Deep Learning in MATLAB

In this section...

What Is Deep Learning?

Deep learning is a branch of machine learning that teaches computers to do what comes naturally to humans: learn from experience. Machine learning algorithms use computational methods to “learn” information directly from data without relying on a predetermined equation as a model. Deep learning is especially suited for image recognition, which is important for solving problems such as facial recognition, motion detection, and many advanced driver assistance technologies such as autonomous driving, lane detection, pedestrian detection, and autonomous parking.

Deep Learning Toolbox provides simple MATLAB commands for creating and interconnecting the layers of a deep neural network. Examples and pretrained networks make it easy to use MATLAB for deep learning, even without knowledge of advanced computer vision algorithms or neural networks.

For a free hands-on introduction to practical deep learning methods, see Deep Learning Onramp.

What Do You Want to Do?	Learn More
Perform transfer learning to fine-tune a network with your data	“Start Deep Learning Faster Using Transfer Learning” on page 1-5 **Tip** Fine-tuning a pretrained network to learn a new task is typically much faster and easier than training a new network.
Classify images with pretrained networks	“Pretrained Deep Neural Networks” on page 1-8

Train on CPU, GPU, multiple GPUs, in parallel on your desktop or on clusters in the cloud, and work with data sets too large to fit in memory	"Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud" on page 7-2 "Deep Learning with Big Data" on page 7-17

To learn more about deep learning application areas, including automated driving, see "Deep Learning Applications".

To choose whether to use a pretrained network or create a new deep network, consider the scenarios in this table.

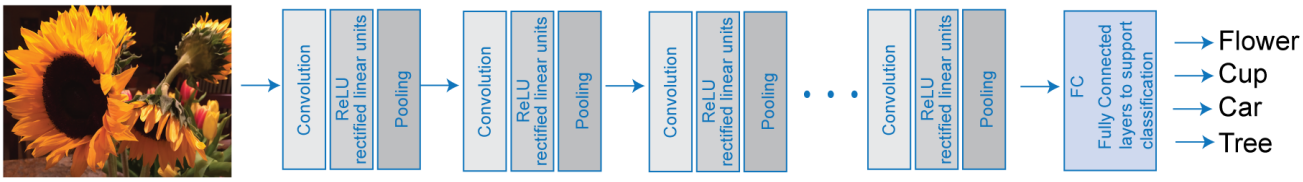
	Use a Pretrained Network for Transfer Learning	Create a New Deep Network
Training Data	Hundreds to thousands of labeled images (small)	Thousands to millions of labeled images
Computation	Moderate computation (GPU optional)	Compute intensive (requires GPU for speed)
Training Time	Seconds to minutes	Days to weeks for real problems
Model Accuracy	Good, depends on the pretrained model	High, but can overfit to small data sets

For more information, see "Choose Network Architecture" on page 1-67.

Deep learning uses neural networks to learn useful representations of features directly from data. Neural networks combine multiple nonlinear processing layers, using simple elements operating in parallel and inspired by biological nervous systems. Deep learning models can achieve state-of-the-art accuracy in object classification, sometimes exceeding human-level performance.

You train models using a large set of labeled data and neural network architectures that contain many layers, usually including some convolutional layers. Training these models is computationally

intensive and you can usually accelerate training by using a high performance GPU. This diagram shows how convolutional neural networks combine layers that automatically learn features from many images to classify new images.



Many deep learning applications use image files, and sometimes millions of image files. To access many image files for deep learning efficiently, MATLAB provides the `imageDatastore` function. Use this function to:

- Automatically read batches of images for faster processing in machine learning and computer vision applications
- Import data from image collections that are too large to fit in memory
- Label your image data automatically based on folder names

Try Deep Learning in 10 Lines of MATLAB Code

This example shows how to use deep learning to identify objects on a live webcam using only 10 lines of MATLAB code. Try the example to see how simple it is to get started with deep learning in MATLAB.

1. Run these commands to get the downloads if needed, connect to the webcam, and get a pretrained neural network.

   ```
   camera = webcam; % Connect to the camera
   net = alexnet;   % Load the neural network
   ```

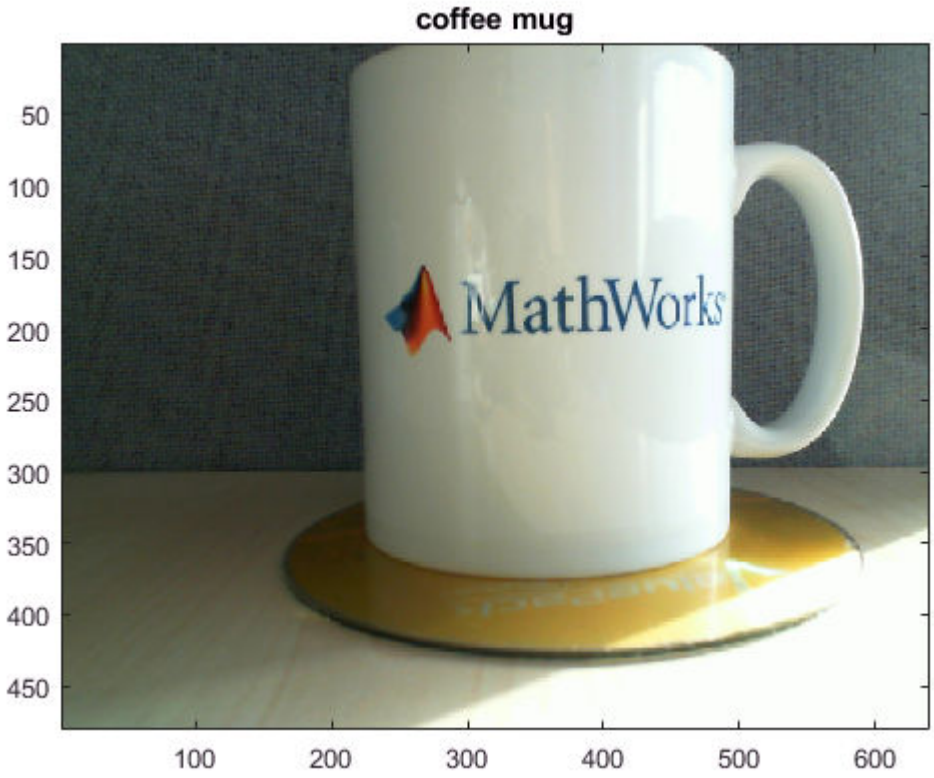
   If you need to install the `webcam` and `alexnet` add-ons, a message from each function appears with a link to help you download the free add-ons using Add-On Explorer. Alternatively, see Deep Learning Toolbox Model *for AlexNet Network* and MATLAB Support Package for USB Webcams.

   After you install Deep Learning Toolbox Model *for AlexNet Network*, you can use it to classify images. AlexNet is a pretrained convolutional neural network (CNN) that has been trained on more than a million images and can classify images into 1000 object categories (for example, keyboard, mouse, coffee mug, pencil, and many animals).
2. Run the following code to show and classify live images. Point the webcam at an object and the neural network reports what class of object it thinks the webcam is showing. It will keep classifying images until you press **Ctrl+C**. The code resizes the image for the network using `imresize`.

   ```
   while true
       im = snapshot(camera);       % Take a picture
       image(im);                   % Show the picture
       im = imresize(im,[227 227]); % Resize the picture for alexnet
       label = classify(net,im);    % Classify the picture
       title(char(label));          % Show the class label
   ```

```
    drawnow
end
```

In this example, the network correctly classifies a coffee mug. Experiment with objects in your surroundings to see how accurate the network is.



To watch a video of this example, see Deep Learning in 11 Lines of MATLAB Code.

To learn how to extend this example and show the probability scores of classes, see “Classify Webcam Images Using Deep Learning” on page 3-2.

For next steps in deep learning, you can use the pretrained network for other tasks. Solve new classification problems on your image data with transfer learning or feature extraction. For examples, see “Start Deep Learning Faster Using Transfer Learning” on page 1-5 and “Train Classifiers Using Features Extracted from Pretrained Networks” on page 1-6. To try other pretrained networks, see “Pretrained Deep Neural Networks” on page 1-8.

Start Deep Learning Faster Using Transfer Learning

Transfer learning is commonly used in deep learning applications. You can take a pretrained network and use it as a starting point to learn a new task. Fine-tuning a network with transfer learning is much faster and easier than training from scratch. You can quickly make the network learn a new task using a smaller number of training images. The advantage of transfer learning is that the pretrained network has already learned a rich set of features that can be applied to a wide range of other similar tasks.

For example, if you take a network trained on thousands or millions of images, you can retrain it for new object detection using only hundreds of images. You can effectively fine-tune a pretrained

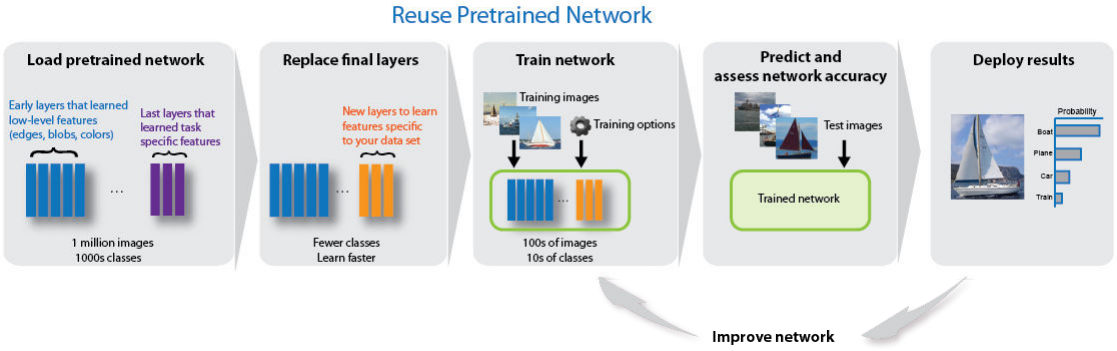
network with much smaller data sets than the original training data. If you have a very large dataset, then transfer learning might not be faster than training a new network.

Transfer learning enables you to:

- Transfer the learned features of a pretrained network to a new problem
- Transfer learning is faster and easier than training a new network
- Reduce training time and dataset size
- Perform deep learning without needing to learn how to create a whole new network

For an interactive example, see “Transfer Learning with Deep Network Designer” on page 2-2.

For a programmatic example, see “Train Deep Learning Network to Classify New Images” on page 3-6.



Train Classifiers Using Features Extracted from Pretrained Networks

Feature extraction allows you to use the power of pretrained networks without investing time and effort into training. Feature extraction can be the fastest way to use deep learning. You extract learned features from a pretrained network, and use those features to train a classifier, for example, a support vector machine (SVM — requires Statistics and Machine Learning Toolbox™). For example, if an SVM trained using `alexnet` can achieve >90% accuracy on your training and validation set, then fine-tuning with transfer learning might not be worth the effort to gain some extra accuracy. If you perform fine-tuning on a small dataset, then you also risk overfitting. If the SVM cannot achieve good enough accuracy for your application, then fine-tuning is worth the effort to seek higher accuracy.

For an example, see “Extract Image Features Using Pretrained Network” on page 3-28.

Deep Learning with Big Data on CPUs, GPUs, in Parallel, and on the Cloud

Neural networks are inherently parallel algorithms. You can take advantage of this parallelism by using Parallel Computing Toolbox™ to distribute training across multicore CPUs, graphical processing units (GPUs), and clusters of computers with multiple CPUs and GPUs.

