.1000    0.8000    0.1000    0.9000
    0.2000    0.9000    0.1000    0.8000
```

There are two vectors near the origin and two vectors near (1,1).

First, create a two-neuron competitive layer.:

```
net = competlayer(2);
```

Now you have a network, but you need to train it to do the classification job.

The first time the network is trained, its weights will initialized to the centers of the input ranges with the function `midpoint`. You can check see these initial values using the number of neurons and the input data:

```
wts = midpoint(2,p)

wts =
    0.5000    0.5000
    0.5000    0.5000
```

These weights are indeed the values at the midpoint of the range (0 to 1) of the inputs.

The initial biases are computed by `initcon`, which gives

```
biases = initcon(2)

biases =
    5.4366
    5.4366
```

Recall that each neuron competes to respond to an input vector **p**. If the biases are all 0, the neuron whose weight vector is closest to **p** gets the highest net input and, therefore, wins the competition, and outputs 1. All other neurons output 0. You want to adjust the winning neuron so as to move it closer to the input. A learning rule to do this is discussed in the next section.

Kohonen Learning Rule (learnk)

The weights of the winning neuron (a row of the input weight matrix) are adjusted with the *Kohonen learning* rule. Supposing that the *i*th neuron wins, the elements of the *i*th row of the input weight matrix are adjusted as shown below.

$$ {}_i\mathbf{IW}^{1,1}(q) = {}_i\mathbf{IW}^{1,1}(q-1) + \alpha(\mathbf{p}(q) - {}_i\mathbf{IW}^{1,1}(q-1)) $$

The Kohonen rule allows the weights of a neuron to learn an input vector, and because of this it is useful in recognition applications.

Thus, the neuron whose weight vector was closest to the input vector is updated to be even closer. The result is that the winning neuron is more likely to win the competition the next time a similar vector is presented, and less likely to win when a very different input vector is presented. As more and more inputs are presented, each neuron in the layer closest to a group of input vectors soon

adjusts its weight vector toward those input vectors. Eventually, if there are enough neurons, every cluster of similar input vectors will have a neuron that outputs 1 when a vector in the cluster is presented, while outputting a 0 at all other times. Thus, the competitive network learns to categorize the input vectors it sees.

The function `learnk` is used to perform the Kohonen learning rule in this toolbox.

Bias Learning Rule (learncon)

One of the limitations of competitive networks is that some neurons might not always be *allocated*. In other words, some neuron weight vectors might start out far from any input vectors and never win the competition, no matter how long the training is continued. The result is that their weights do not get to learn and they never win. These unfortunate neurons, referred to as *dead neurons*, never perform a useful function.

To stop this, use biases to give neurons that only win the competition rarely (if ever) an advantage over neurons that win often. A positive bias, added to the negative distance, makes a distant neuron more likely to win.

To do this job a running average of neuron outputs is kept. It is equivalent to the percentages of times each output is 1. This average is used to update the biases with the learning function `learncon` so that the biases of frequently active neurons become smaller, and biases of infrequently active neurons become larger.

As the biases of infrequently active neurons increase, the input space to which those neurons respond increases. As that input space increases, the infrequently active neuron responds and moves toward more input vectors. Eventually, the neuron responds to the same number of vectors as other neurons.

This has two good effects. First, if a neuron never wins a competition because its weights are far from any of the input vectors, its bias eventually becomes large enough so that it can win. When this happens, it moves toward some group of input vectors. Once the neuron's weights have moved into a group of input vectors and the neuron is winning consistently, its bias will decrease to 0. Thus, the problem of dead neurons is resolved.

The second advantage of biases is that they force each neuron to classify roughly the same percentage of input vectors. Thus, if a region of the input space is associated with a larger number of input vectors than another region, the more densely filled region will attract more neurons and be classified into smaller subsections.

The learning rates for `learncon` are typically set an order of magnitude or more smaller than for `learnk` to make sure that the running average is accurate.

Training

Now train the network for 500 epochs. You can use either `train` or `adapt`.

```
net.trainParam.epochs = 500;
net = train(net,p);
```

Note that `train` for competitive networks uses the training function `trainru`. You can verify this by executing the following code after creating the network.

```
net.trainFcn
```

```
ans =
trainru
```

For each epoch, all training vectors (or sequences) are each presented once in a different random order with the network and weight and bias values updated after each individual presentation.

Next, supply the original vectors as input to the network, simulate the network, and finally convert its output vectors to class indices.

```
a = sim(net,p);
ac = vec2ind(a)

ac =
     1     2     1     2
```

You see that the network is trained to classify the input vectors into two groups, those near the origin, class 1, and those near (1,1), class 2.

It might be interesting to look at the final weights and biases.

```
net.IW{1,1}

ans =
    0.1000    0.1500
    0.8500    0.8500

net.b{1}

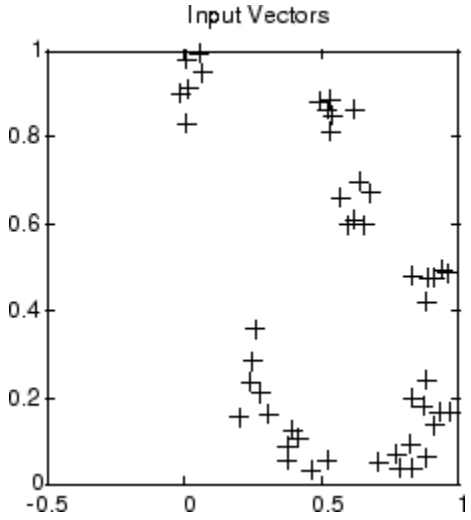
ans =
    5.4367
    5.4365
```

(You might get different answers when you run this problem, because a random seed is used to pick the order of the vectors presented to the network for training.) Note that the first vector (formed from the first row of the weight matrix) is near the input vectors close to the origin, while the vector formed from the second row of the weight matrix is close to the input vectors near (1,1). Thus, the network has been trained—just by exposing it to the inputs—to classify them.

During training each neuron in the layer closest to a group of input vectors adjusts its weight vector toward those input vectors. Eventually, if there are enough neurons, every cluster of similar input vectors has a neuron that outputs 1 when a vector in the cluster is presented, while outputting a 0 at all other times. Thus, the competitive network learns to categorize the input.

Graphical Example

Competitive layers can be understood better when their weight vectors and input vectors are shown graphically. The diagram below shows 48 two-element input vectors represented with + markers.



The input vectors above appear to fall into clusters. You can use a competitive network of eight neurons to classify the vectors into such clusters.

Try “Competitive Learning” on page 31-106 to see a dynamic example of competitive learning.

Cluster with Self-Organizing Map Neural Network

In this section...

Self-organizing feature maps (SOFM) learn to classify input vectors according to how they are grouped in the input space. They differ from competitive layers in that neighboring neurons in the self-organizing map learn to recognize neighboring sections of the input space. Thus, self-organizing maps learn both the distribution (as do competitive layers) and topology of the input vectors they are trained on.

The neurons in the layer of an SOFM are arranged originally in physical positions according to a topology function. The function `gridtop`, `hextop`, or `randtop` can arrange the neurons in a grid, hexagonal, or random topology. Distances between neurons are calculated from their positions with a distance function. There are four distance functions, `dist`, `boxdist`, `linkdist`, and `mandist`. Link distance is the most common. These topology and distance functions are described in “Topologies (gridtop, hextop, randtop)” on page 26-9 and “Distance Functions (dist, linkdist, mandist, boxdist)” on page 26-12.

Here a self-organizing feature map network identifies a winning neuron i^* using the same procedure as employed by a competitive layer. However, instead of updating only the winning neuron, all neurons within a certain neighborhood $N_{i^*}(d)$ of the winning neuron are updated, using the Kohonen rule. Specifically, all such neurons $i \in N_{i^*}(d)$ are adjusted as follows:

$$_i\mathbf{w}(q) = {}_i\mathbf{w}(q-1) + \alpha(\mathbf{p}(q) - {}_i\mathbf{w}(q-1))$$

or

$$_i\mathbf{w}(q) = (1-\alpha){}_i\mathbf{w}(q-1) + \alpha\mathbf{p}(q)$$

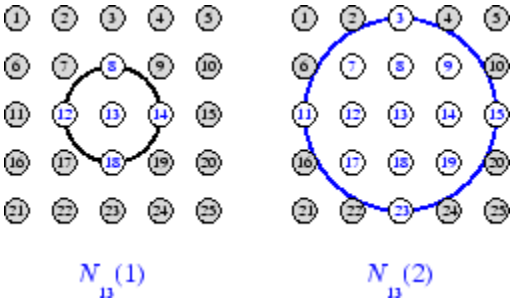
Here the *neighborhood* $N_{i^*}(d)$ contains the indices for all of the neurons that lie within a radius d of the winning neuron i^*.

$$N_i(d) = \left\{ j, d_{ij} \le d \right\}$$

Thus, when a vector **p** is presented, the weights of the winning neuron *and* its close neighbors move toward **p**. Consequently, after many presentations, neighboring neurons have learned vectors similar to each other.

Another version of SOFM training, called the *batch algorithm*, presents the whole data set to the network before any weights are updated. The algorithm then determines a winning neuron for each input vector. Each weight vector then moves to the average position of all of the input vectors for which it is a winner, or for which it is in the neighborhood of a winner.

To illustrate the concept of neighborhoods, consider the figure below. The left diagram shows a two-dimensional neighborhood of radius $d = 1$ around neuron 13. The right diagram shows a neighborhood of radius $d = 2$.



These neighborhoods could be written as $N_{13}(1) = \{8, 12, 13, 14, 18\}$ and $N_{13}(2) = \{3, 7, 8, 9, 11, 12, 13, 14, 15, 17, 18, 19, 23\}$.

The neurons in an SOFM do not have to be arranged in a two-dimensional pattern. You can use a one-dimensional arrangement, or three or more dimensions. For a one-dimensional SOFM, a neuron has only two neighbors within a radius of 1 (or a single neighbor if the neuron is at the end of the line). You can also define distance in different ways, for instance, by using rectangular and hexagonal arrangements of neurons and neighborhoods. The performance of the network is not sensitive to the exact shape of the neighborhoods.

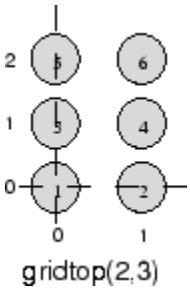
Topologies (gridtop, hextop, randtop)

You can specify different topologies for the original neuron locations with the functions `gridtop`, `hextop`, and `randtop`.

The `gridtop` topology starts with neurons in a rectangular grid similar to that shown in the previous figure. For example, suppose that you want a 2-by-3 array of six neurons. You can get this with

```
pos = gridtop([2, 3])
pos =
     0     1     0     1     0     1
     0     0     1     1     2     2
```

Here neuron 1 has the position (0,0), neuron 2 has the position (1,0), and neuron 3 has the position (0,1), etc.

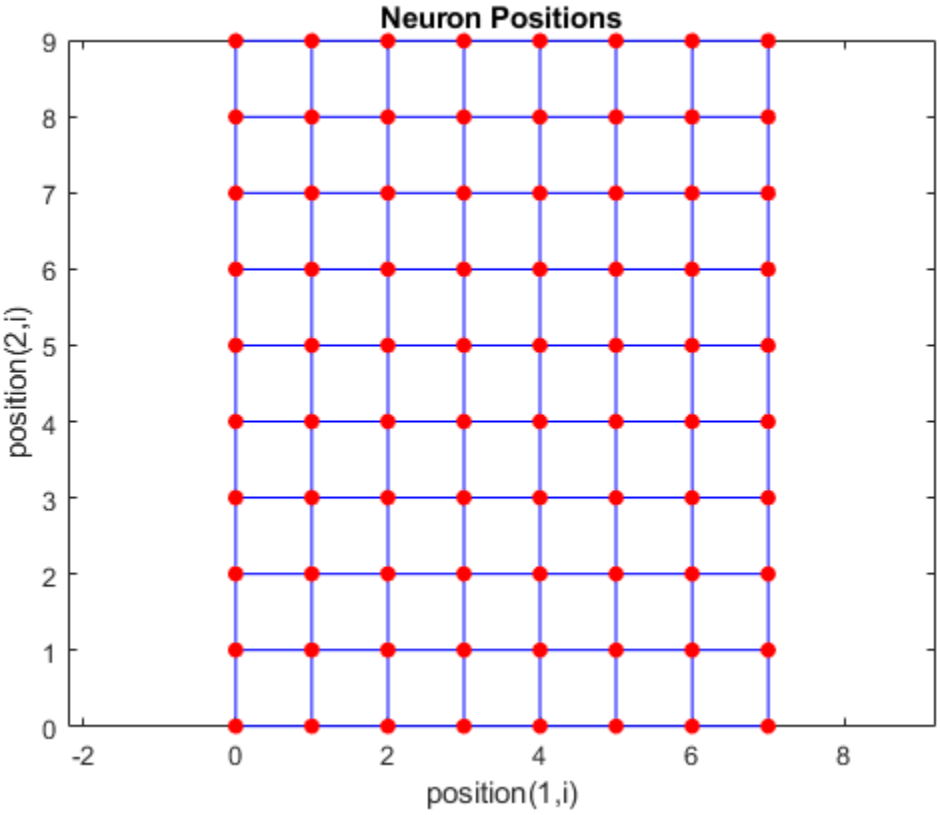


Note that had you asked for a `gridtop` with the dimension sizes reversed, you would have gotten a slightly different arrangement:

```
pos = gridtop([3, 2])
pos =
     0     1     2     0     1     2
     0     0     0     1     1     1
```

You can create an 8-by-10 set of neurons in a `gridtop` topology with the following code:

```
pos = gridtop([8 10]);
plotsom(pos)
```



As shown, the neurons in the `gridtop` topology do indeed lie on a grid.

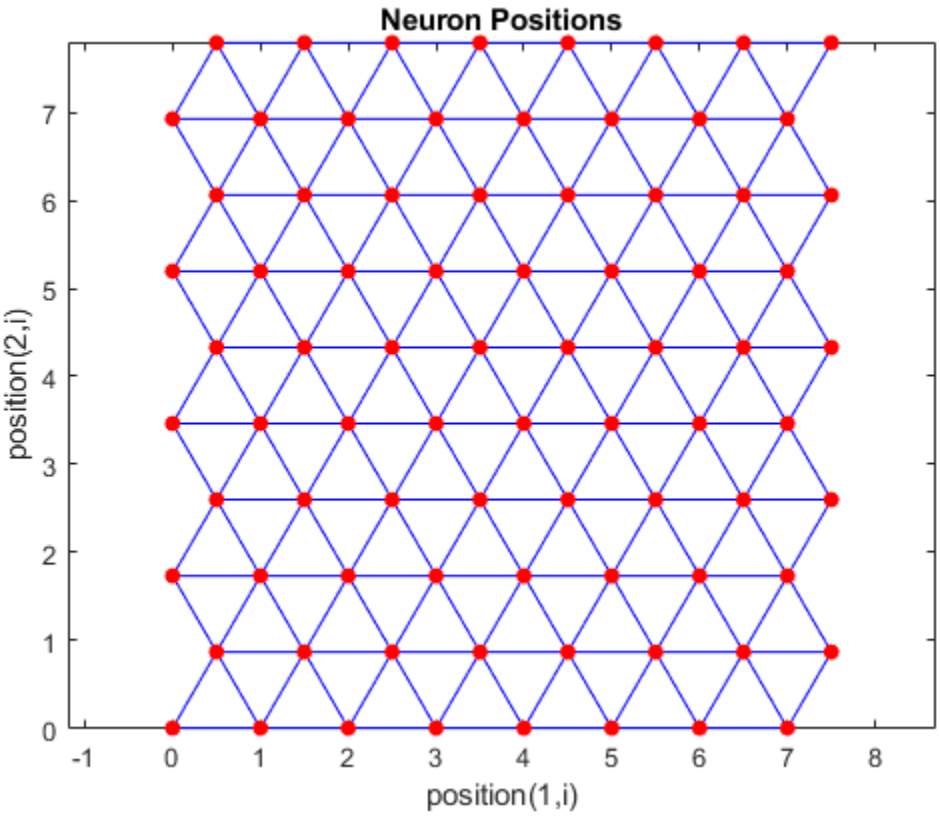
The `hextop` function creates a similar set of neurons, but they are in a hexagonal pattern. A 2-by-3 pattern of `hextop` neurons is generated as follows:

```
pos = hextop([2, 3])
pos =
         0    1.0000    0.5000    1.5000         0    1.0000
         0         0    0.8660    0.8660    1.7321    1.7321
```

Note that `hextop` is the default pattern for SOM networks generated with `selforgmap`.

You can create and plot an 8-by-10 set of neurons in a `hextop` topology with the following code:

```
pos = hextop([8 10]);
plotsom(pos)
```



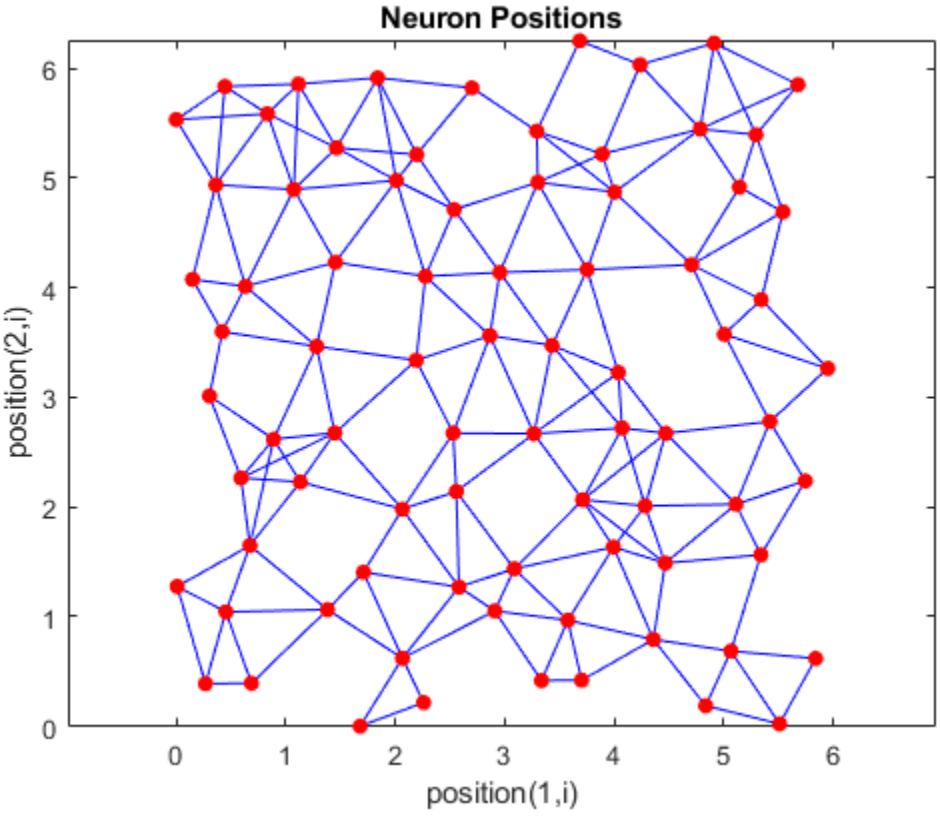
Note the positions of the neurons in a hexagonal arrangement.

Finally, the `randtop` function creates neurons in an N-dimensional random pattern. The following code generates a random pattern of neurons.

```
pos = randtop([2, 3])
pos =
         0    0.7620    0.6268    1.4218    0.0663    0.7862
    0.0925         0    0.4984    0.6007    1.1222    1.4228
```

You can create and plot an 8-by-10 set of neurons in a `randtop` topology with the following code:

```
pos = randtop([8 10]);
plotsom(pos)
```



For examples, see the help for these topology functions.

Distance Functions (dist, linkdist, mandist, boxdist)

In this toolbox, there are four ways to calculate distances from a particular neuron to its neighbors. Each calculation method is implemented with a special function.

The `dist` function calculates the Euclidean distances from a *home* neuron to other neurons. Suppose you have three neurons:

```
pos2 = [0 1 2; 0 1 2]
pos2 =
     0     1     2
     0     1     2
```

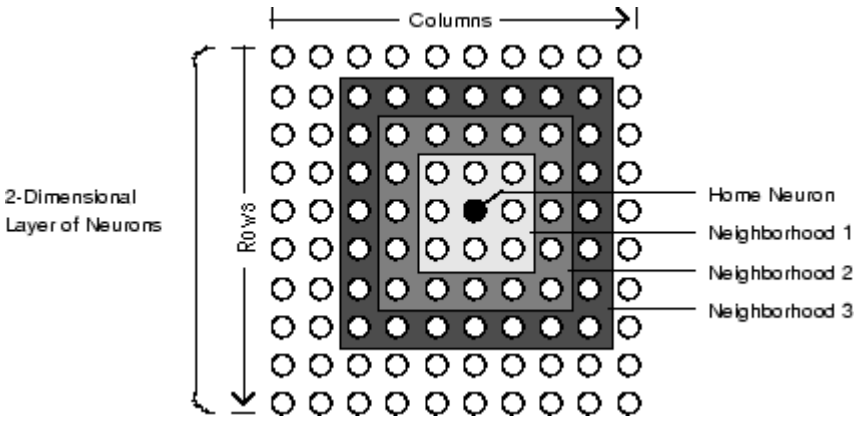
You find the distance from each neuron to the other with

```
D2 = dist(pos2)
D2 =
         0    1.4142    2.8284
    1.4142         0    1.4142
    2.8284    1.4142         0
```

Thus, the distance from neuron 1 to itself is 0, the distance from neuron 1 to neuron 2 is 1.4142, etc.

The graph below shows a home neuron in a two-dimensional (`gridtop`) layer of neurons. The home neuron has neighborhoods of increasing diameter surrounding it. A neighborhood of diameter 1

includes the home neuron and its immediate neighbors. The neighborhood of diameter 2 includes the diameter 1 neurons and their immediate neighbors.



As for the `dist` function, all the neighborhoods for an S-neuron layer map are represented by an *S*-by-*S* matrix of distances. The particular distances shown above (1 in the immediate neighborhood, 2 in neighborhood 2, etc.), are generated by the function `boxdist`. Suppose that you have six neurons in a `gridtop` configuration.

```
pos = gridtop([2, 3])
pos =
     0     1     0     1     0     1
     0     0     1     1     2     2
```

Then the box distances are

```
d = boxdist(pos)
d =
     0     1     1     1     2     2
     1     0     1     1     2     2
     1     1     0     1     1     1
     1     1     1     0     1     1
     2     2     1     1     0     1
     2     2     1     1     1     0
```

The distance from neuron 1 to 2, 3, and 4 is just 1, for they are in the immediate neighborhood. The distance from neuron 1 to both 5 and 6 is 2. The distance from both 3 and 4 to all other neurons is just 1.

The *link distance* from one neuron is just the number of links, or steps, that must be taken to get to the neuron under consideration. Thus, if you calculate the distances from the same set of neurons with `linkdist`, you get

```
dlink =
     0     1     1     2     2     3
     1     0     2     1     3     2
     1     2     0     1     1     2
     2     1     1     0     2     1
     2     3     1     2     0     1
     3     2     2     1     1     0
```

The Manhattan distance between two vectors **x** and **y** is calculated as

```
D = sum(abs(x-y))
```

Thus if you have

```
W1 = [1 2; 3 4; 5 6]
W1 =
     1     2
     3     4
     5     6
```

and

```
P1 = [1;1]
P1 =
     1
     1
```

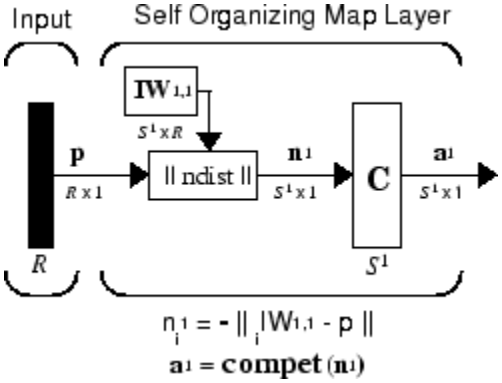
then you get for the distances

```
Z1 = mandist(W1,P1)
Z1 =
     1
     5
     9
```

The distances calculated with `mandist` do indeed follow the mathematical expression given above.

Architecture

The architecture for this SOFM is shown below.



This architecture is like that of a competitive network, except no bias is used here. The competitive transfer function produces a 1 for output element $\mathbf{a}^1_i$ corresponding to i^*, the winning neuron. All other output elements in $\mathbf{a}^1$ are 0.

Now, however, as described above, neurons close to the winning neuron are updated along with the winning neuron. You can choose from various topologies of neurons. Similarly, you can choose from various distance expressions to calculate neurons that are close to the winning neuron.

Create a Self-Organizing Map Neural Network (selforgmap)

You can create a new SOM network with the function `selforgmap`. This function defines variables used in two phases of learning:

- Ordering-phase learning rate
- Ordering-phase steps
- Tuning-phase learning rate
- Tuning-phase neighborhood distance

These values are used for training and adapting.

Consider the following example.

Suppose that you want to create a network having input vectors with two elements, and that you want to have six neurons in a hexagonal 2-by-3 network. The code to obtain this network is:

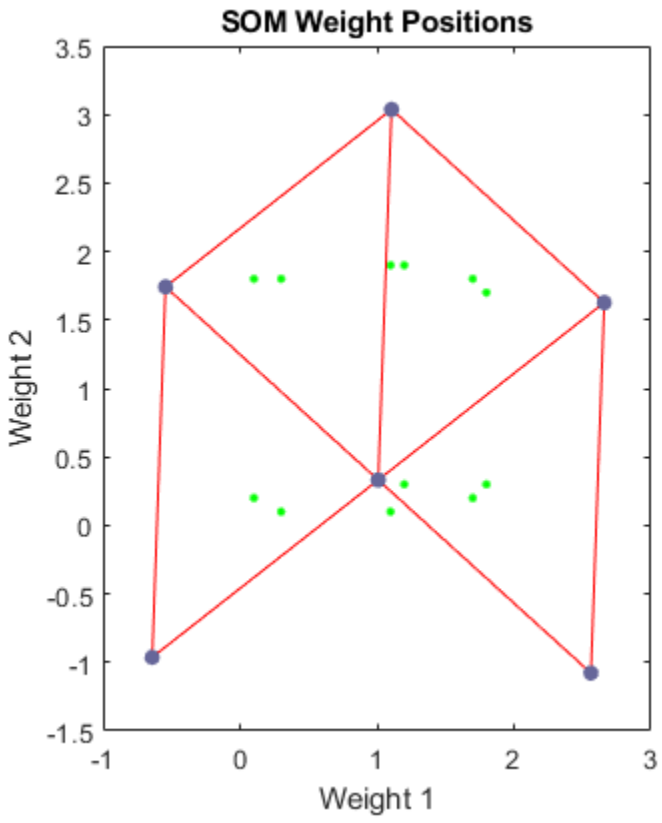
```
net = selforgmap([2 3]);
```

Suppose that the vectors to train on are:

```
P = [.1 .3 1.2 1.1 1.8 1.7 .1 .3 1.2 1.1 1.8 1.7;...
0.2 0.1 0.3 0.1 0.3 0.2 1.8 1.8 1.9 1.9 1.7 1.8];
```

You can configure the network to input the data and plot all of this with:

```
net = configure(net,P);
plotsompos(net,P)
```



The green spots are the training vectors. The initialization for `selforgmap` spreads the initial weights across the input space. Note that they are initially some distance from the training vectors.

When simulating a network, the negative distances between each neuron's weight vector and the input vector are calculated (`negdist`) to get the weighted inputs. The weighted inputs are also the net inputs (`netsum`). The net inputs compete (`compet`) so that only the neuron with the most positive net input will output a 1.

Training (learnsomb)

The default learning in a self-organizing feature map occurs in the batch mode (`trainbu`). The weight learning function for the self-organizing map is `learnsomb`.

First, the network identifies the winning neuron for each input vector. Each weight vector then moves to the average position of all of the input vectors for which it is a winner or for which it is in the neighborhood of a winner. The distance that defines the size of the neighborhood is altered during training through two phases.

Ordering Phase

This phase lasts for the given number of steps. The neighborhood distance starts at a given initial distance, and decreases to the tuning neighborhood distance (1.0). As the neighborhood distance decreases over this phase, the neurons of the network typically order themselves in the input space with the same topology in which they are ordered physically.

Tuning Phase

This phase lasts for the rest of training or adaption. The neighborhood size has decreased below 1 so only the winning neuron learns for each sample.

Now take a look at some of the specific values commonly used in these networks.

Learning occurs according to the `learnsomb` learning parameter, shown here with its default value.

Learning Parameter	Default Value	Purpose
`LP.init_neighborhood`	`3`	Initial neighborhood size
`LP.steps`	`100`	Ordering phase steps

The neighborhood size `NS` is altered through two phases: an ordering phase and a tuning phase.

The ordering phase lasts as many steps as `LP.steps`. During this phase, the algorithm adjusts `ND` from the initial neighborhood size `LP.init_neighborhood` down to 1. It is during this phase that neuron weights order themselves in the input space consistent with the associated neuron positions.

During the tuning phase, `ND` is less than 1. During this phase, the weights are expected to spread out relatively evenly over the input space while retaining their topological order found during the ordering phase.

Thus, the neuron's weight vectors initially take large steps all together toward the area of input space where input vectors are occurring. Then as the neighborhood size decreases to 1, the map tends to order itself topologically over the presented input vectors. Once the neighborhood size is 1, the network should be fairly well ordered. The training continues in order to give the neurons time to spread out evenly across the input vectors.

As with competitive layers, the neurons of a self-organizing map will order themselves with approximately equal distances between them if input vectors appear with even probability throughout

a section of the input space. If input vectors occur with varying frequency throughout the input space, the feature map layer tends to allocate neurons to an area in proportion to the frequency of input vectors there.

Thus, feature maps, while learning to categorize their input, also learn both the topology and distribution of their input.

You can train the network for 1000 epochs with

```
net.trainParam.epochs = 1000;
net = train(net,P);
plotsompos(net,P)
```

You can see that the neurons have started to move toward the various training groups. Additional training is required to get the neurons closer to the various groups.

As noted previously, self-organizing maps differ from conventional competitive learning in terms of which neurons get their weights updated. Instead of updating only the winner, feature maps update the weights of the winner and its neighbors. The result is that neighboring neurons tend to have similar weight vectors and to be responsive to similar input vectors.

Examples

Two examples are described briefly below. You also might try the similar examples “One-Dimensional Self-organizing Map” on page 31-109 and “Two-Dimensional Self-organizing Map” on page 31-111.

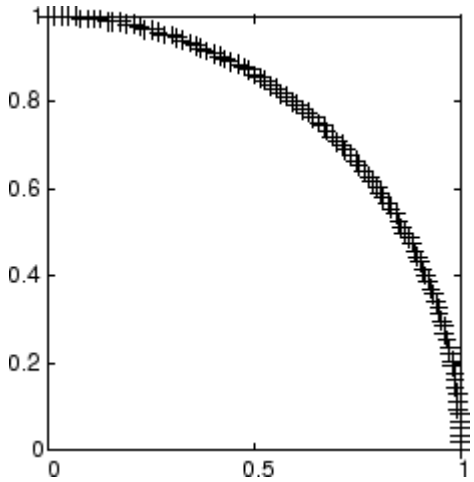
One-Dimensional Self-Organizing Map

Consider 100 two-element unit input vectors spread evenly between 0° and 90°.

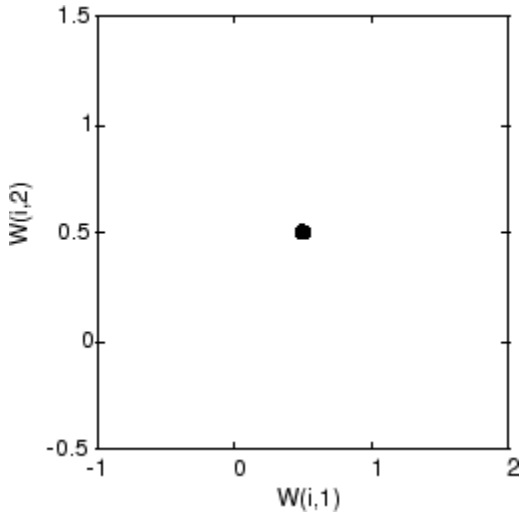
```
angles = 0:0.5*pi/99:0.5*pi;
```

Here is a plot of the data.

```
P = [sin(angles); cos(angles)];
```

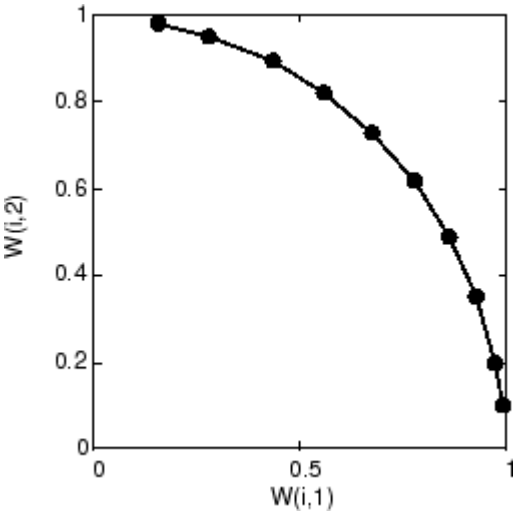


A self-organizing map is defined as a one-dimensional layer of 10 neurons. This map is to be trained on these input vectors shown above. Originally these neurons are at the center of the figure.



Of course, because all the weight vectors start in the middle of the input vector space, all you see now is a single circle.

As training starts the weight vectors move together toward the input vectors. They also become ordered as the neighborhood size decreases. Finally the layer adjusts its weights so that each neuron responds strongly to a region of the input space occupied by input vectors. The placement of neighboring neuron weight vectors also reflects the topology of the input vectors.



Note that self-organizing maps are trained with input vectors in a random order, so starting with the same initial vectors does not guarantee identical training results.

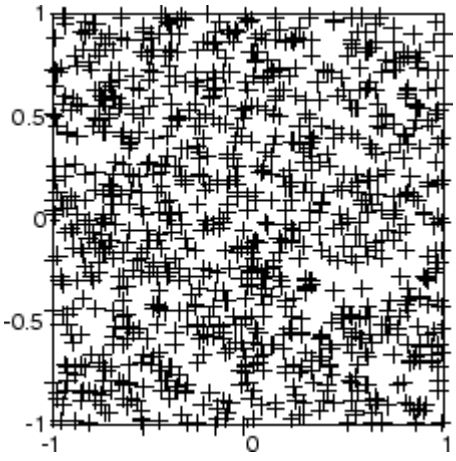
Two-Dimensional Self-Organizing Map

This example shows how a two-dimensional self-organizing map can be trained.

First some random input data is created with the following code:

```
P = rands(2,1000);
```

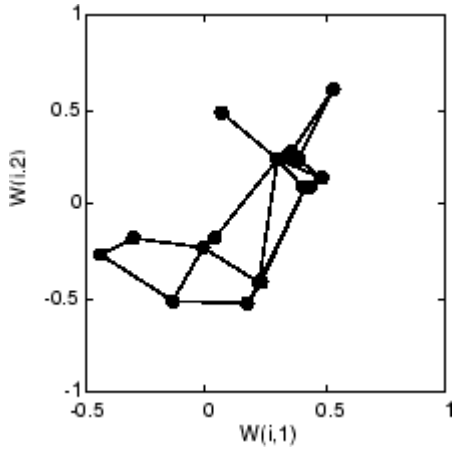
Here is a plot of these 1000 input vectors.



A 5-by-6 two-dimensional map of 30 neurons is used to classify these input vectors. The two-dimensional map is five neurons by six neurons, with distances calculated according to the Manhattan distance neighborhood function `mandist`.

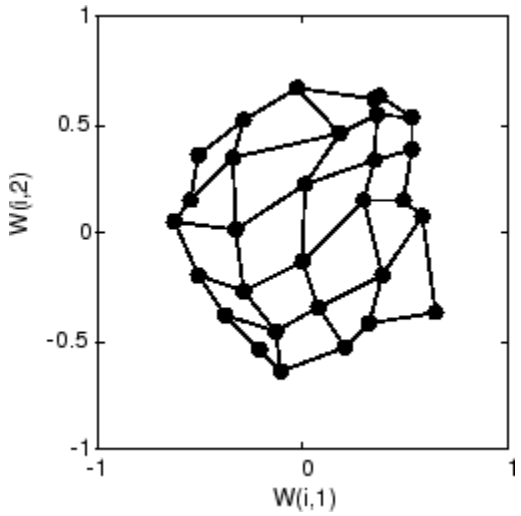
The map is then trained for 5000 presentation cycles, with displays every 20 cycles.

Here is what the self-organizing map looks like after 40 cycles.



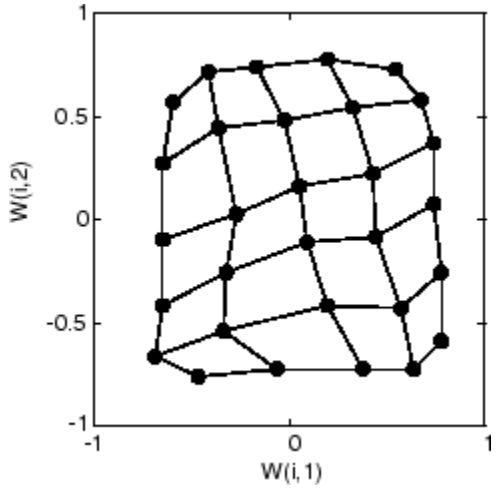
The weight vectors, shown with circles, are almost randomly placed. However, even after only 40 presentation cycles, neighboring neurons, connected by lines, have weight vectors close together.

Here is the map after 120 cycles.

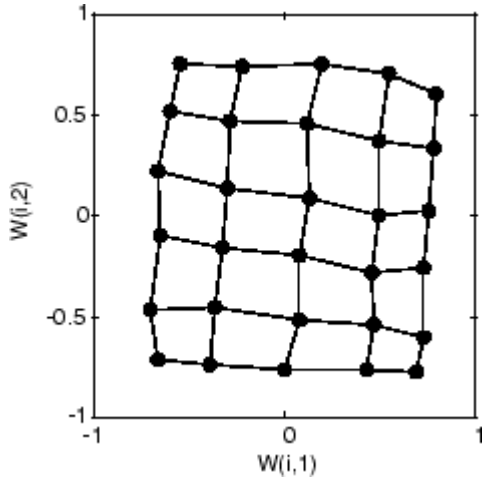


After 120 cycles, the map has begun to organize itself according to the topology of the input space, which constrains input vectors.

The following plot, after 500 cycles, shows the map more evenly distributed across the input space.



Finally, after 5000 cycles, the map is rather evenly spread across the input space. In addition, the neurons are very evenly spaced, reflecting the even distribution of input vectors in this problem.



Thus a two-dimensional self-organizing map has learned the topology of its inputs' space.

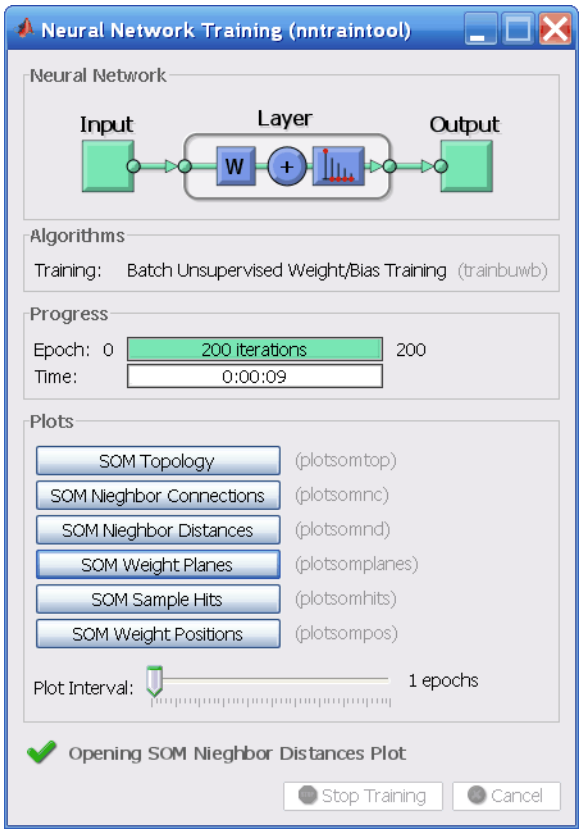
It is important to note that while a self-organizing map does not take long to organize itself so that neighboring neurons recognize similar inputs, it can take a long time for the map to finally arrange itself according to the distribution of input vectors.

Training with the Batch Algorithm

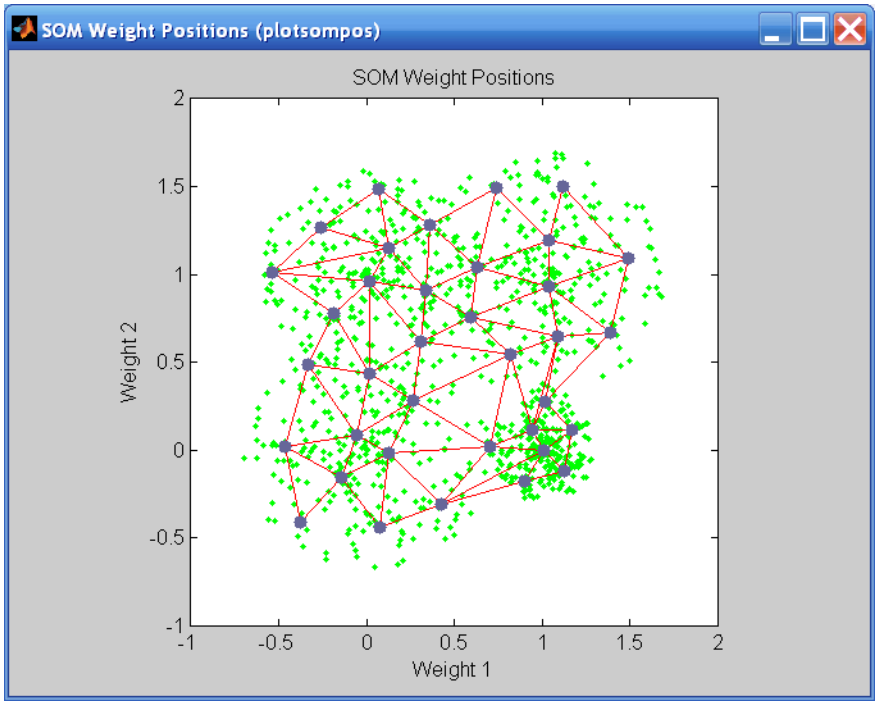
The batch training algorithm is generally much faster than the incremental algorithm, and it is the default algorithm for SOFM training. You can experiment with this algorithm on a simple data set with the following commands:

```
x = simplecluster_dataset
net = selforgmap([6 6]);
net = train(net,x);
```

This command sequence creates and trains a 6-by-6 two-dimensional map of 36 neurons. During training, the following figure appears.



There are several useful visualizations that you can access from this window. If you click **SOM Weight Positions**, the following figure appears, which shows the locations of the data points and the weight vectors. As the figure indicates, after only 200 iterations of the batch algorithm, the map is well distributed through the input space.

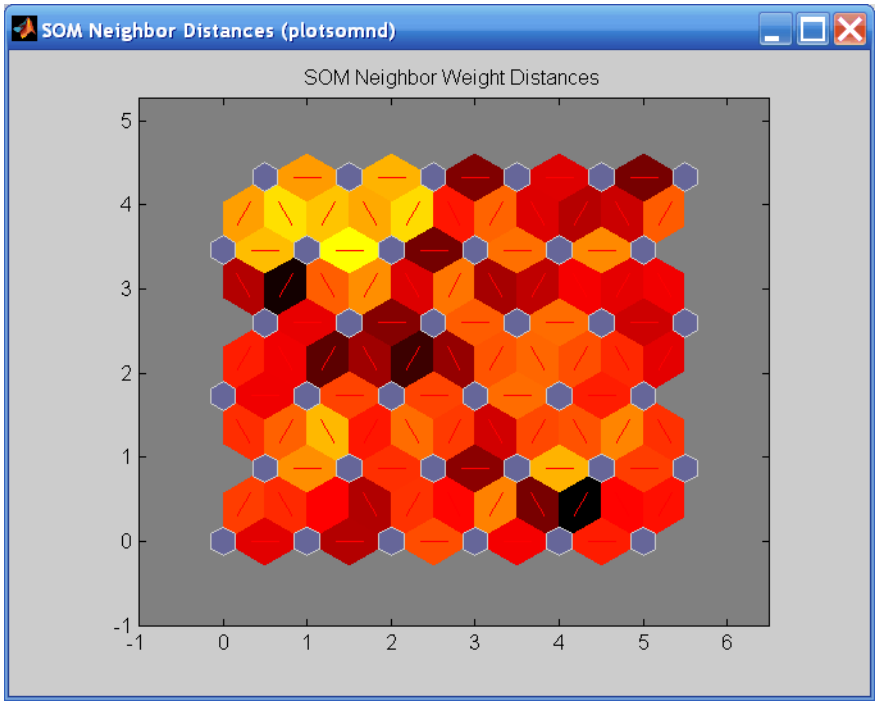


When the input space is high dimensional, you cannot visualize all the weights at the same time. In this case, click **SOM Neighbor Distances**. The following figure appears, which indicates the distances between neighboring neurons.

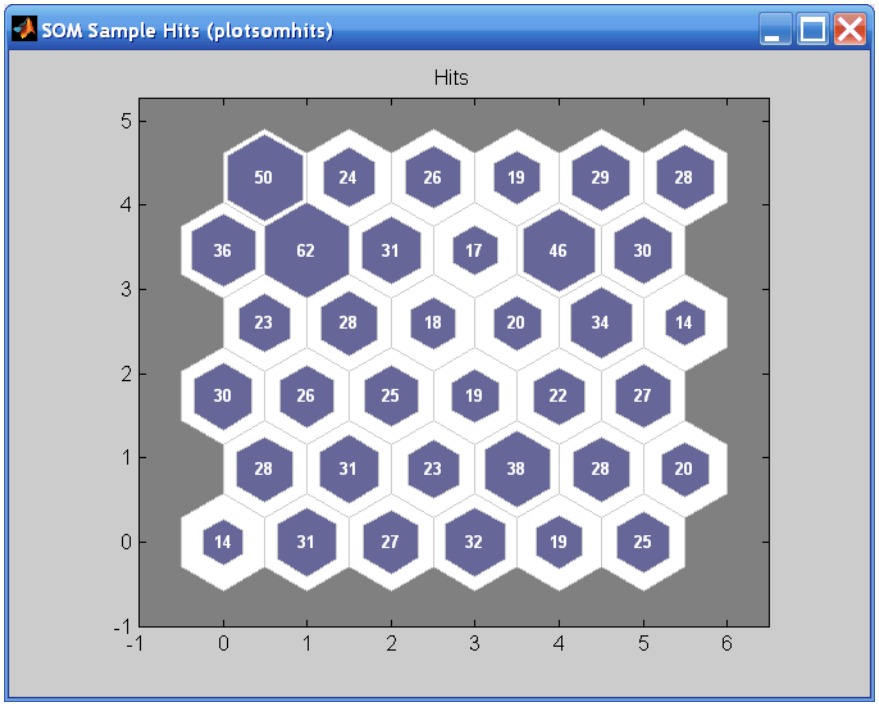
This figure uses the following color coding:

- The blue hexagons represent the neurons.
- The red lines connect neighboring neurons.
- The colors in the regions containing the red lines indicate the distances between neurons.
- The darker colors represent larger distances.
- The lighter colors represent smaller distances.

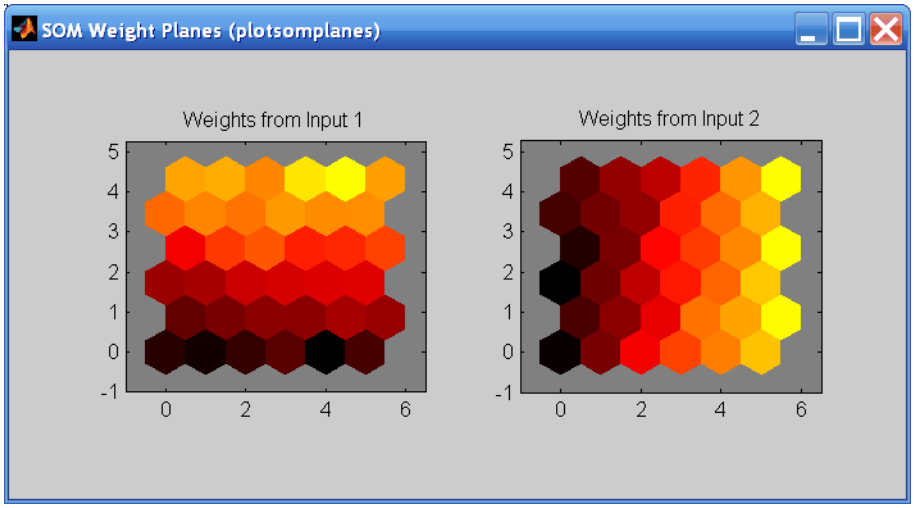
A group of light segments appear in the upper-left region, bounded by some darker segments. This grouping indicates that the network has clustered the data into two groups. These two groups can be seen in the previous weight position figure. The lower-right region of that figure contains a small group of tightly clustered data points. The corresponding weights are closer together in this region, which is indicated by the lighter colors in the neighbor distance figure. Where weights in this small region connect to the larger region, the distances are larger, as indicated by the darker band in the neighbor distance figure. The segments in the lower-right region of the neighbor distance figure are darker than those in the upper left. This color difference indicates that data points in this region are farther apart. This distance is confirmed in the weight positions figure.



Another useful figure can tell you how many data points are associated with each neuron. Click **SOM Sample Hits** to see the following figure. It is best if the data are fairly evenly distributed across the neurons. In this example, the data are concentrated a little more in the upper-left neurons, but overall the distribution is fairly even.



You can also visualize the weights themselves using the weight plane figure. Click **SOM Weight Planes** in the training window to obtain the next figure. There is a weight plane for each element of the input vector (two, in this case). They are visualizations of the weights that connect each input to each of the neurons. (Lighter and darker colors represent larger and smaller weights, respectively.) If the connection patterns of two inputs are very similar, you can assume that the inputs were highly correlated. In this case, input 1 has connections that are very different than those of input 2.



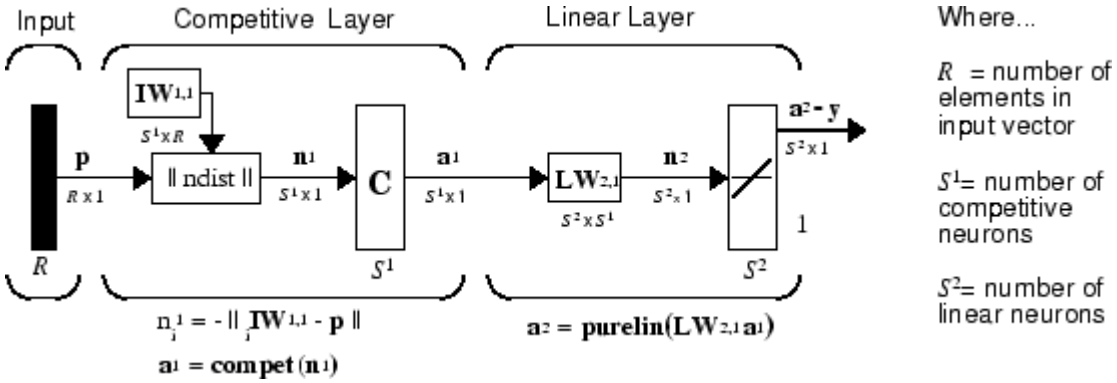
You can also produce all of the previous figures from the command line. Try these plotting commands: `plotsomhits`, `plotsomnc`, `plotsomnd`, `plotsomplanes`, `plotsompos`, and `plotsomtop`.

Learning Vector Quantization (LVQ) Neural Networks

In this section...

Architecture

The LVQ network architecture is shown below.



An LVQ network has a first competitive layer and a second linear layer. The competitive layer learns to classify input vectors in much the same way as the competitive layers of “Cluster with Self-Organizing Map Neural Network” on page 26-8 described in this topic. The linear layer transforms the competitive layer’s classes into target classifications defined by the user. The classes learned by the competitive layer are referred to as *subclasses* and the classes of the linear layer as *target classes*.

Both the competitive and linear layers have one neuron per (sub or target) class. Thus, the competitive layer can learn up to S^1 subclasses. These, in turn, are combined by the linear layer to form S^2 target classes. (S^1 is always larger than S^2.)

For example, suppose neurons 1, 2, and 3 in the competitive layer all learn subclasses of the input space that belongs to the linear layer target class 2. Then competitive neurons 1, 2, and 3 will have $\mathbf{LW}^{2,1}$ weights of 1.0 to neuron $\mathbf{n}^2$ in the linear layer, and weights of 0 to all other linear neurons. Thus, the linear neuron produces a 1 if any of the three competitive neurons (1, 2, or 3) wins the competition and outputs a 1. This is how the subclasses of the competitive layer are combined into target classes in the linear layer.

In short, a 1 in the ith row of $\mathbf{a}^1$ (the rest to the elements of $\mathbf{a}^1$ will be zero) effectively picks the ith column of $\mathbf{LW}^{2,1}$ as the network output. Each such column contains a single 1, corresponding to a specific class. Thus, subclass 1s from layer 1 are put into various classes by the $\mathbf{LW}^{2,1}\mathbf{a}^1$ multiplication in layer 2.

You know ahead of time what fraction of the layer 1 neurons should be classified into the various class outputs of layer 2, so you can specify the elements of $\mathbf{LW}^{2,1}$ at the start. However, you have to go

through a training procedure to get the first layer to produce the correct subclass output for each vector of the training set. This training is discussed in “Training” on page 26-5. First, consider how to create the original network.

Creating an LVQ Network

You can create an LVQ network with the function `lvqnet`,

```
net = lvqnet(S1,LR,LF)
```

where

- `S1` is the number of first-layer hidden neurons.
- `LR` is the learning rate (default 0.01).
- `LF` is the learning function (default is `learnlv1`).

Suppose you have 10 input vectors. Create a network that assigns each of these input vectors to one of four subclasses. Thus, there are four neurons in the first competitive layer. These subclasses are then assigned to one of two output classes by the two neurons in layer 2. The input vectors and targets are specified by

```
P = [-3 -2 -2 0 0 0 0 2 2 3; 0 1 -1 2 1 -1 -2 1 -1 0];
```

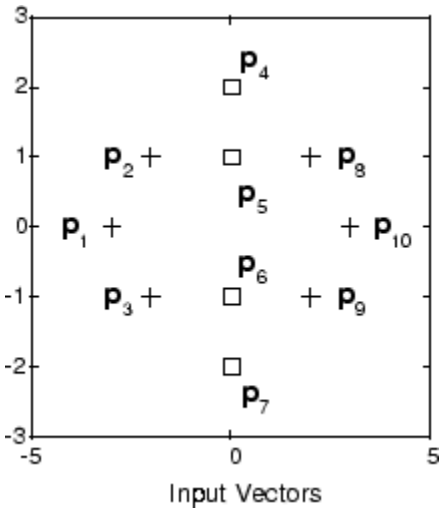
and

```
Tc = [1 1 1 2 2 2 2 1 1 1];
```

It might help to show the details of what you get from these two lines of code.

```
P,Tc
P =
    -3    -2    -2     0     0     0     0     2     2     3
     0     1    -1     2     1    -1    -2     1    -1     0
Tc =
     1     1     1     2     2     2     2     1     1     1
```

A plot of the input vectors follows.



As you can see, there are four subclasses of input vectors. You want a network that classifies $\mathbf{p}_1$, $\mathbf{p}_2$, $\mathbf{p}_3$, $\mathbf{p}_8$, $\mathbf{p}_9$, and $\mathbf{p}_{10}$ to produce an output of 1, and that classifies vectors $\mathbf{p}_4$, $\mathbf{p}_5$, $\mathbf{p}_6$, and $\mathbf{p}_7$ to produce an output of 2. Note that this problem is nonlinearly separable, and so cannot be solved by a perceptron, but an LVQ network has no difficulty.

Next convert the `Tc` matrix to target vectors.

```
T = ind2vec(Tc);
```

This gives a sparse matrix `T` that can be displayed in full with

```
targets = full(T)
```

which gives

```
targets =
     1     1     1     0     0     0     0     1     1     1
     0     0     0     1     1     1     1     0     0     0
```

This looks right. It says, for instance, that if you have the first column of `P` as input, you should get the first column of `targets` as an output; and that output says the input falls in class 1, which is correct. Now you are ready to call `lvqnet`.

Call `lvqnet` to create a network with four neurons.

```
net = lvqnet(4);
```

Configure and confirm the initial values of the first-layer weight matrix are initialized by the function midpoint to values in the center of the input data range.

```
net = configure(net,P,T);
net.IW{1}
ans =
     0     0
     0     0
     0     0
     0     0
```

Confirm that the second-layer weights have 60% (6 of the 10 in `Tc`) of its columns with a 1 in the first row, (corresponding to class 1), and 40% of its columns have a 1 in the second row (corresponding to class 2). With only four columns, the 60% and 40% actually round to 50% and there are two 1's in each row.

```
net.LW{2,1}
ans =
     1     1     0     0
     0     0     1     1
```

This makes sense too. It says that if the competitive layer produces a 1 as the first or second element, the input vector is classified as class 1; otherwise it is a class 2.

You might notice that the first two competitive neurons are connected to the first linear neuron (with weights of 1), while the second two competitive neurons are connected to the second linear neuron. All other weights between the competitive neurons and linear neurons have values of 0. Thus, each of the two target classes (the linear neurons) is, in fact, the union of two subclasses (the competitive neurons).

You can simulate the network with `sim`. Use the original `P` matrix as input just to see what you get.

```
Y = net(P);
Yc = vec2ind(Y)
Yc =
     1     1     1     1     1     1     1     1     1     1
```

The network classifies all inputs into class 1. Because this is not what you want, you have to train the network (adjusting the weights of layer 1 only), before you can expect a good result. The next two sections discuss two LVQ learning rules and the training process.

LVQ1 Learning Rule (learnlv1)

LVQ learning in the competitive layer is based on a set of input/target pairs.

$$\{\mathbf{p}_1, \mathbf{t}_1\}, \{\mathbf{p}_2, \mathbf{t}_2\}, \ldots \{\mathbf{p}_Q, \mathbf{t}_Q\}$$

Each target vector has a single 1. The rest of its elements are 0. The 1 tells the proper classification of the associated input. For instance, consider the following training pair.

$$\left\{\mathbf{p}_1 = \begin{bmatrix} 2 \\ -1 \\ 0 \end{bmatrix}, \mathbf{t}_1 = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \end{bmatrix}\right\}$$

Here there are input vectors of three elements, and each input vector is to be assigned to one of four classes. The network is to be trained so that it classifies the input vector shown above into the third of four classes.

To train the network, an input vector **p** is presented, and the distance from **p** to each row of the input weight matrix $\mathbf{IW}^{1,1}$ is computed with the function `negdist`. The hidden neurons of layer 1 compete. Suppose that the ith element of $\mathbf{n}^1$ is most positive, and neuron i^* wins the competition. Then the competitive transfer function produces a 1 as the i^*th element of $\mathbf{a}^1$. All other elements of $\mathbf{a}^1$ are 0.

When $\mathbf{a}^1$ is multiplied by the layer 2 weights $\mathbf{LW}^{2,1}$, the single 1 in $\mathbf{a}^1$ selects the class k^* associated with the input. Thus, the network has assigned the input vector **p** to class k^* and $\alpha^2_{k^*}$ will be 1. Of course, this assignment can be a good one or a bad one, for t_{k^*} can be 1 or 0, depending on whether the input belonged to class k^* or not.

Adjust the i^*th row of $\mathbf{IW}^{1,1}$ in such a way as to move this row closer to the input vector **p** if the assignment is correct, and to move the row away from **p** if the assignment is incorrect. If **p** is classified correctly,

$$\left(\alpha^2_{k^*} = t_{k^*} = 1\right)$$

compute the new value of the i^*th row of $\mathbf{IW}^{1,1}$ as

$${}_{i^*}\mathbf{IW}^{1,1}(q) = {}_{i^*}\mathbf{IW}^{1,1}(q-1) + \alpha(\mathbf{p}(q) - {}_{i^*}\mathbf{IW}^{1,1}(q-1))$$

On the other hand, if **p** is classified incorrectly,

$$\left(\alpha^2_{k^*} = 1 \neq t_{k^*} = 0\right)$$

compute the new value of the i^*th row of $\mathbf{IW}^{1,1}$ as

$$_{i*}\mathbf{IW}^{1,1}(q) = {}_{i*}\mathbf{IW}^{1,1}(q-1) - \alpha(\mathbf{p}(q) - {}_{i*}\mathbf{IW}^{1,1}(q-1))$$

You can make these corrections to the i*th row of $\mathbf{IW}^{1,1}$ automatically, without affecting other rows of $\mathbf{IW}^{1,1}$, by back-propagating the output errors to layer 1.

Such corrections move the hidden neuron toward vectors that fall into the class for which it forms a subclass, and away from vectors that fall into other classes.

The learning function that implements these changes in the layer 1 weights in LVQ networks is `learnlv1`. It can be applied during training.

Training

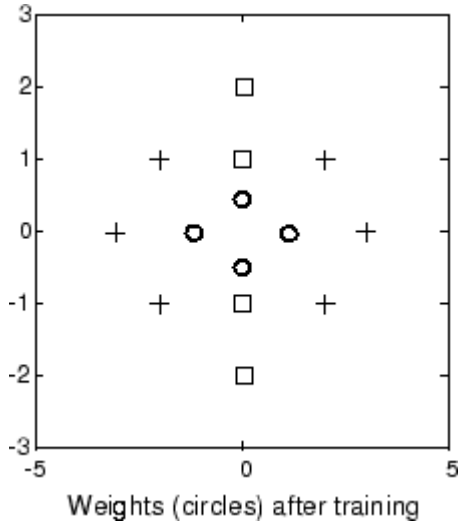
Next you need to train the network to obtain first-layer weights that lead to the correct classification of input vectors. You do this with `train` as with the following commands. First, set the training epochs to 150. Then, use `train`:

```
net.trainParam.epochs = 150;
net = train(net,P,T);
```

Now confirm the first-layer weights.

```
net.IW{1,1}
ans =
    0.3283    0.0051
   -0.1366    0.0001
   -0.0263    0.2234
         0   -0.0685
```

The following plot shows that these weights have moved toward their respective classification groups.



To confirm that these weights do indeed lead to the correct classification, take the matrix `P` as input and simulate the network. Then see what classifications are produced by the network.

```
Y = net(P);
Yc = vec2ind(Y)
```

This gives

```
Yc =
     1     1     1     2     2     2     2     1     1     1
```

which is expected. As a last check, try an input close to a vector that was used in training.

```
pchk1 = [0; 0.5];
Y = net(pchk1);
Yc1 = vec2ind(Y)
```

This gives

```
Yc1 =
     2
```

This looks right, because `pchk1` is close to other vectors classified as 2. Similarly,

```
pchk2 = [1; 0];
Y = net(pchk2);
Yc2 = vec2ind(Y)
```

gives

```
Yc2 =
     1
```

This looks right too, because `pchk2` is close to other vectors classified as 1.

You might want to try the example program “Learning Vector Quantization” on page 31-130. It follows the discussion of training given above.

Supplemental LVQ2.1 Learning Rule (learnlv2)

The following learning rule is one that might be applied *after* first applying LVQ1. It can improve the result of the first learning. This particular version of LVQ2 (referred to as LVQ2.1 in the literature [Koho97 on page 32-2]) is embodied in the function `learnlv2`. Note again that LVQ2.1 is to be used only after LVQ1 has been applied.

Learning here is similar to that in `learnlv2` except now two vectors of layer 1 that are closest to the input vector can be updated, provided that one belongs to the correct class and one belongs to a wrong class, and further provided that the input falls into a “window” near the midplane of the two vectors.

The window is defined by

$$\min\left(\frac{d_i}{d_j}, \frac{d_j}{d_i}\right) > s$$

where

$$s \equiv \frac{1-w}{1+w}$$

(where d_i and d_j are the Euclidean distances of $\mathbf{p}$ from ${}_{i*}\mathbf{IW}^{1,1}$ and ${}_{j*}\mathbf{IW}^{1,1}$, respectively). Take a value for w in the range 0.2 to 0.3. If you pick, for instance, 0.25, then $s = 0.6$. This means that if the

minimum of the two distance ratios is greater than 0.6, the two vectors are adjusted. That is, if the input is near the midplane, adjust the two vectors, provided also that the input vector $\mathbf{p}$ and ${}_{j*}\mathbf{IW}^{1,1}$ belong to the same class, and $\mathbf{p}$ and ${}_{i*}\mathbf{IW}^{1,1}$ do not belong in the same class.

The adjustments made are

$${}_{i*}\mathbf{IW}^{1,1}(q) = {}_{i*}\mathbf{IW}^{1,1}(q-1) - \alpha(\mathbf{p}(q) - {}_{i*}\mathbf{IW}^{1,1}(q-1))$$

and

$${}_{j*}\mathbf{IW}^{1,1}(q) = {}_{j*}\mathbf{IW}^{1,1}(q-1) + \alpha(\mathbf{p}(q) - {}_{j*}\mathbf{IW}^{1,1}(q-1))$$

Thus, given two vectors closest to the input, as long as one belongs to the wrong class and the other to the correct class, and as long as the input falls in a midplane window, the two vectors are adjusted. Such a procedure allows a vector that is just barely classified correctly with LVQ1 to be moved even closer to the input, so the results are more robust.

Function	Description
`competlayer`	Create a competitive layer.
`learnk`	Kohonen learning rule.
`selforgmap`	Create a self-organizing map.
`learncon`	Conscience bias learning function.
`boxdist`	Distance between two position vectors.
`dist`	Euclidean distance weight function.
`linkdist`	Link distance function.
`mandist`	Manhattan distance weight function.
`gridtop`	Gridtop layer topology function.
`hextop`	Hexagonal layer topology function.
`randtop`	Random layer topology function.
`lvqnet`	Create a learning vector quantization network.
`learnlv1`	LVQ1 weight learning function.
`learnlv2`	LVQ2 weight learning function.

Adaptive Filters and Adaptive Training

Adaptive Neural Network Filters

In this section...

The ADALINE (adaptive linear neuron) networks discussed in this topic are similar to the perceptron, but their transfer function is linear rather than hard-limiting. This allows their outputs to take on any value, whereas the perceptron output is limited to either 0 or 1. Both the ADALINE and the perceptron can solve only linearly separable problems. However, here the LMS (least mean squares) learning rule, which is much more powerful than the perceptron learning rule, is used. The LMS, or Widrow-Hoff, learning rule minimizes the mean square error and thus moves the decision boundaries as far as it can from the training patterns.

In this section, you design an adaptive linear system that responds to changes in its environment as it is operating. Linear networks that are adjusted at each time step based on new input and target vectors can find weights and biases that minimize the network's sum-squared error for recent input and target vectors. Networks of this sort are often used in error cancelation, signal processing, and control systems.

The pioneering work in this field was done by Widrow and Hoff, who gave the name ADALINE to adaptive linear elements. The basic reference on this subject is Widrow, B., and S.D. Sterns, *Adaptive Signal Processing*, New York, Prentice-Hall, 1985.

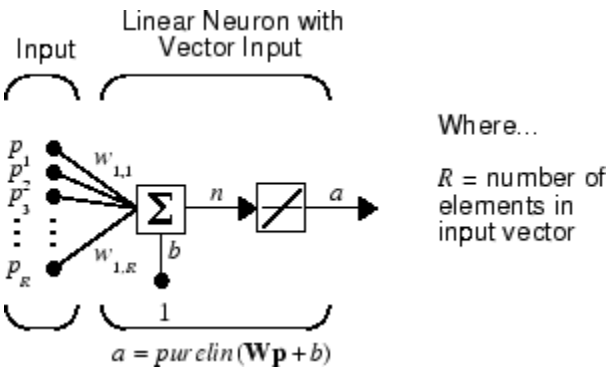
The adaptive training of self-organizing and competitive networks is also considered in this section.

Adaptive Functions

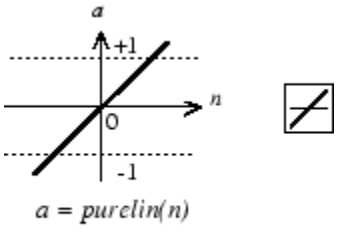
This section introduces the function `adapt`, which changes the weights and biases of a network incrementally during training.

Linear Neuron Model

A linear neuron with R inputs is shown below.



This network has the same basic structure as the perceptron. The only difference is that the linear neuron uses a linear transfer function, named `purelin`.



Linear Transfer Function

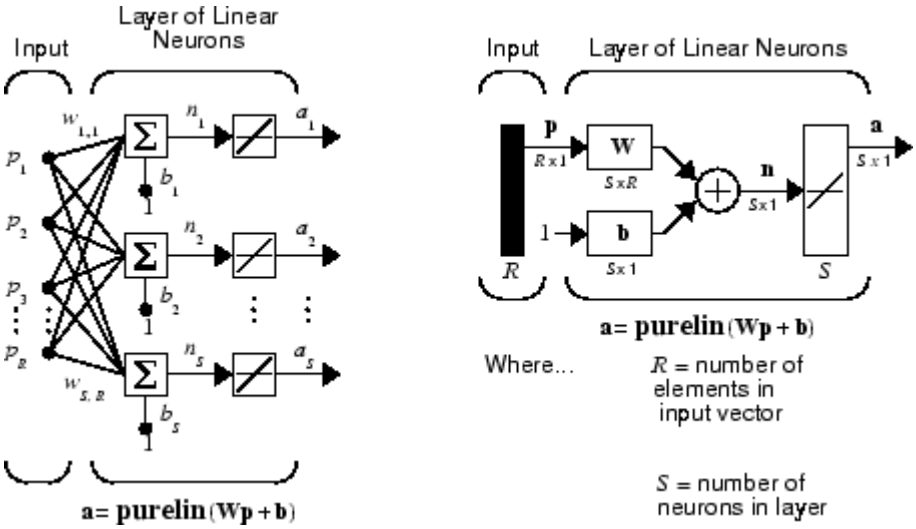
The linear transfer function calculates the neuron's output by simply returning the value passed to it.

$\alpha = purelin(n) = purelin(\mathbf{Wp} + b) = \mathbf{Wp} + b$

This neuron can be trained to learn an affine function of its inputs, or to find a linear approximation to a nonlinear function. A linear network cannot, of course, be made to perform a nonlinear computation.

Adaptive Linear Network Architecture

The ADALINE network shown below has one layer of S neurons connected to R inputs through a matrix of weights $\mathbf{W}$.

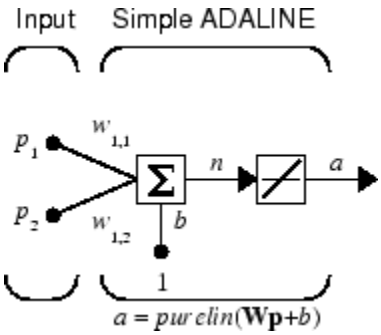


This network is sometimes called a MADALINE for Many ADALINEs. Note that the figure on the right defines an S-length output vector $\mathbf{a}$.

The Widrow-Hoff rule can only train single-layer linear networks. This is not much of a disadvantage, however, as single-layer linear networks are just as capable as multilayer linear networks. For every multilayer linear network, there is an equivalent single-layer linear network.

Single ADALINE (linearlayer)

Consider a single ADALINE with two inputs. The following figure shows the diagram for this network.



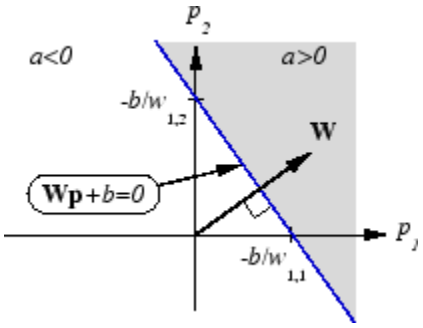
The weight matrix **W** in this case has only one row. The network output is

$$\alpha = purelin(n) = purelin(\mathbf{Wp} + b) = \mathbf{Wp} + b$$

or

$$\alpha = w_{1,1}p_1 + w_{1,2}p_2 + b$$

Like the perceptron, the ADALINE has a *decision boundary* that is determined by the input vectors for which the net input n is zero. For $n = 0$ the equation $\mathbf{Wp} + b = 0$ specifies such a decision boundary, as shown below (adapted with thanks from [HDB96 on page 32-2]).



Input vectors in the upper right gray area lead to an output greater than 0. Input vectors in the lower left white area lead to an output less than 0. Thus, the ADALINE can be used to classify objects into two categories.

However, ADALINE can classify objects in this way only when the objects are linearly separable. Thus, ADALINE has the same limitation as the perceptron.

You can create a network similar to the one shown using this command:

```
net = linearlayer;
net = configure(net,[0;0],[0]);
```

The sizes of the two arguments to configure indicate that the layer is to have two inputs and one output. Normally `train` does this configuration for you, but this allows us to inspect the weights before training.

The network weights and biases are set to zero, by default. You can see the current values using the commands:

```
W = net.IW{1,1}
W =
     0     0
```

and

```
b = net.b{1}
b =
     0
```

You can also assign arbitrary values to the weights and bias, such as 2 and 3 for the weights and −4 for the bias:

```
net.IW{1,1} = [2 3];
net.b{1} = -4;
```

You can simulate the ADALINE for a particular input vector.

```
p = [5; 6];
a = sim(net,p)
a =
    24
```

To summarize, you can create an ADALINE network with `linearlayer`, adjust its elements as you want, and simulate it with `sim`.

Least Mean Square Error

Like the perceptron learning rule, the least mean square error (LMS) algorithm is an example of supervised training, in which the learning rule is provided with a set of examples of desired network behavior.

$$\{\mathbf{p}_1, \mathbf{t}_1\}, \{\mathbf{p}_2, \mathbf{t}_2\}, \ldots \{\mathbf{p}_Q, \mathbf{t}_Q\}$$

Here $\mathbf{p}_q$ is an input to the network, and $\mathbf{t}_q$ is the corresponding target output. As each input is applied to the network, the network output is compared to the target. The error is calculated as the difference between the target output and the network output. The goal is to minimize the average of the sum of these errors.

$$mse = \frac{1}{Q}\sum_{k=1}^{Q} e(k)^2 = \frac{1}{Q}\sum_{k=1}^{Q} t(k) - \alpha(k))^2$$

The LMS algorithm adjusts the weights and biases of the ADALINE so as to minimize this mean square error.

Fortunately, the mean square error performance index for the ADALINE network is a quadratic function. Thus, the performance index will either have one global minimum, a weak minimum, or no minimum, depending on the characteristics of the input vectors. Specifically, the characteristics of the input vectors determine whether or not a unique solution exists.

You can learn more about this topic in Chapter 10 of [HDB96 on page 32-2].

LMS Algorithm (learnwh)

Adaptive networks will use the LMS algorithm or Widrow-Hoff learning algorithm based on an approximate steepest descent procedure. Here again, adaptive linear networks are trained on examples of correct behavior.

The LMS algorithm, shown here, is discussed in detail in “Linear Neural Networks” on page 29-14.

$$\mathbf{W}(k+1) = \mathbf{W}(k) + 2\alpha\mathbf{e}(k)\mathbf{p}^T(k)$$

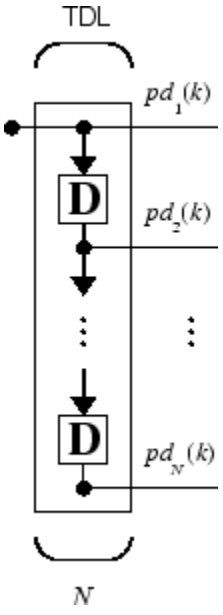
$$\mathbf{b}(k+1) = \mathbf{b}(k) + 2\alpha\mathbf{e}(k)$$

Adaptive Filtering (adapt)

The ADALINE network, much like the perceptron, can only solve linearly separable problems. It is, however, one of the most widely used neural networks found in practical applications. Adaptive filtering is one of its major application areas.

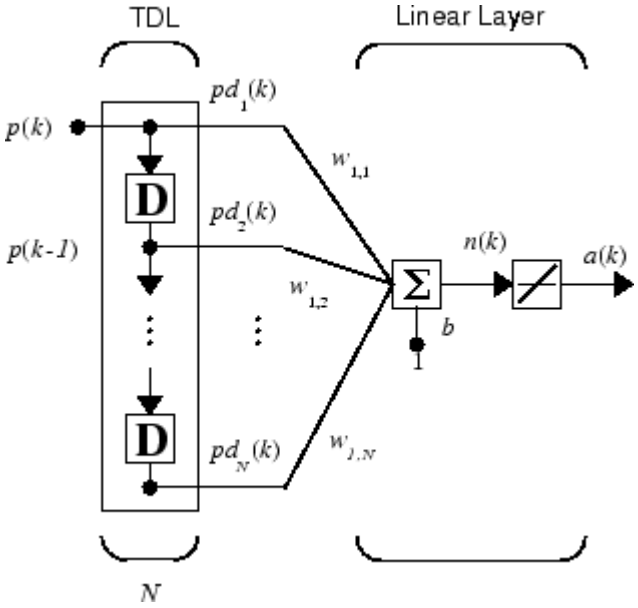
Tapped Delay Line

You need a new component, the tapped delay line, to make full use of the ADALINE network. Such a delay line is shown in the next figure. The input signal enters from the left and passes through N-1 delays. The output of the tapped delay line (TDL) is an N-dimensional vector, made up of the input signal at the current time, the previous input signal, etc.



Adaptive Filter

You can combine a tapped delay line with an ADALINE network to create the *adaptive filter* shown in the next figure.



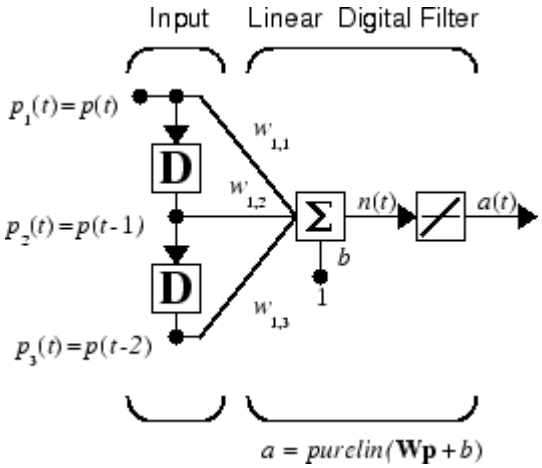
The output of the filter is given by

$$a(k) = purelin(\mathbf{Wp} + b) = \sum_{i=1}^{R} w_{1,i}\alpha(k - i + 1) + b$$

In digital signal processing, this network is referred to as a *finite impulse response (FIR)* filter [WiSt85 on page 32-2]. Take a look at the code used to generate and simulate such an adaptive network.

Adaptive Filter Example

First, define a new linear network using `linearlayer`.



Assume that the linear layer has a single neuron with a single input and a tap delay of 0, 1, and 2 delays.

```
net = linearlayer([0 1 2]);
net = configure(net,0,0);
```

You can specify as many delays as you want, and can omit some values if you like. They must be in ascending order.

You can give the various weights and the bias values with

```
net.IW{1,1} = [7 8 9];
net.b{1} = [0];
```

Finally, define the initial values of the outputs of the delays as

```
pi = {1 2};
```

These are ordered from left to right to correspond to the delays taken from top to bottom in the figure. This concludes the setup of the network.

To set up the input, assume that the input scalars arrive in a sequence: first the value 3, then the value 4, next the value 5, and finally the value 6. You can indicate this sequence by defining the values as elements of a cell array in curly braces.

```
p = {3 4 5 6};
```

Now, you have a network and a sequence of inputs. Simulate the network to see what its output is as a function of time.

```
[a,pf] = sim(net,p,pi)
```

This simulation yields an output sequence

```
a
    [46]    [70]    [94]    [118]
```

and final values for the delay outputs of

```
pf
    [5]    [6]
```

The example is sufficiently simple that you can check it without a calculator to make sure that you understand the inputs, initial values of the delays, etc.

The network just defined can be trained with the function `adapt` to produce a particular output sequence. Suppose, for instance, you want the network to produce the sequence of values 10, 20, 30, 40.

```
t = {10 20 30 40};
```

You can train the defined network to do this, starting from the initial delay conditions used above.

Let the network adapt for 10 passes over the data.

```
for i = 1:10
    [net,y,E,pf,af] = adapt(net,p,t,pi);
end
```

This code returns the final weights, bias, and output sequence shown here.

```
wts = net.IW{1,1}
wts =
    0.5059    3.1053    5.7046
```

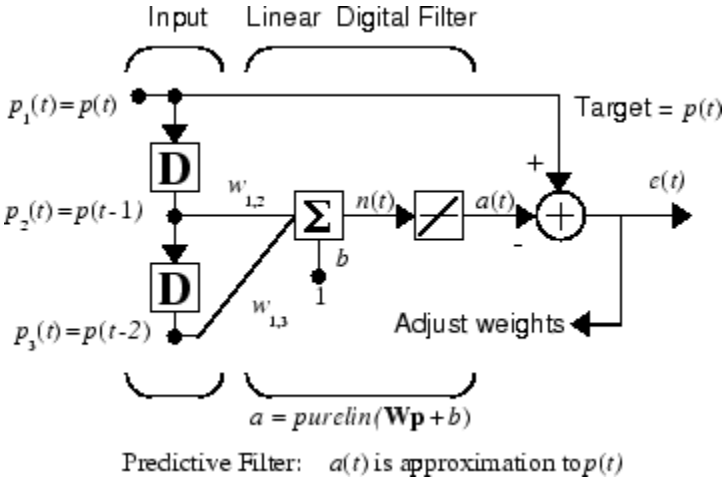
```
bias = net.b{1}
bias =
   -1.5993
y
y =
    [11.8558]    [20.7735]    [29.6679]    [39.0036]
```

Presumably, if you ran additional passes the output sequence would have been even closer to the desired values of 10, 20, 30, and 40.

Thus, adaptive networks can be specified, simulated, and finally trained with `adapt`. However, the outstanding value of adaptive networks lies in their use to perform a particular function, such as prediction or noise cancelation.

Prediction Example

Suppose that you want to use an adaptive filter to predict the next value of a stationary random process, $p(t)$. You can use the network shown in the following figure to do this prediction.



Predictive Filter: $a(t)$ is approximation to $p(t)$

The signal to be predicted, $p(t)$, enters from the left into a tapped delay line. The previous two values of $p(t)$ are available as outputs from the tapped delay line. The network uses `adapt` to change the weights on each time step so as to minimize the error $e(t)$ on the far right. If this error is 0, the network output $a(t)$ is exactly equal to $p(t)$, and the network has done its prediction properly.

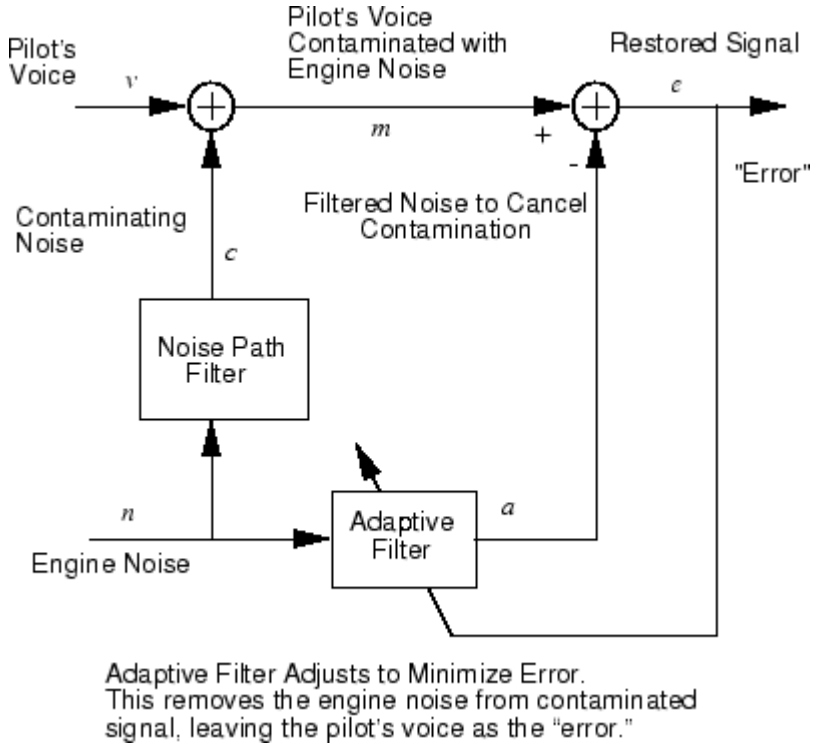
Given the autocorrelation function of the stationary random process $p(t)$, you can calculate the error surface, the maximum learning rate, and the optimum values of the weights. Commonly, of course, you do not have detailed information about the random process, so these calculations cannot be performed. This lack does not matter to the network. After it is initialized and operating, the network adapts at each time step to minimize the error and in a relatively short time is able to predict the input $p(t)$.

Chapter 10 of [HDB96 on page 32-2] presents this problem, goes through the analysis, and shows the weight trajectory during training. The network finds the optimum weights on its own without any difficulty whatsoever.

You also can try the example `nnd10nc` to see an adaptive noise cancelation program example in action. This example allows you to pick a learning rate and *momentum* (see “Multilayer Shallow Neural Networks and Backpropagation Training” on page 22-2), and shows the learning trajectory, and the original and cancelation signals versus time.

Noise Cancelation Example

Consider a pilot in an airplane. When the pilot speaks into a microphone, the engine noise in the cockpit combines with the voice signal. This additional noise makes the resultant signal heard by passengers of low quality. The goal is to obtain a signal that contains the pilot's voice, but not the engine noise. You can cancel the noise with an adaptive filter if you obtain a sample of the engine noise and apply it as the input to the adaptive filter.



As the preceding figure shows, you adaptively train the neural linear network to predict the combined pilot/engine signal *m* from an engine signal *n*. The engine signal *n* does not tell the adaptive network anything about the pilot's voice signal contained in *m*. However, the engine signal *n* does give the network information it can use to predict the engine's contribution to the pilot/engine signal *m*.

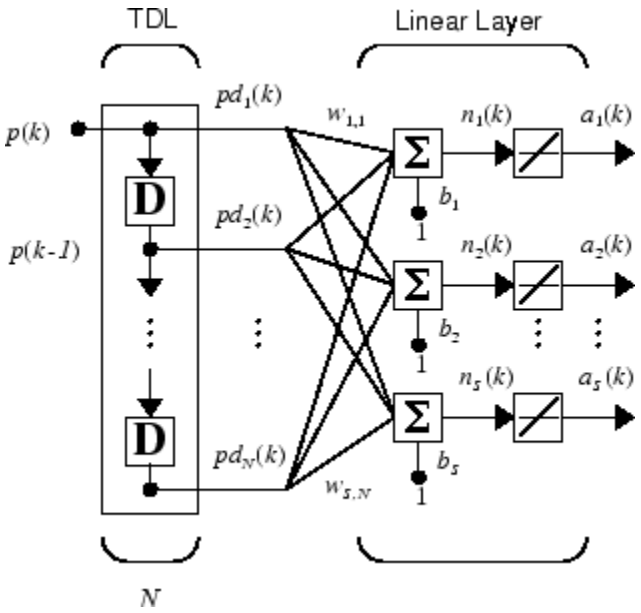
The network does its best to output *m* adaptively. In this case, the network can only predict the engine interference noise in the pilot/engine signal *m*. The network error *e* is equal to *m*, the pilot/engine signal, minus the predicted contaminating engine noise signal. Thus, *e* contains only the pilot's voice. The linear adaptive network adaptively learns to cancel the engine noise.

Such adaptive noise canceling generally does a better job than a classical filter, because it subtracts from the signal rather than filtering it out the noise of the signal *m*.

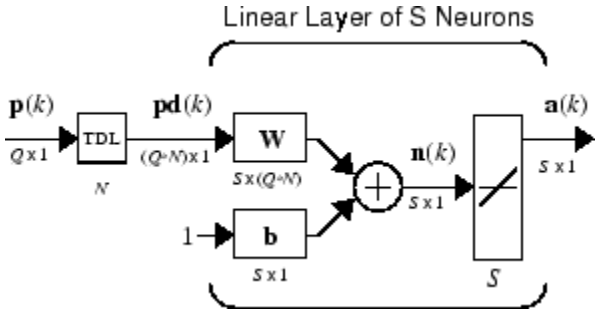
Try “Adaptive Noise Cancellation” on page 31-180 for an example of adaptive noise cancellation.

Multiple Neuron Adaptive Filters

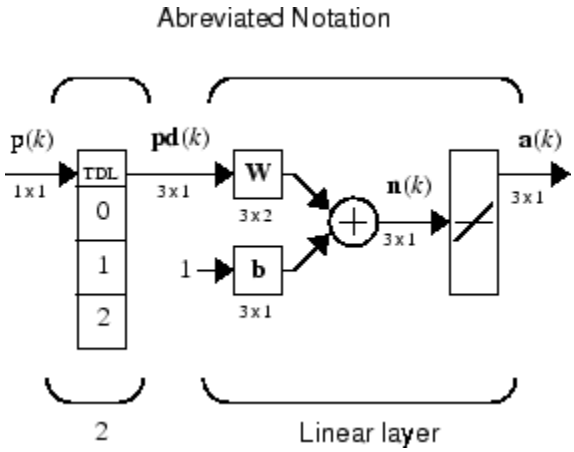
You might want to use more than one neuron in an adaptive system, so you need some additional notation. You can use a tapped delay line with *S* linear neurons, as shown in the next figure.



Alternatively, you can represent this same network in abbreviated form.



If you want to show more of the detail of the tapped delay line—and there are not too many delays—you can use the following notation:



Here, a tapped delay line sends to the weight matrix:

- The current signal
- The previous signal
- The signal delayed before that

You could have a longer list, and some delay values could be omitted if desired. The only requirement is that the delays must appears in increasing order as they go from top to bottom.

Advanced Topics

Shallow Neural Networks with Parallel and GPU Computing

In this section...

Note For deep learning, parallel and GPU support is automatic. You can train a convolutional neural network (CNN, ConvNet) or long short-term memory networks (LSTM or BiLSTM networks) using the `trainNetwork` function and choose the execution environment (CPU, GPU, multi-GPU, and parallel) using `trainingOptions`.

Training in parallel, or on a GPU, requires Parallel Computing Toolbox. For more information on deep learning with GPUs and in parallel, see “Deep Learning with Big Data on CPUs, GPUs, in Parallel, and on the Cloud” on page 1-6.

Modes of Parallelism

Neural networks are inherently parallel algorithms. Multicore CPUs, graphical processing units (GPUs), and clusters of computers with multiple CPUs and GPUs can take advantage of this parallelism.

Parallel Computing Toolbox, when used in conjunction with Deep Learning Toolbox, enables neural network training and simulation to take advantage of each mode of parallelism.

For example, the following shows a standard single-threaded training and simulation session:

```
[x, t] = bodyfat_dataset;
net1 = feedforwardnet(10);
net2 = train(net1, x, t);
y = net2(x);
```

The two steps you can parallelize in this session are the call to `train` and the implicit call to `sim` (where the network `net2` is called as a function).

In Deep Learning Toolbox you can divide any data, such as `x` and `t` in the previous example code, across samples. If `x` and `t` contain only one sample each, there is no parallelism. But if `x` and `t` contain hundreds or thousands of samples, parallelism can provide both speed and problem size benefits.

Distributed Computing

Parallel Computing Toolbox allows neural network training and simulation to run across multiple CPU cores on a single PC, or across multiple CPUs on multiple computers on a network using MATLAB Parallel Server.

Using multiple cores can speed calculations. Using multiple computers can allow you to solve problems using data sets too big to fit in the RAM of a single computer. The only limit to problem size is the total quantity of RAM available across all computers.

To manage cluster configurations, use the Cluster Profile Manager from the MATLAB **Home** tab **Environment** menu **Parallel > Manage Cluster Profiles**.

To open a pool of MATLAB workers using the default cluster profile, which is usually the local CPU cores, use this command:

```
pool = parpool
```

```
Starting parallel pool (parpool) using the 'local' profile ... connected to 4 workers.
```

When `parpool` runs, it displays the number of workers available in the pool. Another way to determine the number of workers is to query the pool:

```
pool.NumWorkers
```

```
   4
```

Now you can train and simulate the neural network with data split by sample across all the workers. To do this, set the `train` and `sim` parameter `'useParallel'` to `'yes'`.

```
net2 = train(net1,x,t,'useParallel','yes')
y = net2(x,'useParallel','yes')
```

Use the `'showResources'` argument to verify that the calculations ran across multiple workers.

```
net2 = train(net1,x,t,'useParallel','yes','showResources','yes');
y = net2(x,'useParallel','yes','showResources','yes');
```

MATLAB indicates which resources were used. For example:

```
Computing Resources:
Parallel Workers
  Worker 1 on MyComputer, MEX on PCWIN64
  Worker 2 on MyComputer, MEX on PCWIN64
  Worker 3 on MyComputer, MEX on PCWIN64
  Worker 4 on MyComputer, MEX on PCWIN64
```

When `train` and `sim` are called, they divide the input matrix or cell array data into distributed Composite values before training and simulation. When `sim` has calculated a Composite, this output is converted back to the same matrix or cell array form before it is returned.

However, you might want to perform this data division manually if:

- The problem size is too large for the host computer. Manually defining the elements of Composite values sequentially allows much bigger problems to be defined.
- It is known that some workers are on computers that are faster or have more memory than others. You can distribute the data with differing numbers of samples per worker. This is called load balancing.

The following code sequentially creates a series of random datasets and saves them to separate files:

```
pool = gcp;
for i=1:pool.NumWorkers
```

```
  x = rand(2,1000);
  save(['inputs' num2str(i)],'x');
  t = x(1,:) .* x(2,:) + 2 * (x(1,:) + x(2,:));
  save(['targets' num2str(i)],'t');
  clear x t
end
```

Because the data was defined sequentially, you can define a total dataset larger than can fit in the host PC memory. PC memory must accommodate only a sub-dataset at a time.

Now you can load the datasets sequentially across parallel workers, and train and simulate a network on the Composite data. When `train` or `sim` is called with Composite data, the `'useParallel'` argument is automatically set to `'yes'`. When using Composite data, configure the network's input and outputs to match one of the datasets manually using the `configure` function before training.