Training deep networks is extremely computationally intensive and you can usually accelerate training by using a high performance GPU. If you do not have a suitable GPU, you can train on one or more CPU cores instead. You can train a convolutional neural network on a single GPU or CPU, or on

multiple GPUs or CPU cores, or in parallel on a cluster. Using GPU or parallel options requires Parallel Computing Toolbox.

You do not need multiple computers to solve problems using data sets too large to fit in memory. You can use the `imageDatastore` function to work with batches of data without needing a cluster of machines. However, if you have a cluster available, it can be helpful to take your code to the data repository rather than moving large amounts of data around.

To learn more about deep learning with large data sets, see “Deep Learning with Big Data” on page 7-17.

Pretrained Deep Neural Networks

In this section...

You can take a pretrained image classification network that has already learned to extract powerful and informative features from natural images and use it as a starting point to learn a new task. The majority of the pretrained networks are trained on a subset of the ImageNet database [1], which is used in the ImageNet Large-Scale Visual Recognition Challenge (ILSVRC) [2]. These networks have been trained on more than a million images and can classify images into 1000 object categories, such as keyboard, coffee mug, pencil, and many animals. Using a pretrained network with transfer learning is typically much faster and easier than training a network from scratch.

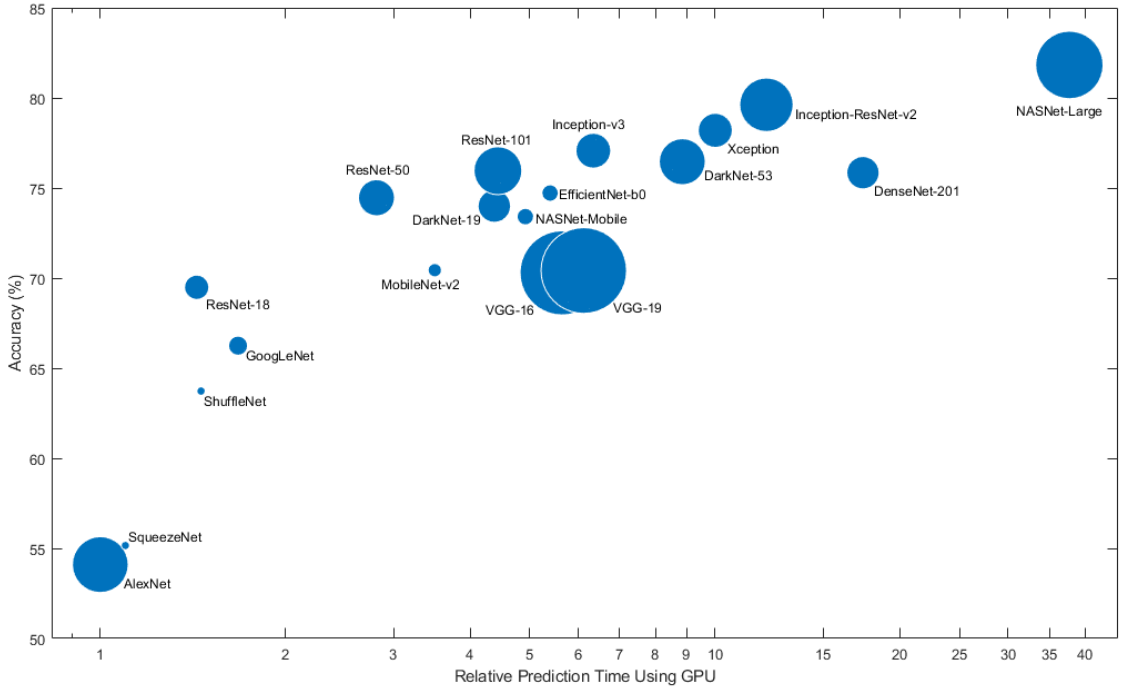
You can use previously trained networks for the following tasks:

Purpose	Description
Classification	Apply pretrained networks directly to classification problems. To classify a new image, use `classify`. For an example showing how to use a pretrained network for classification, see “Classify Image Using GoogLeNet” on page 3-23.
Feature Extraction	Use a pretrained network as a feature extractor by using the layer activations as features. You can use these activations as features to train another machine learning model, such as a support vector machine (SVM). For more information, see “Feature Extraction” on page 1-13. For an example, see “Extract Image Features Using Pretrained Network” on page 3-28.
Transfer Learning	Take layers from a network trained on a large data set and fine-tune on a new data set. For more information, see “Transfer Learning” on page 1-14. For a simple example, see “Get Started with Transfer Learning”. To try more pretrained networks, see “Train Deep Learning Network to Classify New Images” on page 3-6.

Compare Pretrained Networks

Pretrained networks have different characteristics that matter when choosing a network to apply to your problem. The most important characteristics are network accuracy, speed, and size. Choosing a network is generally a tradeoff between these characteristics. Use the plot below to compare the ImageNet validation accuracy with the time required to make a prediction using the network.

Tip To get started with transfer learning, try choosing one of the faster networks, such as SqueezeNet or GoogLeNet. You can then iterate quickly and try out different settings such as data preprocessing steps and training options. Once you have a feeling of which settings work well, try a more accurate network such as Inception-v3 or a ResNet and see if that improves your results.



Note The plot above only shows an indication of the relative speeds of the different networks. The exact prediction and training iteration times depend on the hardware and mini-batch size that you use.

A good network has a high accuracy and is fast. The plot displays the classification accuracy versus the prediction time when using a modern GPU (an NVIDIA® Tesla® P100) and a mini-batch size of 128. The prediction time is measured relative to the fastest network. The area of each marker is proportional to the size of the network on disk.

The classification accuracy on the ImageNet validation set is the most common way to measure the accuracy of networks trained on ImageNet. Networks that are accurate on ImageNet are also often accurate when you apply them to other natural image data sets using transfer learning or feature

extraction. This generalization is possible because the networks have learned to extract powerful and informative features from natural images that generalize to other similar data sets. However, high accuracy on ImageNet does not always transfer directly to other tasks, so it is a good idea to try multiple networks.

If you want to perform prediction using constrained hardware or distribute networks over the Internet, then also consider the size of the network on disk and in memory.

Network Accuracy

There are multiple ways to calculate the classification accuracy on the ImageNet validation set and different sources use different methods. Sometimes an ensemble of multiple models is used and sometimes each image is evaluated multiple times using multiple crops. Sometimes the top-5 accuracy instead of the standard (top-1) accuracy is quoted. Because of these differences, it is often not possible to directly compare the accuracies from different sources. The accuracies of pretrained networks in Deep Learning Toolbox are standard (top-1) accuracies using a single model and single central image crop.

Load Pretrained Networks

To load the SqueezeNet network, type `squeezenet` at the command line.

```
net = squeezenet;
```

For other networks, use functions such as `googlenet` to get links to download pretrained networks from the Add-On Explorer.

The following table lists the available pretrained networks trained on ImageNet and some of their properties. The network depth is defined as the largest number of sequential convolutional or fully connected layers on a path from the input layer to the output layer. The inputs to all networks are RGB images.

Network	Depth	Size	Parameters (Millions)	Image Input Size
`squeezenet`	18	5.2 MB	1.24	227-by-227
`googlenet`	22	27 MB	7.0	224-by-224
`inceptionv3`	48	89 MB	23.9	299-by-299
`densenet201`	201	77 MB	20.0	224-by-224
`mobilenetv2`	53	13 MB	3.5	224-by-224
`resnet18`	18	44 MB	11.7	224-by-224
`resnet50`	50	96 MB	25.6	224-by-224
`resnet101`	101	167 MB	44.6	224-by-224
`xception`	71	85 MB	22.9	299-by-299
`inceptionresnetv2`	164	209 MB	55.9	299-by-299
`shufflenet`	50	5.4 MB	1.4	224-by-224
`nasnetmobile`	*	20 MB	5.3	224-by-224

Network	Depth	Size	Parameters (Millions)	Image Input Size
`nasnetlarge`	*	332 MB	88.9	331-by-331
`darknet19`	19	78 MB	20.8	256-by-256
`darknet53`	53	155 MB	41.6	256-by-256
`efficientnetb0`	82	20 MB	5.3	224-by-224
`alexnet`	8	227 MB	61.0	227-by-227
`vgg16`	16	515 MB	138	224-by-224
`vgg19`	19	535 MB	144	224-by-224

*The NASNet-Mobile and NASNet-Large networks do not consist of a linear sequence of modules.

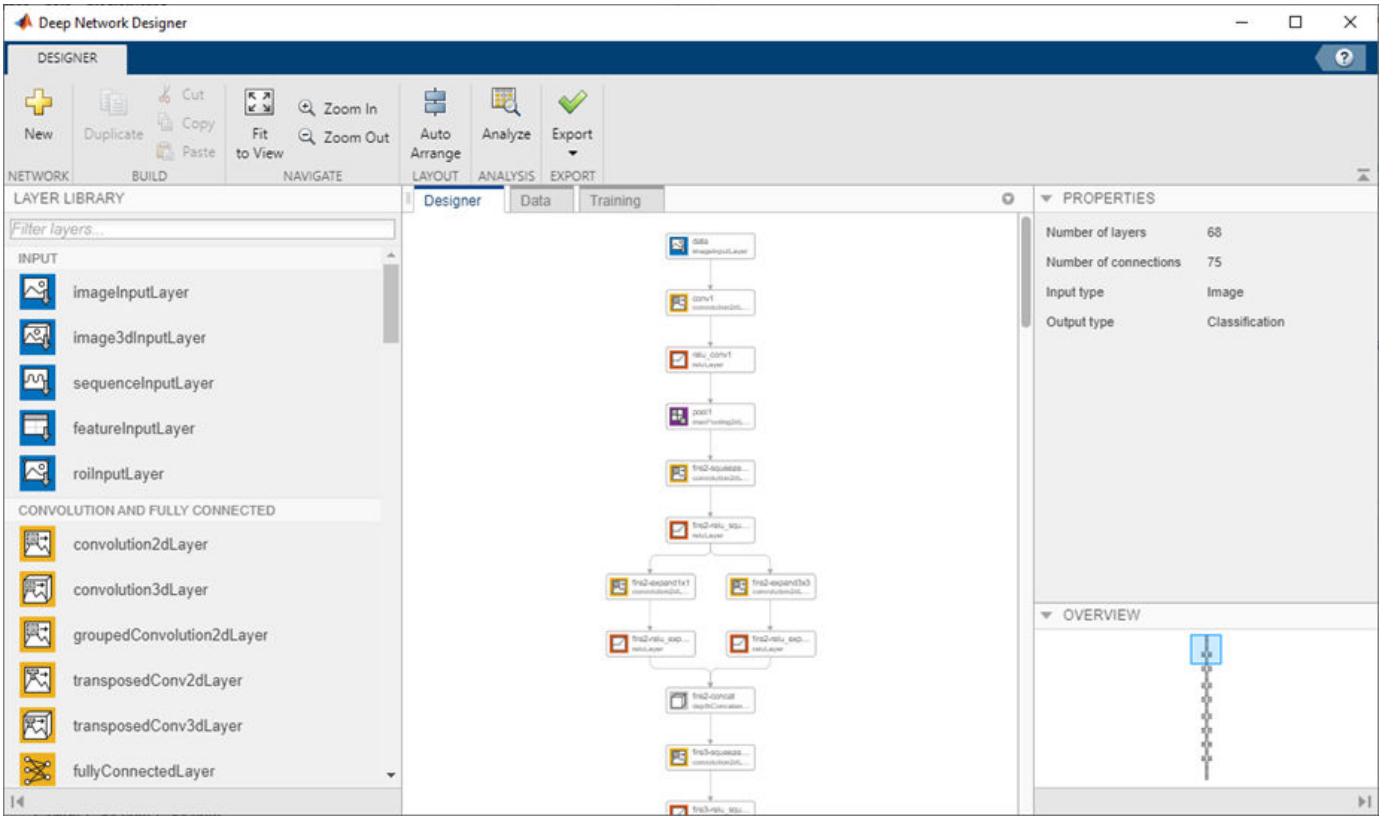
GoogLeNet Trained on Places365

The standard GoogLeNet network is trained on the ImageNet data set but you can also load a network trained on the Places365 data set [3] [4]. The network trained on Places365 classifies images into 365 different place categories, such as field, park, runway, and lobby. To load a pretrained GoogLeNet network trained on the Places365 data set, use `googlenet('Weights','places365')`. When performing transfer learning to perform a new task, the most common approach is to use networks pretrained on ImageNet. If the new task is similar to classifying scenes, then using the network trained on Places365 could give higher accuracies.