```
xc = Composite;
tc = Composite;
for i=1:pool.NumWorkers
  data = load(['inputs' num2str(i)],'x');
  xc{i} = data.x;
  data = load(['targets' num2str(i)],'t');
  tc{i} = data.t;
  clear data
end
net2 = configure(net1,xc{1},tc{1});
net2 = train(net2,xc,tc);
yc = net2(xc);
```

To convert the Composite output returned by `sim`, you can access each of its elements, separately if concerned about memory limitations.

```
for i=1:pool.NumWorkers
  yi = yc{i}
end
```

Combined the Composite value into one local value if you are not concerned about memory limitations.

```
y = {yc{:}};
```

When load balancing, the same process happens, but, instead of each dataset having the same number of samples (1000 in the previous example), the numbers of samples can be adjusted to best take advantage of the memory and speed differences of the worker host computers.

It is not required that each worker have data. If element `i` of a Composite value is undefined, worker `i` will not be used in the computation.

Single GPU Computing

The number of cores, size of memory, and speed efficiencies of GPU cards are growing rapidly with each new generation. Where video games have long benefited from improved GPU performance, these cards are now flexible enough to perform general numerical computing tasks like training neural networks.

For the latest GPU requirements, see the web page for Parallel Computing Toolbox; or query MATLAB to determine whether your PC has a supported GPU. This function returns the number of GPUs in your system:

```
count = gpuDeviceCount
```

```
count =

    1
```

If the result is one or more, you can query each GPU by index for its characteristics. This includes its name, number of multiprocessors, `SIMDWidth` of each multiprocessor, and total memory.

```
gpu1 = gpuDevice(1)
```

```
gpu1 =

  CUDADevice with properties:

                      Name: 'GeForce GTX 470'
                     Index: 1
         ComputeCapability: '2.0'
            SupportsDouble: 1
             DriverVersion: 4.1000
        MaxThreadsPerBlock: 1024
          MaxShmemPerBlock: 49152
        MaxThreadBlockSize: [1024 1024 64]
               MaxGridSize: [65535 65535 1]
                 SIMDWidth: 32
               TotalMemory: 1.3422e+09
           AvailableMemory: 1.1056e+09
       MultiprocessorCount: 14
              ClockRateKHz: 1215000
               ComputeMode: 'Default'
      GPUOverlapsTransfers: 1
    KernelExecutionTimeout: 1
          CanMapHostMemory: 1
           DeviceSupported: 1
            DeviceSelected: 1
```

The simplest way to take advantage of the GPU is to specify call `train` and `sim` with the parameter argument `'useGPU'` set to `'yes'` (`'no'` is the default).

```
net2 = train(net1,x,t,'useGPU','yes')
y = net2(x,'useGPU','yes')
```

If `net1` has the default training function `trainlm`, you see a warning that GPU calculations do not support Jacobian training, only gradient training. So the training function is automatically changed to the gradient training function `trainscg`. To avoid the notice, you can specify the function before training:

```
net1.trainFcn = 'trainscg';
```

To verify that the training and simulation occur on the GPU device, request that the computer resources be shown:

```
net2 = train(net1,x,t,'useGPU','yes','showResources','yes')
y = net2(x,'useGPU','yes','showResources','yes')
```

Each of the above lines of code outputs the following resources summary:

```
Computing Resources:
GPU device #1, GeForce GTX 470
```

Many MATLAB functions automatically execute on a GPU when any of the input arguments is a gpuArray. Normally you move arrays to and from the GPU with the functions `gpuArray` and `gather`. However, for neural network calculations on a GPU to be efficient, matrices need to be transposed and the columns padded so that the first element in each column aligns properly in the GPU memory. Deep Learning Toolbox provides a special function called `nndata2gpu` to move an array to a GPU and properly organize it:

```
xg = nndata2gpu(x);
tg = nndata2gpu(t);
```

Now you can train and simulate the network using the converted data already on the GPU, without having to specify the `'useGPU'` argument. Then convert and return the resulting GPU array back to MATLAB with the complementary function `gpu2nndata`.

Before training with gpuArray data, the network's input and outputs must be manually configured with regular MATLAB matrices using the `configure` function:

```
net2 = configure(net1,x,t);  % Configure with MATLAB arrays
net2 = train(net2,xg,tg);    % Execute on GPU with NNET formatted gpuArrays
yg = net2(xg);               % Execute on GPU
y = gpu2nndata(yg);          % Transfer array to local workspace
```

On GPUs and other hardware where you might want to deploy your neural networks, it is often the case that the exponential function `exp` is not implemented with hardware, but with a software library. This can slow down neural networks that use the `tansig` sigmoid transfer function. An alternative function is the Elliot sigmoid function whose expression does not include a call to any higher order functions:

```
(equation)    a = n / (1 + abs(n))
```

Before training, the network's `tansig` layers can be converted to `elliotsig` layers as follows:

```
for i=1:net.numLayers
  if strcmp(net.layers{i}.transferFcn,'tansig')
    net.layers{i}.transferFcn = 'elliotsig';
  end
end
```

Now training and simulation might be faster on the GPU and simpler deployment hardware.

Distributed GPU Computing

Distributed and GPU computing can be combined to run calculations across multiple CPUs and/or GPUs on a single computer, or on a cluster with MATLAB Parallel Server.

The simplest way to do this is to specify `train` and `sim` to do so, using the parallel pool determined by the cluster profile you use. The `'showResources'` option is especially recommended in this case, to verify that the expected hardware is being employed:

```
net2 = train(net1,x,t,'useParallel','yes','useGPU','yes','showResources','yes')
y = net2(x,'useParallel','yes','useGPU','yes','showResources','yes')
```

These lines of code use all available workers in the parallel pool. One worker for each unique GPU employs that GPU, while other workers operate as CPUs. In some cases, it might be faster to use only

GPUs. For instance, if a single computer has three GPUs and four workers each, the three workers that are accelerated by the three GPUs might be speed limited by the fourth CPU worker. In these cases, you can specify that `train` and `sim` use only workers with unique GPUs.

```
net2 = train(net1,x,t,'useParallel','yes','useGPU','only','showResources','yes')
y = net2(x,'useParallel','yes','useGPU','only','showResources','yes')
```

As with simple distributed computing, distributed GPU computing can benefit from manually created Composite values. Defining the Composite values yourself lets you indicate which workers to use, how many samples to assign to each worker, and which workers use GPUs.

For instance, if you have four workers and only three GPUs, you can define larger datasets for the GPU workers. Here, a random dataset is created with different sample loads per Composite element:

```
numSamples = [1000 1000 1000 300];
xc = Composite;
tc = Composite;
for i=1:4
  xi = rand(2,numSamples(i));
  ti = xi(1,:).^2 + 3*xi(2,:);
  xc{i} = xi;
  tc{i} = ti;
end
```

You can now specify that `train` and `sim` use the three GPUs available:

```
net2 = configure(net1,xc{1},tc{1});
net2 = train(net2,xc,tc,'useGPU','yes','showResources','yes');
yc = net2(xc,'showResources','yes');
```

To ensure that the GPUs get used by the first three workers, manually converting each worker's Composite elements to gpuArrays. Each worker performs this transformation within a parallel executing `spmd` block.

```
spmd
  if labindex <= 3
    xc = nndata2gpu(xc);
    tc = nndata2gpu(tc);
  end
end
```

Now the data specifies when to use GPUs, so you do not need to tell `train` and `sim` to do so.

```
net2 = configure(net1,xc{1},tc{1});
net2 = train(net2,xc,tc,'showResources','yes');
yc = net2(xc,'showResources','yes');
```

Ensure that each GPU is used by only one worker, so that the computations are most efficient. If multiple workers assign gpuArray data on the same GPU, the computation will still work but will be slower, because the GPU will operate on the multiple workers' data sequentially.

Parallel Time Series

For time series networks, simply use cell array values for `x` and `t`, and optionally include initial input delay states `xi` and initial layer delay states `ai`, as required.

```
net2 = train(net1,x,t,xi,ai,'useGPU','yes')
y = net2(x,xi,ai,'useParallel','yes','useGPU','yes')
```

```
net2 = train(net1,x,t,xi,ai,'useParallel','yes')
y = net2(x,xi,ai,'useParallel','yes','useGPU','only')

net2 = train(net1,x,t,xi,ai,'useParallel','yes','useGPU','only')
y = net2(x,xi,ai,'useParallel','yes','useGPU','only')
```

Note that parallelism happens across samples, or in the case of time series across different series. However, if the network has only input delays, with no layer delays, the delayed inputs can be precalculated so that for the purposes of computation, the time steps become different samples and can be parallelized. This is the case for networks such as `timedelaynet` and open-loop versions of `narxnet` and `narnet`. If a network has layer delays, then time cannot be “flattened” for purposes of computation, and so single series data cannot be parallelized. This is the case for networks such as `layrecnet` and closed-loop versions of `narxnet` and `narnet`. However, if the data consists of multiple sequences, it can be parallelized across the separate sequences.

Parallel Availability, Fallbacks, and Feedback

As mentioned previously, you can query MATLAB to discover the current parallel resources that are available.

To see what GPUs are available on the host computer:

```
gpuCount = gpuDeviceCount
for i=1:gpuCount
  gpuDevice(i)
end
```

To see how many workers are running in the current parallel pool:

```
poolSize = pool.NumWorkers
```

To see the GPUs available across a parallel pool running on a PC cluster using MATLAB Parallel Server:

```
spmd
  worker.index = labindex;
  worker.name = system('hostname');
  worker.gpuCount = gpuDeviceCount;
  try
    worker.gpuInfo = gpuDevice;
  catch
    worker.gpuInfo = [];
  end
  worker
end
```

When `'useParallel'` or `'useGPU'` are set to `'yes'`, but parallel or GPU workers are unavailable, the convention is that when resources are requested, they are used if available. The computation is performed without error even if they are not. This process of falling back from requested resources to actual resources happens as follows:

- If `'useParallel'` is `'yes'` but Parallel Computing Toolbox is unavailable, or a parallel pool is not open, then computation reverts to single-threaded MATLAB.
- If `'useGPU'` is `'yes'` but the gpuDevice for the current MATLAB session is unassigned or not supported, then computation reverts to the CPU.

- If `'useParallel'` and `'useGPU'` are `'yes'`, then each worker with a unique GPU uses that GPU, and other workers revert to CPU.
- If `'useParallel'` is `'yes'` and `'useGPU'` is `'only'`, then workers with unique GPUs are used. Other workers are not used, unless no workers have GPUs. In the case with no GPUs, all workers use CPUs.

When unsure about what hardware is actually being employed, check `gpuDeviceCount`, `gpuDevice`, and `pool.NumWorkers` to ensure the desired hardware is available, and call `train` and `sim` with `'showResources'` set to `'yes'` to verify what resources were actually used.

Optimize Neural Network Training Speed and Memory

In this section...

Memory Reduction

Depending on the particular neural network, simulation and gradient calculations can occur in MATLAB or MEX. MEX is more memory efficient, but MATLAB can be made more memory efficient in exchange for time.

To determine whether MATLAB or MEX is being used, use the `'showResources'` option, as shown in this general form of the syntax:

```
net2 = train(net1,x,t,'showResources','yes')
```

If MATLAB is being used and memory limitations are a problem, the amount of temporary storage needed can be reduced by a factor of `N`, in exchange for performing the computations `N` times sequentially on each of `N` subsets of the data.

```
net2 = train(net1,x,t,'reduction',N);
```

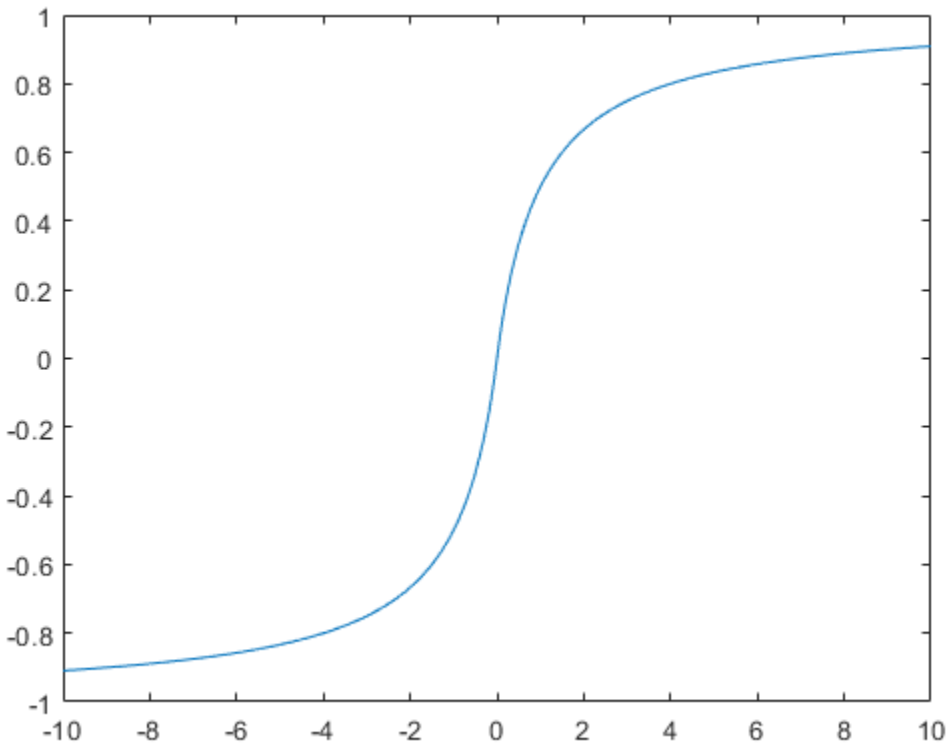
This is called memory reduction.

Fast Elliot Sigmoid

Some simple computing hardware might not support the exponential function directly, and software implementations can be slow. The Elliot sigmoid `elliotsig` function performs the same role as the symmetric sigmoid `tansig` function, but avoids the exponential function.

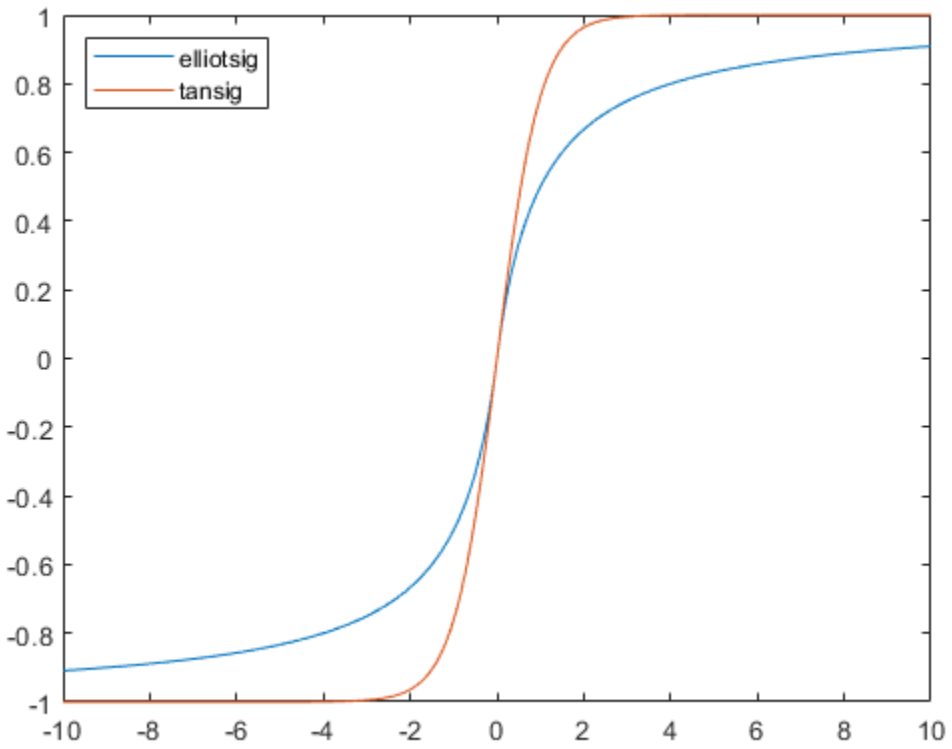
Here is a plot of the Elliot sigmoid:

```
n = -10:0.01:10;
a = elliotsig(n);
plot(n,a)
```



Next, `elliotsig` is compared with `tansig`.

```
a2 = tansig(n);
h = plot(n,a,n,a2);
legend(h,'elliotsig','tansig','Location','NorthWest')
```



To train a neural network using `elliotsig` instead of `tansig`, transform the network's transfer functions:

```
[x,t] = bodyfat_dataset;
net = feedforwardnet;
view(net)
net.layers{1}.transferFcn = 'elliotsig';
view(net)
net = train(net,x,t);
y = net(x)
```

Here, the times to execute `elliotsig` and `tansig` are compared. `elliotsig` is approximately four times faster on the test system.

```
n = rand(5000,5000);
tic,for i=1:100,a=tansig(n); end, tansigTime = toc;
tic,for i=1:100,a=elliotsig(n); end, elliotTime = toc;
speedup = tansigTime / elliotTime

speedup =

    4.1406
```

However, while simulation is faster with `elliotsig`, training is not guaranteed to be faster, due to the different shapes of the two transfer functions. Here, 10 networks are each trained for `tansig` and `elliotsig`, but training times vary significantly even on the same problem with the same network.

```
[x,t] = bodyfat_dataset;
tansigNet = feedforwardnet;
tansigNet.trainParam.showWindow = false;
elliotNet = tansigNet;
elliotNet.layers{1}.transferFcn = 'elliotsig';
for i=1:10, tic, net = train(tansigNet,x,t); tansigTime = toc, end
for i=1:10, tic, net = train(elliotNet,x,t), elliotTime = toc, end
```

Choose a Multilayer Neural Network Training Function

In this section...

It is very difficult to know which training algorithm will be the fastest for a given problem. It depends on many factors, including the complexity of the problem, the number of data points in the training set, the number of weights and biases in the network, the error goal, and whether the network is being used for pattern recognition (discriminant analysis) or function approximation (regression). This section compares the various training algorithms. Feedforward networks are trained on six different problems. Three of the problems fall in the pattern recognition category and the three others fall in the function approximation category. Two of the problems are simple “toy” problems, while the other four are “real world” problems. Networks with a variety of different architectures and complexities are used, and the networks are trained to a variety of different accuracy levels.

The following table lists the algorithms that are tested and the acronyms used to identify them.

Acronym	Algorithm	Description
LM	`trainlm`	Levenberg-Marquardt
BFG	`trainbfg`	BFGS Quasi-Newton
RP	`trainrp`	Resilient Backpropagation
SCG	`trainscg`	Scaled Conjugate Gradient
CGB	`traincgb`	Conjugate Gradient with Powell/Beale Restarts
CGF	`traincgf`	Fletcher-Powell Conjugate Gradient
CGP	`traincgp`	Polak-Ribiére Conjugate Gradient
OSS	`trainoss`	One Step Secant
GDX	`traingdx`	Variable Learning Rate Backpropagation

The following table lists the six benchmark problems and some characteristics of the networks, training processes, and computers used.

Problem Title	Problem Type	Network Structure	Error Goal	Computer
SIN	Function approximation	1-5-1	0.002	Sun Sparc 2
PARITY	Pattern recognition	3-10-10-1	0.001	Sun Sparc 2
ENGINE	Function approximation	2-30-2	0.005	Sun Enterprise 4000

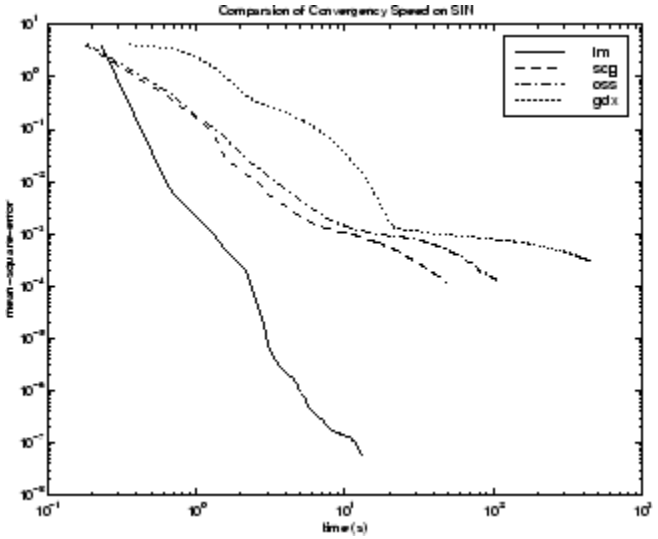
Problem Title	Problem Type	Network Structure	Error Goal	Computer
CANCER	Pattern recognition	9-5-5-2	0.012	Sun Sparc 2
CHOLESTEROL	Function approximation	21-15-3	0.027	Sun Sparc 20
DIABETES	Pattern recognition	8-15-15-2	0.05	Sun Sparc 20

SIN Data Set

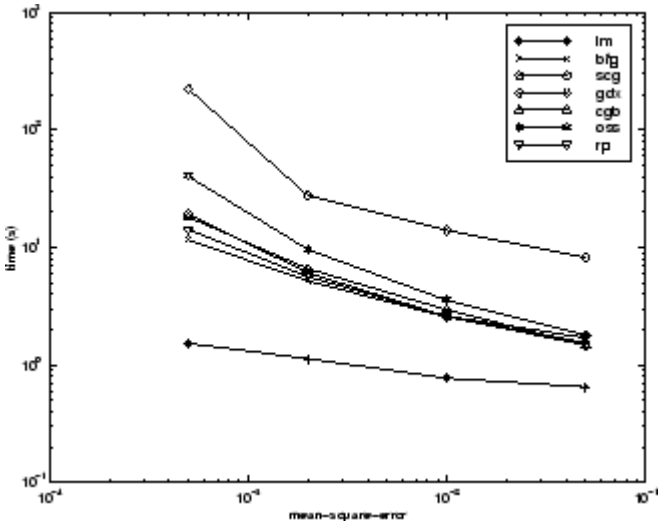
The first benchmark data set is a simple function approximation problem. A 1-5-1 network, with `tansig` transfer functions in the hidden layer and a linear transfer function in the output layer, is used to approximate a single period of a sine wave. The following table summarizes the results of training the network using nine different training algorithms. Each entry in the table represents 30 different trials, where different random initial weights are used in each trial. In each case, the network is trained until the squared error is less than 0.002. The fastest algorithm for this problem is the Levenberg-Marquardt algorithm. On the average, it is over four times faster than the next fastest algorithm. This is the type of problem for which the LM algorithm is best suited—a function approximation problem where the network has fewer than one hundred weights and the approximation must be very accurate.

Algorithm	Mean Time (s)	Ratio	Min. Time (s)	Max. Time (s)	Std. (s)
LM	1.14	1.00	0.65	1.83	0.38
BFG	5.22	4.58	3.17	14.38	2.08
RP	5.67	4.97	2.66	17.24	3.72
SCG	6.09	5.34	3.18	23.64	3.81
CGB	6.61	5.80	2.99	23.65	3.67
CGF	7.86	6.89	3.57	31.23	4.76
CGP	8.24	7.23	4.07	32.32	5.03
OSS	9.64	8.46	3.97	59.63	9.79
GDX	27.69	24.29	17.21	258.15	43.65

The performance of the various algorithms can be affected by the accuracy required of the approximation. This is shown in the following figure, which plots the mean square error versus execution time (averaged over the 30 trials) for several representative algorithms. Here you can see that the error in the LM algorithm decreases much more rapidly with time than the other algorithms shown.



The relationship between the algorithms is further illustrated in the following figure, which plots the time required to converge versus the mean square error convergence goal. Here you can see that as the error goal is reduced, the improvement provided by the LM algorithm becomes more pronounced. Some algorithms perform better as the error goal is reduced (LM and BFG), and other algorithms degrade as the error goal is reduced (OSS and GDX).



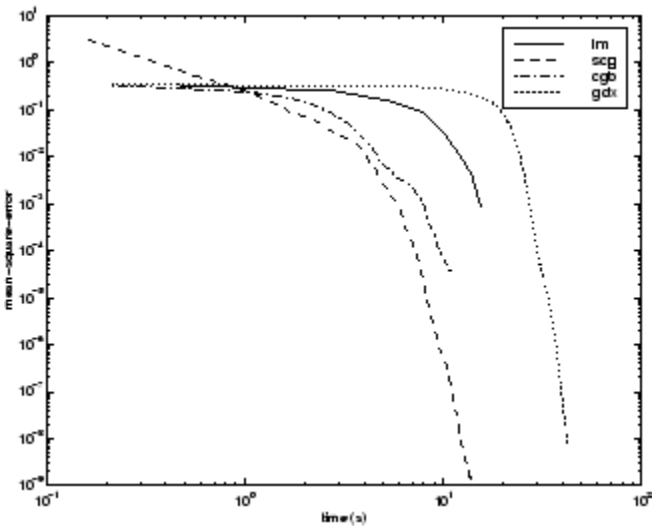
PARITY Data Set

The second benchmark problem is a simple pattern recognition problem—detect the parity of a 3-bit number. If the number of ones in the input pattern is odd, then the network should output a 1; otherwise, it should output a -1. The network used for this problem is a 3-10-10-1 network with tansig neurons in each layer. The following table summarizes the results of training this network with the nine different algorithms. Each entry in the table represents 30 different trials, where different random initial weights are used in each trial. In each case, the network is trained until the squared error is less than 0.001. The fastest algorithm for this problem is the resilient backpropagation algorithm, although the conjugate gradient algorithms (in particular, the scaled conjugate gradient algorithm) are almost as fast. Notice that the LM algorithm does not perform well on this problem. In

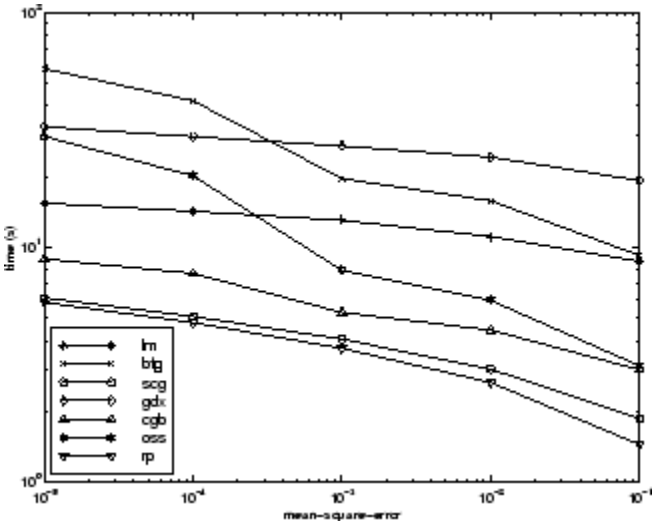
general, the LM algorithm does not perform as well on pattern recognition problems as it does on function approximation problems. The LM algorithm is designed for least squares problems that are approximately linear. Because the output neurons in pattern recognition problems are generally saturated, you will not be operating in the linear region.

Algorithm	Mean Time (s)	Ratio	Min. Time (s)	Max. Time (s)	Std. (s)
RP	3.73	1.00	2.35	6.89	1.26
SCG	4.09	1.10	2.36	7.48	1.56
CGP	5.13	1.38	3.50	8.73	1.05
CGB	5.30	1.42	3.91	11.59	1.35
CGF	6.62	1.77	3.96	28.05	4.32
OSS	8.00	2.14	5.06	14.41	1.92
LM	13.07	3.50	6.48	23.78	4.96
BFG	19.68	5.28	14.19	26.64	2.85
GDX	27.07	7.26	25.21	28.52	0.86

As with function approximation problems, the performance of the various algorithms can be affected by the accuracy required of the network. This is shown in the following figure, which plots the mean square error versus execution time for some typical algorithms. The LM algorithm converges rapidly after some point, but only after the other algorithms have already converged.



The relationship between the algorithms is further illustrated in the following figure, which plots the time required to converge versus the mean square error convergence goal. Again you can see that some algorithms degrade as the error goal is reduced (OSS and BFG).

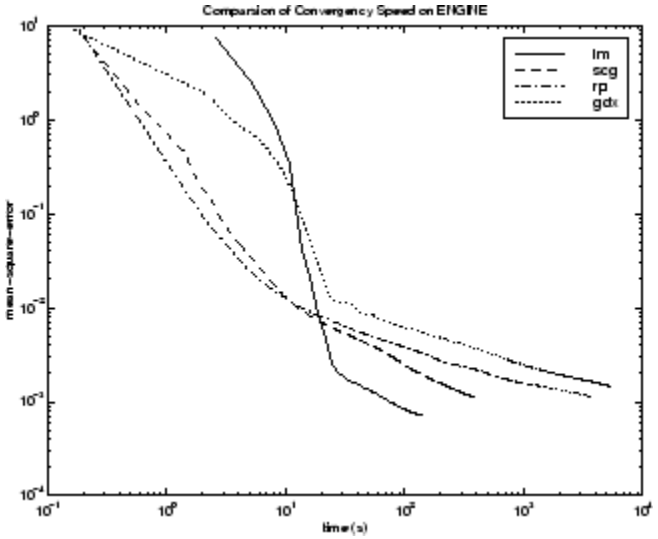


ENGINE Data Set

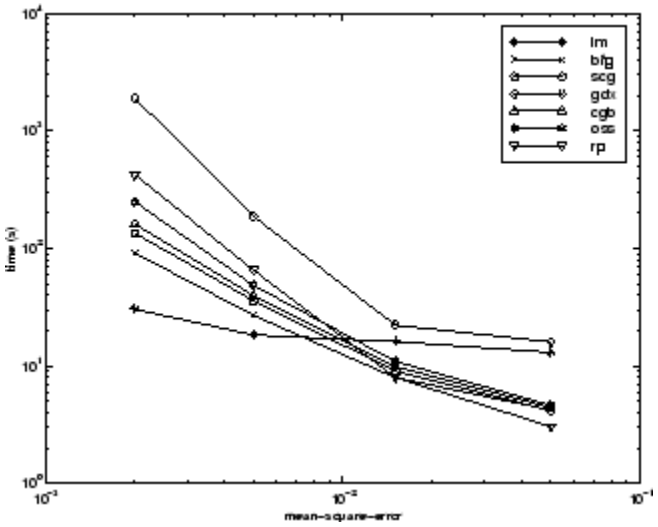
The third benchmark problem is a realistic function approximation (or nonlinear regression) problem. The data is obtained from the operation of an engine. The inputs to the network are engine speed and fueling levels and the network outputs are torque and emission levels. The network used for this problem is a 2-30-2 network with tansig neurons in the hidden layer and linear neurons in the output layer. The following table summarizes the results of training this network with the nine different algorithms. Each entry in the table represents 30 different trials (10 trials for RP and GDX because of time constraints), where different random initial weights are used in each trial. In each case, the network is trained until the squared error is less than 0.005. The fastest algorithm for this problem is the LM algorithm, followed by the BFGS quasi-Newton algorithm and the conjugate gradient algorithms. Although this is a function approximation problem, the LM algorithm is not as clearly superior as it was on the SIN data set. In this case, the number of weights and biases in the network is much larger than the one used on the SIN problem (152 versus 16), and the advantages of the LM algorithm decrease as the number of network parameters increases.

Algorithm	Mean Time (s)	Ratio	Min. Time (s)	Max. Time (s)	Std. (s)
LM	18.45	1.00	12.01	30.03	4.27
BFG	27.12	1.47	16.42	47.36	5.95
SCG	36.02	1.95	19.39	52.45	7.78
CGF	37.93	2.06	18.89	50.34	6.12
CGB	39.93	2.16	23.33	55.42	7.50
CGP	44.30	2.40	24.99	71.55	9.89
OSS	48.71	2.64	23.51	80.90	12.33
RP	65.91	3.57	31.83	134.31	34.24
GDX	188.50	10.22	81.59	279.90	66.67

The following figure plots the mean square error versus execution time for some typical algorithms. The performance of the LM algorithm improves over time relative to the other algorithms.



The relationship between the algorithms is further illustrated in the following figure, which plots the time required to converge versus the mean square error convergence goal. Again you can see that some algorithms degrade as the error goal is reduced (GDX and RP), while the LM algorithm improves.



CANCER Data Set

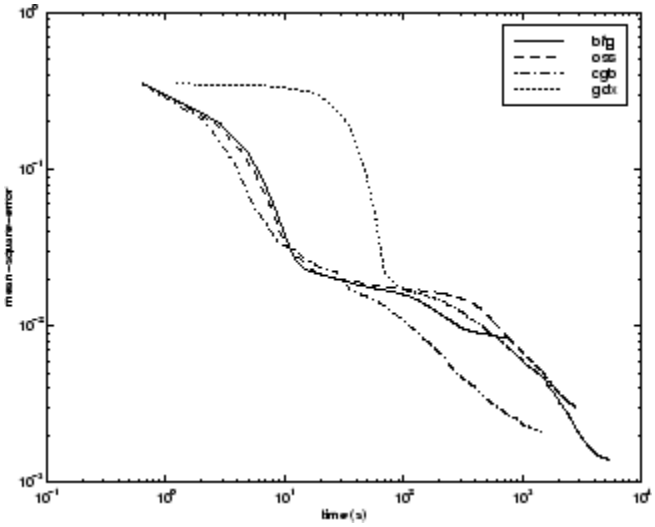
The fourth benchmark problem is a realistic pattern recognition (or nonlinear discriminant analysis) problem. The objective of the network is to classify a tumor as either benign or malignant based on cell descriptions gathered by microscopic examination. Input attributes include clump thickness, uniformity of cell size and cell shape, the amount of marginal adhesion, and the frequency of bare nuclei. The data was obtained from the University of Wisconsin Hospitals, Madison, from Dr. William H. Wolberg. The network used for this problem is a 9-5-5-2 network with tansig neurons in all layers. The following table summarizes the results of training this network with the nine different algorithms. Each entry in the table represents 30 different trials, where different random initial weights are used in each trial. In each case, the network is trained until the squared error is less than

0.012. A few runs failed to converge for some of the algorithms, so only the top 75% of the runs from each algorithm were used to obtain the statistics.

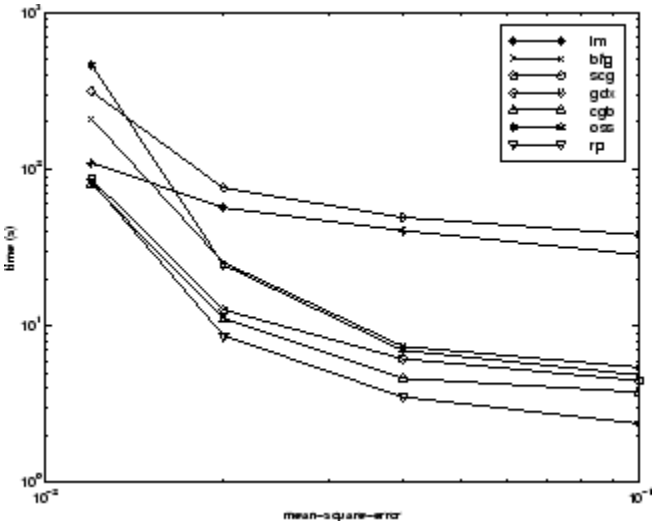
The conjugate gradient algorithms and resilient backpropagation all provide fast convergence, and the LM algorithm is also reasonably fast. As with the parity data set, the LM algorithm does not perform as well on pattern recognition problems as it does on function approximation problems.

Algorithm	Mean Time (s)	Ratio	Min. Time (s)	Max. Time (s)	Std. (s)
CGB	80.27	1.00	55.07	102.31	13.17
RP	83.41	1.04	59.51	109.39	13.44
SCG	86.58	1.08	41.21	112.19	18.25
CGP	87.70	1.09	56.35	116.37	18.03
CGF	110.05	1.37	63.33	171.53	30.13
LM	110.33	1.37	58.94	201.07	38.20
BFG	209.60	2.61	118.92	318.18	58.44
GDX	313.22	3.90	166.48	446.43	75.44
OSS	463.87	5.78	250.62	599.99	97.35

The following figure plots the mean square error versus execution time for some typical algorithms. For this problem there is not as much variation in performance as in previous problems.



The relationship between the algorithms is further illustrated in the following figure, which plots the time required to converge versus the mean square error convergence goal. Again you can see that some algorithms degrade as the error goal is reduced (OSS and BFG) while the LM algorithm improves. It is typical of the LM algorithm on any problem that its performance improves relative to other algorithms as the error goal is reduced.



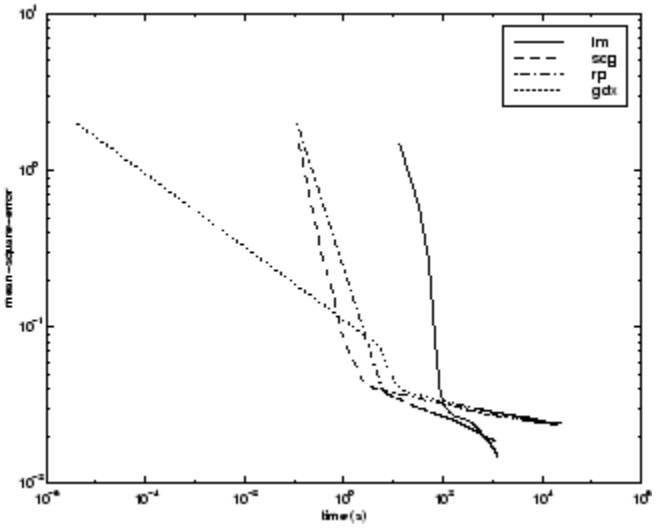
CHOLESTEROL Data Set

The fifth benchmark problem is a realistic function approximation (or nonlinear regression) problem. The objective of the network is to predict cholesterol levels (ldl, hdl, and vldl) based on measurements of 21 spectral components. The data was obtained from Dr. Neil Purdie, Department of Chemistry, Oklahoma State University [PuLu92 on page 32-2]. The network used for this problem is a 21-15-3 network with tansig neurons in the hidden layers and linear neurons in the output layer. The following table summarizes the results of training this network with the nine different algorithms. Each entry in the table represents 20 different trials (10 trials for RP and GDX), where different random initial weights are used in each trial. In each case, the network is trained until the squared error is less than 0.027.

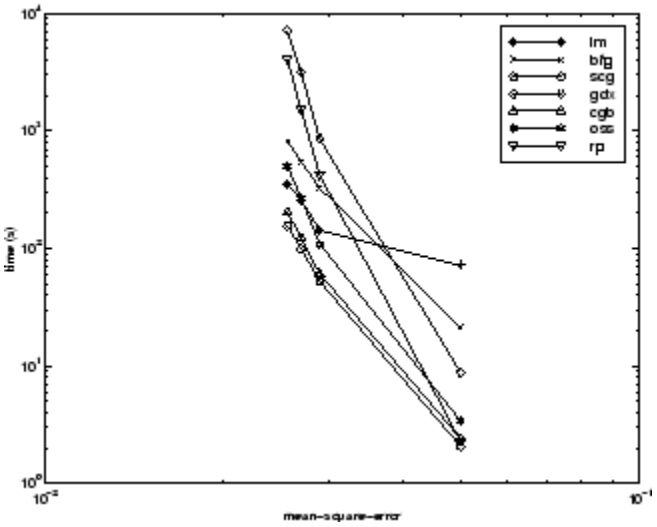
The scaled conjugate gradient algorithm has the best performance on this problem, although all the conjugate gradient algorithms perform well. The LM algorithm does not perform as well on this function approximation problem as it did on the other two. That is because the number of weights and biases in the network has increased again (378 versus 152 versus 16). As the number of parameters increases, the computation required in the LM algorithm increases geometrically.

Algorithm	Mean Time (s)	Ratio	Min. Time (s)	Max. Time (s)	Std. (s)
SCG	99.73	1.00	83.10	113.40	9.93
CGP	121.54	1.22	101.76	162.49	16.34
CGB	124.06	1.2	107.64	146.90	14.62
CGF	136.04	1.36	106.46	167.28	17.67
LM	261.50	2.62	103.52	398.45	102.06
OSS	268.55	2.69	197.84	372.99	56.79
BFG	550.92	5.52	471.61	676.39	46.59
RP	1519.00	15.23	581.17	2256.10	557.34
GDX	3169.50	31.78	2514.90	4168.20	610.52

The following figure plots the mean square error versus execution time for some typical algorithms. For this problem, you can see that the LM algorithm is able to drive the mean square error to a lower level than the other algorithms. The SCG and RP algorithms provide the fastest initial convergence.



The relationship between the algorithms is further illustrated in the following figure, which plots the time required to converge versus the mean square error convergence goal. You can see that the LM and BFG algorithms improve relative to the other algorithms as the error goal is reduced.



DIABETES Data Set

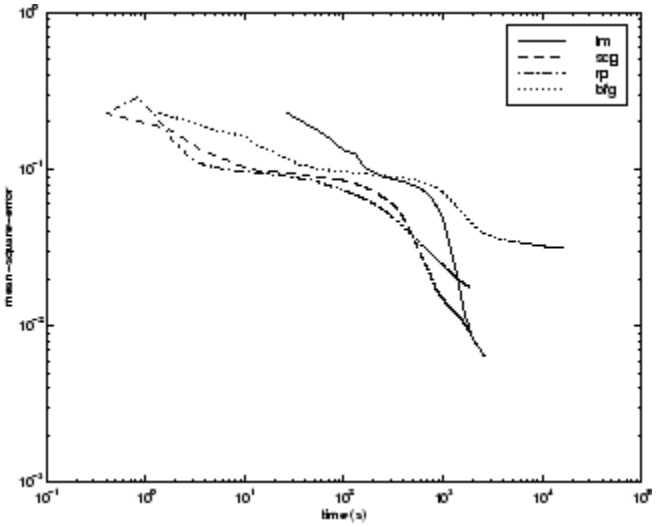
The sixth benchmark problem is a pattern recognition problem. The objective of the network is to decide whether an individual has diabetes, based on personal data (age, number of times pregnant) and the results of medical examinations (e.g., blood pressure, body mass index, result of glucose tolerance test, etc.). The data was obtained from the University of California, Irvine, machine learning data base. The network used for this problem is an 8-15-15-2 network with tansig neurons in all layers. The following table summarizes the results of training this network with the nine different algorithms. Each entry in the table represents 10 different trials, where different random initial

weights are used in each trial. In each case, the network is trained until the squared error is less than 0.05.

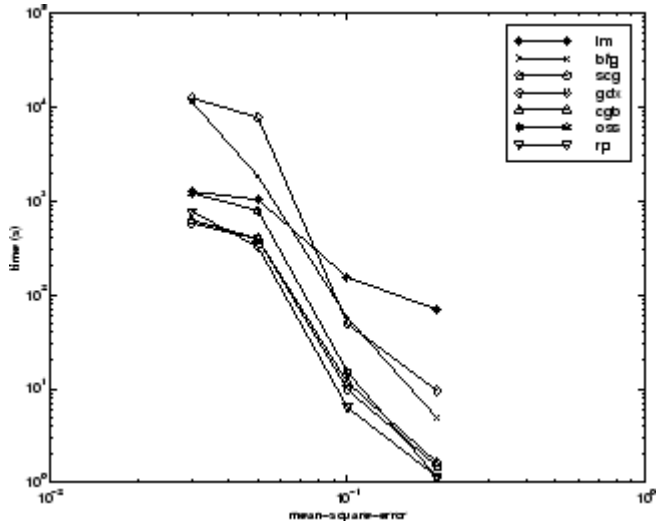
The conjugate gradient algorithms and resilient backpropagation all provide fast convergence. The results on this problem are consistent with the other pattern recognition problems considered. The RP algorithm works well on all the pattern recognition problems. This is reasonable, because that algorithm was designed to overcome the difficulties caused by training with sigmoid functions, which have very small slopes when operating far from the center point. For pattern recognition problems, you use sigmoid transfer functions in the output layer, and you want the network to operate at the tails of the sigmoid function.

Algorithm	Mean Time (s)	Ratio	Min. Time (s)	Max. Time (s)	Std. (s)
RP	323.90	1.00	187.43	576.90	111.37
SCG	390.53	1.21	267.99	487.17	75.07
CGB	394.67	1.22	312.25	558.21	85.38
CGP	415.90	1.28	320.62	614.62	94.77
OSS	784.00	2.42	706.89	936.52	76.37
CGF	784.50	2.42	629.42	1082.20	144.63
LM	1028.10	3.17	802.01	1269.50	166.31
BFG	1821.00	5.62	1415.80	3254.50	546.36
GDX	7687.00	23.73	5169.20	10350.00	2015.00

The following figure plots the mean square error versus execution time for some typical algorithms. As with other problems, you see that the SCG and RP have fast initial convergence, while the LM algorithm is able to provide smaller final error.



The relationship between the algorithms is further illustrated in the following figure, which plots the time required to converge versus the mean square error convergence goal. In this case, you can see that the BFG algorithm degrades as the error goal is reduced, while the LM algorithm improves. The RP algorithm is best, except at the smallest error goal, where SCG is better.



Summary

There are several algorithm characteristics that can be deduced from the experiments described. In general, on function approximation problems, for networks that contain up to a few hundred weights, the Levenberg-Marquardt algorithm will have the fastest convergence. This advantage is especially noticeable if very accurate training is required. In many cases, `trainlm` is able to obtain lower mean square errors than any of the other algorithms tested. However, as the number of weights in the network increases, the advantage of `trainlm` decreases. In addition, `trainlm` performance is relatively poor on pattern recognition problems. The storage requirements of `trainlm` are larger than the other algorithms tested.

The `trainrp` function is the fastest algorithm on pattern recognition problems. However, it does not perform well on function approximation problems. Its performance also degrades as the error goal is reduced. The memory requirements for this algorithm are relatively small in comparison to the other algorithms considered.

The conjugate gradient algorithms, in particular `trainscg`, seem to perform well over a wide variety of problems, particularly for networks with a large number of weights. The SCG algorithm is almost as fast as the LM algorithm on function approximation problems (faster for large networks) and is almost as fast as `trainrp` on pattern recognition problems. Its performance does not degrade as quickly as `trainrp` performance does when the error is reduced. The conjugate gradient algorithms have relatively modest memory requirements.

The performance of `trainbfg` is similar to that of `trainlm`. It does not require as much storage as `trainlm`, but the computation required does increase geometrically with the size of the network, because the equivalent of a matrix inverse must be computed at each iteration.

The variable learning rate algorithm `traingdx` is usually much slower than the other methods, and has about the same storage requirements as `trainrp`, but it can still be useful for some problems. There are certain situations in which it is better to converge more slowly. For example, when using early stopping you can have inconsistent results if you use an algorithm that converges too quickly. You might overshoot the point at which the error on the validation set is minimized.

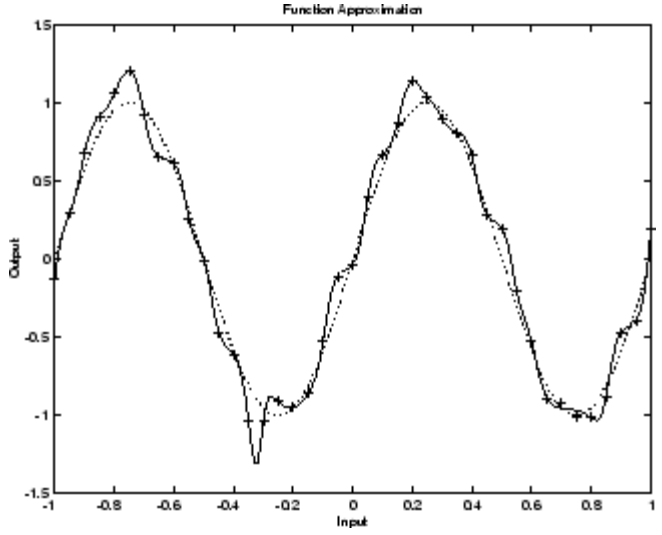
Improve Shallow Neural Network Generalization and Avoid Overfitting

In this section...

Tip To learn how to set up parameters for a deep learning network, see “Set Up Parameters and Train Convolutional Neural Network” on page 1-42.

One of the problems that occur during neural network training is called overfitting. The error on the training set is driven to a very small value, but when new data is presented to the network the error is large. The network has memorized the training examples, but it has not learned to generalize to new situations.

The following figure shows the response of a 1-20-1 neural network that has been trained to approximate a noisy sine function. The underlying sine function is shown by the dotted line, the noisy measurements are given by the + symbols, and the neural network response is given by the solid line. Clearly this network has overfitted the data and will not generalize well.



One method for improving network generalization is to use a network that is just large enough to provide an adequate fit. The larger network you use, the more complex the functions the network can create. If you use a small enough network, it will not have enough power to overfit the data. Run the *Neural Network Design* example nnd11gn [HDB96 on page 32-2] to investigate how reducing the size of a network can prevent overfitting.

Unfortunately, it is difficult to know beforehand how large a network should be for a specific application. There are two other methods for improving generalization that are implemented in Deep Learning Toolbox software: regularization and early stopping. The next sections describe these two techniques and the routines to implement them.

Note that if the number of parameters in the network is much smaller than the total number of points in the training set, then there is little or no chance of overfitting. If you can easily collect more data and increase the size of the training set, then there is no need to worry about the following techniques to prevent overfitting. The rest of this section only applies to those situations in which you want to make the most of a limited supply of data.

Retraining Neural Networks

Typically each backpropagation training session starts with different initial weights and biases, and different divisions of data into training, validation, and test sets. These different conditions can lead to very different solutions for the same problem.

It is a good idea to train several networks to ensure that a network with good generalization is found.

Here a dataset is loaded and divided into two parts: 90% for designing networks and 10% for testing them all.

```
[x, t] = bodyfat_dataset;
Q = size(x, 2);
Q1 = floor(Q * 0.90);
Q2 = Q - Q1;
ind = randperm(Q);
ind1 = ind(1:Q1);
ind2 = ind(Q1 + (1:Q2));
x1 = x(:, ind1);
t1 = t(:, ind1);
x2 = x(:, ind2);
t2 = t(:, ind2);
```

Next a network architecture is chosen and trained ten times on the first part of the dataset, with each network's mean square error on the second part of the dataset.

```
net = feedforwardnet(10);
numNN = 10;
NN = cell(1, numNN);
perfs = zeros(1, numNN);
for i = 1:numNN
  fprintf('Training %d/%d\n', i, numNN);
  NN{i} = train(net, x1, t1);
  y2 = NN{i}(x2);
  perfs(i) = mse(net, t2, y2);
end
```

Each network will be trained starting from different initial weights and biases, and with a different division of the first dataset into training, validation, and test sets. Note that the test sets are a good

measure of generalization for each respective network, but not for all the networks, because data that is a test set for one network will likely be used for training or validation by other neural networks. This is why the original dataset was divided into two parts, to ensure that a completely independent test set is preserved.

The neural network with the lowest performance is the one that generalized best to the second part of the dataset.

Multiple Neural Networks

Another simple way to improve generalization, especially when caused by noisy data or a small dataset, is to train multiple neural networks and average their outputs.

For instance, here 10 neural networks are trained on a small problem and their mean squared errors compared to the means squared error of their average.

First, the dataset is loaded and divided into a design and test set.

```
[x, t] = bodyfat_dataset;
Q = size(x, 2);
Q1 = floor(Q * 0.90);
Q2 = Q - Q1;
ind = randperm(Q);
ind1 = ind(1:Q1);
ind2 = ind(Q1 + (1:Q2));
x1 = x(:, ind1);
t1 = t(:, ind1);
x2 = x(:, ind2);
t2 = t(:, ind2);
```

Then, ten neural networks are trained.

```
net = feedforwardnet(10);
numNN = 10;
nets = cell(1, numNN);
for i = 1:numNN
  fprintf('Training %d/%d\n', i, numNN)
  nets{i} = train(net, x1, t1);
end
```

Next, each network is tested on the second dataset with both individual performances and the performance for the average output calculated.

```
perfs = zeros(1, numNN);
y2Total = 0;
for i = 1:numNN
  neti = nets{i};
  y2 = neti(x2);
  perfs(i) = mse(neti, t2, y2);
  y2Total = y2Total + y2;
end
perfs
y2AverageOutput = y2Total / numNN;
perfAveragedOutputs = mse(nets{1}, t2, y2AverageOutput)
```

The mean squared error for the average output is likely to be lower than most of the individual performances, perhaps not all. It is likely to generalize better to additional new data.

For some very difficult problems, a hundred networks can be trained and the average of their outputs taken for any input. This is especially helpful for a small, noisy dataset in conjunction with the Bayesian Regularization training function `trainbr`, described below.

Early Stopping

The default method for improving generalization is called *early stopping*. This technique is automatically provided for all of the supervised network creation functions, including the backpropagation network creation functions such as `feedforwardnet`.

In this technique the available data is divided into three subsets. The first subset is the training set, which is used for computing the gradient and updating the network weights and biases. The second subset is the validation set. The error on the validation set is monitored during the training process. The validation error normally decreases during the initial phase of training, as does the training set error. However, when the network begins to overfit the data, the error on the validation set typically begins to rise. When the validation error increases for a specified number of iterations (`net.trainParam.max_fail`), the training is stopped, and the weights and biases at the minimum of the validation error are returned.

The test set error is not used during training, but it is used to compare different models. It is also useful to plot the test set error during the training process. If the error in the test set reaches a minimum at a significantly different iteration number than the validation set error, this might indicate a poor division of the data set.

There are four functions provided for dividing data into training, validation and test sets. They are `dividerand` (the default), `divideblock`, `divideint`, and `divideind`. You can access or change the division function for your network with this property:

```
net.divideFcn
```

Each of these functions takes parameters that customize its behavior. These values are stored and can be changed with the following network property:

```
net.divideParam
```

Index Data Division (divideind)

Create a simple test problem. For the full data set, generate a noisy sine wave with 201 input points ranging from −1 to 1 at steps of 0.01:

```
p = [-1:0.01:1];
t = sin(2*pi*p)+0.1*randn(size(p));
```

Divide the data by index so that successive samples are assigned to the training set, validation set, and test set successively:

```
trainInd = 1:3:201
valInd = 2:3:201;
testInd = 3:3:201;
[trainP,valP,testP] = divideind(p,trainInd,valInd,testInd);
[trainT,valT,testT] = divideind(t,trainInd,valInd,testInd);
```

Random Data Division (dividerand)

You can divide the input data randomly so that 60% of the samples are assigned to the training set, 20% to the validation set, and 20% to the test set, as follows:

```
[trainP,valP,testP,trainInd,valInd,testInd] = dividerand(p);
```

This function not only divides the input data, but also returns indices so that you can divide the target data accordingly using `divideind`:

```
[trainT,valT,testT] = divideind(t,trainInd,valInd,testInd);
```

Block Data Division (divideblock)

You can also divide the input data randomly such that the first 60% of the samples are assigned to the training set, the next 20% to the validation set, and the last 20% to the test set, as follows:

```
[trainP,valP,testP,trainInd,valInd,testInd] = divideblock(p);
```

Divide the target data accordingly using `divideind`:

```
[trainT,valT,testT] = divideind(t,trainInd,valInd,testInd);
```

Interleaved Data Division (divideint)

Another way to divide the input data is to cycle samples between the training set, validation set, and test set according to percentages. You can interleave 60% of the samples to the training set, 20% to the validation set and 20% to the test set as follows:

```
[trainP,valP,testP,trainInd,valInd,testInd] = divideint(p);
```

Divide the target data accordingly using `divideind`.

```
[trainT,valT,testT] = divideind(t,trainInd,valInd,testInd);
```

Regularization

Another method for improving generalization is called regularization. This involves modifying the performance function, which is normally chosen to be the sum of squares of the network errors on the training set. The next section explains how the performance function can be modified, and the following section describes a routine that automatically sets the optimal performance function to achieve the best generalization.

Modified Performance Function

The typical performance function used for training feedforward neural networks is the mean sum of squares of the network errors.

$$F = mse = \frac{1}{N}\sum_{i=1}^{N}(e_i)^2 = \frac{1}{N}\sum_{i=1}^{N}(t_i - a_i)^2$$

It is possible to improve generalization if you modify the performance function by adding a term that consists of the mean of the sum of squares of the network weights and biases
$msereg = \gamma * msw + (1 - \gamma) * mse$, where γ is the performance ratio, and

$$msw = \frac{1}{n}\sum_{j=1}^{n} w_j^2$$

Using this performance function causes the network to have smaller weights and biases, and this forces the network response to be smoother and less likely to overfit.

The following code reinitializes the previous network and retrains it using the BFGS algorithm with the regularized performance function. Here the performance ratio is set to 0.5, which gives equal weight to the mean square errors and the mean square weights.

```
[x,t] = simplefit_dataset;
net = feedforwardnet(10,'trainbfg');
net.divideFcn = '';
net.trainParam.epochs = 300;
net.trainParam.goal = 1e-5;
net.performParam.regularization = 0.5;
net = train(net,x,t);
```

The problem with regularization is that it is difficult to determine the optimum value for the performance ratio parameter. If you make this parameter too large, you might get overfitting. If the ratio is too small, the network does not adequately fit the training data. The next section describes a routine that automatically sets the regularization parameters.

Automated Regularization (trainbr)

It is desirable to determine the optimal regularization parameters in an automated fashion. One approach to this process is the Bayesian framework of David MacKay [MacK92 on page 32-2]. In this framework, the weights and biases of the network are assumed to be random variables with specified distributions. The regularization parameters are related to the unknown variances associated with these distributions. You can then estimate these parameters using statistical techniques.

A detailed discussion of Bayesian regularization is beyond the scope of this user guide. A detailed discussion of the use of Bayesian regularization, in combination with Levenberg-Marquardt training, can be found in [FoHa97 on page 32-2].

Bayesian regularization has been implemented in the function `trainbr`. The following code shows how you can train a 1-20-1 network using this function to approximate the noisy sine wave shown in the figure in “Improve Shallow Neural Network Generalization and Avoid Overfitting” on page 28-25. (Data division is cancelled by setting `net.divideFcn` so that the effects of `trainbr` are isolated from early stopping.)

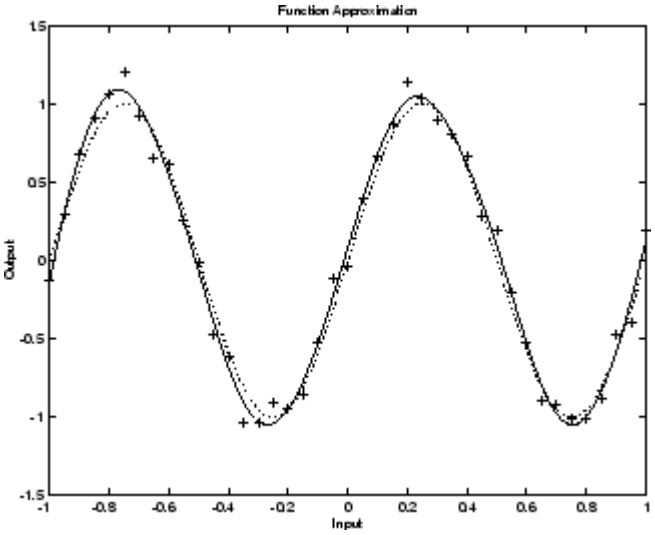
```
x = -1:0.05:1;
t = sin(2*pi*x) + 0.1*randn(size(x));
net = feedforwardnet(20,'trainbr');
net = train(net,x,t);
```

One feature of this algorithm is that it provides a measure of how many network parameters (weights and biases) are being effectively used by the network. In this case, the final trained network uses approximately 12 parameters (indicated by `#Par` in the printout) out of the 61 total weights and biases in the 1-20-1 network. This effective number of parameters should remain approximately the same, no matter how large the number of parameters in the network becomes. (This assumes that the network has been trained for a sufficient number of iterations to ensure convergence.)

The `trainbr` algorithm generally works best when the network inputs and targets are scaled so that they fall approximately in the range [−1,1]. That is the case for the test problem here. If your inputs and targets do not fall in this range, you can use the function `mapminmax` or `mapstd` to perform the scaling, as described in “Choose Neural Network Input-Output Processing Functions” on page 22-7. Networks created with `feedforwardnet` include `mapminmax` as an input and output processing function by default.

The following figure shows the response of the trained network. In contrast to the previous figure, in which a 1-20-1 network overfits the data, here you see that the network response is very close to the underlying sine function (dotted line), and, therefore, the network will generalize well to new inputs. You could have tried an even larger network, but the network response would never overfit the data. This eliminates the guesswork required in determining the optimum network size.

When using `trainbr`, it is important to let the algorithm run until the effective number of parameters has converged. The training might stop with the message "Maximum MU reached." This is typical, and is a good indication that the algorithm has truly converged. You can also tell that the algorithm has converged if the sum squared error (SSE) and sum squared weights (SSW) are relatively constant over several iterations. When this occurs you might want to click the **Stop Training** button in the training window.



Summary and Discussion of Early Stopping and Regularization

Early stopping and regularization can ensure network generalization when you apply them properly.

For early stopping, you must be careful not to use an algorithm that converges too rapidly. If you are using a fast algorithm (like `trainlm`), set the training parameters so that the convergence is relatively slow. For example, set `mu` to a relatively large value, such as 1, and set `mu_dec` and `mu_inc` to values close to 1, such as 0.8 and 1.5, respectively. The training functions `trainscg` and `trainbr` usually work well with early stopping.

With early stopping, the choice of the validation set is also important. The validation set should be representative of all points in the training set.

When you use Bayesian regularization, it is important to train the network until it reaches convergence. The sum-squared error, the sum-squared weights, and the effective number of parameters should reach constant values when the network has converged.

With both early stopping and regularization, it is a good idea to train the network starting from several different initial conditions. It is possible for either method to fail in certain circumstances. By testing several different initial conditions, you can verify robust network performance.

When the data set is small and you are training function approximation networks, Bayesian regularization provides better generalization performance than early stopping. This is because Bayesian regularization does not require that a validation data set be separate from the training data set; it uses all the data.

To provide some insight into the performance of the algorithms, both early stopping and Bayesian regularization were tested on several benchmark data sets, which are listed in the following table.

Data Set Title	Number of Points	Network	Description
BALL	67	2-10-1	Dual-sensor calibration for a ball position measurement
SINE (5% N)	41	1-15-1	Single-cycle sine wave with Gaussian noise at 5% level
SINE (2% N)	41	1-15-1	Single-cycle sine wave with Gaussian noise at 2% level
ENGINE (ALL)	1199	2-30-2	Engine sensor—full data set
ENGINE (1/4)	300	2-30-2	Engine sensor—1/4 of data set
CHOLEST (ALL)	264	5-15-3	Cholesterol measurement—full data set
CHOLEST (1/2)	132	5-15-3	Cholesterol measurement—1/2 data set

These data sets are of various sizes, with different numbers of inputs and targets. With two of the data sets the networks were trained once using all the data and then retrained using only a fraction of the data. This illustrates how the advantage of Bayesian regularization becomes more noticeable when the data sets are smaller. All the data sets are obtained from physical systems except for the SINE data sets. These two were artificially created by adding various levels of noise to a single cycle of a sine wave. The performance of the algorithms on these two data sets illustrates the effect of noise.

The following table summarizes the performance of early stopping (ES) and Bayesian regularization (BR) on the seven test sets. (The `trainscg` algorithm was used for the early stopping tests. Other algorithms provide similar performance.)

Mean Squared Test Set Error

Method	Ball	Engine (All)	Engine (1/4)	Choles (All)	Choles (1/2)	Sine (5% N)	Sine (2% N)
ES	1.2e-1	1.3e-2	1.9e-2	1.2e-1	1.4e-1	1.7e-1	1.3e-1
BR	1.3e-3	2.6e-3	4.7e-3	1.2e-1	9.3e-2	3.0e-2	6.3e-3
ES/BR	92	5	4	1	1.5	5.7	21

You can see that Bayesian regularization performs better than early stopping in most cases. The performance improvement is most noticeable when the data set is small, or if there is little noise in the data set. The BALL data set, for example, was obtained from sensors that had very little noise.

Although the generalization performance of Bayesian regularization is often better than early stopping, this is not always the case. In addition, the form of Bayesian regularization implemented in the toolbox does not perform as well on pattern recognition problems as it does on function approximation problems. This is because the approximation to the Hessian that is used in the

Levenberg-Marquardt algorithm is not as accurate when the network output is saturated, as would be the case in pattern recognition problems. Another disadvantage of the Bayesian regularization method is that it generally takes longer to converge than early stopping.

Posttraining Analysis (regression)

The performance of a trained network can be measured to some extent by the errors on the training, validation, and test sets, but it is often useful to investigate the network response in more detail. One option is to perform a regression analysis between the network response and the corresponding targets. The routine `regression` is designed to perform this analysis.

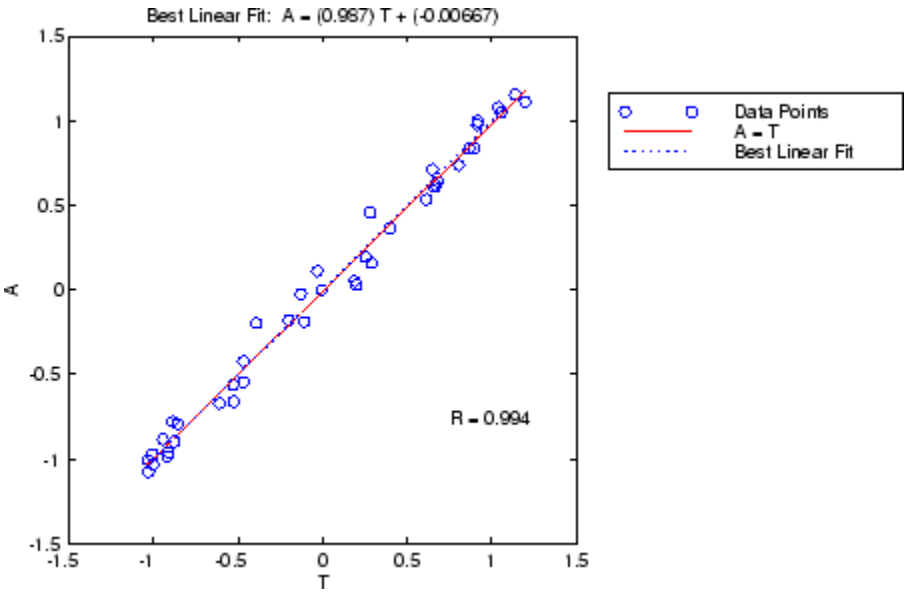
The following commands illustrate how to perform a regression analysis on a network trained.

```
x = [-1:.05:1];
t = sin(2*pi*x)+0.1*randn(size(x));
net = feedforwardnet(10);
net = train(net,x,t);
y = net(x);
[r,m,b] = regression(t,y)
```

```
r =
    0.9935
m =
    0.9874
b =
   -0.0067
```

The network output and the corresponding targets are passed to `regression`. It returns three parameters. The first two, `m` and `b`, correspond to the slope and the *y*-intercept of the best linear regression relating targets to network outputs. If there were a perfect fit (outputs exactly equal to targets), the slope would be 1, and the *y*-intercept would be 0. In this example, you can see that the numbers are very close. The third variable returned by `regression` is the correlation coefficient (R-value) between the outputs and targets. It is a measure of how well the variation in the output is explained by the targets. If this number is equal to 1, then there is perfect correlation between targets and outputs. In the example, the number is very close to 1, which indicates a good fit.

The following figure illustrates the graphical output provided by `regression`. The network outputs are plotted versus the targets as open circles. The best linear fit is indicated by a dashed line. The perfect fit (output equal to targets) is indicated by the solid line. In this example, it is difficult to distinguish the best linear fit line from the perfect fit line because the fit is so good.



Best Linear Fit: A = (0.987) T + (-0.00667)
R = 0.994
A
T
Data Points
A = T
Best Linear Fit

Edit Shallow Neural Network Properties

In this section...

Tip To learn how to define your own layers for deep learning networks, see “Define Custom Deep Learning Layers” on page 18-9.

Deep Learning Toolbox software provides a flexible network object type that allows many kinds of networks to be created and then used with functions such as `init`, `sim`, and `train`.

Type the following to see all the network creation functions in the toolbox.

```
help nnnetwork
```

This flexibility is possible because networks have an object-oriented representation. The representation allows you to define various architectures and assign various algorithms to those architectures.

To create custom networks, start with an empty network (obtained with the `network` function) and set its properties as desired.

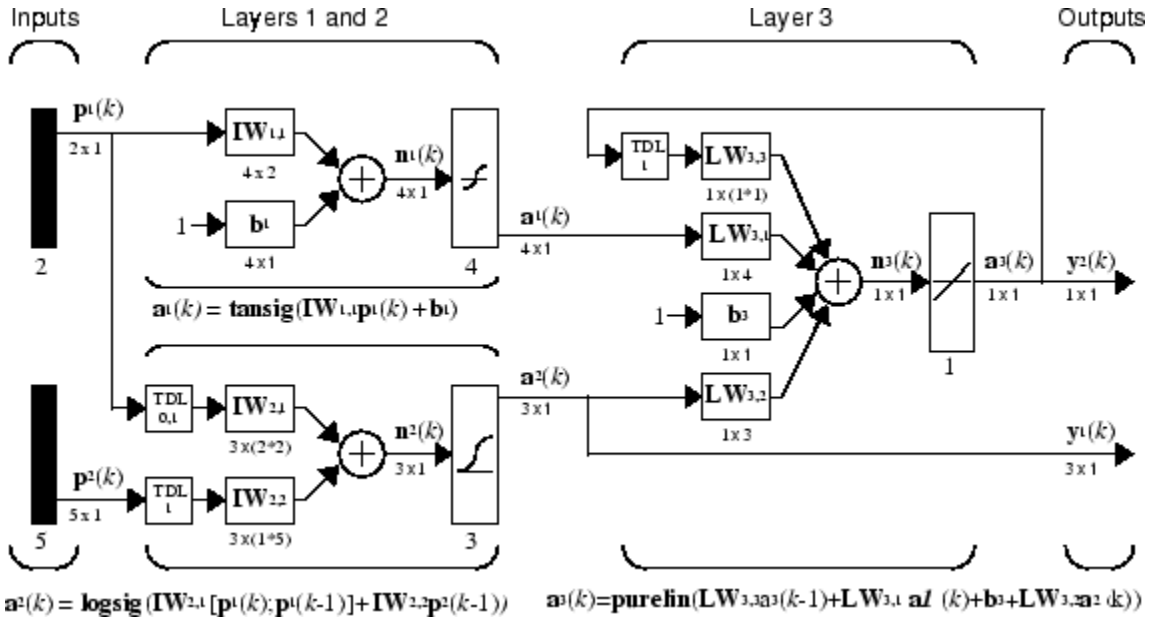
```
net = network
```

The network object consists of many properties that you can set to specify the structure and behavior of your network.

The following sections show how to create a custom network by using these properties.

Custom Network

Before you can build a network you need to know what it looks like. For dramatic purposes (and to give the toolbox a workout) this section leads you through the creation of the wild and complicated network shown below.



Each of the two elements of the first network input is to accept values ranging between 0 and 10. Each of the five elements of the second network input ranges from −2 to 2.

Before you can complete your design of this network, the algorithms it employs for initialization and training must be specified.

Each layer's weights and biases are initialized with the Nguyen-Widrow layer initialization method (`initnw`). The network is trained with Levenberg-Marquardt backpropagation (`trainlm`), so that, given example input vectors, the outputs of the third layer learn to match the associated target vectors with minimal mean squared error (`mse`).

Network Definition

The first step is to create a new network. Type the following code to create a network and view its many properties:

```
net = network
```

Architecture Properties

The first group of properties displayed is labeled `architecture` properties. These properties allow you to select the number of inputs and layers and their connections.

Number of Inputs and Layers

The first two properties displayed in the dimensions group are `numInputs` and `numLayers`. These properties allow you to select how many inputs and layers you want the network to have.

```
net =

    dimensions:
         numInputs: 0
         numLayers: 0
         ...
```

Note that the network has no inputs or layers at this time.

Change that by setting these properties to the number of inputs and number of layers in the custom network diagram.

```
net.numInputs = 2;
net.numLayers = 3;
```

`net.numInputs` is the number of input sources, not the number of elements in an input vector (`net.inputs{i}.size`).

Bias Connections

Type `net` and press **Enter** to view its properties again. The network now has two inputs and three layers.

```
net =
    Neural Network:
    dimensions:
         numInputs: 2
         numLayers: 3
```

Examine the next four properties in the connections group:

```
       biasConnect: [0; 0; 0]
      inputConnect: [0 0; 0 0; 0 0]
      layerConnect: [0 0 0; 0 0 0; 0 0 0]
     outputConnect: [0 0 0]
```

These matrices of 1s and 0s represent the presence and absence of bias, input weight, layer weight, and output connections. They are currently all zeros, indicating that the network does not have any such connections.

The bias connection matrix is a 3-by-1 vector. To create a bias connection to the *i*th layer you can set `net.biasConnect(i)` to `1`. Specify that the first and third layers are to have bias connections, as the diagram indicates, by typing the following code:

```
net.biasConnect(1) = 1;
net.biasConnect(3) = 1;
```

You could also define those connections with a single line of code.

```
net.biasConnect = [1; 0; 1];
```

Input and Layer Weight Connections

The input connection matrix is 3-by-2, representing the presence of connections from two sources (the two inputs) to three destinations (the three layers). Thus, `net.inputConnect(i,j)` represents the presence of an input weight connection going to the *i*th layer from the *j*th input.

To connect the first input to the first and second layers, and the second input to the second layer (as indicated by the custom network diagram), type

```
net.inputConnect(1,1) = 1;
net.inputConnect(2,1) = 1;
net.inputConnect(2,2) = 1;
```

or this single line of code:

```
net.inputConnect = [1 0; 1 1; 0 0];
```

Similarly, `net.layerConnect(i.j)` represents the presence of a layer-weight connection going to the *i*th layer from the *j*th layer. Connect layers 1, 2, and 3 to layer 3 as follows:

```
net.layerConnect = [0 0 0; 0 0 0; 1 1 1];
```

Output Connections

The output connections are a 1-by-3 matrix, indicating that they connect to one destination (the external world) from three sources (the three layers).

To connect layers 2 and 3 to the network output, type

```
net.outputConnect = [0 1 1];
```

Number of Outputs

Type `net` and press **Enter** to view the updated properties. The final three architecture properties are read-only values, which means their values are determined by the choices made for other properties. The first read-only property in the dimension group is the number of outputs:

```
numOutputs: 2
```

By defining output connection from layers 2 and 3, you specified that the network has two outputs.

Subobject Properties

The next group of properties in the output display is subobjects:

```
subobjects:
            inputs: {2x1 cell array of 2 inputs}
            layers: {3x1 cell array of 3 layers}
           outputs: {1x3 cell array of 2 outputs}
            biases: {3x1 cell array of 2 biases}
      inputWeights: {3x2 cell array of 3 weights}
      layerWeights: {3x3 cell array of 3 weights}
```

Inputs

When you set the number of inputs (`net.numInputs`) to 2, the `inputs` property becomes a cell array of two input structures. Each *i*th input structure (`net.inputs{i}`) contains additional properties associated with the *i*th input.

To see how the input structures are arranged, type

```
net.inputs
ans =
    [1x1 nnetInput]
    [1x1 nnetInput]
```

To see the properties associated with the first input, type

```
net.inputs{1}
```

The properties appear as follows:

```
ans =
              name: 'Input'
```

```
    feedbackOutput: []
       processFcns: {}
     processParams: {1x0 cell array of 0 params}
   processSettings: {0x0 cell array of 0 settings}
    processedRange: []
     processedSize: 0
             range: []
              size: 0
          userdata: (your custom info)
```

If you set the `exampleInput` property, the `range`, `size`, `processedSize`, and `processedRange` properties will automatically be updated to match the properties of the value of `exampleInput`.

Set the `exampleInput` property as follows:

```
net.inputs{1}.exampleInput = [0 10 5; 0 3 10];
```

If you examine the structure of the first input again, you see that it now has new values.

The property `processFcns` can be set to one or more processing functions. Type `help nnprocess` to see a list of these functions.

Set the second input vector ranges to be from −2 to 2 for five elements as follows:

```
net.inputs{1}.processFcns = {'removeconstantrows','mapminmax'};
```

View the new input properties. You will see that `processParams`, `processSettings`, `processedRange` and `processedSize` have all been updated to reflect that inputs will be processed using `removeconstantrows` and `mapminmax` before being given to the network when the network is simulated or trained. The property `processParams` contains the default parameters for each processing function. You can alter these values, if you like. See the reference page for each processing function to learn more about their parameters.

You can set the size of an input directly when no processing functions are used:

```
net.inputs{2}.size = 5;
```

Layers

When you set the number of layers (`net.numLayers`) to 3, the `layers` property becomes a cell array of three-layer structures. Type the following line of code to see the properties associated with the first layer.

```
net.layers{1}
ans =
    Neural Network Layer

              name: 'Layer'
        dimensions: 0
       distanceFcn: (none)
     distanceParam: (none)
         distances: []
            initFcn: 'initwb'
       netInputFcn: 'netsum'
     netInputParam: (none)
         positions: []
             range: []
              size: 0
```

```
       topologyFcn: (none)
       transferFcn: 'purelin'
     transferParam: (none)
          userdata: (your custom info)
```

Type the following three lines of code to change the first layer's size to 4 neurons, its transfer function to `tansig`, and its initialization function to the Nguyen-Widrow function, as required for the custom network diagram.

```
net.layers{1}.size = 4;
net.layers{1}.transferFcn = 'tansig';
net.layers{1}.initFcn = 'initnw';
```

The second layer is to have three neurons, the `logsig` transfer function, and be initialized with `initnw`. Set the second layer's properties to the desired values as follows:

```
net.layers{2}.size = 3;
net.layers{2}.transferFcn = 'logsig';
net.layers{2}.initFcn = 'initnw';
```

The third layer's size and transfer function properties don't need to be changed, because the defaults match those shown in the network diagram. You need to set only its initialization function, as follows:

```
net.layers{3}.initFcn = 'initnw';
```

Outputs

Use this line of code to see how the `outputs` property is arranged:

```
net.outputs
ans =
    []    [1x1 nnetOutput]    [1x1 nnetOutput]
```

Note that `outputs` contains two output structures, one for layer 2 and one for layer 3. This arrangement occurs automatically when `net.outputConnect` is set to `[0 1 1]`.

View the second layer's output structure with the following expression:

```
net.outputs{2}
ans =
    Neural Network Output

              name: 'Output'
     feedbackInput: []
     feedbackDelay: 0
      feedbackMode: 'none'
       processFcns: {}
     processParams: {1x0 cell array of 0 params}
   processSettings: {0x0 cell array of 0 settings}
    processedRange: [3x2 double]
     processedSize: 3
             range: [3x2 double]
              size: 3
          userdata: (your custom info)
```

The `size` is automatically set to 3 when the second layer's size (`net.layers{2}.size`) is set to that value. Look at the third layer's output structure if you want to verify that it also has the correct `size`.

Outputs have processing properties that are automatically applied to target values before they are used by the network during training. The same processing settings are applied in reverse on layer output values before they are returned as network output values during network simulation or training.

Similar to input-processing properties, setting the `exampleOutput` property automatically causes `size`, `range`, `processedSize`, and `processedRange` to be updated. Setting `processFcns` to a cell array list of processing function names causes `processParams`, `processSettings`, `processedRange` to be updated. You can then alter the `processParam` values, if you want to.

Biases, Input Weights, and Layer Weights

Enter the following commands to see how bias and weight structures are arranged:

```
net.biases
net.inputWeights
net.layerWeights
```

Here are the results of typing `net.biases`:

```
ans =
    [1x1 nnetBias]
    []
    [1x1 nnetBias]
```

Each contains a structure where the corresponding connections (`net.biasConnect`, `net.inputConnect`, and `net.layerConnect`) contain a 1.

Look at their structures with these lines of code:

```
net.biases{1}
net.biases{3}
net.inputWeights{1,1}
net.inputWeights{2,1}
net.inputWeights{2,2}
net.layerWeights{3,1}
net.layerWeights{3,2}
net.layerWeights{3,3}
```

For example, typing `net.biases{1}` results in the following output:

```
    initFcn: (none)
      learn: true
   learnFcn: (none)
 learnParam: (none)
       size: 4
   userdata: (your custom info)
```

Specify the weights' tap delay lines in accordance with the network diagram by setting each weight's `delays` property:

```
net.inputWeights{2,1}.delays = [0 1];
net.inputWeights{2,2}.delays = 1;
net.layerWeights{3,3}.delays = 1;
```

Network Functions

Type `net` and press **Return** again to see the next set of properties.

```
functions:
      adaptFcn: (none)
    adaptParam: (none)
      derivFcn: 'defaultderiv'
     divideFcn: (none)
   divideParam: (none)
    divideMode: 'sample'
       initFcn: 'initlay'
    performFcn: 'mse'
  performParam: .regularization, .normalization
      plotFcns: {}
    plotParams: {1x0 cell array of 0 params}
      trainFcn: (none)
    trainParam: (none)
```

Each of these properties defines a function for a basic network operation.

Set the initialization function to `initlay` so the network initializes itself according to the layer initialization functions already set to `initnw`, the Nguyen-Widrow initialization function.

```
net.initFcn = 'initlay';
```

This meets the initialization requirement of the network.

Set the performance function to `mse` (mean squared error) and the training function to `trainlm` (Levenberg-Marquardt backpropagation) to meet the final requirement of the custom network.

```
net.performFcn = 'mse';
net.trainFcn = 'trainlm';
```

Set the divide function to `dividerand` (divide training data randomly).

```
net.divideFcn = 'dividerand';
```

During supervised training, the input and target data are randomly divided into training, test, and validation data sets. The network is trained on the training data until its performance begins to decrease on the validation data, which signals that generalization has peaked. The test data provides a completely independent test of network generalization.

Set the plot functions to `plotperform` (plot training, validation and test performance) and `plottrainstate` (plot the state of the training algorithm with respect to epochs).

```
net.plotFcns = {'plotperform','plottrainstate'};
```

Weight and Bias Values

Before initializing and training the network, type `net` and press **Return**, then look at the weight and bias group of network properties.

```
weight and bias values:
           IW: {3x2 cell} containing 3 input weight matrices
           LW: {3x3 cell} containing 3 layer weight matrices
            b: {3x1 cell} containing 2 bias vectors
```

These cell arrays contain weight matrices and bias vectors in the same positions that the connection properties (`net.inputConnect`, `net.layerConnect`, `net.biasConnect`) contain 1s and the subobject properties (`net.inputWeights`, `net.layerWeights`, `net.biases`) contain structures.

Evaluating each of the following lines of code reveals that all the bias vectors and weight matrices are set to zeros.

```
net.IW{1,1}, net.IW{2,1}, net.IW{2,2}
net.LW{3,1}, net.LW{3,2}, net.LW{3,3}
net.b{1}, net.b{3}
```

Each input weight `net.IW{i,j}`, layer weight `net.LW{i,j}`, and bias vector `net.b{i}` has as many rows as the size of the *i*th layer (`net.layers{i}.size`).

Each input weight `net.IW{i,j}` has as many columns as the size of the *j*th input (`net.inputs{j}.size`) multiplied by the number of its delay values (`length(net.inputWeights{i,j}.delays)`).

Likewise, each layer weight has as many columns as the size of the *j*th layer (`net.layers{j}.size`) multiplied by the number of its delay values (`length(net.layerWeights{i,j}.delays)`).

Network Behavior

Initialization

Initialize your network with the following line of code:

```
net = init(net);
```

Check the network's biases and weights again to see how they have changed:

```
net.IW{1,1}, net.IW{2,1}, net.IW{2,2}
net.LW{3,1}, net.LW{3,2}, net.LW{3,3}
net.b{1}, net.b{3}
```

For example,

```
net.IW{1,1}
ans =
   -0.3040    0.4703
   -0.5423   -0.1395
    0.5567    0.0604
    0.2667    0.4924
```

Training

Define the following cell array of two input vectors (one with two elements, one with five) for two time steps (i.e., two columns).

```
X = {[0; 0] [2; 0.5]; [2; -2; 1; 0; 1] [-1; -1; 1; 0; 1]};
```

You want the network to respond with the following target sequences for the second layer, which has three neurons, and the third layer with one neuron:

```
T = {[1; 1; 1] [0; 0; 0]; 1 -1};
```

Before training, you can simulate the network to see whether the initial network's response `Y` is close to the target `T`.

```
Y = sim(net,X)
Y =
```

```
    [3x1 double]    [3x1 double]
    [      1.7148]    [      2.2726]
```

The cell array Y is the output sequence of the network, which is also the output sequence of the second and third layers. The values you got for the second row can differ from those shown because of different initial weights and biases. However, they will almost certainly not be equal to targets T, which is also true of the values shown.

The next task is optional. On some occasions you may wish to alter the training parameters before training. The following line of code displays the default Levenberg-Marquardt training parameters (defined when you set `net.trainFcn` to `trainlm`).

```
net.trainParam
```

The following properties should be displayed.

```
ans =
    Show Training Window Feedback   showWindow: true
    Show Command Line Feedback showCommandLine: false
    Command Line Frequency                show: 25
    Maximum Epochs                      epochs: 1000
    Maximum Training Time                 time: Inf
    Performance Goal                      goal: 0
    Minimum Gradient                   min_grad: 1e-07
    Maximum Validation Checks          max_fail: 6
    Mu                                       mu: 0.001
    Mu Decrease Ratio                   mu_dec: 0.1
    Mu Increase Ratio                   mu_inc: 10
    Maximum mu                          mu_max: 10000000000
```

You will not often need to modify these values. See the documentation for the training function for information about what each of these means. They have been initialized with default values that work well for a large range of problems, so there is no need to change them here.

Next, train the network with the following call:

```
net = train(net,X,T);
```

Training launches the neural network training window. To open the performance and training state plots, click the plot buttons.

After training, you can simulate the network to see if it has learned to respond correctly:

```
Y = sim(net,X)

    [3x1 double]    [3x1 double]
    [      1.0000]    [     -1.0000]
```

The second network output (i.e., the second row of the cell array Y), which is also the third layer's output, matches the target sequence T.

Custom Neural Network Helper Functions

The toolbox allows you to create and use your own custom functions. This gives you a great deal of control over the algorithms used to initialize, simulate, and train your networks.

Be aware, however, that custom functions may need updating to remain compatible with future versions of the software. Backward compatibility of custom functions cannot be guaranteed.

Template functions are available for you to copy, rename and customize, to create your own versions of these kinds of functions. You can see the list of all template functions by typing the following:

```
help nncustom
```

Each template is a simple version of a different type of function that you can use with your own custom networks.

For instance, make a copy of the file `tansig.m` with the new name `mytransfer.m`. Start editing the new file by changing the function name a the top from `tansig` to `mytransfer`.

You can now edit each of the sections of code that make up a transfer function, using the help comments in each of those sections to guide you.

Once you are done, store the new function in your working folder, and assign the name of your transfer function to the `transferFcn` property of any layer of any network object to put it to use.

Automatically Save Checkpoints During Neural Network Training

During neural network training, intermediate results can be periodically saved to a MAT file for recovery if the computer fails or you kill the training process. This helps protect the value of long training runs, which if interrupted would need to be completely restarted otherwise. This feature is especially useful for long parallel training sessions, which are more likely to be interrupted by computing resource failures.

Checkpoint saves are enabled with the optional `'CheckpointFile'` training argument followed by the checkpoint file name or path. If you specify only a file name, the file is placed in the working directory by default. The file must have the `.mat` file extension, but if this is not specified it is automatically appended. In this example, checkpoint saves are made to the file called `MyCheckpoint.mat` in the current working directory.

```
[x,t] = bodyfat_dataset;
net = feedforwardnet(10);
net2 = train(net,x,t,'CheckpointFile','MyCheckpoint.mat');
```

```
22-Mar-2013 04:49:05 First Checkpoint #1: /WorkingDir/MyCheckpoint.mat
22-Mar-2013 04:49:06 Final Checkpoint #2: /WorkingDir/MyCheckpoint.mat
```

By default, checkpoint saves occur at most once every 60 seconds. For the previous short training example, this results in only two checkpoint saves: one at the beginning and one at the end of training.

The optional training argument `'CheckpointDelay'` can change the frequency of saves. For example, here the minimum checkpoint delay is set to 10 seconds for a time-series problem where a neural network is trained to model a levitated magnet.

```
[x,t] = maglev_dataset;
net = narxnet(1:2,1:2,10);
[X,Xi,Ai,T] = preparets(net,x,{},t);
net2 = train(net,X,T,Xi,Ai,'CheckpointFile','MyCheckpoint.mat','CheckpointDelay',10);
```

```
22-Mar-2013 04:59:28 First Checkpoint #1: /WorkingDir/MyCheckpoint.mat
22-Mar-2013 04:59:38 Write Checkpoint #2: /WorkingDir/MyCheckpoint.mat
22-Mar-2013 04:59:48 Write Checkpoint #3: /WorkingDir/MyCheckpoint.mat
22-Mar-2013 04:59:58 Write Checkpoint #4: /WorkingDir/MyCheckpoint.mat
22-Mar-2013 05:00:08 Write Checkpoint #5: /WorkingDir/MyCheckpoint.mat
22-Mar-2013 05:00:09 Final Checkpoint #6: /WorkingDir/MyCheckpoint.mat
```

After a computer failure or training interruption, you can reload the checkpoint structure containing the best neural network obtained before the interruption, and the training record. In this case, the `stage` field value is `'Final'`, indicating the last save was at the final epoch because training completed successfully. The first epoch checkpoint is indicated by `'First'`, and intermediate checkpoints by `'Write'`.

```
load('MyCheckpoint.mat')
```

```
checkpoint =

      file: '/WorkdingDir/MyCheckpoint.mat'
      time: [2013 3 22 5 0 9.0712]
    number: 6
     stage: 'Final'
       net: [1x1 network]
        tr: [1x1 struct]
```

You can resume training from the last checkpoint by reloading the dataset (if necessary), then calling train with the recovered network.

```
net = checkpoint.net;
[x,t] = maglev_dataset;
load('MyCheckpoint.mat');
[X,Xi,Ai,T] = preparets(net,x,{},t);
net2 = train(net,X,T,Xi,Ai,'CheckpointFile','MyCheckpoint.mat','CheckpointDelay',10);
```

Deploy Shallow Neural Network Functions

In this section...

Deployment Functions and Tools for Trained Networks

The function `genFunction` allows stand-alone MATLAB functions for a trained shallow neural network. The generated code contains all the information needed to simulate a neural network, including settings, weight and bias values, module functions, and calculations.

The generated MATLAB function can be used to inspect the exact simulation calculations that a particular shallow neural network performs, and makes it easier to deploy neural networks for many purposes with a wide variety of MATLAB deployment products and tools.

The function `genFunction` is used by the **Neural Net Fitting**, **Neural Net Pattern Recognition**, **Neural Net Clustering** and **Neural Net Time Series** apps. For information on these apps, see “Fit Data with a Shallow Neural Network”, “Classify Patterns with a Shallow Neural Network”, “Cluster Data with a Self-Organizing Map”, and “Shallow Neural Network Time-Series Prediction and Modeling”.

The comprehensive scripts generated by these apps includes an example of deploying networks with `genFunction`.

Generate Neural Network Functions for Application Deployment

The function `genFunction` generates a stand-alone MATLAB function for simulating any trained shallow neural network and preparing it for deployment. This might be useful for several tasks:

- Document the input-output transforms of a neural network used as a calculation template for manual reimplementations of the network
- Use the MATLAB Function block to create a Simulink block
- Use MATLAB Compiler to:
  - Generate stand-alone executables
  - Generate Excel® add-ins
- Use MATLAB Compiler SDK™ to:
  - Generate C/C++ libraries
  - Generate .COM components
  - Generate Java® components
  - Generate .NET components
- Use MATLAB Coder to:
  - Generate C/C++ code

- Generate efficient MEX-functions

`genFunction(net,'pathname')` takes a neural network and file path, and produces a standalone MATLAB function file `filename.m`.

`genFunction(...,'MatrixOnly','yes')` overrides the default cell/matrix notation and instead generates a function that uses only matrix arguments compatible with MATLAB Coder tools. For static networks, the matrix columns are interpreted as independent samples. For dynamic networks, the matrix columns are interpreted as a series of time steps. The default value is `'no'`.

`genFunction(___,'ShowLinks','no')` disables the default behavior of displaying links to generated help and source code. The default is `'yes'`.

Here a static network is trained and its outputs calculated.

```
[x, t] = bodyfat_dataset;
bodyfatNet = feedforwardnet(10);
bodyfatNet = train(bodyfatNet, x, t);
y = bodyfatNet(x);
```

The following code generates, tests, and displays a MATLAB function with the same interface as the neural network object.

```
genFunction(bodyfatNet, 'bodyfatFcn');
y2 = bodyfatFcn(x);
accuracy2 = max(abs(y - y2))
edit bodyfatFcn
```

You can compile the new function with the MATLAB Compiler tools (license required) to a shared/dynamically linked library with `mcc`.

```
mcc -W lib:libBodyfat -T link:lib bodyfatFcn
```

The next code generates another version of the MATLAB function that supports only matrix arguments (no cell arrays). This function is tested. Then it is used to generate a MEX-function with the MATLAB Coder tool `codegen` (license required), which is also tested.

```
genFunction(bodyfatNet, 'bodyfatFcn', 'MatrixOnly', 'yes');
y3 = bodyfatFcn(x);
accuracy3 = max(abs(y - y3))

x1Type = coder.typeof(double(0), [13, Inf]); % Coder type of input 1
codegen bodyfatFcn.m -config:mex -o bodyfatCodeGen -args {x1Type}
y4 = bodyfatCodeGen(x);
accuracy4 = max(abs(y - y4))
```

Here a dynamic network is trained and its outputs calculated.

```
[x,t] = maglev_dataset;
maglevNet = narxnet(1:2,1:2,10);
[X,Xi,Ai,T] = preparets(maglevNet,x,{},t);
maglevNet = train(maglevNet,X,T,Xi,Ai);
[y,xf,af] = maglevNet(X,Xi,Ai);
```

Next a MATLAB function is generated and tested. The function is then used to create a shared/dynamically linked library with `mcc`.

```
genFunction(maglevNet,'maglevFcn');
[y2,xf,af] = maglevFcn(X,Xi,Ai);
```

```
accuracy2 = max(abs(cell2mat(y)-cell2mat(y2)))
mcc -W lib:libMaglev -T link:lib maglevFcn
```

The following code generates another version of the MATLAB function that supports only matrix arguments (no cell arrays). This function is tested. Then it is used to generate a MEX-function with the MATLAB Coder tool `codegen`, which is also tested.

```
genFunction(maglevNet,'maglevFcn','MatrixOnly','yes');
x1 = cell2mat(X(1,:)); % Convert each input to matrix
x2 = cell2mat(X(2,:));
xi1 = cell2mat(Xi(1,:)); % Convert each input state to matrix
xi2 = cell2mat(Xi(2,:));
[y3,xf1,xf2] = maglevFcn(x1,x2,xi1,xi2);
accuracy3 = max(abs(cell2mat(y)-y3))

x1Type = coder.typeof(double(0),[1 Inf]); % Coder type of input 1
x2Type = coder.typeof(double(0),[1 Inf]); % Coder type of input 2
xi1Type = coder.typeof(double(0),[1 2]); % Coder type of input 1 states
xi2Type = coder.typeof(double(0),[1 2]); % Coder type of input 2 states
codegen maglevFcn.m -config:mex -o maglevNetCodeGen ...
                    -args {x1Type x2Type xi1Type xi2Type}
[y4,xf1,xf2] = maglevNetCodeGen(x1,x2,xi1,xi2);
dynamic_codegen_accuracy = max(abs(cell2mat(y)-y4))
```

Generate Simulink Diagrams

For information on simulating shallow neural networks and deploying trained neural networks with Simulink tools, see “Deploy Shallow Neural Network Simulink Diagrams” on page B-5.

Deploy Training of Shallow Neural Networks

Tip To learn about code generation for deep learning, see “Deep Learning Code Generation”.

Use MATLAB Runtime to deploy functions that can train a model. You can deploy MATLAB code that trains neural networks as described in “Create Standalone Application from MATLAB” (MATLAB Compiler).

The following methods and functions are NOT supported in deployed mode:

- Training progress dialog, `nntraintool`.
- `genFunction` and `gensim` to generate MATLAB code or Simulink blocks
- `view` method
- `nctool`, `nftool`, `nnstart`, `nprtool`, `ntstool`
- Plot functions (such as `plotperform`, `plottrainstate`, `ploterrhist`, `plotregression`, `plotfit`, and so on)
- `perceptron`, `newlind`, and `elmannet` functions.

Here is an example of how you can deploy training of a network. Create a script to train a neural network, for example, `mynntraining.m`:

```
% Create the predictor and response (target)
x = [0.054 0.78 0.13 0.47 0.34 0.79 0.53 0.6 0.65 0.75 0.084 0.91 0.83
     0.53 0.93 0.57 0.012 0.16 0.31 0.17 0.26 0.69 0.45 0.23 0.15 0.54];
t = [0.46 0.079 0.42 0.48 0.95 0.63 0.48 0.51 0.16 0.51 1 0.28 0.3];
% Create and display the network
net = fitnet();
disp('Training fitnet')
% Train the network using the data in x and t
net = train(net,x,t);
% Predict the responses using the trained network
y = net(x);
% Measure the performance
perf = perform(net,y,t)
```

Compile the script `mynntraining.m` by using the command line:

```
mcc -m 'mynntraining.m'
```

`mcc` invokes the MATLAB Compiler to compile code at the prompt. The flag `–m` compiles a MATLAB function and generates a standalone executable. The EXE file is now in your local computer in the working directory.

To run the compiled EXE application on computers that do not have MATLAB installed, you need to download and install MATLAB Runtime. The `readme.txt` created in your working folder has more information about the deployment requirements.

Historical Neural Networks

Historical Neural Networks Overview

This section covers networks that are of historical interest, but that are not as actively used today as networks presented in other sections. Two of the networks are single-layer networks that were the first neural networks for which practical training algorithms were developed: perceptron networks and ADALINE networks.

The perceptron network is a single-layer network whose weights and biases can be trained to produce a correct target vector when presented with the corresponding input vector. This perceptron rule was the first training algorithm developed for neural networks. The original book on the perceptron is Rosenblatt, F., *Principles of Neurodynamics*, Washington D.C., Spartan Press, 1961 [Rose61 on page 32-2].

At about the same time that Rosenblatt developed the perceptron network, Widrow and Hoff developed a single-layer linear network and associated learning rule, which they called the ADALINE (Adaptive Linear Neuron). This network was used to implement adaptive filters, which are still actively used today. The original paper describing this network is Widrow, B., and M.E. Hoff, "Adaptive switching circuits," *1960 IRE WESCON Convention Record, New York IRE*, 1960, pp. 96–104.

Perceptron Neural Networks

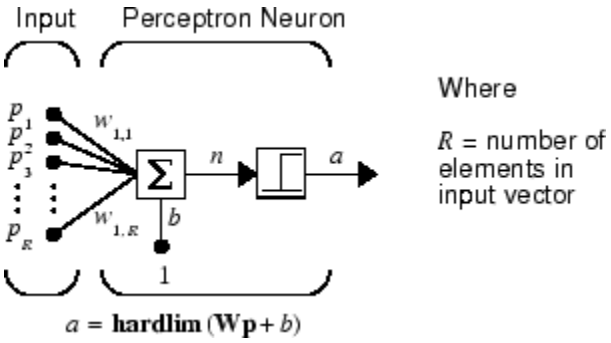
In this section...

Rosenblatt [Rose61 on page 32-2] created many variations of the perceptron. One of the simplest was a single-layer network whose weights and biases could be trained to produce a correct target vector when presented with the corresponding input vector. The training technique used is called the perceptron learning rule. The perceptron generated great interest due to its ability to generalize from its training vectors and learn from initially randomly distributed connections. Perceptrons are especially suited for simple problems in pattern classification. They are fast and reliable networks for the problems they can solve. In addition, an understanding of the operations of the perceptron provides a good basis for understanding more complex networks.

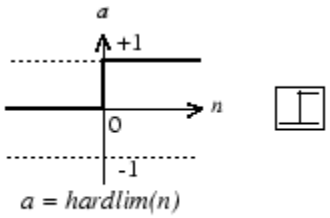
The discussion of perceptrons in this section is necessarily brief. For a more thorough discussion, see Chapter 4, “Perceptron Learning Rule,” of [HDB1996 on page 32-2], which discusses the use of multiple layers of perceptrons to solve more difficult problems beyond the capability of one layer.

Neuron Model

A perceptron neuron, which uses the hard-limit transfer function `hardlim`, is shown below.



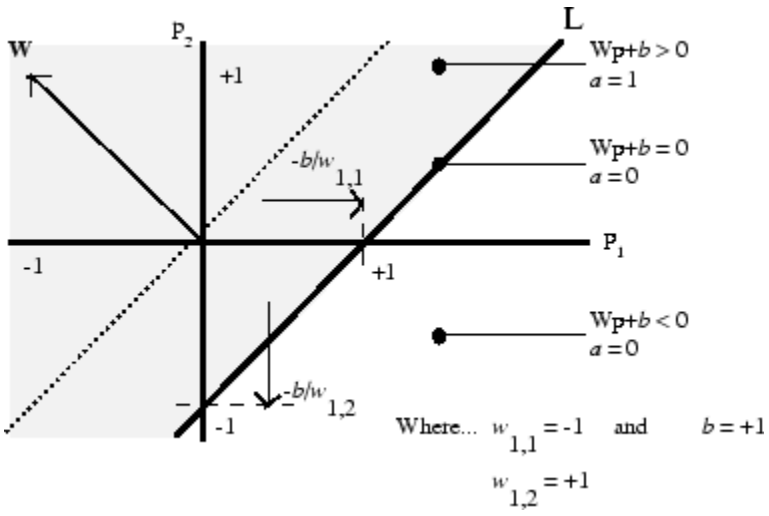
Each external input is weighted with an appropriate weight w_{1j}, and the sum of the weighted inputs is sent to the hard-limit transfer function, which also has an input of 1 transmitted to it through the bias. The hard-limit transfer function, which returns a 0 or a 1, is shown below.



Hard-Limit Transfer Function

The perceptron neuron produces a 1 if the net input into the transfer function is equal to or greater than 0; otherwise it produces a 0.

The hard-limit transfer function gives a perceptron the ability to classify input vectors by dividing the input space into two regions. Specifically, outputs will be 0 if the net input n is less than 0, or 1 if the net input n is 0 or greater. The following figure show the input space of a two-input hard limit neuron with the weights $w_{1,1} = -1$, $w_{1,2} = 1$ and a bias $b = 1$.



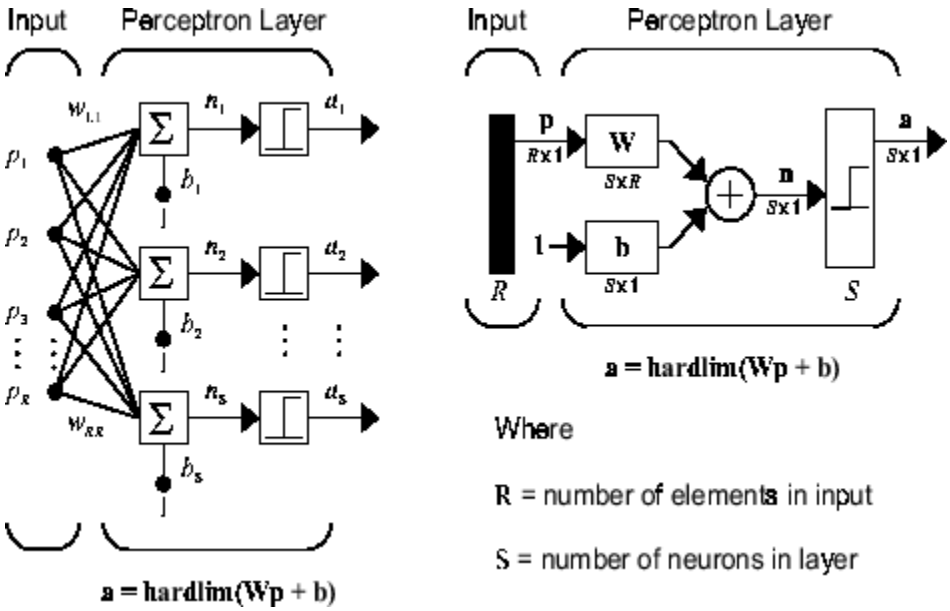
Two classification regions are formed by the *decision boundary* line L at **Wp** + b = 0. This line is perpendicular to the weight matrix **W** and shifted according to the bias b. Input vectors above and to the left of the line L will result in a net input greater than 0 and, therefore, cause the hard-limit neuron to output a 1. Input vectors below and to the right of the line L cause the neuron to output 0. You can pick weight and bias values to orient and move the dividing line so as to classify the input space as desired.

Hard-limit neurons without a bias will always have a classification line going through the origin. Adding a bias allows the neuron to solve problems where the two sets of input vectors are not located on different sides of the origin. The bias allows the decision boundary to be shifted away from the origin, as shown in the plot above.

You might want to run the example program nnd4db. With it you can move a decision boundary around, pick new inputs to classify, and see how the repeated application of the learning rule yields a network that does classify the input vectors properly.

Perceptron Architecture

The perceptron network consists of a single layer of S perceptron neurons connected to R inputs through a set of weights $w_{i,j}$, as shown below in two forms. As before, the network indices i and j indicate that $w_{i,j}$ is the strength of the connection from the jth input to the ith neuron.



The perceptron learning rule described shortly is capable of training only a single layer. Thus only one-layer networks are considered here. This restriction places limitations on the computation a perceptron can perform. The types of problems that perceptrons are capable of solving are discussed in “Limitations and Cautions” on page 29-12.

Create a Perceptron

You can create a perceptron with the following:

```
net = perceptron;
net = configure(net,P,T);
```

where input arguments are as follows:

- `P` is an R-by-Q matrix of Q input vectors of R elements each.
- `T` is an S-by-Q matrix of Q target vectors of S elements each.

Commonly, the `hardlim` function is used in perceptrons, so it is the default.

The following commands create a perceptron network with a single one-element input vector with the values 0 and 2, and one neuron with outputs that can be either 0 or 1:

```
P = [0 2];
T = [0 1];
net = perceptron;
net = configure(net,P,T);
```

You can see what network has been created by executing the following command:

```
inputweights = net.inputweights{1,1}
```

which yields

```
inputweights =
        delays: 0
```

```
       initFcn: 'initzero'
         learn: true
      learnFcn: 'learnp'
    learnParam: (none)
          size: [1 1]
     weightFcn: 'dotprod'
   weightParam: (none)
      userdata: (your custom info)
```

The default learning function is `learnp`, which is discussed in “Perceptron Learning Rule (learnp)” on page 29-6. The net input to the `hardlim` transfer function is `dotprod`, which generates the product of the input vector and weight matrix and adds the bias to compute the net input.

The default initialization function `initzero` is used to set the initial values of the weights to zero.

Similarly,

```
biases = net.biases{1}
```

gives

```
biases =
       initFcn: 'initzero'
         learn: 1
      learnFcn: 'learnp'
    learnParam: []
          size: 1
      userdata: [1x1 struct]
```

You can see that the default initialization for the bias is also 0.

Perceptron Learning Rule (learnp)

Perceptrons are trained on examples of desired behavior. The desired behavior can be summarized by a set of input, output pairs

$$\mathbf{p}_1\mathbf{t}_1, \mathbf{p}_2\mathbf{t}_1, \ldots, \mathbf{p}_Q\mathbf{t}_Q$$

where **p** is an input to the network and **t** is the corresponding correct (target) output. The objective is to reduce the error **e**, which is the difference $\mathbf{t} - \mathbf{a}$ between the neuron response **a** and the target vector **t**. The perceptron learning rule `learnp` calculates desired changes to the perceptron's weights and biases, given an input vector **p** and the associated error **e**. The target vector **t** must contain values of either 0 or 1, because perceptrons (with `hardlim` transfer functions) can only output these values.

Each time `learnp` is executed, the perceptron has a better chance of producing the correct outputs. The perceptron rule is proven to converge on a solution in a finite number of iterations if a solution exists.

If a bias is not used, `learnp` works to find a solution by altering only the weight vector **w** to point toward input vectors to be classified as 1 and away from vectors to be classified as 0. This results in a decision boundary that is perpendicular to **w** and that properly classifies the input vectors.

There are three conditions that can occur for a single neuron once an input vector **p** is presented and the network's response **a** is calculated:

CASE 1. If an input vector is presented and the output of the neuron is correct (**a** = **t** and **e** = **t** – **a** = 0), then the weight vector **w** is not altered.

CASE 2. If the neuron output is 0 and should have been 1 (**a** = 0 and **t** = 1, and **e** = **t** – **a** = 1), the input vector **p** is added to the weight vector **w**. This makes the weight vector point closer to the input vector, increasing the chance that the input vector will be classified as a 1 in the future.

CASE 3. If the neuron output is 1 and should have been 0 (**a** = 1 and **t** = 0, and **e** = **t** – **a** = –1), the input vector **p** is subtracted from the weight vector **w**. This makes the weight vector point farther away from the input vector, increasing the chance that the input vector will be classified as a 0 in the future.

The perceptron learning rule can be written more succinctly in terms of the error **e** = **t** – **a** and the change to be made to the weight vector Δ**w**:

CASE 1. If **e** = 0, then make a change Δ**w** equal to 0.

CASE 2. If **e** = 1, then make a change Δ**w** equal to $\mathbf{p}^T$.

CASE 3. If **e** = –1, then make a change Δ**w** equal to $-\mathbf{p}^T$.

All three cases can then be written with a single expression:

$$\Delta\mathbf{w} = (t - a)\mathbf{p}^T = e\mathbf{p}^T$$

You can get the expression for changes in a neuron's bias by noting that the bias is simply a weight that always has an input of 1:

$$\Delta b = (t - a)(1) = e$$

For the case of a layer of neurons you have

$$\Delta\mathbf{W} = (\mathbf{t} - \mathbf{a})(\mathbf{p})^T = \mathbf{e}(\mathbf{p})^T$$

and

$$\Delta\mathbf{b} = (\mathbf{t} - \mathbf{a}) = e$$

The perceptron learning rule can be summarized as follows:

$$\mathbf{W}^{new} = \mathbf{W}^{old} + \mathbf{e}\mathbf{p}^T$$

and

$$\mathbf{b}^{new} = \mathbf{b}^{old} + \mathbf{e}$$

where **e** = **t** – **a**.

Now try a simple example. Start with a single neuron having an input vector with just two elements.

```
net = perceptron;
net = configure(net,[0;0],0);
```

To simplify matters, set the bias equal to 0 and the weights to 1 and -0.8:

```
net.b{1} =  [0];
w = [1 -0.8];
net.IW{1,1} = w;
```

The input target pair is given by

```
p = [1; 2];
t = [1];
```

You can compute the output and error with

```
a = net(p)
a =
     0
e = t-a
e =
     1
```

and use the function `learnp` to find the change in the weights.

```
dw = learnp(w,p,[],[],[],[],e,[],[],[],[],[])
dw =
     1     2
```

The new weights, then, are obtained as

```
w = w + dw
w =
    2.0000    1.2000
```

The process of finding new weights (and biases) can be repeated until there are no errors. Recall that the perceptron learning rule is guaranteed to converge in a finite number of steps for all problems that can be solved by a perceptron. These include all classification problems that are linearly separable. The objects to be classified in such cases can be separated by a single line.

You might want to try the example `nnd4pr`. It allows you to pick new input vectors and apply the learning rule to classify them.

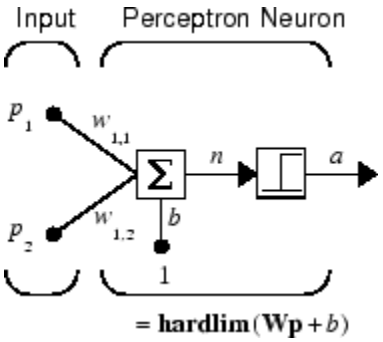
Training (train)

If `sim` and `learnp` are used repeatedly to present inputs to a perceptron, and to change the perceptron weights and biases according to the error, the perceptron will eventually find weight and bias values that solve the problem, given that the perceptron *can* solve it. Each traversal through all the training input and target vectors is called a *pass*.

The function `train` carries out such a loop of calculation. In each pass the function `train` proceeds through the specified sequence of inputs, calculating the output, error, and network adjustment for each input vector in the sequence as the inputs are presented.

Note that `train` does not guarantee that the resulting network does its job. You must check the new values of **W** and **b** by computing the network output for each input vector to see if all targets are reached. If a network does not perform successfully you can train it further by calling `train` again with the new weights and biases for more training passes, or you can analyze the problem to see if it is a suitable problem for the perceptron. Problems that cannot be solved by the perceptron network are discussed in “Limitations and Cautions” on page 29-12.

To illustrate the training procedure, work through a simple problem. Consider a one-neuron perceptron with a single vector input having two elements:



This network, and the problem you are about to consider, are simple enough that you can follow through what is done with hand calculations if you want. The problem discussed below follows that found in [HDB1996 on page 32-2].

Suppose you have the following classification problem and would like to solve it with a single vector input, two-element perceptron network.

$$\left\{\mathbf{p}_1 = \begin{bmatrix}2\\2\end{bmatrix}, t_1 = 0\right\}\left\{\mathbf{p}_2 = \begin{bmatrix}1\\-2\end{bmatrix}, t_2 = 1\right\}\left\{\mathbf{p}_3 = \begin{bmatrix}-2\\2\end{bmatrix}, t_3 = 0\right\}\left\{\mathbf{p}_4 = \begin{bmatrix}-1\\1\end{bmatrix}, t_4 = 1\right\}$$

Use the initial weights and bias. Denote the variables at each step of this calculation by using a number in parentheses after the variable. Thus, above, the initial values are $\mathbf{W}(0)$ and $b(0)$.

$$\mathbf{W}(0) = [0\ \ 0]\ \ b(0) = 0$$

Start by calculating the perceptron's output a for the first input vector $\mathbf{p}_1$, using the initial weights and bias.

$$a = hardlim(\mathbf{W}(0)\mathbf{p}_1 + b(0))$$
$$= hardlim\left([0\ \ 0]\begin{bmatrix}2\\2\end{bmatrix} + 0\right) = hardlim(0) = 1$$

The output a does not equal the target value t_1, so use the perceptron rule to find the incremental changes to the weights and biases based on the error.

$$e = t_1 - a = 0 - 1 = -1$$
$$\Delta\mathbf{W} = e\mathbf{p}_1^T = (-1)[2\ \ 2] = [-2\ \ -2]$$
$$\Delta b = e = (-1) = -1$$

You can calculate the new weights and bias using the perceptron update rules.

$$\mathbf{W}^{new} = \mathbf{W}^{old} + \mathbf{e}\mathbf{p}^T = [0\ \ 0] + [-2\ \ -2] = [-2\ \ -2] = \mathbf{W}(1)$$
$$b^{new} = b^{old} + e = 0 + (-1) = -1 = b(1)$$

Now present the next input vector, $\mathbf{p}_2$. The output is calculated below.

$$\alpha = hardlim(\mathbf{W}(1)\mathbf{p}_2 + b(1))$$
$$= hardlim\left([-2\ -2]\begin{bmatrix}1\\-2\end{bmatrix} - 1\right) = hardlim(1) = 1$$

On this occasion, the target is 1, so the error is zero. Thus there are no changes in weights or bias, so $\mathbf{W}(2) = \mathbf{W}(1) = [-2\ -2]$ and $b(2) = b(1) = -1$.

You can continue in this fashion, presenting $\mathbf{p}_3$ next, calculating an output and the error, and making changes in the weights and bias, etc. After making one pass through all of the four inputs, you get the values $\mathbf{W}(4) = [-3\ -1]$ and $b(4) = 0$. To determine whether a satisfactory solution is obtained, make one pass through all input vectors to see if they all produce the desired target values. This is not true for the fourth input, but the algorithm does converge on the sixth presentation of an input. The final values are

$\mathbf{W}(6) = [-2\ -3]$ and $b(6) = 1$.

This concludes the hand calculation. Now, how can you do this using the `train` function?

The following code defines a perceptron.

```
net = perceptron;
```

Consider the application of a single input

```
p = [2; 2];
```

having the target

```
t = [0];
```

Set `epochs` to 1, so that `train` goes through the input vectors (only one here) just one time.

```
net.trainParam.epochs = 1;
net = train(net,p,t);
```

The new weights and bias are

```
w = net.iw{1,1}, b = net.b{1}
w =
    -2    -2
b =
    -1
```

Thus, the initial weights and bias are 0, and after training on only the first vector, they have the values $[-2\ -2]$ and -1, just as you hand calculated.

Now apply the second input vector $\mathbf{p}_2$. The output is 1, as it will be until the weights and bias are changed, but now the target is 1, the error will be 0, and the change will be zero. You could proceed in this way, starting from the previous result and applying a new input vector time after time. But you can do this job automatically with `train`.

Apply `train` for one epoch, a single pass through the sequence of all four input vectors. Start with the network definition.

```
net = perceptron;
net.trainParam.epochs = 1;
```

The input vectors and targets are

```
p = [[2;2] [1;-2] [-2;2] [-1;1]]
t = [0 1 0 1]
```

Now train the network with

```
net = train(net,p,t);
```

The new weights and bias are

```
w = net.iw{1,1}, b = net.b{1}
w =
    -3    -1
b =
     0
```

This is the same result as you got previously by hand.

Finally, simulate the trained network for each of the inputs.

```
a = net(p)
a =
      0     0     1     1
```

The outputs do not yet equal the targets, so you need to train the network for more than one pass. Try more epochs. This run gives a mean absolute error performance of 0 after two epochs:

```
net.trainParam.epochs = 1000;
net = train(net,p,t);
```

Thus, the network was trained by the time the inputs were presented on the third epoch. (As you know from hand calculation, the network converges on the presentation of the sixth input vector. This occurs in the middle of the second epoch, but it takes the third epoch to detect the network convergence.) The final weights and bias are

```
w = net.iw{1,1}, b = net.b{1}
w =
    -2    -3
b =
     1
```

The simulated output and errors for the various inputs are

```
a = net(p)
a =
             0             1             0             1
error = a-t
error =
             0             0             0             0
```

You confirm that the training procedure is successful. The network converges and produces the correct target outputs for the four input vectors.

The default training function for networks created with `perceptron` is `trainc`. (You can find this by executing `net.trainFcn`.) This training function applies the perceptron learning rule in its pure form, in that individual input vectors are applied individually, in sequence, and corrections to the weights and bias are made after each presentation of an input vector. Thus, perceptron training with

`train` will converge in a finite number of steps unless the problem presented cannot be solved with a simple perceptron.

The function `train` can be used in various ways by other networks as well. Type `help train` to read more about this basic function.

You might want to try various example programs. For instance, “Classification with a Two-Input Perceptron” on page 31-141 illustrates classification and training of a simple perceptron.

Limitations and Cautions

Perceptron networks should be trained with `adapt`, which presents the input vectors to the network one at a time and makes corrections to the network based on the results of each presentation. Use of `adapt` in this way guarantees that any linearly separable problem is solved in a finite number of training presentations.

As noted in the previous pages, perceptrons can also be trained with the function `train`. Commonly when `train` is used for perceptrons, it presents the inputs to the network in batches, and makes corrections to the network based on the sum of all the individual corrections. Unfortunately, there is no proof that such a training algorithm converges for perceptrons. On that account the use of `train` for perceptrons is not recommended.

Perceptron networks have several limitations. First, the output values of a perceptron can take on only one of two values (0 or 1) because of the hard-limit transfer function. Second, perceptrons can only classify linearly separable sets of vectors. If a straight line or a plane can be drawn to separate the input vectors into their correct categories, the input vectors are linearly separable. If the vectors are not linearly separable, learning will never reach a point where all vectors are classified properly. However, it has been proven that if the vectors are linearly separable, perceptrons trained adaptively will always find a solution in finite time. You might want to try “Linearly Non-separable Vectors” on page 31-158. It shows the difficulty of trying to classify input vectors that are not linearly separable.

It is only fair, however, to point out that networks with more than one perceptron can be used to solve more difficult problems. For instance, suppose that you have a set of four vectors that you would like to classify into distinct groups, and that two lines can be drawn to separate them. A two-neuron network can be found such that its two decision boundaries classify the inputs into four categories. For additional discussion about perceptrons and to examine more complex perceptron problems, see [HDB1996 on page 32-2].

Outliers and the Normalized Perceptron Rule

Long training times can be caused by the presence of an *outlier* input vector whose length is much larger or smaller than the other input vectors. Applying the perceptron learning rule involves adding and subtracting input vectors from the current weights and biases in response to error. Thus, an input vector with large elements can lead to changes in the weights and biases that take a long time for a much smaller input vector to overcome. You might want to try “Outlier Input Vectors” on page 31-146 to see how an outlier affects the training.

By changing the perceptron learning rule slightly, you can make training times insensitive to extremely large or small outlier input vectors.

Here is the original rule for updating weights:

$$\Delta \mathbf{w} = (t - a)\mathbf{p}^T = e\mathbf{p}^T$$

As shown above, the larger an input vector **p**, the larger its effect on the weight vector **w**. Thus, if an input vector is much larger than other input vectors, the smaller input vectors must be presented many times to have an effect.

The solution is to normalize the rule so that the effect of each input vector on the weights is of the same magnitude:

$$\Delta\mathbf{w} = (t - \alpha)\frac{\mathbf{p}^T}{\|\mathbf{p}\|} = e\frac{\mathbf{p}^T}{\|\mathbf{p}\|}$$

The normalized perceptron rule is implemented with the function `learnpn`, which is called exactly like `learnp`. The normalized perceptron rule function `learnpn` takes slightly more time to execute, but reduces the number of epochs considerably if there are outlier input vectors. You might try “Normalized Perceptron Rule” on page 31-152 to see how this normalized training rule works.

Linear Neural Networks

In this section...

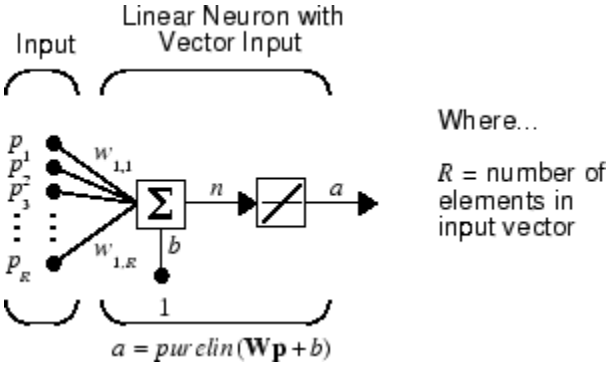
The linear networks discussed in this section are similar to the perceptron, but their transfer function is linear rather than hard-limiting. This allows their outputs to take on any value, whereas the perceptron output is limited to either 0 or 1. Linear networks, like the perceptron, can only solve linearly separable problems.

Here you design a linear network that, when presented with a set of given input vectors, produces outputs of corresponding target vectors. For each input vector, you can calculate the network's output vector. The difference between an output vector and its target vector is the error. You would like to find values for the network weights and biases such that the sum of the squares of the errors is minimized or below a specific value. This problem is manageable because linear systems have a single error minimum. In most cases, you can calculate a linear network directly, such that its error is a minimum for the given input vectors and target vectors. In other cases, numerical problems prohibit direct calculation. Fortunately, you can always train the network to have a minimum error by using the least mean squares (Widrow-Hoff) algorithm.

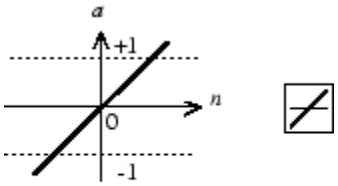
This section introduces `linearlayer`, a function that creates a linear layer, and `newlind`, a function that designs a linear layer for a specific purpose.

Neuron Model

A linear neuron with R inputs is shown below.



This network has the same basic structure as the perceptron. The only difference is that the linear neuron uses a linear transfer function `purelin`.



Linear Transfer Function

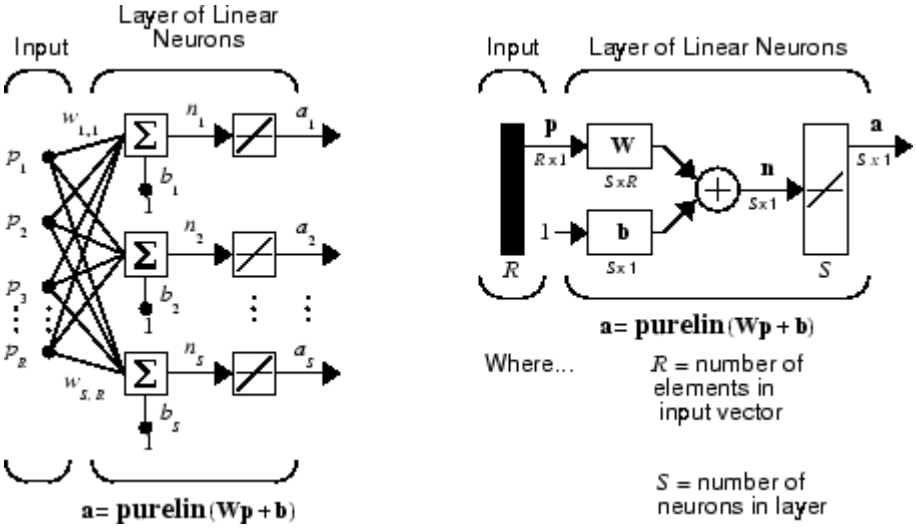
The linear transfer function calculates the neuron's output by simply returning the value passed to it.

$$\alpha = purelin(n) = purelin(\mathbf{Wp} + b) = \mathbf{Wp} + b$$

This neuron can be trained to learn an affine function of its inputs, or to find a linear approximation to a nonlinear function. A linear network cannot, of course, be made to perform a nonlinear computation.

Network Architecture

The linear network shown below has one layer of S neurons connected to R inputs through a matrix of weights **W**.

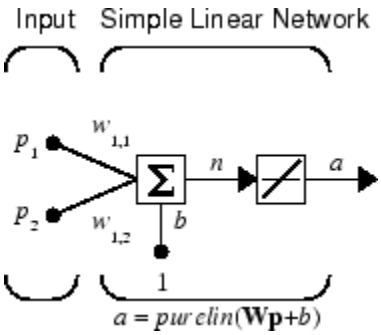


Note that the figure on the right defines an S-length output vector **a**.

A single-layer linear network is shown. However, this network is just as capable as multilayer linear networks. For every multilayer linear network, there is an equivalent single-layer linear network.

Create a Linear Neuron (linearlayer)

Consider a single linear neuron with two inputs. The following figure shows the diagram for this network.



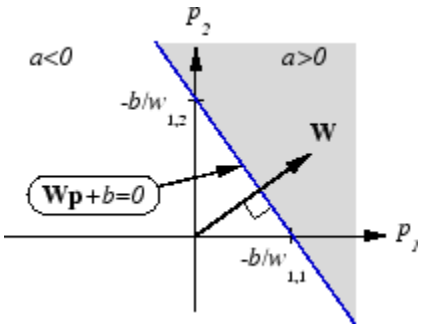
The weight matrix **W** in this case has only one row. The network output is

$$\alpha = purelin(n) = purelin(\mathbf{Wp} + b) = \mathbf{Wp} + b$$

or

$$\alpha = w_{1,1}p_1 + w_{1,2}p_2 + b$$

Like the perceptron, the linear network has a *decision boundary* that is determined by the input vectors for which the net input n is zero. For $n = 0$ the equation $\mathbf{Wp} + b = 0$ specifies such a decision boundary, as shown below (adapted with thanks from [HDB96 on page 32-2]).



Input vectors in the upper right gray area lead to an output greater than 0. Input vectors in the lower left white area lead to an output less than 0. Thus, the linear network can be used to classify objects into two categories. However, it can classify in this way only if the objects are linearly separable. Thus, the linear network has the same limitation as the perceptron.

You can create this network using `linearlayer`, and configure its dimensions with two values so the input has two elements and the output has one.

```
net = linearlayer;
net = configure(net,[0;0],0);
```

The network weights and biases are set to zero by default. You can see the current values with the commands

```
W = net.IW{1,1}
W =
     0     0
```

and

```
b= net.b{1}
b =
     0
```

However, you can give the weights any values that you want, such as 2 and 3, respectively, with

```
net.IW{1,1} = [2 3];
W = net.IW{1,1}
W =
     2     3
```

You can set and check the bias in the same way.

```
net.b{1} = [-4];
b = net.b{1}
b =
     -4
```

You can simulate the linear network for a particular input vector. Try

```
p = [5;6];
```

You can find the network output with the function `sim`.

```
a = net(p)
a =
    24
```

To summarize, you can create a linear network with `linearlayer`, adjust its elements as you want, and simulate it with `sim`.

Least Mean Square Error

Like the perceptron learning rule, the least mean square error (LMS) algorithm is an example of supervised training, in which the learning rule is provided with a set of examples of desired network behavior:

$$\{\mathbf{p}_1, \mathbf{t}_1\}, \{\mathbf{p}_2, \mathbf{t}_2\}, \ldots \{\mathbf{p}_Q, \mathbf{t}_Q\}$$

Here $\mathbf{p}_q$ is an input to the network, and $\mathbf{t}_q$ is the corresponding target output. As each input is applied to the network, the network output is compared to the target. The error is calculated as the difference between the target output and the network output. The goal is to minimize the average of the sum of these errors.

$$mse = \frac{1}{Q}\sum_{k=1}^{Q} e(k)^2 = \frac{1}{Q}\sum_{k=1}^{Q} (t(k) - a(k))^2$$

The LMS algorithm adjusts the weights and biases of the linear network so as to minimize this mean square error.

Fortunately, the mean square error performance index for the linear network is a quadratic function. Thus, the performance index will either have one global minimum, a weak minimum, or no minimum, depending on the characteristics of the input vectors. Specifically, the characteristics of the input vectors determine whether or not a unique solution exists.

You can find more about this topic in Chapter 10 of [HDB96 on page 32-2].

Linear System Design (newlind)

Unlike most other network architectures, linear networks can be designed directly if input/target vector pairs are known. You can obtain specific network values for weights and biases to minimize the mean square error by using the function `newlind`.

Suppose that the inputs and targets are

```
P = [1 2 3];
T= [2.0 4.1 5.9];
```

Now you can design a network.

```
net = newlind(P,T);
```

You can simulate the network behavior to check that the design was done properly.

```
Y = net(P)
Y =
    2.0500    4.0000    5.9500
```

Note that the network outputs are quite close to the desired targets.

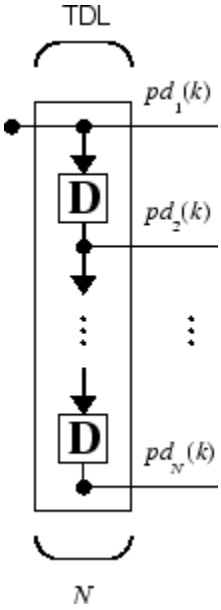
You might try “Pattern Association Showing Error Surface” on page 31-161. It shows error surfaces for a particular problem, illustrates the design, and plots the designed solution.

You can also use the function `newlind` to design linear networks having delays in the input. Such networks are discussed in “Linear Networks with Delays” on page 29-18. First, however, delays must be discussed.

Linear Networks with Delays

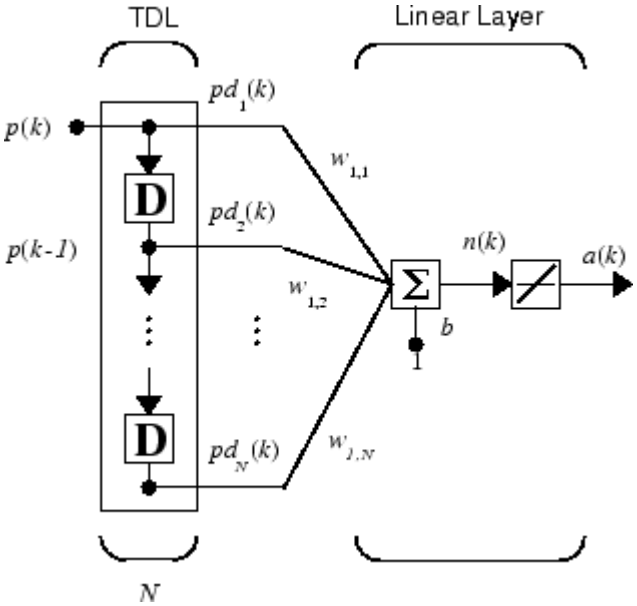
Tapped Delay Line

You need a new component, the tapped delay line, to make full use of the linear network. Such a delay line is shown below. There the input signal enters from the left and passes through *N*-1 delays. The output of the tapped delay line (TDL) is an *N*-dimensional vector, made up of the input signal at the current time, the previous input signal, etc.



Linear Filter

You can combine a tapped delay line with a linear network to create the linear *filter shown*.



The output of the filter is given by

$$a(k) = purelin(\mathbf{Wp} + b) = \sum_{i=1}^{R} w_{1,i} p(k - i + 1) + b$$

The network shown is referred to in the digital signal processing field as a finite impulse response (FIR) filter [WiSt85 on page 32-2]. Look at the code used to generate and simulate such a network.

Suppose that you want a linear layer that outputs the sequence T, given the sequence P and two initial input delay states Pi.

```
P = {1 2 1 3 3 2};
Pi = {1 3};
T = {5 6 4 20 7 8};
```

You can use newlind to design a network with delays to give the appropriate outputs for the inputs. The delay initial outputs are supplied as a third argument, as shown below.

```
net = newlind(P,T,Pi);
```

You can obtain the output of the designed network with

```
Y = net(P,Pi)
```

to give

```
Y = [2.7297] [10.5405] [5.0090] [14.9550] [10.7838] [5.9820]
```

As you can see, the network outputs are not exactly equal to the targets, but they are close and the mean square error is minimized.

LMS Algorithm (learnwh)

The LMS algorithm, or Widrow-Hoff learning algorithm, is based on an approximate steepest descent procedure. Here again, linear networks are trained on examples of correct behavior.

Widrow and Hoff had the insight that they could estimate the mean square error by using the squared error at each iteration. If you take the partial derivative of the squared error with respect to the weights and biases at the kth iteration, you have

$$\frac{\partial e^2(k)}{\partial w_{1,j}} = 2e(k)\frac{\partial e(k)}{\partial w_{1,j}}$$

for $j = 1,2,\ldots,R$ and

$$\frac{\partial e^2(k)}{\partial b} = 2e(k)\frac{\partial e(k)}{\partial b}$$

Next look at the partial derivative with respect to the error.

$$\frac{\partial e(k)}{\partial w_{1,j}} = \frac{\partial [t(k) - \alpha(k)]}{\partial w_{1,j}} = \frac{\partial}{\partial w_{1,j}}[t(k) - (\mathbf{W}\mathbf{p}(k) + b)]$$

or

$$\frac{\partial e(k)}{\partial w_{1,j}} = \frac{\partial}{\partial w_{1,j}}\left[t(k) - \left(\sum_{i=1}^{R} w_{1,i}p_i(k) + b\right)\right]$$

Here $p_i(k)$ is the ith element of the input vector at the kth iteration.

This can be simplified to

$$\frac{\partial e(k)}{\partial w_{1,j}} = -p_j(k)$$

and

$$\frac{\partial e(k)}{\partial b} = -1$$

Finally, change the weight matrix, and the bias will be

$2\alpha e(k)\mathbf{p}(k)$

and

$2\alpha e(k)$

These two equations form the basis of the Widrow-Hoff (LMS) learning algorithm.

These results can be extended to the case of multiple neurons, and written in matrix form as

$$\mathbf{W}(k+1) = \mathbf{W}(k) + 2\alpha\mathbf{e}(k)\mathbf{p}^T(k)$$
$$\mathbf{b}(k+1) = \mathbf{b}(k) + 2\alpha\mathbf{e}(k)$$

Here the error **e** and the bias **b** are vectors, and α is a *learning rate*. If α is large, learning occurs quickly, but if it is too large it can lead to instability and errors might even increase. To ensure stable learning, the learning rate must be less than the reciprocal of the largest eigenvalue of the correlation matrix $\mathbf{p}^T\mathbf{p}$ of the input vectors.

You might want to read some of Chapter 10 of [HDB96 on page 32-2] for more information about the LMS algorithm and its convergence.

Fortunately, there is a toolbox function, `learnwh`, that does all the calculation for you. It calculates the change in weights as

```
dw = lr*e*p'
```

and the bias change as

```
db = lr*e
```

The constant 2, shown a few lines above, has been absorbed into the code learning rate `lr`. The function `maxlinlr` calculates this maximum stable learning rate `lr` as 0.999 * `P'*P`.

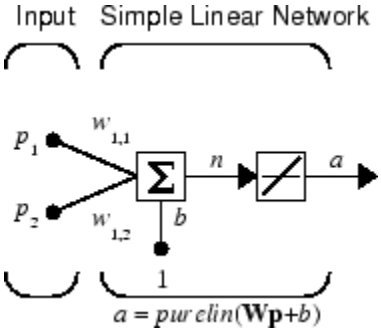
Type `help learnwh` and `help maxlinlr` for more details about these two functions.

Linear Classification (train)

Linear networks can be trained to perform linear classification with the function `train`. This function applies each vector of a set of input vectors and calculates the network weight and bias increments due to each of the inputs according to `learnp`. Then the network is adjusted with the sum of all these corrections. Each pass through the input vectors is called an *epoch*. This contrasts with `adapt` which adjusts weights for each input vector as it is presented.

Finally, `train` applies the inputs to the new network, calculates the outputs, compares them to the associated targets, and calculates a mean square error. If the error goal is met, or if the maximum number of epochs is reached, the training is stopped, and `train` returns the new network and a training record. Otherwise `train` goes through another epoch. Fortunately, the LMS algorithm converges when this procedure is executed.

A simple problem illustrates this procedure. Consider the linear network introduced earlier.



Suppose you have the following classification problem.

$$\left\{\mathbf{p}_1 = \begin{bmatrix}2\\2\end{bmatrix}, t_1 = 0\right\}\left\{\mathbf{p}_2 = \begin{bmatrix}1\\-2\end{bmatrix}, t_2 = 1\right\}\left\{\mathbf{p}_3 = \begin{bmatrix}-2\\2\end{bmatrix}, t_3 = 0\right\}\left\{\mathbf{p}_4 = \begin{bmatrix}-1\\1\end{bmatrix}, t_4 = 1\right\}$$

Here there are four input vectors, and you want a network that produces the output corresponding to each input vector when that vector is presented.

Use `train` to get the weights and biases for a network that produces the correct targets for each input vector. The initial weights and bias for the new network are 0 by default. Set the error goal to 0.1 rather than accept its default of 0.

```
P = [2 1 -2 -1;2 -2 2 1];
T = [0 1 0 1];
net = linearlayer;
net.trainParam.goal= 0.1;
net = train(net,P,T);
```

The problem runs for 64 epochs, achieving a mean square error of 0.0999. The new weights and bias are

```
weights = net.iw{1,1}
weights =
   -0.0615   -0.2194
bias = net.b(1)
bias =
    [0.5899]
```

You can simulate the new network as shown below.

```
A = net(P)
A =
    0.0282    0.9672    0.2741    0.4320
```

You can also calculate the error.

```
err = T - sim(net,P)
err =
   -0.0282    0.0328   -0.2741    0.5680
```

Note that the targets are not realized exactly. The problem would have run longer in an attempt to get perfect results had a smaller error goal been chosen, but in this problem it is not possible to

obtain a goal of 0. The network is limited in its capability. See “Limitations and Cautions” on page 29-23 for examples of various limitations.

This example program, “Training a Linear Neuron” on page 31-164, shows the training of a linear neuron and plots the weight trajectory and error during training.

You might also try running the example program `nnd10lc`. It addresses a classic and historically interesting problem, shows how a network can be trained to classify various patterns, and shows how the trained network responds when noisy patterns are presented.

Limitations and Cautions

Linear networks can only learn linear relationships between input and output vectors. Thus, they cannot find solutions to some problems. However, even if a perfect solution does not exist, the linear network will minimize the sum of squared errors if the learning rate `lr` is sufficiently small. The network will find as close a solution as is possible given the linear nature of the network's architecture. This property holds because the error surface of a linear network is a multidimensional parabola. Because parabolas have only one minimum, a gradient descent algorithm (such as the LMS rule) must produce a solution at that minimum.

Linear networks have various other limitations. Some of them are discussed below.

Overdetermined Systems

Consider an overdetermined system. Suppose that you have a network to be trained with four one-element input vectors and four targets. A perfect solution to $wp + b = t$ for each of the inputs might not exist, for there are four constraining equations, and only one weight and one bias to adjust. However, the LMS rule still minimizes the error. You might try “Linear Fit of Nonlinear Problem” on page 31-167 to see how this is done.

Underdetermined Systems

Consider a single linear neuron with one input. This time, in “Underdetermined Problem” on page 31-171, train it on only one one-element input vector and its one-element target vector:

```
P = [1.0];
T = [0.5];
```

Note that while there is only one constraint arising from the single input/target pair, there are two variables, the weight and the bias. Having more variables than constraints results in an underdetermined problem with an infinite number of solutions. You can try “Underdetermined Problem” on page 31-171 to explore this topic.

Linearly Dependent Vectors

Normally it is a straightforward job to determine whether or not a linear network can solve a problem. Commonly, if a linear network has at least as many degrees of freedom ($S*R + S$ = number of weights and biases) as constraints (Q = pairs of input/target vectors), then the network can solve the problem. This is true except when the input vectors are linearly dependent and they are applied to a network without biases. In this case, as shown with the example “Linearly Dependent Problem” on page 31-175, the network cannot solve the problem with zero error. You might want to try “Linearly Dependent Problem” on page 31-175.

Too Large a Learning Rate

You can always train a linear network with the Widrow-Hoff rule to find the minimum error solution for its weights and biases, as long as the learning rate is small enough. Example “Too Large a Learning Rate” on page 31-176 shows what happens when a neuron with one input and a bias is trained with a learning rate larger than that recommended by `maxlinlr`. The network is trained with two different learning rates to show the results of using too large a learning rate.

Neural Network Object Reference

Neural Network Object Properties

In this section...

These properties define the basic features of a network. “Neural Network Subobject Properties” on page 30-11 describes properties that define network details.

General

Here are the general properties of neural networks.

net.name

This property consists of a string defining the network name. Network creation functions, such as `feedforwardnet`, define this appropriately. But it can be set to any string as desired.

net.userdata

This property provides a place for users to add custom information to a network object. Only one field is predefined. It contains a *secret* message to all Deep Learning Toolbox users:

```
net.userdata.note
```

Architecture

These properties determine the number of network subobjects (which include inputs, layers, outputs, targets, biases, and weights), and how they are connected.

net.numInputs

This property defines the number of inputs a network receives. It can be set to 0 or a positive integer.

Clarification

The number of network inputs and the size of a network input are *not* the same thing. The number of inputs defines how many sets of vectors the network receives as input. The size of each input (i.e., the number of elements in each input vector) is determined by the input size (`net.inputs{i}.size`).

Most networks have only one input, whose size is determined by the problem.

Side Effects

Any change to this property results in a change in the size of the matrix defining connections to layers from inputs, (`net.inputConnect`) and the size of the cell array of input subobjects (`net.inputs`).

net.numLayers

This property defines the number of layers a network has. It can be set to 0 or a positive integer.

Side Effects

Any change to this property changes the size of each of these Boolean matrices that define connections to and from layers:

```
net.biasConnect
net.inputConnect
net.layerConnect
net.outputConnect
```

and changes the size of each cell array of subobject structures whose size depends on the number of layers:

```
net.biases
net.inputWeights
net.layerWeights
net.outputs
```

and also changes the size of each of the network's adjustable parameter's properties:

```
net.IW
net.LW
net.b
```

net.biasConnect

This property defines which layers have biases. It can be set to any N-by-1 matrix of Boolean values, where N_l is the number of network layers (`net.numLayers`). The presence (or absence) of a bias to the ith layer is indicated by a 1 (or 0) at

```
net.biasConnect(i)
```

Side Effects

Any change to this property alters the presence or absence of structures in the cell array of biases (`net.biases`) and, in the presence or absence of vectors in the cell array, of bias vectors (`net.b`).

net.inputConnect

This property defines which layers have weights coming from inputs.

It can be set to any $N_l \times N_i$ matrix of Boolean values, where N_l is the number of network layers (`net.numLayers`), and N_i is the number of network inputs (`net.numInputs`). The presence (or absence) of a weight going to the ith layer from the jth input is indicated by a 1 (or 0) at `net.inputConnect(i,j)`.

Side Effects

Any change to this property alters the presence or absence of structures in the cell array of input weight subobjects (`net.inputWeights`) and the presence or absence of matrices in the cell array of input weight matrices (`net.IW`).

net.layerConnect

This property defines which layers have weights coming from other layers. It can be set to any $N_l \times N_l$ matrix of Boolean values, where N_l is the number of network layers (`net.numLayers`). The presence (or absence) of a weight going to the *i*th layer from the *j*th layer is indicated by a 1 (or 0) at

```
net.layerConnect(i,j)
```

Side Effects

Any change to this property alters the presence or absence of structures in the cell array of layer weight subobjects (`net.layerWeights`) and the presence or absence of matrices in the cell array of layer weight matrices (`net.LW`).

net.outputConnect

This property defines which layers generate network outputs. It can be set to any $1 \times N_l$ matrix of Boolean values, where N_l is the number of network layers (`net.numLayers`). The presence (or absence) of a network output from the *i*th layer is indicated by a 1 (or 0) at `net.outputConnect(i)`.

Side Effects

Any change to this property alters the number of network outputs (`net.numOutputs`) and the presence or absence of structures in the cell array of output subobjects (`net.outputs`).

net.numOutputs (read only)

This property indicates how many outputs the network has. It is always equal to the number of 1s in `net.outputConnect`.

net.numInputDelays (read only)

This property indicates the number of time steps of past inputs that must be supplied to simulate the network. It is always set to the maximum delay value associated with any of the network's input weights:

```
numInputDelays = 0;
for i=1:net.numLayers
  for j=1:net.numInputs
    if net.inputConnect(i,j)
      numInputDelays = max( ...
        [numInputDelays net.inputWeights{i,j}.delays]);
    end
  end
end
```

net.numLayerDelays (read only)

This property indicates the number of time steps of past layer outputs that must be supplied to simulate the network. It is always set to the maximum delay value associated with any of the network's layer weights:

```
numLayerDelays = 0;
for i=1:net.numLayers
  for j=1:net.numLayers
    if net.layerConnect(i,j)
```

```
      numLayerDelays = max( ...
       [numLayerDelays net.layerWeights{i,j}.delays]);
    end
  end
end
```

net.numWeightElements (read only)

This property indicates the number of weight and bias values in the network. It is the sum of the number of elements in the matrices stored in the two cell arrays:

```
net.IW
new.b
```

Subobject Structures

These properties consist of cell arrays of structures that define each of the network's inputs, layers, outputs, targets, biases, and weights.

The properties for each kind of subobject are described in “Neural Network Subobject Properties” on page 30-11.

net.inputs

This property holds structures of properties for each of the network's inputs. It is always an $N_i \times 1$ cell array of input structures, where N_i is the number of network inputs (`net.numInputs`).

The structure defining the properties of the ith network input is located at

```
net.inputs{i}
```

If a neural network has only one input, then you can access `net.inputs{1}` without the cell array notation as follows:

```
net.input
```

Input Properties

See “Inputs” on page 30-11 for descriptions of input properties.

net.layers

This property holds structures of properties for each of the network's layers. It is always an $N_l \times 1$ cell array of layer structures, where N_l is the number of network layers (`net.numLayers`).

The structure defining the properties of the ith layer is located at `net.layers{i}`.

Layer Properties

See “Layers” on page 30-12 for descriptions of layer properties.

net.outputs

This property holds structures of properties for each of the network's outputs. It is always a $1 \times N_l$ cell array, where N_l is the number of network outputs (`net.numOutputs`).

The structure defining the properties of the output from the *i*th layer (or a null matrix `[]`) is located at `net.outputs{i}` if `net.outputConnect(i)` is 1 (or 0).

If a neural network has only one output at layer `i`, then you can access `net.outputs{i}` without the cell array notation as follows:

```
net.output
```

Output Properties

See “Outputs” on page 30-16 for descriptions of output properties.

net.biases

This property holds structures of properties for each of the network's biases. It is always an $N_l \times 1$ cell array, where N_l is the number of network layers (`net.numLayers`).

The structure defining the properties of the bias associated with the *i*th layer (or a null matrix `[]`) is located at `net.biases{i}` if `net.biasConnect(i)` is 1 (or 0).

Bias Properties

See “Biases” on page 30-18 for descriptions of bias properties.

net.inputWeights

This property holds structures of properties for each of the network's input weights. It is always an $N_l \times N_i$ cell array, where N_l is the number of network layers (`net.numLayers`), and N_i is the number of network inputs (`net.numInputs`).

The structure defining the properties of the weight going to the *i*th layer from the *j*th input (or a null matrix `[]`) is located at `net.inputWeights{i,j}` if `net.inputConnect(i,j)` is 1 (or 0).

Input Weight Properties

See “Input Weights” on page 30-19 for descriptions of input weight properties.

net.layerWeights

This property holds structures of properties for each of the network's layer weights. It is always an $N_l \times N_l$ cell array, where N_l is the number of network layers (`net.numLayers`).

The structure defining the properties of the weight going to the *i*th layer from the *j*th layer (or a null matrix `[]`) is located at `net.layerWeights{i,j}` if `net.layerConnect(i,j)` is 1 (or 0).

Layer Weight Properties

See “Layer Weights” on page 30-20 for descriptions of layer weight properties.

Functions

These properties define the algorithms to use when a network is to adapt, is to be initialized, is to have its performance measured, or is to be trained.

net.adaptFcn

This property defines the function to be used when the network adapts. It can be set to the name of any network adapt function. The network adapt function is used to perform adaption whenever `adapt` is called.

```
[net,Y,E,Pf,Af] = adapt(NET,P,T,Pi,Ai)
```

For a list of functions, type `help nntrain`.

Side Effects

Whenever this property is altered, the network's adaption parameters (`net.adaptParam`) are set to contain the parameters and default values of the new function.

net.adaptParam

This property defines the parameters and values of the current adapt function. Call `help` on the current adapt function to get a description of what each field means:

```
help(net.adaptFcn)
```

net.derivFcn

This property defines the derivative function to be used to calculate error gradients and Jacobians when the network is trained using a supervised algorithm, such as backpropagation. You can set this property to the name of any derivative function.

For a list of functions, type `help nnderivative`.

net.divideFcn

This property defines the data division function to be used when the network is trained using a supervised algorithm, such as backpropagation. You can set this property to the name of a division function.

For a list of functions, type `help nndivision`.

Side Effects

Whenever this property is altered, the network's adaption parameters (`net.divideParam`) are set to contain the parameters and default values of the new function.

net.divideParam

This property defines the parameters and values of the current data-division function. To get a description of what each field means, type the following command:

```
help(net.divideFcn)
```

net.divideMode

This property defines the target data dimensions which to divide up when the data division function is called. Its default value is `'sample'` for static networks and `'time'` for dynamic networks. It may also be set to `'sampletime'` to divide targets by both sample and timestep, `'all'` to divide up targets by every scalar value, or `'none'` to not divide up data at all (in which case all data is used for training, none for validation or testing).

net.initFcn

This property defines the function used to initialize the network's weight matrices and bias vectors. . The initialization function is used to initialize the network whenever `init` is called:

```
net = init(net)
```

Side Effects

Whenever this property is altered, the network's initialization parameters (`net.initParam`) are set to contain the parameters and default values of the new function.

net.initParam

This property defines the parameters and values of the current initialization function. Call `help` on the current initialization function to get a description of what each field means:

```
help(net.initFcn)
```

net.performFcn

This property defines the function used to measure the network’s performance. The performance function is used to calculate network performance during training whenever `train` is called.

```
[net,tr] = train(NET,P,T,Pi,Ai)
```

For a list of functions, type `help nnperformance`.

Side Effects

Whenever this property is altered, the network's performance parameters (`net.performParam`) are set to contain the parameters and default values of the new function.

net.performParam

This property defines the parameters and values of the current performance function. Call `help` on the current performance function to get a description of what each field means:

```
help(net.performFcn)
```

net.plotFcns

This property consists of a row cell array of strings, defining the plot functions associated with a network. The neural network training window, which is opened by the `train` function, shows a button for each plotting function. Click the button during or after training to open the desired plot.

net.plotParams

This property consists of a row cell array of structures, defining the parameters and values of each plot function in `net.plotFcns`. Call `help` on the each plot function to get a description of what each field means:

```
help(net.plotFcns{i})
```

net.trainFcn

This property defines the function used to train the network. It can be set to the name of any of the training functions, which is used to train the network whenever `train` is called.

```
[net,tr] = train(NET,P,T,Pi,Ai)
```

For a list of functions, type `help nntrain`.

Side Effects

Whenever this property is altered, the network's training parameters (`net.trainParam`) are set to contain the parameters and default values of the new function.

net.trainParam

This property defines the parameters and values of the current training function. Call `help` on the current training function to get a description of what each field means:

```
help(net.trainFcn)
```

Weight and Bias Values

These properties define the network's adjustable parameters: its weight matrices and bias vectors.

net.IW

This property defines the weight matrices of weights going to layers from network inputs. It is always an $N_l \times N_i$ cell array, where N_l is the number of network layers (`net.numLayers`), and N_i is the number of network inputs (`net.numInputs`).

The weight matrix for the weight going to the *i*th layer from the *j*th input (or a null matrix `[]`) is located at `net.IW{i,j}` if `net.inputConnect(i,j)` is `1` (or `0`).

The weight matrix has as many rows as the size of the layer it goes to (`net.layers{i}.size`). It has as many columns as the product of the input size with the number of delays associated with the weight:

```
net.inputs{j}.size * length(net.inputWeights{i,j}.delays)
```

The preprocessing function `net.inputs{i}.processFcns` is specified as `'removeconstantrows'` by default in some networks. In this case, if the network input `X` contains `m` rows where all row elements have the same value, the weight matrix has `m` less columns than the above product. For more details about the network input `X`, see `train`.

These dimensions can also be obtained from the input weight properties:

```
net.inputWeights{i,j}.size
```

net.LW

This property defines the weight matrices of weights going to layers from other layers. It is always an $N_l \times N_l$ cell array, where N_l is the number of network layers (`net.numLayers`).

The weight matrix for the weight going to the *i*th layer from the *j*th layer (or a null matrix `[]`) is located at `net.LW{i,j}` if `net.layerConnect(i,j)` is 1 (or 0).

The weight matrix has as many rows as the size of the layer it goes to (`net.layers{i}.size`). It has as many columns as the product of the size of the layer it comes from with the number of delays associated with the weight:

```
net.layers{j}.size * length(net.layerWeights{i,j}.delays)
```

These dimensions can also be obtained from the layer weight properties:

```
net.layerWeights{i,j}.size
```

net.b

This property defines the bias vectors for each layer with a bias. It is always an $N_l \times 1$ cell array, where N_l is the number of network layers (`net.numLayers`).

The bias vector for the *i*th layer (or a null matrix `[]`) is located at `net.b{i}` if `net.biasConnect(i)` is 1 (or 0).

The number of elements in the bias vector is always equal to the size of the layer it is associated with (`net.layers{i}.size`).

This dimension can also be obtained from the bias properties:

```
net.biases{i}.size
```

Neural Network Subobject Properties

These properties define the details of a network's inputs, layers, outputs, targets, biases, and weights.

In this section...

Inputs

These properties define the details of each *i*th network input.

net.inputs{1}.name

This property consists of a string defining the input name. Network creation functions, such as `feedforwardnet`, define this appropriately. But it can be set to any string as desired.

net.inputs{i}.feedbackInput (read only)

If this network is associated with an open-loop feedback output, then this property will indicate the index of that output. Otherwise it will be an empty matrix.

net.inputs{i}.processFcns

This property defines a row cell array of processing function names to be used by *i*th network input. The processing functions are applied to input values before the network uses them.

Side Effects

Whenever this property is altered, the input `processParams` are set to default values for the given processing functions, `processSettings`, `processedSize`, and `processedRange` are defined by applying the process functions and parameters to `exampleInput`.

For a list of processing functions, type `help nnprocess`.

net.inputs{i}.processParams

This property holds a row cell array of processing function parameters to be used by *i*th network input. The processing parameters are applied by the processing functions to input values before the network uses them.

Side Effects

Whenever this property is altered, the input `processSettings`, `processedSize`, and `processedRange` are defined by applying the process functions and parameters to `exampleInput`.

net.inputs{i}.processSettings (read only)

This property holds a row cell array of processing function settings to be used by *i*th network input. The processing settings are found by applying the processing functions and parameters to

exampleInput and then used to provide consistent results to new input values before the network uses them.

net.inputs{i}.processedRange (read only)

This property defines the range of exampleInput values after they have been processed with processingFcns and processingParams.

net.inputs{i}.processedSize (read only)

This property defines the number of rows in the exampleInput values after they have been processed with processingFcns and processingParams.

net.inputs{i}.range

This property defines the range of each element of the *i*th network input.

It can be set to any $R_i \times 2$ matrix, where R_i is the number of elements in the input (net.inputs{i}.size), and each element in column 1 is less than the element next to it in column 2.

Each *j*th row defines the minimum and maximum values of the *j*th input element, in that order:

```
net.inputs{i}(j,:)
```

Uses

Some initialization functions use input ranges to find appropriate initial values for input weight matrices.

Side Effects

Whenever the number of rows in this property is altered, the input size, processedSize, and processedRange change to remain consistent. The sizes of any weights coming from this input and the dimensions of the weight matrices also change.

net.inputs{i}.size

This property defines the number of elements in the *i*th network input. It can be set to 0 or a positive integer.

Side Effects

Whenever this property is altered, the input range, processedRange, and processedSize are updated. Any associated input weights change size accordingly.

net.inputs{i}.userdata

This property provides a place for users to add custom information to the *i*th network input.

Layers

These properties define the details of each *i*th network layer.

net.layers{i}.name

This property consists of a string defining the layer name. Network creation functions, such as `feedforwardnet`, define this appropriately. But it can be set to any string as desired.

net.layers{i}.dimensions

This property defines the *physical* dimensions of the *i*th layer's neurons. Being able to arrange a layer's neurons in a multidimensional manner is important for self-organizing maps.

It can be set to any row vector of 0 or positive integer elements, where the product of all the elements becomes the number of neurons in the layer (`net.layers{i}.size`).

Uses

Layer dimensions are used to calculate the neuron positions within the layer (`net.layers{i}.positions`) using the layer's topology function (`net.layers{i}.topologyFcn`).

Side Effects

Whenever this property is altered, the layer's size (`net.layers{i}.size`) changes to remain consistent. The layer's neuron positions (`net.layers{i}.positions`) and the distances between the neurons (`net.layers{i}.distances`) are also updated.

net.layers{i}.distanceFcn

This property defines which of the distance functions is used to calculate `distances` between neurons in the *i*th layer from the neuron `positions`. Neuron distances are used by self-organizing maps. It can be set to the name of any distance function.

For a list of functions, type `help nndistance`.

Side Effects

Whenever this property is altered, the distances between the layer's neurons (`net.layers{i}.distances`) are updated.

net.layers{i}.distances (read only)

This property defines the distances between neurons in the *i*th layer. These distances are used by self-organizing maps:

```
net.layers{i}.distances
```

It is always set to the result of applying the layer's distance function (`net.layers{i}.distanceFcn`) to the positions of the layer's neurons (`net.layers{i}.positions`).

net.layers{i}.initFcn

This property defines which of the layer initialization functions are used to initialize the *i*th layer, if the network initialization function (`net.initFcn`) is `initlay`. If the network initialization is set to `initlay`, then the function indicated by this property is used to initialize the layer's weights and biases.

net.layers{i}.netInputFcn

This property defines which of the net input functions is used to calculate the *i*th layer's net input, given the layer's weighted inputs and bias during simulating and training.

For a list of functions, type `help nnnetinput`.

net.layers{i}.netInputParam

This property defines the parameters of the layer's net input function. Call `help` on the current net input function to get a description of each field:

```
help(net.layers{i}.netInputFcn)
```

net.layers{i}.positions (read only)

This property defines the positions of neurons in the *i*th layer. These positions are used by self-organizing maps.

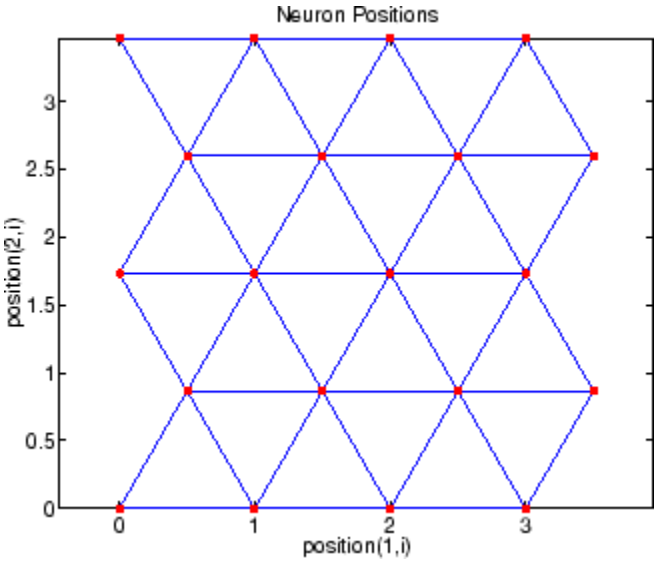
It is always set to the result of applying the layer's topology function (`net.layers{i}.topologyFcn`) to the positions of the layer's dimensions (`net.layers{i}.dimensions`).

Plotting

Use `plotsom` to plot the positions of a layer's neurons.

For instance, if the first-layer neurons of a network are arranged with dimensions (`net.layers{1}.dimensions`) of [4 5], and the topology function (`net.layers{1}.topologyFcn`) is `hextop`, the neurons' positions can be plotted as follows:

```
plotsom(net.layers{1}.positions)
```



net.layers{i}.range (read only)

This property defines the output range of each neuron of the *i*th layer.

It is set to an $S_i \times 2$ matrix, where S_i is the number of neurons in the layer (`net.layers{i}.size`), and each element in column 1 is less than the element next to it in column 2.

Each *j*th row defines the minimum and maximum output values of the layer's transfer function `net.layers{i}.transferFcn`.

net.layers{i}.size

This property defines the number of neurons in the *i*th layer. It can be set to 0 or a positive integer.

Side Effects

Whenever this property is altered, the sizes of any input weights going to the layer (`net.inputWeights{i,:}.size`), any layer weights going to the layer (`net.layerWeights{i,:}.size`) or coming from the layer (`net.layerWeights{i,:}.size`), and the layer's bias (`net.biases{i}.size`), change.

The dimensions of the corresponding weight matrices (`net.IW{i,:}`, `net.LW{i,:}`, `net.LW{:,i}`), and biases (`net.b{i}`) also change.

Changing this property also changes the size of the layer's output (`net.outputs{i}.size`) and target (`net.targets{i}.size`) if they exist.

Finally, when this property is altered, the dimensions of the layer's neurons (`net.layers{i}.dimension`) are set to the same value. (This results in a one-dimensional arrangement of neurons. If another arrangement is required, set the `dimensions` property directly instead of using `size`.)

net.layers{i}.topologyFcn

This property defines which of the topology functions are used to calculate the *i*th layer's neuron positions (`net.layers{i}.positions`) from the layer's dimensions (`net.layers{i}.dimensions`).

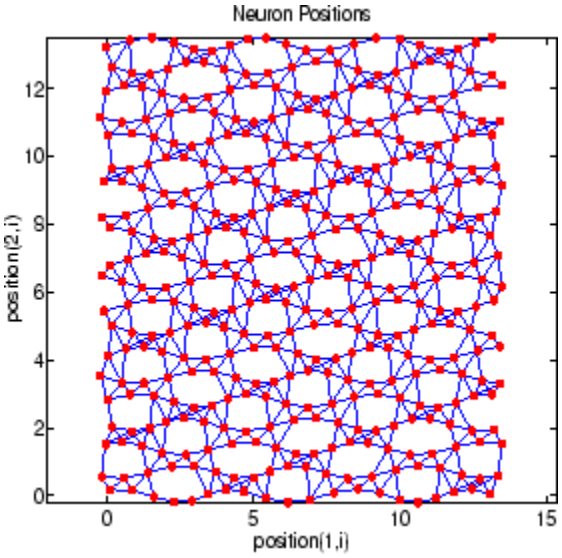
For a list of functions, type `help nntopology`.

Side Effects

Whenever this property is altered, the positions of the layer's neurons (`net.layers{i}.positions`) are updated.

Use `plotsom` to plot the positions of the layer neurons. For instance, if the first-layer neurons of a network are arranged with dimensions (`net.layers{1}.dimensions`) of [8 10] and the topology function (`net.layers{1}.topologyFcn`) is `randtop`, the neuron positions are arranged to resemble the following plot:

```
plotsom(net.layers{1}.positions)
```



net.layers{i}.transferFcn

This function defines which of the transfer functions is used to calculate the *i*th layer's output, given the layer's net input, during simulation and training.

For a list of functions, type `help nntransfer`.

net.layers{i}.transferParam

This property defines the parameters of the layer's transfer function. Call `help` on the current transfer function to get a description of what each field means:

```
help(net.layers{i}.transferFcn)
```

net.layers{i}.userdata

This property provides a place for users to add custom information to the *i*th network layer.

Outputs

net.outputs{i}.name

This property consists of a string defining the output name. Network creation functions, such as `feedforwardnet`, define this appropriately. But it can be set to any string as desired.

net.outputs{i}.feedbackInput

If the output implements open-loop feedback (`net.outputs{i}.feedbackMode = 'open'`), then this property indicates the index of the associated feedback input, otherwise it will be an empty matrix.

net.outputs{i}.feedbackDelay

This property defines the timestep difference between this output and network inputs. Input-to-output network delays can be removed and added with `removedelay` and `adddelay` functions resulting in this property being incremented or decremented respectively. The difference in timing between

inputs and outputs is used by `preparets` to properly format simulation and training data, and used by `closeloop` to add the correct number of delays when closing an open-loop output, and `openloop` to remove delays when opening a closed loop.

net.outputs{i}.feedbackMode

This property is set to the string `'none'` for non-feedback outputs. For feedback outputs it can either be set to `'open'` or `'closed'`. If it is set to `'open'`, then the output will be associated with a feedback input, with the property `feedbackInput` indicating the input's index.

net.outputs{i}.processFcns

This property defines a row cell array of processing function names to be used by the *i*th network output. The processing functions are applied to target values before the network uses them, and applied in reverse to layer output values before being returned as network output values.

Side Effects

When you change this property, you also affect the following settings: the output parameters `processParams` are modified to the default values of the specified processing functions; `processSettings`, `processedSize`, and `processedRange` are defined using the results of applying the process functions and parameters to `exampleOutput`; the *i*th layer size is updated to match the `processedSize`.

For a list of functions, type `help nnprocess`.

net.outputs{i}.processParams

This property holds a row cell array of processing function parameters to be used by *i*th network output on target values. The processing parameters are applied by the processing functions to input values before the network uses them.

Side Effects

Whenever this property is altered, the output `processSettings`, `processedSize` and `processedRange` are defined by applying the process functions and parameters to `exampleOutput`. The *i*th layer's size is also updated to match `processedSize`.

net.outputs{i}.processSettings (read only)

This property holds a row cell array of processing function settings to be used by *i*th network output. The processing settings are found by applying the processing functions and parameters to `exampleOutput` and then used to provide consistent results to new target values before the network uses them. The processing settings are also applied in reverse to layer output values before being returned by the network.

net.outputs{i}.processedRange (read only)

This property defines the range of `exampleOutput` values after they have been processed with `processingFcns` and `processingParams`.

net.outputs{i}.processedSize (read only)

This property defines the number of rows in the `exampleOutput` values after they have been processed with `processingFcns` and `processingParams`.

net.outputs{i}.size (read only)

This property defines the number of elements in the *i*th layer's output. It is always set to the size of the *i*th layer (`net.layers{i}.size`).

net.outputs{i}.userdata

This property provides a place for users to add custom information to the *i*th layer's output.

Biases

net.biases{i}.initFcn

This property defines the weight and bias initialization functions used to set the *i*th layer's bias vector (`net.b{i}`) if the network initialization function is `initlay` and the *i*th layer's initialization function is `initwb`.

net.biases{i}.learn

This property defines whether the *i*th bias vector is to be altered during training and adaption. It can be set to 0 or 1.

It enables or disables the bias's learning during calls to `adapt` and `train`.

net.biases{i}.learnFcn

This property defines which of the learning functions is used to update the *i*th layer's bias vector (`net.b{i}`) during training, if the network training function is `trainb`, `trainc`, or `trainr`, or during adaption, if the network adapt function is `trains`.

For a list of functions, type `help nnlearn`.

Side Effects

Whenever this property is altered, the biases learning parameters (`net.biases{i}.learnParam`) are set to contain the fields and default values of the new function.

net.biases{i}.learnParam

This property defines the learning parameters and values for the current learning function of the *i*th layer's bias. The fields of this property depend on the current learning function. Call `help` on the current learning function to get a description of what each field means.

net.biases{i}.size (read only)

This property defines the size of the *i*th layer's bias vector. It is always set to the size of the *i*th layer (`net.layers{i}.size`).

net.biases{i}.userdata

This property provides a place for users to add custom information to the *i*th layer's bias.

Input Weights

net.inputWeights{i,j}.delays

This property defines a tapped delay line between the *j*th input and its weight to the *i*th layer. It must be set to a row vector of increasing values. The elements must be either 0 or positive integers.

Side Effects

Whenever this property is altered, the weight's size (`net.inputWeights{i,j}.size`) and the dimensions of its weight matrix (`net.IW{i,j}`) are updated.

net.inputWeights{i,j}.initFcn

This property defines which of the Weight and Bias Initialization Functions is used to initialize the weight matrix (`net.IW{i,j}`) going to the *i*th layer from the *j*th input, if the network initialization function is `initlay`, and the *i*th layer's initialization function is `initwb`. This function can be set to the name of any weight initialization function.

net.inputWeights{i,j}.initSettings (read only)

This property is set to values useful for initializing the weight as part of the configuration process that occurs automatically the first time a network is trained, or when the function `configure` is called on a network directly.

net.inputWeights{i,j}.learn

This property defines whether the weight matrix to the *i*th layer from the *j*th input is to be altered during training and adaption. It can be set to 0 or 1.

net.inputWeights{i,j}.learnFcn

This property defines which of the learning functions is used to update the weight matrix (`net.IW{i,j}`) going to the *i*th layer from the *j*th input during training, if the network training function is `trainb`, `trainc`, or `trainr`, or during adaption, if the network adapt function is `trains`. It can be set to the name of any weight learning function.

For a list of functions, type `help nnlearn`.

net.inputWeights{i,j}.learnParam

This property defines the learning parameters and values for the current learning function of the *i*th layer's weight coming from the *j*th input.

The fields of this property depend on the current learning function (`net.inputWeights{i,j}.learnFcn`). Evaluate the above reference to see the fields of the current learning function.

Call `help` on the current learning function to get a description of what each field means.

net.inputWeights{i,j}.size (read only)

This property defines the dimensions of the *i*th layer's weight matrix from the *j*th network input. It is always set to a two-element row vector indicating the number of rows and columns of the associated weight matrix (`net.IW{i,j}`). The first element is equal to the size of the *i*th layer

(`net.layers{i}.size`). The second element is equal to the product of the length of the weight's delay vectors and the size of the *j*th input:

```
length(net.inputWeights{i,j}.delays) * net.inputs{j}.size
```

net.inputWeights{i,j}.userdata

This property provides a place for users to add custom information to the (*i*,*j*)th input weight.

net.inputWeights{i,j}.weightFcn

This property defines which of the weight functions is used to apply the *i*th layer's weight from the *j*th input to that input. It can be set to the name of any weight function. The weight function is used to transform layer inputs during simulation and training.

For a list of functions, type `help nnweight`.

net.inputWeights{i,j}.weightParam

This property defines the parameters of the layer's net input function. Call `help` on the current net input function to get a description of each field.

Layer Weights

net.layerWeights{i,j}.delays

This property defines a tapped delay line between the *j*th layer and its weight to the *i*th layer. It must be set to a row vector of increasing values. The elements must be either 0 or positive integers.

net.layerWeights{i,j}.initFcn

This property defines which of the weight and bias initialization functions is used to initialize the weight matrix (`net.LW{i,j}`) going to the *i*th layer from the *j*th layer, if the network initialization function is `initlay`, and the *i*th layer's initialization function is `initwb`. This function can be set to the name of any weight initialization function.

net.layerWeights{i,j}.initSettings (read only)

This property is set to values useful for initializing the weight as part of the configuration process that occurs automatically the first time a network is trained, or when the function `configure` is called on a network directly.

net.layerWeights{i,j}.learn

This property defines whether the weight matrix to the *i*th layer from the *j*th layer is to be altered during training and adaption. It can be set to 0 or 1.

net.layerWeights{i,j}.learnFcn

This property defines which of the learning functions is used to update the weight matrix (`net.LW{i,j}`) going to the *i*th layer from the *j*th layer during training, if the network training function is `trainb`, `trainc`, or `trainr`, or during adaption, if the network adapt function is `trains`. It can be set to the name of any weight learning function.

For a list of functions, type `help nnlearn`.

net.layerWeights{i,j}.learnParam

This property defines the learning parameters fields and values for the current learning function of the *i*th layer's weight coming from the *j*th layer. The fields of this property depend on the current learning function. Call `help` on the current net input function to get a description of each field.

net.layerWeights{i,j}.size (read only)

This property defines the dimensions of the *i*th layer's weight matrix from the *j*th layer. It is always set to a two-element row vector indicating the number of rows and columns of the associated weight matrix (`net.LW{i,j}`). The first element is equal to the size of the *i*th layer (`net.layers{i}.size`). The second element is equal to the product of the length of the weight's delay vectors and the size of the *j*th layer.

net.layerWeights{i,j}.userdata

This property provides a place for users to add custom information to the (*i*,*j*)th layer weight.

net.layerWeights{i,j}.weightFcn

This property defines which of the weight functions is used to apply the *i*th layer's weight from the *j*th layer to that layer's output. It can be set to the name of any weight function. The weight function is used to transform layer inputs when the network is simulated.

For a list of functions, type `help nnweight`.

net.layerWeights{i,j}.weightParam

This property defines the parameters of the layer's net input function. Call `help` on the current net input function to get a description of each field.

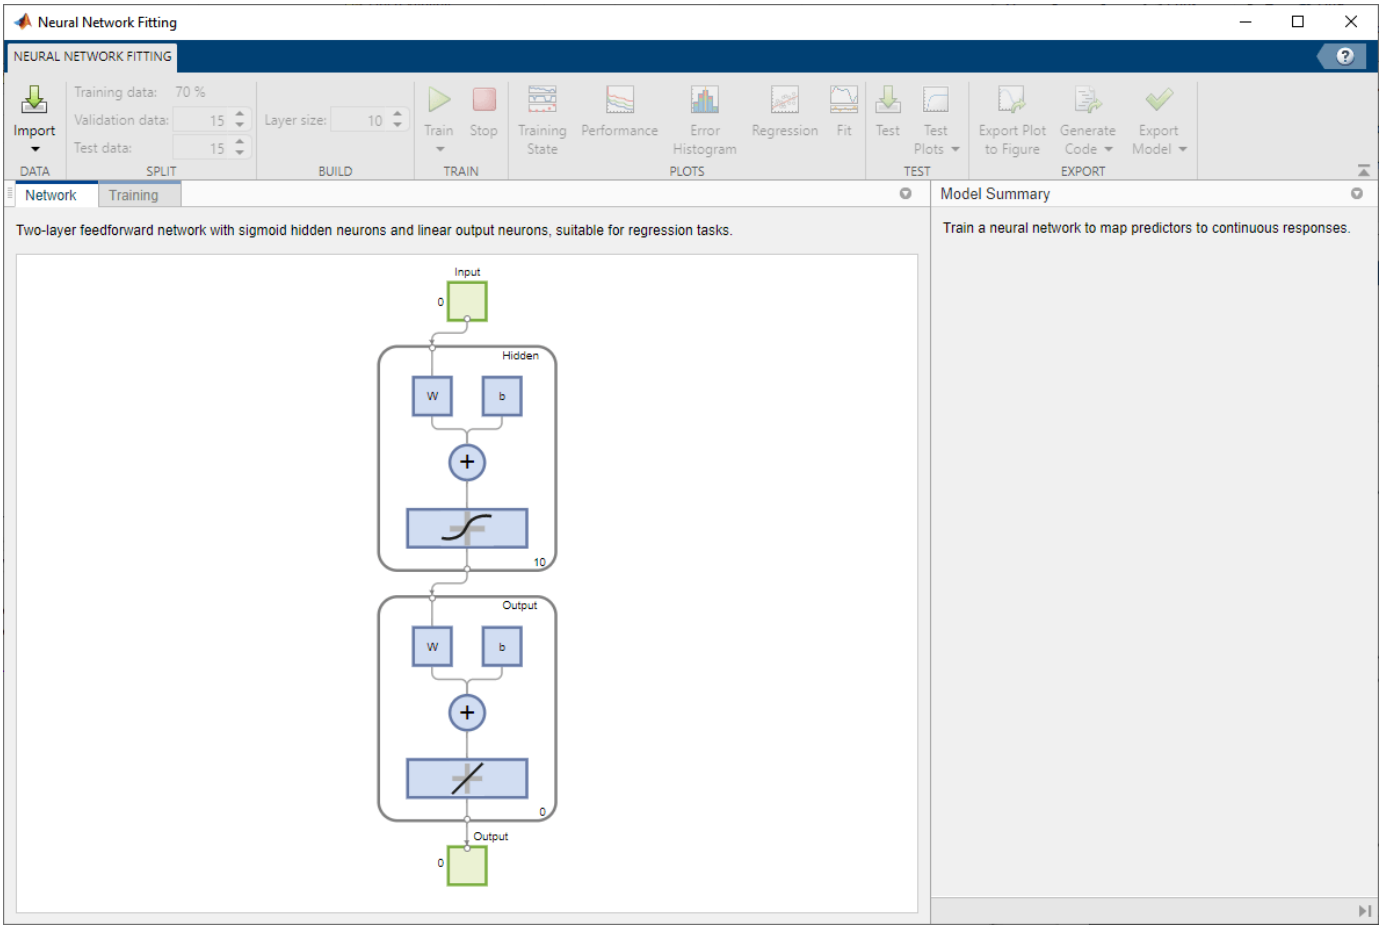
Function Approximation, Clustering, and Control Examples

Fit Data Using the Neural Net Fitting App

This example shows how to train a shallow neural network to fit data using the **Neural Net Fitting** app.

Open the **Neural Net Fitting** app using `nftool`.

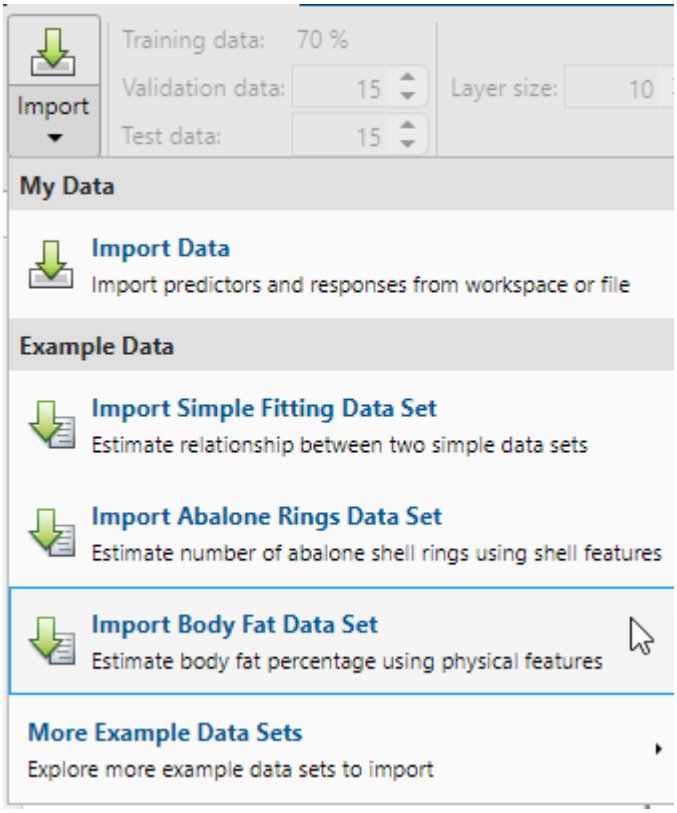
```
nftool
```



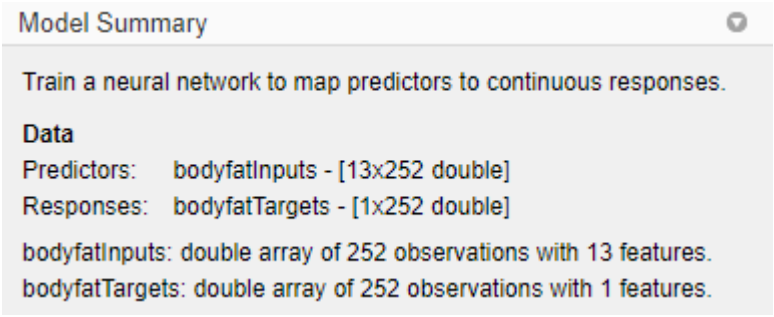
Select Data

The **Neural Net Fitting** app has example data to help you get started training a neural network.

To import example body fat data, select **Import > Import Body Fat Data Set**. You can use this data set to train a neural network to estimate the body fat of someone from various measurements. If you import your own data from file or the workspace, you must specify the predictors and responses, and if the observations are in rows or columns.



Information about the imported data appears in the **Model Summary**. This data set contains 252 observations, each with 13 features. The responses contain the body fat percentage for each observation.



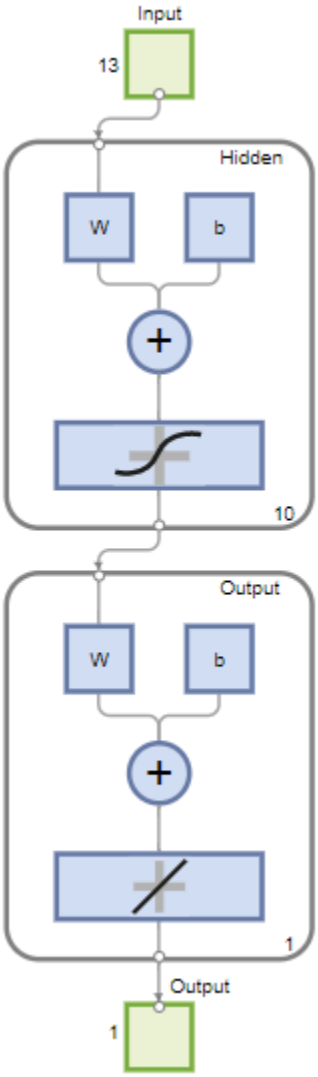
Split the data into training, validation, and test sets. Keep the default settings. The data is split into:

- 70% for training.
- 15% to validate that the network is generalizing and to stop training before overfitting.
- 15% to independently test network generalization.

For more information on data division, see “Divide Data for Optimal Neural Network Training” on page 22-9.

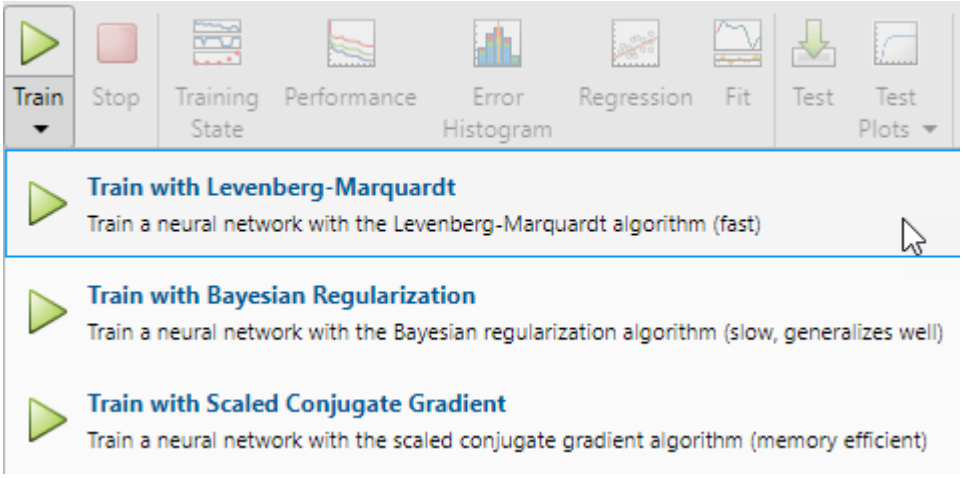
Create Network

The network is a two-layer feedforward network with a sigmoid transfer function in the hidden layer and a linear transfer function in the output layer. The **Layer size** value defines the number of hidden neurons. Keep the default layer size, 10. You can see the network architecture in the **Network** pane. The network plot updates to reflect the input data. In this example, the data has 13 inputs (features) and one output.



Train Network

To train the network, select **Train** > **Train with Levenberg-Marquardt**. This is the default training algorithm and the same as clicking **Train**.



Training with Levenberg-Marquardt (`trainlm`) is recommended for most problems. For noisy or small problems, Bayesian Regularization (`trainbr`) can obtain a better solution, at the cost of taking longer. For large problems, Scaled Conjugate Gradient (`trainscg`) is recommended as it uses gradient calculations which are more memory efficient than the Jacobian calculations the other two algorithms use.

In the **Training** pane, you can see the training progress. Training continues until one of the stopping criteria is met. In this example, training continues until the validation error increases consecutively for six iterations ("Met validation criterion").

Training Results

Training finished: Met validation criterion

Training Progress

Unit	Initial Value	Stopped Value	Target Value
Epoch	0	9	1000
Elapsed time	-	00:00:00	-
Performance	466	8.7	0
Gradient	2.67e+03	20.5	1e-07
Mu	0.001	0.1	1e+10
Validation Checks	0	6	6

Analyze Results

The **Model Summary** contains information about the training algorithm and the training results for each data set.

Algorithm

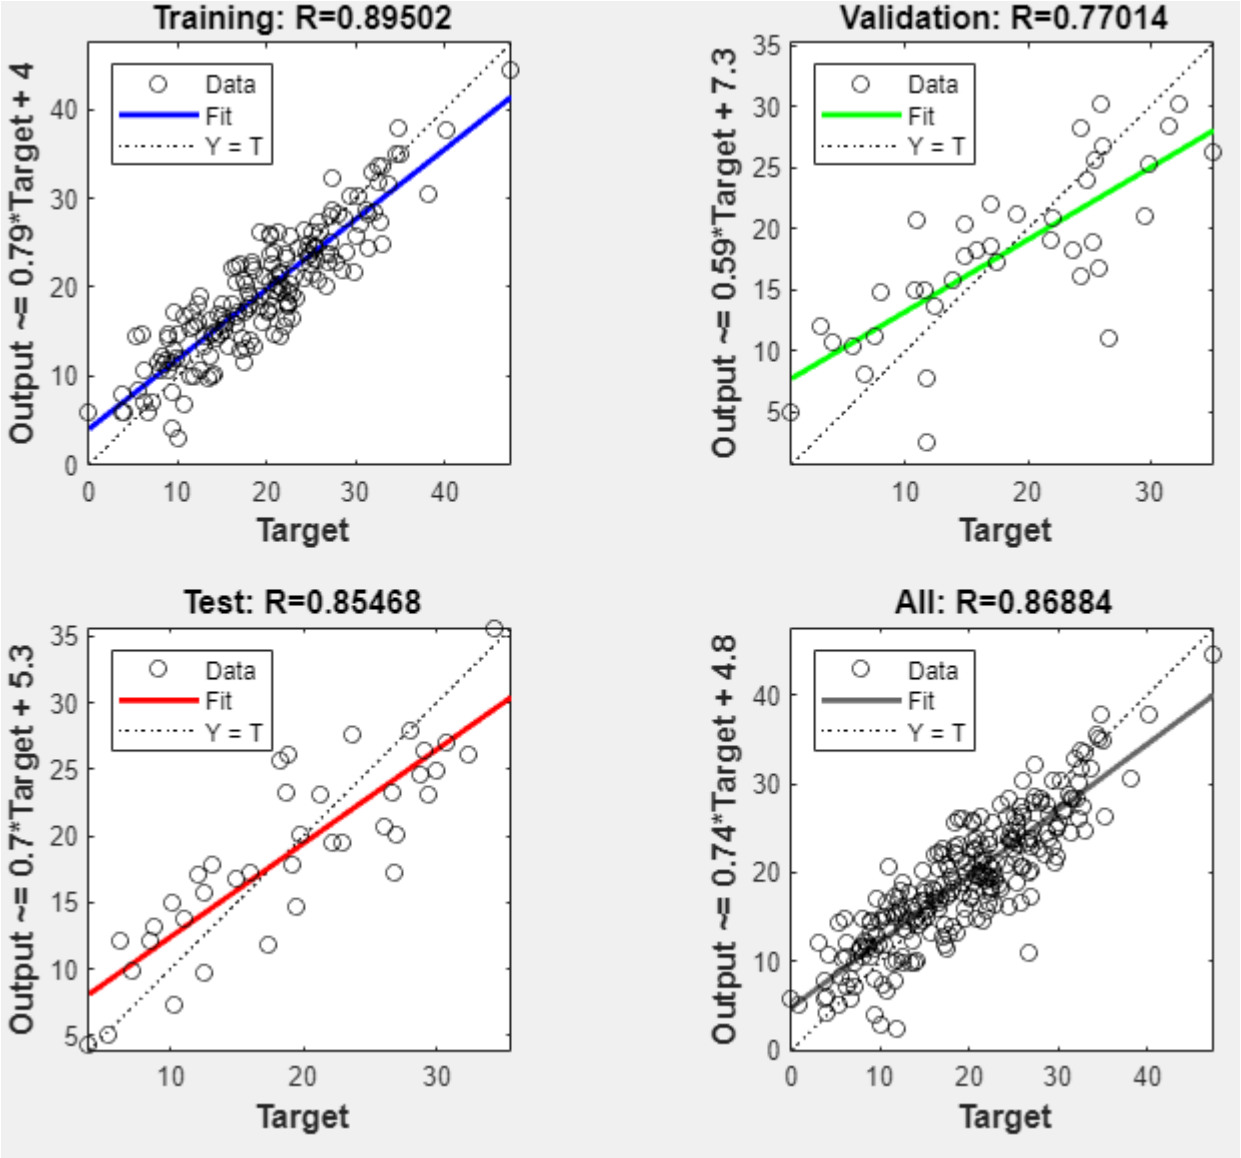
Data division: Random
Training algorithm: Levenberg-Marquardt
Performance: Mean squared error

Training Results

Training start time: 02-Jul-2021 12:10:54
Layer size: 10

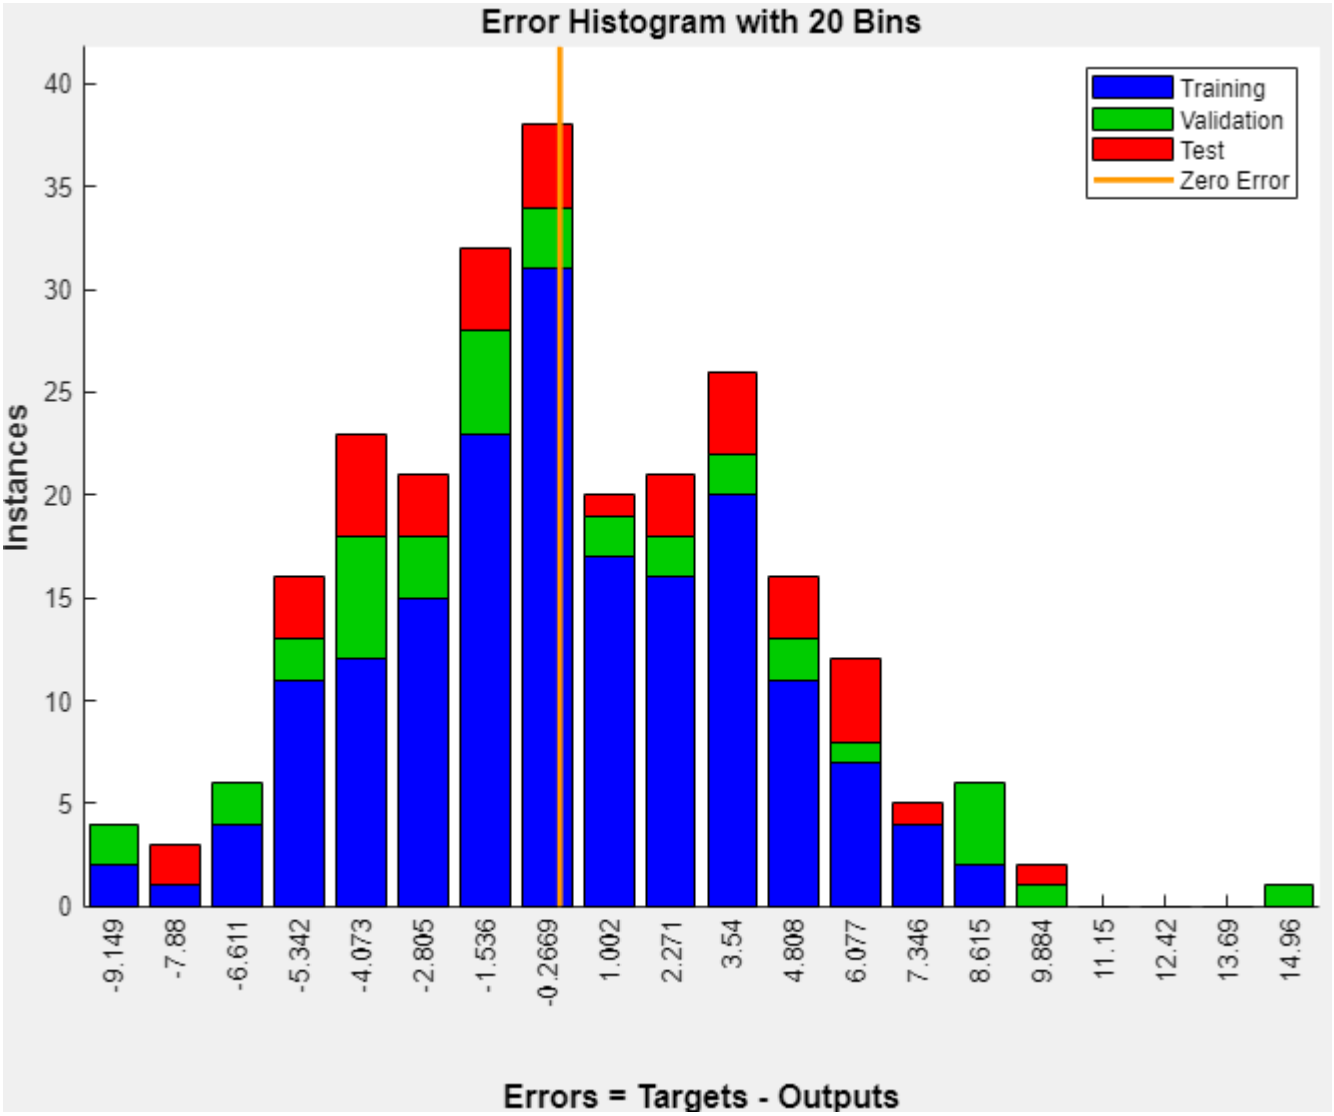
	Observations	MSE	R
Training	176	13.3810	0.8950
Validation	38	32.4817	0.7701
Test	38	19.1691	0.8547

You can further analyze the results by generating plots. To plot the linear regression, in the **Plots** section, click **Regression**. The regression plot displays the network predictions (output) with respect to responses (target) for the training, validation, and test sets.



For a perfect fit, the data should fall along a 45 degree line, where the network outputs are equal to the responses. For this problem, the fit is reasonably good for all of the data sets. If you require more accurate results, you can retrain the network by clicking **Train** again. Each training will have different initial weights and biases of the network, and can produce an improved network after retraining.

View the error histogram to obtain additional verification of network performance. In the **Plots** section, click **Error Histogram**.



The blue bars represent training data, the green bars represent validation data, and the red bars represent testing data. The histogram provides an indication of outliers, which are data points where the fit is significantly worse than most of the data. It is a good idea to check the outliers to determine if the data is poor, or if those data points are different than the rest of the data set. If the outliers are valid data points, but are unlike the rest of the data, then the network is extrapolating for these points. You should collect more data that looks like the outlier points and retrain the network.

If you are unhappy with the network performance, you can do one of the following:

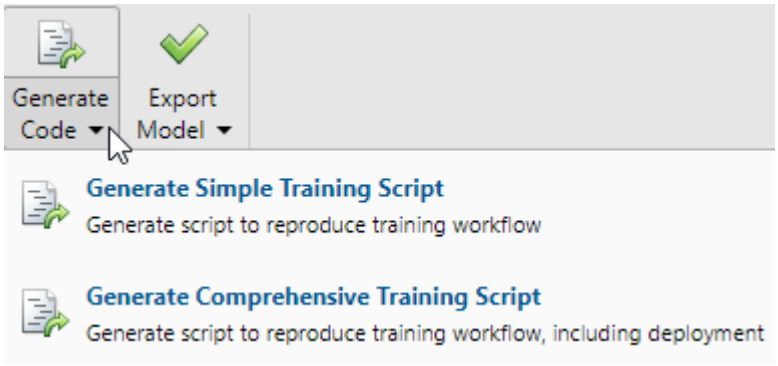
- Train the network again.
- Increase the number of hidden neurons.
- Use a larger training data set.

If performance on the training set is good but the test set performance is poor, this could indicate the model is overfitting. Reducing the number of neurons can reduce the overfitting.

You can also evaluate the network performance on an additional test set. To load additional test data to evaluate the network with, in the **Test** section, click **Test**. The **Model Summary** displays the additional test results. You can also generate plots to analyze the additional test data results.

Generate Code

Select **Generate Code > Generate Simple Training Script** to create MATLAB code to reproduce the previous steps from the command line. Creating MATLAB code can be helpful if you want to learn how to use the command line functionality of the toolbox to customize the training process. In “Fit Data Using Command-Line Functions”, you will investigate the generated scripts in more detail.



Export Network

You can export your trained network to the workspace or Simulink®. You can also deploy the network with MATLAB Compiler™ tools and other MATLAB code generation tools. To export your trained network and results, select **Export Model > Export to Workspace**.

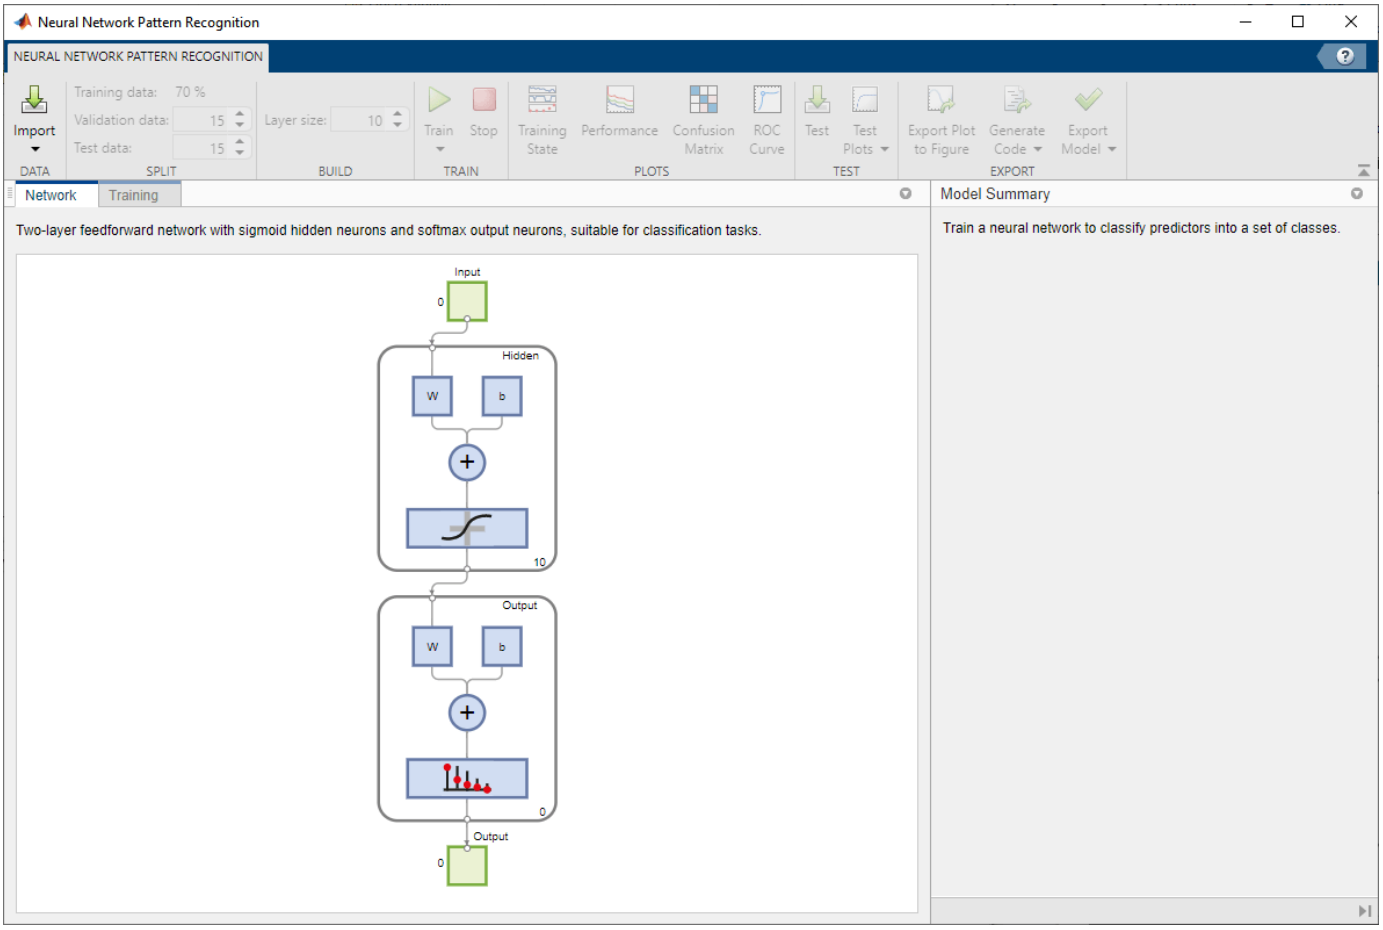
Classify Patterns Using the Neural Net Pattern Recognition App

This example shows how to train a shallow neural network to classify patterns using the **Neural Net Pattern Recognition** app.

Open the **Neural Net Pattern Recognition** app using `nprtool`.

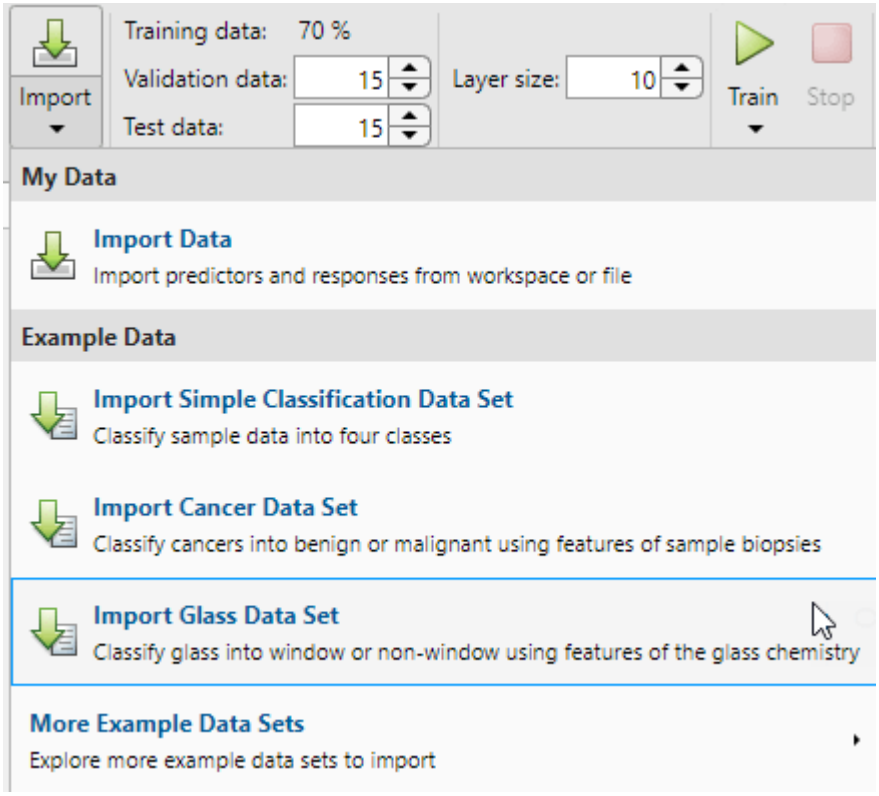
```
nprtool
```



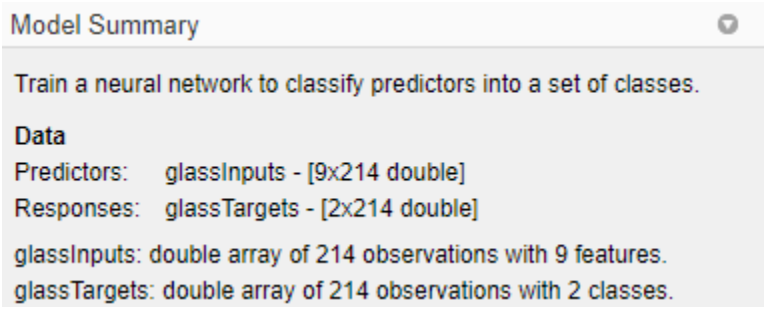
Select Data

The **Neural Net Pattern Recognition** app has example data to help you get started training a neural network.

To import example glass classification data, select **Import** > **Import Glass Data Set**. You can use this data set to train a neural network to classify glass as window or non-window, using properties of the glass chemistry. If you import your own data from file or the workspace, you must specify the predictors and responses, and if the observations are in rows or columns.



Information about the imported data appears in the **Model Summary**. This data set contains 214 observations, each with 9 features. Each observation is classified into one of two classes: window or non-window.



Split the data into training, validation, and test sets. Keep the default settings. The data is split into:

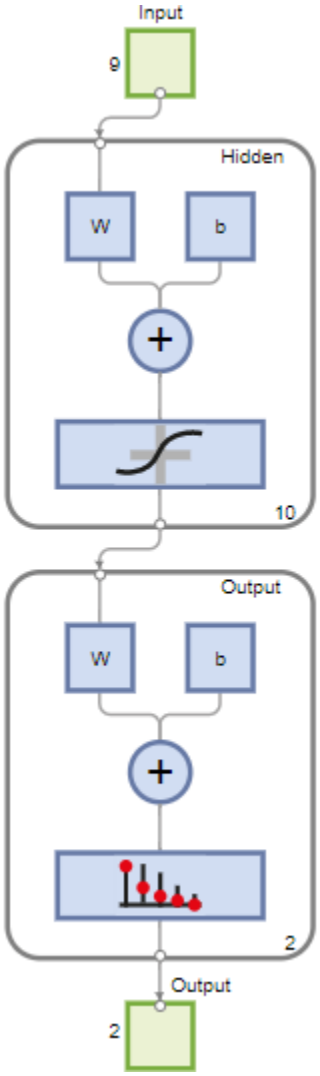
- 70% for training.
- 15% to validate that the network is generalizing and to stop training before overfitting.
- 15% to independently test network generalization.

For more information on data division, see “Divide Data for Optimal Neural Network Training” on page 22-9.

Create Network

The network is a two-layer feedforward network with a sigmoid transfer function in the hidden layer and a softmax transfer function in the output layer. The size of the hidden layer corresponds to the

number of hidden neurons. The default layer size is `10`. You can see the network architecture in the **Network** pane. The number of output neurons is set to 2, which is equal to the number of classes specified by the response data.



Train Network

To train the network, click **Train**.

In the **Training** pane, you can see the training progress. Training continues until one of the stopping criteria is met. In this example, training continues until the validation error increases consecutively for six iterations ("Met validation criterion").

Training Results

Training finished: Met validation criterion

Training Progress

Unit	Initial Value	Stopped Value	Target Value
Epoch	0	14	1000
Elapsed time	-	00:00:00	-
Performance	0.418	0.0523	0
Gradient	0.808	0.017	1e-06
Validation Checks	0	6	6

Analyze Results

The **Model Summary** contains information about the training algorithm and the training results for each data set.

Algorithm

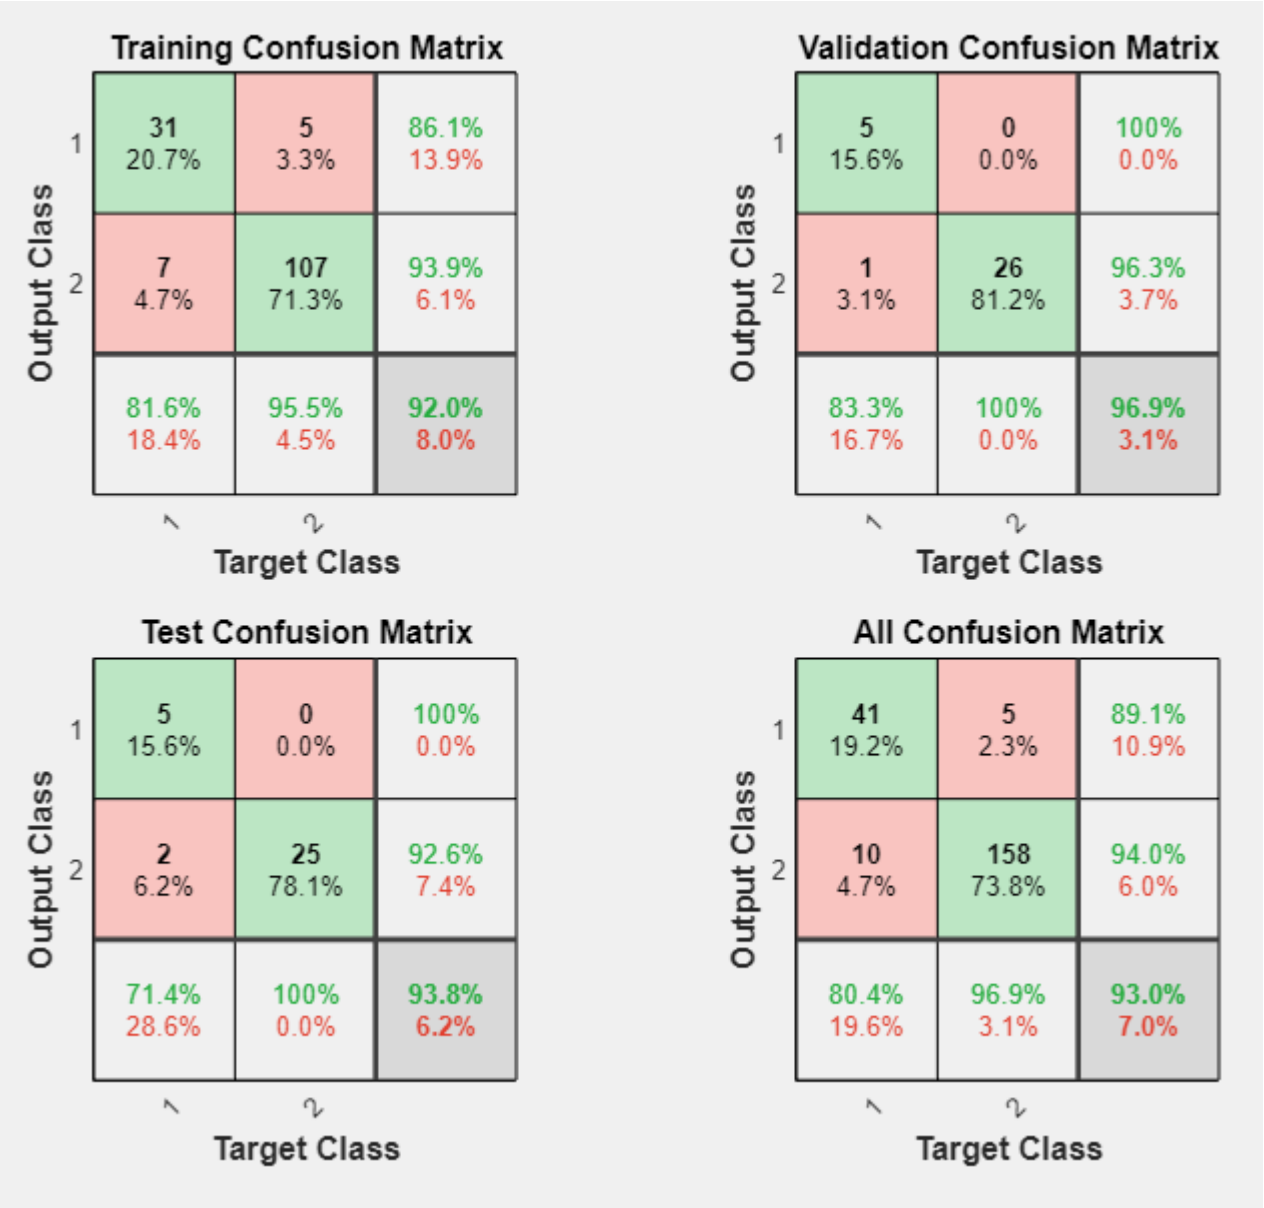
Data division: Random
Training algorithm: Scaled conjugate gradient
Performance: Cross-entropy error

Training Results

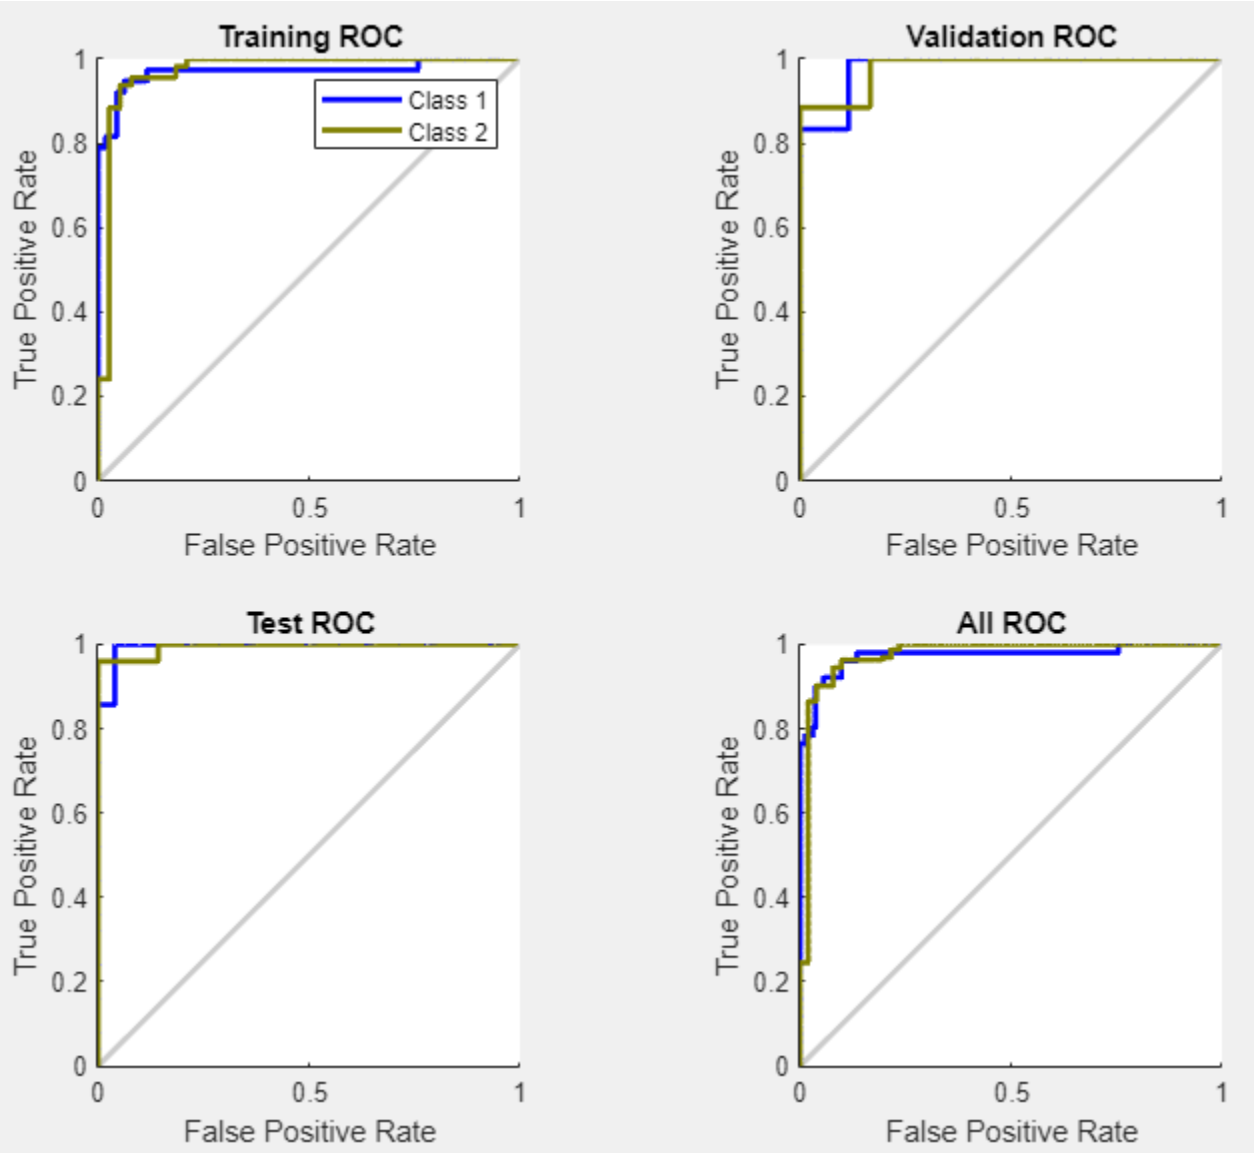
Training start time: 02-Jul-2021 11:53:16
Layer size: 10

	Observations	Cross-entropy	Error
Training	150	0.0749	0.0800
Validation	32	0.0798	0.0312
Test	32	0.0720	0.0625

You can further analyze the results by generating plots. To plot the confusion matrices, in the **Plots** section, click **Confusion Matrix**. The network outputs are very accurate, as you can see by the high numbers of correct classifications in the green squares (diagonal) and the low numbers of incorrect classifications in the red squares (off-diagonal).



View the ROC curve to obtain additional verification of network performance. In the **Plots** section, click **ROC Curve**.



The colored lines in each axis represent the ROC curves. The ROC curve is a plot of the true positive rate (sensitivity) versus the false positive rate (1 - specificity) as the threshold is varied. A perfect test would show points in the upper-left corner, with 100% sensitivity and 100% specificity. For this problem, the network performs very well.

If you are unhappy with the network performance, you can do one of the following:

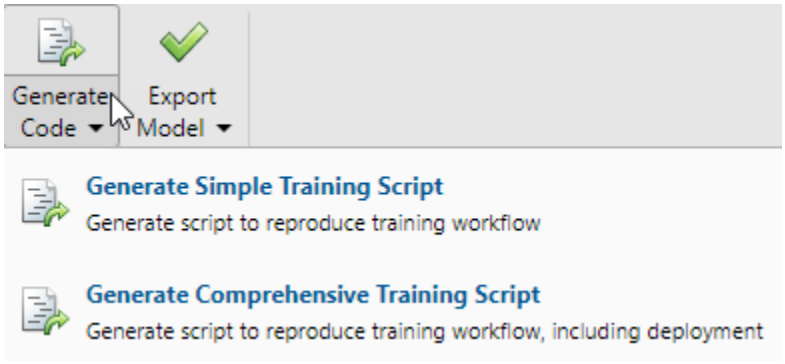
- Train the network again.
- Increase the number of hidden neurons.
- Use a larger training data set.

If performance on the training set is good but the test set performance is poor, this could indicate the model is overfitting. Reducing the number of neurons can reduce the overfitting.

You can also evaluate the network performance on an additional test set. To load additional test data to evaluate the network with, in the **Test** section, click **Test**. The **Model Summary** displays the additional test results. You can also generate plots to analyze the additional test results.

Generate Code

Select **Generate Code > Generate Simple Training Script** to create MATLAB code to reproduce the previous steps from the command line. Creating MATLAB code can be helpful if you want to learn how to use the command line functionality of the toolbox to customize the training process. In “Classify Patterns Using Command-Line Functions”, you will investigate the generated scripts in more detail.



Export Network

You can export your trained network to the workspace or Simulink®. You can also deploy the network with MATLAB Compiler™ and other MATLAB code generation tools. To export your trained network and results, select **Export Model > Export to Workspace**.

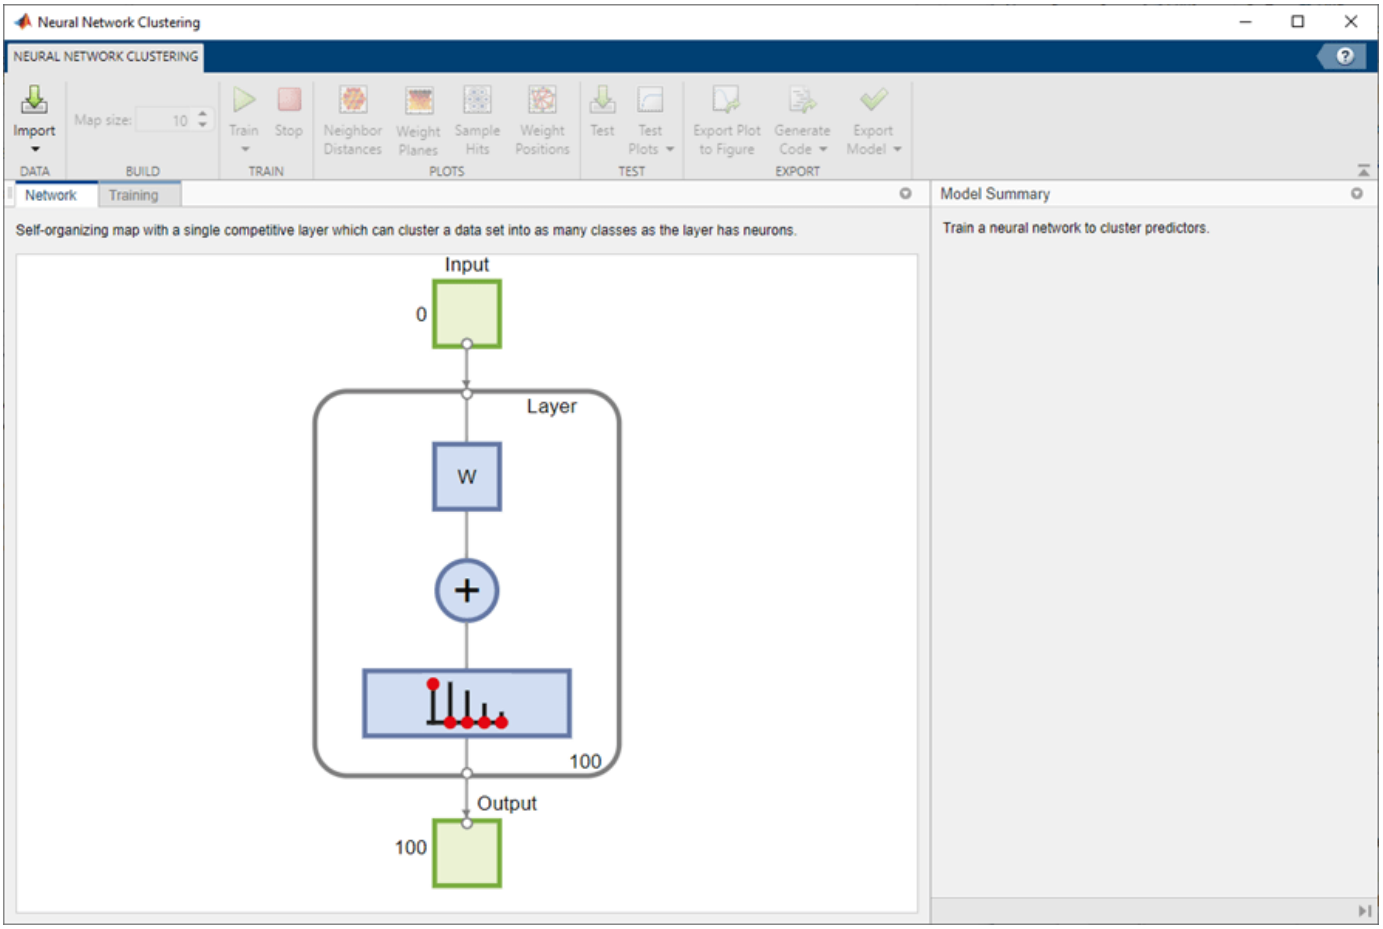
Cluster Data Using the Neural Net Clustering App

This example shows how to train a shallow neural network to cluster data using the **Neural Net Clustering** app.

Open the **Neural Net Clustering** app using `nctool`.

```
nctool
```

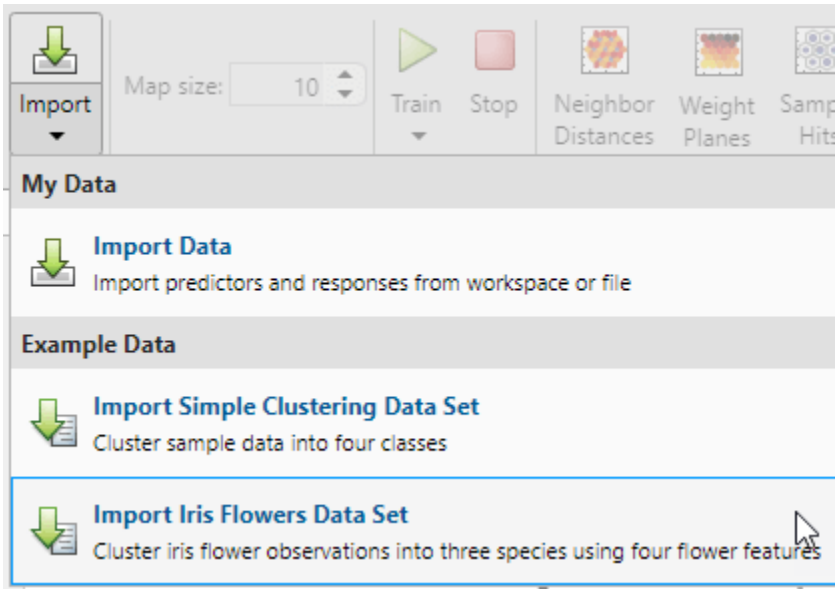


Select Data

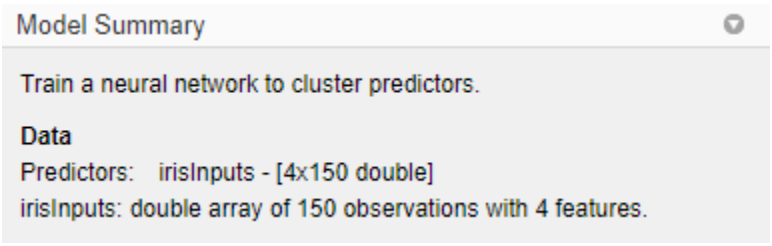
The **Neural Net Clustering** app has example data to help you get started training a neural network.

To import the example iris flower clustering data, select **Import** > **Import Iris Flowers Data Set**. If you import your own data from file or the workspace, you must specify the predictors and if the

observations are in rows or columns.



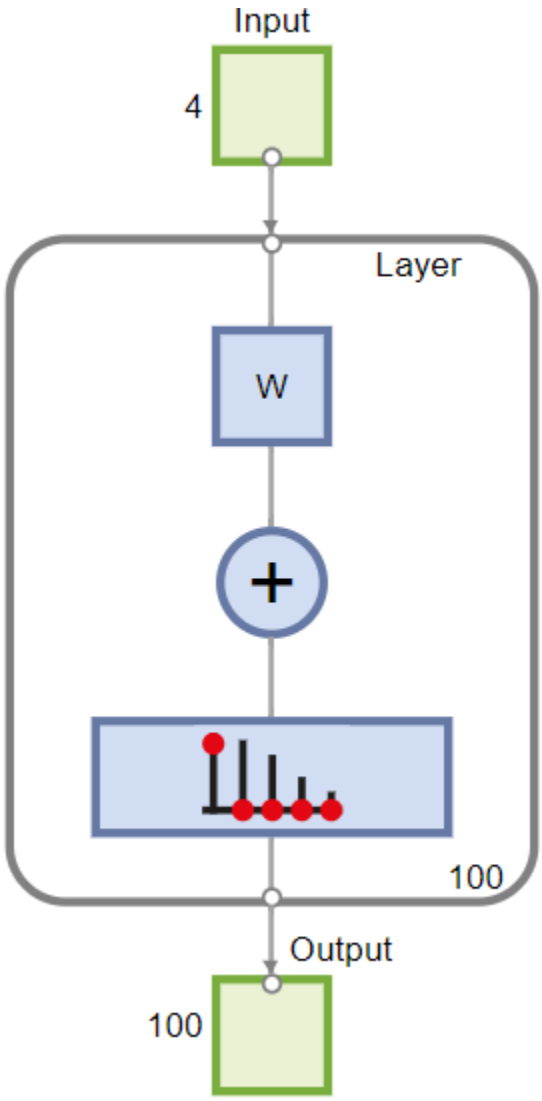
Information about the imported data appears in the **Model Summary**. This data set contains 150 observations, each with four features.



Create Network

For clustering problems, the self-organizing feature map (SOM) is the most commonly used network. This network has one layer, with neurons organized in a grid. Self-organizing maps learn to cluster data based on similarity. For more information on the SOM, see “Cluster with Self-Organizing Map Neural Network” on page 26-8.

To create the network, specify the map size, this corresponds to the number of rows and columns in the grid. For this example, set the **Map size** value to 10, this corresponds to a grid with 10 rows and 10 columns. The total number of neurons is equal to the number of points in the grid, in this example, the map has 100 neurons. You can see the network architecture in the **Network** pane.



Train Network

To train the network, click **Train**. In the **Training** pane, you can see the training progress. Training continues until one of the stopping criteria is met. In this example, training continues until the maximum number of epochs is reached.

Training Results

Training finished: Reached maximum number of epochs

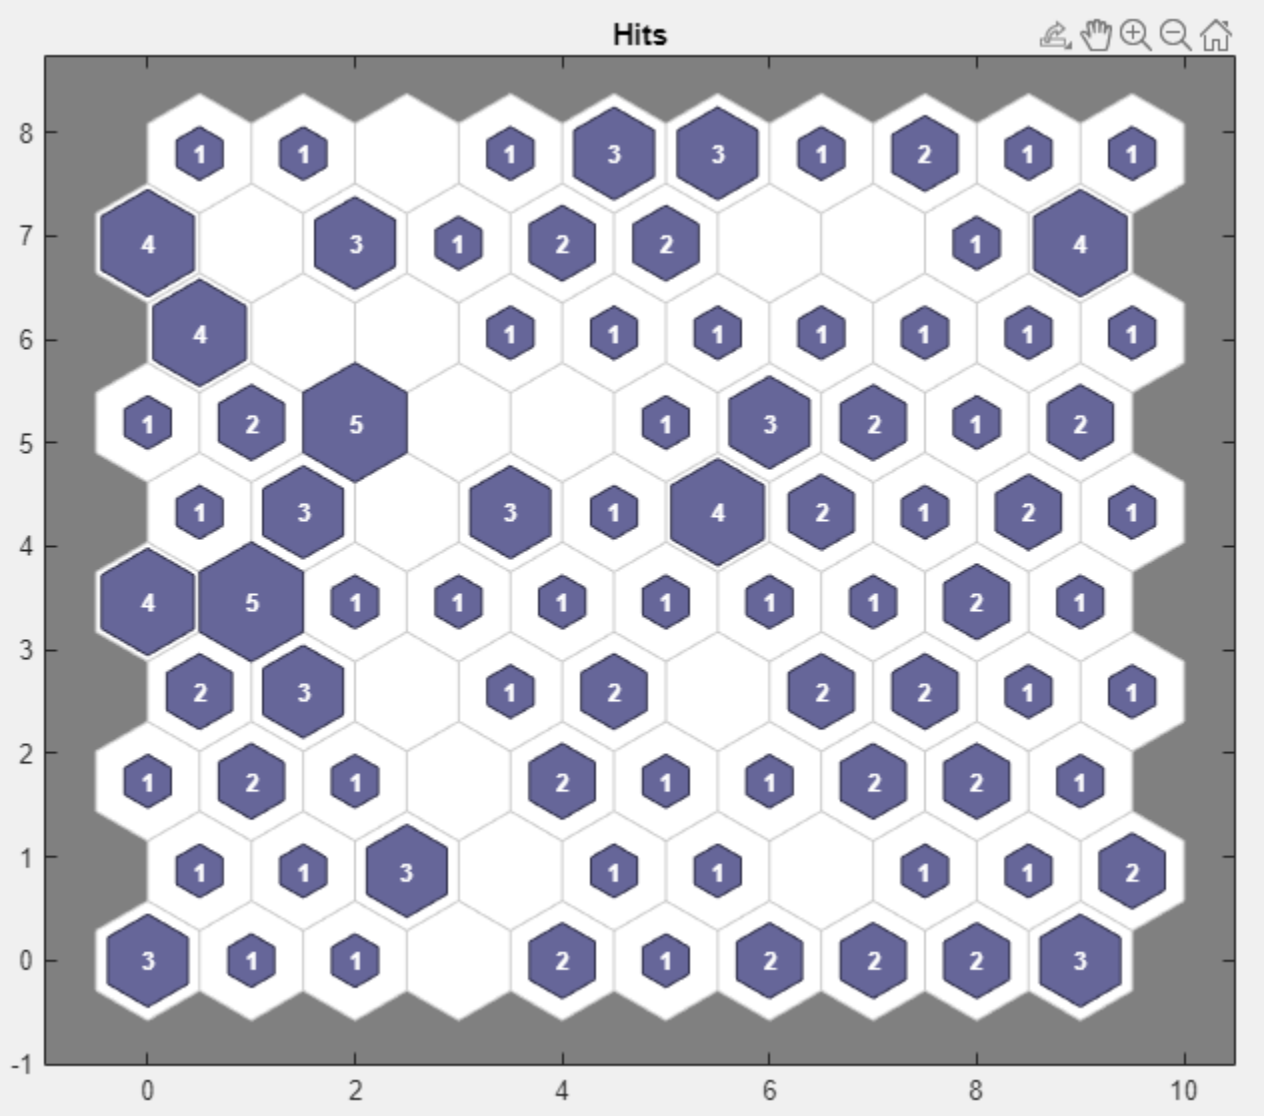
Training Progress

Unit	Initial Value	Stopped Value	Target Value
Epoch	0	200	200
Elapsed time	-	00:00:00	-

Analyze Results

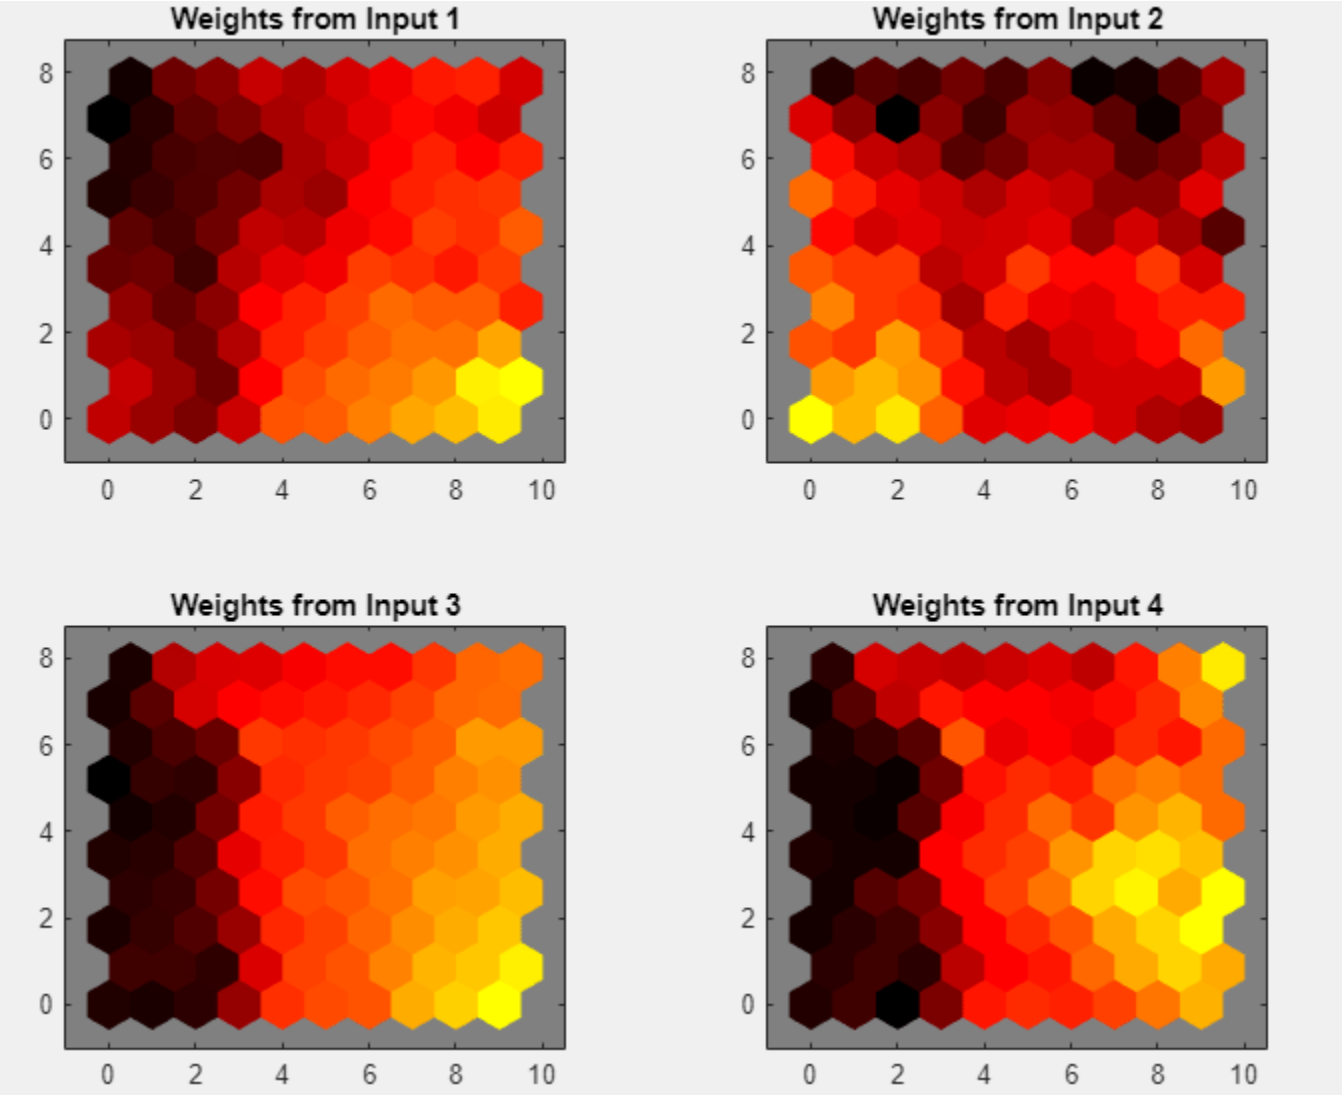
To analyze the training results, generate plots. For SOM training, the weight vector associated with each neuron moves to become the center of a cluster of input vectors. In addition, neurons that are adjacent to each other in the topology should also move close to each other in the input space, therefore it is possible to visualize a high-dimensional inputs space in the two dimensions of the network topology. The default topology of the SOM is hexagonal.

To plot the SOM Sample Hits, in the **Plots** section, click **Sample Hits**. This figure shows the neuron locations in the topology, and indicates how many of the observations are associated with each of the neurons (cluster centers). The topology is a 10-by-10 grid, so there are 100 neurons. The maximum number of hits associated with any neuron is 5. Thus, there are 5 input vectors in that cluster.



Plot the weight planes (also referred to as *component planes*). In the **Plots** section, click **Weight Planes**. This figure shows a weight plane for each element of the input features (four, in this example). The plot shows the weights that connect each input to each of the neurons, with darker

colors representing larger weights. If the connection patterns of two features are very similar, you can assume that the features are highly correlated.



If you are unhappy with the network performance, you can do one of the following:

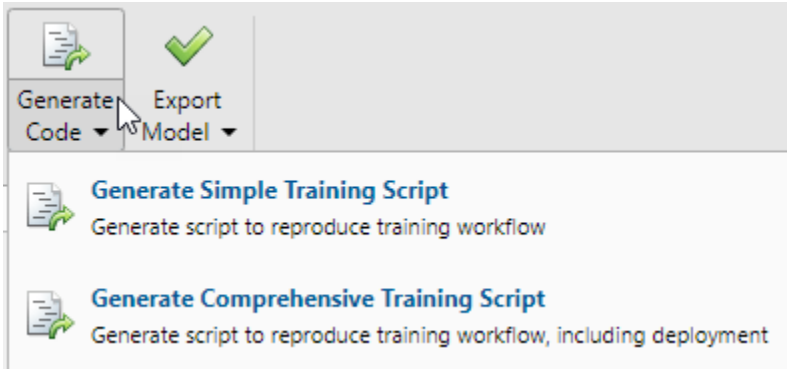
- Train the network again. Each training will have different initial weights and biases of the network, and can produce an improved network after retraining.
- Increase the number of neurons by increasing the map size.
- Use a larger training data set.

You can also evaluate the network performance on an additional test set. To load additional test data to evaluate the network with, in the **Test** section, click **Test**. Generate plots to analyze the additional test results.

Generate Code

Select **Generate Code > Generate Simple Training Script** to create MATLAB code to reproduce the previous steps from the command line. Creating MATLAB code can be helpful if you want to learn

how to use the command-line functionality of the toolbox to customize the training process. In "Cluster Data Using Command-Line Functions", you will investigate the generated scripts in more detail.



Export Network

You can export your trained network to the workspace or Simulink®. You can also deploy the network with MATLAB Compiler™ tools and other MATLAB code generation tools. To export your trained network and results, select **Export Model > Export to Workspace**.

Fit Time Series Data Using the Neural Net Time Series App

This example shows how to train a shallow neural network to fit time series data using the **Neural Net Time Series** app.

Open the **Neural Net Time Series** app using `ntstool`.

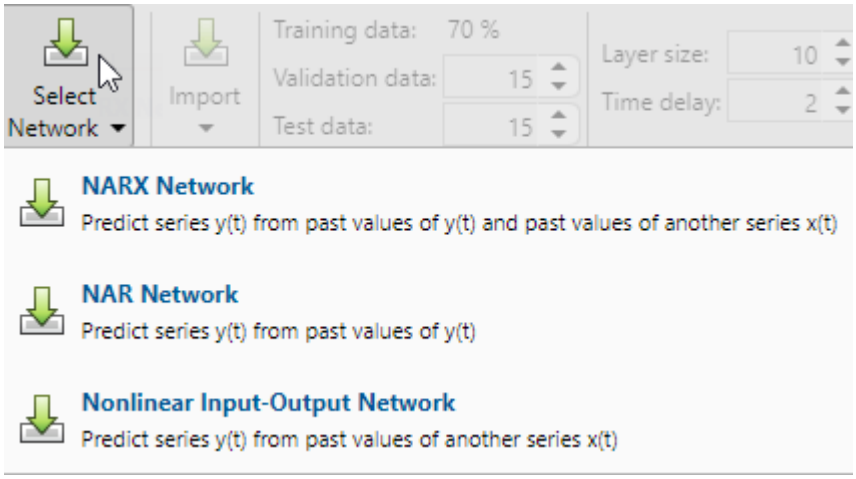
```
ntstool
```

Select Network

You can use the **Neural Net Time Series** app to solve three different kinds of time series problems.

- In the first type of time series problem, you would like to predict future values of a time series $y(t)$ from past values of that time series and past values of a second time series $x(t)$. This form of prediction is called nonlinear autoregressive network with exogenous (external) input, or NARX.
- In the second type of time series problem, there is only one series involved. The future values of a time series $y(t)$ are predicted only from past values of that series. This form of prediction is called nonlinear autoregressive, or NAR.
- The third time series problem is similar to the first type, in that two series are involved, an input series (predictors) $x(t)$ and an output series (responses) $y(t)$. Here you want to predict values of $y(t)$ from previous values of $x(t)$, but without knowledge of previous values of $y(t)$.

For this example, use a NARX network. Click **Select Network > NARX Network**.

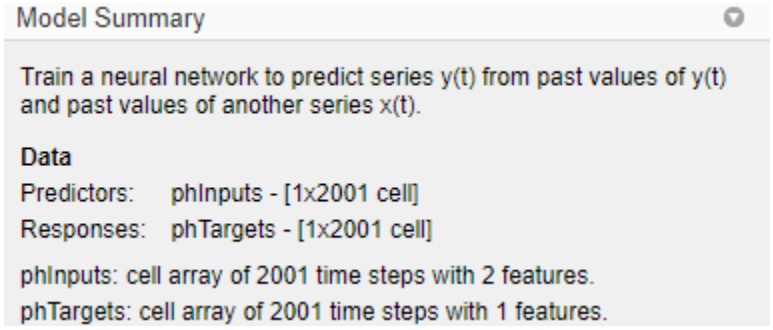


Select Data

The **Neural Net Time Series** app has example data to help you get started training a neural network.

To import example pH neutralization process data, select **Import > More Example Data Sets > Import pH Neutralization Data Set**. You can use this data set to train a neural network to predict the pH of a solution using acid and base solution flow. If you import your own data from file or the workspace, you must specify the predictors and responses.

Information about the imported data appears in the **Model Summary**. This data set contains 2001 time steps. The predictors have two features (acid and base solution flow) and the responses have a single feature (solution pH).



Split the data into training, validation, and test sets. Keep the default settings. The data is split into:

- 70% for training.
- 15% to validate that the network is generalizing and to stop training before overfitting.
- 15% to independently test network generalization.

For more information on data division, see “Divide Data for Optimal Neural Network Training” on page 22-9.

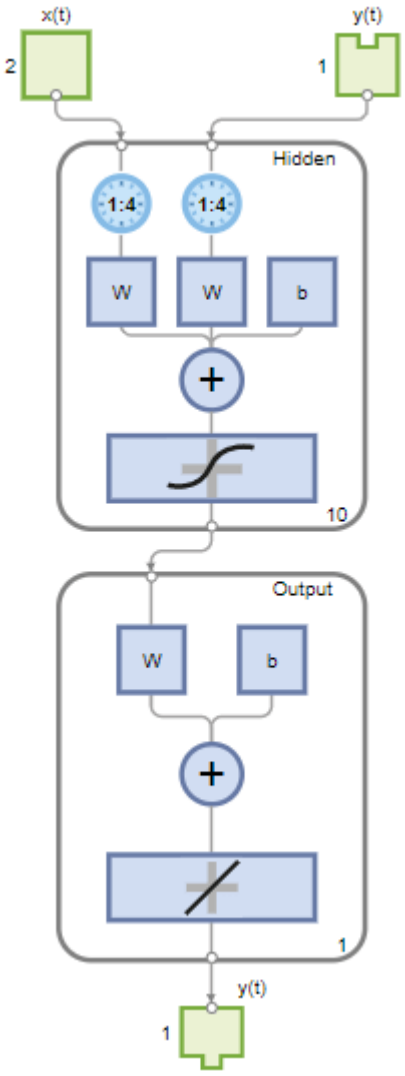
Create Network

The standard NARX network is a two-layer feedforward network, with a sigmoid transfer function in the hidden layer and a linear transfer function in the output layer. This network also uses tapped delay lines to store previous values of the $x(t)$ and $y(t)$ sequences. Note that the output of the NARX network, $y(t)$, is fed back to the input of the network (through delays), since $y(t)$ is a function of $y(t–1), y(t–2), \ldots, y(t–d)$. However, for efficient training this feedback loop can be opened.

Because the true output is available during the training of the network, you can use the open-loop architecture shown below, in which the true output is used instead of feeding back the estimated output. This has two advantages. The first is that the input to the feedforward network is more accurate. The second is that the resulting network has a purely feedforward architecture, and therefore a more efficient algorithm can be used for training. This network is discussed in more detail in “Design Time Series NARX Feedback Neural Networks” on page 23-16.

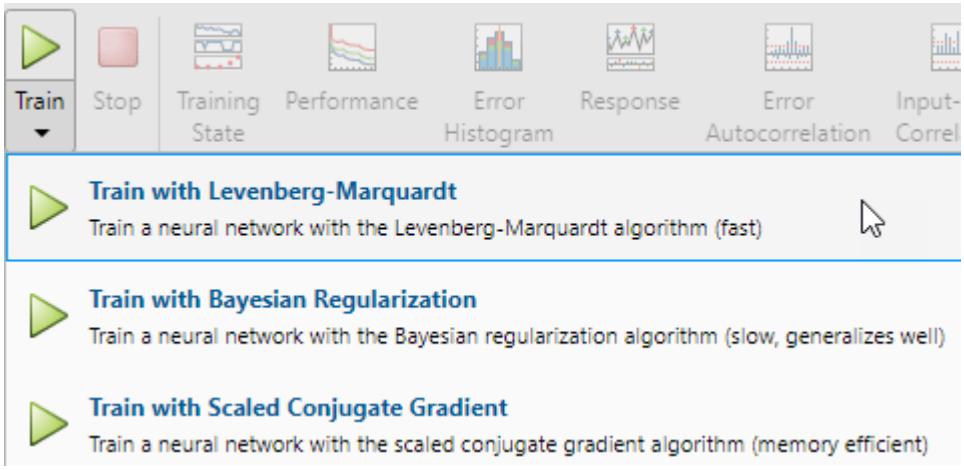
The **Layer size** value defines the number of hidden neurons. Keep the default layer size, `10`. Change the **Time delay** value to `4`. You might want to adjust these numbers if the network training performance is poor.

You can see the network architecture in the **Network** pane.



Train Network

To train the network, select **Train > Train with Levenberg-Marquardt**. This is the default training algorithm and the same as clicking **Train**.



Training with Levenberg-Marquardt (`trainlm`) is recommended for most problems. For noisy or small problems, Bayesian Regularization (`trainbr`) can obtain a better solution, at the cost of taking longer. For large problems, Scaled Conjugate Gradient (`trainscg`) is recommended as it uses gradient calculations which are more memory efficient than the Jacobian calculations the other two algorithms use.

In the **Training** pane, you can see the training progress. Training continues until one of the stopping criteria is met. In this example, training continues until the validation error increases consecutively for six iterations ("Met validation criterion").

Training Results

Training finished: Met validation criterion

Training Progress

Unit	Initial Value	Stopped Value	Target Value
Epoch	0	43	1000
Elapsed time	-	00:00:00	-
Performance	69	0.00212	0
Gradient	125	0.0068	1e-07
Mu	0.001	1e-06	1e+10
Validation Checks	0	6	6

Analyze Results

The **Model Summary** contains information about the training algorithm and the training results for each data set.

Algorithm

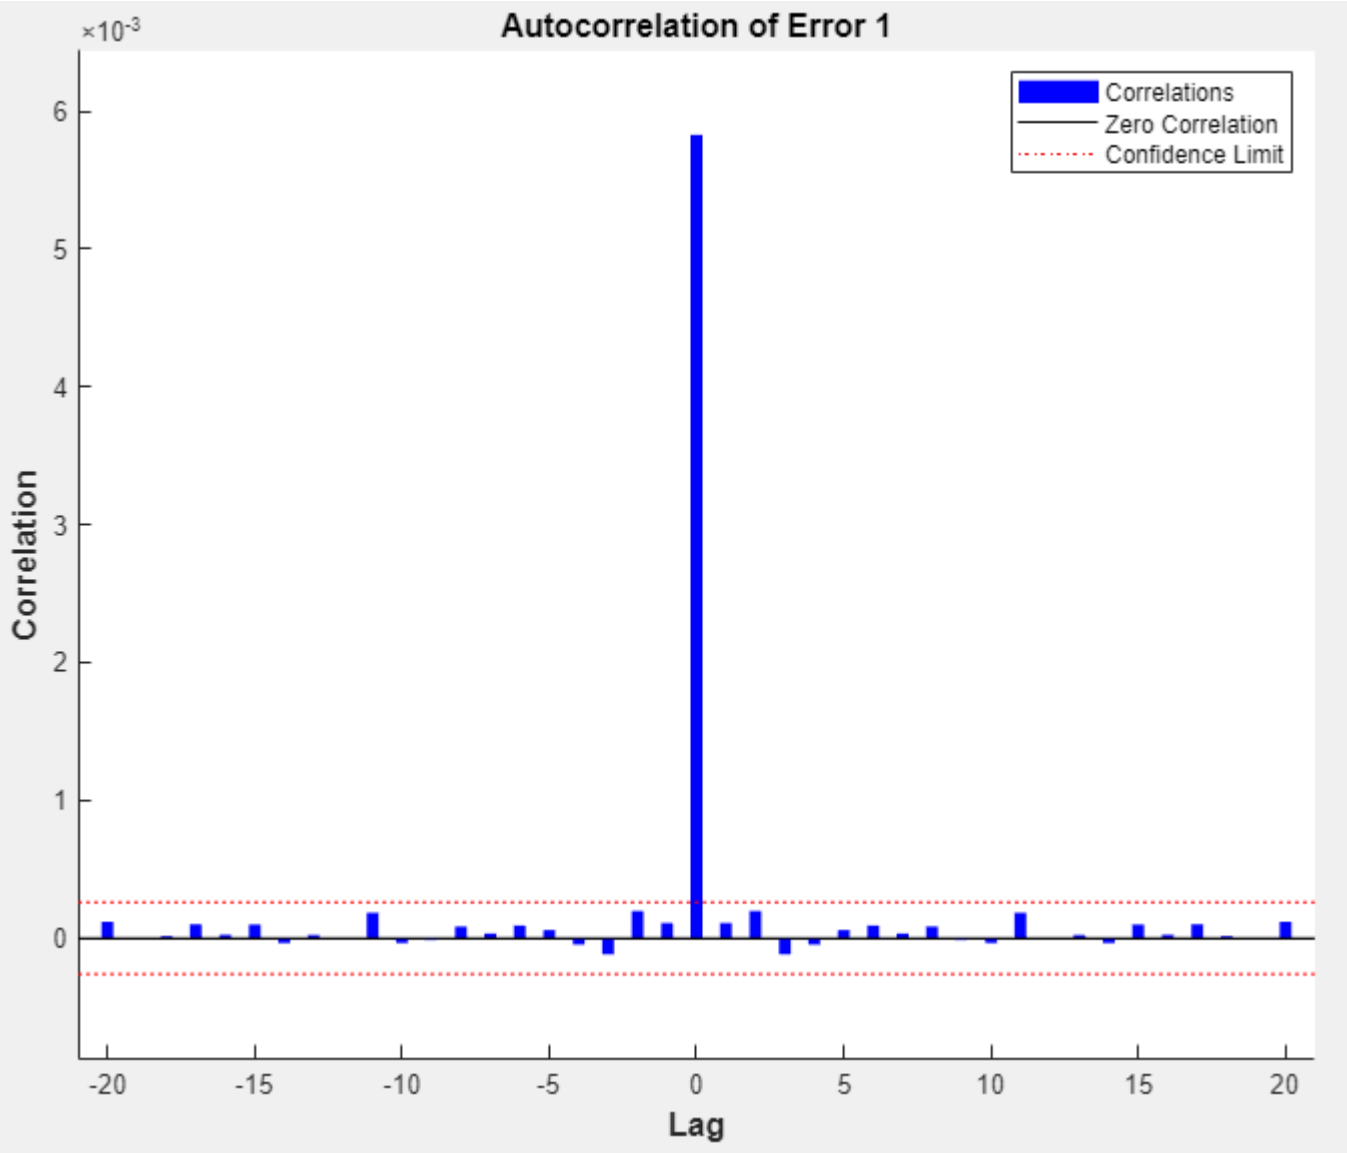
Data division:	Random
Training algorithm:	Levenberg-Marquardt
Performance:	Mean squared error

Training Results

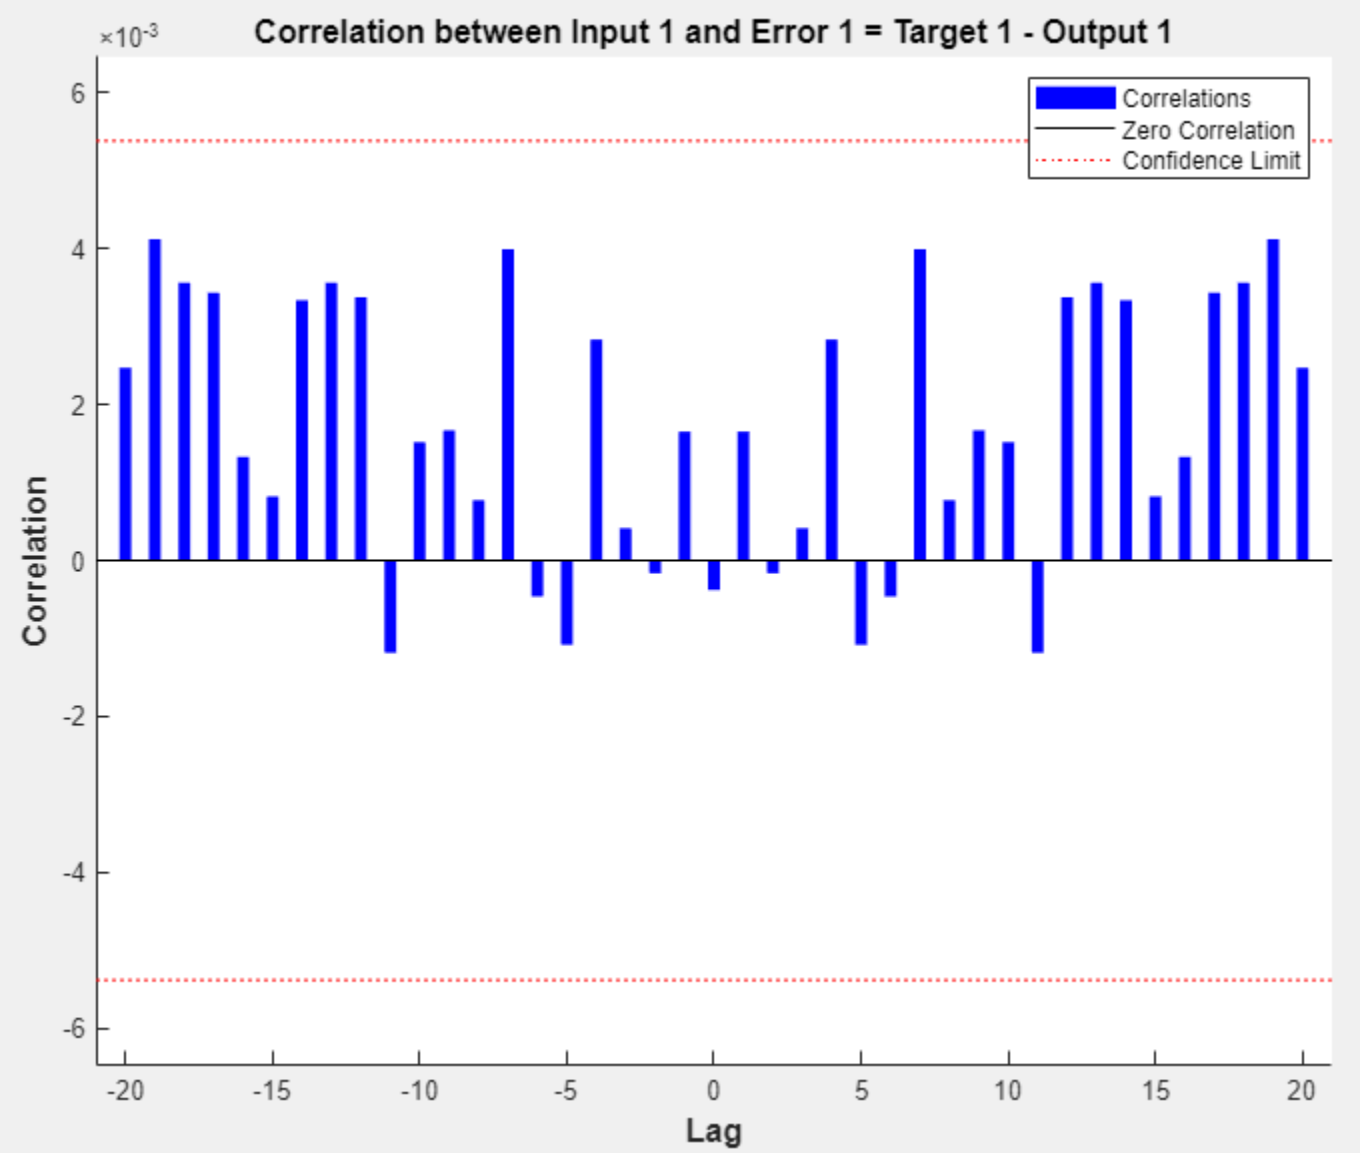
Training start time:	02-Jul-2021 11:27:58
Layer size:	10
Time delay:	4

	Observations	MSE	R
Training	1397	0.0021	0.9998
Validation	300	0.0069	0.9994
Test	300	0.0220	0.9985

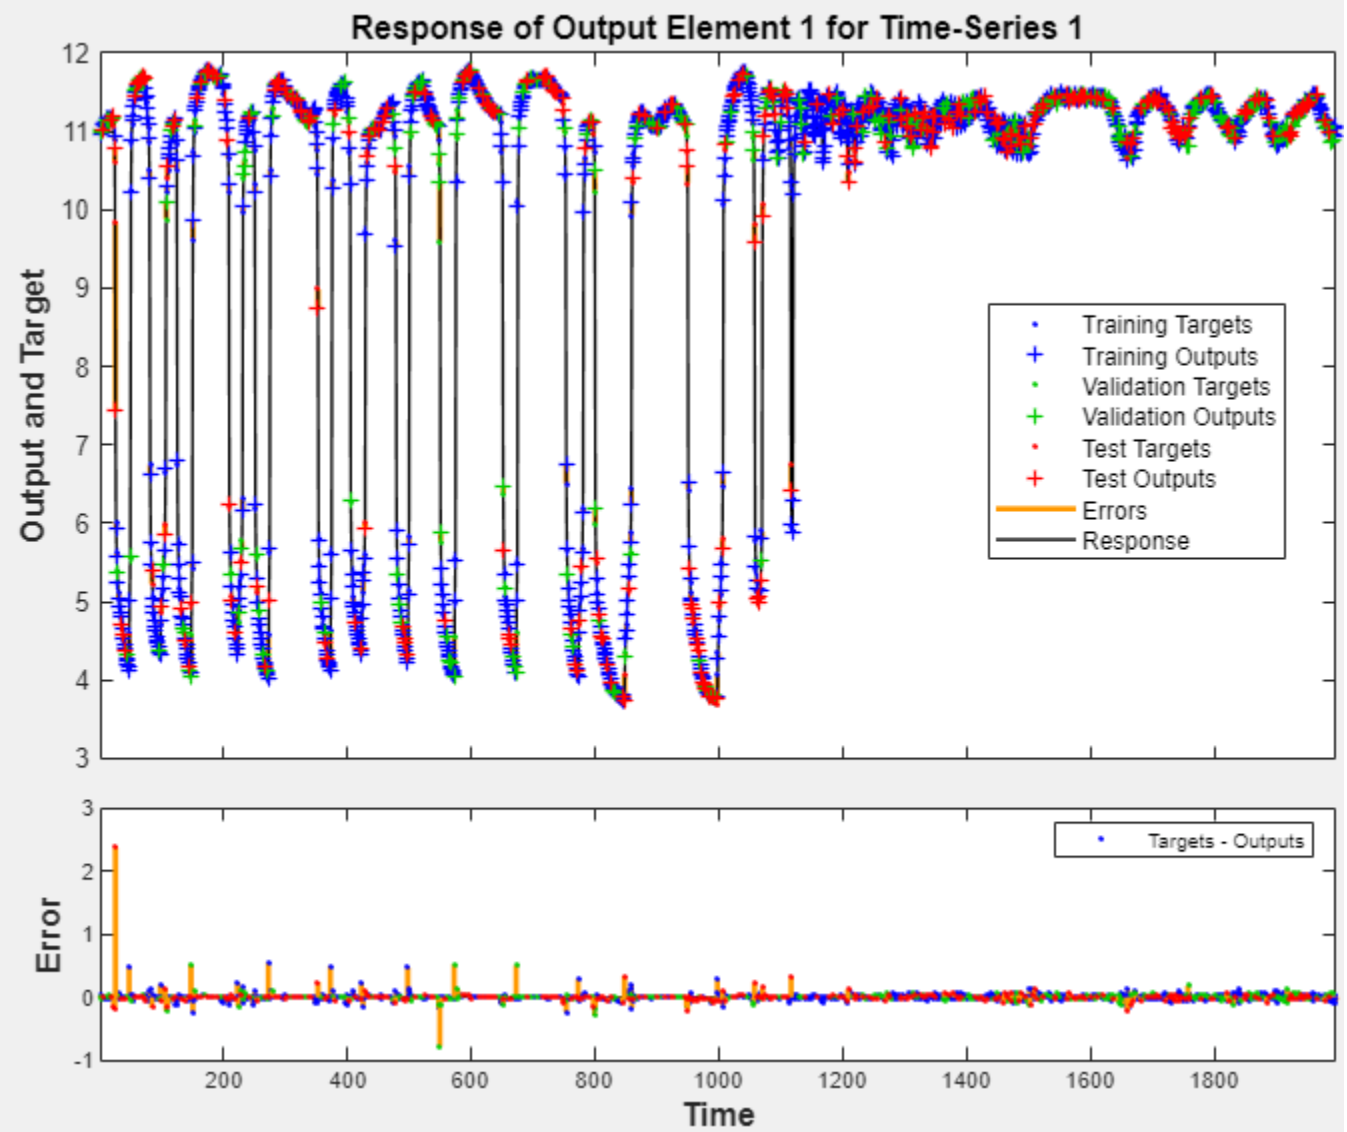
You can further analyze the results by generating plots. To plot the error autocorrelation, in the **Plots** section, click **Error Autocorrelation**. The autocorrelation plot describes how the prediction errors are related in time. For a perfect prediction model, there should only be one nonzero value of the autocorrelation function, and it should occur at zero lag (this is the mean square error). This would mean that the prediction errors were completely uncorrelated with each other (white noise). If there was significant correlation in the prediction errors, then it should be possible to improve the prediction - perhaps by increasing the number of delays in the tapped delay lines. In this case, the correlations, except for the one at zero lag, fall approximately within the 95% confidence limits around zero, so the model seems to be adequate. If even more accurate results were required, you could retrain the network. This will change the initial weights and biases of the network, and may produce an improved network after retraining.



View the input-error cross-correlation plot to obtain additional verification of network performance. In the **Plots** section, click **Input-Error Correlation**. The input-error cross-correlation plot illustrates how the errors are correlated with the input sequence $x(t)$. For a perfect prediction model, all of the correlations should be zero. If the input is correlated with the error, then it should be possible to improve the prediction, perhaps by increasing the number of delays in the tapped delay lines. In this case, most of the correlations fall within the confidence bounds around zero.



In the **Plots** section, click **Response**. This displays the outputs, responses (targets), and errors versus time. It also indicates which time points were selected for training, testing, and validation.



If you are unhappy with the network performance, you can do one of the following:

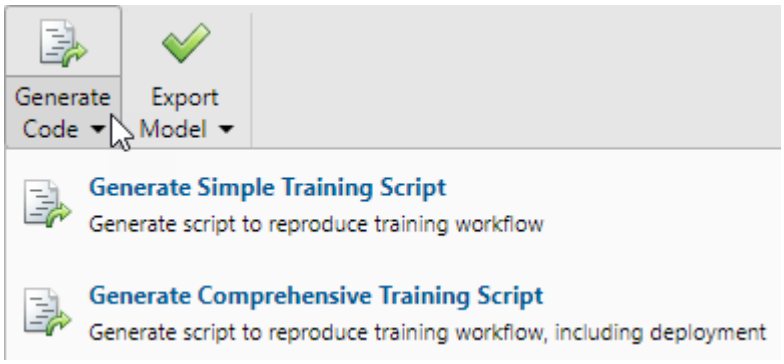
- Train the network again.
- Increase the number of hidden neurons.
- Use a larger training data set.

If performance on the training set is good but the test set performance is poor, this could indicate the model is overfitting. Decreasing the layer size, and therefore decreasing the number of neurons, can reduce the overfitting.

You can also evaluate the network performance on an additional test set. To load additional test data to evaluate the network with, in the **Test** section, click **Test**. The **Model Summary** displays the additional test data results. You can also generate plots to analyze the additional test data results.

Generate Code

Select **Generate Code** > **Generate Simple Training Script** to create MATLAB code to reproduce the previous steps from the command line. Creating MATLAB code can be helpful if you want to learn how to use the command-line functionality of the toolbox to customize the training process. In “Fit Time Series Data Using Command-Line Functions”, you will investigate the generated scripts in more detail.



Export Network

You can export your trained network to the workspace or Simulink®. You can also deploy the network with MATLAB Compiler™ tools and other MATLAB code generation tools. To export your trained network and results, select **Export Model** > **Export to Workspace**.

Body Fat Estimation

This example illustrates how a function fitting neural network can estimate body fat percentage based on anatomical measurements.

The Problem: Estimate Body Fat Percentage

In this example we attempt to build a neural network that can estimate the body fat percentage of a person described by thirteen physical attributes:

- Age (years)
- Weight (lbs)
- Height (inches)
- Neck circumference (cm)
- Chest circumference (cm)
- Abdomen circumference (cm)
- Hip circumference (cm)
- Thigh circumference (cm)
- Knee circumference (cm)
- Ankle circumference (cm)
- Biceps (extended) circumference (cm)
- Forearm circumference (cm)
- Wrist circumference (cm)

This is an example of a fitting problem, where inputs are matched up to associated target outputs, and we would like to create a neural network which not only estimates the known targets given known inputs, but can also generalize to accurately estimate outputs for inputs that were not used to design the solution.

Why Neural Networks?

Neural networks are very good at function fit problems. A neural network with enough elements (called neurons) can fit any data with arbitrary accuracy. They are particularly well suited for addressing nonlinear problems. Given the nonlinear nature of real world phenomena, like body fat accretion, neural networks are a good candidate for solving the problem.

The thirteen physical attributes will act as inputs to a neural network, and the body fat percentage will be the target.

The network will be designed by using the anatomical quantities of bodies whose body fat percentage is already known to train it to produce the target valuations.

Preparing the Data

Data for function fitting problems are set up for a neural network by organizing the data into two matrices, the input matrix X and the target matrix T.

Each ith column of the input matrix will have thirteen elements representing a body with known body fat percentage.

Each corresponding column of the target matrix will have one element, representing the body fat percentage.

Here such a dataset is loaded.

```
[X,T] = bodyfat_dataset;
```

We can view the sizes of inputs X and targets T.

Note that both X and T have 252 columns. These represent 252 physiques (inputs) and associated body fat percentages (targets).

The input matrix X has thirteen rows, for the thirteen attributes. The target matrix T has only one row, as for each example we only have one desired output, the body fat percentage.

```
size(X)
```

```
ans = 1×2

    13   252
```

```
size(T)
```

```
ans = 1×2

     1   252
```

Fitting a Function with a Neural Network

The next step is to create a neural network that will learn to estimate body fat percentages.

Since the neural network starts with random initial weights, the results of this example will differ slightly every time it is run. The random seed is set to avoid this randomness. However this is not necessary for your own applications.

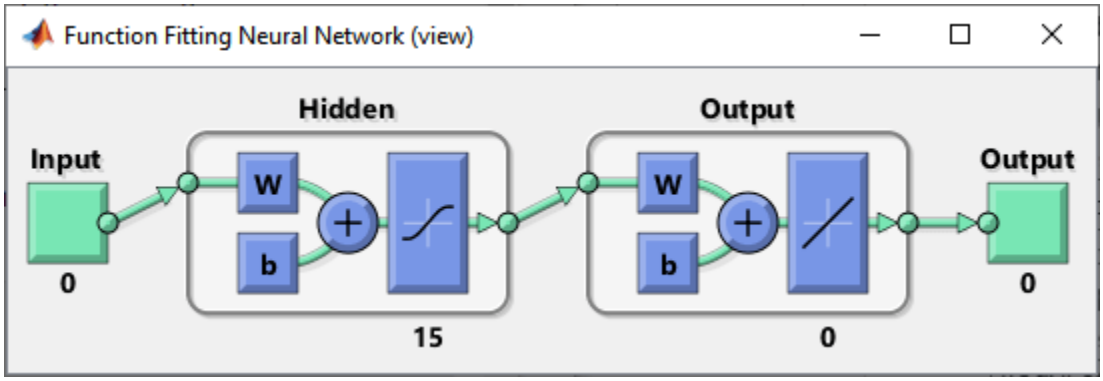
```
setdemorandstream(491218382)
```

Two-layer (i.e. one-hidden-layer) feed forward neural networks can fit any input-output relationship given enough neurons in the hidden layer. Layers which are not output layers are called hidden layers.

We will try a single hidden layer of 15 neurons for this example. In general, more difficult problems require more neurons, and perhaps more layers. Simpler problems require fewer neurons.

The input and output have sizes of 0 because the network has not yet been configured to match our input and target data. This will happen when the network is trained.

```
net = fitnet(15);
view(net)
```



Now the network is ready to be trained. The samples are automatically divided into training, validation and test sets. The training set is used to teach the network. Training continues as long as the network continues improving on the validation set. The test set provides a completely independent measure of network accuracy.

The Neural Network Training Tool shows the network being trained and the algorithms used to train it. It also displays the training state during training and the criteria which stopped training will be highlighted in green.

The buttons at the bottom open useful plots which can be opened during and after training. Links next to the algorithm names and plot buttons open documentation on those subjects.

```
[net,tr] = train(net,X,T);
```

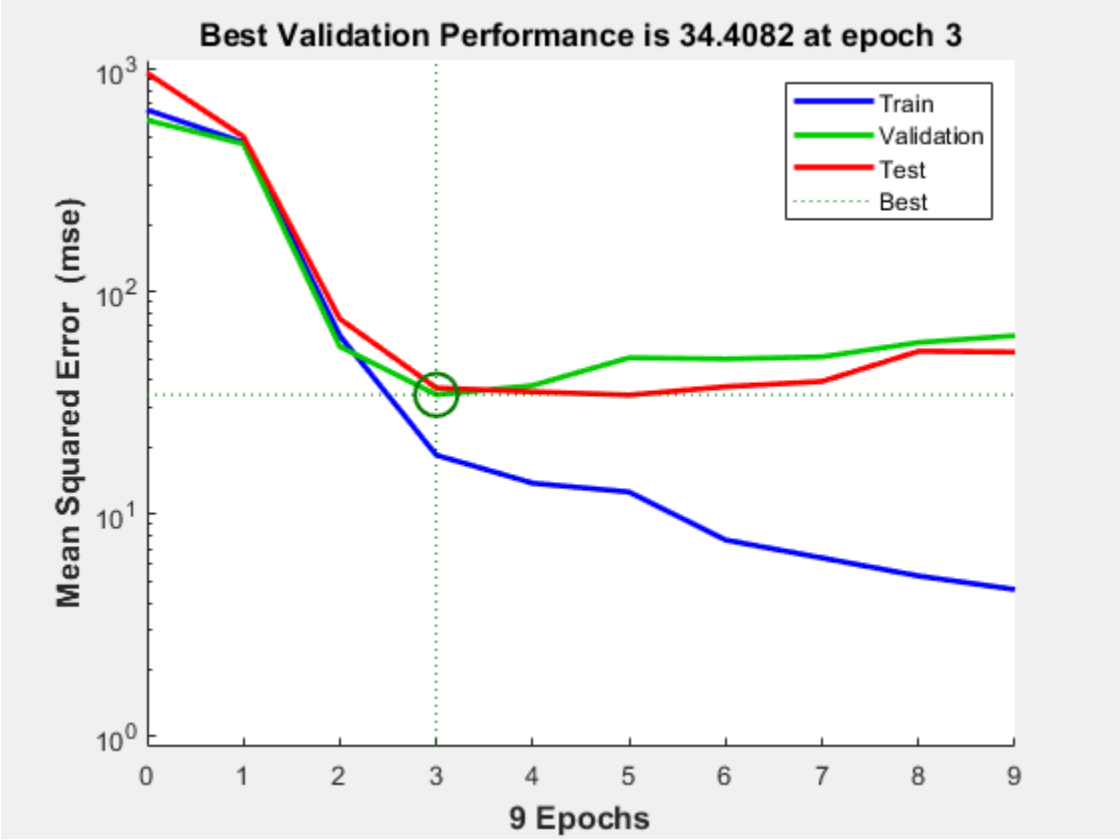
To see how the network's performance improved during training, either click the "Performance" button in the training tool, or call PLOTPERFORM.

Performance is measured in terms of mean squared error, and shown in log scale. It rapidly decreased as the network was trained.

Performance is shown for each of the training, validation, and test sets. The final network is the network that performed best on the validation set.

```
plotperform(tr)
```



Testing the Neural Network

The mean squared error of the trained neural network can now be measured with respect to the testing samples. This will give us a sense of how well the network will do when applied to data from the real world.

```
testX = X(:,tr.testInd);
testT = T(:,tr.testInd);

testY = net(testX);

perf = mse(net,testT,testY)
```

```
perf = 36.9404
```

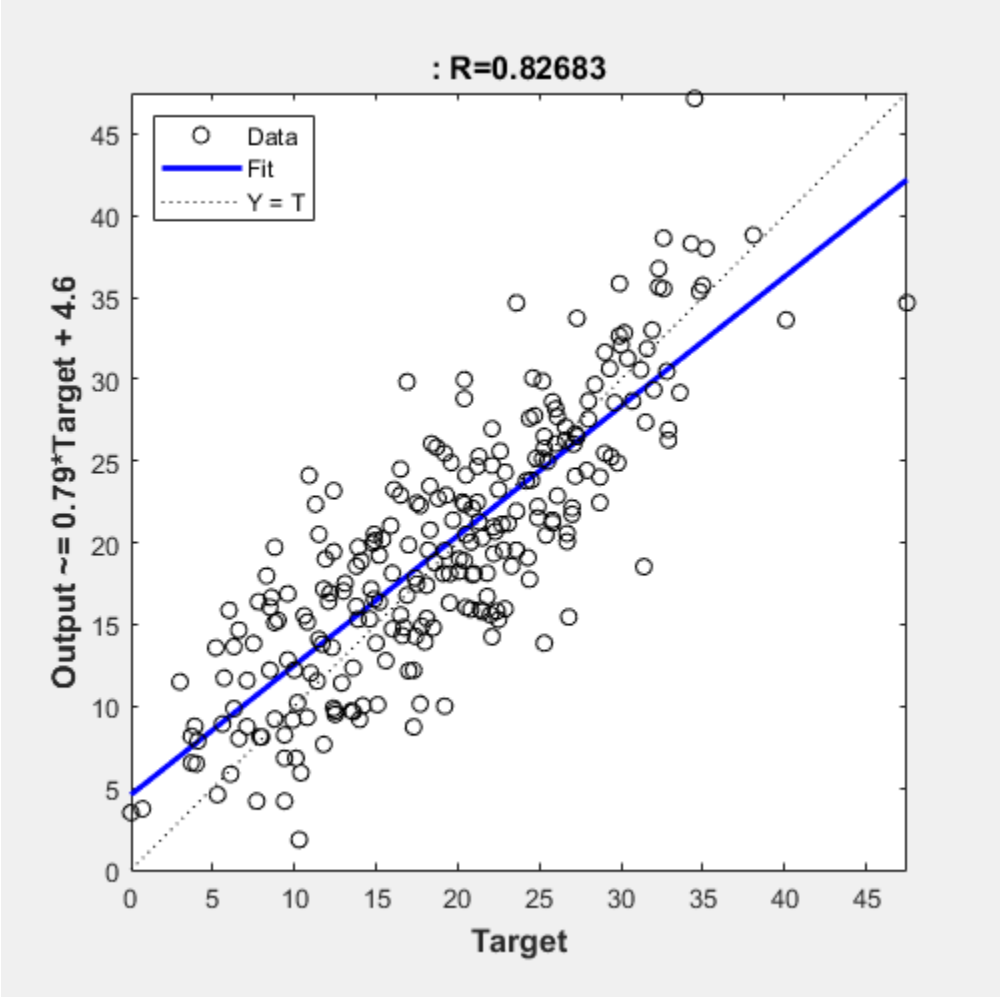
Another measure of how well the neural network has fit the data is the regression plot. Here the regression is plotted across all samples.

The regression plot shows the actual network outputs plotted in terms of the associated target values. If the network has learned to fit the data well, the linear fit to this output-target relationship should closely intersect the bottom-left and top-right corners of the plot.

If this is not the case then further training, or training a network with more hidden neurons, would be advisable.