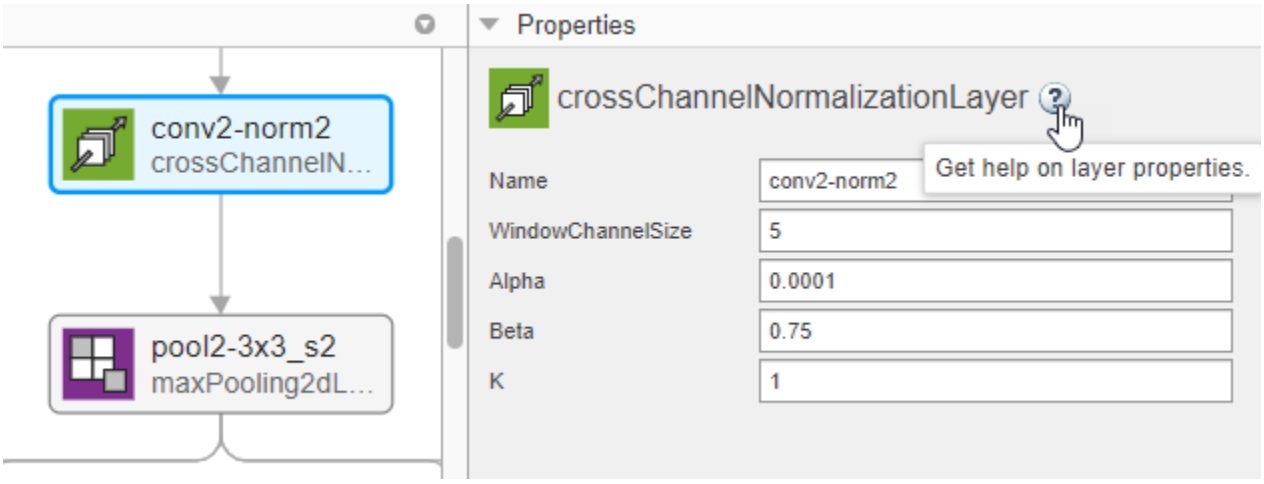
Visualize Pretrained Networks

You can load and visualize pretrained networks using **Deep Network Designer**.

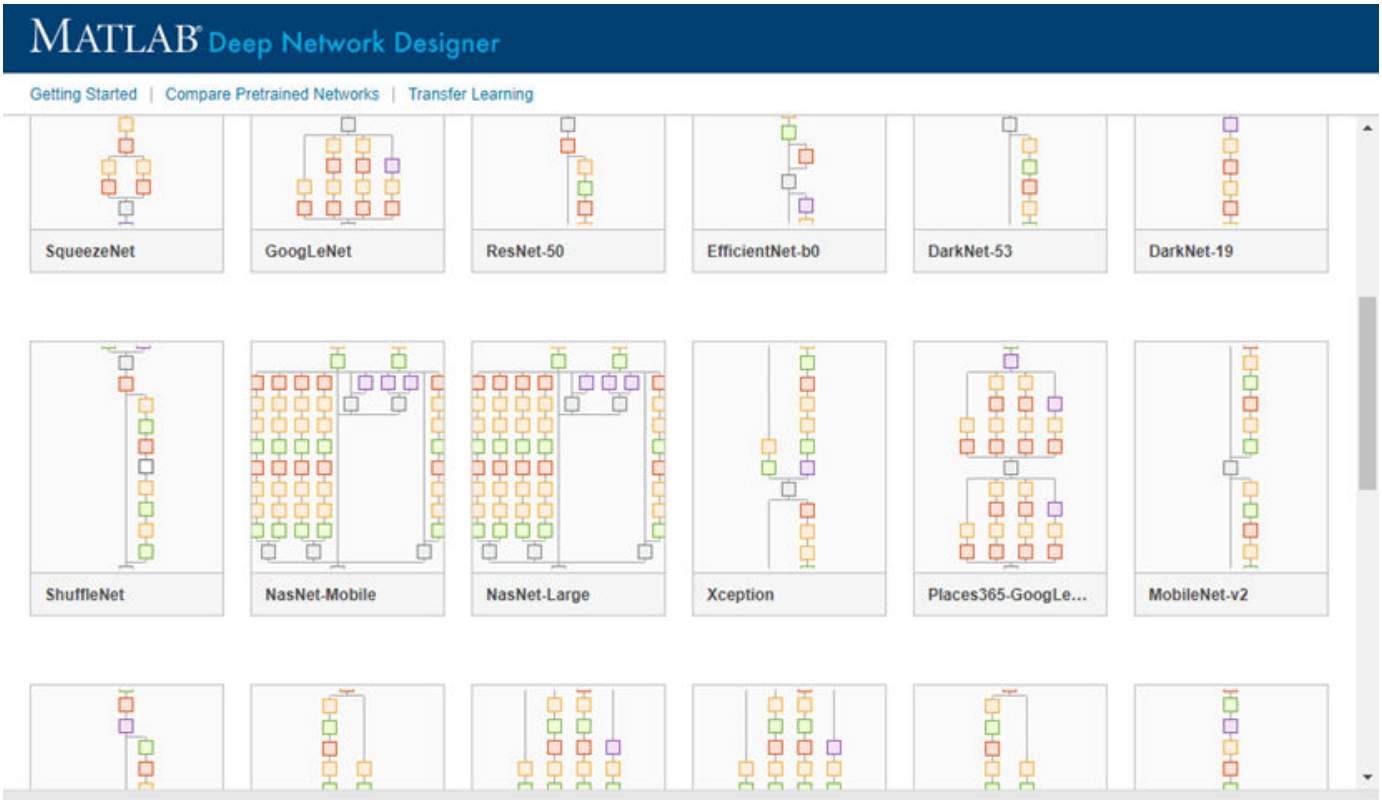
```
deepNetworkDesigner(squeezenet)
```



To view and edit layer properties, select a layer. Click the help icon next to the layer name for information on the layer properties.



Explore other pretrained networks in Deep Network Designer by clicking **New**.



If you need to download a network, pause on the desired network and click **Install** to open the Add-On Explorer.

Feature Extraction

Feature extraction is an easy and fast way to use the power of deep learning without investing time and effort into training a full network. Because it only requires a single pass over the training images, it is especially useful if you do not have a GPU. You extract learned image features using a pretrained network, and then use those features to train a classifier, such as a support vector machine using `fitcsvm`.

Try feature extraction when your new data set is very small. Since you only train a simple classifier on the extracted features, training is fast. It is also unlikely that fine-tuning deeper layers of the network improves the accuracy since there is little data to learn from.

- If your data is very similar to the original data, then the more specific features extracted deeper in the network are likely to be useful for the new task.
- If your data is very different from the original data, then the features extracted deeper in the network might be less useful for your task. Try training the final classifier on more general features extracted from an earlier network layer. If the new data set is large, then you can also try training a network from scratch.

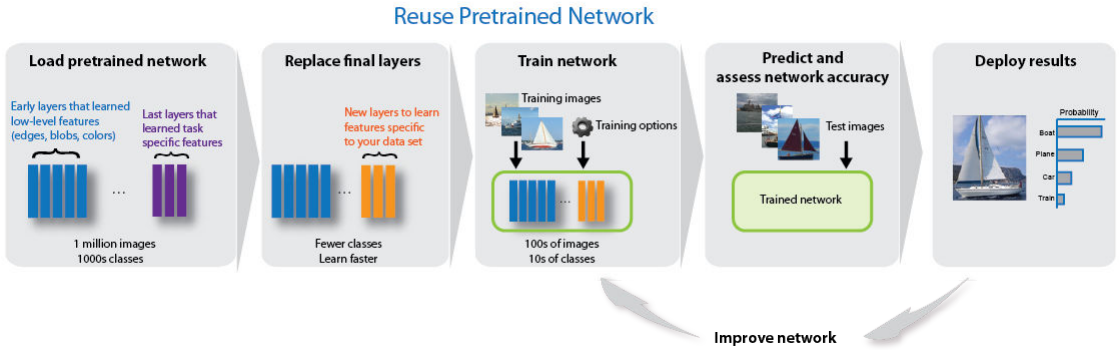
ResNets are often good feature extractors. For an example showing how to use a pretrained network for feature extraction, see “Extract Image Features Using Pretrained Network” on page 3-28.

Transfer Learning

You can fine-tune deeper layers in the network by training the network on your new data set with the pretrained network as a starting point. Fine-tuning a network with transfer learning is often faster and easier than constructing and training a new network. The network has already learned a rich set of image features, but when you fine-tune the network it can learn features specific to your new data set. If you have a very large data set, then transfer learning might not be faster than training from scratch.

Tip Fine-tuning a network often gives the highest accuracy. For very small data sets (fewer than about 20 images per class), try feature extraction instead.

Fine-tuning a network is slower and requires more effort than simple feature extraction, but since the network can learn to extract a different set of features, the final network is often more accurate. Fine-tuning usually works better than feature extraction as long as the new data set is not very small, because then the network has data to learn new features from. For examples showing how to perform transfer learning, see “Transfer Learning with Deep Network Designer” on page 2-2 and “Train Deep Learning Network to Classify New Images” on page 3-6.



Import and Export Networks

You can import networks and network architectures from TensorFlow®-Keras, Caffe, and the ONNX™ (Open Neural Network Exchange) model format. You can also export trained networks to the ONNX model format.

Import from Keras

Import pretrained networks from TensorFlow-Keras by using `importKerasNetwork`. You can import the network and weights either from the same HDF5 (.h5) file or separate HDF5 and JSON (.json) files. For more information, see `importKerasNetwork`.

Import network architectures from TensorFlow-Keras by using `importKerasLayers`. You can import the network architecture, either with or without weights. You can import the network architecture and weights either from the same HDF5 (.h5) file or separate HDF5 and JSON (.json) files. For more information, see `importKerasLayers`.

Import from Caffe

Import pretrained networks from Caffe by using the `importCaffeNetwork` function. There are many pretrained networks available in Caffe Model Zoo [5]. Download the desired `.prototxt`

and `.caffemodel` files and use `importCaffeNetwork` to import the pretrained network into MATLAB. For more information, see `importCaffeNetwork`.