```
Y = net(X);

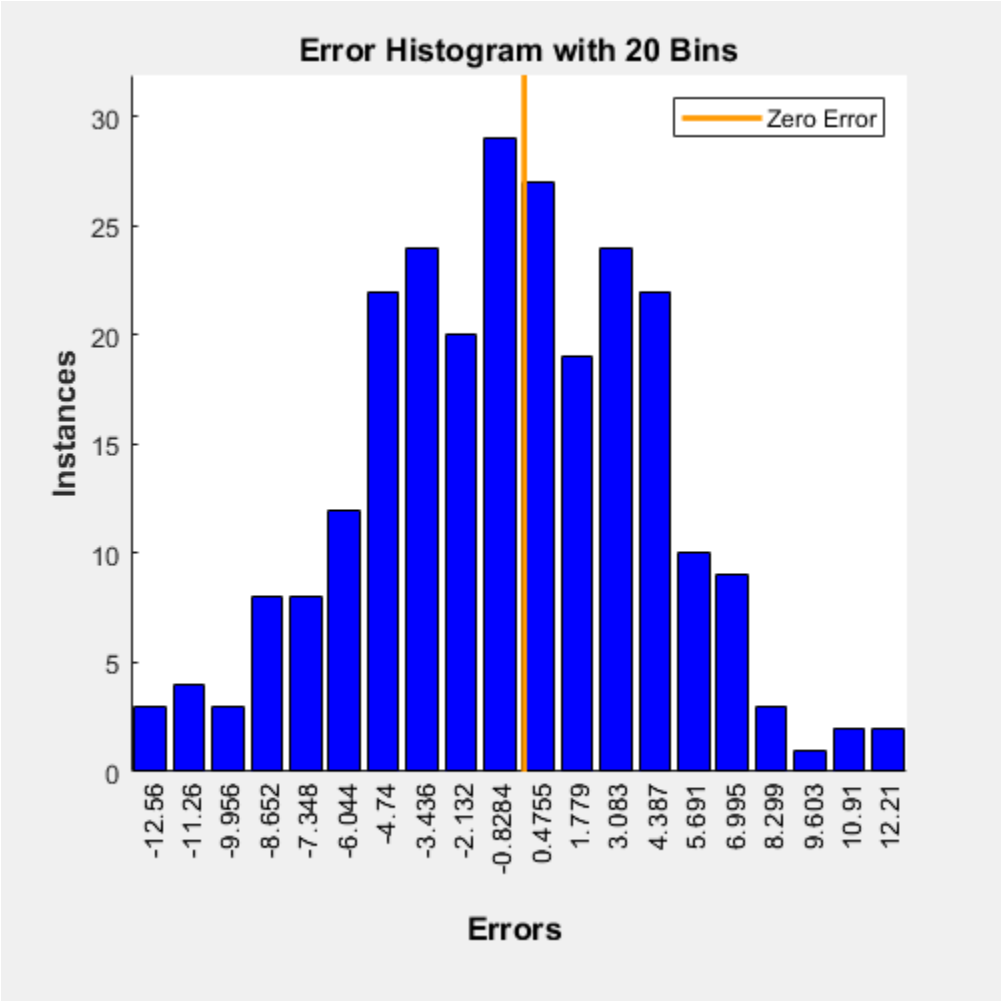
plotregression(T,Y)
```



Another third measure of how well the neural network has fit data is the error histogram. This shows how the error sizes are distributed. Typically most errors are near zero, with very few errors far from that.

```
e = T - Y;

ploterrhist(e)
```



This example illustrated how to design a neural network that estimates the body fat percentage from physical characteristics.

Crab Classification

This example illustrates using a neural network as a classifier to identify the sex of crabs from physical dimensions of the crab.

The Problem: Classification of Crabs

In this example we attempt to build a classifier that can identify the sex of a crab from its physical measurements. Six physical characteristics of a crab are considered: species, frontallip, rearwidth, length, width and depth. The problem on hand is to identify the sex of a crab given the observed values for each of these 6 physical characteristics.

Why Neural Networks?

Neural networks have proven themselves as proficient classifiers and are particularly well suited for addressing non-linear problems. Given the non-linear nature of real world phenomena, like crab classification, neural networks are certainly a good candidate for solving the problem.

The six physical characteristics will act as inputs to a neural network and the sex of the crab will be the target. Given an input, which constitutes the six observed values for the physical characteristics of a crab, the neural network is expected to identify if the crab is male or female.

This is achieved by presenting previously recorded inputs to a neural network and then tuning it to produce the desired target outputs. This process is called neural network training.

Preparing the Data

Data for classification problems are set up for a neural network by organizing the data into two matrices, the input matrix X and the target matrix T.

Each ith column of the input matrix will have six elements representing a crab's species, frontallip, rearwidth, length, width, and depth.

Each corresponding column of the target matrix will have two elements. Female crabs are represented with a one in the first element, male crabs with a one in the second element. (All other elements are zero).

Here the dataset is loaded.

```
[x,t] = crab_dataset;
size(x)
```

```
ans = 1×2

     6   200
```

```
size(t)
```

```
ans = 1×2

     2   200
```

Building the Neural Network Classifier

The next step is to create a neural network that will learn to identify the sex of the crabs.

Since the neural network starts with random initial weights, the results of this example will differ slightly every time it is run. The random seed is set to avoid this randomness. However this is not necessary for your own applications.

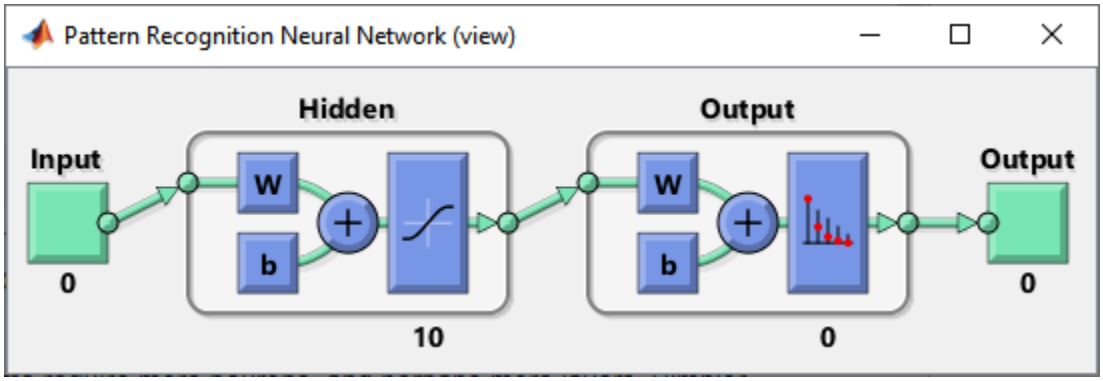
```
setdemorandstream(491218382)
```

Two-layer (i.e. one-hidden-layer) feed forward neural networks can learn any input-output relationship given enough neurons in the hidden layer. Layers which are not output layers are called hidden layers.

We will try a single hidden layer of 10 neurons for this example. In general, more difficult problems require more neurons, and perhaps more layers. Simpler problems require fewer neurons.

The input and output have sizes of 0 because the network has not yet been configured to match our input and target data. This will happen when the network is trained.

```
net = patternnet(10);
view(net)
```



Now the network is ready to be trained. The samples are automatically divided into training, validation and test sets. The training set is used to teach the network. Training continues as long as the network continues improving on the validation set. The test set provides a completely independent measure of network accuracy.

```
[net,tr] = train(net,x,t);

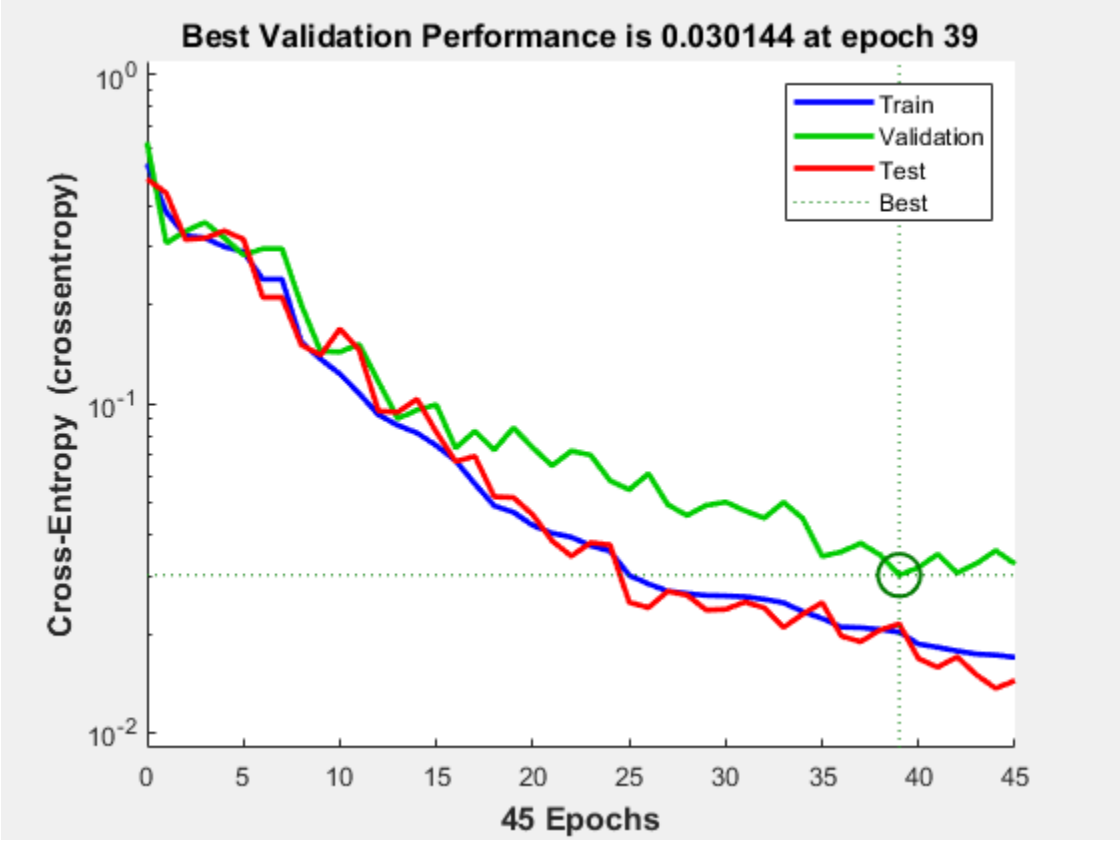
Performance is shown for each of the training, validation and test sets.

```
plotperform(tr)
```



Testing the Classifier

The trained neural network can now be tested with the testing samples. This will give us a sense of how well the network will do when applied to data from the real world.

The network outputs will be in the range 0 to 1, so we can use **vec2ind** function to get the class indices as the position of the highest element in each output vector.

```
testX = x(:,tr.testInd);
testT = t(:,tr.testInd);

testY = net(testX);
testIndices = vec2ind(testY)
```

```
testIndices = 1×30

```

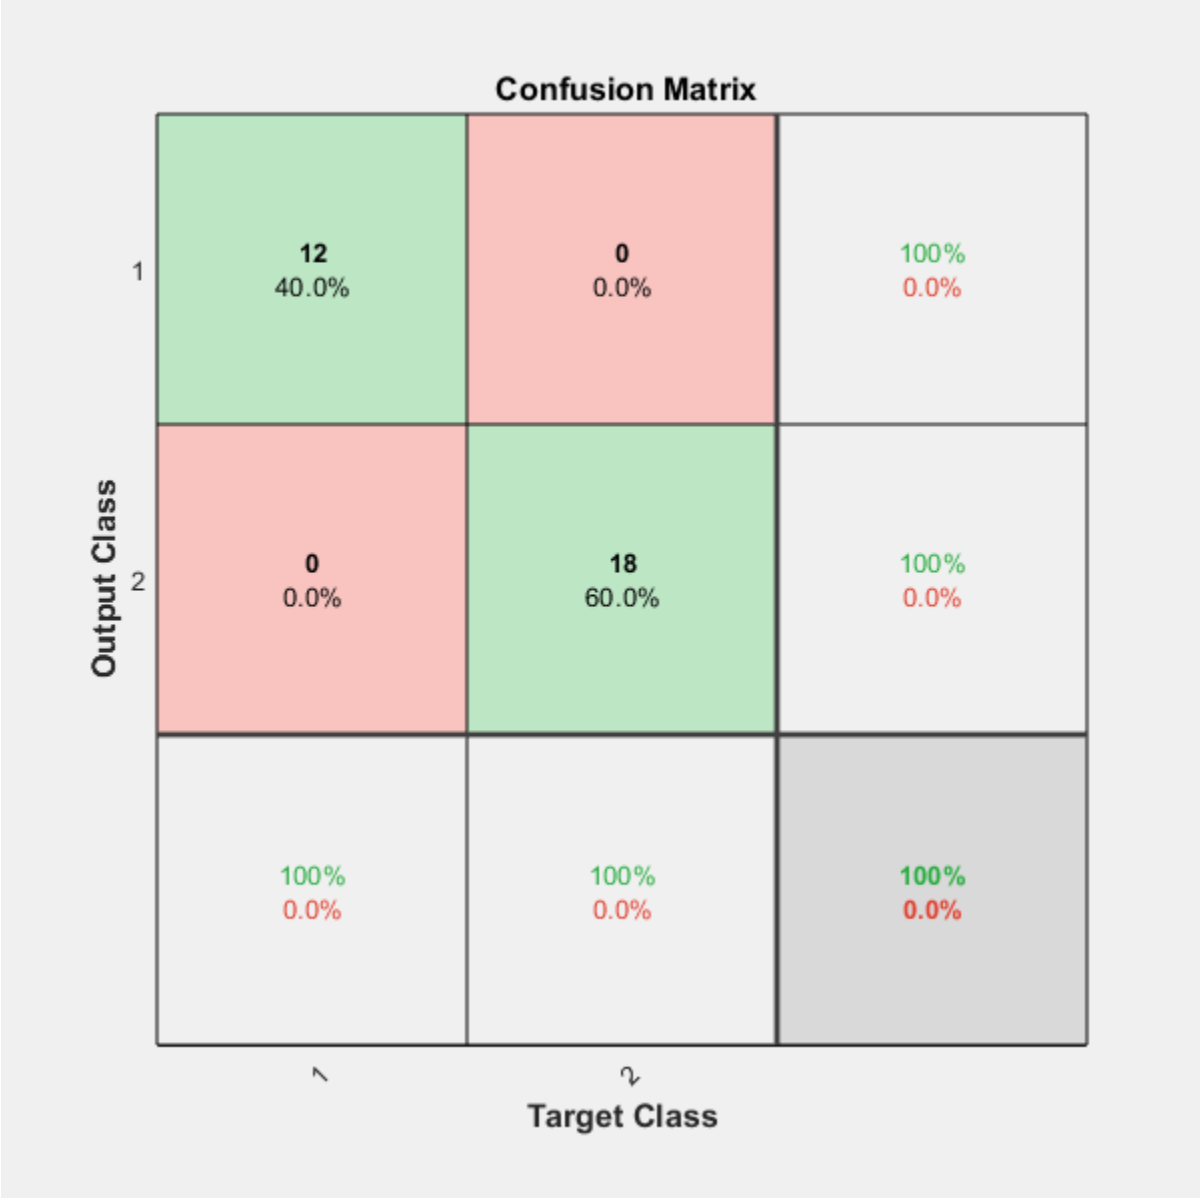
One measure of how well the neural network has fit the data is the confusion plot. Here the confusion matrix is plotted across all samples.

The confusion matrix shows the percentages of correct and incorrect classifications. Correct classifications are the green squares on the matrices diagonal. Incorrect classifications form the red squares.

If the network has learned to classify properly, the percentages in the red squares should be very small, indicating few misclassifications.

If this is not the case then further training, or training a network with more hidden neurons, would be advisable.

```
plotconfusion(testT,testY)
```



Here are the overall percentages of correct and incorrect classification.

```
[c,cm] = confusion(testT,testY)
```

```
c = 0
```

```
cm = 2×2

    12     0
     0    18
```

```
fprintf('Percentage Correct Classification   : %f%%\n', 100*(1-c));
```

```
Percentage Correct Classification   : 100.000000%
```

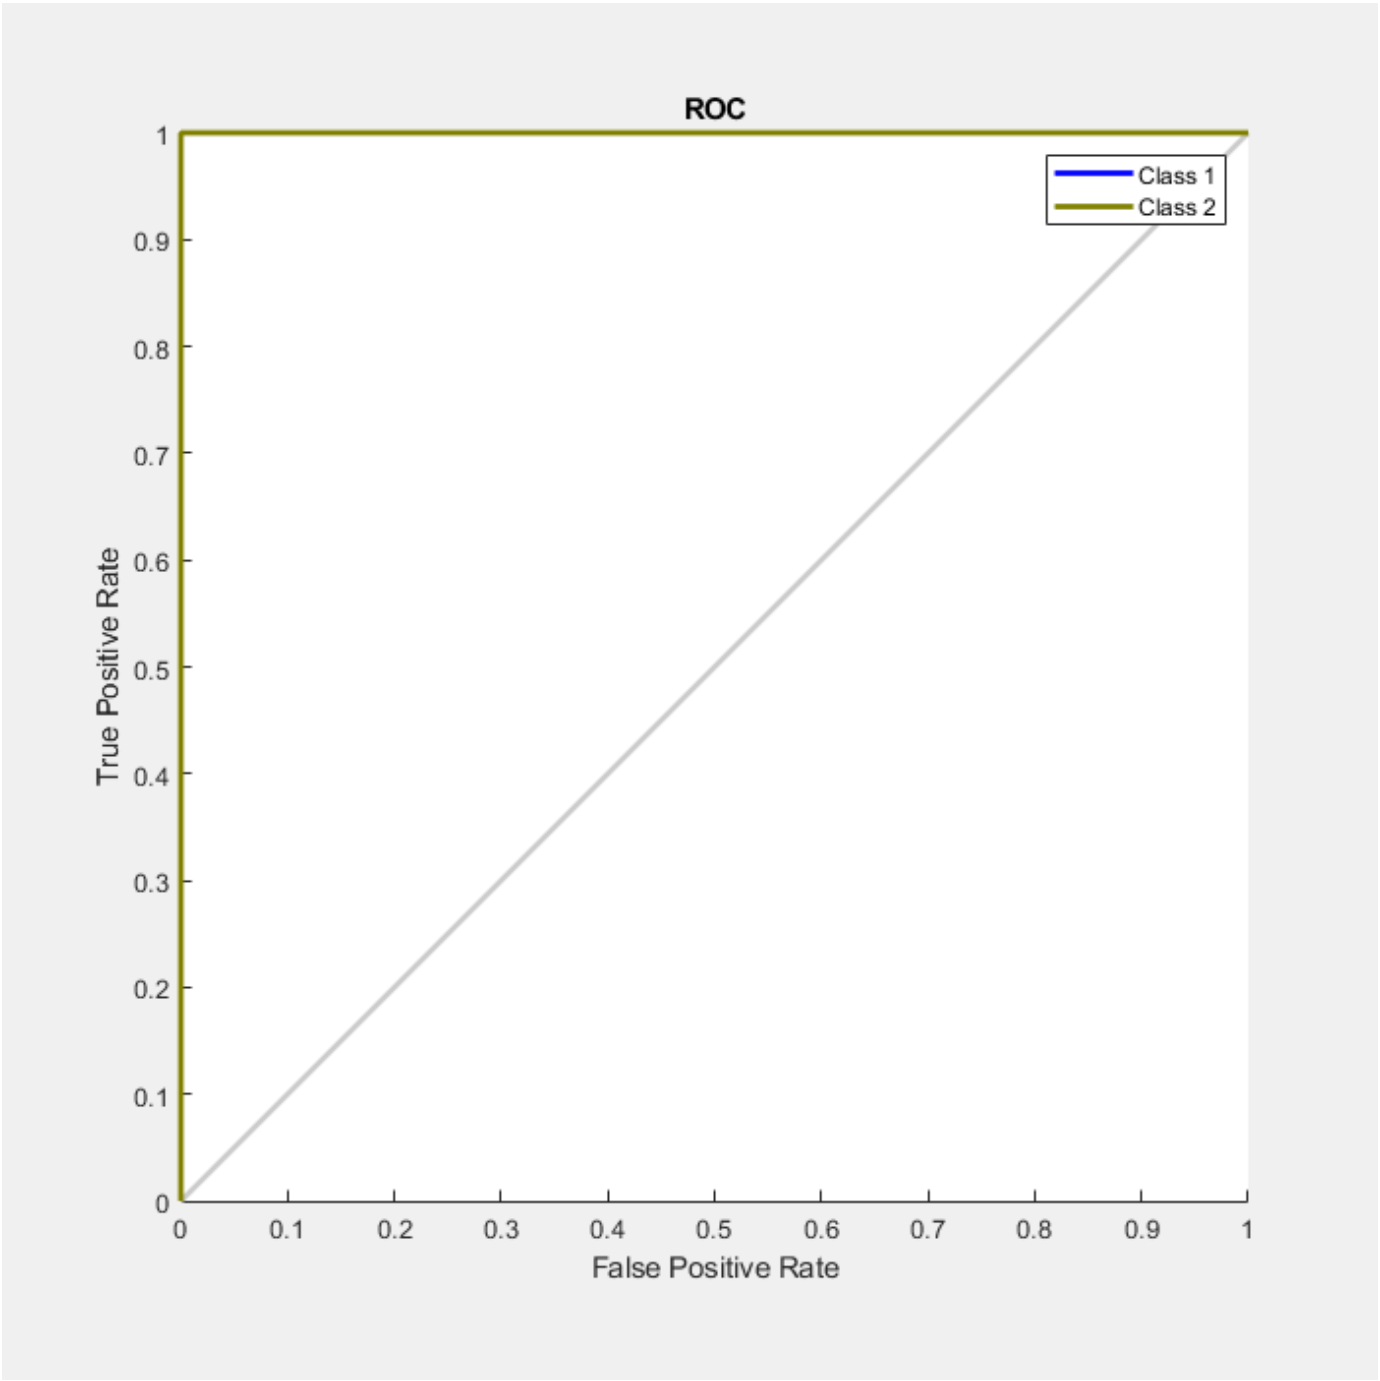
```
fprintf('Percentage Incorrect Classification : %f%%\n', 100*c);
```

```
Percentage Incorrect Classification : 0.000000%
```

Another measure of how well the neural network has fit data is the receiver operating characteristic plot. This shows how the false positive and true positive rates relate as the thresholding of outputs is varied from 0 to 1.

The farther left and up the line is, the fewer false positives need to be accepted in order to get a high true positive rate. The best classifiers will have a line going from the bottom left corner, to the top left corner, to the top right corner, or close to that.

```
plotroc(testT,testY)
```



This example illustrated using a neural network to classify crabs.

Explore other examples and the documentation for more insight into neural networks and their applications.

Wine Classification

This example illustrates how a pattern recognition neural network can classify wines by winery based on its chemical characteristics.

The Problem: Classify Wines

In this example we attempt to build a neural network that can classify wines from three wineries by thirteen attributes:

- Alcohol
- Malic acid
- Ash
- Alkalinity of ash
- Magnesium
- Total phenols
- Flavonoids
- Nonflavonoid phenols
- Proanthocyanidins
- Color intensity
- Hue
- OD280/OD315 of diluted wines
- Proline

This is an example of a pattern recognition problem, where inputs are associated with different classes, and we would like to create a neural network that not only classifies the known wines properly, but can also generalize to accurately classify wines that were not used to design the solution.

Why Neural Networks?

Neural networks are very good at pattern recognition problems. A neural network with enough elements (called neurons) can classify any data with arbitrary accuracy. They are particularly well suited for complex decision boundary problems over many variables. Therefore, neural networks are a good candidate for solving the wine classification problem.

The thirteen neighborhood attributes will act as inputs to a neural network, and the respective target for each will be a 3-element class vector with a 1 in the position of the associated winery, #1, #2 or #3.

The network will be designed by using the attributes of neighborhoods to train the network to produce the correct target classes.

Prepare Data

Data for classification problems are set up for a neural network by organizing the data into two matrices, the input matrix X and the target matrix T.

Each ith column of the input matrix will have thirteen elements representing a wine whose winery is already known.

Each corresponding column of the target matrix will have three elements, consisting of two zeros and a 1 in the location of the associated winery.

Here such a dataset is loaded.

```
[x,t] = wine_dataset;
```

We can view the sizes of inputs X and targets T.

Note that both X and T have 178 columns. These represent 178 wine sample attributes (inputs) and associated winery class vectors (targets).

Input matrix X has thirteen rows, for the thirteen attributes. Target matrix T has three rows, as for each example we have three possible wineries.

```
size(x)
```

```
ans = 1×2

    13   178
```

```
size(t)
```

```
ans = 1×2

     3   178
```

Pattern Recognition with a Neural Network

The next step is to create a neural network that will learn to classify the wines.

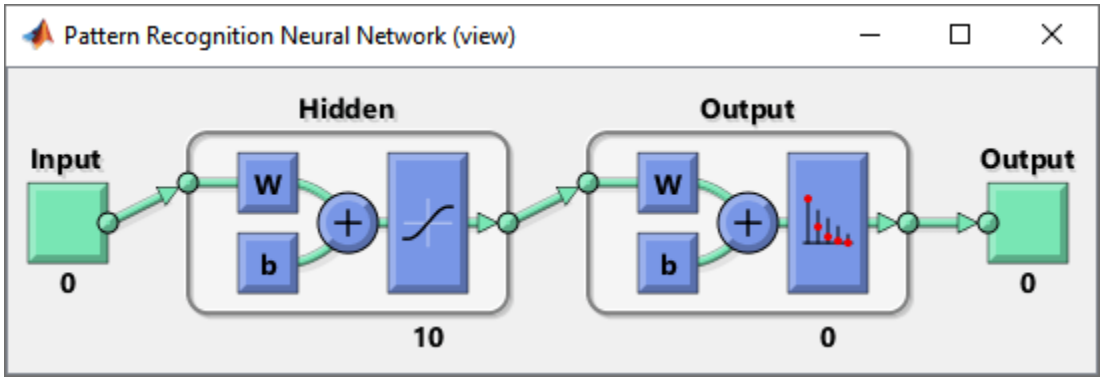
Since the neural network starts with random initial weights, the results of this example will differ slightly every time it is run.

Two-layer (i.e. one-hidden-layer) feed forward neural networks can learn any input-output relationship given enough neurons in the hidden layer. Layers which are not output layers are called hidden layers.

We will try a single hidden layer of 10 neurons for this example. In general, more difficult problems require more neurons, and perhaps more layers. Simpler problems require fewer neurons.

The input and output have sizes of 0 because the network has not yet been configured to match our input and target data. This will happen when the network is trained.

```
net = patternnet(10);
view(net)
```



Now the network is ready to be trained. The samples are automatically divided into training, validation and test sets. The training set is used to teach the network. Training continues as long as the network continues improving on the validation set. The test set provides a completely independent measure of network accuracy.

```

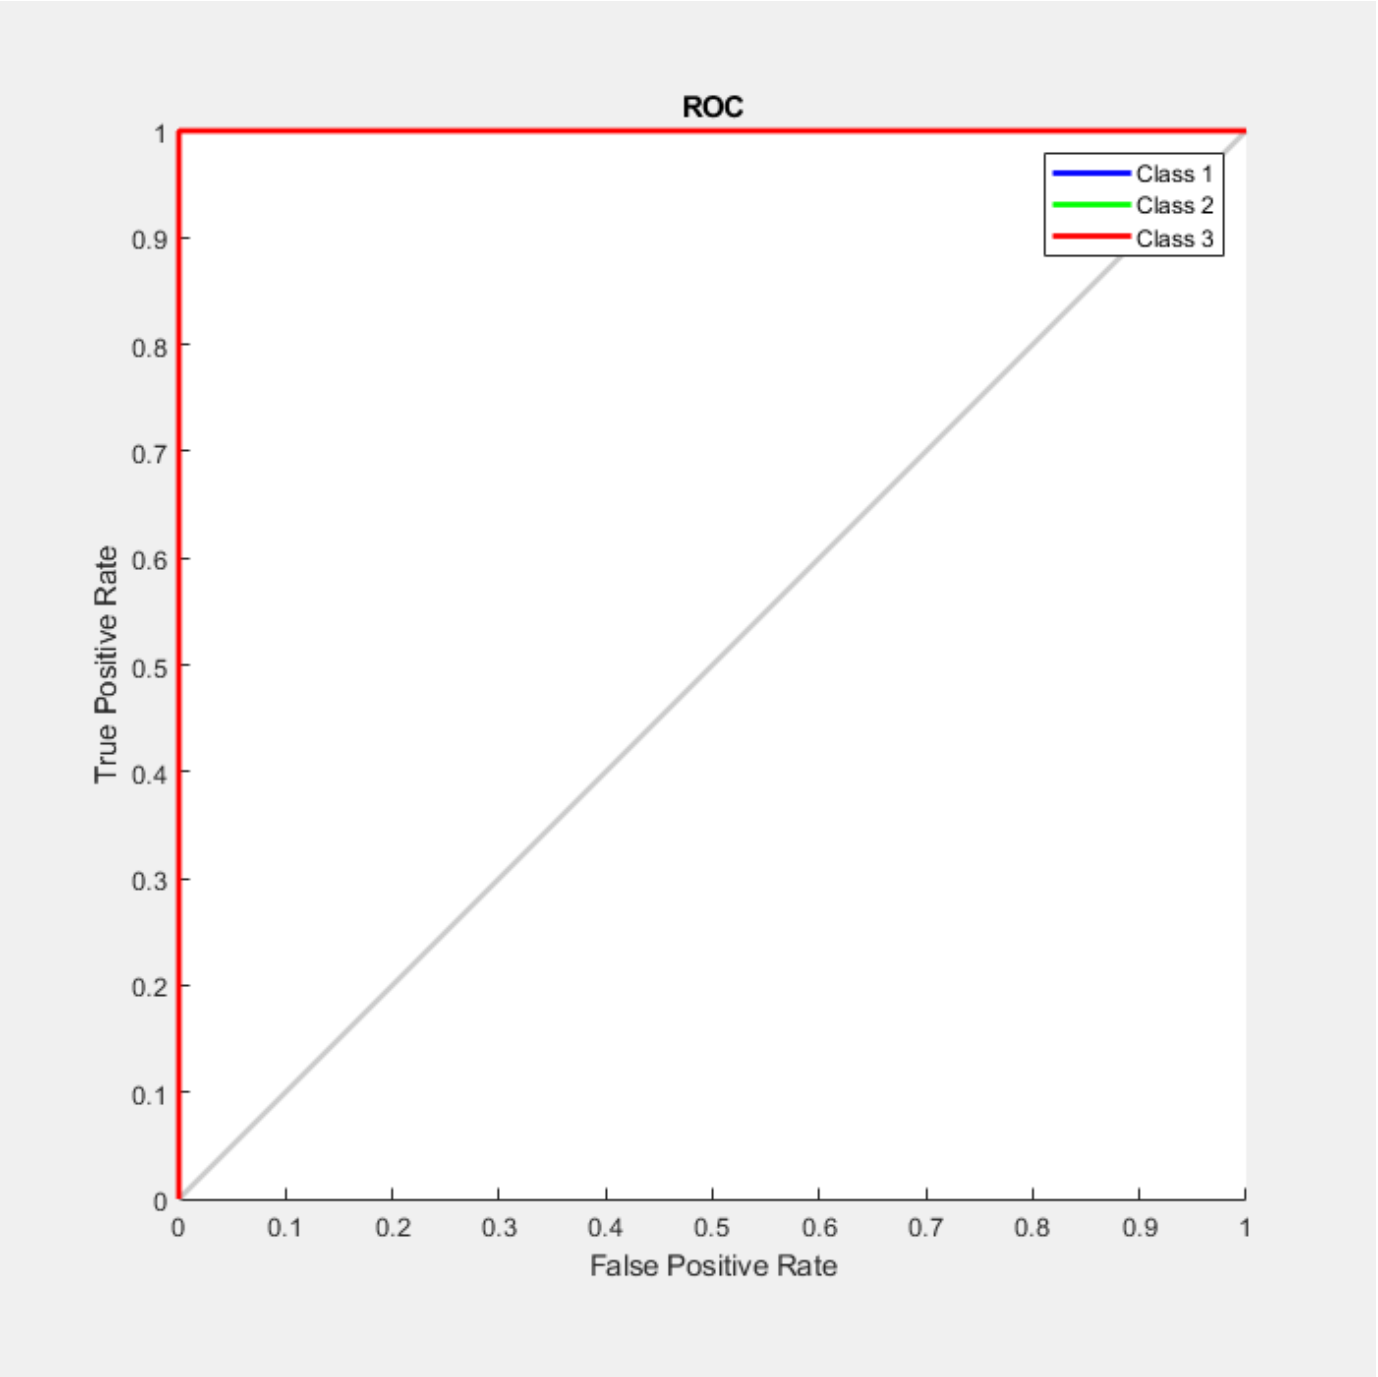
A third measure of how well the neural network has fit data is the receiver operating characteristic plot. This shows how the false positive and true positive rates relate as the thresholding of outputs is varied from 0 to 1.

The farther left and up the line is, the fewer false positives need to be accepted in order to get a high true positive rate. The best classifiers will have a line going from the bottom left corner, to the top left corner, to the top right corner, or close to that.

```
plotroc(testT,testY)
```



This example illustrated how to design a neural network that classifies wines into three wineries from each wine's characteristics.

Explore other examples and the documentation for more insight into neural networks and their applications.

Cancer Detection

This example shows how to train a neural network to detect cancer using mass spectrometry data on protein profiles.

Introduction

Serum proteomic pattern diagnostics can be used to differentiate samples from patients with and without disease. Profile patterns are generated using surface-enhanced laser desorption and ionization (SELDI) protein mass spectrometry. This technology has the potential to improve clinical diagnostics tests for cancer pathologies.

The Problem: Cancer Detection

The goal is to build a classifier that can distinguish between cancer and control patients from the mass spectrometry data.

The methodology followed in this example is to select a reduced set of measurements or "features" that can be used to distinguish between cancer and control patients using a classifier. These features are ion intensity levels at specific mass/charge values.

Formatting the Data

The data used in this example, provided in the file `ovarian_dataset.mat`, is from the FDA-NCI Clinical Proteomics Program Databank. For a detailed description of this data set, see [1] and [2].

Create the data file `OvarianCancerQAQCdataset.mat` by following the steps in “Batch Processing of Spectra Using Sequential and Parallel Computing” (Bioinformatics Toolbox). The new file contains the variables `Y`, `MZ`, and `grp`.

Each column in `Y` represents measurements taken from a patient. There are `216` columns in `Y` representing `216` patients, out of which `121` are ovarian cancer patients and `95` are normal patients.

Each row in `Y` represents the ion intensity level at a specific mass-charge value indicated in `MZ`. There are `15000` mass-charge values in `MZ` and each row in `Y` represents the ion-intensity levels of the patients at that particular mass-charge value.

The variable `grp` holds the index information as to which of these samples represent cancer patients and which ones represent normal patients.

Ranking Key Features

This task is a typical classification problem where the number of features is much larger than the number of observations but single feature achieves a correct classification. Therefore, the goal is to find a classifier which appropriately learns how to weight multiple features and at the same time produces a generalized mapping which is not over-fitted.

A simple approach for finding significant features is to assume that each M/Z value is independent and compute a two-way t-test. `rankfeatures` returns an index to the most significant M/Z values, for instance 100 indices ranked by the absolute value of the test statistic.

Load the `OvarianCancerQAQCdataset.mat` and rank features using `rankfeatures` (Bioinformatics Toolbox) to choose 100 highest ranked measurements as inputs `x`.

```
ind = rankfeatures(Y,grp,'Criterion','ttest','NumberOfIndices',100);
x = Y(ind,:);
```

Define the targets `t` for the two classes as follows:

```
t = double(strcmp('Cancer',grp));
t = [t; 1-t];
```

The preprocessing steps from the script and example listed above are intended to demonstrate a representative set of possible preprocessing and feature selection procedures. Using different steps or parameters can lead to different and possibly better results.

```
[x,t] = ovarian_dataset;
whos x t
```

```
  Name        Size              Bytes  Class     Attributes

  t           2x216              3456  double
  x         100x216            172800  double
```

Each column in `x` represents one of 216 different patients.

Each row in `x` represents the ion intensity level at one of the 100 specific mass-charge values for each patient.

The variable `t` has two rows with 216 values each of which are either [1;0], indicating a cancer patient, or [0;1] for a normal patient.

Classification Using a Feed Forward Neural Network

Now that you have identified some significant features, you can use this information to classify the cancer and normal samples.

Since the neural network is initialized with random initial weights, the results after training the network vary slightly every time the example is run. To avoid this randomness, the random seed is set to reproduce the same results every time. However, setting the random seed is not necessary for your own applications.

```
setdemorandstream(672880951)
```

A 1-hidden layer feed forward neural network with 5 hidden layer neurons is created and trained. The input and target samples are automatically divided into training, validation, and test sets. The training set is used to teach the network. Training continues as long as the network continues improving on the validation set. The test set provides an independent measure of the network accuracy.

The input and output have sizes of 0 because the network has not yet been configured to match the input and target data. This configuration happens when you train the network.

```
net = patternnet(5);
view(net)
```

Now the network is ready to be trained. The samples are automatically divided into training, validation, and test sets. The training set is used to teach the network. Training continues as long as the network continues improving on the validation set. The test set provides an independent measure of network accuracy.

The Neural Network Training Tool shows the network being trained and the algorithms used to train it. It also displays the training state during training and the criteria which stopped training are highlighted in green.

The buttons at the bottom open useful plots which can be opened during and after training. Links next to the algorithm names and plot buttons open documentation on those subjects.

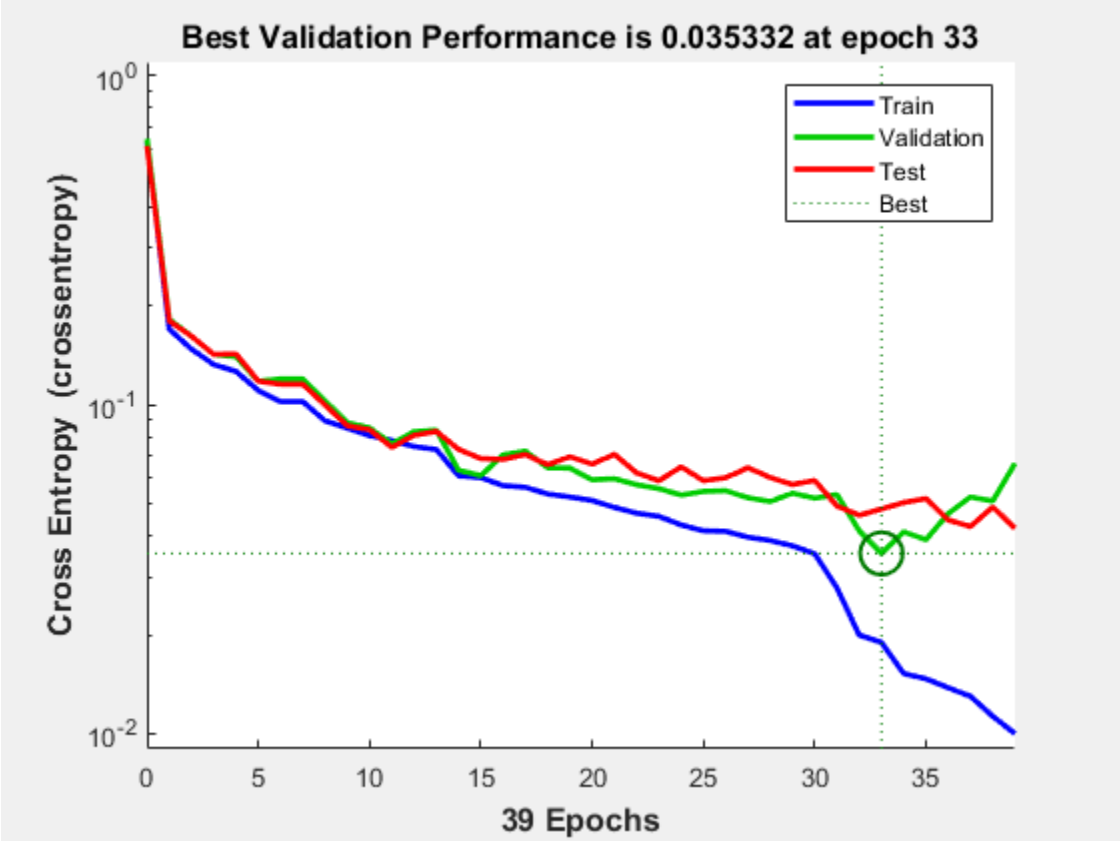
```
[net,tr] = train(net,x,t);
```

To see how the network's performance improved during training, either click the "Performance" button in the training tool, or use the `plotperform` function.

Performance is measured in terms of mean squared error, and shown on a logarithmic scale. It rapidly decreased as the network was trained.

Performance is shown for each of the training, validation, and test sets.

```
plotperform(tr)
```



The trained neural network can now be tested with the testing samples we partitioned from the main dataset. The testing data was not used in training in any way and hence provides an "out-of-sample" dataset to test the network on. This gives an estimate of how well the network will perform when tested with data from the real world.

The network outputs are in the range 0-1. Threshold the outputs to obtain 1's and 0's indicating cancer or normal patients, respectively.

```
testX = x(:,tr.testInd);
testT = t(:,tr.testInd);

testY = net(testX);
testClasses = testY > 0.5
```

```
testClasses = 2x32 logical array

   0   1   1   0   1   1   1   1   1   1   1   1   1   1   1   1   1   0   0   0   0   1   0
   1   0   0   1   0   0   0   0   0   0   0   0   0   0   0   0   0   1   1   1   1   0   1
```

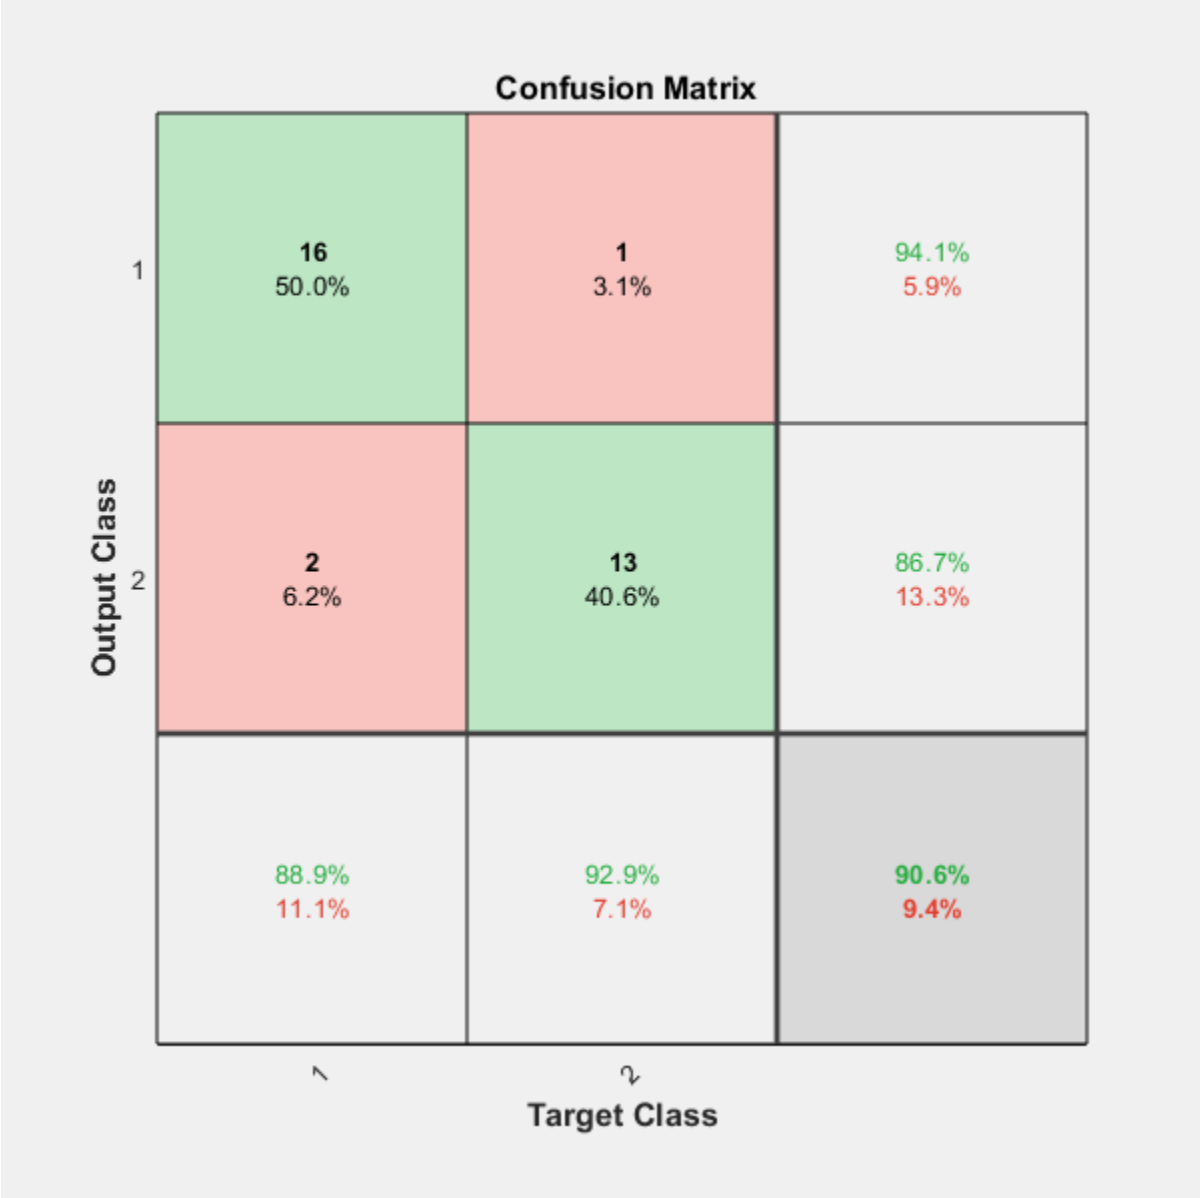
One measure of how well the neural network has fit the data is the confusion plot.

The confusion matrix shows the percentages of correct and incorrect classifications. Correct classifications are the green squares on the matrix diagonal. The red squares represent incorrect classifications.

If the network is accurate, then the percentages in the red squares are small, indicating few misclassifications.

If the network is not accurate, then you can try training for a longer time, or training a network with more hidden neurons.

```
plotconfusion(testT,testY)
```



Here are the overall percentages of correct and incorrect classification.

```
[c,cm] = confusion(testT,testY);
```

```
fprintf('Percentage Correct Classification   : %f%%\n', 100*(1-c));
```

```
Percentage Correct Classification   : 90.625000%
```

```
fprintf('Percentage Incorrect Classification : %f%%\n', 100*c);
```

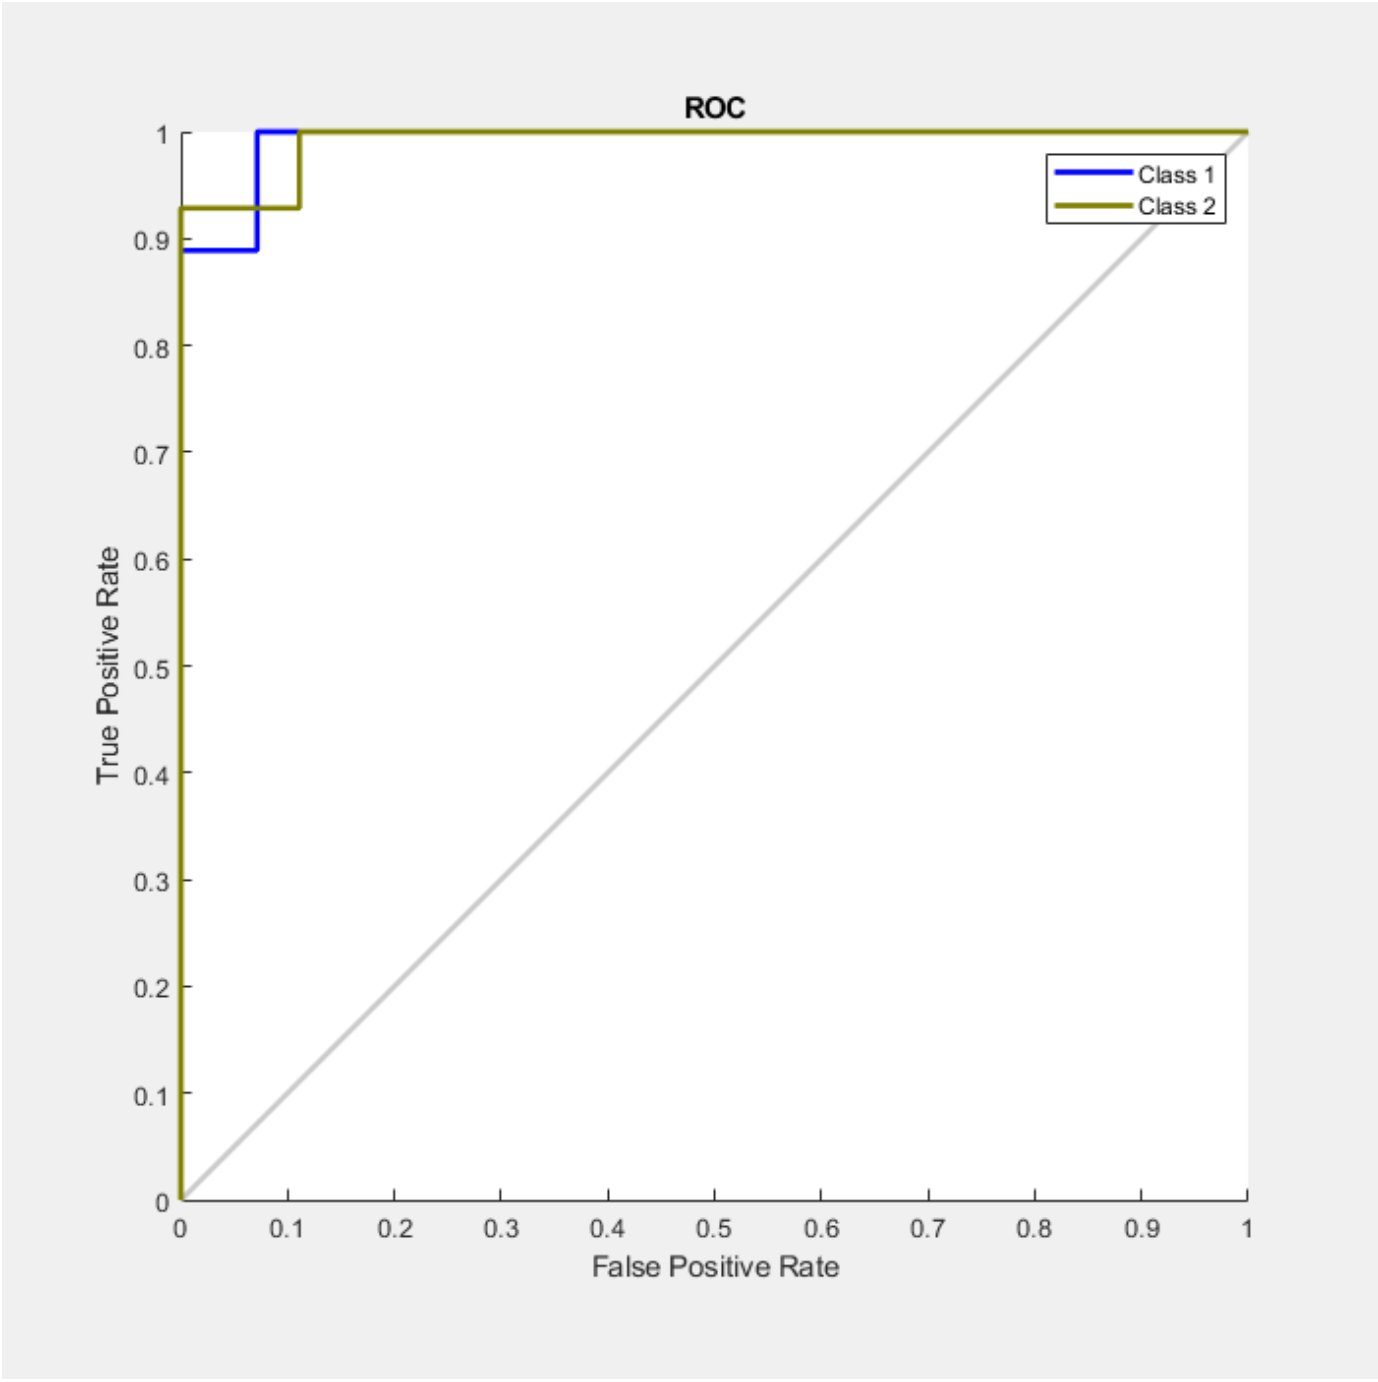
```
Percentage Incorrect Classification : 9.375000%
```

Another measure of how well the neural network has fit data is the receiver operating characteristic plot. This plot shows how the false positive and true positive rates relate as the thresholding of outputs is varied from 0 to 1.

The farther left and up the line is, the fewer false positives need to be accepted in order to get a high true positive rate. The best classifiers have a line going from the bottom left corner, to the top left corner, to the top right corner, or close to that.

Class 1 indicates cancer patients and class 2 indicates normal patients.

```
plotroc(testT,testY)
```



This example demonstrates how neural networks can be used as classifiers for cancer detection. To improve classifier performance, you can also try using techniques like principal component analysis for reducing the dimensionality of the data used for neural network training.

Character Recognition

This example illustrates how to train a neural network to perform simple character recognition.

Defining the Problem

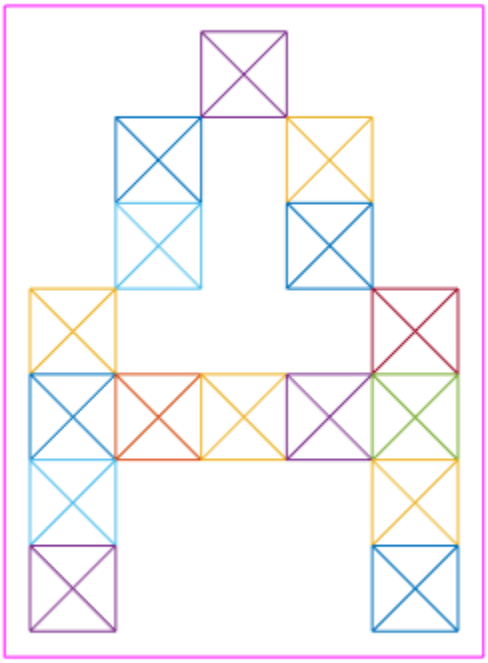
The script **prprob** defines a matrix X with 26 columns, one for each letter of the alphabet. Each column has 35 values which can either be 1 or 0. Each column of 35 values defines a 5x7 bitmap of a letter.

The matrix T is a 26x26 identity matrix which maps the 26 input vectors to the 26 classes.

```
[X,T] = prprob;
```

Here A, the first letter, is plotted as a bit map.

```
plotchar(X(:,1))
```



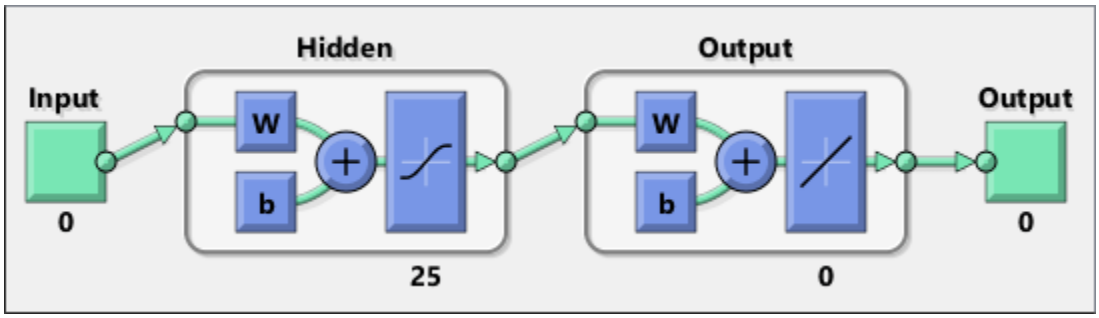
Creating the First Neural Network

To solve this problem we will use a feedforward neural network set up for pattern recognition with 25 hidden neurons.

Since the neural network is initialized with random initial weights, the results after training vary slightly every time the example is run. To avoid this randomness, the random seed is set to reproduce the same results every time. This is not necessary for your own applications.

```
setdemorandstream(pi);

net1 = feedforwardnet(25);
view(net1)
```



Training the first Neural Network

The function **train** divides up the data into training, validation and test sets. The training set is used to update the network, the validation set is used to stop the network before it overfits the training data, thus preserving good generalization. The test set acts as a completely independent measure of how well the network can be expected to do on new samples.

Training stops when the network is no longer likely to improve on the training or validation sets.

```
net1.divideFcn = '';
net1 = train(net1,X,T,nnMATLAB);

Computing Resources:
MATLAB on PCWIN64
```

Training the Second Neural Network

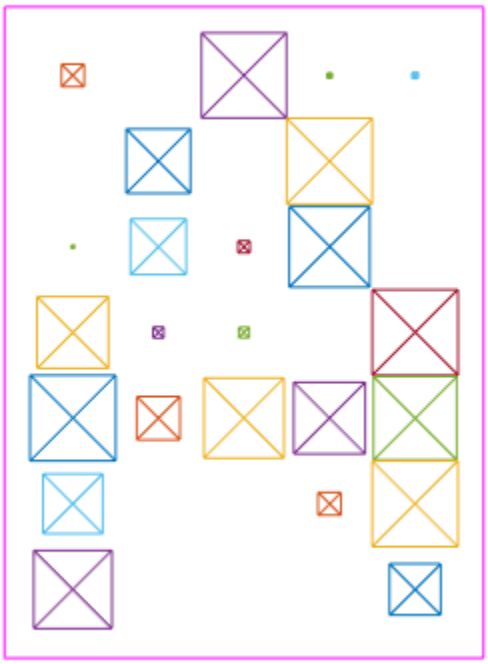
We would like the network to not only recognize perfectly formed letters, but also noisy versions of the letters. So we will try training a second network on noisy data and compare its ability to generalize with the first network.

Here 30 noisy copies of each letter Xn are created. Values are limited by **min** and **max** to fall between 0 and 1. The corresponding targets Tn are also defined.

```
numNoise = 30;
Xn = min(max(repmat(X,1,numNoise)+randn(35,26*numNoise)*0.2,0),1);
Tn = repmat(T,1,numNoise);
```

Here is a noise version of A.

```
figure
plotchar(Xn(:,1))
```



Here the second network is created and trained.

```
net2 = feedforwardnet(25);
net2 = train(net2,Xn,Tn,nnMATLAB);
```

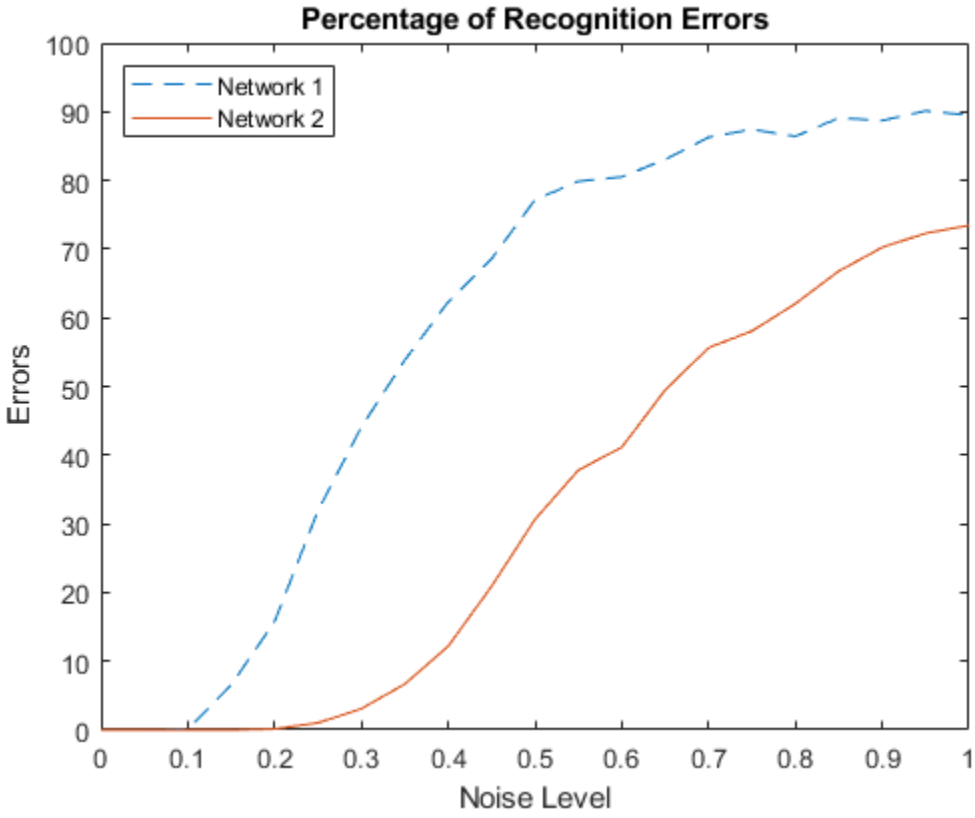
```
Computing Resources:
MATLAB on PCWIN64
```

Testing Both Neural Networks

```
noiseLevels = 0:.05:1;
numLevels = length(noiseLevels);
percError1 = zeros(1,numLevels);
percError2 = zeros(1,numLevels);
for i = 1:numLevels
  Xtest = min(max(repmat(X,1,numNoise)+randn(35,26*numNoise)*noiseLevels(i),0),1);
  Y1 = net1(Xtest);
  percError1(i) = sum(sum(abs(Tn-compet(Y1))))/(26*numNoise*2);
  Y2 = net2(Xtest);
  percError2(i) = sum(sum(abs(Tn-compet(Y2))))/(26*numNoise*2);
end

figure
plot(noiseLevels,percError1*100,'--',noiseLevels,percError2*100);
title('Percentage of Recognition Errors');
xlabel('Noise Level');
```

```
ylabel('Errors');
legend('Network 1','Network 2','Location','NorthWest')
```



Network 1, trained without noise, has more errors due to noise than does Network 2, which was trained with noise.

Train Stacked Autoencoders for Image Classification

This example shows how to train stacked autoencoders to classify images of digits.

Neural networks with multiple hidden layers can be useful for solving classification problems with complex data, such as images. Each layer can learn features at a different level of abstraction. However, training neural networks with multiple hidden layers can be difficult in practice.

One way to effectively train a neural network with multiple layers is by training one layer at a time. You can achieve this by training a special type of network known as an autoencoder for each desired hidden layer.

This example shows you how to train a neural network with two hidden layers to classify digits in images. First you train the hidden layers individually in an unsupervised fashion using autoencoders. Then you train a final softmax layer, and join the layers together to form a stacked network, which you train one final time in a supervised fashion.

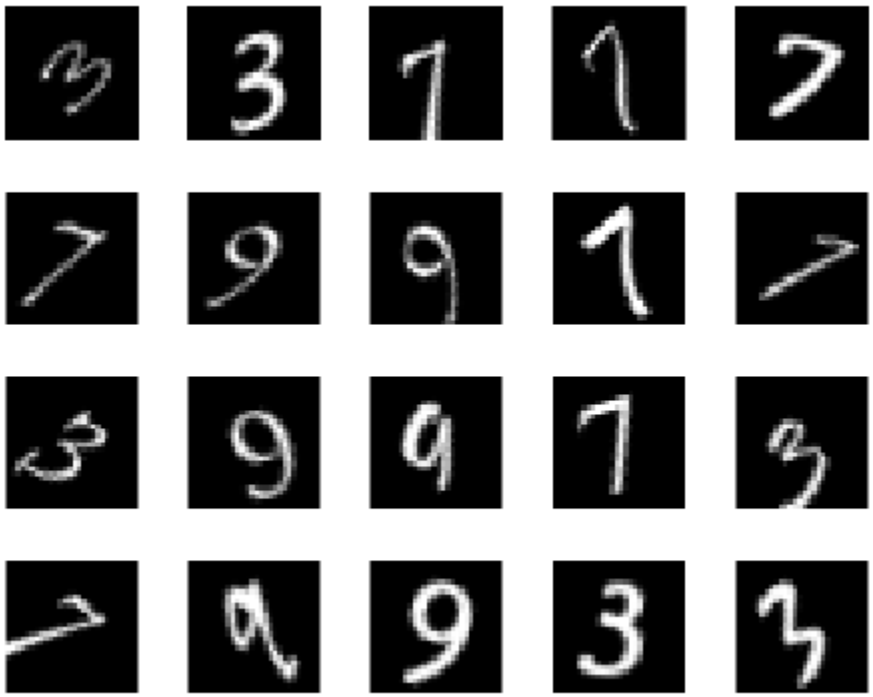
Data set

This example uses synthetic data throughout, for training and testing. The synthetic images have been generated by applying random affine transformations to digit images created using different fonts.

Each digit image is 28-by-28 pixels, and there are 5,000 training examples. You can load the training data, and view some of the images.

```
% Load the training data into memory
[xTrainImages,tTrain] = digitTrainCellArrayData;

% Display some of the training images
clf
for i = 1:20
    subplot(4,5,i);
    imshow(xTrainImages{i});
end
```



The labels for the images are stored in a 10-by-5000 matrix, where in every column a single element will be 1 to indicate the class that the digit belongs to, and all other elements in the column will be 0. It should be noted that if the tenth element is 1, then the digit image is a zero.

Training the first autoencoder

Begin by training a sparse autoencoder on the training data without using the labels.

An autoencoder is a neural network which attempts to replicate its input at its output. Thus, the size of its input will be the same as the size of its output. When the number of neurons in the hidden layer is less than the size of the input, the autoencoder learns a compressed representation of the input.

Neural networks have weights randomly initialized before training. Therefore the results from training are different each time. To avoid this behavior, explicitly set the random number generator seed.

```
rng('default')
```

Set the size of the hidden layer for the autoencoder. For the autoencoder that you are going to train, it is a good idea to make this smaller than the input size.

```
hiddenSize1 = 100;
```

The type of autoencoder that you will train is a sparse autoencoder. This autoencoder uses regularizers to learn a sparse representation in the first layer. You can control the influence of these regularizers by setting various parameters:

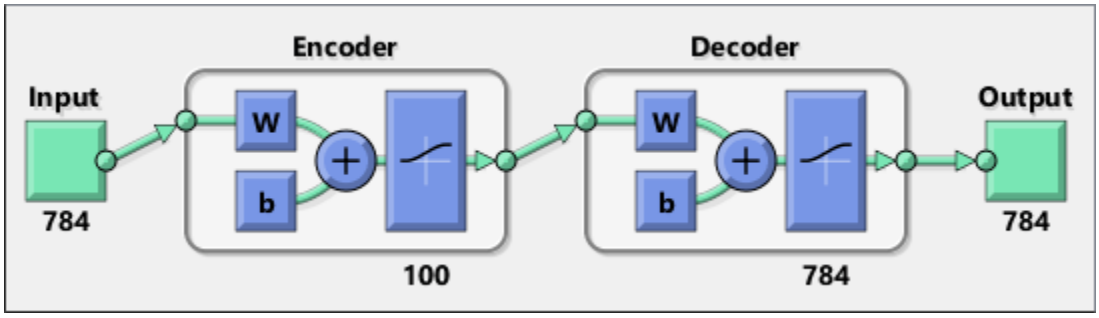
- `L2WeightRegularization` controls the impact of an L2 regularizer for the weights of the network (and not the biases). This should typically be quite small.
- `SparsityRegularization` controls the impact of a sparsity regularizer, which attempts to enforce a constraint on the sparsity of the output from the hidden layer. Note that this is different from applying a sparsity regularizer to the weights.
- `SparsityProportion` is a parameter of the sparsity regularizer. It controls the sparsity of the output from the hidden layer. A low value for `SparsityProportion` usually leads to each neuron in the hidden layer "specializing" by only giving a high output for a small number of training examples. For example, if `SparsityProportion` is set to 0.1, this is equivalent to saying that each neuron in the hidden layer should have an average output of 0.1 over the training examples. This value must be between 0 and 1. The ideal value varies depending on the nature of the problem.

Now train the autoencoder, specifying the values for the regularizers that are described above.

```
autoenc1 = trainAutoencoder(xTrainImages,hiddenSize1, ...
    'MaxEpochs',400, ...
    'L2WeightRegularization',0.004, ...
    'SparsityRegularization',4, ...
    'SparsityProportion',0.15, ...
    'ScaleData', false);
```

You can view a diagram of the autoencoder. The autoencoder is comprised of an encoder followed by a decoder. The encoder maps an input to a hidden representation, and the decoder attempts to reverse this mapping to reconstruct the original input.

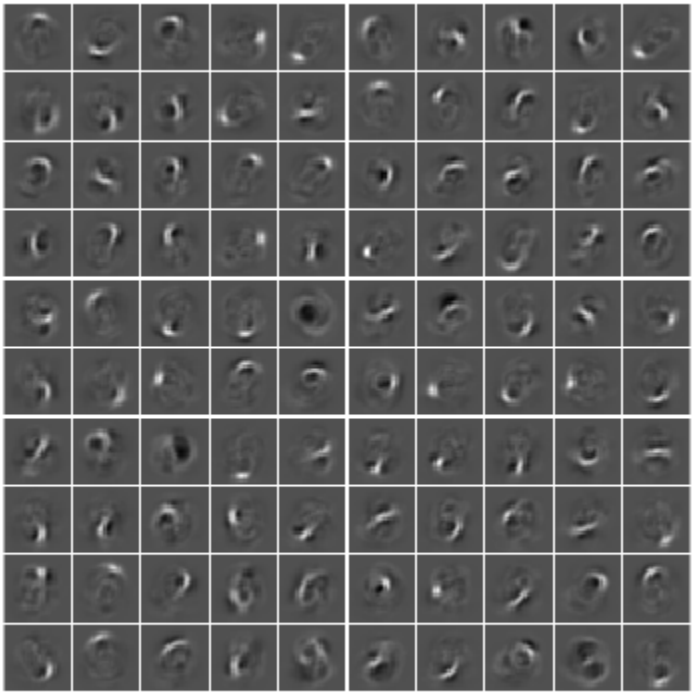
```
view(autoenc1)
```



Visualizing the weights of the first autoencoder

The mapping learned by the encoder part of an autoencoder can be useful for extracting features from data. Each neuron in the encoder has a vector of weights associated with it which will be tuned to respond to a particular visual feature. You can view a representation of these features.

```
figure()
plotWeights(autoenc1);
```



You can see that the features learned by the autoencoder represent curls and stroke patterns from the digit images.

The 100-dimensional output from the hidden layer of the autoencoder is a compressed version of the input, which summarizes its response to the features visualized above. Train the next autoencoder on a set of these vectors extracted from the training data. First, you must use the encoder from the trained autoencoder to generate the features.

```
feat1 = encode(autoenc1,xTrainImages);
```

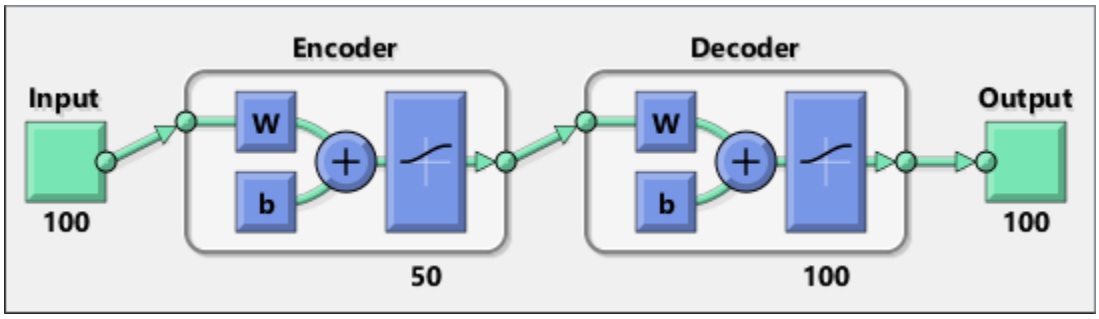
Training the second autoencoder

After training the first autoencoder, you train the second autoencoder in a similar way. The main difference is that you use the features that were generated from the first autoencoder as the training data in the second autoencoder. Also, you decrease the size of the hidden representation to 50, so that the encoder in the second autoencoder learns an even smaller representation of the input data.

```
hiddenSize2 = 50;
autoenc2 = trainAutoencoder(feat1,hiddenSize2, ...
    'MaxEpochs',100, ...
    'L2WeightRegularization',0.002, ...
    'SparsityRegularization',4, ...
    'SparsityProportion',0.1, ...
    'ScaleData', false);
```

Once again, you can view a diagram of the autoencoder with the `view` function.

```
view(autoenc2)
```



You can extract a second set of features by passing the previous set through the encoder from the second autoencoder.

```
feat2 = encode(autoenc2,feat1);
```

The original vectors in the training data had 784 dimensions. After passing them through the first encoder, this was reduced to 100 dimensions. After using the second encoder, this was reduced again to 50 dimensions. You can now train a final layer to classify these 50-dimensional vectors into different digit classes.

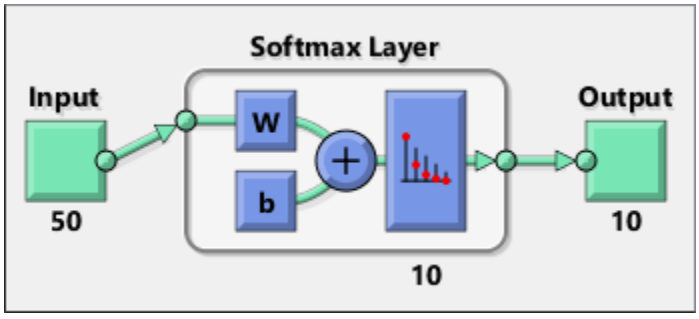
Training the final softmax layer

Train a softmax layer to classify the 50-dimensional feature vectors. Unlike the autoencoders, you train the softmax layer in a supervised fashion using labels for the training data.

```
softnet = trainSoftmaxLayer(feat2,tTrain,'MaxEpochs',400);
```

You can view a diagram of the softmax layer with the `view` function.

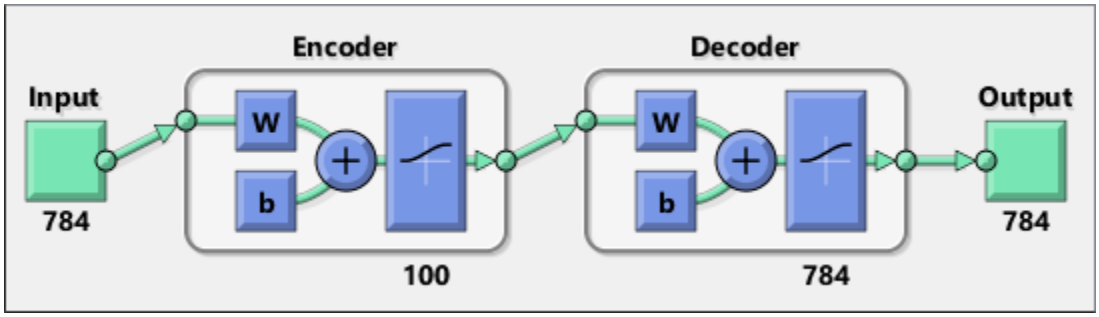
```
view(softnet)
```

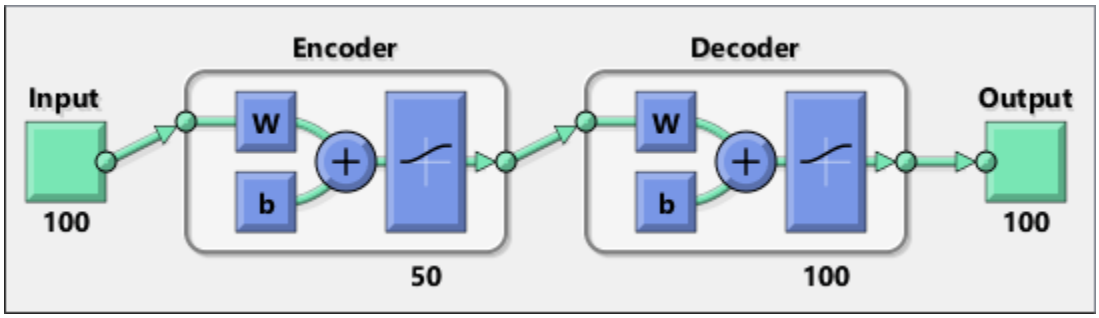


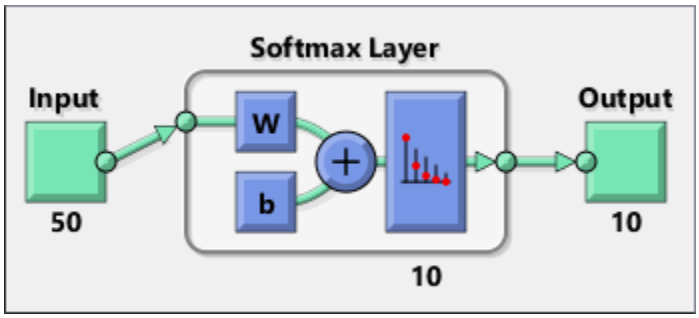
Forming a stacked neural network

You have trained three separate components of a stacked neural network in isolation. At this point, it might be useful to view the three neural networks that you have trained. They are `autoenc1`, `autoenc2`, and `softnet`.

```
view(autoenc1)
view(autoenc2)
view(softnet)
```





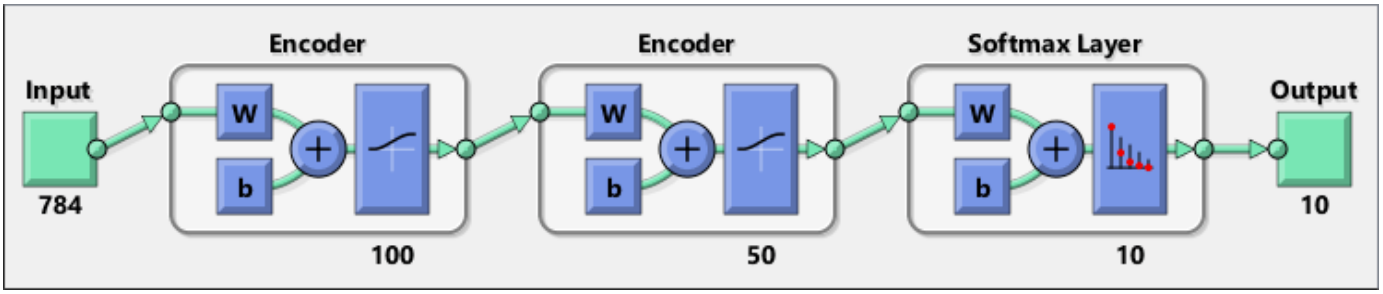


As was explained, the encoders from the autoencoders have been used to extract features. You can stack the encoders from the autoencoders together with the softmax layer to form a stacked network for classification.

```
stackednet = stack(autoenc1,autoenc2,softnet);
```

You can view a diagram of the stacked network with the `view` function. The network is formed by the encoders from the autoencoders and the softmax layer.

```
view(stackednet)
```



With the full network formed, you can compute the results on the test set. To use images with the stacked network, you have to reshape the test images into a matrix. You can do this by stacking the columns of an image to form a vector, and then forming a matrix from these vectors.

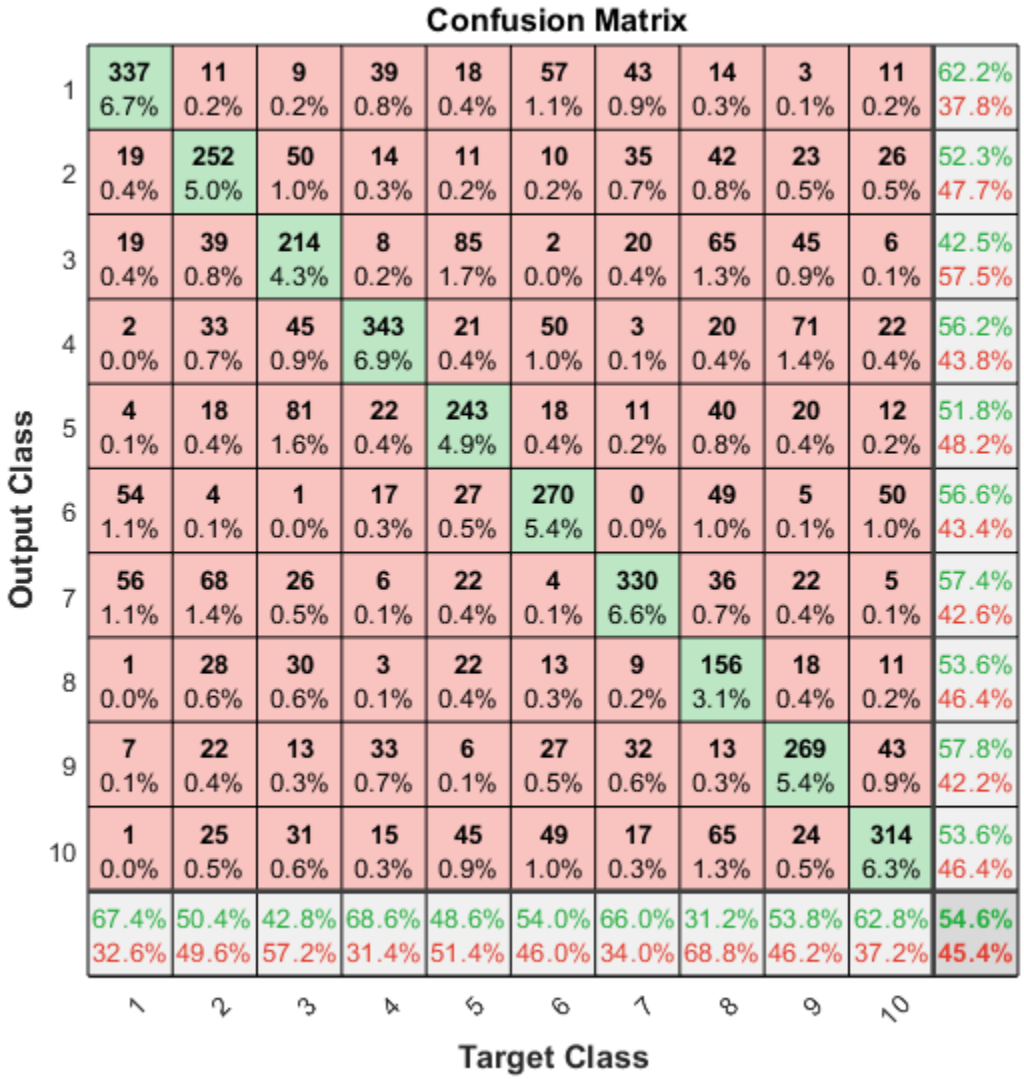
```
% Get the number of pixels in each image
imageWidth = 28;
imageHeight = 28;
inputSize = imageWidth*imageHeight;

% Load the test images
[xTestImages,tTest] = digitTestCellArrayData;

% Turn the test images into vectors and put them in a matrix
xTest = zeros(inputSize,numel(xTestImages));
for i = 1:numel(xTestImages)
    xTest(:,i) = xTestImages{i}(:);
end
```

You can visualize the results with a confusion matrix. The numbers in the bottom right-hand square of the matrix give the overall accuracy.

```
y = stackednet(xTest);
plotconfusion(tTest,y);
```



Fine tuning the stacked neural network

The results for the stacked neural network can be improved by performing backpropagation on the whole multilayer network. This process is often referred to as fine tuning.

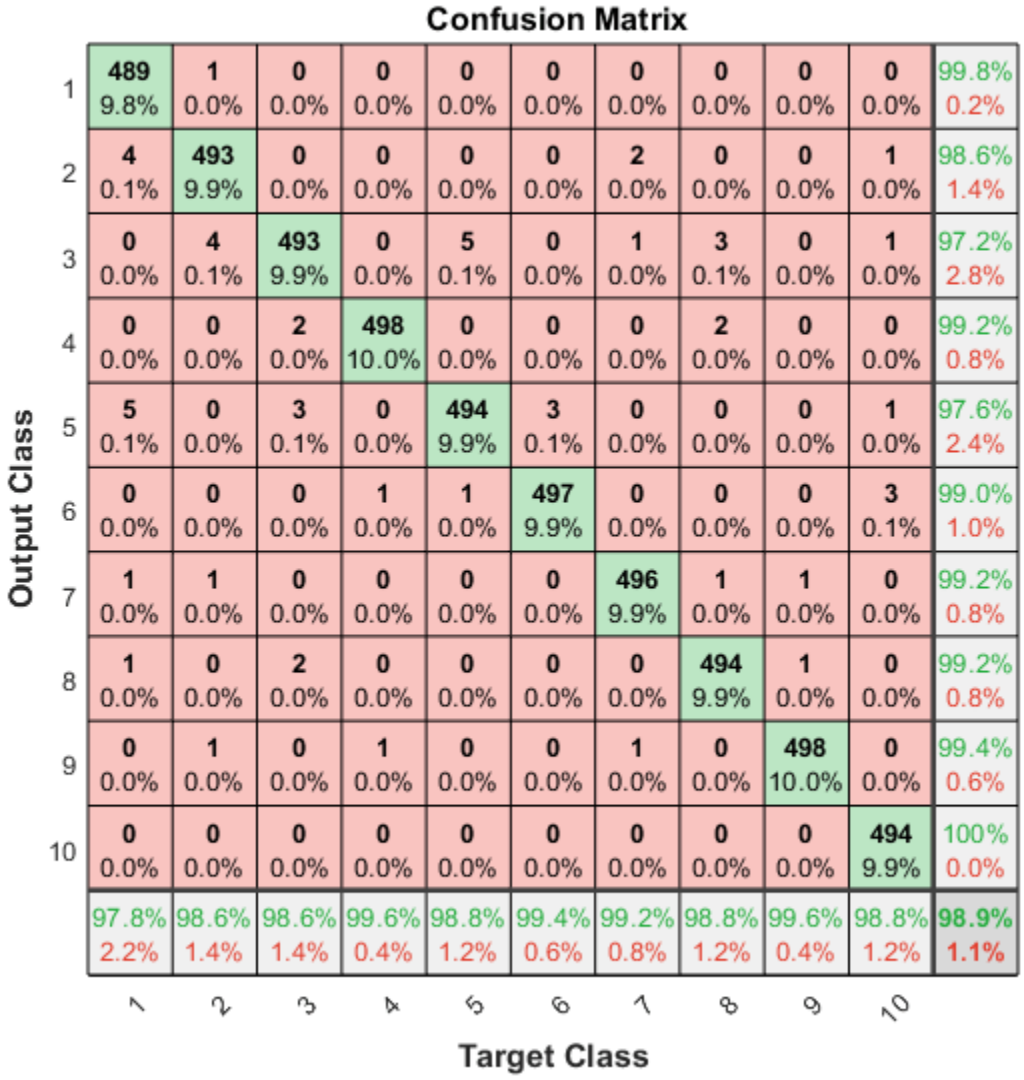
You fine tune the network by retraining it on the training data in a supervised fashion. Before you can do this, you have to reshape the training images into a matrix, as was done for the test images.

```
% Turn the training images into vectors and put them in a matrix
xTrain = zeros(inputSize,numel(xTrainImages));
for i = 1:numel(xTrainImages)
    xTrain(:,i) = xTrainImages{i}(:);
end
```

```
% Perform fine tuning
stackednet = train(stackednet,xTrain,tTrain);
```

You then view the results again using a confusion matrix.

```
y = stackednet(xTest);
plotconfusion(tTest,y);
```



Summary

This example showed how to train a stacked neural network to classify digits in images using autoencoders. The steps that have been outlined can be applied to other similar problems, such as classifying images of letters, or even small images of objects of a specific category.

Iris Clustering

This example illustrates how a self-organizing map neural network can cluster iris flowers into classes topologically, providing insight into the types of flowers and a useful tool for further analysis.

The Problem: Cluster Iris Flowers

In this example we attempt to build a neural network that clusters iris flowers into natural classes, such that similar classes are grouped together. Each iris is described by four features:

- Sepal length in cm
- Sepal width in cm
- Petal length in cm
- Petal width in cm

This is an example of a clustering problem, where we would like to group samples into classes based on the similarity between samples. We would like to create a neural network which not only creates class definitions for the known inputs, but will also let us classify unknown inputs accordingly.

Why Self-Organizing Map Neural Networks?

Self-organizing maps (SOMs) are very good at creating classifications. Further, the classifications retain topological information about which classes are most similar to others. Self-organizing maps can be created with any desired level of detail. They are particularly well suited for clustering data in many dimensions and with complexly shaped and connected feature spaces. They are well suited to cluster iris flowers.

The four flower attributes will act as inputs to the SOM, which will map them onto a 2-dimensional layer of neurons.

Preparing the Data

Data for clustering problems are set up for a SOM by organizing the data into an input matrix X.

Each ith column of the input matrix will have four elements representing the four measurements taken on a single flower.

Here such a dataset is loaded.

```
x = iris_dataset;
```

We can view the size of inputs X.

Note that X has 150 columns. These represent 150 sets of iris flower attributes. It has four rows, for the four measurements.

```
size(x)
```

```
ans = 1×2

     4   150
```

Clustering with a Neural Network

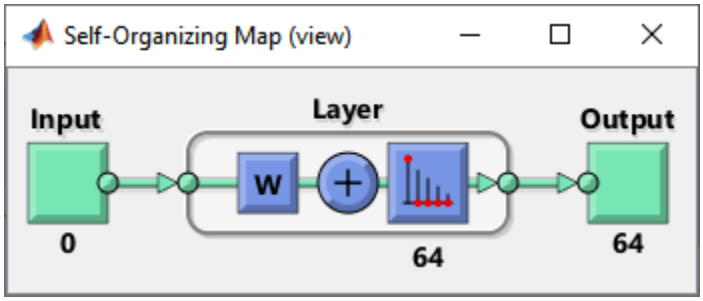
The next step is to create a neural network that will learn to cluster.

selforgmap creates self-organizing maps for classifying samples with as much detail as desired by selecting the number of neurons in each dimension of the layer.

We will try a 2-dimension layer of 64 neurons arranged in an 8x8 hexagonal grid for this example. In general, greater detail is achieved with more neurons, and more dimensions allows for modelling the topology of more complex feature spaces.

The input size is 0 because the network has not yet been configured to match our input data. This will happen when the network is trained.

```
net = selforgmap([8 8]);
view(net)
```



Now the network is ready to be optimized with **train**.

The Neural Network Training Tool shows the network being trained and the algorithms used to train it. It also displays the training state during training and the criteria which stopped training will be highlighted in green.

The buttons at the bottom open useful plots which can be opened during and after training. Links next to the algorithm names and plot buttons open documentation on those subjects.

```
[net,tr] = train(net,x);
```

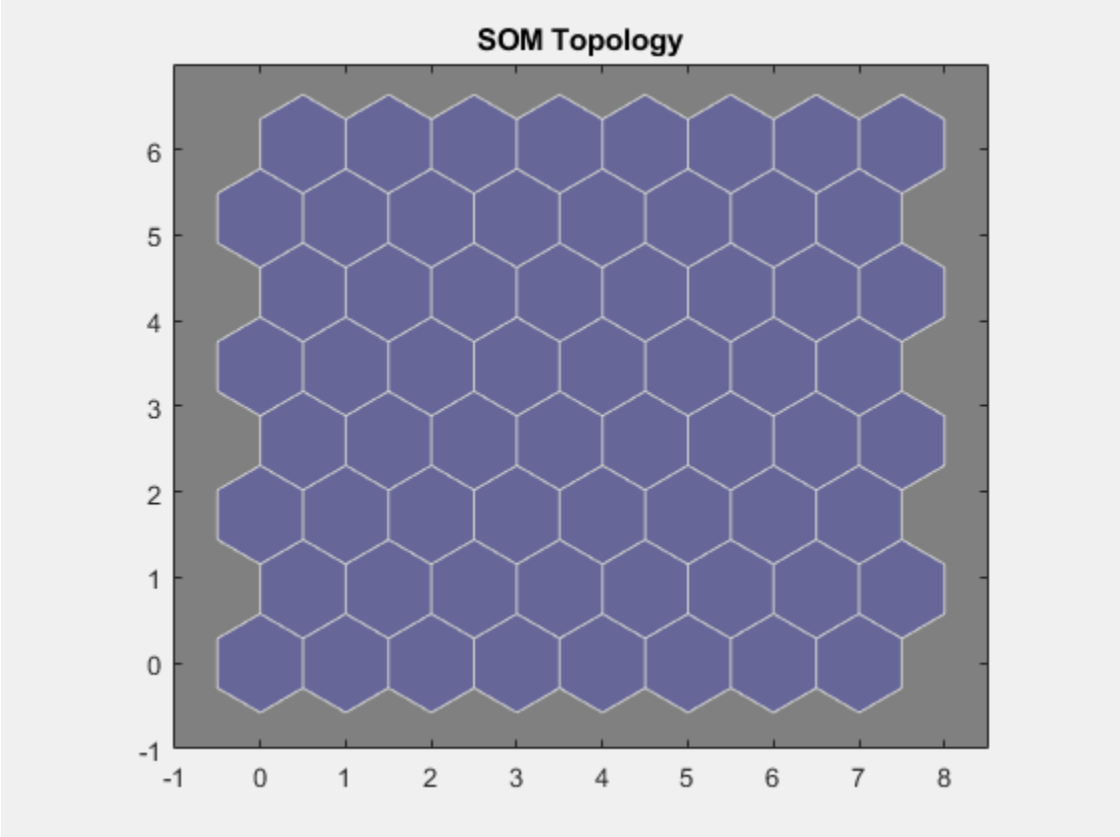
Here the self-organizing map is used to compute the class vectors of each of the training inputs. These classifications cover the feature space populated by the known flowers, and can now be used to classify new flowers accordingly. The network output will be a 64x150 matrix, where each ith column represents the jth cluster for each ith input vector with a 1 in its jth element.

The function **vec2ind** returns the index of the neuron with an output of 1, for each vector. The indices will range between 1 and 64 for the 64 clusters represented by the 64 neurons.

```
y = net(x);
cluster_index = vec2ind(y);
```

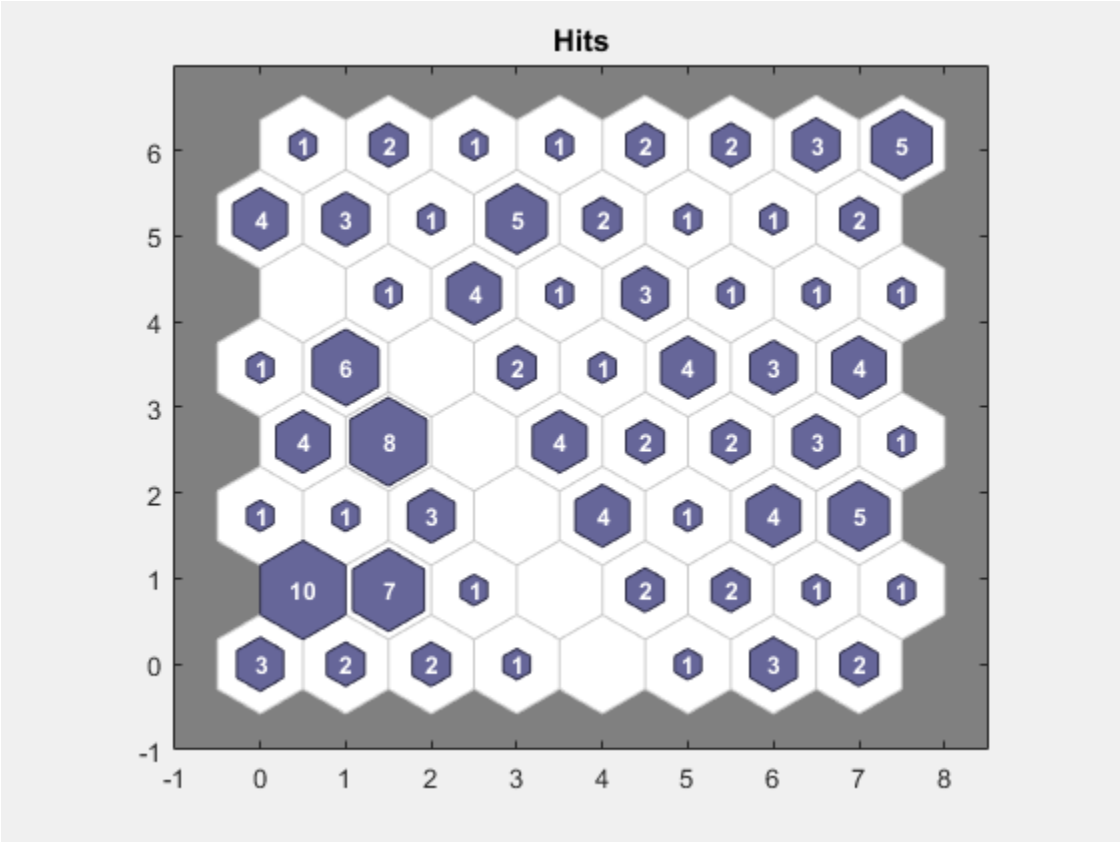
plotsomtop plots the self-organizing maps topology of 64 neurons positioned in an 8x8 hexagonal grid. Each neuron has learned to represent a different class of flower, with adjacent neurons typically representing similar classes.

```
plotsomtop(net)
```



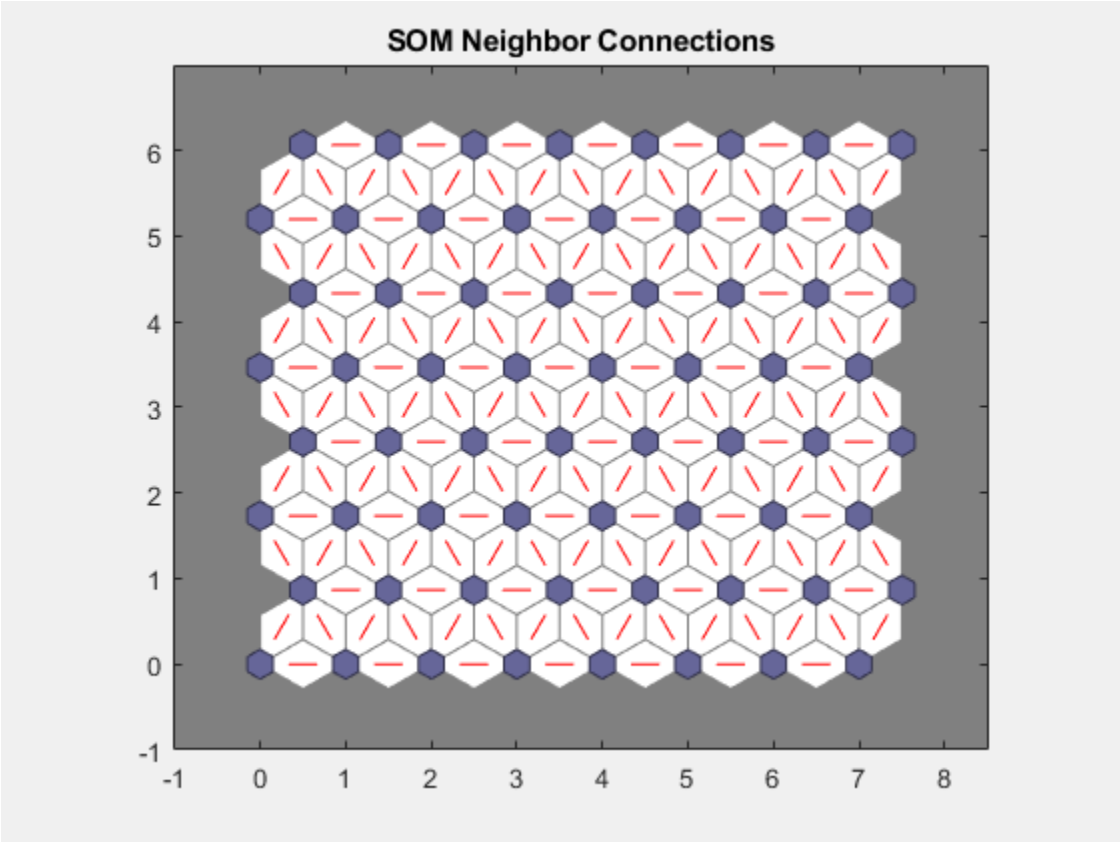
plotsomhits calculates the classes for each flower and shows the number of flowers in each class. Areas of neurons with large numbers of hits indicate classes representing similar highly populated regions of the feature space. Whereas areas with few hits indicate sparsely populated regions of the feature space.

```
plotsomhits(net,x)
```



plotsomnc shows the neuron neighbor connections. Neighbors typically classify similar samples.

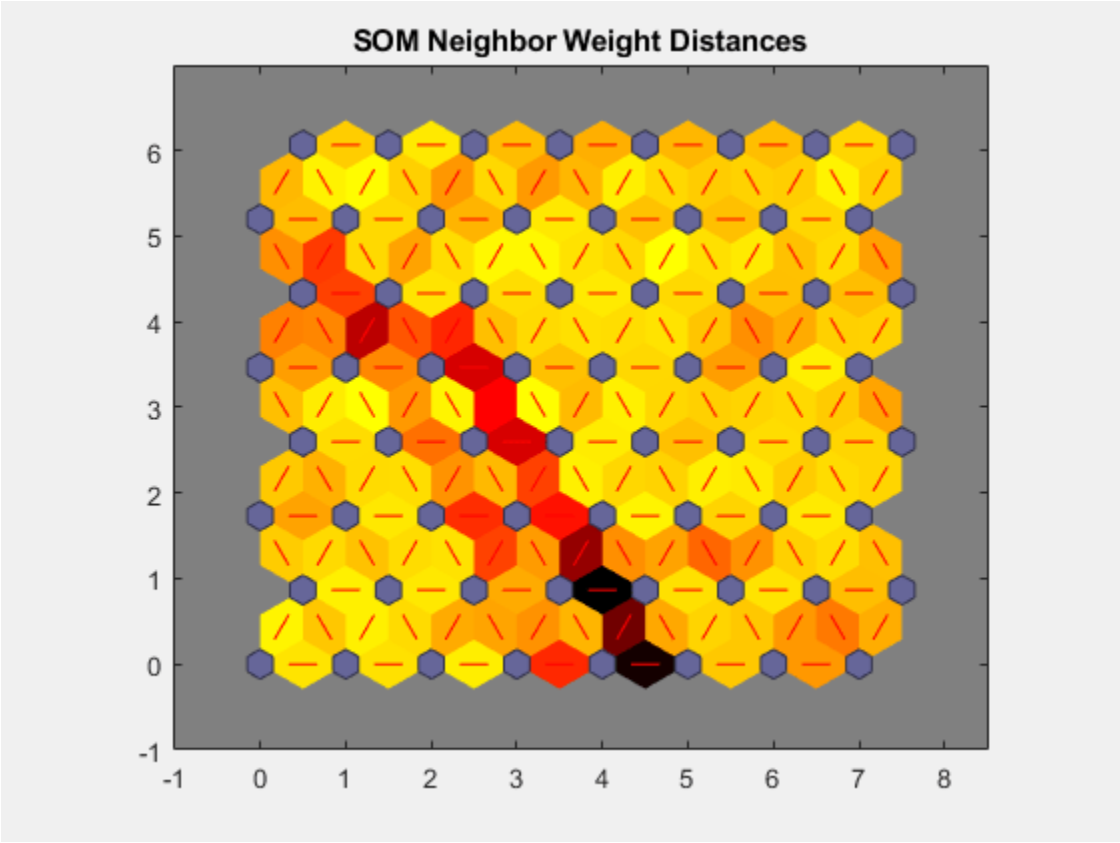
```
plotsomnc(net)
```



plotsomnd shows how distant (in terms of Euclidian distance) each neuron's class is from its neighbors. Connections which are bright indicate highly connected areas of the input space. While dark connections indicate classes representing regions of the feature space which are far apart, with few or no flowers between them.

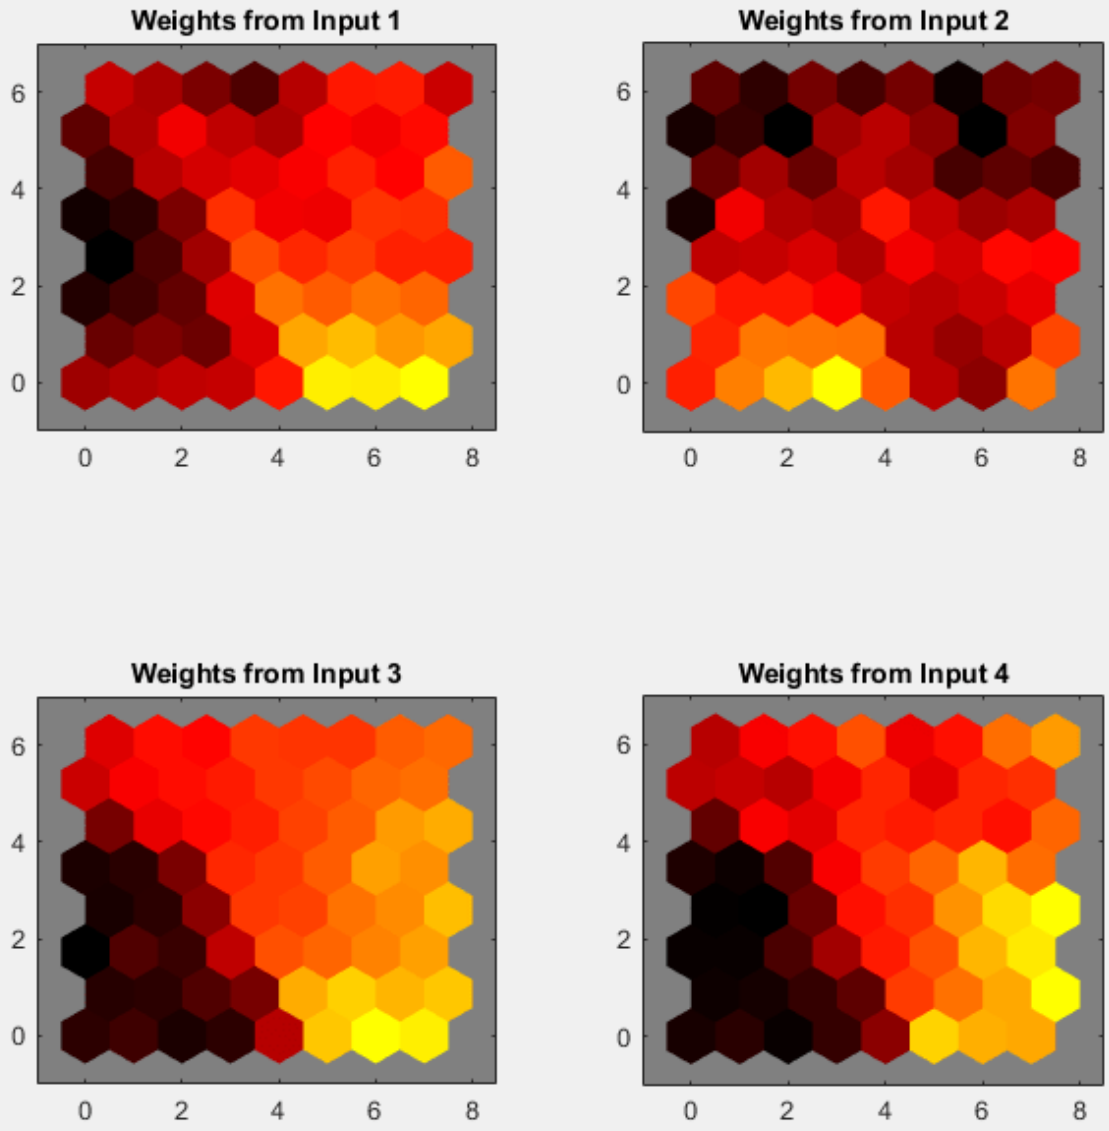
Long borders of dark connections separating large regions of the input space indicate that the classes on either side of the border represent flowers with very different features.

```
plotsomnd(net)
```



plotsomplanes shows a weight plane for each of the four input features. They are visualizations of the weights that connect each input to each of the 64 neurons in the 8x8 hexagonal grid. Darker colors represent larger weights. If two inputs have similar weight planes (their color gradients may be the same or in reverse) it indicates they are highly correlated.

```
plotsomplanes(net)
```



This example illustrated how to design a neural network that clusters iris flowers based on four of their characteristics.

Explore other examples and the documentation for more insight into neural networks and their applications.

Gene Expression Analysis

This example demonstrates looking for patterns in gene expression profiles in baker's yeast using neural networks.

The Problem: Analyzing Gene Expressions in Baker's Yeast (Saccharomyces Cerevisiae)

The goal is to gain some understanding of gene expressions in Saccharomyces cerevisiae, which is commonly known as baker's yeast or brewer's yeast. It is the fungus that is used to bake bread and ferment wine from grapes.

Saccharomyces cerevisiae, when introduced in a medium rich in glucose, can convert glucose to ethanol. Initially, yeast converts glucose to ethanol by a metabolic process called "fermentation". However, once the supply of glucose is exhausted yeast shifts from anaerobic fermentation of glucose to aerobic respiration of ethanol. This process is called diauxic shift. This process is of considerable interest since it is accompanied by major changes in gene expression.

The example uses DNA microarray data to study temporal gene expression of almost all genes in Saccharomyces cerevisiae during the diauxic shift.

You need Bioinformatics Toolbox™ to run this example.

```
if ~nnDependency.bioInfoAvailable
    errordlg('This example requires Bioinformatics Toolbox.');
    return;
end
```

The Data

This example uses data from DeRisi, JL, Iyer, VR, Brown, PO. "Exploring the metabolic and genetic control of gene expression on a genomic scale." Science. 1997 Oct 24;278(5338):680-6. PMID: 9381177

The full data set can be downloaded from the Gene Expression Omnibus website: https://www.yeastgenome.org

Start by loading the data into MATLAB®.

```
load yeastdata.mat
```

Gene expression levels were measured at seven time points during the diauxic shift. The variable `times` contains the times at which the expression levels were measured in the experiment. The variable `genes` contains the names of the genes whose expression levels were measured. The variable `yeastvalues` contains the "VALUE" data or LOG_RAT2N_MEAN, or log2 of ratio of CH2DN_MEAN and CH1DN_MEAN from the seven time steps in the experiment.

To get an idea of the size of the data you can use **numel(genes)** to show how many genes there are in the data set.

```
numel(genes)
```

```
ans = 6400
```

genes is a cell array of the gene names. You can access the entries using MATLAB cell array indexing:

```
genes{15}
```

```
ans =
'YAL054C'
```

This indicates that the 15th row of the variable **yeastvalues** contains expression levels for the ORF YAL054C.

Filtering the Genes

The data set is quite large and a lot of the information corresponds to genes that do not show any interesting changes during the experiment. To make it easier to find the interesting genes, the first thing to do is to reduce the size of the data set by removing genes with expression profiles that do not show anything of interest. There are 6400 expression profiles. You can use a number of techniques to reduce this to some subset that contains the most significant genes.

If you look through the gene list you will see several spots marked as 'EMPTY'. These are empty spots on the array, and while they might have data associated with them, for the purposes of this example, you can consider these points to be noise. These points can be found using the **strcmp** function and removed from the data set with indexing commands.

```
emptySpots = strcmp('EMPTY',genes);
yeastvalues(emptySpots,:) = [];
genes(emptySpots) = [];
numel(genes)
```

```
ans = 6314
```

In the yeastvalues data you will also see several places where the expression level is marked as NaN. This indicates that no data was collected for this spot at the particular time step. One approach to dealing with these missing values would be to impute them using the mean or median of data for the particular gene over time. This example uses a less rigorous approach of simply throwing away the data for any genes where one or more expression level was not measured.

The function **isnan** is used to identify the genes with missing data and indexing commands are used to remove the genes with missing data.

```
nanIndices = any(isnan(yeastvalues),2);
yeastvalues(nanIndices,:) = [];
genes(nanIndices) = [];
numel(genes)
```

```
ans = 6276
```

If you were to plot the expression profiles of all the remaining profiles, you would see that most profiles are flat and not significantly different from the others. This flat data is obviously of use as it indicates that the genes associated with these profiles are not significantly affected by the diauxic shift; however, in this example, you are interested in the genes with large changes in expression accompanying the diauxic shift. You can use filtering functions in the Bioinformatics Toolbox™ to remove genes with various types of profiles that do not provide useful information about genes affected by the metabolic change.

You can use the **genevarfilter** function to filter out genes with small variance over time. The function returns a logical array of the same size as the variable genes with ones corresponding to rows of yeastvalues with variance greater than the 10th percentile and zeros corresponding to those below the threshold.

```
mask = genevarfilter(yeastvalues);
% Use the mask as an index into the values to remove the filtered genes.
```

```
yeastvalues = yeastvalues(mask,:);
genes = genes(mask);
numel(genes)

ans = 5648
```

The function **genelowvalfilter** removes genes that have very low absolute expression values. Note that the gene filter functions can also automatically calculate the filtered data and names.

```
[mask, yeastvalues, genes] = ...
    genelowvalfilter(yeastvalues,genes,'absval',log2(3));
numel(genes)

ans = 822
```

Use **geneentropyfilter** to remove genes whose profiles have low entropy:

```
[mask, yeastvalues, genes] = ...
    geneentropyfilter(yeastvalues,genes,'prctile',15);
numel(genes)

ans = 614
```

Principal Component Analysis

Now that you have a manageable list of genes, you can look for relationships between the profiles.

Normalizing the standard deviation and mean of data allows the network to treat each input as equally important over its range of values.

Principal-component analysis (PCA) is a useful technique that can be used to reduce the dimensionality of large data sets, such as those from microarray analysis. This technique isolates the principal components of the dataset eliminating those components that contribute the least to the variation in the data set.

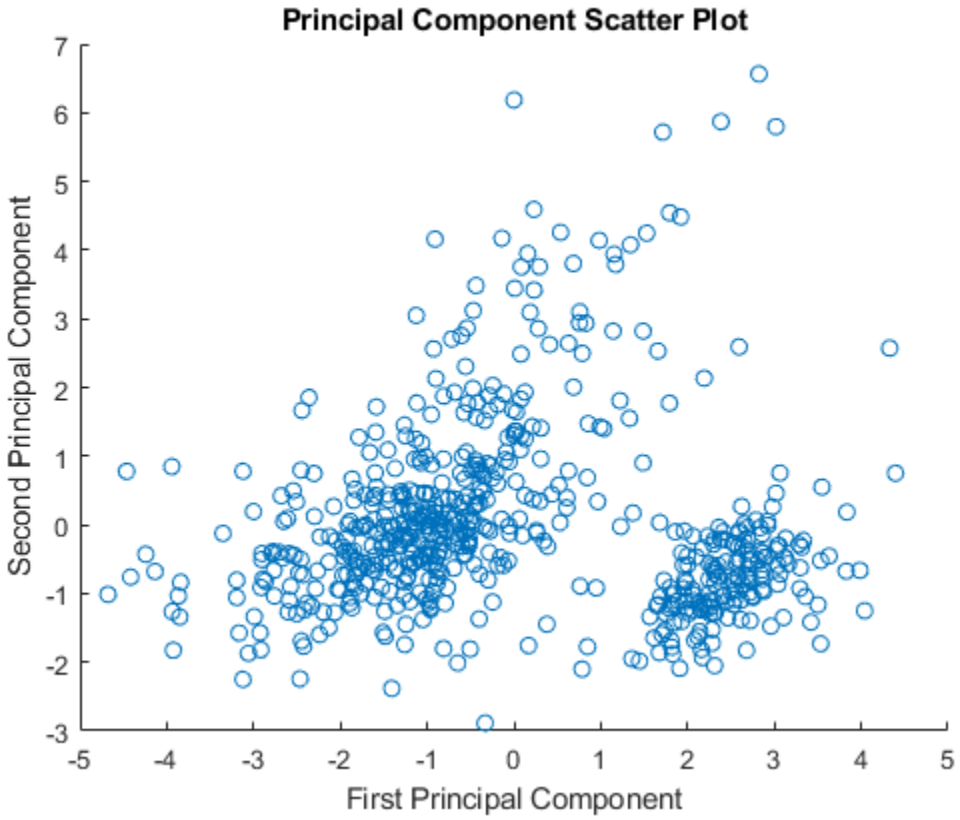
The two settings variables can be used to apply **mapstd** and **processpca** to new data to be consistent.

```
[x,std_settings] = mapstd(yeastvalues');  % Normalize data
[x,pca_settings] = processpca(x,0.15);    % PCA
```

The input vectors are first normalized, using `mapstd`, so that they have zero mean and unity variance. `processpca` is the function that implements the PCA algorithm. The second argument passed to `processpca` is 0.15. This means that `processpca` eliminates those principal components that contribute less than 15% to the total variation in the data set. The variable `pc` now contains the principal components of the yeastvalues data.

The principal components can be visualized using the **scatter** function.

```
figure
scatter(x(1,:),x(2,:));
xlabel('First Principal Component');
ylabel('Second Principal Component');
title('Principal Component Scatter Plot');
```



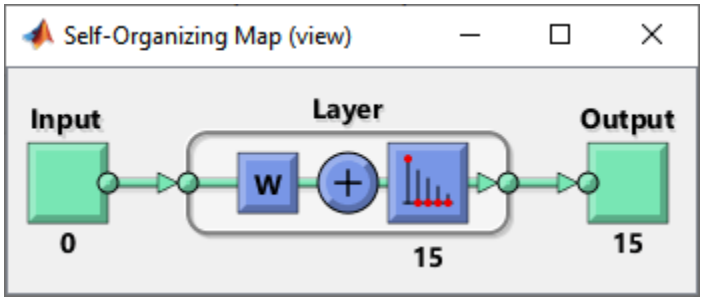
Cluster Analysis: Self-Organizing Maps

The principal components can now be clustered using the Self-Organizing map (SOM) clustering algorithm.

The **selforgmap** function creates a Self-Organizing map network which can then be trained with the **train** function.

The input size is 0 because the network has not yet been configured to match our input data. This will happen when the network is trained.

```
net = selforgmap([5 3]);
view(net)
```



Now the network is ready to be trained.

The Neural Network Training Tool shows the network being trained and the algorithms used to train it. It also displays the training state during training and the criteria which stopped training will be highlighted in green.

The buttons at the bottom open useful plots which can be opened during and after training. Links next to the algorithm names and plot buttons open documentation on those subjects.

```
net = train(net,x);

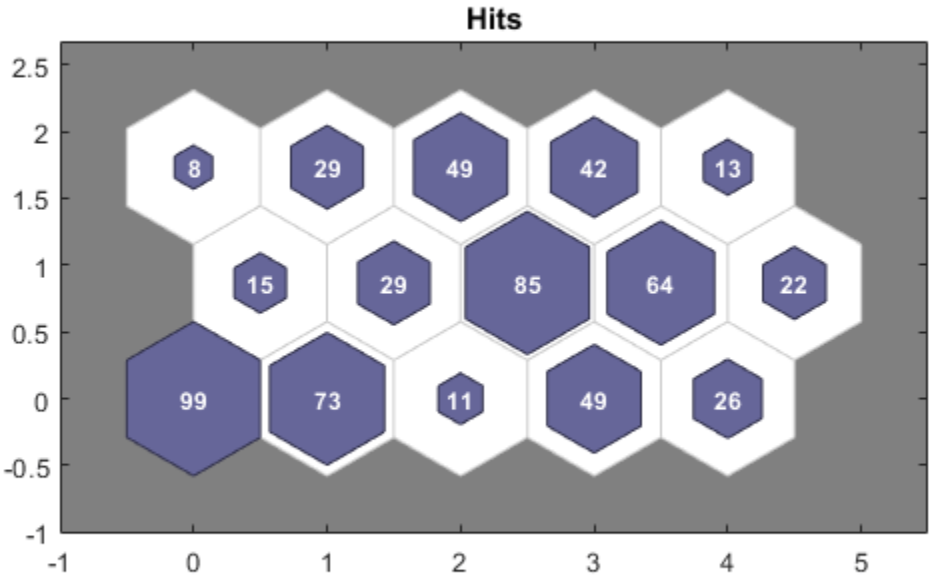
plotsomhits(net,x);
```



You can also use other clustering algorithms like Hierarchical clustering and K-means, available in the Statistics and Machine Learning Toolbox™ for cluster analysis.

Glossary

ORF - An open reading frame (ORF) is a portion of a gene's sequence that contains a sequence of bases, uninterrupted by stop sequences, that could potentially encode a protein.

Maglev Modeling

This example illustrates how a NARX (Nonlinear AutoRegressive with eXternal input) neural network can model a magnet levitation dynamical system.

The Problem: Model a Magnetic Levitation System

In this example we attempt to build a neural network that can predict the dynamic behavior of a magnet levitated using a control current.

The system is characterized by the magnet's position and a control current, both of which determine where the magnet will be an instant later.

This is an example of a time series problem, where past values of a feedback time series (the magnet position) and an external input series (the control current) are used to predict future values of the feedback series.

Why Neural Networks?

Neural networks are very good at time series problems. A neural network with enough elements (called neurons) can model dynamic systems with arbitrary accuracy. They are particularly well suited for addressing non-linear dynamic problems. Neural networks are a good candidate for solving this problem.

The network will be designed by using recordings of an actual levitated magnet's position responding to a control current.

Preparing the Data

Data for function fitting problems are set up for a neural network by organizing the data into two matrices, the input time series X and the target time series T.

The input series X is a row cell array, where each element is the associated timestep of the control current.

The target series T is a row cell array, where each element is the associated timestep of the levitated magnet position.

Here such a dataset is loaded.

```
[x,t] = maglev_dataset;
```

We can view the sizes of inputs X and targets T.

Note that both X and T have 4001 columns. These represent 4001 timesteps of the control current and magnet position.

```
size(x)
```

```
ans = 1×2

           1        4001
```

```
size(t)
```

```
ans = 1×2

     1        4001
```

Time Series Modelling with a Neural Network

The next step is to create a neural network that will learn to model how the magnet changes position.

Since the neural network starts with random initial weights, the results of this example will differ slightly every time it is run. The random seed is set to avoid this randomness. However this is not necessary for your own applications.

```
setdemorandstream(491218381)
```

Two-layer (i.e. one-hidden-layer) NARX neural networks can fit any dynamical input-output relationship given enough neurons in the hidden layer. Layers which are not output layers are called hidden layers.

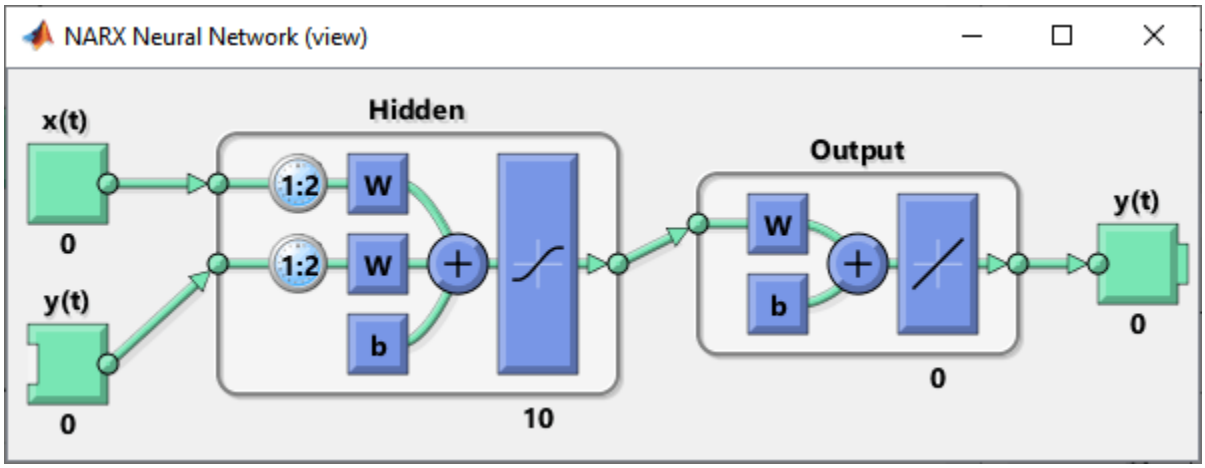
We will try a single hidden layer of 10 neurons for this example. In general, more difficult problems require more neurons, and perhaps more layers. Simpler problems require fewer neurons.

We will also try using tap delays with two delays for the external input (control current) and feedback (magnet position). More delays allow the network to model more complex dynamic systems.

The input and output have sizes of 0 because the network has not yet been configured to match our input and target data. This will happen when the network is trained.

The output y(t) is also an input, whose delayed version is fed back into the network.

```
net = narxnet(1:2,1:2,10);
view(net)
```



Before we can train the network, we must use the first two timesteps of the external input and feedback time series to fill the two tap delay states of the network.

Furthermore, we need to use the feedback series both as an input series and target series.

The function PREPARETS prepares time series data for simulation and training for us. Xs will consist of shifted input and target series to be presented to the network. Xi is the initial input delay states. Ai

is the layer delay states (empty in this case as there are no layer-to-layer delays), and Ts is the shifted feedback series.

```
[Xs,Xi,Ai,Ts] = preparets(net,x,{},t);
```

Now the network is ready to be trained. The timesteps are automatically divided into training, validation and test sets. The training set is used to teach the network. Training continues as long as the network continues improving on the validation set. The test set provides a completely independent measure of network accuracy.

The Neural Network Training Tool shows the network being trained and the algorithms used to train it. It also displays the training state during training and the criteria which stopped training will be highlighted in green.

The buttons at the bottom open useful plots which can be opened during and after training. Links next to the algorithm names and plot buttons open documentation on those subjects.

```
[net,tr] = train(net,Xs,Ts,Xi,Ai);
```

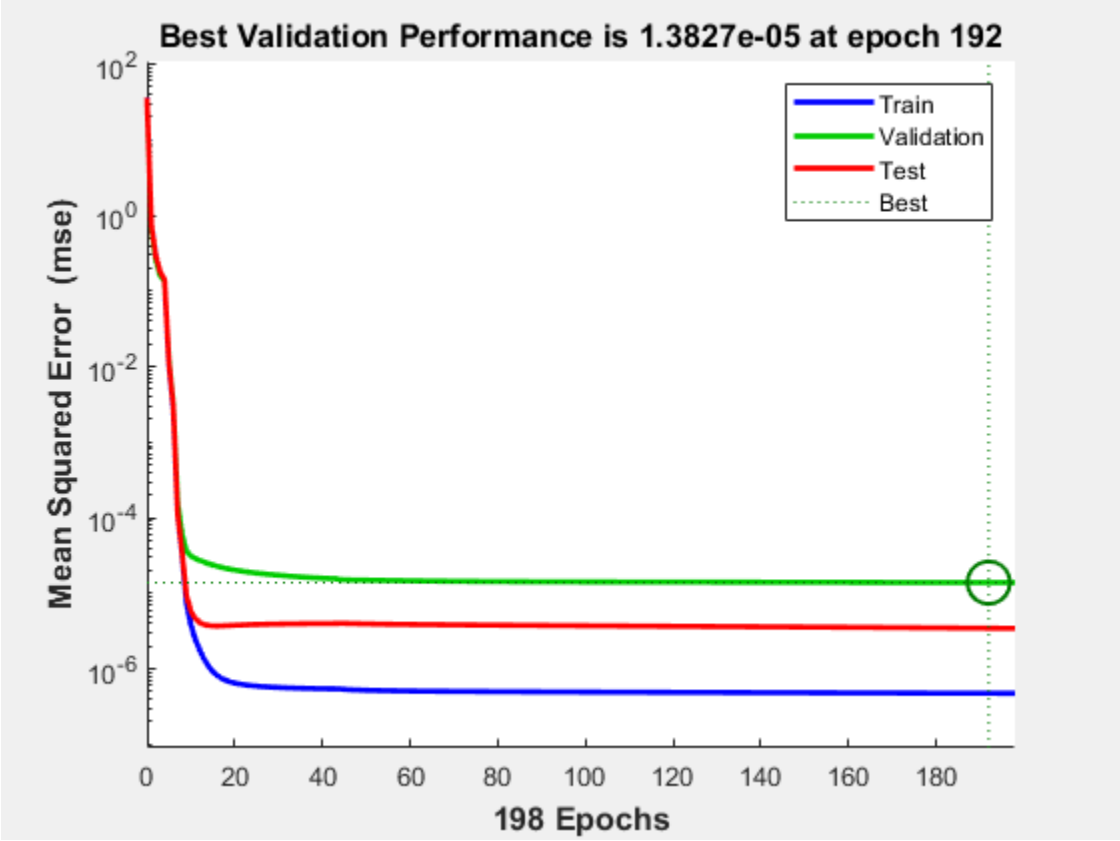
To see how the network's performance improved during training, either click the "Performance" button in the training tool, or call PLOTPERFORM.

Performance is measured in terms of mean squared error, and is shown in a log scale. It rapidly decreased as the network was trained.

Performance is shown for each of the training, validation and test sets.

```
plotperform(tr)
```



Testing the Neural Network

The mean squared error of the trained neural network for all timesteps can now be measured.

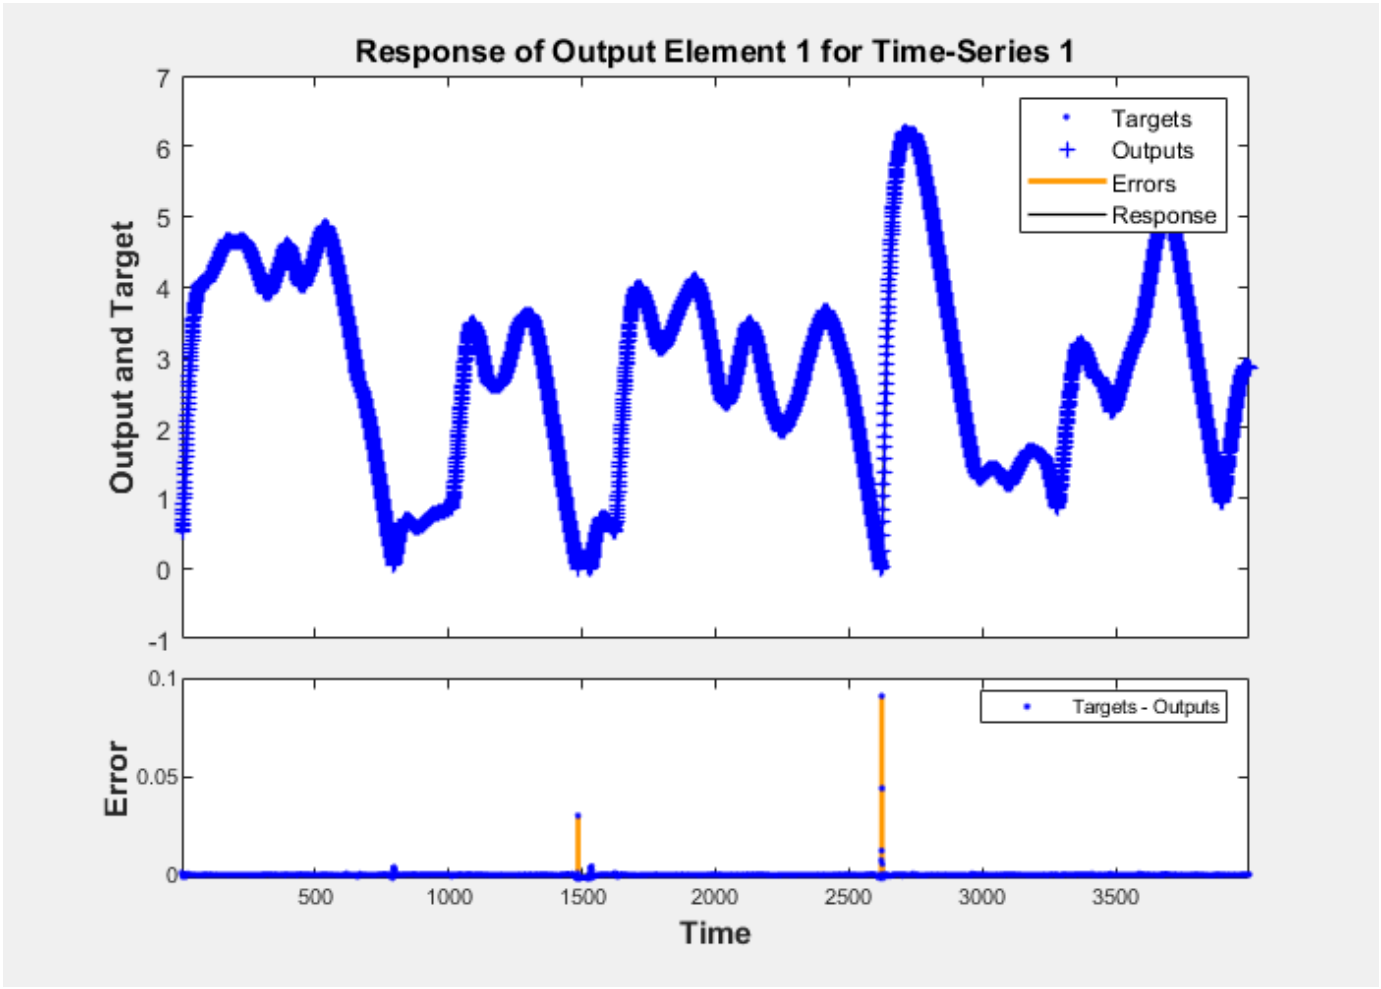
```
Y = net(Xs,Xi,Ai);

perf = mse(net,Ts,Y)

perf = 2.9245e-06
```

PLOTRESPONSE will show us the network's response in comparison to the actual magnet position. If the model is accurate the '+' points will track the diamond points, and the errors in the bottom axis will be very small.

```
plotresponse(Ts,Y)
```

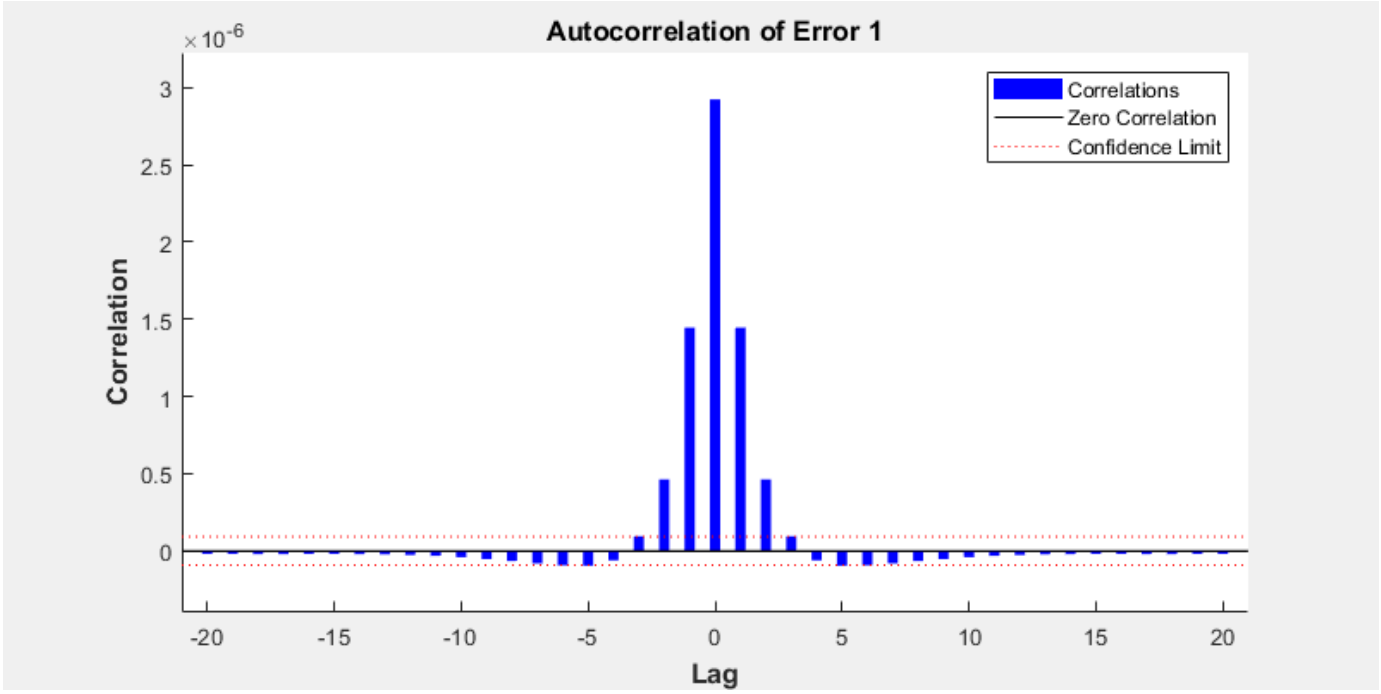


PLOTERRCORR shows the correlation of error at time t, e(t) with errors over varying lags, e(t+lag). The center line shows the mean squared error. If the network has been trained well all the other lines will be much shorter, and most if not all will fall within the red confidence limits.

The function GSUBTRACT is used to calculate the error. This function generalizes subtraction to support differences between cell array data.

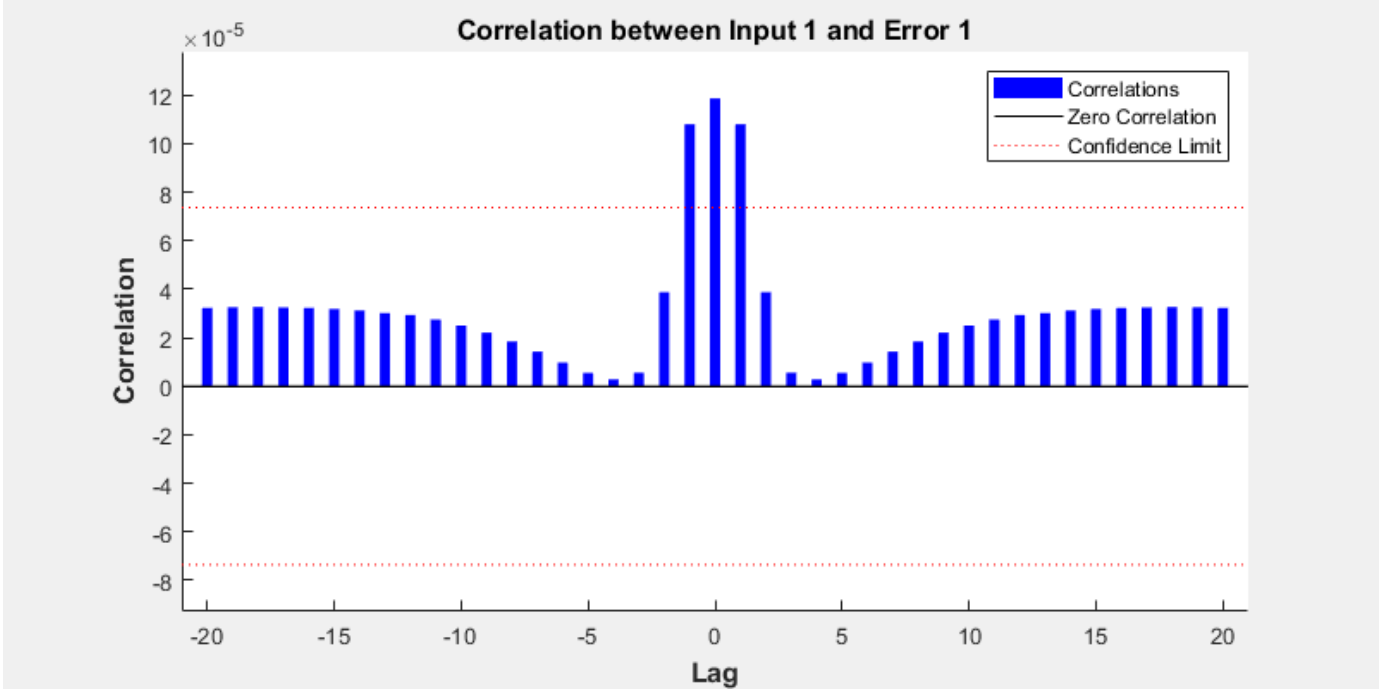
```
E = gsubtract(Ts,Y);

ploterrcorr(E)
```



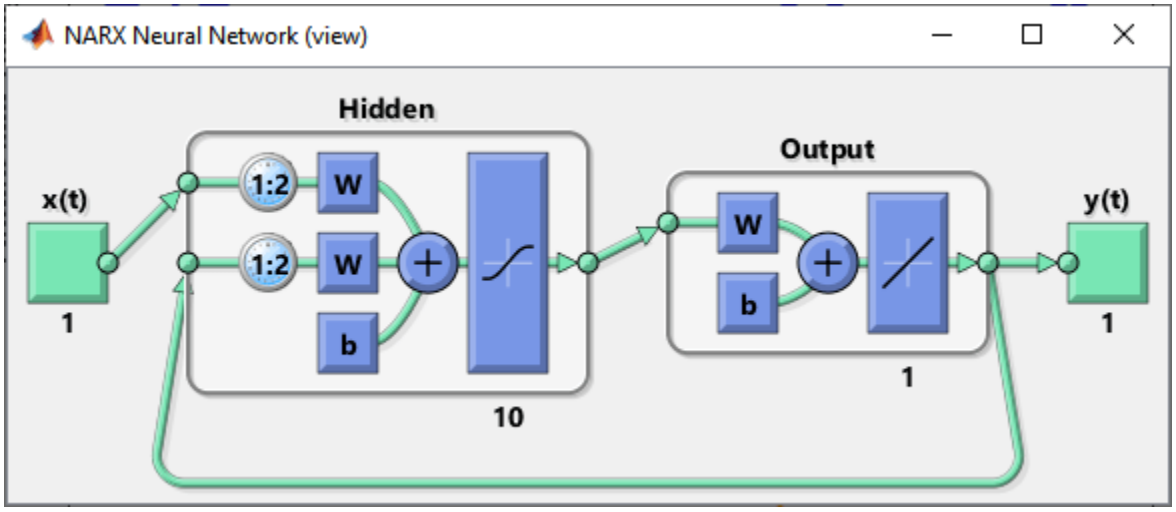
Similarly, PLOTINERRCORR shows the correlation of error with respect to the inputs, with varying degrees of lag. In this case, most or all the lines should fall within the confidence limits, including the center line.

```
plotinerrcorr(Xs,E)
```



The network was trained in open loop form, where targets were used as feedback inputs. The network can also be converted to closed loop form, where its own predictions become the feedback inputs.

```
net2 = closeloop(net);
view(net2)
```

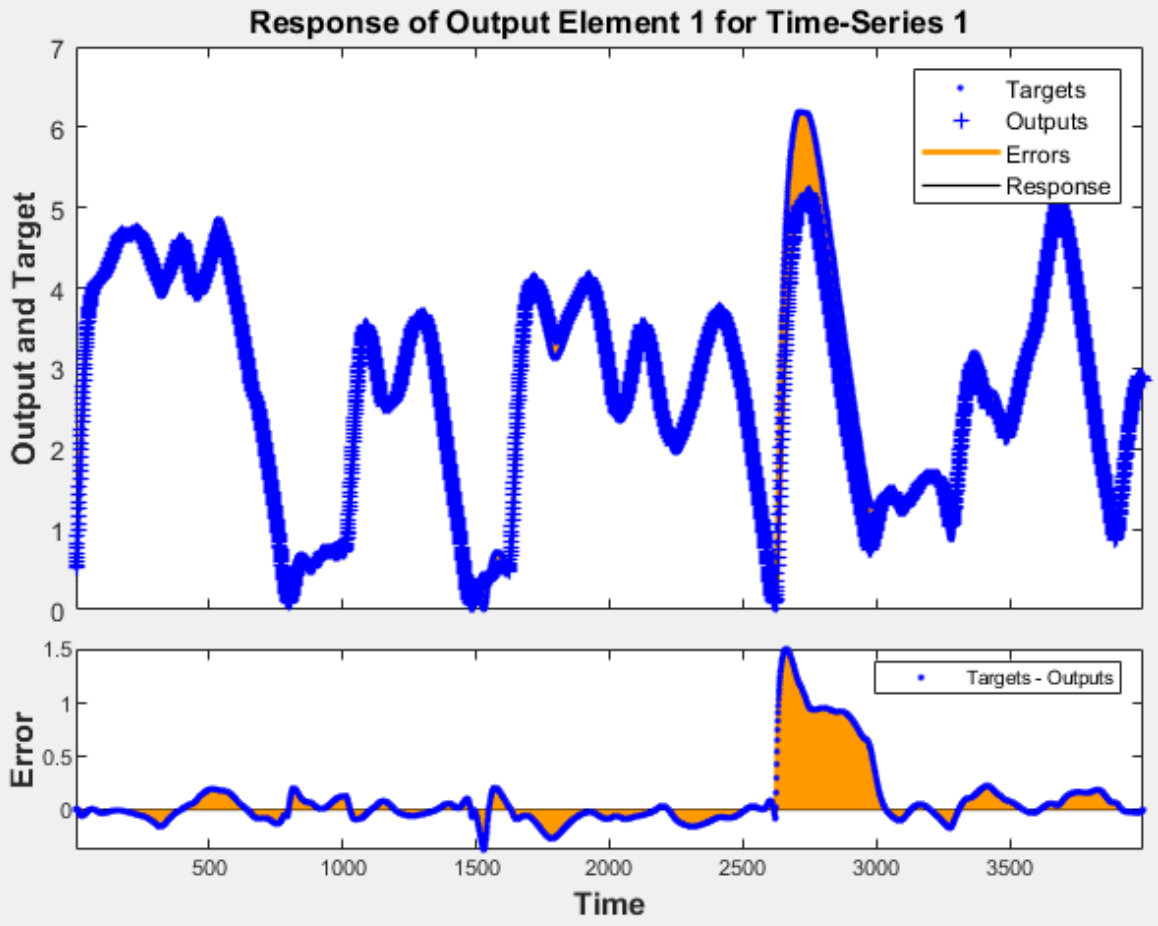


We can simulate the network in closed loop form. In this case the network is only given initial magnet positions, and then must use its own predicted positions recursively to predict new positions.

This quickly results in a poor fit between the predicted and actual response. This will occur even if the model is very good. But it is interesting to see how many steps they match before separating.

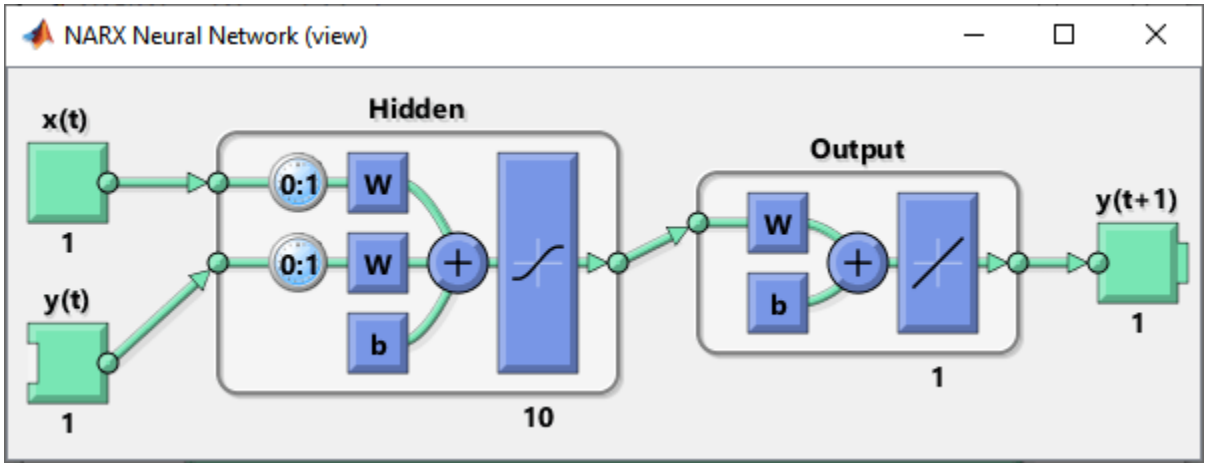
Again, PREPARETS does the work of preparing the time series data for us taking into account the altered network.

```
[Xs,Xi,Ai,Ts] = preparets(net2,x,{},t);
Y = net2(Xs,Xi,Ai);
plotresponse(Ts,Y)
```



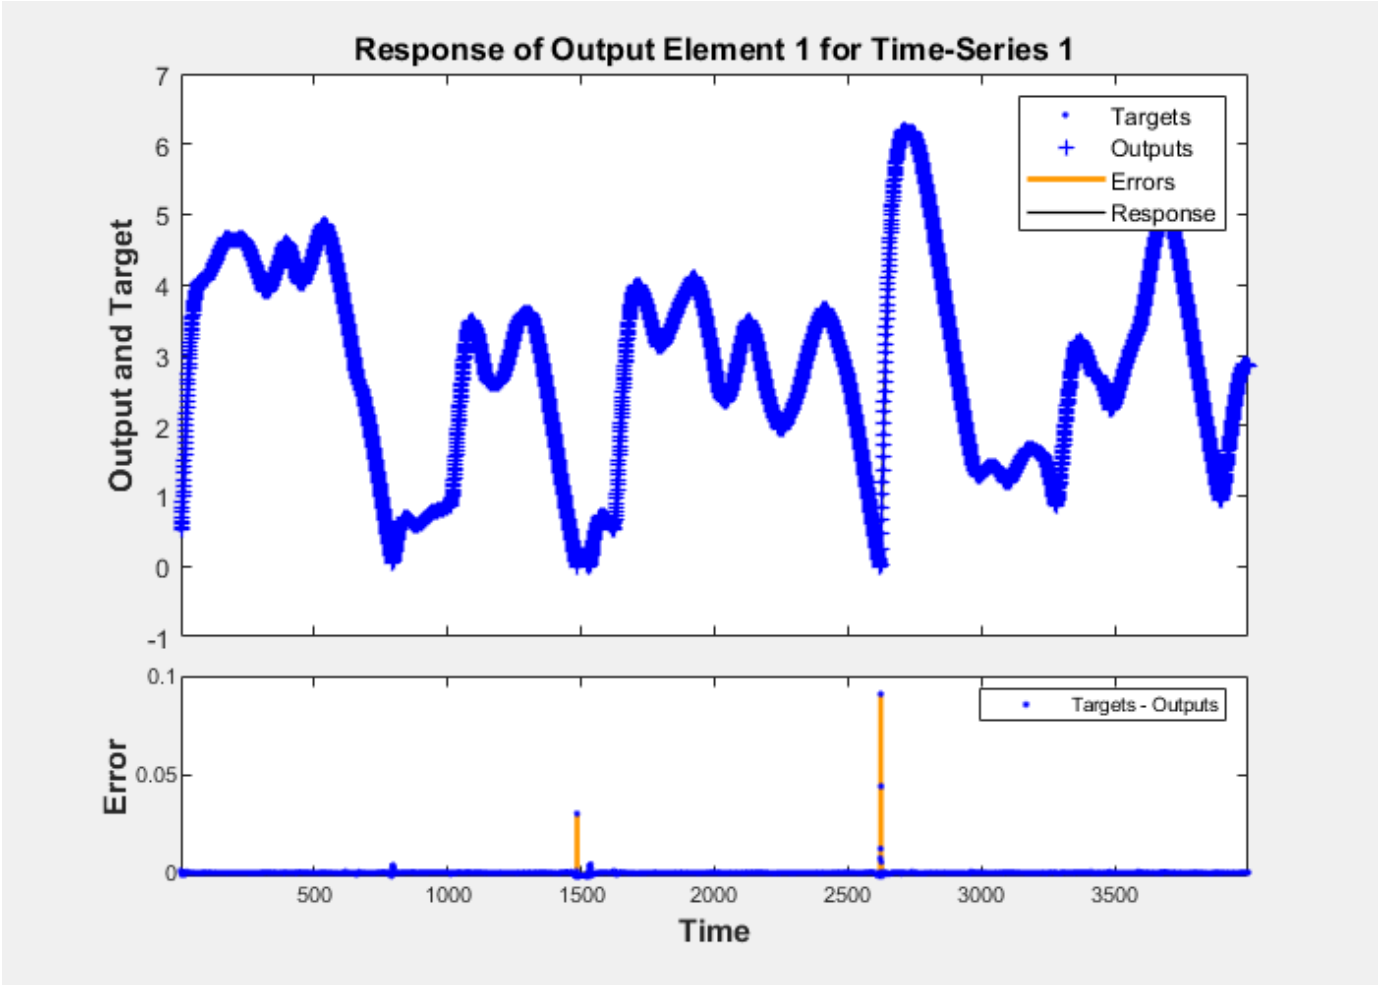
If the application required us to access the predicted magnet position a timestep ahead of when it actually occurs, we can remove a delay from the network so at any given time t, the output is an estimate of the position at time t+1.

```
net3 = removedelay(net);
view(net3)
```



Again we use PREPARETS to prepare the time series for simulation. This time the network is again very accurate as it is doing open loop prediction, but the output is shifted one timestep.

```
[Xs,Xi,Ai,Ts] = preparets(net3,x,{},t);
Y = net3(Xs,Xi,Ai);
plotresponse(Ts,Y)
```



This example illustrated how to design a neural network that models the behavior of a dynamical magnet levitation system.

Explore other examples and the documentation for more insight into neural networks and their applications.

Competitive Learning

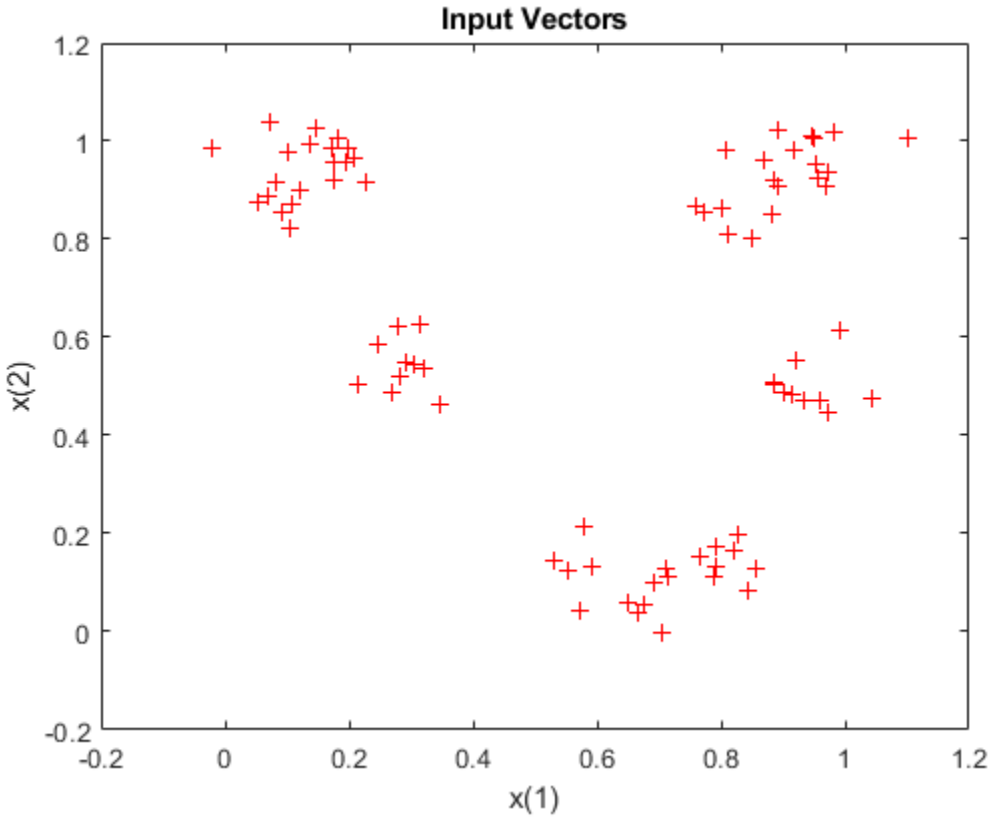
Neurons in a competitive layer learn to represent different regions of the input space where input vectors occur.

P is a set of randomly generated but clustered test data points. Here the data points are plotted.

A competitive network will be used to classify these points into natural classes.

```
% Create inputs X.
bounds = [0 1; 0 1];   % Cluster centers to be in these bounds.
clusters = 8;          % This many clusters.
points = 10;           % Number of points in each cluster.
std_dev = 0.05;        % Standard deviation of each cluster.
x = nngenc(bounds,clusters,points,std_dev);

% Plot inputs X.
plot(x(1,:),x(2,:),'+r');
title('Input Vectors');
xlabel('x(1)');
ylabel('x(2)');
```

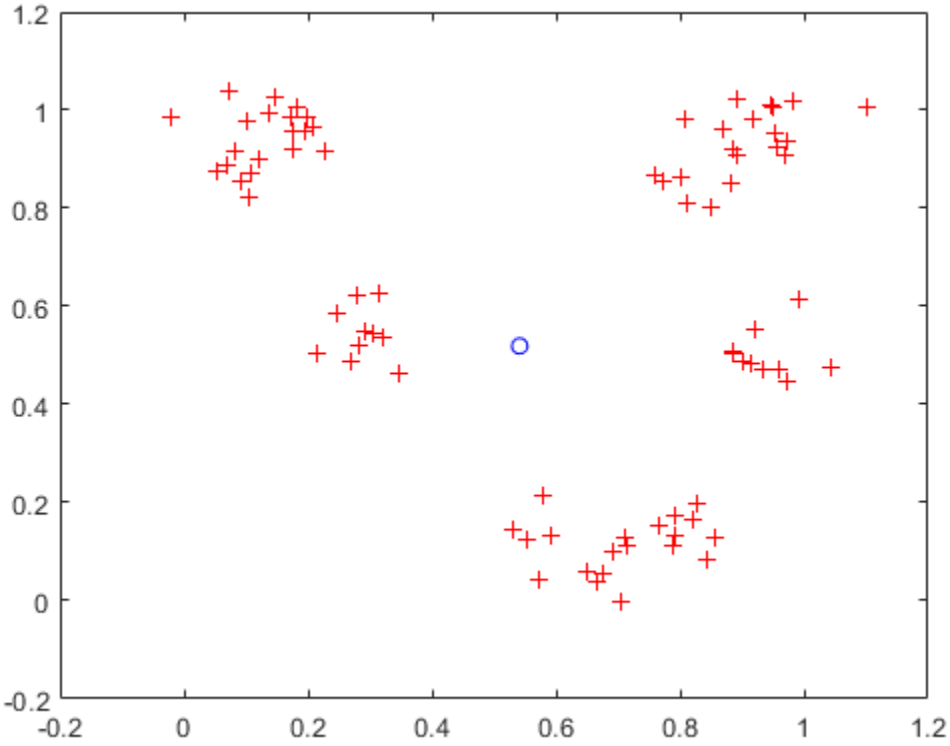


Here COMPETLAYER takes two arguments, the number of neurons and the learning rate.

We can configure the network inputs (normally done automatically by TRAIN) and plot the initial weight vectors to see their attempt at classification.

The weight vectors (o's) will be trained so that they occur centered in clusters of input vectors (+'s).

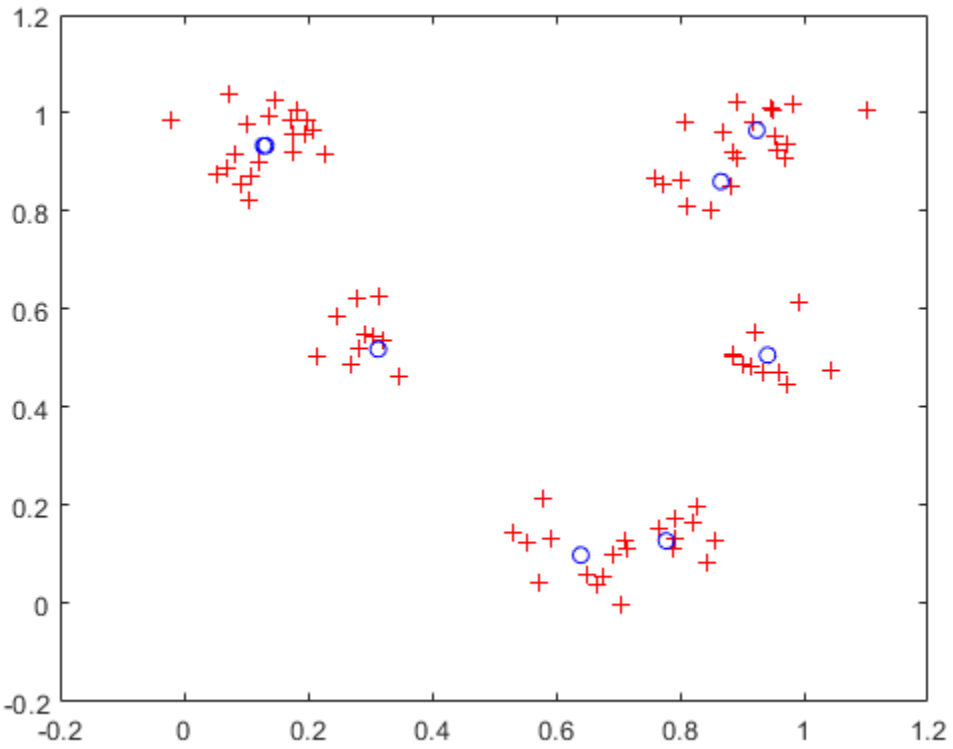
```
net = competlayer(8,.1);
net = configure(net,x);
w = net.IW{1};
plot(x(1,:),x(2,:),'+r');
hold on;
circles = plot(w(:,1),w(:,2),'ob');
```



Set the number of epochs to train before stopping and train this competitive layer (may take several seconds).

Plot the updated layer weights on the same graph.

```
net.trainParam.epochs = 7;
net = train(net,x);
w = net.IW{1};
delete(circles);
plot(w(:,1),w(:,2),'ob');
```



Now we can use the competitive layer as a classifier, where each neuron corresponds to a different category. Here we define am input vector X1 as [0; 0.2].

The output Y, indicates which neuron is responding, and thereby which class the input belongs.

```
x1 = [0; 0.2];
y = net(x1)
```

```
y = 8×1

     0
     1
     0
     0
     0
     0
     0
     0
```

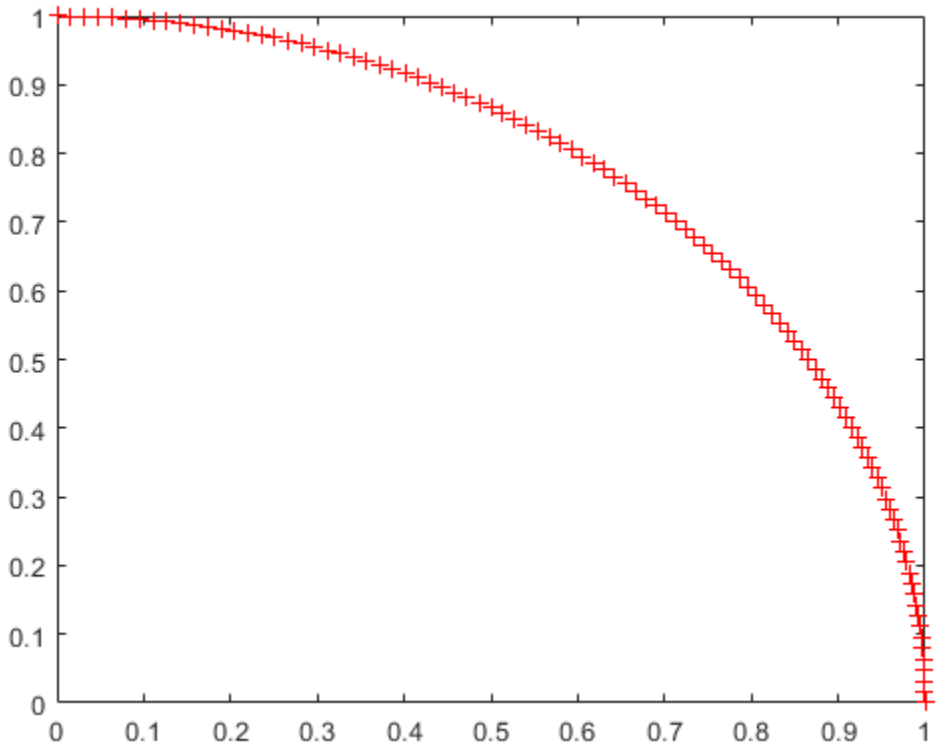
One-Dimensional Self-organizing Map

Neurons in a 2-D layer learn to represent different regions of the input space where input vectors occur. In addition, neighboring neurons learn to respond to similar inputs, thus the layer learns the topology of the presented input space.

Here 100 data points are created on the unit circle.

A competitive network will be used to classify these points into natural classes.

```
angles = 0:0.5*pi/99:0.5*pi;
X = [sin(angles); cos(angles)];
plot(X(1,:),X(2,:),'+r')
```



The map will be a 1-dimensional layer of 10 neurons.

```
net = selforgmap(10);
```

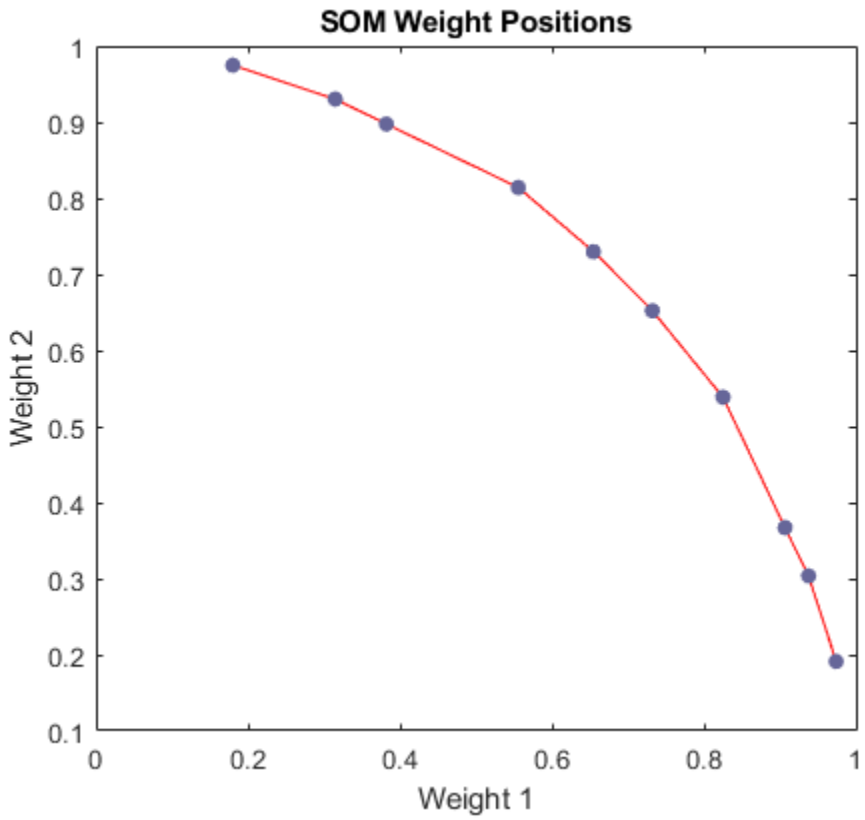
Specify that the network is to be trained for 10 epochs and use `train` to train the network on the input data.

```
net.trainParam.epochs = 10;
net = train(net,X);
```

Now plot the trained network's weight positions by using `plotsompos`.

The red dots are the neuron's weight vectors, and the blue lines connect each pair within a distance of 1.

```
plotsompos(net)
```



The map can now be used to classify inputs, such as [1; 0]. Either neuron 1 or 10 should have an output of 1, as the above input vector was at one end of the presented input space. The first pair of numbers indicate the neuron, and the single number indicates its output.

```
x = [1;0];
a = net(x)
```

```
a = 10×1

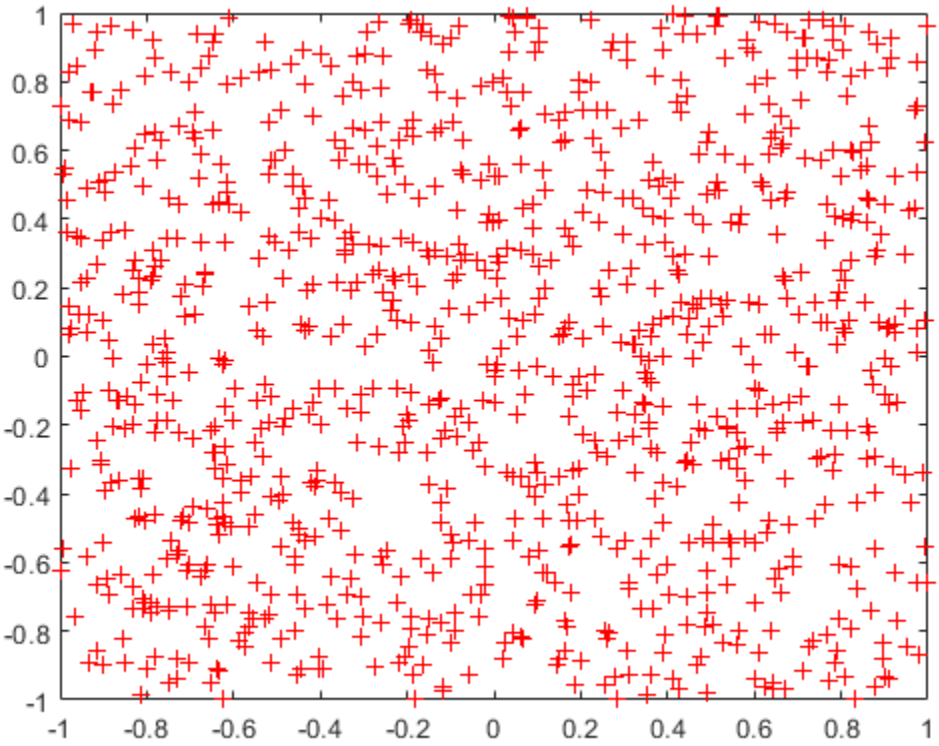
     0
     0
     0
     0
     0
     0
     0
     0
     0
     1
```

Two-Dimensional Self-organizing Map

As in one-dimensional problems, this self-organizing map will learn to represent different regions of the input space where input vectors occur. In this example, however, the neurons will arrange themselves in a two-dimensional grid, rather than a line.

We would like to classify 1000 two-element vectors in a rectangle.

```
X = rands(2,1000);
plot(X(1,:),X(2,:),'+r')
```



We will use a 5-by-6 layer of neurons to classify the vectors above. We would like each neuron to respond to a different region of the rectangle, and neighboring neurons to respond to adjacent regions.

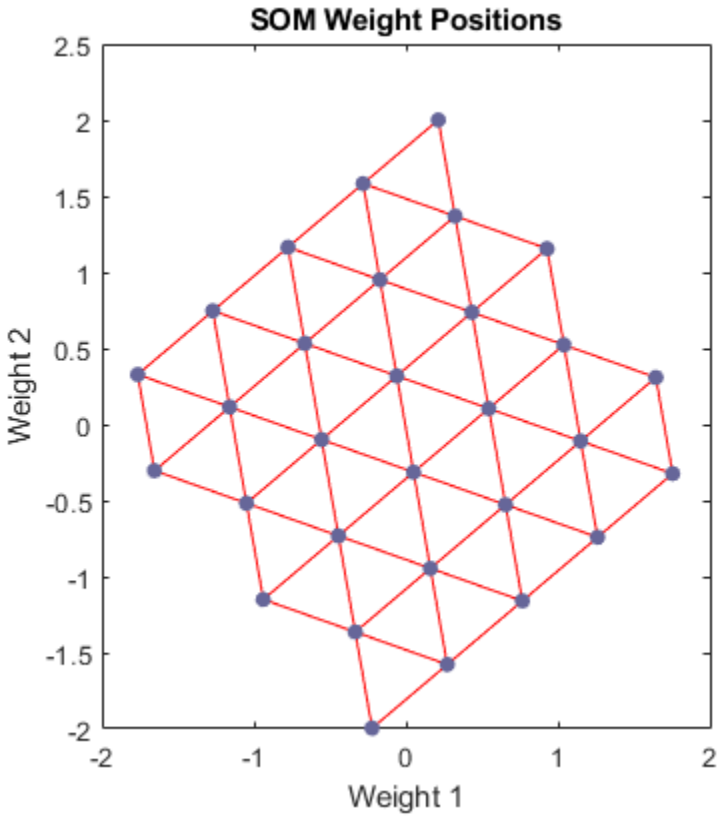
The network is configured to match the dimensions of the inputs. This step is required here because we will plot the initial weights. Normally configuration is performed automatically when training.

```
net = selforgmap([5 6]);
net = configure(net,X);
```

We can visualize the network we have just created by using `plotsompos`.

Each neuron is represented by a red dot at the location of its two weights. Initially, all the neurons have the same weights in the middle of the vectors, so only one dot appears.

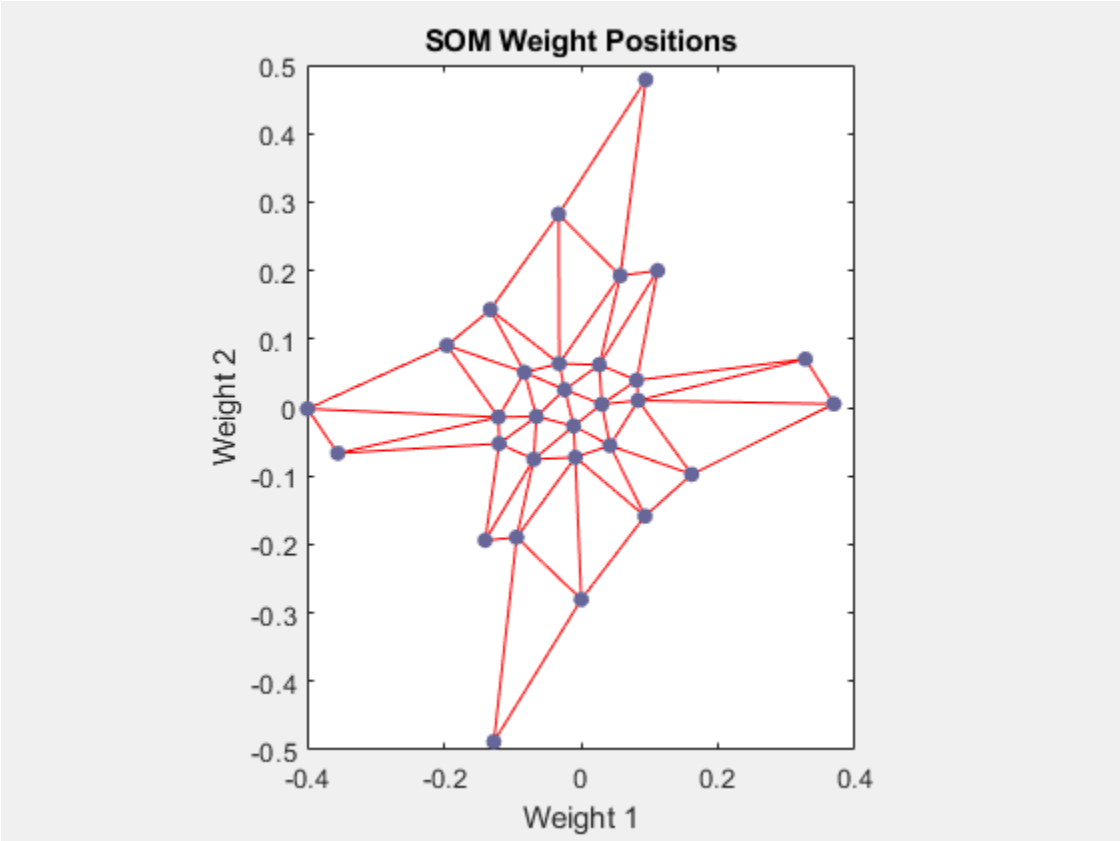
```
plotsompos(net)
```



Now we train the map on the 1000 vectors for 1 epoch and replot the network weights.

After training, note that the layer of neurons has begun to self-organize so that each neuron now classifies a different region of the input space, and adjacent (connected) neurons respond to adjacent regions.

```
net.trainParam.epochs = 1;
net = train(net,X);
plotsompos(net)
```



We can now classify vectors by giving them to the network and seeing which neuron responds.

The neuron indicated by a "1" responded, so x belongs to that class.

```
x = [0.5;0.3];
y = net(x)
```

```
y = 30×1

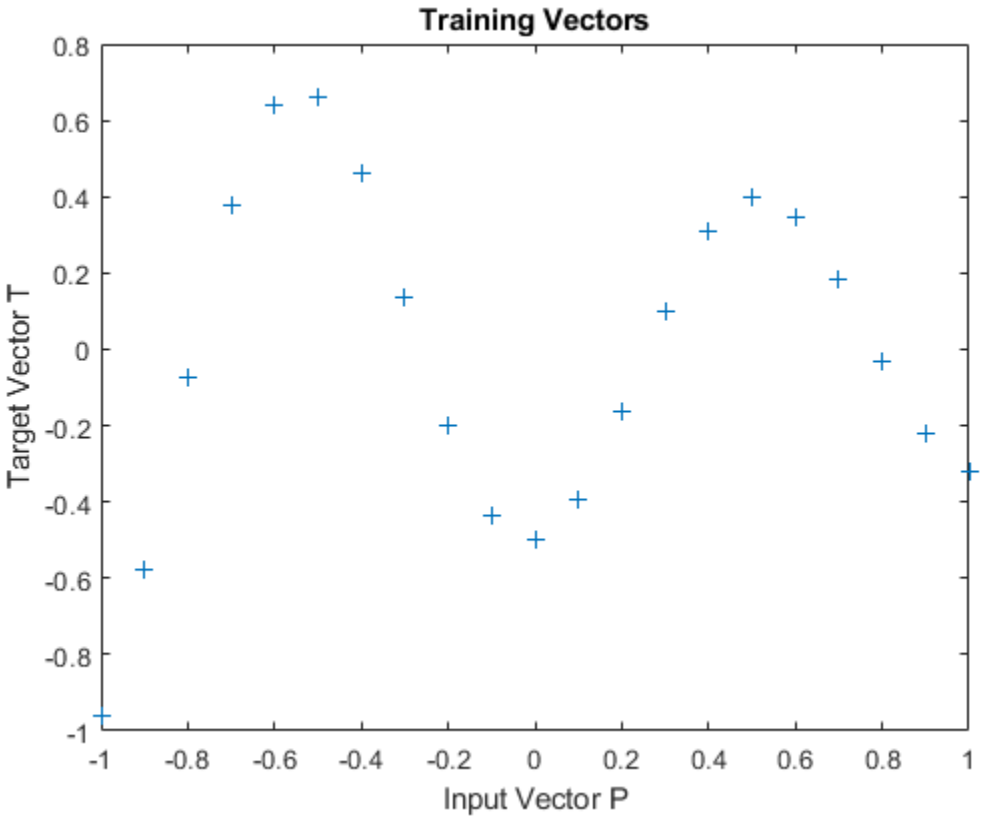
Radial Basis Approximation

This example uses the NEWRB function to create a radial basis network that approximates a function defined by a set of data points.

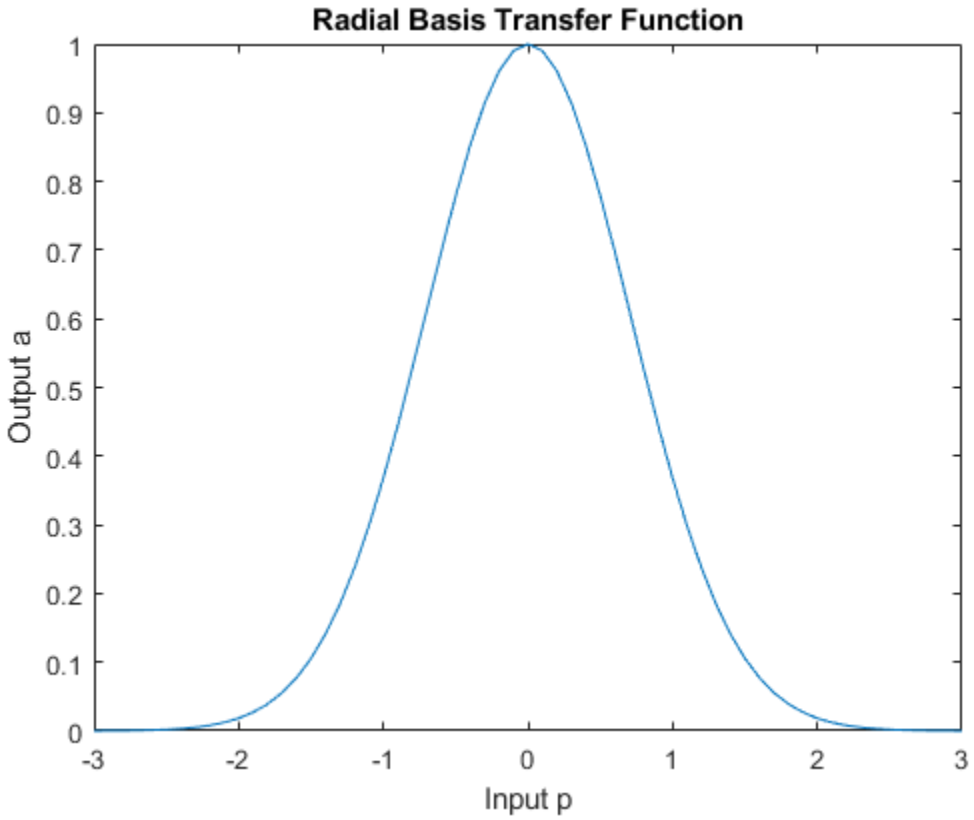
Define 21 inputs P and associated targets T.

```
X = -1:.1:1;
T = [-.9602 -.5770 -.0729  .3771  .6405  .6600  .4609 ...
      .1336 -.2013 -.4344 -.5000 -.3930 -.1647  .0988 ...
      .3072  .3960  .3449  .1816 -.0312 -.2189 -.3201];
plot(X,T,'+');
title('Training Vectors');
xlabel('Input Vector P');
ylabel('Target Vector T');
```



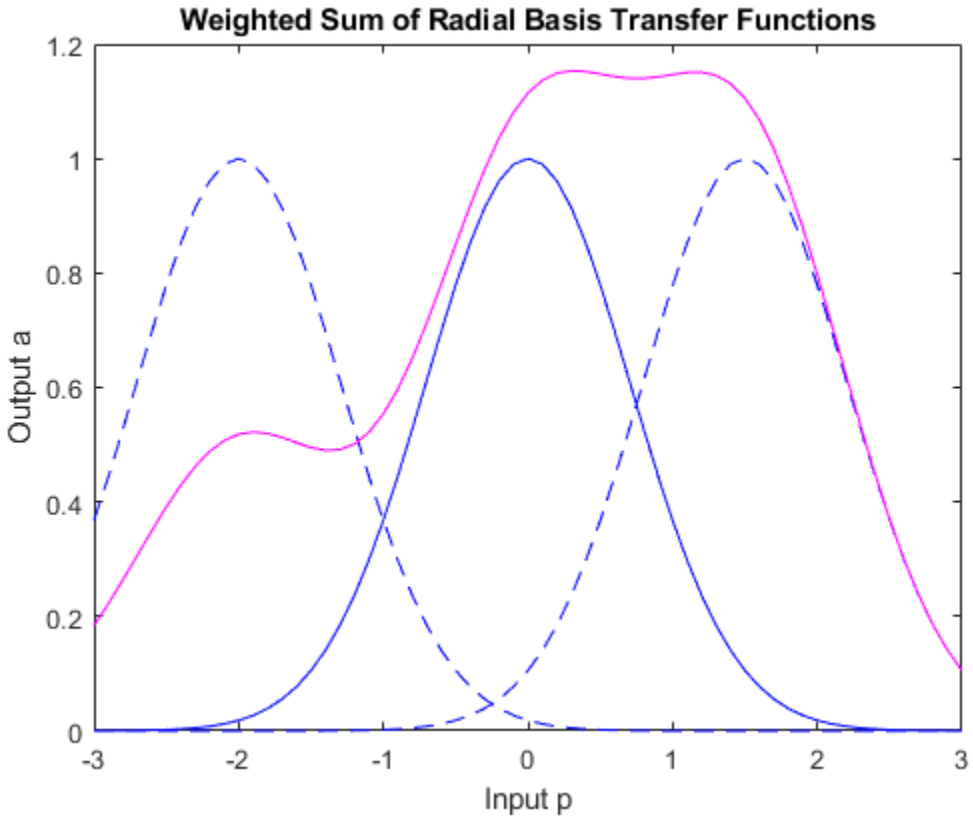
We would like to find a function which fits the 21 data points. One way to do this is with a radial basis network. A radial basis network is a network with two layers. A hidden layer of radial basis neurons and an output layer of linear neurons. Here is the radial basis transfer function used by the hidden layer.

```
x = -3:.1:3;
a = radbas(x);
plot(x,a)
title('Radial Basis Transfer Function');
xlabel('Input p');
ylabel('Output a');
```



The weights and biases of each neuron in the hidden layer define the position and width of a radial basis function. Each linear output neuron forms a weighted sum of these radial basis functions. With the correct weight and bias values for each layer, and enough hidden neurons, a radial basis network can fit any function with any desired accuracy. This is an example of three radial basis functions (in blue) are scaled and summed to produce a function (in magenta).

```
a2 = radbas(x-1.5);
a3 = radbas(x+2);
a4 = a + a2*1 + a3*0.5;
plot(x,a,'b-',x,a2,'b--',x,a3,'b--',x,a4,'m-')
title('Weighted Sum of Radial Basis Transfer Functions');
xlabel('Input p');
ylabel('Output a');
```



The function NEWRB quickly creates a radial basis network which approximates the function defined by P and T. In addition to the training set and targets, NEWRB takes two arguments, the sum-squared error goal and the spread constant.

```
eg = 0.02; % sum-squared error goal
sc = 1;    % spread constant
net = newrb(X,T,eg,sc);
```

```
NEWRB, neurons = 0, MSE = 0.176192
```

To see how the network performs, replot the training set. Then simulate the network response for inputs over the same range. Finally, plot the results on the same graph.

```
plot(X,T,'+');
xlabel('Input');

X = -1:.01:1;
Y = net(X);

hold on;
plot(X,Y);
hold off;
legend({'Target','Output'})

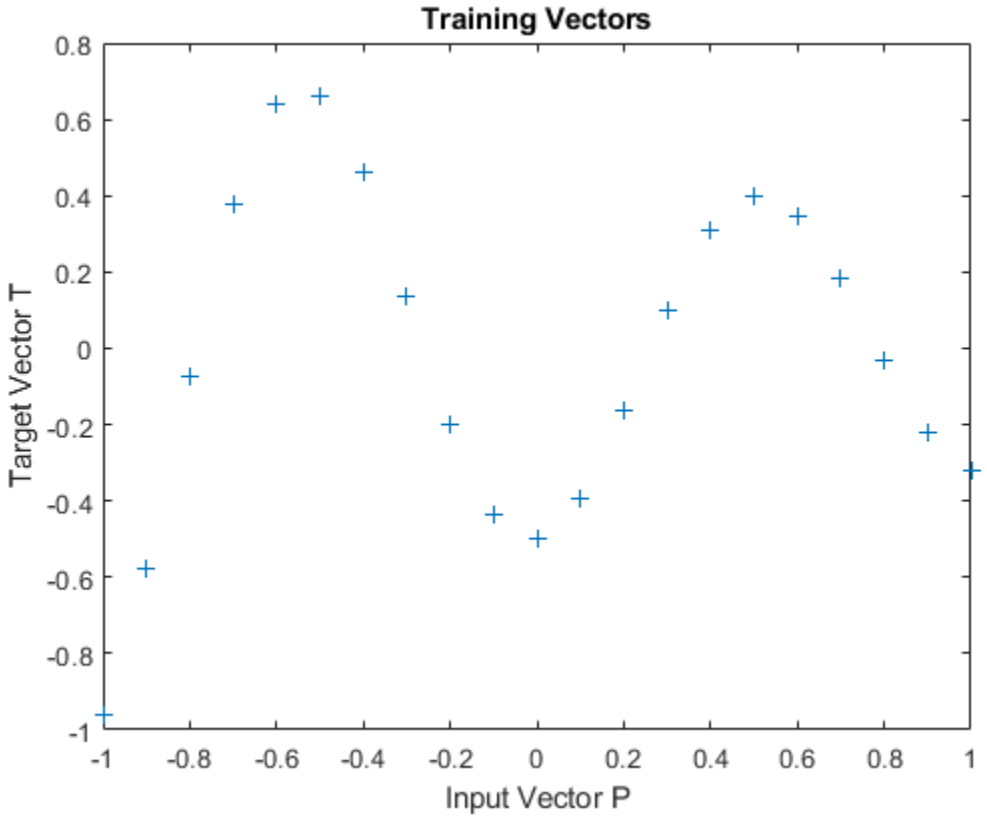
Radial Basis Underlapping Neurons

A radial basis network is trained to respond to specific inputs with target outputs. However, because the spread of the radial basis neurons is too low, the network requires many neurons.

Define 21 inputs P and associated targets T.