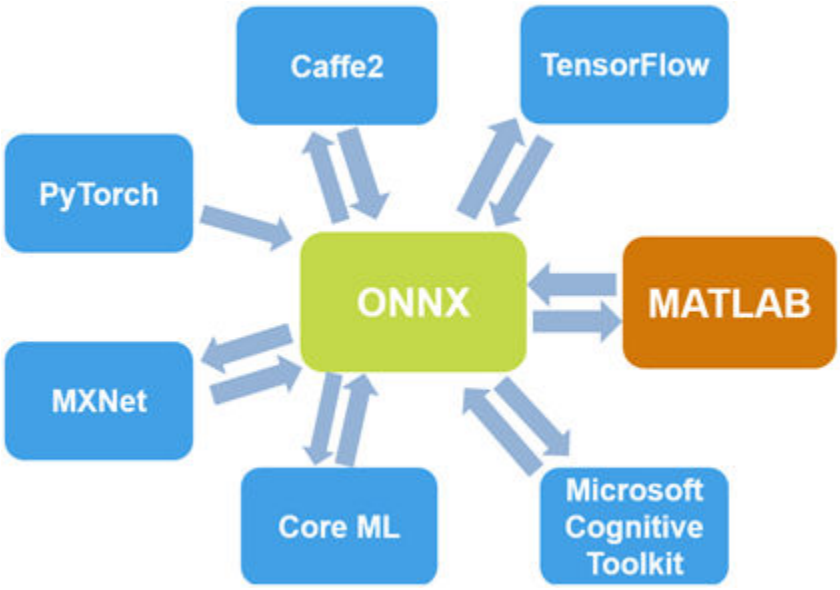
You can import network architectures of Caffe networks. Download the desired `.prototxt` file and use `importCaffeLayers` to import the network layers into MATLAB. For more information, see `importCaffeLayers`.

Export to and Import from ONNX

By using ONNX as an intermediate format, you can interoperate with other deep learning frameworks that support ONNX model export or import, such as TensorFlow, PyTorch, Caffe2, Microsoft® Cognitive Toolkit (CNTK), Core ML, and Apache MXNet.

Export a trained Deep Learning Toolbox network to the ONNX model format by using the `exportONNXNetwork` function. You can then import the ONNX model to other deep learning frameworks that support ONXX model import.

Import pretrained networks from ONNX using `importONNXNetwork` and import network architectures with or without weights using `importONNXLayers`.



Pretrained Networks for Audio Applications

Use pretrained networks for audio and speech processing applications by using Deep Learning Toolbox together with Audio Toolbox™.

Audio Toolbox provides the pretrained VGGish and YAMNet networks. Use the `vggish` and `yamnet` functions to interact directly with the pretrained networks. The `classifySound` function performs required preprocessing and postprocessing for YAMNet so that you can locate and classify sounds into one of 521 categories. You can explore the YAMNet ontology using the `yamnetGraph` function. The `vggishFeatures` function performs necessary preprocessing and postprocessing for VGGish so that you can extract feature embeddings to input to machine learning and deep learning systems. For more information on using deep learning for audio applications, see “Introduction to Deep Learning for Audio Applications” (Audio Toolbox).

Use VGGish and YAMNet to perform transfer learning and feature extraction. For example, see "Transfer Learning with Pretrained Audio Networks" (Audio Toolbox).

Pretrained Models on GitHub

To find the latest pretrained models and examples, see MATLAB Deep Learning (GitHub).

For example:

- For transformer models, such as GPT-2, BERT, and FinBERT, see the Transformer Models for MATLAB GitHub® repository.
- For pretrained YOLO-v4 object detection models such as YOLOv4-coco and YOLOv4-tiny-coco, see the Pretrained YOLO-v4 Network for Object Detection GitHub repository.

Learn About Convolutional Neural Networks

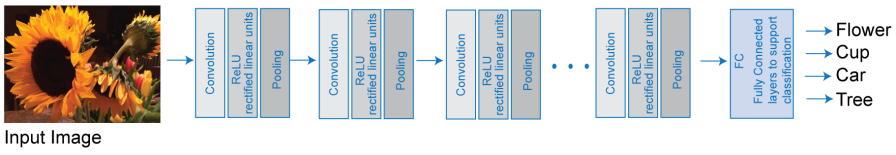
Convolutional neural networks (ConvNets) are widely used tools for deep learning. They are specifically suitable for images as inputs, although they are also used for other applications such as text, signals, and other continuous responses. They differ from other types of neural networks in a few ways:

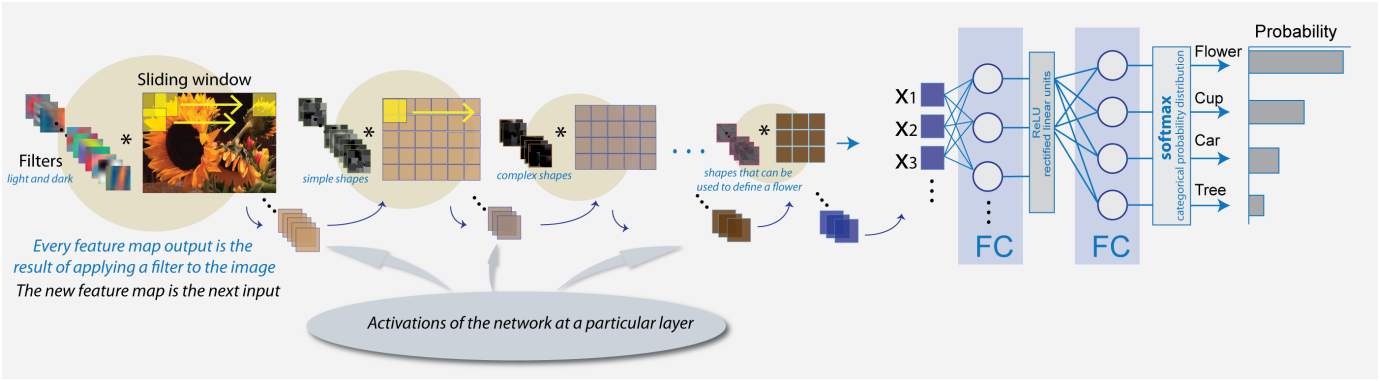
Convolutional neural networks are inspired from the biological structure of a visual cortex, which contains arrangements of simple and complex cells [1]. These cells are found to activate based on the subregions of a visual field. These subregions are called receptive fields. Inspired from the findings of this study, the neurons in a convolutional layer connect to the subregions of the layers before that layer instead of being fully-connected as in other types of neural networks. The neurons are unresponsive to the areas outside of these subregions in the image.

These subregions might overlap, hence the neurons of a ConvNet produce spatially-correlated outcomes, whereas in other types of neural networks, the neurons do not share any connections and produce independent outcomes.

In addition, in a neural network with fully-connected neurons, the number of parameters (weights) can increase quickly as the size of the input increases. A convolutional neural network reduces the number of parameters with the reduced number of connections, shared weights, and downsampling.

A ConvNet consists of multiple layers, such as convolutional layers, max-pooling or average-pooling layers, and fully-connected layers.





The neurons in each layer of a ConvNet are arranged in a 3-D manner, transforming a 3-D input to a 3-D output. For example, for an image input, the first layer (input layer) holds the images as 3-D inputs, with the dimensions being height, width, and the color channels of the image. The neurons in the first convolutional layer connect to the regions of these images and transform them into a 3-D output. The hidden units (neurons) in each layer learn nonlinear combinations of the original inputs, which is called feature extraction [2]. These learned features, also known as activations, from one layer become the inputs for the next layer. Finally, the learned features become the inputs to the classifier or the regression function at the end of the network.

The architecture of a ConvNet can vary depending on the types and numbers of layers included. The types and number of layers included depends on the particular application or data. For example, if you have categorical responses, you must have a classification function and a classification layer, whereas if your response is continuous, you must have a regression layer at the end of the network. A smaller network with only one or two convolutional layers might be sufficient to learn a small number of gray scale image data. On the other hand, for more complex data with millions of colored images, you might need a more complicated network with multiple convolutional and fully connected layers.

You can concatenate the layers of a convolutional neural network in MATLAB in the following way:

```
layers = [imageInputLayer([28 28 1])
          convolution2dLayer(5,20)
          reluLayer
          maxPooling2dLayer(2,'Stride',2)
          fullyConnectedLayer(10)
          softmaxLayer
          classificationLayer];
```

After defining the layers of your network, you must specify the training options using the `trainingOptions` function. For example,

```
options = trainingOptions('sgdm');
```

Then, you can train the network with your training data using the `trainNetwork` function. The data, layers, and training options become the inputs to the training function. For example,

```
convnet = trainNetwork(data,layers,options);
```

For detailed discussion of layers of a ConvNet, see “Specify Layers of Convolutional Neural Network” on page 1-31. For setting up training parameters, see “Set Up Parameters and Train Convolutional Neural Network” on page 1-42.

Multiple-Input and Multiple-Output Networks

In Deep Learning Toolbox, you can define network architectures with multiple inputs (for example, networks trained on multiple sources and types of data) or multiple outputs (for example, networks that predicts both classification and regression responses).

Multiple-Input Networks

Define networks with multiple inputs when the network requires data from multiple sources or in different formats. For example, networks that require image data captured from multiple sensors at different resolutions.

Training

To define and train a deep learning network with multiple inputs, specify the network architecture using a `layerGraph` object and train using the `trainNetwork` function with datastore input.

To use a datastore for networks with multiple input layers, use the `combine` and `transform` functions to create a datastore that outputs a cell array with (`numInputs` + 1) columns, where `numInputs` is the number of network inputs. In this case, the first `numInputs` columns specify the predictors for each input and the last column specifies the responses. The order of inputs is given by the `InputNames` property of the layer graph `layers`.

Tip If the network also has multiple outputs, then you must use a custom training loop. for more information, see “Multiple-Output Networks” on page 1-19.

Prediction

To make predictions on a trained deep learning network with multiple inputs, use either the `predict` or `classify` function. Specify multiple inputs using one of the following:

- `combinedDatastore` object
- `transformedDatastore` object
- multiple numeric arrays

Multiple-Output Networks

Define networks with multiple outputs for tasks requiring multiple responses in different formats. For example, tasks requiring both categorical and numeric output.

Training

To train a deep learning network with multiple outputs, use a custom training loop. For an example, see “Train Network with Multiple Outputs” on page 3-61.

Prediction

To make predictions using a model function, use the model function directly with the trained parameters. For an example, see “Make Predictions Using Model Function” on page 18-286.

Alternatively, convert the model function to a `DAGNetwork` object using the `assembleNetwork` function. With the assembled network, you can:

- Make predictions with other data types such as datastores using the `predict` function for `DAGNetwork` objects.
- Specify prediction options such as the mini-batch size using the `predict` function for `DAGNetwork` objects.
- Save the network in a MAT file.

For an example, see “Assemble Multiple-Output Network for Prediction” on page 18-196.

List of Deep Learning Layers

This page provides a list of deep learning layers in MATLAB.

To learn how to create networks from layers for different tasks, see the following examples.

Task	Learn More
Create deep learning networks for image classification or regression.	“Create Simple Deep Learning Network for Classification” on page 3-47 “Train Convolutional Neural Network for Regression” on page 3-53 “Train Residual Network for Image Classification” on page 3-13
Create deep learning networks for sequence and time series data.	“Sequence Classification Using Deep Learning” on page 4-2 “Time Series Forecasting Using Deep Learning” on page 4-15
Create deep learning network for audio data.	“Speech Command Recognition Using Deep Learning” on page 4-23
Create deep learning network for text data.	“Classify Text Data Using Deep Learning” on page 4-89 “Generate Text Using Deep Learning” on page 4-180

Deep Learning Layers

Use the following functions to create different layer types. Alternatively, use the **Deep Network Designer** app to create networks interactively.