```
P = -1:.1:1;
T = [-.9602 -.5770 -.0729  .3771  .6405  .6600  .4609 ...
      .1336 -.2013 -.4344 -.5000 -.3930 -.1647  .0988 ...
      .3072  .3960  .3449  .1816 -.0312 -.2189 -.3201];
plot(P,T,'+');
title('Training Vectors');
xlabel('Input Vector P');
ylabel('Target Vector T');
```



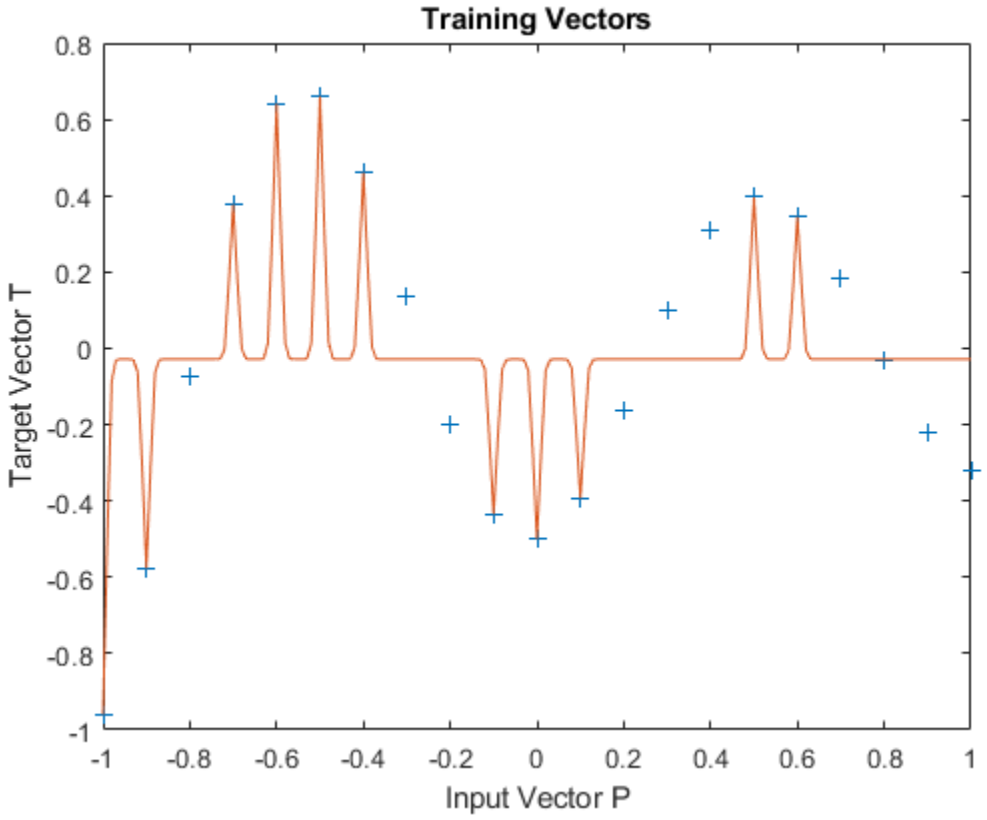
The function NEWRB quickly creates a radial basis network which approximates the function defined by P and T. In addition to the training set and targets, NEWRB takes two arguments, the sum-squared error goal and the spread constant. The spread of the radial basis neurons B is set to a very small number.

```
eg = 0.02; % sum-squared error goal
sc = .01;  % spread constant
net = newrb(P,T,eg,sc);
```

```
NEWRB, neurons = 0, MSE = 0.176192
```

To check that the network fits the function in a smooth way, define another set of test input vectors and simulate the network with these new inputs. Plot the results on the same graph as the training set. The test vectors reveal that the function has been overfit! The network could have done better with a higher spread constant.

```
X = -1:.01:1;
Y = net(X);
hold on;
plot(X,Y);
hold off;
```

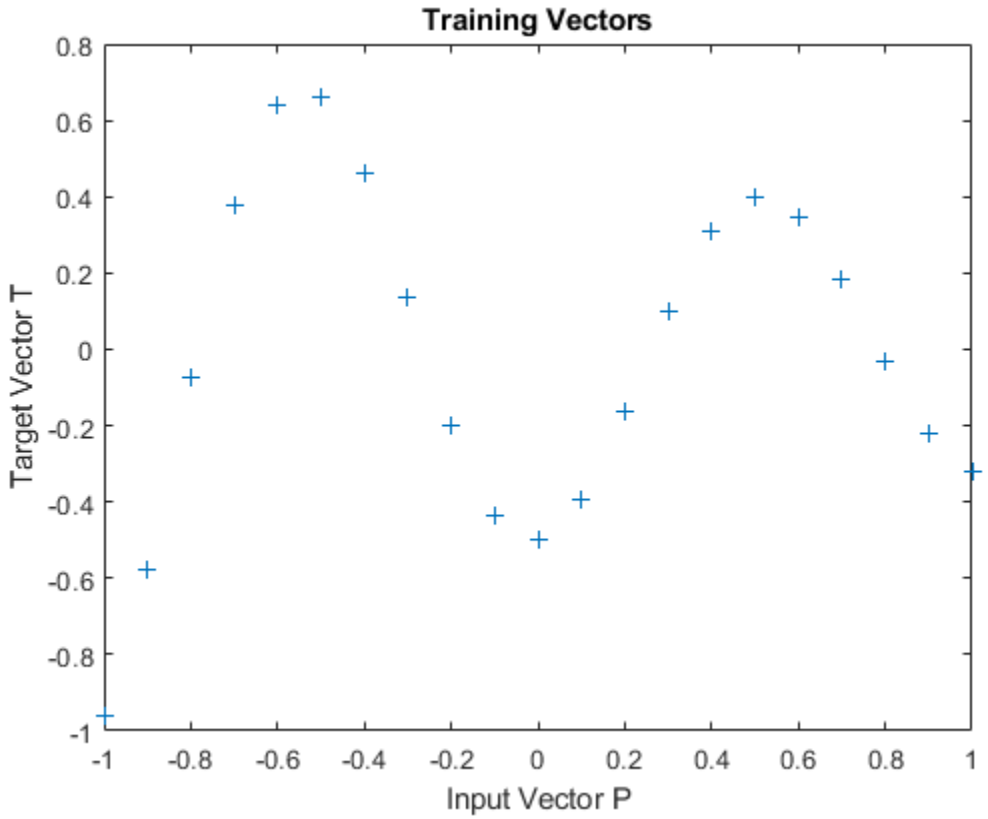


Radial Basis Overlapping Neurons

A radial basis network is trained to respond to specific inputs with target outputs. However, because the spread of the radial basis neurons is too high, each neuron responds essentially the same, and the network cannot be designed.

Define 21 inputs P and associated targets T.

```
P = -1:.1:1;
T = [-.9602 -.5770 -.0729  .3771  .6405  .6600  .4609 ...
      .1336 -.2013 -.4344 -.5000 -.3930 -.1647  .0988 ...
      .3072  .3960  .3449  .1816 -.0312 -.2189 -.3201];
plot(P,T,'+');
title('Training Vectors');
xlabel('Input Vector P');
ylabel('Target Vector T');
```



The function NEWRB quickly creates a radial basis network which approximates the function defined by P and T.

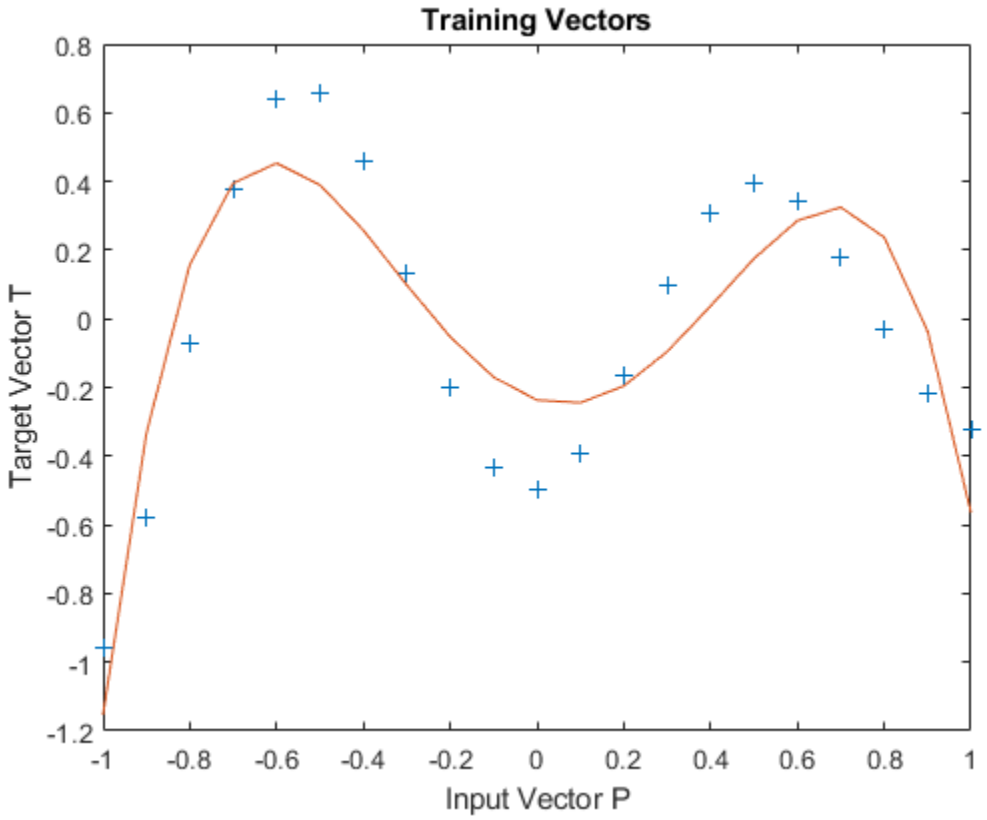
In addition to the training set and targets, NEWRB takes two arguments, the sum-squared error goal and the spread constant. The spread of the radial basis neurons B is set to a very large number.

```
eg = 0.02; % sum-squared error goal
sc = 100;  % spread constant
net = newrb(P,T,eg,sc);
```

```
NEWRB, neurons = 0, MSE = 0.176192
```

NEWRB cannot properly design a radial basis network due to the large overlap of the input regions of the radial basis neurons. All the neurons always output 1, and so cannot be used to generate different responses. To see how the network performs with the training set, simulate the network with the original inputs. Plot the results on the same graph as the training set.

```
Y = net(P);
hold on;
plot(P,Y);
hold off;
```



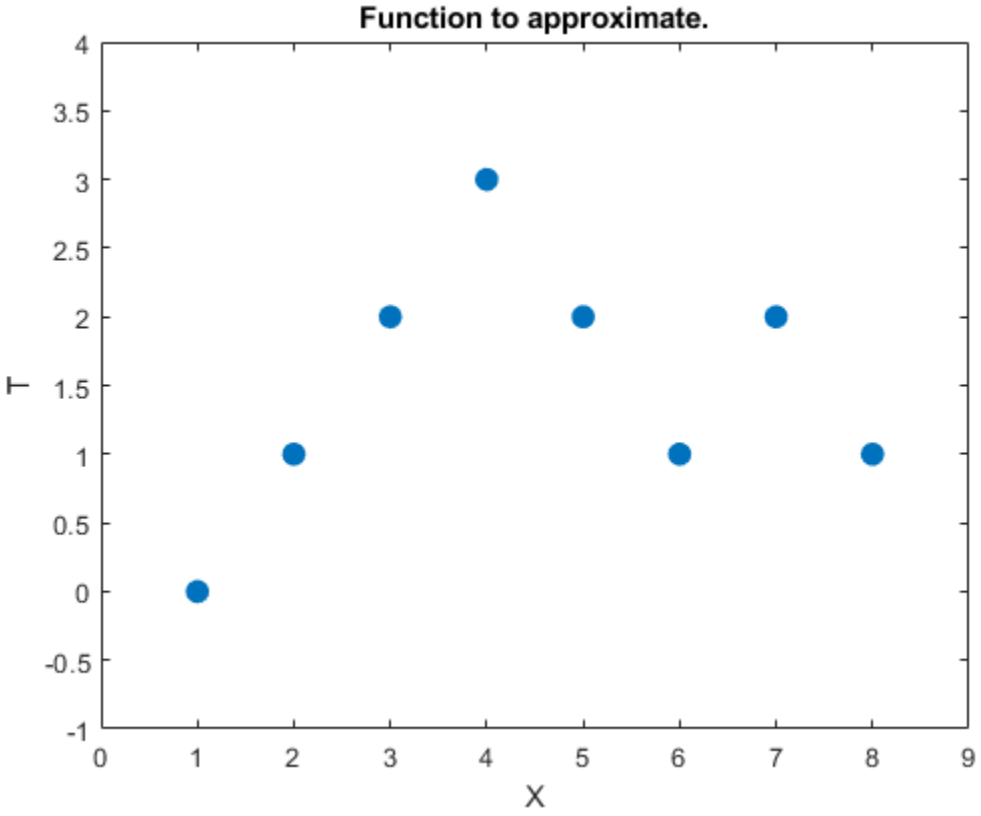
GRNN Function Approximation

This example uses functions NEWGRNN and SIM.

Here are eight data points of y function we would like to fit. The functions inputs X should result in target outputs T.

```
X = [1 2 3 4 5 6 7 8];
T = [0 1 2 3 2 1 2 1];

plot(X,T,'.','markersize',30)
axis([0 9 -1 4])
title('Function to approximate.')
xlabel('X')
ylabel('T')
```

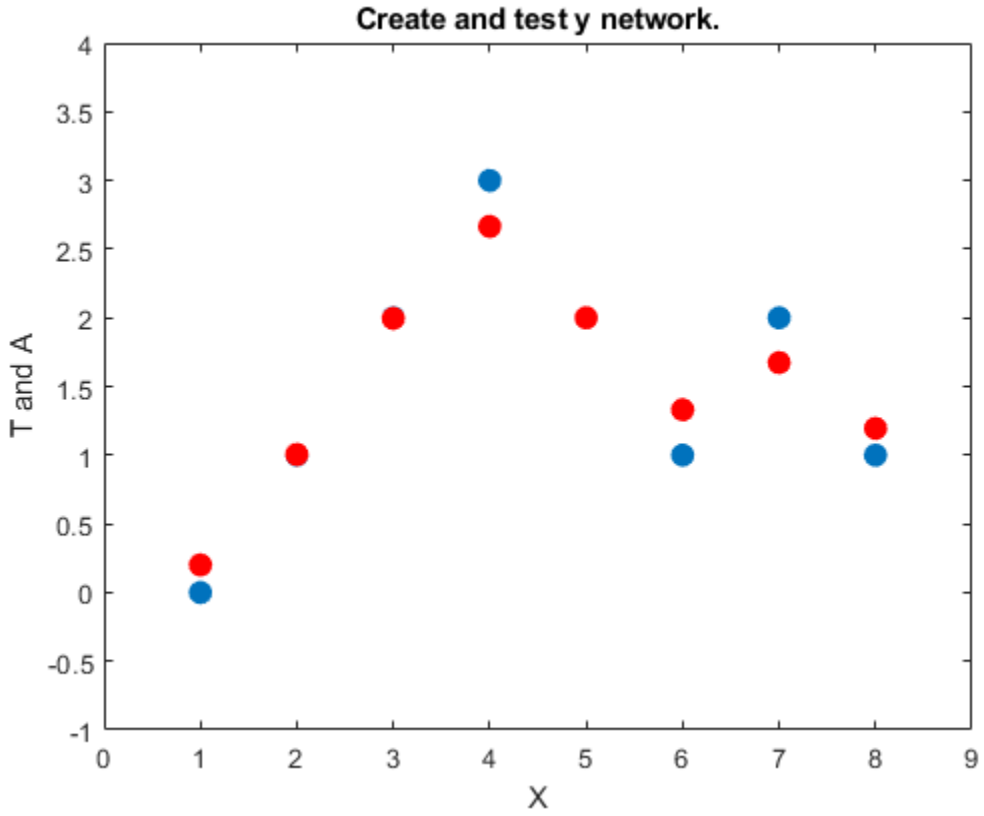


We use NEWGRNN to create y generalized regression network. We use y SPREAD slightly lower than 1, the distance between input values, in order, to get y function that fits individual data points fairly closely. A smaller spread would fit data better but be less smooth.

```
spread = 0.7;
net = newgrnn(X,T,spread);
A = net(X);

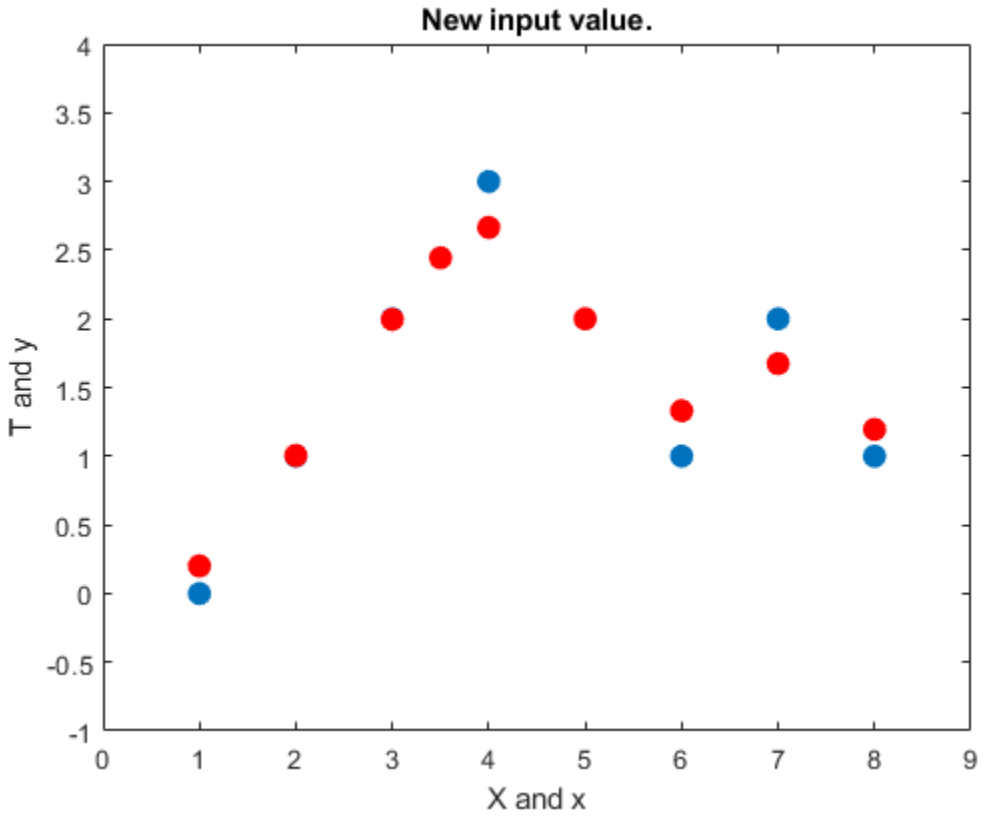
hold on
outputline = plot(X,A,'.','markersize',30,'color',[1 0 0]);
title('Create and test y network.')
```

```
xlabel('X')
ylabel('T and A')
```



We can use the network to approximate the function at y new input value.

```
x = 3.5;
y = net(x);
plot(x,y,'.','markersize',30,'color',[1 0 0]);
title('New input value.')
xlabel('X and x')
ylabel('T and y')
```



Here the network's response is simulated for many values, allowing us to see the function it represents.

```
X2 = 0:.1:9;
Y2 = net(X2);
plot(X2,Y2,'linewidth',4,'color',[1 0 0])
title('Function to approximate.')
xlabel('X and X2')
ylabel('T and Y2')
```

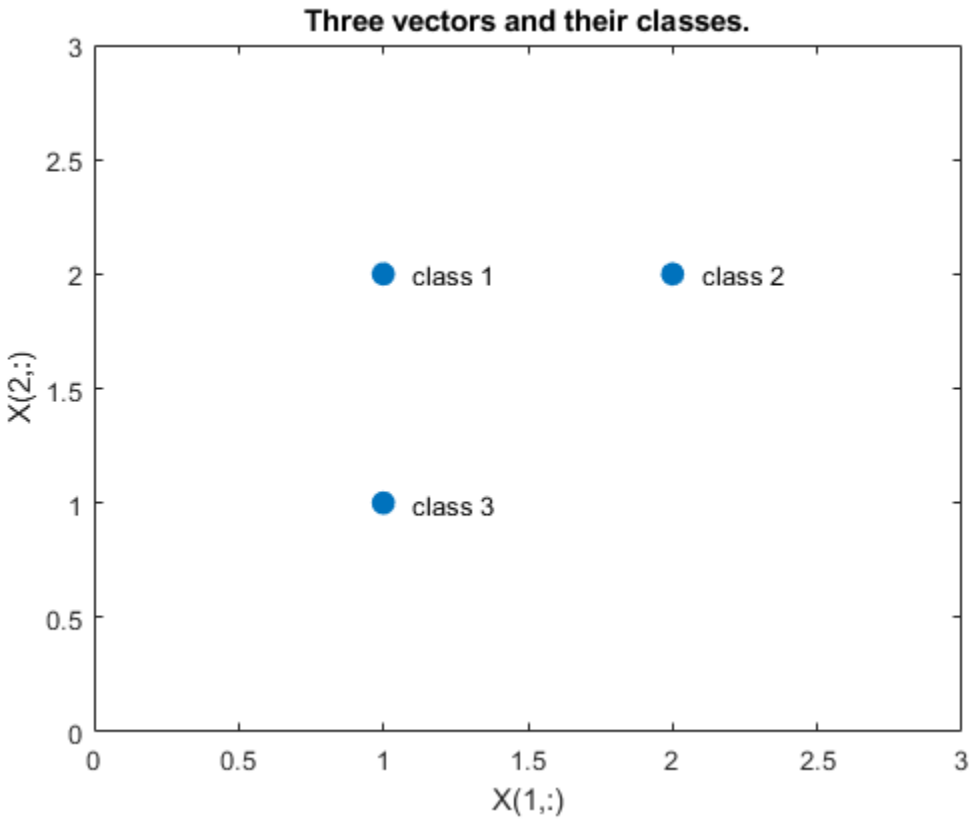
PNN Classification

This example uses functions NEWPNN and SIM.

Here are three two-element input vectors X and their associated classes Tc. We would like to create y probabilistic neural network that classifies these vectors properly.

```
X = [1 2; 2 2; 1 1]';
Tc = [1 2 3];
plot(X(1,:),X(2,:),'.','markersize',30)
for i = 1:3, text(X(1,i)+0.1,X(2,i),sprintf('class %g',Tc(i))), end
axis([0 3 0 3])
title('Three vectors and their classes.')
xlabel('X(1,:)')
ylabel('X(2,:)')
```

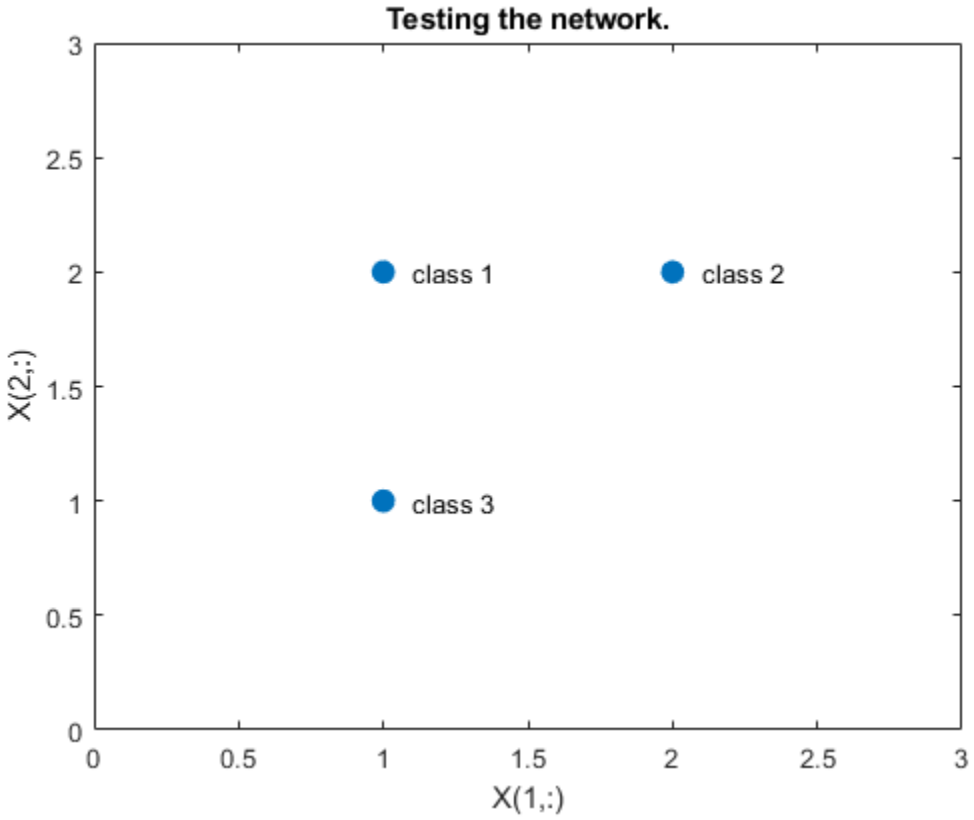


First we convert the target class indices Tc to vectors T. Then we design y probabilistic neural network with NEWPNN. We use y SPREAD value of 1 because that is y typical distance between the input vectors.

```
T = ind2vec(Tc);
spread = 1;
net = newpnn(X,T,spread);
```

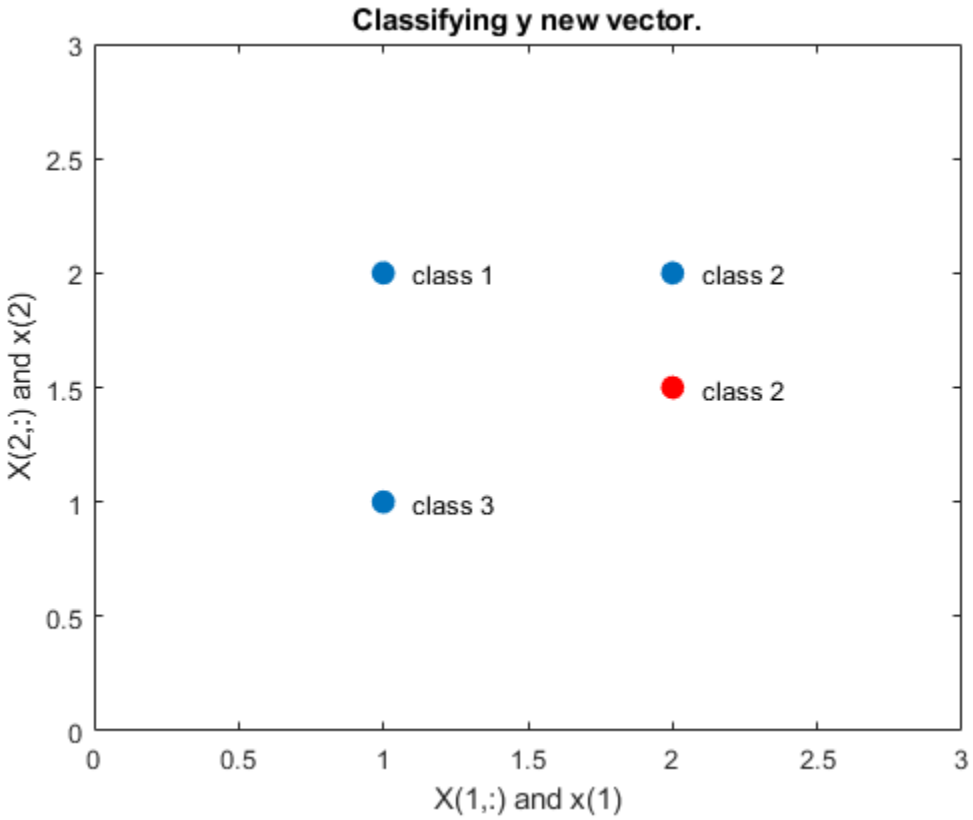
Now we test the network on the design input vectors. We do this by simulating the network and converting its vector outputs to indices.

```
Y = net(X);
Yc = vec2ind(Y);
plot(X(1,:),X(2,:),'.','markersize',30)
axis([0 3 0 3])
for i = 1:3,text(X(1,i)+0.1,X(2,i),sprintf('class %g',Yc(i))),end
title('Testing the network.')
xlabel('X(1,:)')
ylabel('X(2,:)')
```



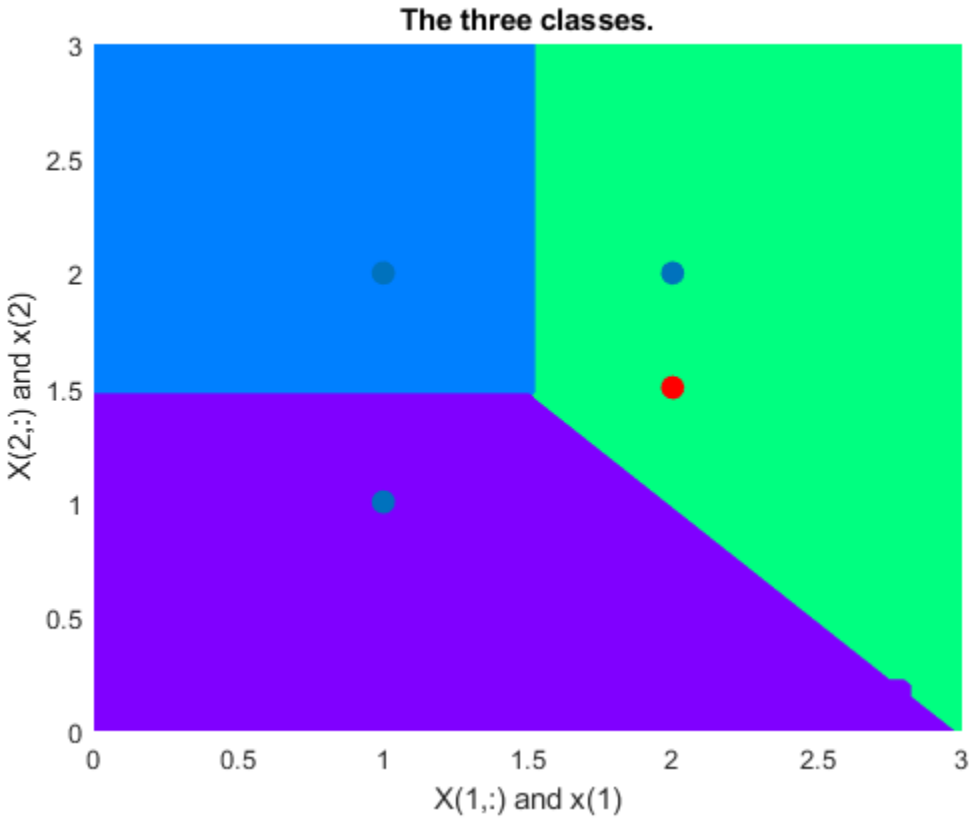
Let's classify y new vector with our network.

```
x = [2; 1.5];
y = net(x);
ac = vec2ind(y);
hold on
plot(x(1),x(2),'.','markersize',30,'color',[1 0 0])
text(x(1)+0.1,x(2),sprintf('class %g',ac))
hold off
title('Classifying y new vector.')
xlabel('X(1,:) and x(1)')
ylabel('X(2,:) and x(2)')
```



This diagram shows how the probabilistic neural network divides the input space into the three classes.

```
x1 = 0:.05:3;
x2 = x1;
[X1,X2] = meshgrid(x1,x2);
xx = [X1(:) X2(:)]';
yy = net(xx);
yy = full(yy);
m = mesh(X1,X2,reshape(yy(1,:),length(x1),length(x2)));
m.FaceColor = [0 0.5 1];
m.LineStyle = 'none';
hold on
m = mesh(X1,X2,reshape(yy(2,:),length(x1),length(x2)));
m.FaceColor = [0 1.0 0.5];
m.LineStyle = 'none';
m = mesh(X1,X2,reshape(yy(3,:),length(x1),length(x2)));
m.FaceColor = [0.5 0 1];
m.LineStyle = 'none';
plot3(X(1,:),X(2,:),[1 1 1]+0.1,'.','markersize',30)
plot3(x(1),x(2),1.1,'.','markersize',30,'color',[1 0 0])
hold off
view(2)
title('The three classes.')
xlabel('X(1,:) and x(1)')
ylabel('X(2,:) and x(2)')
```



The three classes.

Learning Vector Quantization

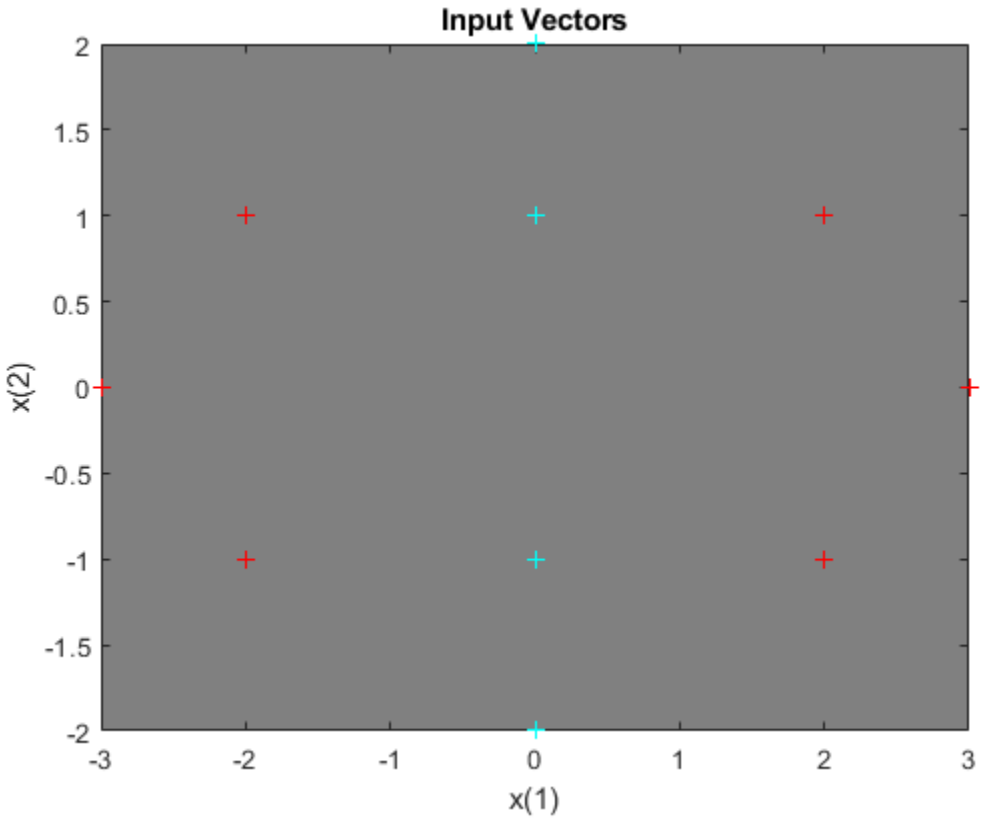
An LVQ network is trained to classify input vectors according to given targets.

Let X be 10 2-element example input vectors and C be the classes these vectors fall into. These classes can be transformed into vectors to be used as targets, T, with IND2VEC.

```
x = [-3 -2 -2  0  0  0  0 +2 +2 +3;
      0 +1 -1 +2 +1 -1 -2 +1 -1  0];
c = [1 1 1 2 2 2 2 1 1 1];
t = ind2vec(c);
```

Here the data points are plotted. Red = class 1, Cyan = class 2. The LVQ network represents clusters of vectors with hidden neurons, and groups the clusters with output neurons to form the desired classes.

```
colormap(hsv);
plotvec(x,c)
title('Input Vectors');
xlabel('x(1)');
ylabel('x(2)');
```

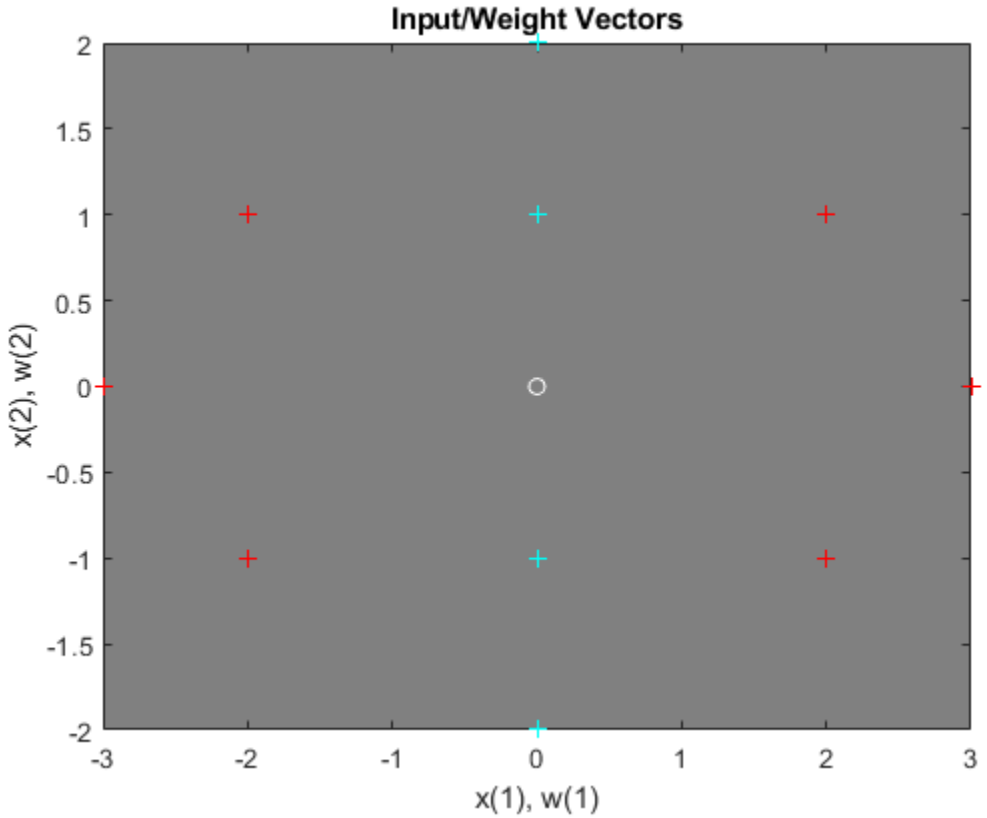


Here LVQNET creates an LVQ layer with four hidden neurons and a learning rate of 0.1. The network is then configured for inputs X and targets T. (Configuration normally an unnecessary step as it is done automatically by TRAIN.)

```
net = lvqnet(4,0.1);
net = configure(net,x,t);
```

The competitive neuron weight vectors are plotted as follows.

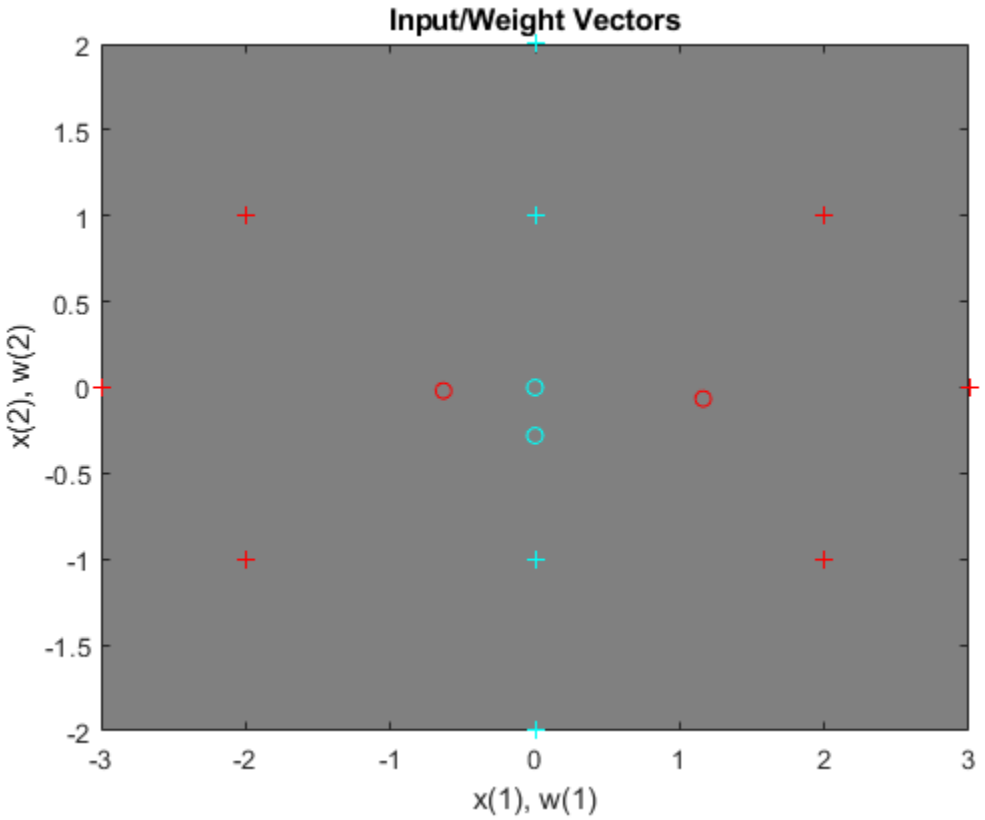
```
hold on
w1 = net.IW{1};
plot(w1(1,1),w1(1,2),'ow')
title('Input/Weight Vectors');
xlabel('x(1), w(1)');
ylabel('x(2), w(2)');
```



To train the network, first override the default number of epochs, and then train the network. When it is finished, replot the input vectors '+' and the competitive neurons' weight vectors 'o'. Red = class 1, Cyan = class 2.

```
net.trainParam.epochs=150;
net=train(net,x,t);

cla;
plotvec(x,c);
hold on;
plotvec(net.IW{1}',vec2ind(net.LW{2}),'o');
```



Now use the LVQ network as a classifier, where each neuron corresponds to a different category. Present the input vector [0.2; 1]. Red = class 1, Cyan = class 2.

```
x1 = [0.2; 1];
y1 = vec2ind(net(x1))
```

```
y1 = 2
```

Linear Prediction Design

This example illustrates how to design a linear neuron to predict the next value in a time series given the last five values.

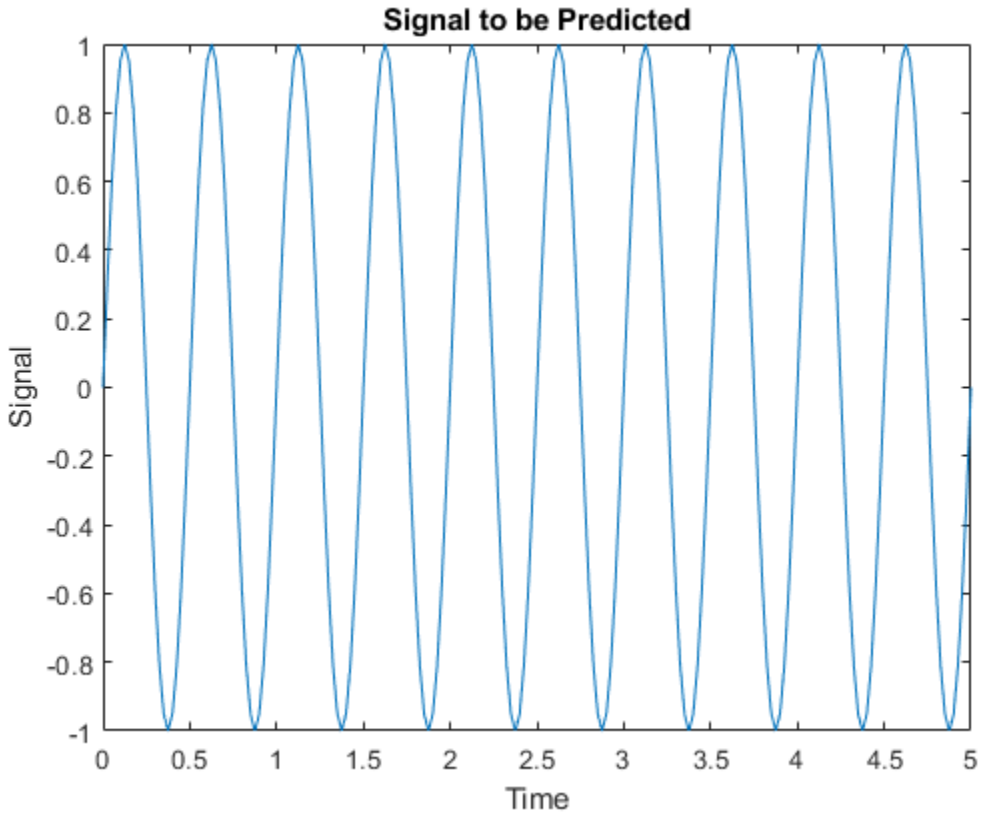
Defining a Wave Form

Here time is defined from 0 to 5 seconds in steps of 1/40 of a second.

```
time = 0:0.025:5;
```

We can define a signal with respect to time.

```
signal = sin(time*4*pi);
plot(time,signal)
xlabel('Time');
ylabel('Signal');
title('Signal to be Predicted');
```



Setting up the Problem for a Neural Network

The signal convert is then converted to a cell array. Neural Networks represent timesteps as columns of a cell array, do distinguish them from different samples at a given time, which are represented with columns of matrices.

```
signal = con2seq(signal);
```

To set up the problem we will use the first four values of the signal as initial input delay states, and the rest except for the last step as inputs.

```
Xi = signal(1:4);
X = signal(5:(end-1));
timex = time(5:(end-1));
```

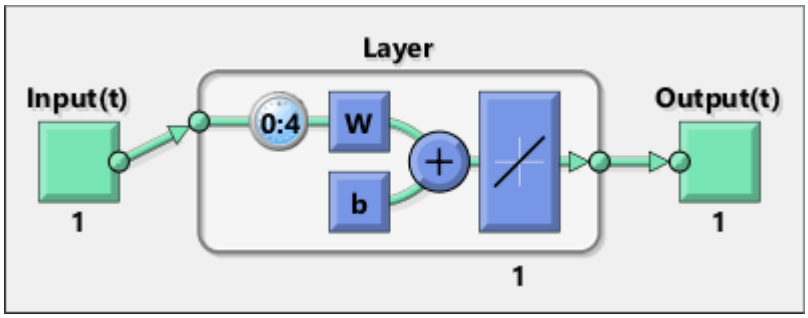
The targets are now defined to match the inputs, but shifted earlier by one timestep.

```
T = signal(6:end);
```

Designing the Linear Layer

The function **newlind** will now design a linear layer with a single neuron which predicts the next timestep of the signal given the current and four past values.

```
net = newlind(X,T,Xi);
view(net)
```



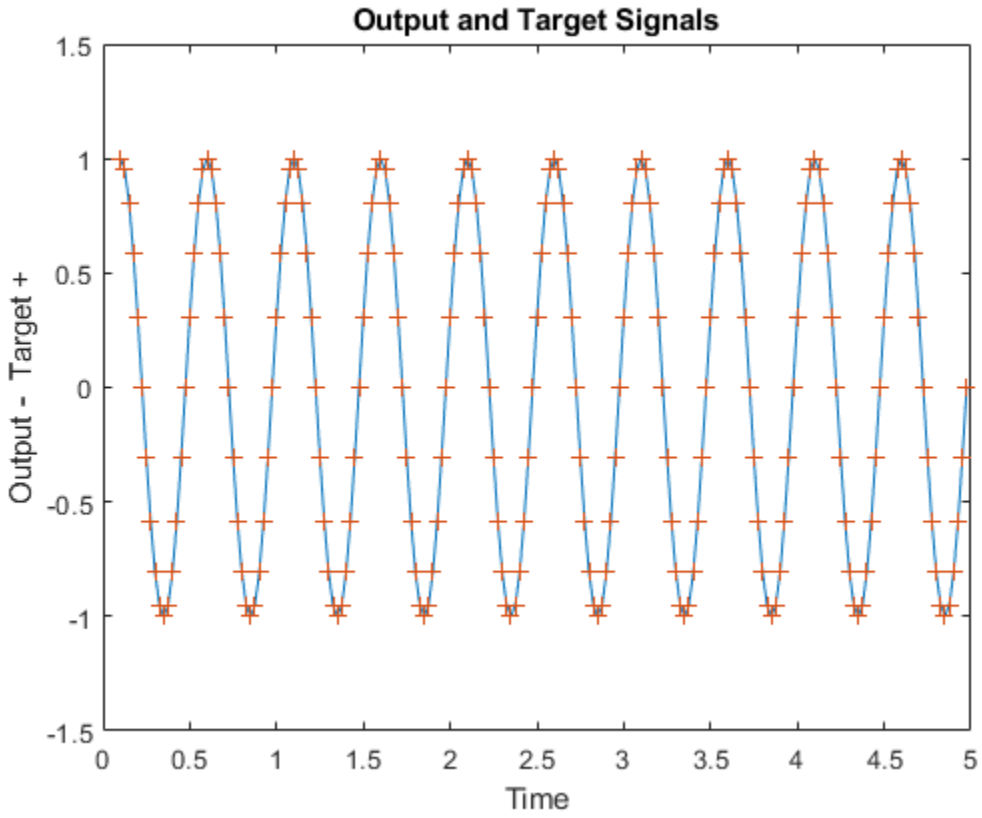
Testing the Linear Layer

The network can now be called like a function on the inputs and delayed states to get its time response.

```
Y = net(X,Xi);
```

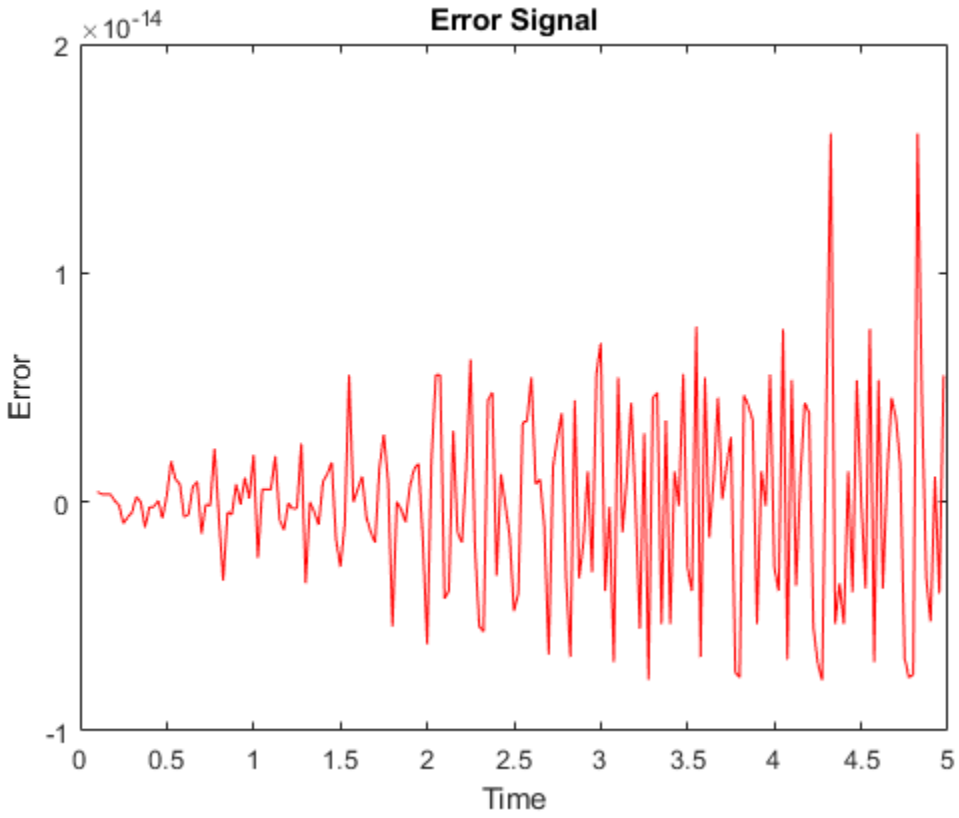
The output signal is plotted with the targets.

```
figure
plot(timex,cell2mat(Y),timex,cell2mat(T),'+')
xlabel('Time');
ylabel('Output -  Target +');
title('Output and Target Signals');
```



The error can also be plotted.

```
figure
E = cell2mat(T)-cell2mat(Y);
plot(timex,E,'r')
hold off
xlabel('Time');
ylabel('Error');
title('Error Signal');
```



Notice how small the error is!

This example illustrated how to design a dynamic linear network which can predict a signal's next value from current and past values.

Adaptive Linear Prediction

This example shows how an adaptive linear layer can learn to predict the next value in a signal, given the current and last four values.

To learn how to forecast time series data using a deep learning network, see “Time Series Forecasting Using Deep Learning” on page 4-15.

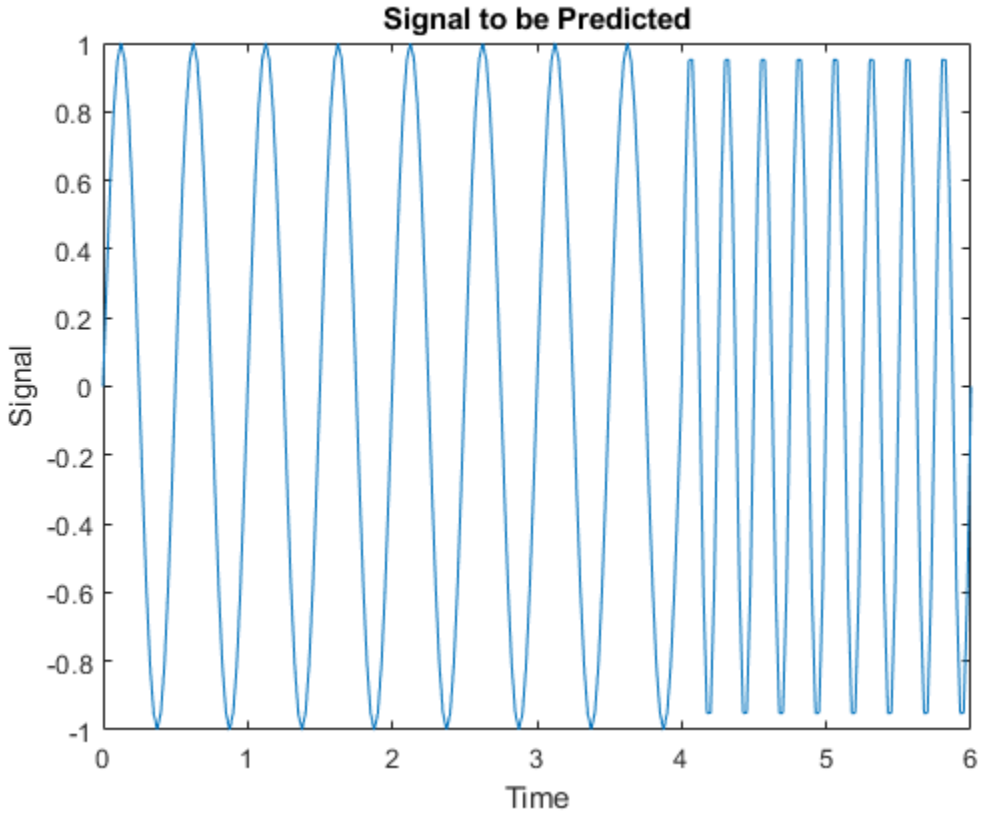
Defining a Wave Form

Here two time segments are defined from 0 to 6 seconds in steps of 1/40 of a second.

```
time1 = 0:0.025:4;      % from 0 to 4 seconds
time2 = 4.025:0.025:6;  % from 4 to 6 seconds
time = [time1 time2];  % from 0 to 6 seconds
```

Here is a signal which starts at one frequency but then transitions to another frequency.

```
signal = [sin(time1*4*pi) sin(time2*8*pi)];
plot(time,signal)
xlabel('Time');
ylabel('Signal');
title('Signal to be Predicted');
```



Setting up the Problem for a Neural Network

The signal convert is then converted to a cell array. Neural Networks represent timesteps as columns of a cell array, do distinguish them from different samples at a given time, which are represented with columns of matrices.

```
signal = con2seq(signal);
```

To set up the problem we will use the first five values of the signal as initial input delay states, and the rest for inputs.

```
Xi = signal(1:5);
X = signal(6:end);
timex = time(6:end);
```

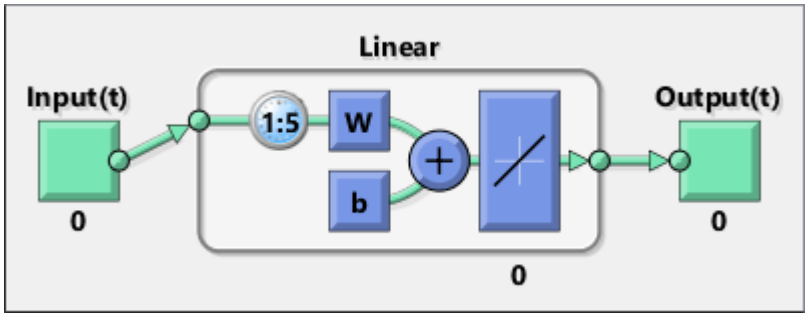
The targets are now defined to match the inputs. The network is to predict the current input, only using the last five values.

```
T = signal(6:end);
```

Creating the Linear Layer

The function **linearlayer** creates a linear layer with a single neuron with a tap delay of the last five inputs.

```
net = linearlayer(1:5,0.1);
view(net)
```



Adapting the Linear Layer

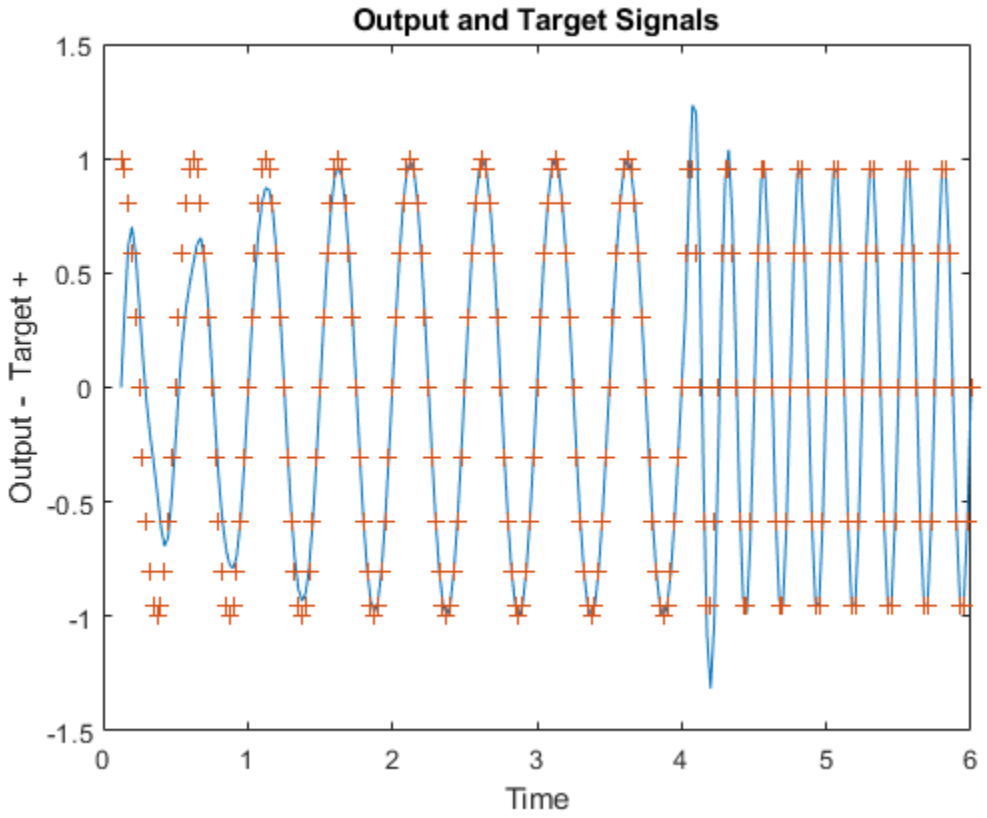
```
The function *adapt* simulates the network on the input, while
adjusting its weights and biases after each timestep in response
to how closely its output matches the target.

It returns the update networks, it outputs, and its errors.

[net,Y] = adapt(net,X,T,Xi);
```

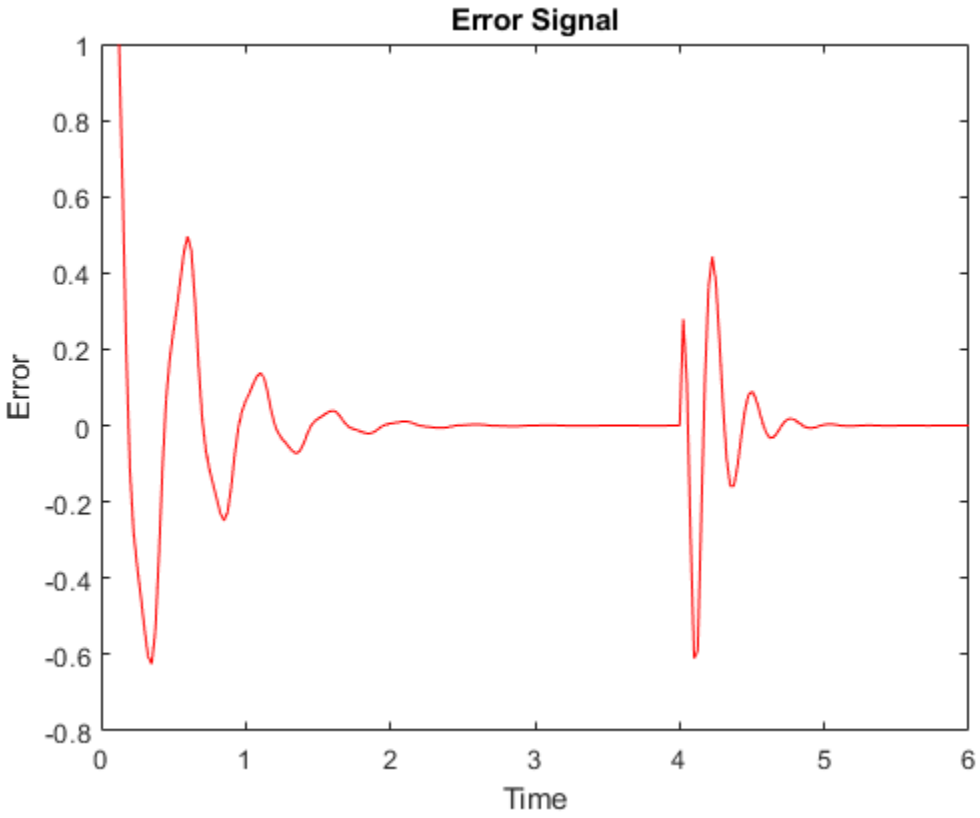
The output signal is plotted with the targets.

```
figure
plot(timex,cell2mat(Y),timex,cell2mat(T),'+')
xlabel('Time');
ylabel('Output -  Target +');
title('Output and Target Signals');
```



The error can also be plotted.

```
figure
E = cell2mat(T)-cell2mat(Y);
plot(timex,E,'r')
hold off
xlabel('Time');
ylabel('Error');
title('Error Signal');
```



Notice how small the error is except for initial errors and the network learns the systems behavior at the beginning and after the system transition.

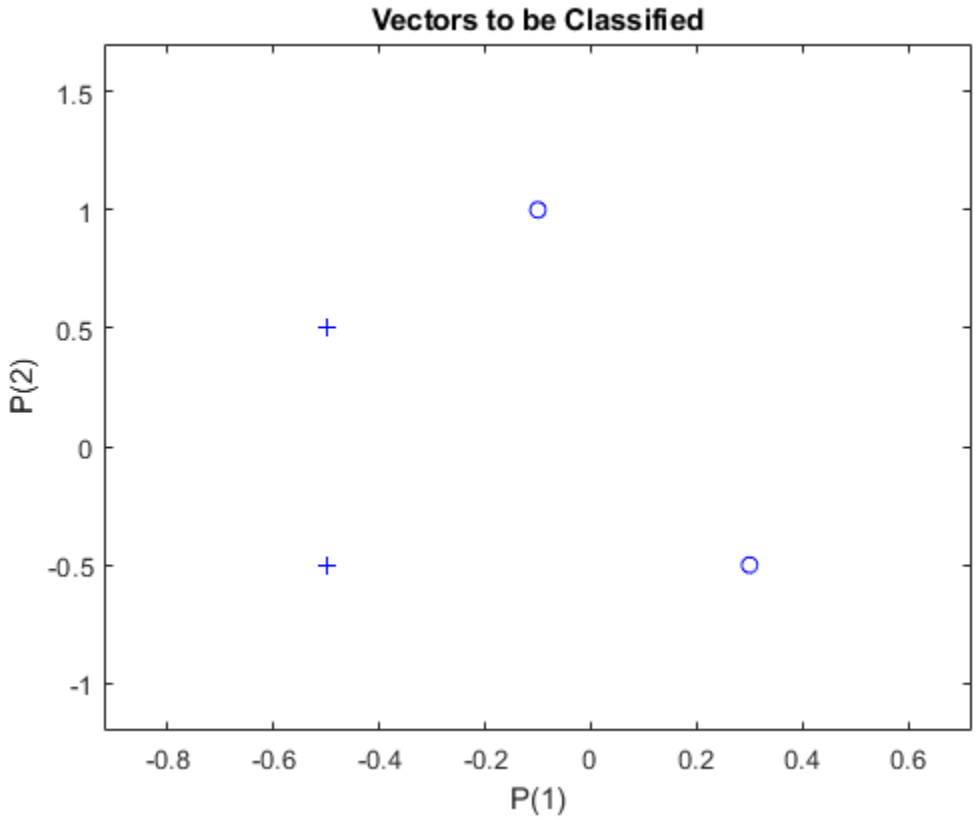
This example illustrated how to simulate an adaptive linear network which can predict a signal's next value from current and past values despite changes in the signals behavior.

Classification with a Two-Input Perceptron

A two-input hard limit neuron is trained to classify four input vectors into two categories.

Each of the four column vectors in X defines a two-element input vectors and a row vector T defines the vector's target categories. We can plot these vectors with PLOTPV.

```
X = [ -0.5 -0.5 +0.3 -0.1;  ...
      -0.5 +0.5 -0.5 +1.0];
T = [1 1 0 0];
plotpv(X,T);
```



The perceptron must properly classify the four input vectors in X into the two categories defined by T. Perceptrons have HARDLIM neurons. These neurons are capable of separating an input space with a straight line into two categories (0 and 1).

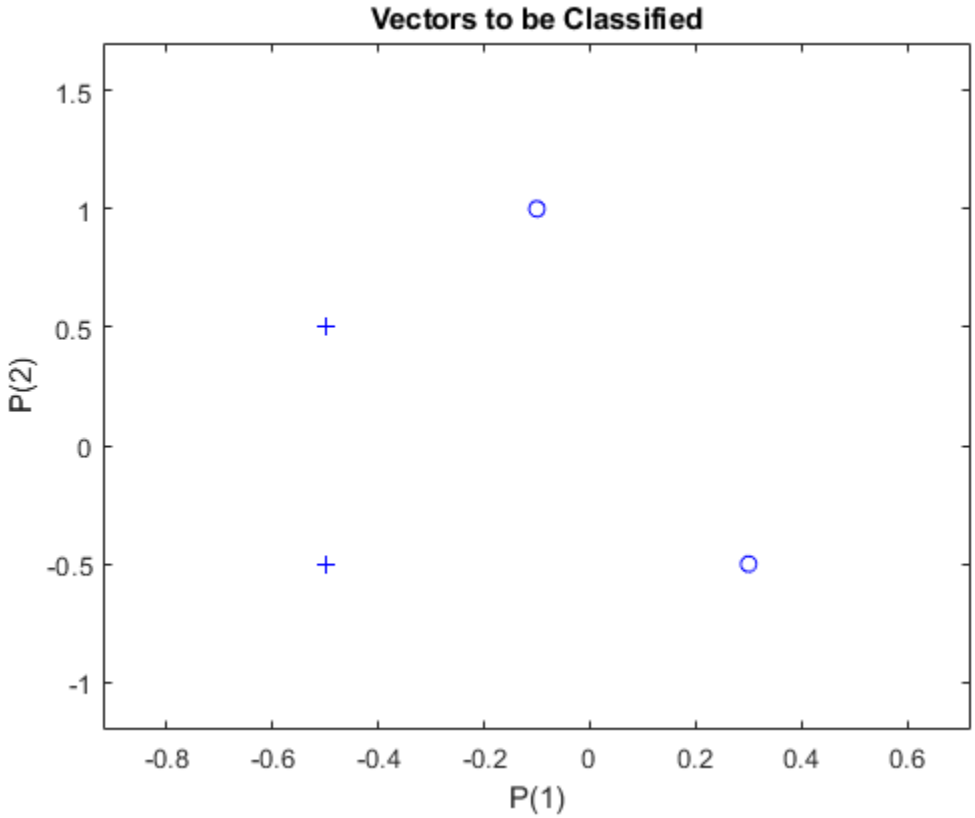
Here PERCEPTRON creates a new neural network with a single neuron. The network is then configured to the data, so we can examine its initial weight and bias values. (Normally the configuration step can be skipped as it is automatically done by ADAPT or TRAIN.)

```
net = perceptron;
net = configure(net,X,T);
```

The input vectors are replotted with the neuron's initial attempt at classification.

The initial weights are set to zero, so any input gives the same output and the classification line does not even appear on the plot. Fear not ... we are going to train it!

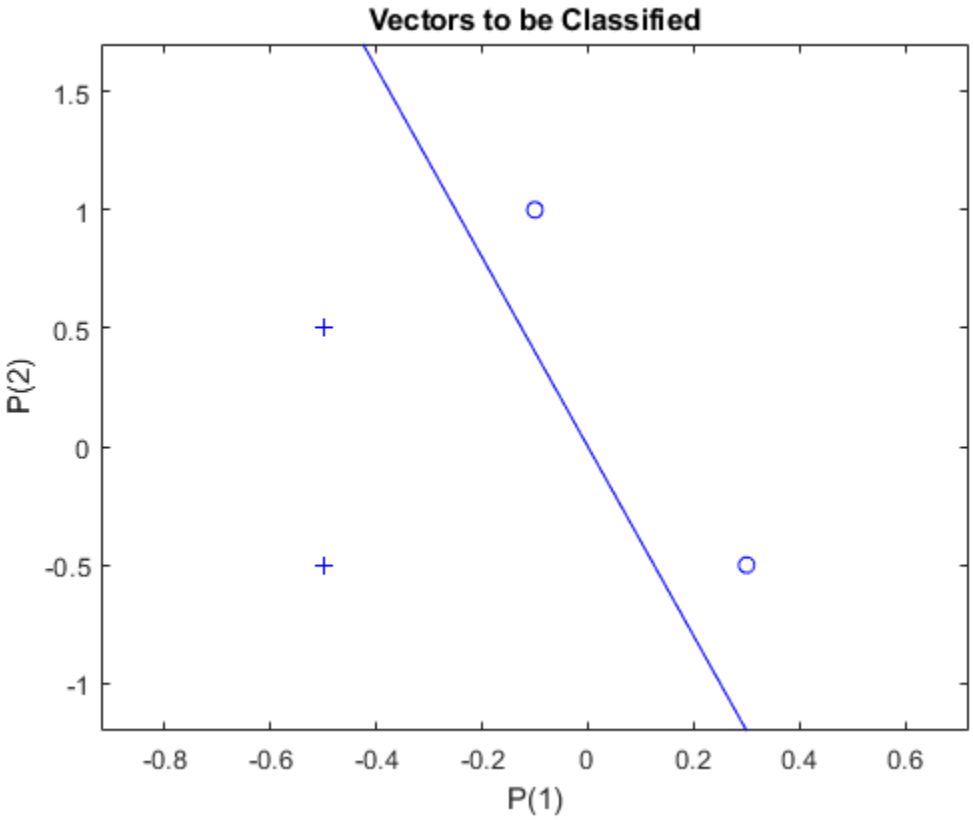
```
plotpv(X,T);
plotpc(net.IW{1},net.b{1});
```



Here the input and target data are converted to sequential data (cell array where each column indicates a timestep) and copied three times to form the series XX and TT.

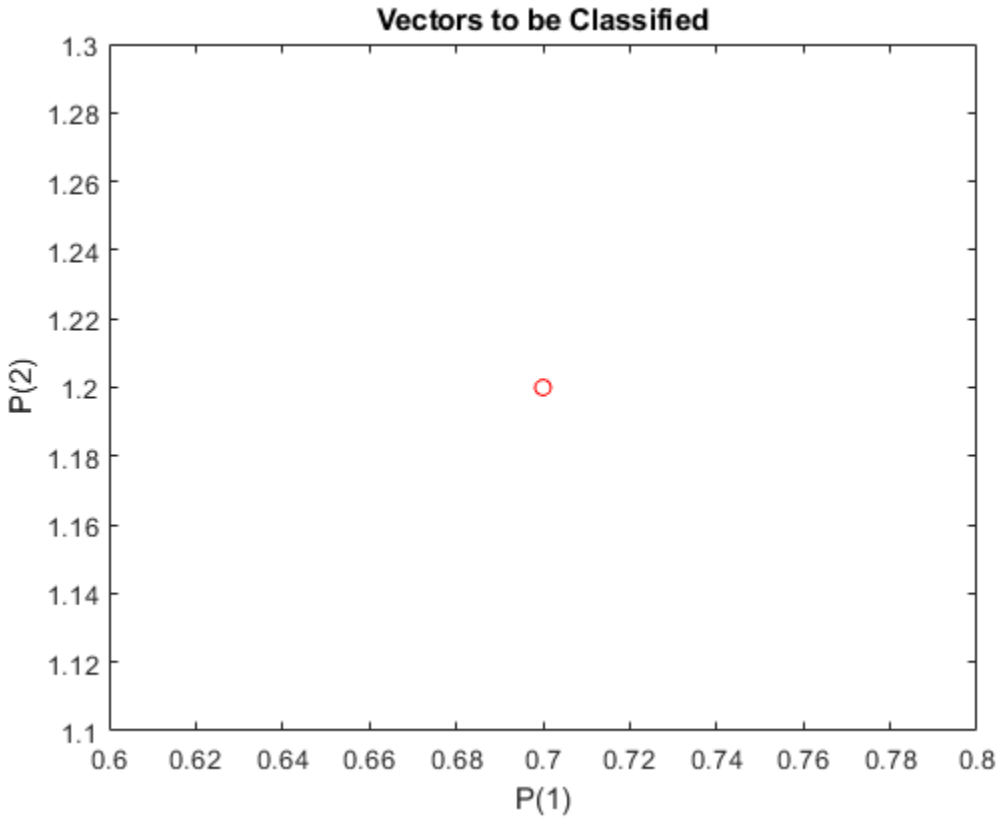
ADAPT updates the network for each timestep in the series and returns a new network object that performs as a better classifier.

```
XX = repmat(con2seq(X),1,3);
TT = repmat(con2seq(T),1,3);
net = adapt(net,XX,TT);
plotpc(net.IW{1},net.b{1});
```



Now SIM is used to classify any other input vector, like [0.7; 1.2]. A plot of this new point with the original training set shows how the network performs. To distinguish it from the training set, color it red.

```
x = [0.7; 1.2];
y = net(x);
plotpv(x,y);
point = findobj(gca,'type','line');
point.Color = 'red';
```



Turn on "hold" so the previous plot is not erased and plot the training set and the classification line.

The perceptron correctly classified our new point (in red) as category "zero" (represented by a circle) and not a "one" (represented by a plus).

```
hold on;
plotpv(X,T);
plotpc(net.IW{1},net.b{1});
hold off;
```

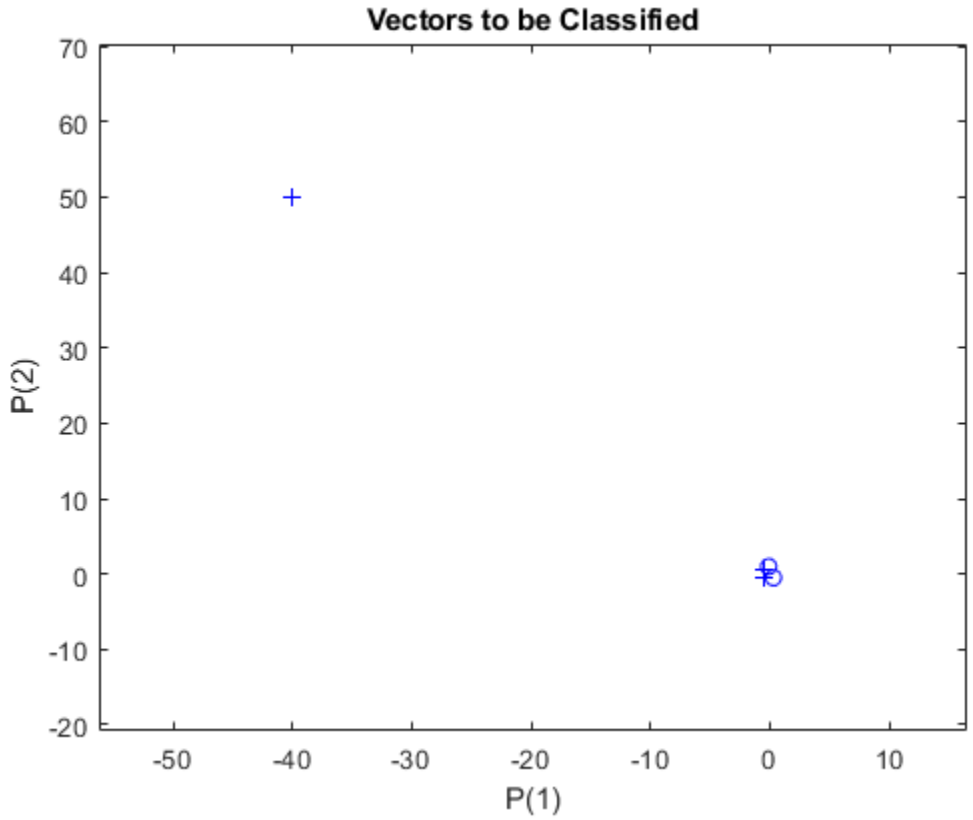
P(1)

Outlier Input Vectors

A 2-input hard limit neuron is trained to classify 5 input vectors into two categories. However, because 1 input vector is much larger than all of the others, training takes a long time.

Each of the five column vectors in X defines a 2-element input vectors, and a row vector T defines the vector's target categories. Plot these vectors with PLOTPV.

```
X = [-0.5 -0.5 +0.3 -0.1 -40; -0.5 +0.5 -0.5 +1.0 50];
T = [1 1 0 0 1];
plotpv(X,T);
```



Note that 4 input vectors have much smaller magnitudes than the fifth vector in the upper left of the plot. The perceptron must properly classify the 5 input vectors in X into the two categories defined by T.

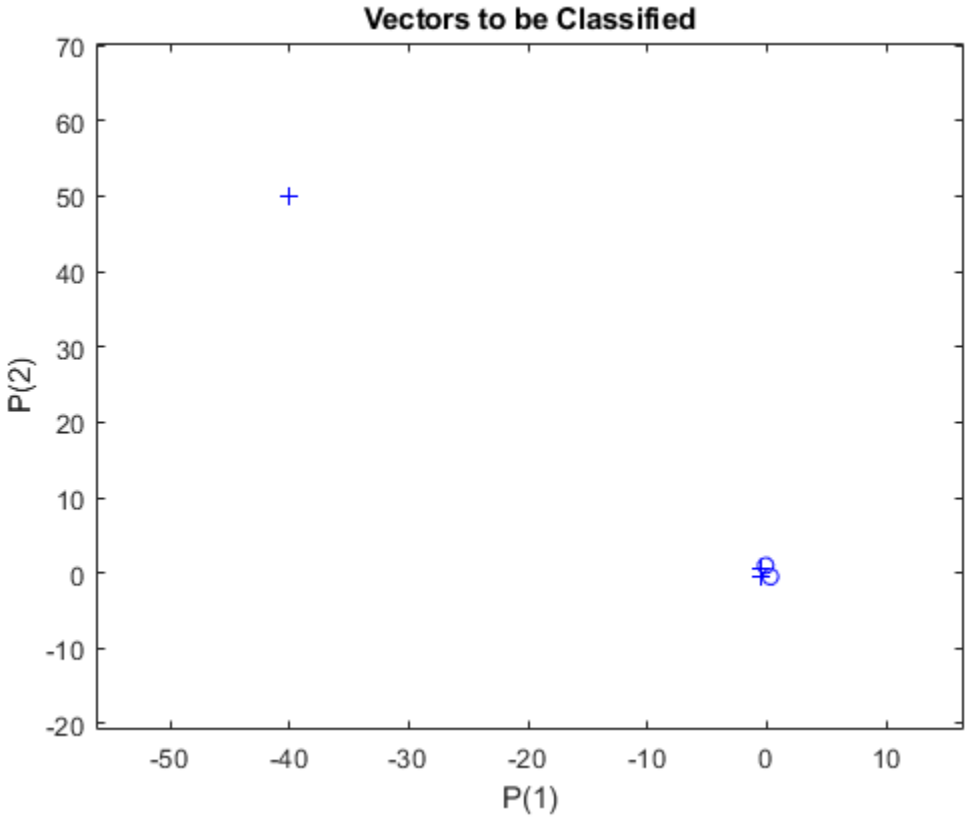
PERCEPTRON creates a new network which is then configured with the input and target data which results in initial values for its weights and bias. (Configuration is normally not necessary, as it is done automatically by ADAPT and TRAIN.)

```
net = perceptron;
net = configure(net,X,T);
```

Add the neuron's initial attempt at classification to the plot.

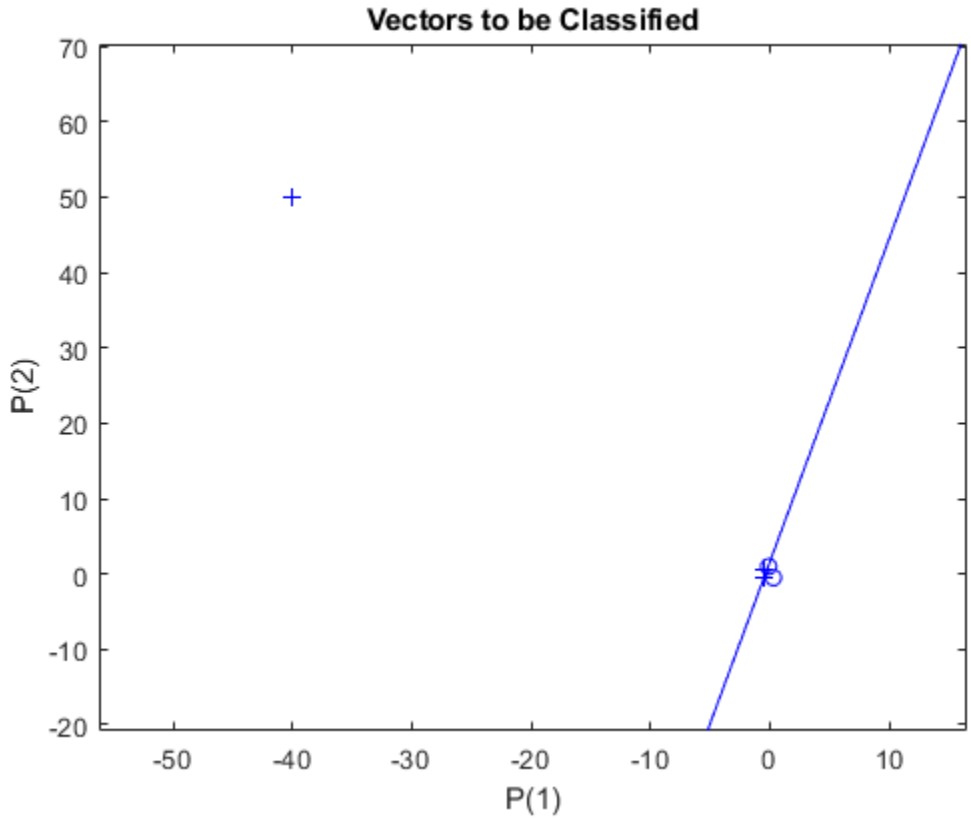
The initial weights are set to zero, so any input gives the same output and the classification line does not even appear on the plot. Fear not... we are going to train it!

```
hold on
linehandle = plotpc(net.IW{1},net.b{1});
```



ADAPT returns a new network object that performs as a better classifier, the network output, and the error. This loop adapts the network and plots the classification line, until the error is zero.

```
E = 1;
while (sse(E))
   [net,Y,E] = adapt(net,X,T);
   linehandle = plotpc(net.IW{1},net.b{1},linehandle);
   drawnow;
end
```

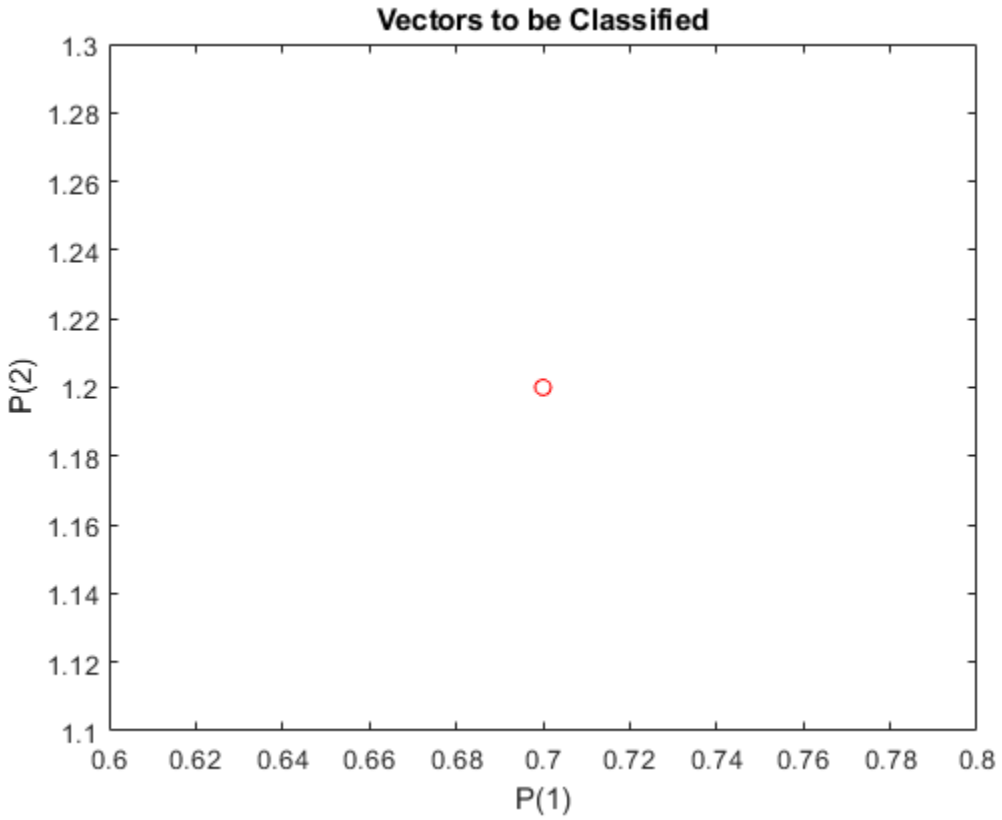


Note that it took the perceptron three passes to get it right. This a long time for such a simple problem. The reason for the long training time is the outlier vector. Despite the long training time, the perceptron still learns properly and can be used to classify other inputs.

Now SIM can be used to classify any other input vector. For example, classify an input vector of [0.7; 1.2].

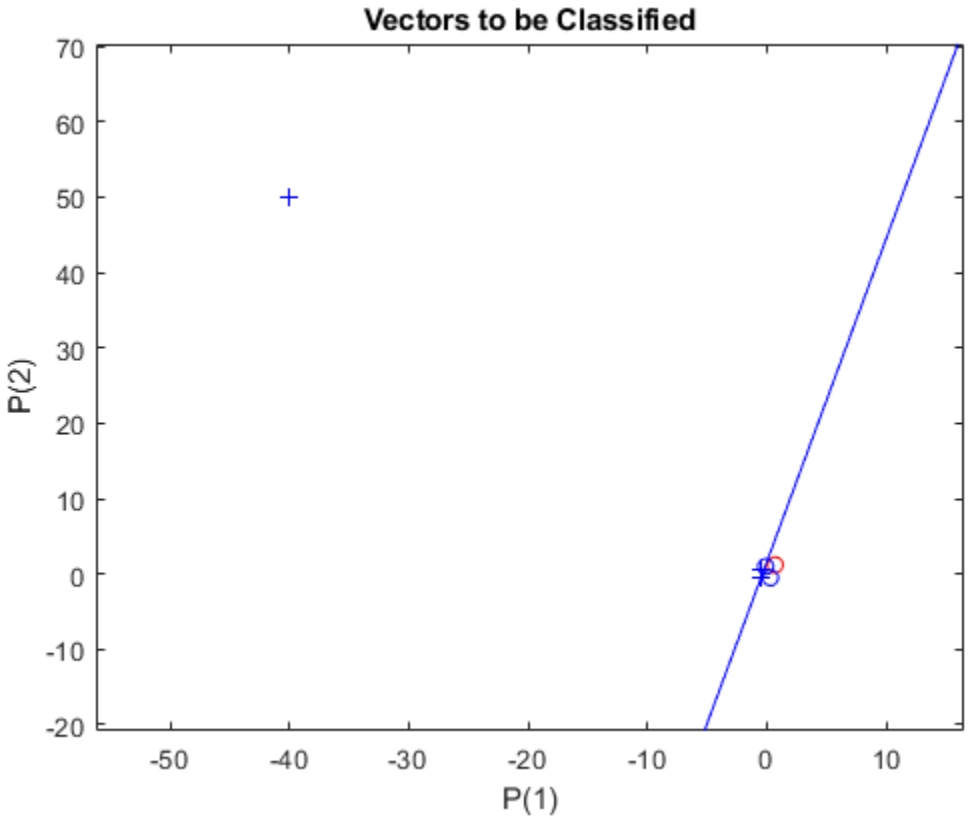
A plot of this new point with the original training set shows how the network performs. To distinguish it from the training set, color it red.

```
x = [0.7; 1.2];
y = net(x);
plotpv(x,y);
circle = findobj(gca,'type','line');
circle.Color = 'red';
```



Turn on "hold" so the previous plot is not erased. Add the training set and the classification line to the plot.

```
hold on;
plotpv(X,T);
plotpc(net.IW{1},net.b{1});
hold off;
```



Finally, zoom into the area of interest.

The perceptron correctly classified our new point (in red) as category "zero" (represented by a circle) and not a "one" (represented by a plus). Despite the long training time, the perceptron still learns properly. To see how to reduce training times associated with outlier vectors, see the "Normalized Perceptron Rule" example.

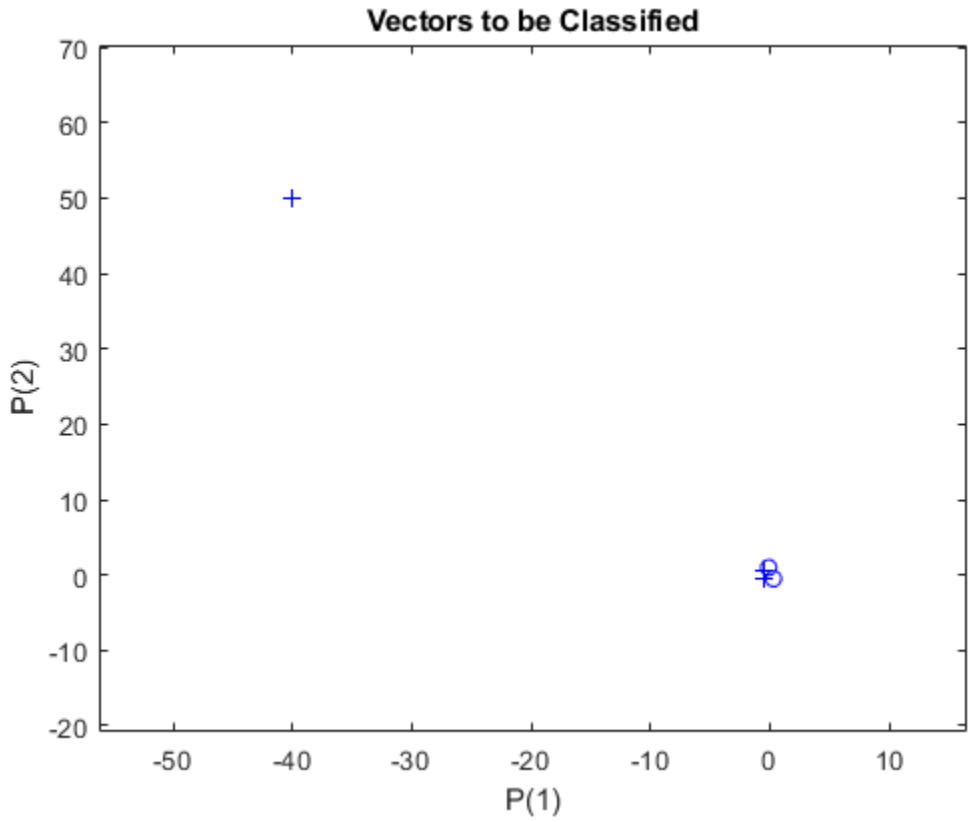
Normalized Perceptron Rule

A 2-input hard limit neuron is trained to classify 5 input vectors into two categories. Despite the fact that one input vector is much bigger than the others, training with LEARNPN is quick.

Each of the five column vectors in X defines a 2-element input vectors, and a row vector T defines the vector's target categories. Plot these vectors with PLOTPV.