To learn how to define your own custom layers, see “Define Custom Deep Learning Layers” on page 18-9.

Input Layers

Layer	Description
 `imageInputLayer`	An image input layer inputs 2-D images to a network and applies data normalization.
 `image3dInputLayer`	A 3-D image input layer inputs 3-D images or volumes to a network and applies data normalization.
 `sequenceInputLayer`	A sequence input layer inputs sequence data to a network.

Layer	Description
 `featureInputLayer`	A feature input layer inputs feature data to a network and applies data normalization. Use this layer when you have a data set of numeric scalars representing features (data without spatial or time dimensions).
 `roiInputLayer`	An ROI input layer inputs images to a Fast R-CNN object detection network.

Convolution and Fully Connected Layers

Layer	Description
 `convolution1dLayer`	A 1-D convolutional layer applies sliding convolutional filters to 1-D input.
 `convolution2dLayer`	A 2-D convolutional layer applies sliding convolutional filters to 2-D input.
 `convolution3dLayer`	A 3-D convolutional layer applies sliding cuboidal convolution filters to 3-D input.
 `groupedConvolution2dLayer`	A 2-D grouped convolutional layer separates the input channels into groups and applies sliding convolutional filters. Use grouped convolutional layers for channel-wise separable (also known as depth-wise separable) convolution.
 `transposedConv2dLayer`	A transposed 2-D convolution layer upsamples feature maps.
 `transposedConv3dLayer`	A transposed 3-D convolution layer upsamples three-dimensional feature maps.
 `fullyConnectedLayer`	A fully connected layer multiplies the input by a weight matrix and then adds a bias vector.

Sequence Layers

Layer	Description
 `sequenceInputLayer`	A sequence input layer inputs sequence data to a network.
 `lstmLayer`	An LSTM layer learns long-term dependencies between time steps in time series and sequence data.
 `bilstmLayer`	A bidirectional LSTM (BiLSTM) layer learns bidirectional long-term dependencies between time steps of time series or sequence data. These dependencies can be useful when you want the network to learn from the complete time series at each time step.

Layer	Description
 `gruLayer`	A GRU layer learns dependencies between time steps in time series and sequence data.
 `convolution1dLayer`	A 1-D convolutional layer applies sliding convolutional filters to 1-D input.
 `maxPooling1dLayer`	A 1-D max pooling layer performs downsampling by dividing the input into 1-D pooling regions, then computing the maximum of each region.
 `averagePooling1dLayer`	A 1-D average pooling layer performs downsampling by dividing the input into 1-D pooling regions, then computing the average of each region.
 `globalMaxPooling1dLayer`	A 1-D global max pooling layer performs downsampling by outputting the maximum of the time or spatial dimensions of the input.
 `sequenceFoldingLayer`	A sequence folding layer converts a batch of image sequences to a batch of images. Use a sequence folding layer to perform convolution operations on time steps of image sequences independently.
 `sequenceUnfoldingLayer`	A sequence unfolding layer restores the sequence structure of the input data after sequence folding.
 `flattenLayer`	A flatten layer collapses the spatial dimensions of the input into the channel dimension.
 `wordEmbeddingLayer`	A word embedding layer maps word indices to vectors.
 `peepholeLSTMLayer` on page 18-75 (Custom layer example)	

Activation Layers

Layer	Description
 `reluLayer`	A ReLU layer performs a threshold operation to each element of the input, where any value less than zero is set to zero.
 `leakyReluLayer`	A leaky ReLU layer performs a threshold operation, where any input value less than zero is multiplied by a fixed scalar.
 `clippedReluLayer`	A clipped ReLU layer performs a threshold operation, where any input value less than zero is set to zero and any value above the *clipping ceiling* is set to that clipping ceiling.

Layer	Description
 `eluLayer`	An ELU activation layer performs the identity operation on positive inputs and an exponential nonlinearity on negative inputs.
 `tanhLayer`	A hyperbolic tangent (tanh) activation layer applies the tanh function on the layer inputs.
 `swishLayer`	A swish activation layer applies the swish function on the layer inputs.
 `softplusLayer`	A softplus layer applies the softplus activation function $Y = \log(1 + e^X)$, which ensures that the output is always positive. This activation function is a smooth continuous version of `reluLayer`. You can incorporate this layer into the deep neural networks you define for actors in reinforcement learning agents. This layer is useful for creating continuous Gaussian policy deep neural networks, for which the standard deviation output must be positive.
 `functionLayer`	A function layer applies a specified function to the layer input.
 `preluLayer` on page 18-35 (Custom layer example)	A peephole LSTM layer is a variant of an LSTM layer, where the gate calculations use the layer cell state.

Normalization, Dropout, and Cropping Layers

Layer	Description
 `batchNormalizationLayer`	A batch normalization layer normalizes a mini-batch of data across all observations for each channel independently. To speed up training of the convolutional neural network and reduce the sensitivity to network initialization, use batch normalization layers between convolutional layers and nonlinearities, such as ReLU layers.
 `groupNormalizationLayer`	A group normalization layer normalizes a mini-batch of data across grouped subsets of channels for each observation independently. To speed up training of the convolutional neural network and reduce the sensitivity to network initialization, use group normalization layers between convolutional layers and nonlinearities, such as ReLU layers.

Layer	Description
 `instanceNormalizationLayer`	An instance normalization layer normalizes a mini-batch of data across each channel for each observation independently. To improve the convergence of training the convolutional neural network and reduce the sensitivity to network hyperparameters, use instance normalization layers between convolutional layers and nonlinearities, such as ReLU layers.
 `layerNormalizationLayer`	A layer normalization layer normalizes a mini-batch of data across all channels for each observation independently. To speed up training of recurrent and multilayer perceptron neural networks and reduce the sensitivity to network initialization, use layer normalization layers after the learnable layers, such as LSTM and fully connected layers.
 `crossChannelNormalizationLayer`	A channel-wise local response (cross-channel) normalization layer carries out channel-wise normalization.
 `dropoutLayer`	A dropout layer randomly sets input elements to zero with a given probability.
 `crop2dLayer`	A 2-D crop layer applies 2-D cropping to the input.
 `crop3dLayer`	A 3-D crop layer crops a 3-D volume to the size of the input feature map.
 `scalingLayer`	A scaling layer linearly scales and biases an input array `U`, giving an output `Y = Scale.*U + Bias`. You can incorporate this layer into the deep neural networks you define for actors or critics in reinforcement learning agents. This layer is useful for scaling and shifting the outputs of nonlinear layers, such as `tanhLayer` and sigmoid.
 `quadraticLayer`	A quadratic layer takes an input vector and outputs a vector of quadratic monomials constructed from the input elements. This layer is useful when you need a layer whose output is some quadratic function of its inputs. For example, to recreate the structure of quadratic value functions such as those used in LQR controller design.
 `resize2dLayer`	A 2-D resize layer resizes 2-D input by a scale factor, to a specified height and width, or to the size of a reference input feature map.

Layer	Description
 `resize3dLayer`	A 3-D resize layer resizes 3-D input by a scale factor, to a specified height, width, and depth, or to the size of a reference input feature map.
 `stftLayer`	An STFT layer computes the short-time Fourier transform of the input.

Pooling and Unpooling Layers

Layer	Description
 `averagePooling1dLayer`	A 1-D average pooling layer performs downsampling by dividing the input into 1-D pooling regions, then computing the average of each region.
 `averagePooling2dLayer`	A 2-D average pooling layer performs downsampling by dividing the input into rectangular pooling regions, then computing the average values of each region.
 `averagePooling3dLayer`	A 3-D average pooling layer performs downsampling by dividing three-dimensional input into cuboidal pooling regions, then computing the average values of each region.
 `globalAveragePooling1dLayer`	A 1-D global average pooling layer performs downsampling by outputting the average of the time or spatial dimensions of the input.
 `globalAveragePooling2dLayer`	A 2-D global average pooling layer performs downsampling by computing the mean of the height and width dimensions of the input.
 `globalAveragePooling3dLayer`	A 3-D global average pooling layer performs downsampling by computing the mean of the height, width, and depth dimensions of the input.
 `maxPooling1dLayer`	A 1-D max pooling layer performs downsampling by dividing the input into 1-D pooling regions, then computing the maximum of each region.
 `maxPooling2dLayer`	A 2-D max pooling layer performs downsampling by dividing the input into rectangular pooling regions, then computing the maximum of each region.
 `maxPooling3dLayer`	A 3-D max pooling layer performs downsampling by dividing three-dimensional input into cuboidal pooling regions, then computing the maximum of each region.
 `globalMaxPooling1dLayer`	A 1-D global max pooling layer performs downsampling by outputting the maximum of the time or spatial dimensions of the input.

Layer	Description
 `globalMaxPooling2dLayer`	A 2-D global max pooling layer performs downsampling by computing the maximum of the height and width dimensions of the input.
 `globalMaxPooling3dLayer`	A 3-D global max pooling layer performs downsampling by computing the maximum of the height, width, and depth dimensions of the input.
 `maxUnpooling2dLayer`	A 2-D max unpooling layer unpools the output of a 2-D max pooling layer.

Combination Layers

Layer	Description
 `additionLayer`	An addition layer adds inputs from multiple neural network layers element-wise.
 `multiplicationLayer`	A multiplication layer multiplies inputs from multiple neural network layers element-wise.
 `depthConcatenationLayer`	A depth concatenation layer takes inputs that have the same height and width and concatenates them along the third dimension (the channel dimension).
 `concatenationLayer`	A concatenation layer takes inputs and concatenates them along a specified dimension. The inputs must have the same size in all dimensions except the concatenation dimension.
 `weightedAdditionLayer` on page 18-48 (Custom layer example)	A weighted addition layer scales and adds inputs from multiple neural network layers element-wise.

Object Detection Layers

Layer	Description
 `roiInputLayer`	An ROI input layer inputs images to a Fast R-CNN object detection network.
 `roiMaxPooling2dLayer`	An ROI max pooling layer outputs fixed size feature maps for every rectangular ROI within the input feature map. Use this layer to create a Fast or Faster R-CNN object detection network.
 `roiAlignLayer`	An ROI align layer outputs fixed size feature maps for every rectangular ROI within an input feature map. Use this layer to create a Mask R-CNN network.
 `anchorBoxLayer`	An anchor box layer stores anchor boxes for a feature map used in object detection networks.

Layer	Description
 `regionProposalLayer`	A region proposal layer outputs bounding boxes around potential objects in an image as part of the region proposal network (RPN) within Faster R-CNN.
 `ssdMergeLayer`	An SSD merge layer merges the outputs of feature maps for subsequent regression and classification loss computation.
 `yolov2TransformLayer`	A transform layer of the you only look once version 2 (YOLO v2) network transforms the bounding box predictions of the last convolution layer in the network to fall within the bounds of the ground truth. Use the transform layer to improve the stability of the YOLO v2 network.
 `spaceToDepthLayer`	A space to depth layer permutes the spatial blocks of the input into the depth dimension. Use this layer when you need to combine feature maps of different size without discarding any feature data.
 `depthToSpace2dLayer`	A 2-D depth to space layer permutes data from the depth dimension into blocks of 2-D spatial data.
 `rpnSoftmaxLayer`	A region proposal network (RPN) softmax layer applies a softmax activation function to the input. Use this layer to create a Faster R-CNN object detection network.
 `focalLossLayer`	A focal loss layer predicts object classes using focal loss.
 `rpnClassificationLayer`	A region proposal network (RPN) classification layer classifies image regions as either *object* or *background* by using a cross entropy loss function. Use this layer to create a Faster R-CNN object detection network.
 `rcnnBoxRegressionLayer`	A box regression layer refines bounding box locations by using a smooth L1 loss function. Use this layer to create a Fast or Faster R-CNN object detection network.