```
X = [ -0.5 -0.5 +0.3 -0.1 -40; ...
      -0.5 +0.5 -0.5 +1.0 50];
T = [1 1 0 0 1];
plotpv(X,T);
```



Note that 4 input vectors have much smaller magnitudes than the fifth vector in the upper left of the plot. The perceptron must properly classify the 5 input vectors in X into the two categories defined by T.

PERCEPTRON creates a new network with LEARPN learning rule, which is less sensitive to large variations in input vector size than LEARNP (the default).

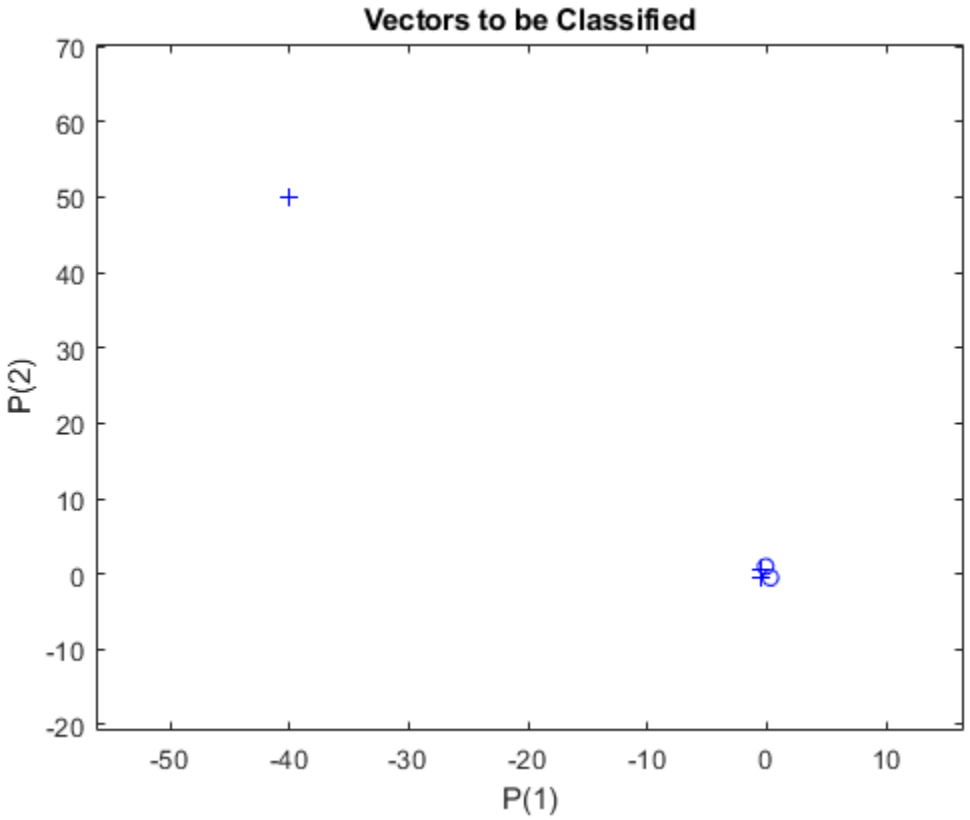
The network is then configured with the input and target data which results in initial values for its weights and bias. (Configuration is normally not necessary, as it is done automatically by ADAPT and TRAIN.)

```
net = perceptron('hardlim','learnpn');
net = configure(net,X,T);
```

Add the neuron's initial attempt at classification to the plot.

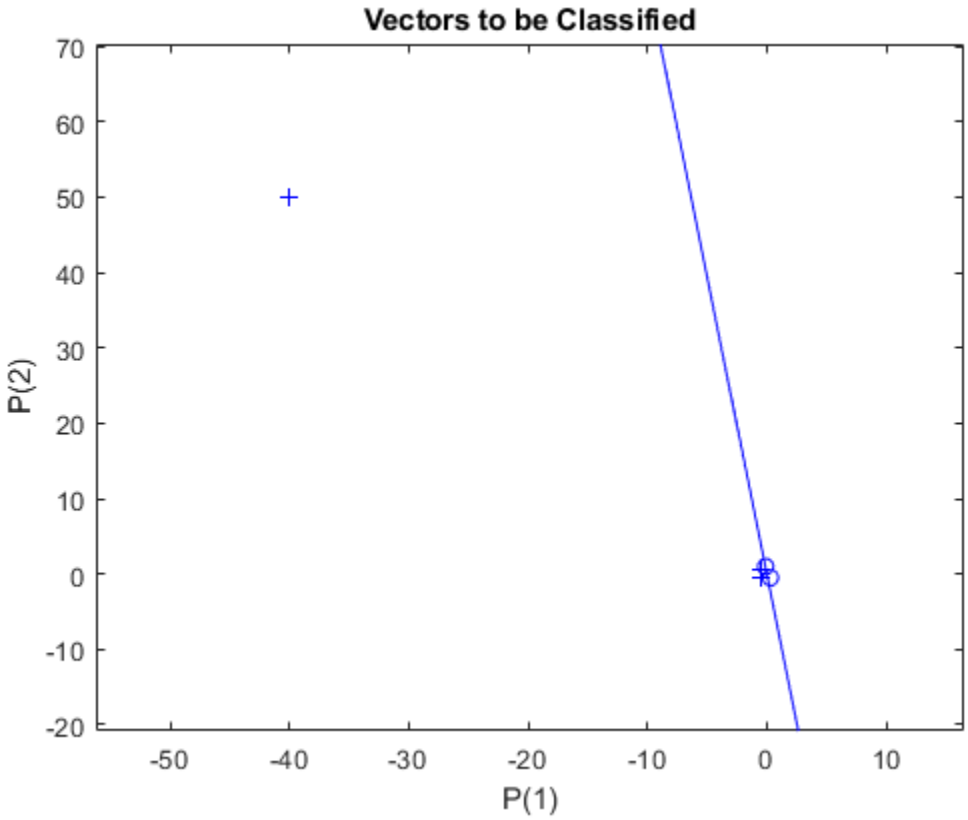
The initial weights are set to zero, so any input gives the same output and the classification line does not even appear on the plot. Fear not... we are going to train it!

```
hold on
linehandle = plotpc(net.IW{1},net.b{1});
```



ADAPT returns a new network object that performs as a better classifier, the network output, and the error. This loop allows the network to adapt, plots the classification line, and continues until the error is zero.

```
E = 1;
while (sse(E))
   [net,Y,E] = adapt(net,X,T);
   linehandle = plotpc(net.IW{1},net.b{1},linehandle);
   drawnow;
end
```

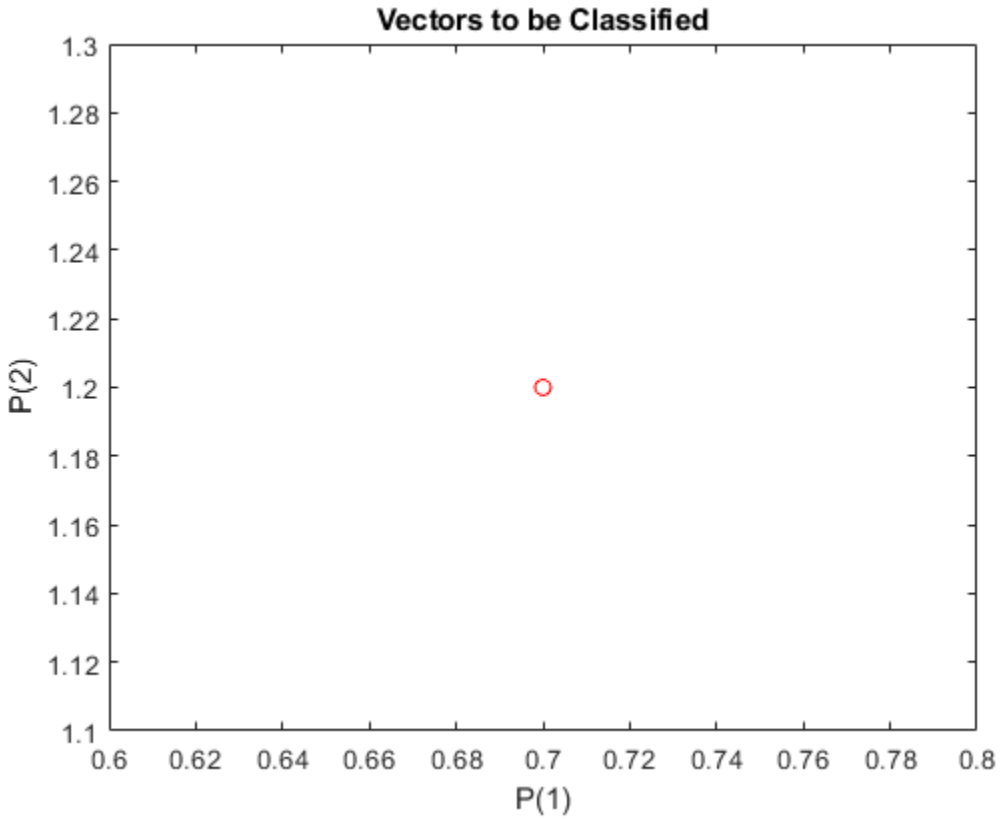


Note that training with LEARNP took only 3 epochs, while solving the same problem with LEARNPN required 32 epochs. Thus, LEARNPN does much better job than LEARNP when there are large variations in input vector size.

Now SIM can be used to classify any other input vector. For example, classify an input vector of [0.7; 1.2].

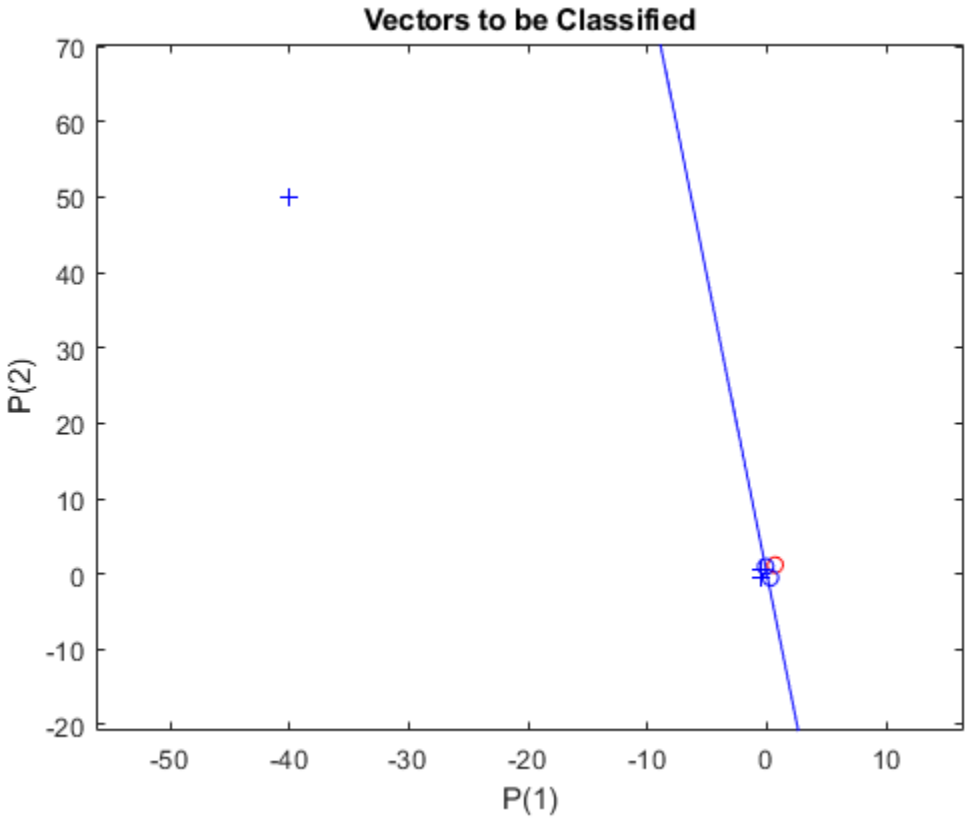
A plot of this new point with the original training set shows how the network performs. To distinguish it from the training set, color it red.

```
x = [0.7; 1.2];
y = net(x);
plotpv(x,y);
circle = findobj(gca,'type','line');
circle.Color = 'red';
```



Turn on "hold" so the previous plot is not erased. Add the training set and the classification line to the plot.

```
hold on;
plotpv(X,T);
plotpc(net.IW{1},net.b{1});
hold off;
```



Finally, zoom into the area of interest.

The perceptron correctly classified our new point (in red) as category "zero" (represented by a circle) and not a "one" (represented by a plus). The perceptron learns properly in much shorter time in spite of the outlier (compare with the "Outlier Input Vectors" example).

```

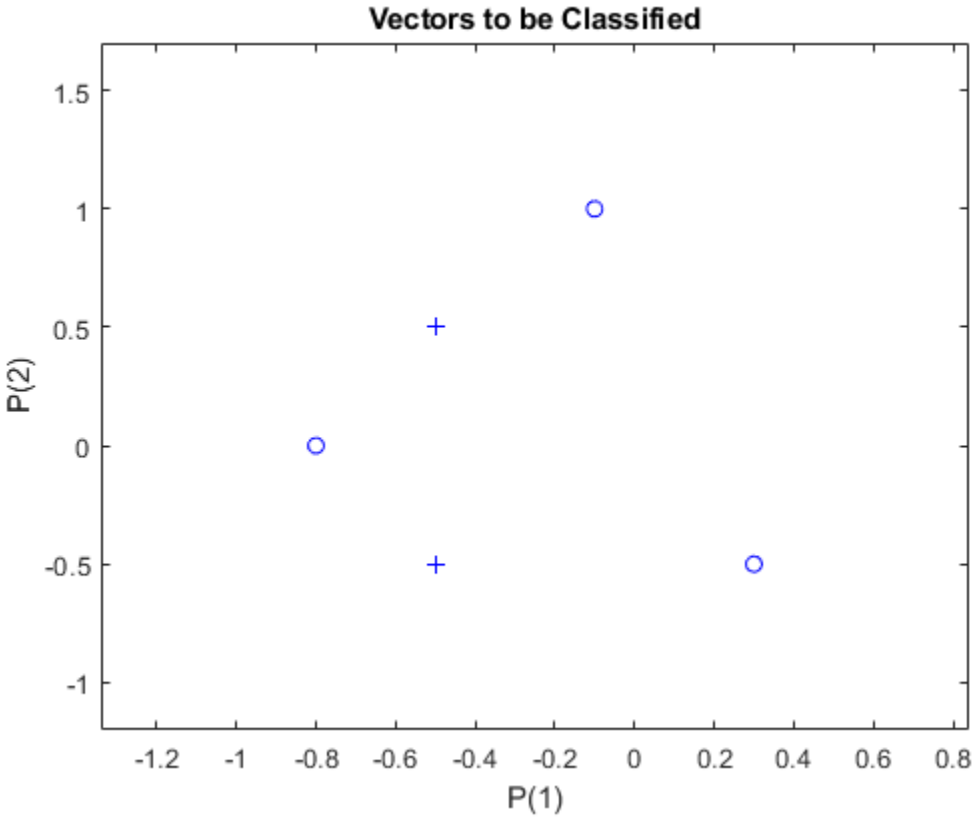
Linearly Non-separable Vectors

A 2-input hard limit neuron fails to properly classify 5 input vectors because they are linearly non-separable.

Each of the five column vectors in X defines a 2-element input vectors, and a row vector T defines the vector's target categories. Plot these vectors with PLOTPV.

```
X = [ -0.5 -0.5 +0.3 -0.1 -0.8; ...
      -0.5 +0.5 -0.5 +1.0 +0.0 ];
T = [1 1 0 0 0];
plotpv(X,T);
```



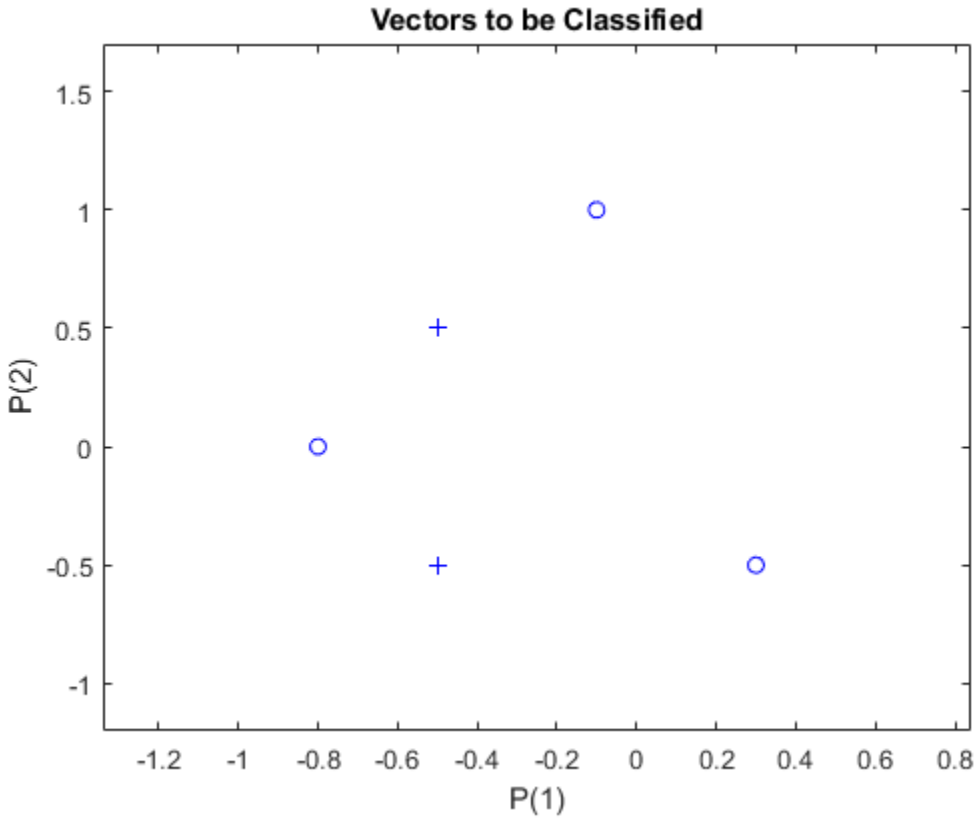
The perceptron must properly classify the input vectors in X into the categories defined by T. Because the two kinds of input vectors cannot be separated by a straight line, the perceptron will not be able to do it.

Here the initial perceptron is created and configured. (The configuration step is normally optional, as it is performed automatically by ADAPT and TRAIN.)

```
net = perceptron;
net = configure(net,X,T);
```

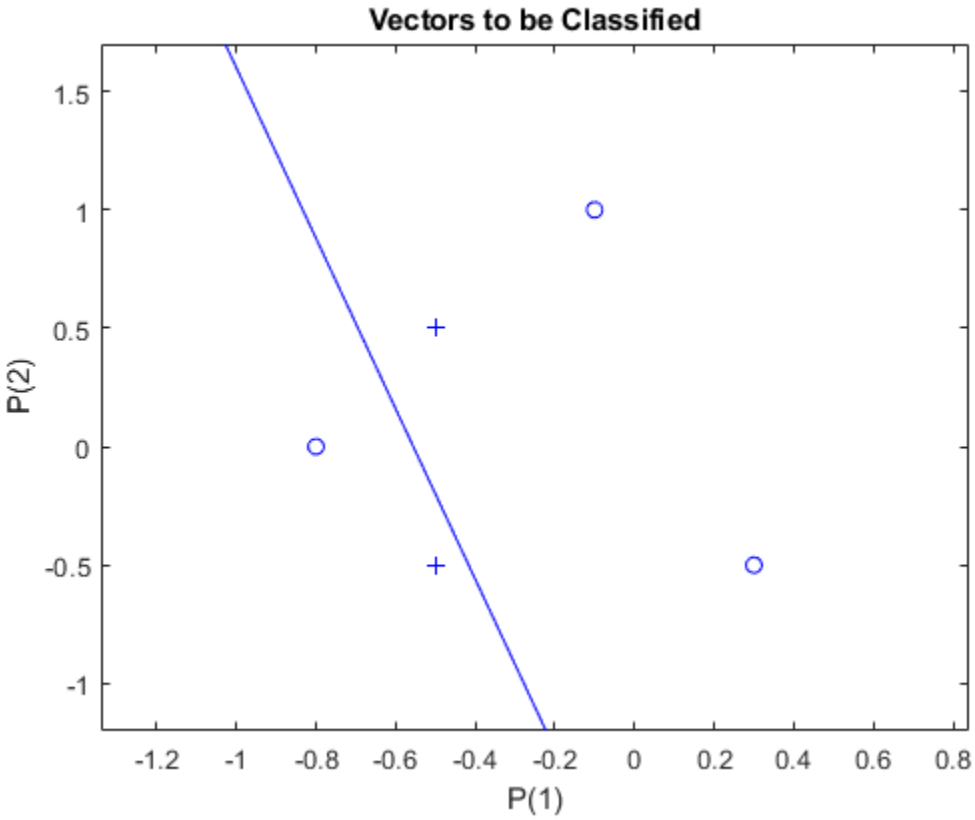
Add the neuron's initial attempt at classification to the plot. The initial weights are set to zero, so any input gives the same output and the classification line does not even appear on the plot.

```
hold on
plotpv(X,T);
linehandle = plotpc(net.IW{1},net.b{1});
```



ADAPT returns a new network after learning on the input and target data, the outputs and error. The loop allows the network to repeatedly adapt, plots the classification line, and stops after 25 iterations.

```
for a = 1:25
   [net,Y,E] = adapt(net,X,T);
   linehandle = plotpc(net.IW{1},net.b{1},linehandle);  drawnow;
end;
```



Note that zero error was never obtained. Despite training, the perceptron has not become an acceptable classifier. Only being able to classify linearly separable data is the fundamental limitation of perceptrons.

Pattern Association Showing Error Surface

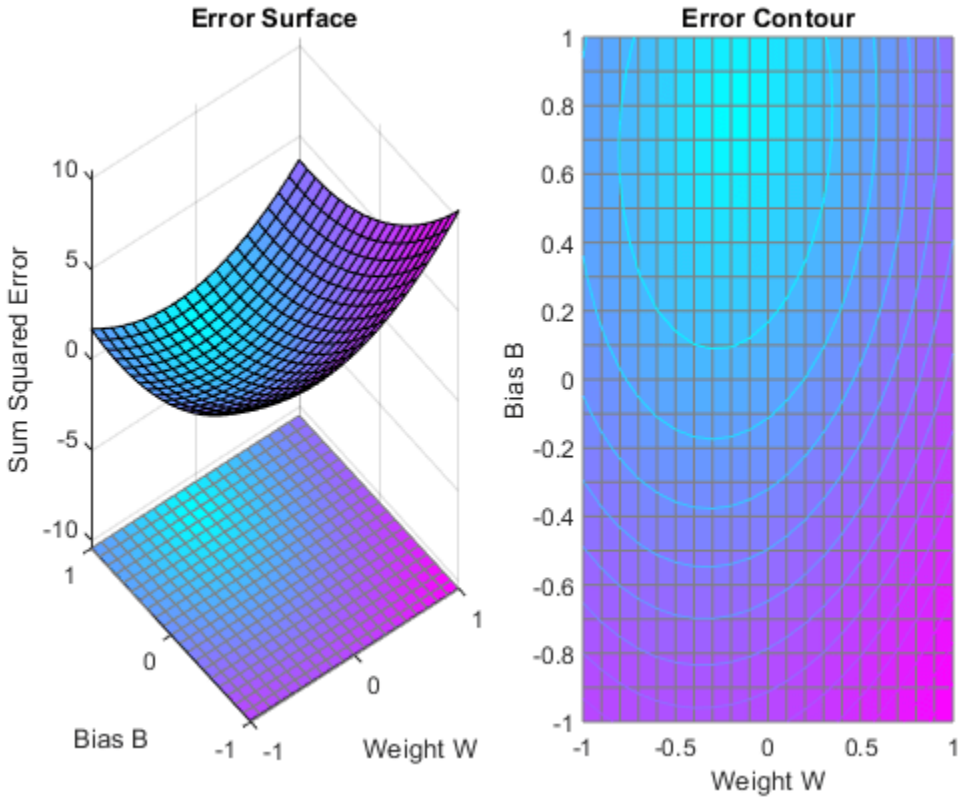
A linear neuron is designed to respond to specific inputs with target outputs.

X defines two 1-element input patterns (column vectors). T defines the associated 1-element targets (column vectors).

```
X = [1.0 -1.2];
T = [0.5 1.0];
```

ERRSURF calculates errors for y neuron with y range of possible weight and bias values. PLOTES plots this error surface with y contour plot underneath. The best weight and bias values are those that result in the lowest point on the error surface.

```
w_range = -1:0.1:1;
b_range = -1:0.1:1;
ES = errsurf(X,T,w_range,b_range,'purelin');
plotes(w_range,b_range,ES);
```



The function NEWLIND will design y network that performs with the minimum error.

```
net = newlind(X,T);
```

SIM is used to simulate the network for inputs X. We can then calculate the neurons errors. SUMSQR adds up the squared errors.

```
A = net(X)
```

```
A = 1×2

    0.5000    1.0000

E = T - A

E = 1×2

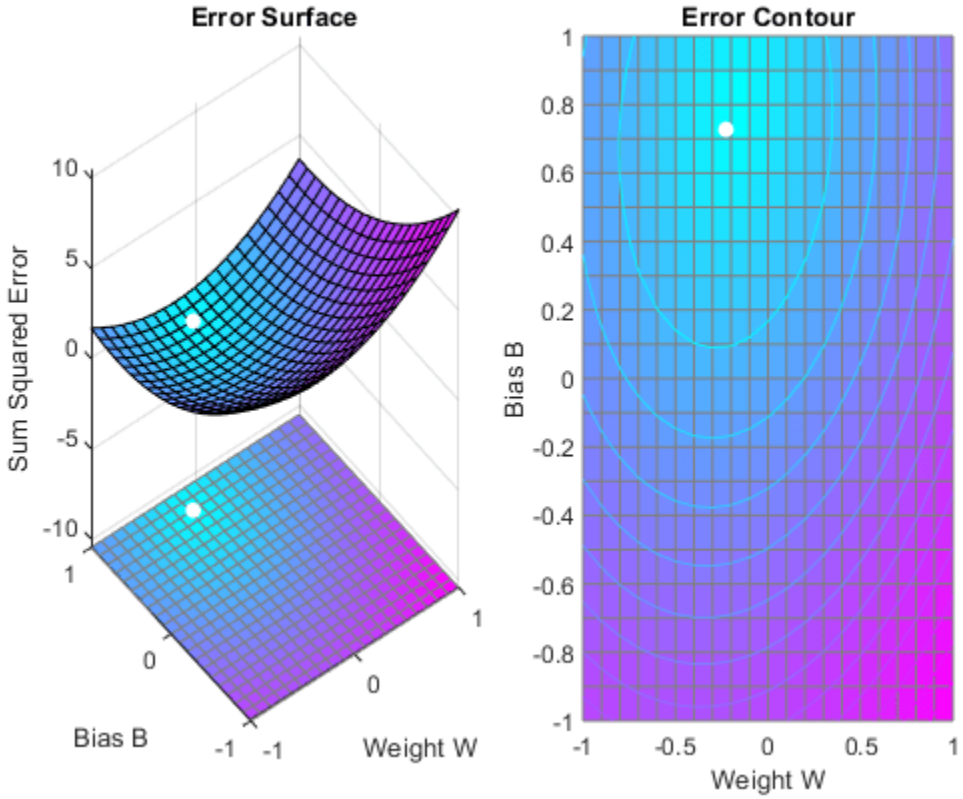
     0     0

SSE = sumsqr(E)

SSE = 0
```

PLOTES replots the error surface. PLOTEP plots the "position" of the network using the weight and bias values returned by SOLVELIN. As can be seen from the plot, SOLVELIN found the minimum error solution.

```
plotes(w_range,b_range,ES);
plotep(net.IW{1,1},net.b{1},SSE);
```



We can now test the associator with one of the original inputs, -1.2, and see if it returns the target, 1.0.

```
x = -1.2;
y = net(x)
```

```
y = 1
```

Training a Linear Neuron

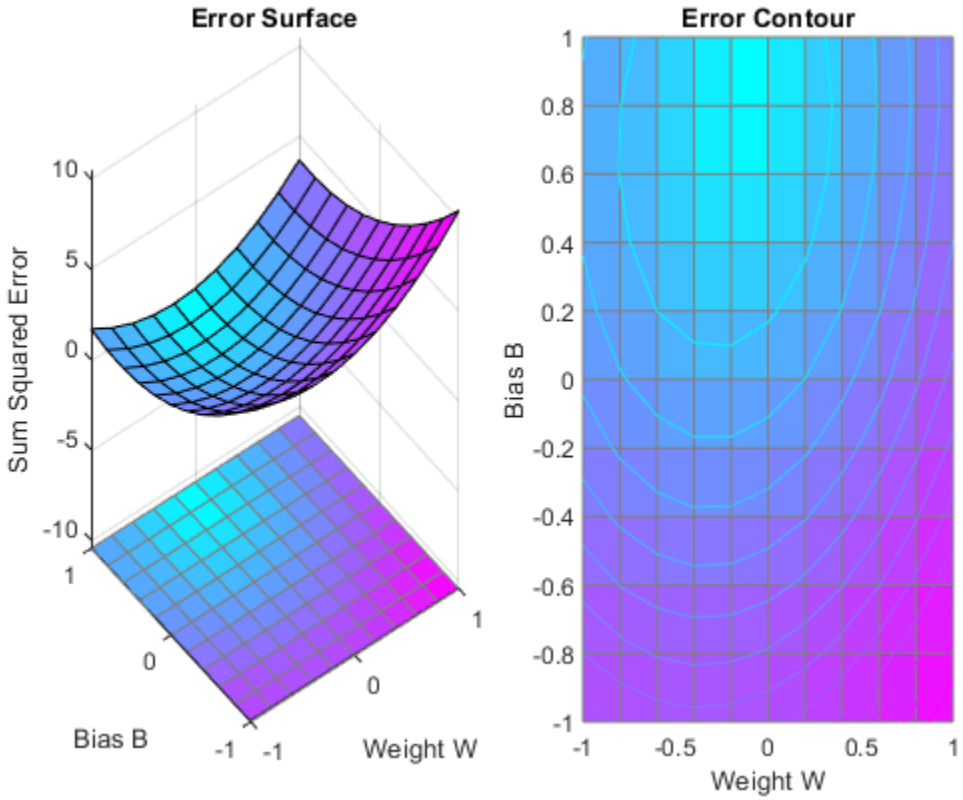
A linear neuron is trained to respond to specific inputs with target outputs.

X defines two 1-element input patterns (column vectors). T defines associated 1-element targets (column vectors). A single input linear neuron with y bias can be used to solve this problem.

```
X = [1.0 -1.2];
T = [0.5 1.0];
```

ERRSURF calculates errors for y neuron with y range of possible weight and bias values. PLOTES plots this error surface with y contour plot underneath. The best weight and bias values are those that result in the lowest point on the error surface.

```
w_range = -1:0.2:1;  b_range = -1:0.2:1;
ES = errsurf(X,T,w_range,b_range,'purelin');
plotes(w_range,b_range,ES);
```



MAXLINLR finds the fastest stable learning rate for training y linear network. For this example, this rate will only be 40% of this maximum. NEWLIN creates y linear neuron. NEWLIN takes these arguments: 1) Rx2 matrix of min and max values for R input elements, 2) Number of elements in the output vector, 3) Input delay vector, and 4) Learning rate.

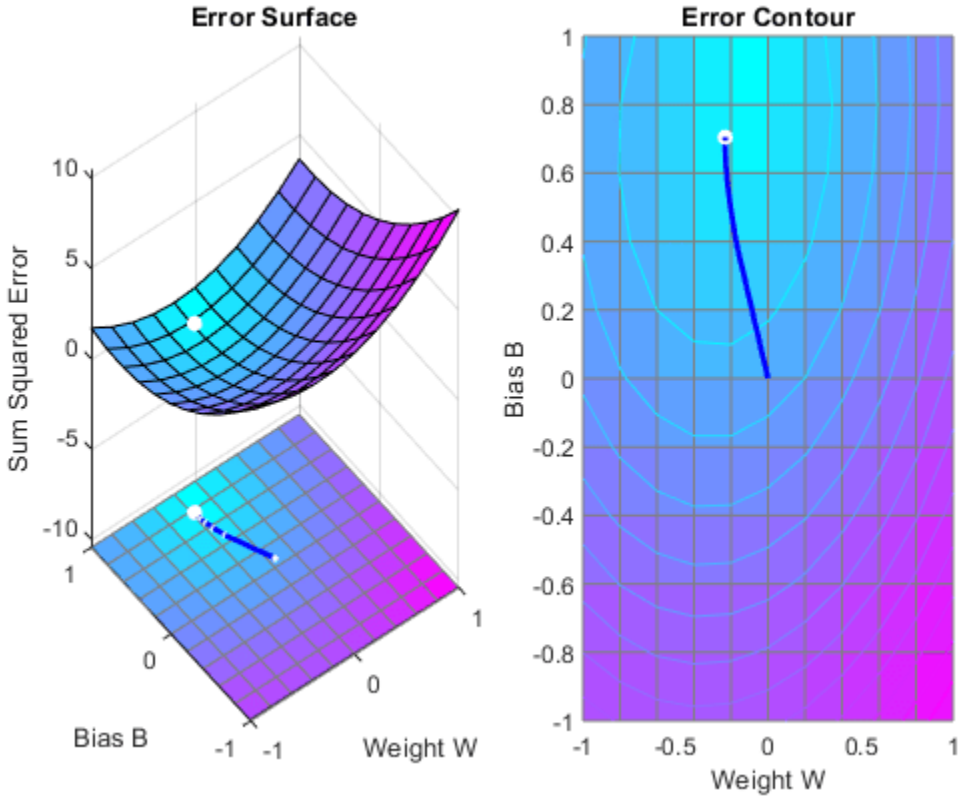
```
maxlr = 0.40*maxlinlr(X,'bias');
net = newlin([-2 2],1,[0],maxlr);
```

Override the default training parameters by setting the performance goal.

```
net.trainParam.goal = .001;
```

To show the path of the training we will train only one epoch at y time and call PLOTEP every epoch. The plot shows y history of the training. Each dot represents an epoch and the blue lines show each change made by the learning rule (Widrow-Hoff by default).

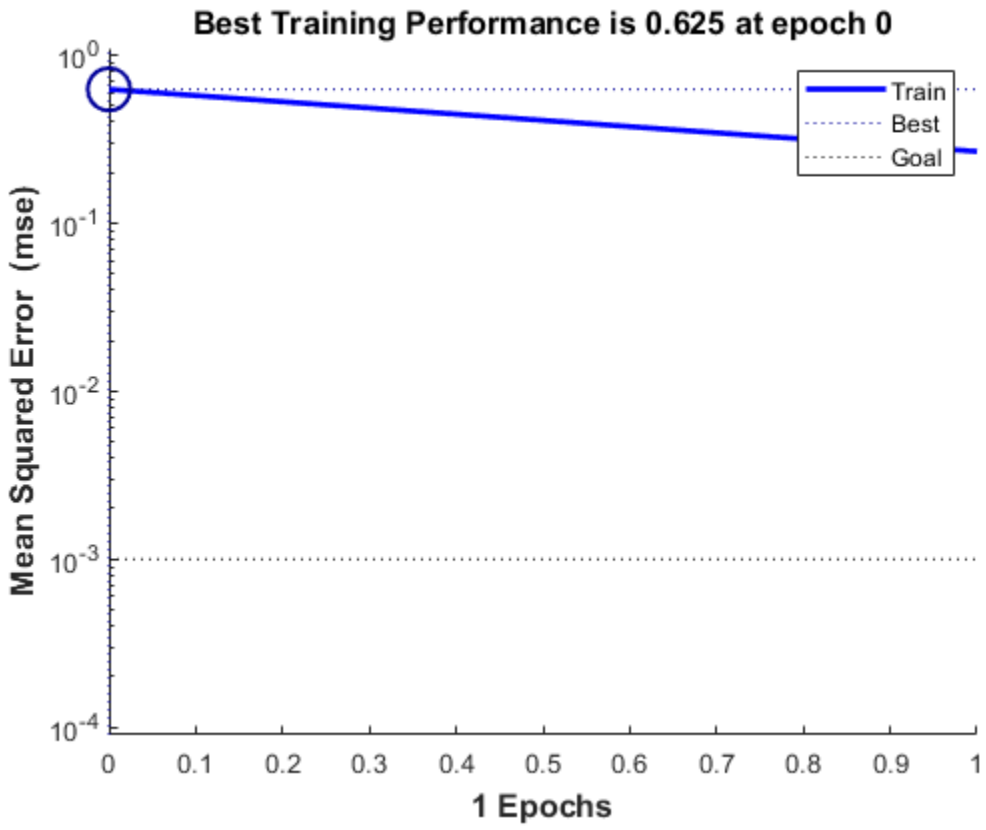
```
% [net,tr] = train(net,X,T);
net.trainParam.epochs = 1;
net.trainParam.show = NaN;
h=plotep(net.IW{1},net.b{1},mse(T-net(X)));
[net,tr] = train(net,X,T);
r = tr;
epoch = 1;
while true
   epoch = epoch+1;
   [net,tr] = train(net,X,T);
   if length(tr.epoch) > 1
      h = plotep(net.IW{1,1},net.b{1},tr.perf(2),h);
      r.epoch=[r.epoch epoch];
      r.perf=[r.perf tr.perf(2)];
      r.vperf=[r.vperf NaN];
      r.tperf=[r.tperf NaN];
   else
      break
   end
end
```



```
tr=r;
```

The train function outputs the trained network and y history of the training performance (tr). Here the errors are plotted with respect to training epochs: The error dropped until it fell beneath the error goal (the black line). At that point training stopped.

```
plotperform(tr);
```



Now use SIM to test the associator with one of the original inputs, -1.2, and see if it returns the target, 1.0. The result is very close to 1, the target. This could be made even closer by lowering the performance goal.

```
x = -1.2;
y = net(x)
```

```
y = 0.9817
```

Linear Fit of Nonlinear Problem

A linear neuron is trained to find the minimum sum-squared error linear fit to y nonlinear input/output problem.

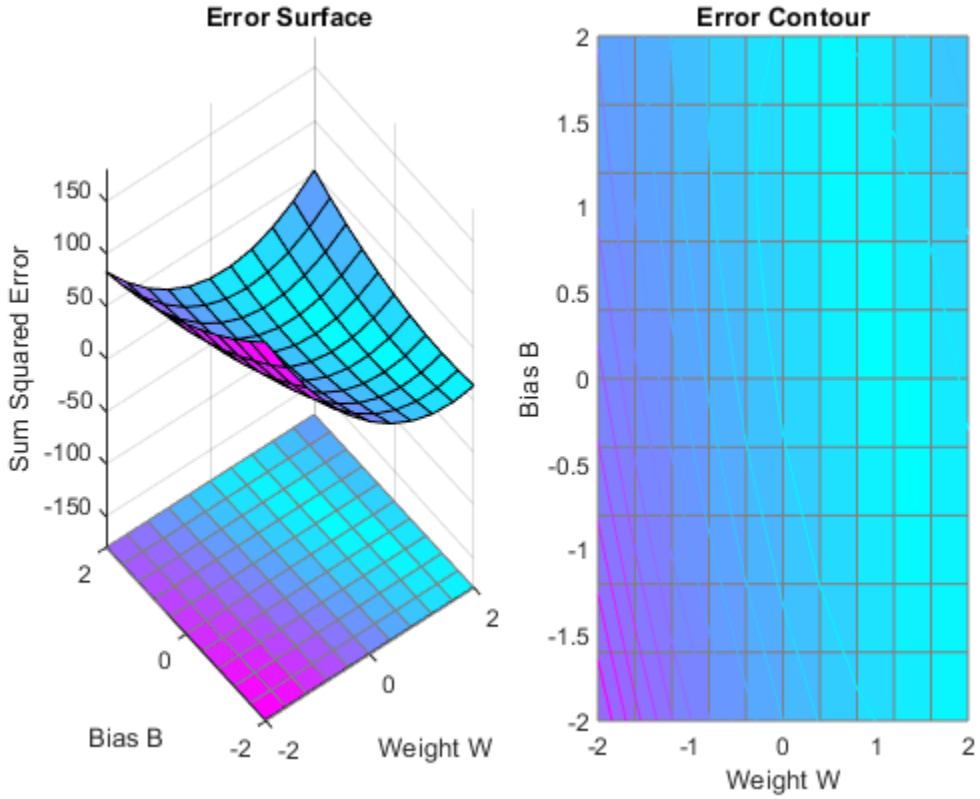
X defines four 1-element input patterns (column vectors). T defines associated 1-element targets (column vectors). Note that the relationship between values in X and in T is nonlinear. I.e. No W and B exist such that X*W+B = T for all of four sets of X and T values above.

```
X = [+1.0 +1.5 +3.0 -1.2];
T = [+0.5 +1.1 +3.0 -1.0];
```

ERRSURF calculates errors for y neuron with y range of possible weight and bias values. PLOTES plots this error surface with y contour plot underneath.

The best weight and bias values are those that result in the lowest point on the error surface. Note that because y perfect linear fit is not possible, the minimum has an error greater than 0.

```
w_range =-2:0.4:2;  b_range = -2:0.4:2;
ES = errsurf(X,T,w_range,b_range,'purelin');
plotes(w_range,b_range,ES);
```



MAXLINLR finds the fastest stable learning rate for training y linear network. NEWLIN creates y linear neuron. NEWLIN takes these arguments: 1) Rx2 matrix of min and max values for R input elements, 2) Number of elements in the output vector, 3) Input delay vector, and 4) Learning rate.

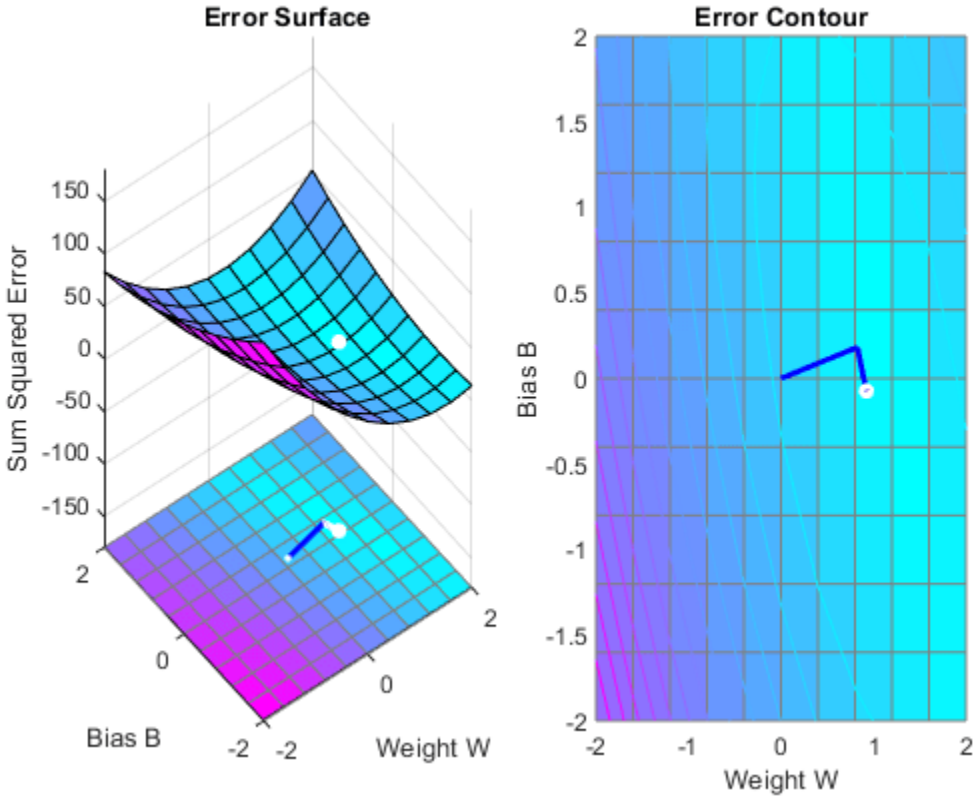
```
maxlr = maxlinlr(X,'bias');
net = newlin([-2 2],1,[0],maxlr);
```

Override the default training parameters by setting the maximum number of epochs. This ensures that training will stop.

```
net.trainParam.epochs = 15;
```

To show the path of the training we will train only one epoch at y time and call PLOTEP every epoch (code not shown here). The plot shows y history of the training. Each dot represents an epoch and the blue lines show each change made by the learning rule (Widrow-Hoff by default).

```
% [net,tr] = train(net,X,T);
net.trainParam.epochs = 1;
net.trainParam.show = NaN;
h=plotep(net.IW{1},net.b{1},mse(T-net(X)));
[net,tr] = train(net,X,T);
r = tr;
epoch = 1;
while epoch < 15
   epoch = epoch+1;
   [net,tr] = train(net,X,T);
   if length(tr.epoch) > 1
      h = plotep(net.IW{1,1},net.b{1},tr.perf(2),h);
      r.epoch=[r.epoch epoch];
      r.perf=[r.perf tr.perf(2)];
      r.vperf=[r.vperf NaN];
      r.tperf=[r.tperf NaN];
   else
      break
   end
end
```

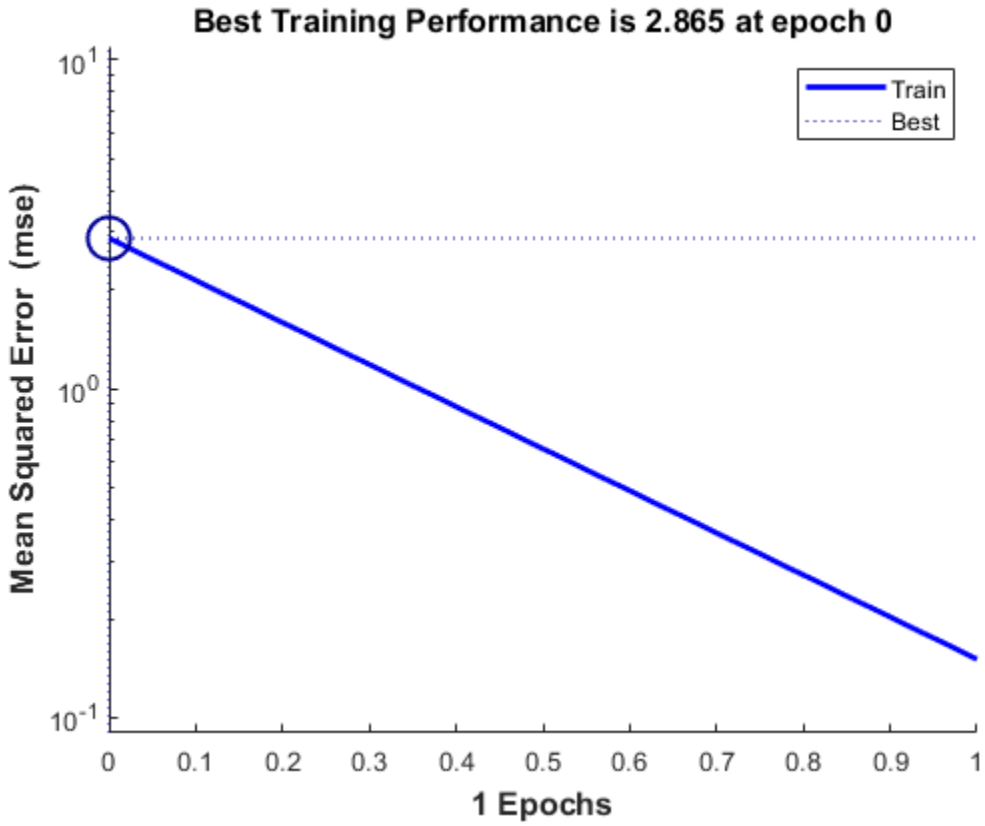


```
tr=r;
```

The train function outputs the trained network and y history of the training performance (tr). Here the errors are plotted with respect to training epochs.

Note that the error never reaches 0. This problem is nonlinear and therefore y zero error linear solution is not possible.

```
plotperform(tr);
```



Now use SIM to test the associator with one of the original inputs, -1.2, and see if it returns the target, 1.0.

The result is not very close to 0.5! This is because the network is the best linear fit to y nonlinear problem.

```
x = -1.2;
y = net(x)
```

```
y = -1.1803
```

Underdetermined Problem

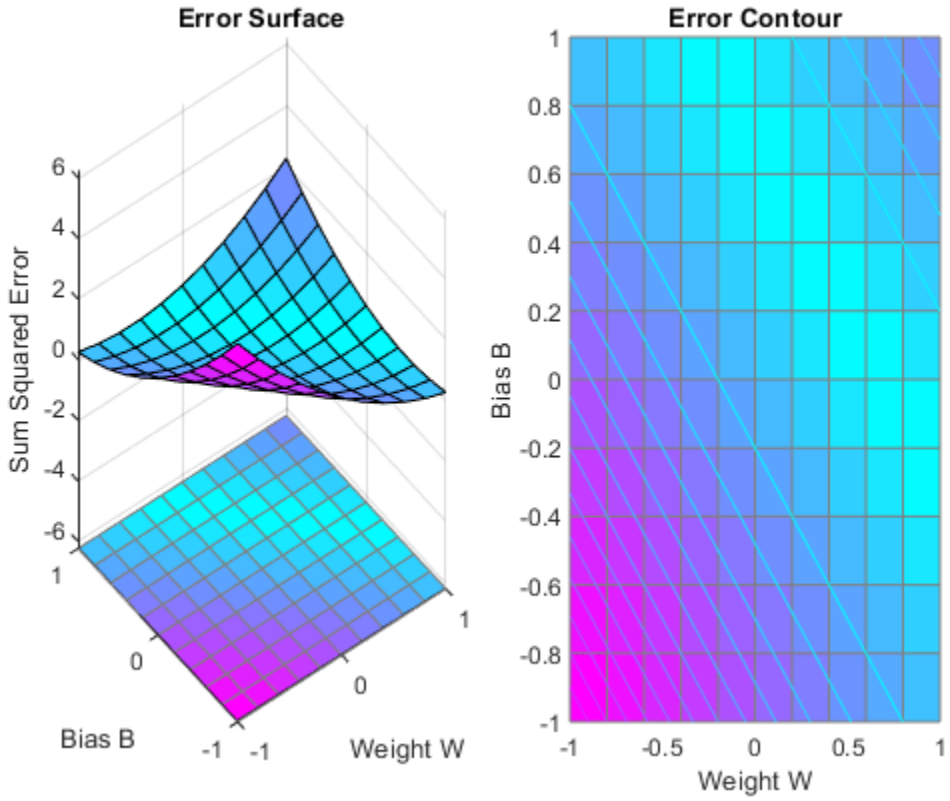
A linear neuron is trained to find y non-unique solution to an undetermined problem.

X defines one 1-element input patterns (column vectors). T defines an associated 1-element target (column vectors). Note that there are infinite values of W and B such that the expression W*X+B = T is true. Problems with multiple solutions are called underdetermined.

```
X = [+1.0];
T = [+0.5];
```

ERRSURF calculates errors for y neuron with y range of possible weight and bias values. PLOTES plots this error surface with y contour plot underneath. The bottom of the valley in the error surface corresponds to the infinite solutions to this problem.

```
w_range = -1:0.2:1;  b_range = -1:0.2:1;
ES = errsurf(X,T,w_range,b_range,'purelin');
plotes(w_range,b_range,ES);
```



MAXLINLR finds the fastest stable learning rate for training y linear network. NEWLIN creates y linear neuron. NEWLIN takes these arguments: 1) Rx2 matrix of min and max values for R input elements, 2) Number of elements in the output vector, 3) Input delay vector, and 4) Learning rate.

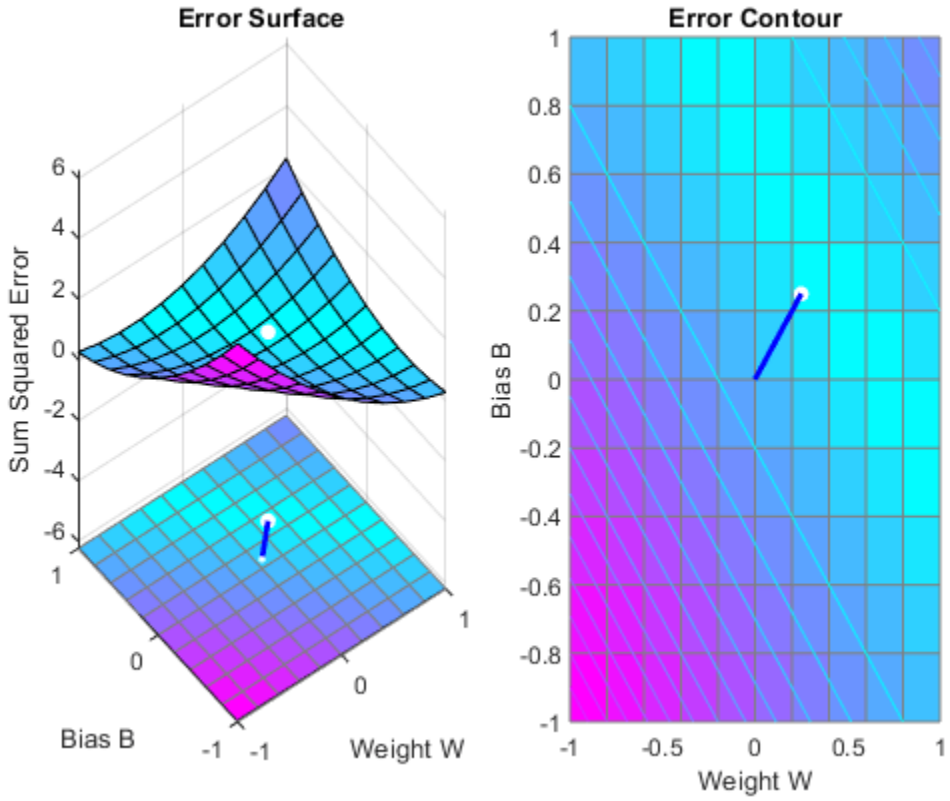
```
maxlr = maxlinlr(X,'bias');
net = newlin([-2 2],1,[0],maxlr);
```

Override the default training parameters by setting the performance goal.

```
net.trainParam.goal = 1e-10;
```

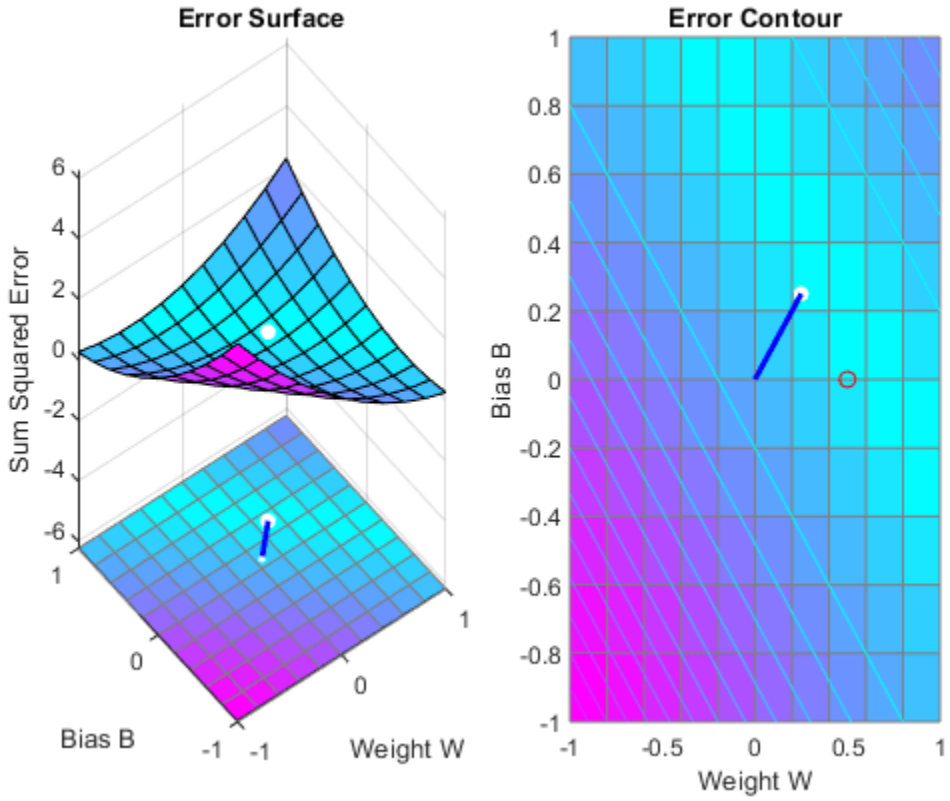
To show the path of the training we will train only one epoch at y time and call PLOTEP every epoch. The plot shows y history of the training. Each dot represents an epoch and the blue lines show each change made by the learning rule (Widrow-Hoff by default).

```
% [net,tr] = train(net,X,T);
net.trainParam.epochs = 1;
net.trainParam.show = NaN;
h=plotep(net.IW{1},net.b{1},mse(T-net(X)));
[net,tr] = train(net,X,T);
r = tr;
epoch = 1;
while true
   epoch = epoch+1;
   [net,tr] = train(net,X,T);
   if length(tr.epoch) > 1
      h = plotep(net.IW{1,1},net.b{1},tr.perf(2),h);
      r.epoch=[r.epoch epoch];
      r.perf=[r.perf tr.perf(2)];
      r.vperf=[r.vperf NaN];
      r.tperf=[r.tperf NaN];
   else
      break
   end
end
tr=r;
```



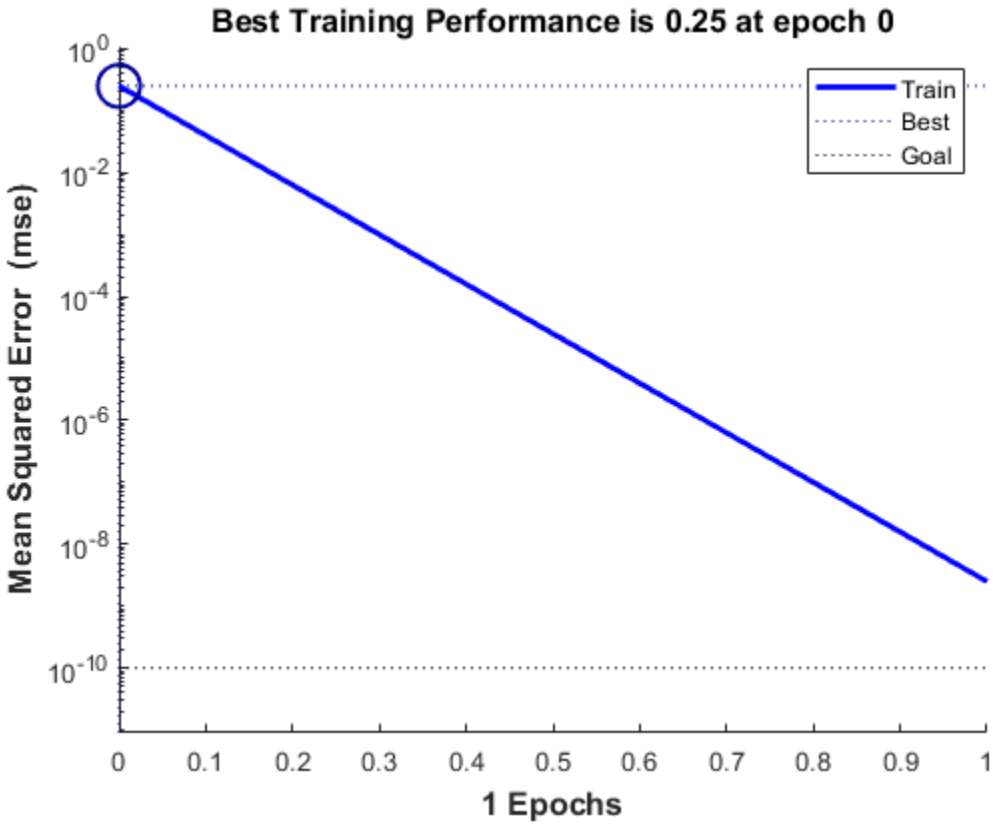
Here we plot the NEWLIND solution. Note that the TRAIN (white dot) and SOLVELIN (red circle) solutions are not the same. In fact, TRAINWH will return y different solution for different initial conditions, while SOLVELIN will always return the same solution.

```
solvednet = newlind(X,T);
hold on;
plot(solvednet.IW{1,1},solvednet.b{1},'ro')
hold off;
```



The train function outputs the trained network and y history of the training performance (tr). Here the errors are plotted with respect to training epochs: Once the error reaches the goal, an adequate solution for W and B has been found. However, because the problem is underdetermined, this solution is not unique.

```
subplot(1,2,1);
plotperform(tr);
```



We can now test the associator with one of the original inputs, 1.0, and see if it returns the target, 0.5. The result is very close to 0.5. The error can be reduced further, if required, by continued training with TRAINWH using y smaller error goal.

```
x = 1.0;
y = net(x)
```

```
y =

    0.5000
```

Linearly Dependent Problem

A linear neuron is trained to find the minimum error solution for y problem with linearly dependent input vectors. If y linear dependence in input vectors is not matched in the target vectors, the problem is nonlinear and does not have y zero error linear solution.

X defines three 2-element input patterns (column vectors). Note that 0.5 times the sum of (column) vectors 1 and 3 results in vector 2. This is called linear dependence.

```
X = [ 1.0   2.0   3.0; ...
      4.0   5.0   6.0];
```

T defines an associated 1-element target (column vectors). Note that 0.5 times the sum of -1.0 and 0.5 does not equal 1.0. Because the linear dependence in X is not matched in T this problem is nonlinear and does not have y zero error linear solution.

```
T = [0.5 1.0 -1.0];
```

MAXLINLR finds the fastest stable learning rate for TRAINWH. NEWLIN creates y linear neuron. NEWLIN takes these arguments: 1) Rx2 matrix of min and max values for R input elements, 2) Number of elements in the output vector, 3) Input delay vector, and 4) Learning rate.

```
maxlr = maxlinlr(X,'bias');
net = newlin([0 10;0 10],1,[0],maxlr);
```

TRAIN uses the Widrow-Hoff rule to train linear networks by default. We will display each 50 epochs and train for y maximum of 500 epochs.

```
net.trainParam.show = 50;     % Frequency of progress displays (in epochs).
net.trainParam.epochs = 500;  % Maximum number of epochs to train.
net.trainParam.goal = 0.001;  % Sum-squared error goal.
```

Now the network is trained on the inputs X and targets T. Note that, due to the linear dependence between input vectors, the problem did not reach the error goal represented by the black line.

```
[net,tr] = train(net,X,T);
```

We can now test the associator with one of the original inputs, [1; 4] , and see if it returns the target, 0.5. The result is not 0.5 as the linear network could not fit the nonlinear problem caused by the linear dependence between input vectors.

```
p = [1.0; 4];
y = net(p)
```

```
y = 0.8971
```

Too Large a Learning Rate

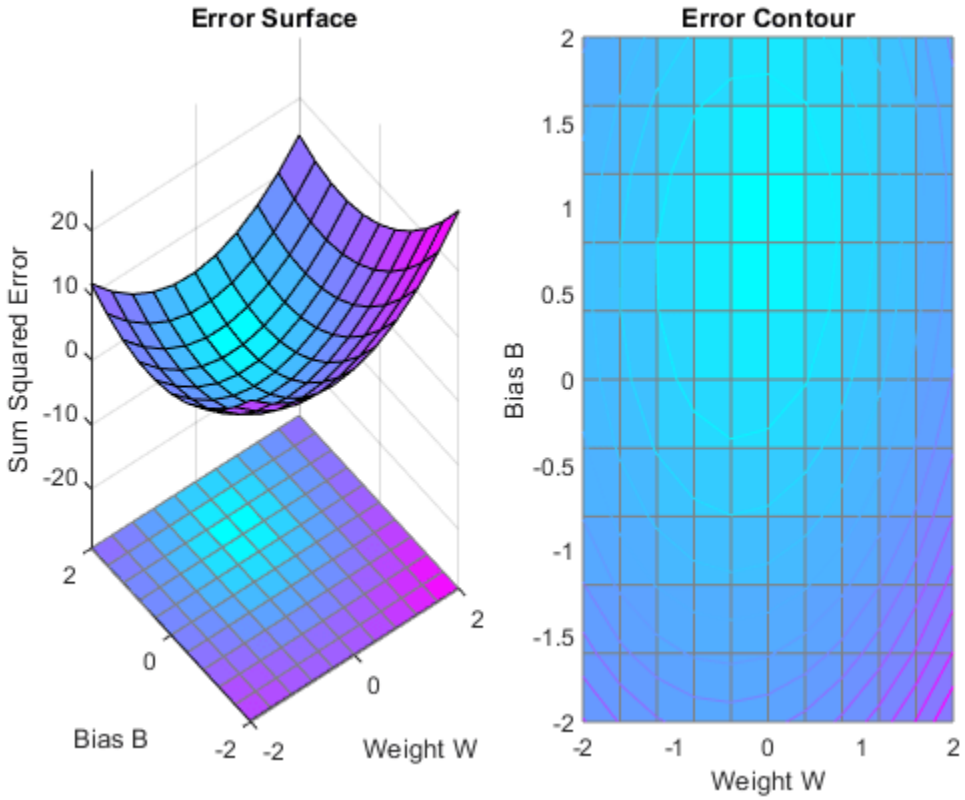
A linear neuron is trained to find the minimum error solution for a simple problem. The neuron is trained with the learning rate larger than the one suggested by MAXLINLR.

X defines two 1-element input patterns (column vectors). T defines associated 1-element targets (column vectors).

```
X = [+1.0 -1.2];
T = [+0.5 +1.0];
```

ERRSURF calculates errors for a neuron with a range of possible weight and bias values. PLOTES plots this error surface with a contour plot underneath. The best weight and bias values are those that result in the lowest point on the error surface.

```
w_range = -2:0.4:2;
b_range = -2:0.4:2;
ES = errsurf(X,T,w_range,b_range,'purelin');
plotes(w_range,b_range,ES);
```



MAXLINLR finds the fastest stable learning rate for training a linear network. NEWLIN creates a linear neuron. To see what happens when the learning rate is too large, increase the learning rate to 225% of the recommended value. NEWLIN takes these arguments: 1) Rx2 matrix of min and max values for R input elements, 2) Number of elements in the output vector, 3) Input delay vector, and 4) Learning rate.

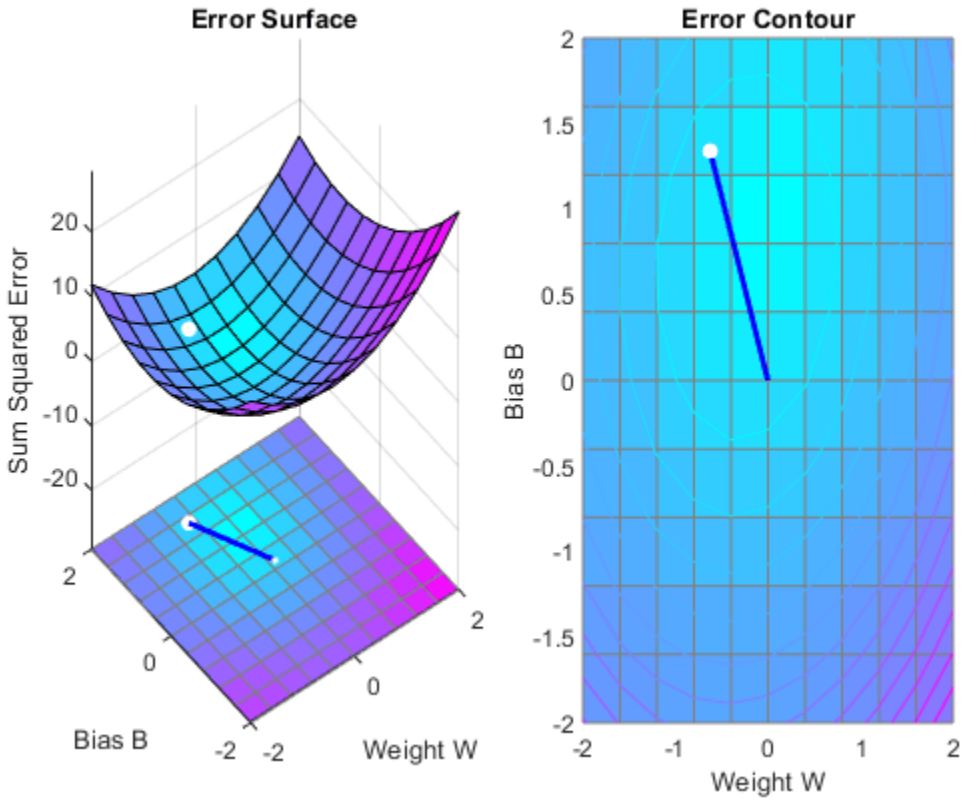
```
maxlr = maxlinlr(X,'bias');
net = newlin([-2 2],1,[0],maxlr*2.25);
```

Override the default training parameters by setting the maximum number of epochs. This ensures that training will stop:

```
net.trainParam.epochs = 20;
```

To show the path of the training we will train only one epoch at a time and call PLOTEP every epoch (code not shown here). The plot shows a history of the training. Each dot represents an epoch and the blue lines show each change made by the learning rule (Widrow-Hoff by default).

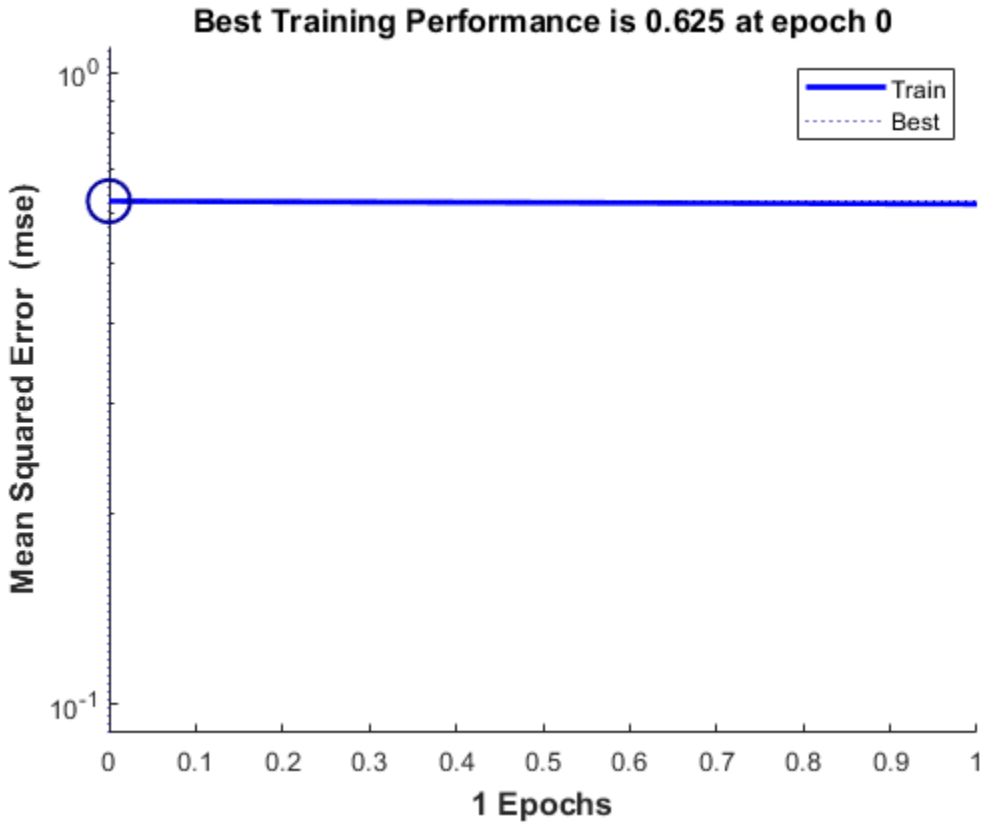
```
%[net,tr] = train(net,X,T);
net.trainParam.epochs = 1;
net.trainParam.show = NaN;
h=plotep(net.IW{1},net.b{1},mse(T-net(X)));
[net,tr] = train(net,X,T);
r = tr;
epoch = 1;
while epoch < 20
   epoch = epoch+1;
   [net,tr] = train(net,X,T);
   if length(tr.epoch) > 1
      h = plotep(net.IW{1,1},net.b{1},tr.perf(2),h);
      r.epoch=[r.epoch epoch];
      r.perf=[r.perf tr.perf(2)];
      r.vperf=[r.vperf NaN];
      r.tperf=[r.tperf NaN];
   else
      break
   end
end
```



```
tr=r;
```

The train function outputs the trained network and a history of the training performance (tr). Here the errors are plotted with respect to training epochs.

```
plotperform(tr);
```



We can now use SIM to test the associator with one of the original inputs, -1.2, and see if it returns the target, 1.0. The result is not very close to 0.5! This is because the network was trained with too large a learning rate.

```
x = -1.2;
y = net(x)
```

```
y = 2.0913
```

Adaptive Noise Cancellation

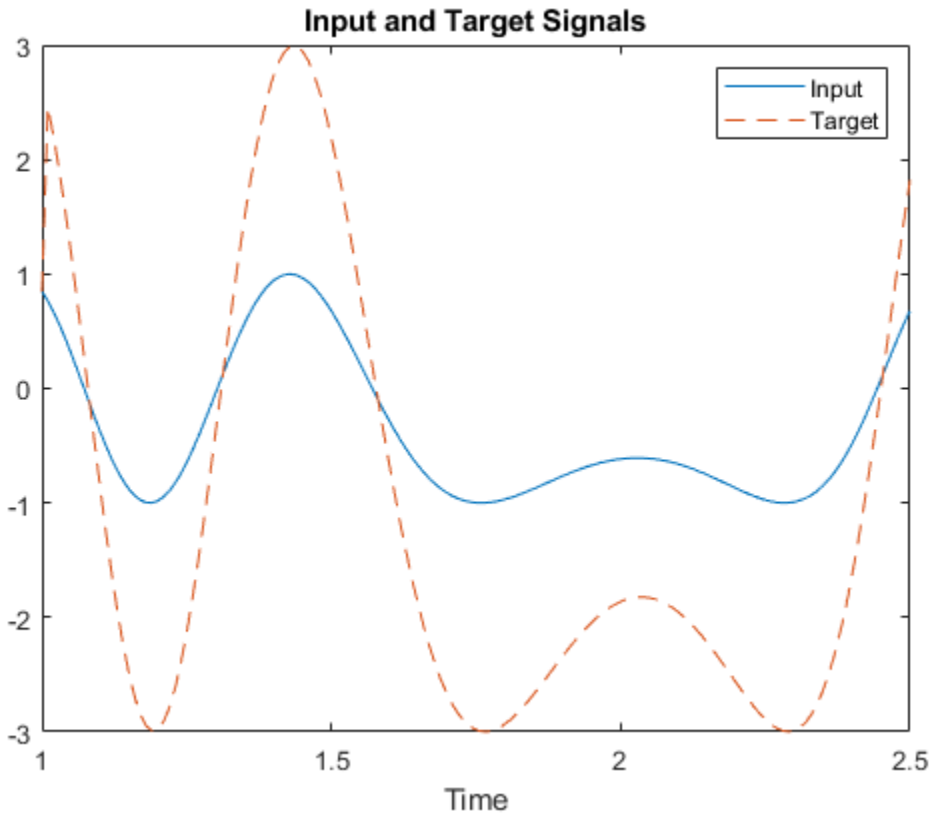
A linear neuron is allowed to adapt so that given one signal, it can predict a second signal.

TIME defines the time steps of this simulation. P defines a signal over these time steps. T is a signal derived from P by shifting it to the left, multiplying it by 2 and adding it to itself.

```
time = 1:0.01:2.5;
X = sin(sin(time).*time*10);
P = con2seq(X);
T = con2seq(2*[0 X(1:(end-1))] + X);
```

Here is how the two signals are plotted:

```
plot(time,cat(2,P{:}),time,cat(2,T{:}),'--')
title('Input and Target Signals')
xlabel('Time')
legend({'Input','Target'})
```



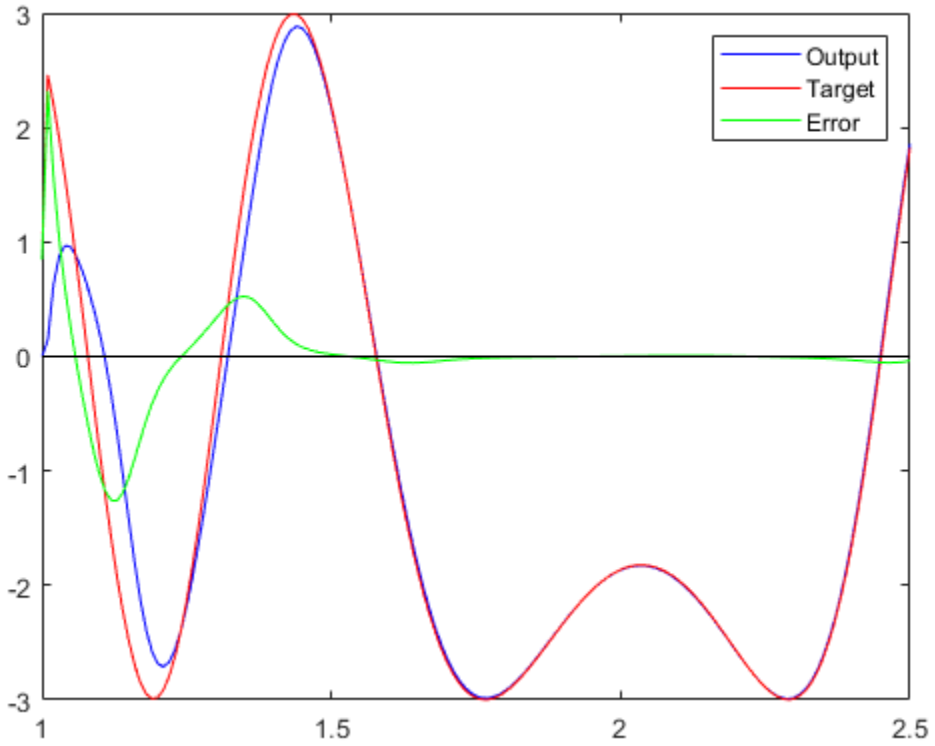
The linear network must have tapped delay in order to learn the time-shifted correlation between P and T. NEWLIN creates a linear layer. [-3 3] is the expected input range. The second argument is the number of neurons in the layer. [0 1] specifies one input with no delay and one input with a delay of one. The last argument is the learning rate.

```
net = newlin([-3 3],1,[0 1],0.1);
```

ADAPT simulates adaptive networks. It takes a network, a signal, and a target signal, and filters the signal adaptively. Plot the output Y in blue, the target T in red and the error E in green. By t=2 the

network has learned the relationship between the input and the target and the error drops to near zero.

```
[net,Y,E,Pf]=adapt(net,P,T);
plot(time,cat(2,Y{:}),'b', ...
   time,cat(2,T{:}),'r', ...
   time,cat(2,E{:}),'g',[1 2.5],[0 0],'k')
legend({'Output','Target','Error'})
```



Shallow Neural Networks Bibliography

Shallow Neural Networks Bibliography

[Batt92] Battiti, R., “First and second order methods for learning: Between steepest descent and Newton's method,” *Neural Computation*, Vol. 4, No. 2, 1992, pp. 141–166.

[Beal72] Beale, E.M.L., “A derivation of conjugate gradients,” in F.A. Lootsma, Ed., *Numerical methods for nonlinear optimization*, London: Academic Press, 1972.

[Koho97] Kohonen, T., *Self-Organizing Maps*, Second Edition, Berlin: Springer-Verlag, 1997.

This book discusses the history, fundamentals, theory, applications, and hardware of self-organizing maps. It also includes a comprehensive literature survey.

[LiMi89] Li, J., A.N. Michel, and W. Porod, “Analysis and synthesis of a class of neural networks: linear systems operating on a closed hypercube,” *IEEE Transactions on Circuits and Systems*, Vol. 36, No. 11, 1989, pp. 1405–1422.

This paper discusses a class of neural networks described by first-order linear differential equations that are defined on a closed hypercube. The systems considered retain the basic structure of the Hopfield model but are easier to analyze and implement. The paper presents an efficient method for determining the set of asymptotically stable equilibrium points and the set of unstable equilibrium points. Examples are presented. The method of Li, et. al., is implemented in Advanced Topics in the *User's Guide*.

[Lipp87] Lippman, R.P., "An introduction to computing with neural nets," *IEEE ASSP Magazine*, 1987, pp. 4–22.

This paper gives an introduction to the field of neural nets by reviewing six neural net models that can be used for pattern classification. The paper shows how existing classification and clustering algorithms can be performed using simple components that are like neurons. This is a highly readable paper.

A

Mathematical Notation

Mathematics and Code Equivalents

In this section...

The transition from mathematics to code or vice versa can be made with the aid of a few rules. They are listed here for reference.

Mathematics Notation to MATLAB Notation

To change from mathematics notation to MATLAB notation:

- Change superscripts to cell array indices. For example,

  $$p^1 \rightarrow p\{1\}$$

- Change subscripts to indices within parentheses. For example,

  $$p_2 \rightarrow p(2)$$

  and

  $$p_2^1 \rightarrow p\{1\}(2)$$

- Change indices within parentheses to a second cell array index. For example,

  $$p^1(k-1) \rightarrow p\{1, k-1\}$$

- Change mathematics operators to MATLAB operators and toolbox functions. For example,

  $$ab \rightarrow a * b$$

Figure Notation

The following equations illustrate the notation used in figures.

$$n = w_{1,1}p_1 + w_{1,2}p_2 + \ldots + 2_{1,R}p_R + b$$

$$W = \begin{bmatrix} w_{1,1} & w_{1,2} & \ldots & w_{1,R} \\ w_{2,1} & w_{2,2} & \ldots & w_{2,R} \\ w_{S,1} & w_{S,2} & \ldots & w_{S,R} \end{bmatrix}$$

B

Neural Network Blocks for the Simulink Environment

Neural Network Simulink Block Library

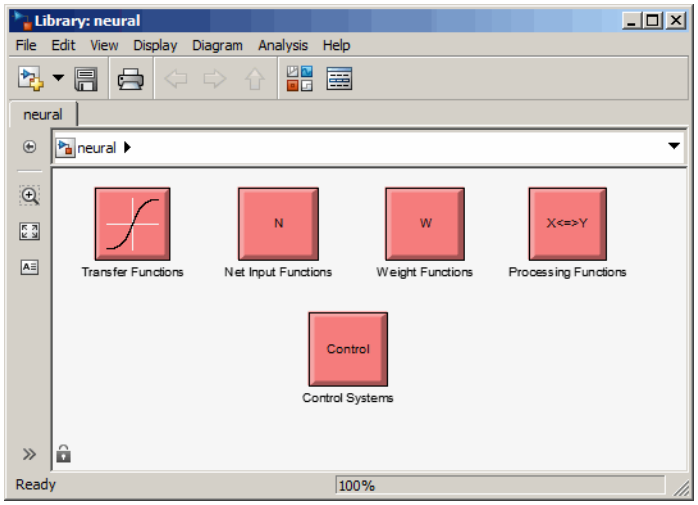
In this section...

The Deep Learning Toolbox product provides a set of blocks you can use to build neural networks using Simulink software, or that the function `gensim` can use to generate the Simulink version of any network you have created using MATLAB software.

Open the Deep Learning Toolbox block library with the command:

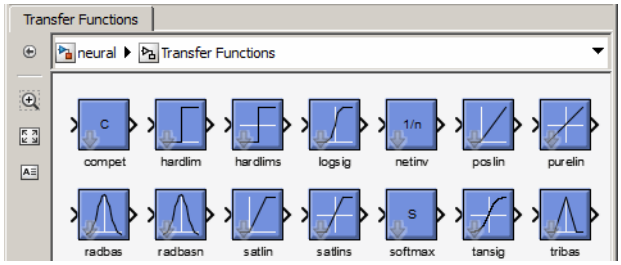
```
neural
```

This opens a library window that contains five blocks. Each of these blocks contains additional blocks.



Transfer Function Blocks

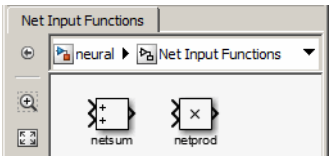
Double-click the Transfer Functions block in the Neural library window to open a window containing several transfer function blocks.



Each of these blocks takes a net input vector and generates a corresponding output vector whose dimensions are the same as the input vector.

Net Input Blocks

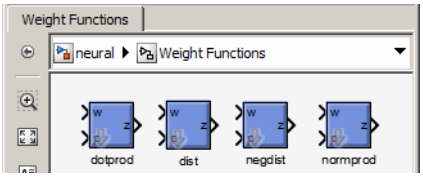
Double-click the Net Input Functions block in the Neural library window to open a window containing two net-input function blocks.



Each of these blocks takes any number of weighted input vectors, weight layer output vectors, and bias vectors, and returns a net-input vector.

Weight Blocks

Double-click the Weight Functions block in the Neural library window to open a window containing three weight function blocks.



Each of these blocks takes a neuron's weight vector and applies it to an input vector (or a layer output vector) to get a weighted input value for a neuron.

It is important to note that these blocks expect the neuron's weight vector to be defined as a column vector. This is because Simulink signals can be column vectors, but cannot be matrices or row vectors.

It is also important to note that because of this limitation you have to create *S* weight function blocks (one for each row), to implement a weight matrix going to a layer with *S* neurons.

This contrasts with the other two kinds of blocks. Only one net input function and one transfer function block are required for each layer.

Processing Blocks

Double-click the Processing Functions block in the Neural library window to open a window containing processing blocks and their corresponding reverse-processing blocks.

Each of these blocks can be used to preprocess inputs and postprocess outputs.

Deploy Shallow Neural Network Simulink Diagrams

In this section...

The function `gensim` generates block descriptions of networks so you can simulate them using Simulink software.

```
gensim(net,st)
```

The second argument to `gensim` determines the sample time, which is normally chosen to be some positive real value.

If a network has no delays associated with its input weights or layer weights, this value can be set to -1. A value of -1 causes `gensim` to generate a network with continuous sampling.

Example

Here is a simple problem defining a set of inputs `p` and corresponding targets `t`.

```
p = [1 2 3 4 5];
t = [1 3 5 7 9];
```

The code below designs a linear layer to solve this problem.

```
net = newlind(p,t)
```

You can test the network on your original inputs with `sim`.

```
y = sim(net,p)
```

The results show the network has solved the problem.

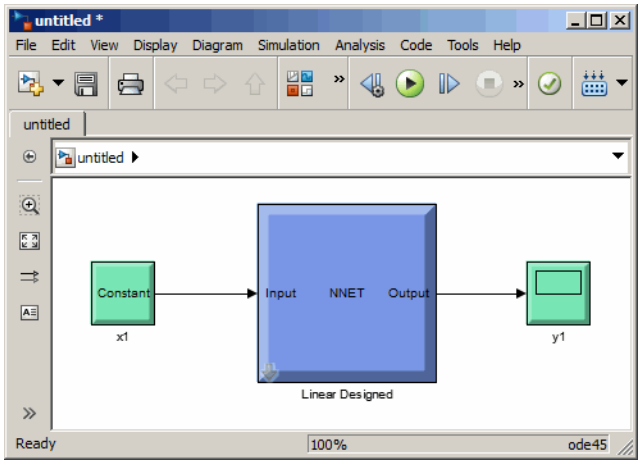
```
y =
      1.0000    3.0000    5.0000    7.0000    9.0000
```

Call `gensim` as follows to generate a Simulink version of the network.

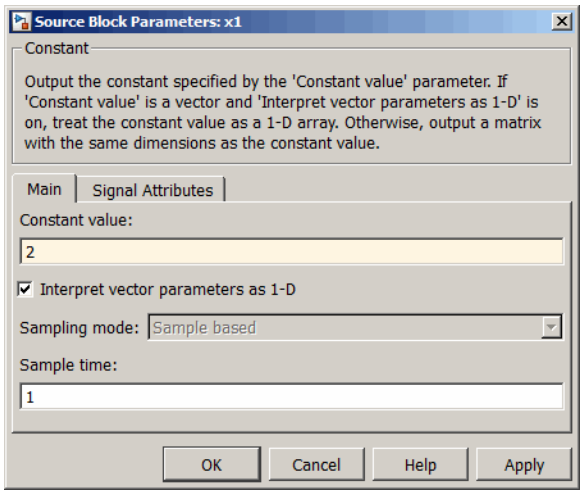
```
gensim(net,-1)
```

The second argument is -1, so the resulting network block samples continuously.

The call to `gensim` opens the following Simulink Editor, showing a system consisting of the linear network connected to a sample input and a scope.



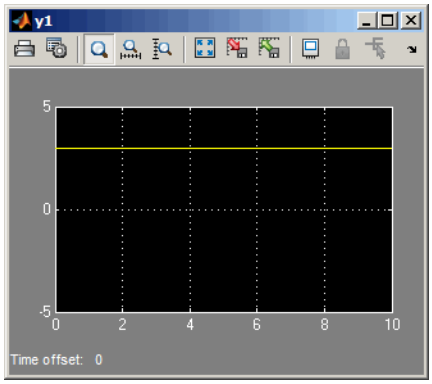
To test the network, double-click the input Constant `x1` block on the left.



The input block is actually a standard Constant block. Change the constant value from the initial randomly generated value to 2, and then click **OK**.

Select the menu option **Simulation** > **Run**. Simulink takes a moment to simulate the system.

When the simulation is complete, double-click the output `y1` block on the right to see the following display of the network's response.



Note that the output is 3, which is the correct output for an input of 2.

Suggested Exercises

Here are a couple exercises you can try.

Change the Input Signal

Replace the constant input block with a signal generator from the standard Simulink Sources blockset. Simulate the system and view the network's response.

Use a Discrete Sample Time

Recreate the network, but with a discrete sample time of 0.5, instead of continuous sampling.

```
gensim(net,0.5)
```

Again, replace the constant input with a signal generator. Simulate the system and view the network's response.

Generate Functions and Objects

For information on simulating and deploying shallow neural networks with MATLAB functions, see "Deploy Shallow Neural Network Functions" on page 28-48.

Code Notes

Deep Learning Toolbox Data Conventions

In this section...

Dimensions

The following code dimensions are used in describing both the network signals that users commonly see, and those used by the utility functions:

`Ni` = Number of network inputs	`= net.numInputs`
`Ri` = Number of elements in input `i`	`= net.inputs{i}.size`
`Nl` = Number of layers	`= net.numLayers`
`Si` = Number of neurons in layer `i`	`= net.layers{i}.size`
`Nt` = Number of targets	
`Vi` = Number of elements in target `i`, equal to `Sj`, where `j` is the `i`th layer with a target. (A layer `n` has a target if `net.targets(n) == 1`.)	
`No` = Number of network outputs	
`Ui` = Number of elements in output `i`, equal to `Sj`, where `j` is the `i`th layer with an output (A layer `n` has an output if `net.outputs(n) == 1`.)	
`ID` = Number of input delays	`= net.numInputDelays`
`LD` = Number of layer delays	`= net.numLayerDelays`
`TS` = Number of time steps	
`Q` = Number of concurrent vectors or sequences	

Variables

The variables a user commonly uses when defining a simulation or training session are

`P`	Network inputs	`Ni`-by-`TS` cell array, where each element `P{i,ts}` is an `Ri`-by-`Q` matrix
`Pi`	Initial input delay conditions	`Ni`-by-`ID` cell array, where each element `Pi{i,k}` is an `Ri`-by-`Q` matrix
`Ai`	Initial layer delay conditions	`Nl`-by-`LD` cell array, where each element `Ai{i,k}` is an `Si`-by-`Q` matrix
`T`	Network targets	`Nt`-by-`TS` cell array, where each element `P{i,ts}` is a `Vi`-by-`Q` matrix

These variables are returned by simulation and training calls:

`Y`	Network outputs	`No`-by-`TS` cell array, where each element `Y{i,ts}` is a `Ui`-by-`Q` matrix
`E`	Network errors	`Nt`-by-`TS` cell array, where each element `P{i,ts}` is a `Vi`-by-`Q` matrix
`perf`	Network performance	

Utility Function Variables

These variables are used only by the utility functions.

`Pc`	Combined inputs	`Ni`-by-`(ID+TS)` cell array, where each element `P{i,ts}` is an `Ri`-by-`Q` matrix `Pc = [Pi P]` = Initial input delay conditions and network inputs
`Pd`	Delayed inputs	Ni-by-Nj-by-TS cell array, where each element Pd{i,j,ts} is an (Ri*IWD(i,j))-by-Q matrix, and where IWD(i,j) is the number of delay taps associated with the input weight to layer i from input j Equivalently, `IWD(i,j) = length(net.inputWeights{i,j}.delays)` `Pd` is the result of passing the elements of `P` through each input weight's tap delay lines. Because inputs are always transformed by input delays in the same way, it saves time to do that operation only once instead of for every training step.
`BZ`	Concurrent bias vectors	`Nl`-by-1 cell array, where each element `BZ{i}` is an `Si`-by-Q matrix Each matrix is simply `Q` copies of the `net.b{i}` bias vector.
`IWZ`	Weighted inputs	`Ni`-by-`Nl`-by-`TS` cell array, where each element `IWZ{i,j,ts}` is an `Si`-by-`???`-by-`Q` matrix
`LWZ`	Weighted layer outputs	`Ni`-by-`Nl`-by-`TS` cell array, where each element `LWZ{i,j,ts}` is an `Si`-by-`Q` matrix
`N`	Net inputs	`Ni`-by-`TS` cell array, where each element `N{i,ts}` is an `Si`-by-`Q` matrix
`A`	Layer outputs	`Nl`-by-`TS` cell array, where each element `A{i,ts}` is an `Si`-by-`Q` matrix
`Ac`	Combined layer outputs	`Nl`-by-`(LD+TS)` cell array, where each element `A{i,ts}` is an `Si`-by-`Q` matrix `Ac = [Ai A]` = Initial layer delay conditions and layer outputs.

`Tl`	Layer targets	`Nl`-by-`TS` cell array, where each element `Tl{i,ts}` is an `Si`-by-`Q` matrix `Tl` contains empty matrices `[]` in rows of layers `i` not associated with targets, indicated by `net.targets(i) == 0`.
`El`	Layer errors	`Nl`-by-`TS` cell array, where each element `El{i,ts}` is an `Si`-by-`Q` matrix `El` contains empty matrices `[]` in rows of layers `i` not associated with targets, indicated by `net.targets(i) == 0`.
`X`	Column vector of all weight and bias values