Output Layers

Layer	Description
 `softmaxLayer`	A softmax layer applies a softmax function to the input.
 `sigmoidLayer`	A sigmoid layer applies a sigmoid function to the input such that the output is bounded in the interval (0,1).

Layer	Description
 `classificationLayer`	A classification layer computes the cross-entropy loss for classification and weighted classification tasks with mutually exclusive classes.
 `regressionLayer`	A regression layer computes the half-mean-squared-error loss for regression tasks.
 `pixelClassificationLayer`	A pixel classification layer provides a categorical label for each image pixel or voxel.
 `dicePixelClassificationLayer`	A Dice pixel classification layer provides a categorical label for each image pixel or voxel using generalized Dice loss.
 `focalLossLayer`	A focal loss layer predicts object classes using focal loss.
 `rpnSoftmaxLayer`	A region proposal network (RPN) softmax layer applies a softmax activation function to the input. Use this layer to create a Faster R-CNN object detection network.
 `rpnClassificationLayer`	A region proposal network (RPN) classification layer classifies image regions as either *object* or *background* by using a cross entropy loss function. Use this layer to create a Faster R-CNN object detection network.
 `rcnnBoxRegressionLayer`	A box regression layer refines bounding box locations by using a smooth L1 loss function. Use this layer to create a Fast or Faster R-CNN object detection network.
 `yolov2OutputLayer`	An output layer of the you only look once version 2 (YOLO v2) network refines the bounding box locations by minimizing the mean squared error loss between the predicted locations and ground truth.
 `tverskyPixelClassificationLayer` on page 8-181 (Custom layer example)	A Tversky pixel classification layer provides a categorical label for each image pixel or voxel using Tversky loss.
 `sseClassificationLayer` on page 18-91 (Custom layer example)	A classification SSE layer computes the sum of squares error loss for classification problems.
 `maeRegressionLayer` on page 18-99 (Custom layer example)	A regression MAE layer computes the mean absolute error loss for regression problems.

Specify Layers of Convolutional Neural Network

In this section...

The first step of creating and training a new convolutional neural network (ConvNet) is to define the network architecture. This topic explains the details of ConvNet layers, and the order they appear in a ConvNet. For a complete list of deep learning layers and how to create them, see “List of Deep Learning Layers” on page 1-21. To learn about LSTM networks for sequence classification and regression, see “Long Short-Term Memory Networks” on page 1-75. To learn how to create your own custom layers, see “Define Custom Deep Learning Layers” on page 18-9.

The network architecture can vary depending on the types and numbers of layers included. The types and number of layers included depends on the particular application or data. For example, classification networks typically have a softmax layer and a classification layer, whereas regression networks must have a regression layer at the end of the network. A smaller network with only one or two convolutional layers might be sufficient to learn on a small number of grayscale image data. On the other hand, for more complex data with millions of colored images, you might need a more complicated network with multiple convolutional and fully connected layers.

To specify the architecture of a deep network with all layers connected sequentially, create an array of layers directly. For example, to create a deep network which classifies 28-by-28 grayscale images into 10 classes, specify the layer array

```
layers = [
    imageInputLayer([28 28 1])
    convolution2dLayer(3,16,'Padding',1)
    batchNormalizationLayer
    reluLayer
    maxPooling2dLayer(2,'Stride',2)
    convolution2dLayer(3,32,'Padding',1)
    batchNormalizationLayer
    reluLayer
    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer];
```

`layers` is an array of `Layer` objects. You can then use `layers` as an input to the training function `trainNetwork`.

To specify the architecture of a neural network with all layers connected sequentially, create an array of layers directly. To specify the architecture of a network where layers can have multiple inputs or outputs, use a `LayerGraph` object.

Image Input Layer

Create an image input layer using `imageInputLayer`.

An image input layer inputs images to a network and applies data normalization.

Specify the image size using the `inputSize` argument. The size of an image corresponds to the height, width, and the number of color channels of that image. For example, for a grayscale image, the number of channels is 1, and for a color image it is 3.

Convolutional Layer

A 2-D convolutional layer applies sliding convolutional filters to 2-D input. Create a 2-D convolutional layer using `convolution2dLayer`.

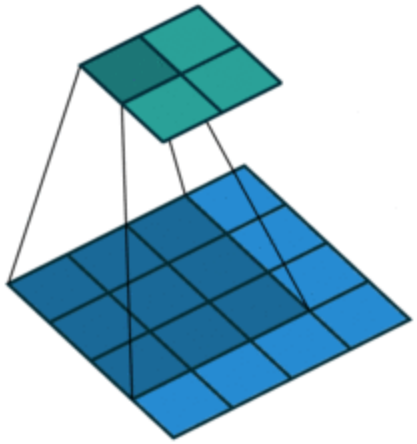
The convolutional layer consists of various components.[1]

Filters and Stride

A convolutional layer consists of neurons that connect to subregions of the input images or the outputs of the previous layer. The layer learns the features localized by these regions while scanning through an image. When creating a layer using the `convolution2dLayer` function, you can specify the size of these regions using the `filterSize` input argument.

For each region, the `trainNetwork` function computes a dot product of the weights and the input, and then adds a bias term. A set of weights that is applied to a region in the image is called a *filter*. The filter moves along the input image vertically and horizontally, repeating the same computation for each region. In other words, the filter convolves the input.

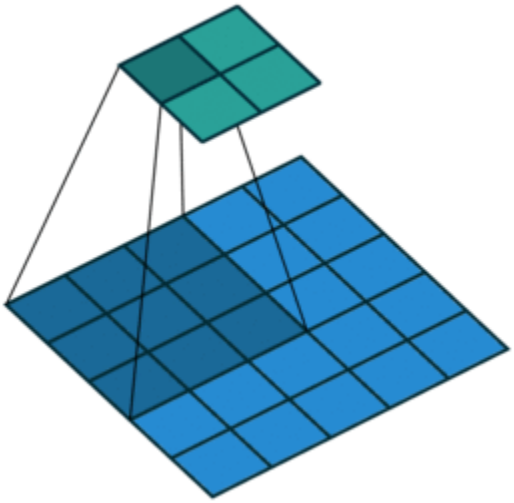
This image shows a 3-by-3 filter scanning through the input. The lower map represents the input and the upper map represents the output.



1. Image credit: Convolution arithmetic (License)

The step size with which the filter moves is called a *stride*. You can specify the step size with the `Stride` name-value pair argument. The local regions that the neurons connect to can overlap depending on the `filterSize` and `'Stride'` values.

This image shows a 3-by-3 filter scanning through the input with a stride of 2. The lower map represents the input and the upper map represents the output.



The number of weights in a filter is *h* * *w* * *c*, where *h* is the height, and *w* is the width of the filter, respectively, and *c* is the number of channels in the input. For example, if the input is a color image, the number of color channels is 3. The number of filters determines the number of channels in the output of a convolutional layer. Specify the number of filters using the `numFilters` argument with the `convolution2dLayer` function.

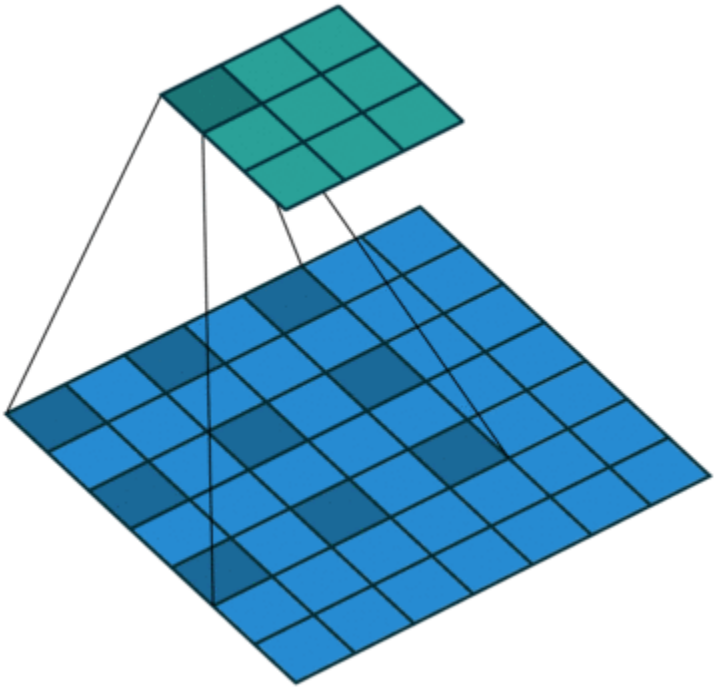
Dilated Convolution

A dilated convolution is a convolution in which the filters are expanded by spaces inserted between the elements of the filter. Specify the dilation factor using the `'DilationFactor'` property.

Use dilated convolutions to increase the receptive field (the area of the input which the layer can see) of the layer without increasing the number of parameters or computation.

The layer expands the filters by inserting zeros between each filter element. The dilation factor determines the step size for sampling the input or equivalently the upsampling factor of the filter. It corresponds to an effective filter size of (*Filter Size* – 1) .* *Dilation Factor* + 1. For example, a 3-by-3 filter with the dilation factor `[2 2]` is equivalent to a 5-by-5 filter with zeros between the elements.

This image shows a 3-by-3 filter dilated by a factor of two scanning through the input. The lower map represents the input and the upper map represents the output.



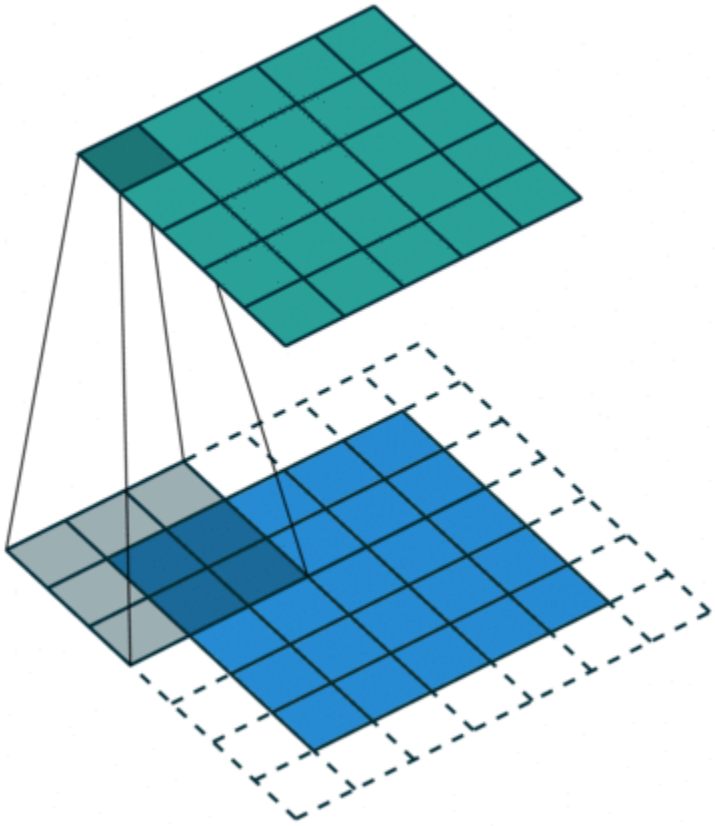
Feature Maps

As a filter moves along the input, it uses the same set of weights and the same bias for the convolution, forming a *feature map*. Each feature map is the result of a convolution using a different set of weights and a different bias. Hence, the number of feature maps is equal to the number of filters. The total number of parameters in a convolutional layer is ((*h***w***c* + 1)**Number of Filters*), where 1 is the bias.

Padding

You can also apply padding to input image borders vertically and horizontally using the `'Padding'` name-value pair argument. Padding is values appended to the borders of a the input to increase its size. By adjusting the padding, you can control the output size of the layer.

This image shows a 3-by-3 filter scanning through the input with padding of size 1. The lower map represents the input and the upper map represents the output.



Output Size

The output height and width of a convolutional layer is (*Input Size* – ((*Filter Size* – 1)**Dilation Factor* + 1) + 2**Padding*)/*Stride* + 1. This value must be an integer for the whole image to be fully covered. If the combination of these options does not lead the image to be fully covered, the software by default ignores the remaining part of the image along the right and bottom edges in the convolution.

Number of Neurons

The product of the output height and width gives the total number of neurons in a feature map, say *Map Size*. The total number of neurons (output size) in a convolutional layer is *Map Size***Number of Filters*.

For example, suppose that the input image is a 32-by-32-by-3 color image. For a convolutional layer with eight filters and a filter size of 5-by-5, the number of weights per filter is 5 * 5 * 3 = 75, and the total number of parameters in the layer is (75 + 1) * 8 = 608. If the stride is 2 in each direction and padding of size 2 is specified, then each feature map is 16-by-16. This is because (32 – 5 + 2 * 2)/2 + 1 = 16.5, and some of the outermost padding to the right and bottom of the image is discarded. Finally, the total number of neurons in the layer is 16 * 16 * 8 = 2048.

Usually, the results from these neurons pass through some form of nonlinearity, such as rectified linear units (ReLU).

Learning Parameters

You can adjust the learning rates and regularization options for the layer using name-value pair arguments while defining the convolutional layer. If you choose not to specify these options, then `trainNetwork` uses the global training options defined with the `trainingOptions` function. For details on global and layer training options, see “Set Up Parameters and Train Convolutional Neural Network” on page 1-42.

Number of Layers

A convolutional neural network can consist of one or multiple convolutional layers. The number of convolutional layers depends on the amount and complexity of the data.

Batch Normalization Layer

Create a batch normalization layer using `batchNormalizationLayer`.

A batch normalization layer normalizes a mini-batch of data across all observations for each channel independently. To speed up training of the convolutional neural network and reduce the sensitivity to network initialization, use batch normalization layers between convolutional layers and nonlinearities, such as ReLU layers.

The layer first normalizes the activations of each channel by subtracting the mini-batch mean and dividing by the mini-batch standard deviation. Then, the layer shifts the input by a learnable offset β and scales it by a learnable scale factor γ. β and γ are themselves learnable parameters that are updated during network training.

Batch normalization layers normalize the activations and gradients propagating through a neural network, making network training an easier optimization problem. To take full advantage of this fact, you can try increasing the learning rate. Since the optimization problem is easier, the parameter updates can be larger and the network can learn faster. You can also try reducing the L_2 and dropout regularization. With batch normalization layers, the activations of a specific image during training depend on which images happen to appear in the same mini-batch. To take full advantage of this regularizing effect, try shuffling the training data before every training epoch. To specify how often to shuffle the data during training, use the `'Shuffle'` name-value pair argument of `trainingOptions`.

ReLU Layer

Create a ReLU layer using `reluLayer`.

A ReLU layer performs a threshold operation to each element of the input, where any value less than zero is set to zero.

Convolutional and batch normalization layers are usually followed by a nonlinear activation function such as a rectified linear unit (ReLU), specified by a ReLU layer. A ReLU layer performs a threshold operation to each element, where any input value less than zero is set to zero, that is,

$$f(x) = \begin{cases} x, & x \geq 0 \\ 0, & x < 0 \end{cases}.$$

The ReLU layer does not change the size of its input.

There are other nonlinear activation layers that perform different operations and can improve the network accuracy for some applications. For a list of activation layers, see “Activation Layers” on page 1-23.

Cross Channel Normalization (Local Response Normalization) Layer

Create a cross channel normalization layer using `crossChannelNormalizationLayer`.

A channel-wise local response (cross-channel) normalization layer carries out channel-wise normalization.

This layer performs a channel-wise local response normalization. It usually follows the ReLU activation layer. This layer replaces each element with a normalized value it obtains using the elements from a certain number of neighboring channels (elements in the normalization window). That is, for each element x in the input, `trainNetwork` computes a normalized value x' using

$$x' = \frac{x}{\left(K + \frac{\alpha * ss}{windowChannelSize}\right)^{\beta}},$$

where K, α, and β are the hyperparameters in the normalization, and ss is the sum of squares of the elements in the normalization window [2]. You must specify the size of the normalization window using the `windowChannelSize` argument of the `crossChannelNormalizationLayer` function. You can also specify the hyperparameters using the `Alpha`, `Beta`, and `K` name-value pair arguments.

The previous normalization formula is slightly different than what is presented in [2]. You can obtain the equivalent formula by multiplying the `alpha` value by the `windowChannelSize`.

Max and Average Pooling Layers

A 2-D max pooling layer performs downsampling by dividing the input into rectangular pooling regions, then computing the maximum of each region. Create a max pooling layer using `maxPooling2dLayer`.

A 2-D average pooling layer performs downsampling by dividing the input into rectangular pooling regions, then computing the average values of each region. Create an average pooling layer using `averagePooling2dLayer`.

Pooling layers follow the convolutional layers for down-sampling, hence, reducing the number of connections to the following layers. They do not perform any learning themselves, but reduce the number of parameters to be learned in the following layers. They also help reduce overfitting.

A max pooling layer returns the maximum values of rectangular regions of its input. The size of the rectangular regions is determined by the `poolSize` argument of `maxPoolingLayer`. For example, if `poolSize` equals `[2,3]`, then the layer returns the maximum value in regions of height 2 and width 3.An average pooling layer outputs the average values of rectangular regions of its input. The size of the rectangular regions is determined by the `poolSize` argument of `averagePoolingLayer`. For example, if `poolSize` is [2,3], then the layer returns the average value of regions of height 2 and width 3.

Pooling layers scan through the input horizontally and vertically in step sizes you can specify using the `'Stride'` name-value pair argument. If the pool size is smaller than or equal to the stride, then the pooling regions do not overlap.

For nonoverlapping regions (*Pool Size* and *Stride* are equal), if the input to the pooling layer is *n*-by-*n*, and the pooling region size is *h*-by-*h*, then the pooling layer down-samples the regions by *h* [6]. That is, the output of a max or average pooling layer for one channel of a convolutional layer is *n*/*h*-by-*n*/*h*. For overlapping regions, the output of a pooling layer is (*Input Size* – *Pool Size* + 2**Padding*)/*Stride* + 1.

Dropout Layer

Create a dropout layer using `dropoutLayer`.

A dropout layer randomly sets input elements to zero with a given probability.

At training time, the layer randomly sets input elements to zero given by the dropout mask `rand(size(X))<Probability`, where `X` is the layer input and then scales the remaining elements by `1/(1-Probability)`. This operation effectively changes the underlying network architecture between iterations and helps prevent the network from overfitting [7], [2]. A higher number results in more elements being dropped during training. At prediction time, the output of the layer is equal to its input.

Similar to max or average pooling layers, no learning takes place in this layer.

Fully Connected Layer

Create a fully connected layer using `fullyConnectedLayer`.

A fully connected layer multiplies the input by a weight matrix and then adds a bias vector.

The convolutional (and down-sampling) layers are followed by one or more fully connected layers.

As the name suggests, all neurons in a fully connected layer connect to all the neurons in the previous layer. This layer combines all of the features (local information) learned by the previous layers across the image to identify the larger patterns. For classification problems, the last fully connected layer combines the features to classify the images. This is the reason that the `outputSize` argument of the last fully connected layer of the network is equal to the number of classes of the data set. For regression problems, the output size must be equal to the number of response variables.

You can also adjust the learning rate and the regularization parameters for this layer using the related name-value pair arguments when creating the fully connected layer. If you choose not to adjust them, then `trainNetwork` uses the global training parameters defined by the `trainingOptions` function. For details on global and layer training options, see “Set Up Parameters and Train Convolutional Neural Network” on page 1-42.

A fully connected layer multiplies the input by a weight matrix W and then adds a bias vector b.

If the input to the layer is a sequence (for example, in an LSTM network), then the fully connected layer acts independently on each time step. For example, if the layer before the fully connected layer outputs an array X of size D-by-N-by-S, then the fully connected layer outputs an array Z of size `outputSize`-by-N-by-S. At time step t, the corresponding entry of Z is $WX_t + b$, where X_t denotes time step t of X.

Output Layers

Softmax and Classification Layers

A softmax layer applies a softmax function to the input. Create a softmax layer using `softmaxLayer`.

A classification layer computes the cross-entropy loss for classification and weighted classification tasks with mutually exclusive classes. Create a classification layer using `classificationLayer`.

For classification problems, a softmax layer and then a classification layer usually follow the final fully connected layer.

The output unit activation function is the softmax function:

$$y_r(x) = \frac{\exp(a_r(x))}{\sum_{j=1}^{k} \exp\left(a_j(x)\right)},$$

where $0 \le y_r \le 1$ and $\sum_{j=1}^{k} y_j = 1$.

The softmax function is the output unit activation function after the last fully connected layer for multi-class classification problems:

$$P(c_r|x,\theta) = \frac{P(x,\theta|c_r)P(c_r)}{\sum_{j=1}^{k} P\left(x,\theta|c_j\right)P\left(c_j\right)} = \frac{\exp(a_r(x,\theta))}{\sum_{j=1}^{k} \exp\left(a_j(x,\theta)\right)},$$

where $0 \le P(c_r|x,\theta) \le 1$ and $\sum_{j=1}^{k} P\left(c_j\middle|x,\theta\right) = 1$. Moreover, $a_r = \ln(P(x,\theta|c_r)P(c_r))$, $P(x,\theta|c_r)$ is the conditional probability of the sample given class r, and $P(c_r)$ is the class prior probability.

The softmax function is also known as the *normalized exponential* and can be considered the multi-class generalization of the logistic sigmoid function [8].

For typical classification networks, the classification layer usually follows a softmax layer. In the classification layer, `trainNetwork` takes the values from the softmax function and assigns each input to one of the K mutually exclusive classes using the cross entropy function for a 1-of-K coding scheme [8]:

$$\text{loss} = -\frac{1}{N}\sum_{n=1}^{N}\sum_{i=1}^{K} w_i t_{ni} \ln y_{ni},$$

where N is the number of samples, K is the number of classes, w_i is the weight for class i, t_{ni} is the indicator that the nth sample belongs to the ith class, and y_{ni} is the output for sample n for class i, which in this case, is the value from the softmax function. In other words, y_{ni} is the probability that the network associates the nth input with class i.

Regression Layer

Create a regression layer using `regressionLayer`.

A regression layer computes the half-mean-squared-error loss for regression tasks. For typical regression problems, a regression layer must follow the final fully connected layer.

For a single observation, the mean-squared-error is given by:

$$\text{MSE} = \sum_{i=1}^{R} \frac{(t_i - y_i)^2}{R},$$

where R is the number of responses, t_i is the target output, and y_i is the network's prediction for response i.

For image and sequence-to-one regression networks, the loss function of the regression layer is the half-mean-squared-error of the predicted responses, not normalized by R:

$$\text{loss} = \frac{1}{2} \sum_{i=1}^{R} (t_i - y_i)^2 .$$

For image-to-image regression networks, the loss function of the regression layer is the half-mean-squared-error of the predicted responses for each pixel, not normalized by R:

$$\text{loss} = \frac{1}{2} \sum_{p=1}^{HWC} (t_p - y_p)^2,$$

where H, W, and C denote the height, width, and number of channels of the output respectively, and p indexes into each element (pixel) of t and y linearly.

For sequence-to-sequence regression networks, the loss function of the regression layer is the half-mean-squared-error of the predicted responses for each time step, not normalized by R:

$$\text{loss} = \frac{1}{2S} \sum_{i=1}^{S} \sum_{j=1}^{R} (t_{ij} - y_{ij})^2,$$

where S is the sequence length.

When training, the software calculates the mean loss over the observations in the mini-batch.

Set Up Parameters and Train Convolutional Neural Network

In this section...

After you define the layers of your neural network as described in “Specify Layers of Convolutional Neural Network” on page 1-31, the next step is to set up the training options for the network. Use the `trainingOptions` function to define the global training parameters. To train a network, use the object returned by `trainingOptions` as an input argument to the `trainNetwork` function. For example:

```
options = trainingOptions('adam');
trainedNet = trainNetwork(data,layers,options);
```

Layers with learnable parameters also have options for adjusting the learning parameters. For more information, see “Set Up Parameters in Convolutional and Fully Connected Layers” on page 1-44.

Specify Solver and Maximum Number of Epochs

`trainNetwork` can use different variants of stochastic gradient descent to train the network. Specify the optimization algorithm by using the `solverName` argument of `trainingOptions`. To minimize the loss, these algorithms update the network parameters by taking small steps in the direction of the negative gradient of the loss function.

The `'adam'` (derived from *adaptive moment estimation*) solver is often a good optimizer to try first. You can also try the `'rmsprop'` (root mean square propagation) and `'sgdm'` (stochastic gradient descent with momentum) optimizers and see if this improves training. Different solvers work better for different problems. For more information about the different solvers, see “Stochastic Gradient Descent”.

The solvers update the parameters using a subset of the data each step. This subset is called a *mini-batch*. You can specify the size of the mini-batch by using the `'MiniBatchSize'` name-value pair argument of `trainingOptions`. Each parameter update is called an *iteration*. A full pass through the entire data set is called an *epoch*. You can specify the maximum number of epochs to train for by using the `'MaxEpochs'` name-value pair argument of `trainingOptions`. The default value is 30, but you can choose a smaller number of epochs for small networks or for fine-tuning and transfer learning, where most of the learning is already done.

By default, the software shuffles the data once before training. You can change this setting by using the `'Shuffle'` name-value pair argument.

Specify and Modify Learning Rate

You can specify the global learning rate by using the `'InitialLearnRate'` name-value pair argument of `trainingOptions`. By default, `trainNetwork` uses this value throughout the entire

training process. You can choose to modify the learning rate every certain number of epochs by multiplying the learning rate with a factor. Instead of using a small, fixed learning rate throughout the training process, you can choose a larger learning rate in the beginning of training and gradually reduce this value during optimization. Doing so can shorten the training time, while enabling smaller steps towards the minimum of the loss as training progresses.

Tip If the mini-batch loss during training ever becomes `NaN`, then the learning rate is likely too high. Try reducing the learning rate, for example by a factor of 3, and restarting network training.

To gradually reduce the learning rate, use the `'LearnRateSchedule','piecewise'` name-value pair argument. Once you choose this option, `trainNetwork` multiplies the initial learning rate by a factor of 0.1 every 10 epochs. You can specify the factor by which to reduce the initial learning rate and the number of epochs by using the `'LearnRateDropFactor'` and `'LearnRateDropPeriod'` name-value pair arguments, respectively.

Specify Validation Data

To perform network validation during training, specify validation data using the `'ValidationData'` name-value pair argument of `trainingOptions`. By default, `trainNetwork` validates the network every 50 iterations by predicting the response of the validation data and calculating the validation loss and accuracy (root mean squared error for regression networks). You can change the validation frequency using the `'ValidationFrequency'` name-value pair argument. If your network has layers that behave differently during prediction than during training (for example, dropout layers), then the validation accuracy can be higher than the training (mini-batch) accuracy. You can also use the validation data to stop training automatically when the validation loss stops decreasing. To turn on automatic validation stopping, use the `'ValidationPatience'` name-value pair argument.

Performing validation at regular intervals during training helps you to determine if your network is overfitting to the training data. A common problem is that the network simply "memorizes" the training data, rather than learning general features that enable the network to make accurate predictions for new data. To check if your network is overfitting, compare the training loss and accuracy to the corresponding validation metrics. If the training loss is significantly lower than the validation loss, or the training accuracy is significantly higher than the validation accuracy, then your network is overfitting.

To reduce overfitting, you can try adding data augmentation. Use an `augmentedImageDatastore` to perform random transformations on your input images. This helps to prevent the network from memorizing the exact position and orientation of objects. You can also try increasing the L_2 regularization using the `'L2Regularization'` name-value pair argument, using batch normalization layers after convolutional layers, and adding dropout layers.

Select Hardware Resource

If a GPU is available, then `trainNetwork` uses it for training, by default. Otherwise, `trainNetwork` uses a CPU. Alternatively, you can specify the execution environment you want using the `'ExecutionEnvironment'` name-value pair argument. You can specify a single CPU (`'cpu'`), a single GPU (`'gpu'`), multiple GPUs (`'multi-gpu'`), or a local parallel pool or compute cluster (`'parallel'`). All options other than `'cpu'` require Parallel Computing Toolbox. Training on a GPU requires a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

Save Checkpoint Networks and Resume Training

Deep Learning Toolbox enables you to save networks as .mat files after each epoch during training. This periodic saving is especially useful when you have a large network or a large data set, and training takes a long time. If the training is interrupted for some reason, you can resume training from the last saved checkpoint network. If you want `trainNetwork` to save checkpoint networks, then you must specify the name of the path by using the `'CheckpointPath'` name-value pair argument of `trainingOptions`. If the path that you specify does not exist, then `trainingOptions` returns an error.

`trainNetwork` automatically assigns unique names to checkpoint network files. In the example name, `net_checkpoint__351__2018_04_12__18_09_52.mat`, 351 is the iteration number, `2018_04_12` is the date, and `18_09_52` is the time at which `trainNetwork` saves the network. You can load a checkpoint network file by double-clicking it or using the load command at the command line. For example:

```
load net_checkpoint__351__2018_04_12__18_09_52.mat
```

You can then resume training by using the layers of the network as an input argument to `trainNetwork`. For example:

```
trainNetwork(XTrain,YTrain,net.Layers,options)
```

You must manually specify the training options and the input data, because the checkpoint network does not contain this information. For an example, see “Resume Training from Checkpoint Network” on page 5-95.

Set Up Parameters in Convolutional and Fully Connected Layers

You can set the learning parameters to be different from the global values specified by `trainingOptions` in layers with learnable parameters, such as convolutional and fully connected layers. For example, to adjust the learning rate for the biases or weights, you can specify a value for the `BiasLearnRateFactor` or `WeightLearnRateFactor` properties of the layer, respectively. The `trainNetwork` function multiplies the learning rate that you specify by using `trainingOptions` with these factors. Similarly, you can also specify the L_2 regularization factors for the weights and biases in these layers by specifying the `BiasL2Factor` and `WeightL2Factor` properties, respectively. `trainNetwork` then multiplies the L_2 regularization factors that you specify by using `trainingOptions` with these factors.

Initialize Weights in Convolutional and Fully Connected Layers

The layer weights are learnable parameters. You can specify the initial value for the weights directly using the `Weights` property of the layer. When you train a network, if the `Weights` property of the layer is nonempty, then `trainNetwork` uses the `Weights` property as the initial value. If the `Weights` property is empty, then `trainNetwork` uses the initializer specified by the `WeightsInitializer` property of the layer.

Train Your Network

After you specify the layers of your network and the training parameters, you can train the network using the training data. The data, layers, and training options are all input arguments of the `trainNetwork` function, as in this example.

```
layers = [imageInputLayer([28 28 1])
          convolution2dLayer(5,20)
          reluLayer
          maxPooling2dLayer(2,'Stride',2)
          fullyConnectedLayer(10)
          softmaxLayer
          classificationLayer];
options = trainingOptions('adam');
convnet = trainNetwork(data,layers,options);
```

Training data can be an array, a table, or an `ImageDatastore` object. For more information, see the `trainNetwork` function reference page.

Train Network with Numeric Features

This example shows how to create and train a simple neural network for deep learning feature data classification.

If you have a data set of numeric features (for example a collection of numeric data without spatial or time dimensions), then you can train a deep learning network using a feature input layer. For an example showing how to train a network for image classification, see “Create Simple Deep Learning Network for Classification” on page 3-47.

This example shows how to train a network to classify the gear tooth condition of a transmission system given a mixture of numeric sensor readings, statistics, and categorical labels.

Load Data

Load the transmission casing dataset for training. The data set consists of 208 synthetic readings of a transmission system consisting of 18 numeric readings and three categorical labels:

1. `SigMean` — Vibration signal mean
2. `SigMedian` — Vibration signal median
3. `SigRMS` — Vibration signal RMS
4. `SigVar` — Vibration signal variance
5. `SigPeak` — Vibration signal peak
6. `SigPeak2Peak` — Vibration signal peak to peak
7. `SigSkewness` — Vibration signal skewness
8. `SigKurtosis` — Vibration signal kurtosis
9. `SigCrestFactor` — Vibration signal crest factor
10. `SigMAD` — Vibration signal MAD
11. `SigRangeCumSum` — Vibration signal range cumulative sum
12. `SigCorrDimension` — Vibration signal correlation dimension
13. `SigApproxEntropy` — Vibration signal approximate entropy
14. `SigLyapExponent` — Vibration signal Lyap exponent
15. `PeakFreq` — Peak frequency.
16. `HighFreqPower` — High frequency power
17. `EnvPower` — Environment power
18. `PeakSpecKurtosis` — Peak frequency of spectral kurtosis
19. `SensorCondition` — Condition of sensor, specified as "Sensor Drift" or "No Sensor Drift"
20. `ShaftCondition` — Condition of shaft, specified as "Shaft Wear" or "No Shaft Wear"
21. `GearToothCondition` — Condition of gear teeth, specified as "Tooth Fault" or "No Tooth Fault"

Read the transmission casing data from the CSV file `"transmissionCasingData.csv"`.

```
filename = "transmissionCasingData.csv";
tbl = readtable(filename,'TextType','String');
```

Convert the labels for prediction to categorical using the `convertvars` function.

```
labelName = "GearToothCondition";
tbl = convertvars(tbl,labelName,'categorical');
```

View the first few rows of the table.

```
head(tbl)
```

```

      1.0123      1.0024     1.4202    0.99233     2.8157       3.6314        -0.014701       2.2
      1.0275      1.0102     1.4338     1.0001     2.8157       3.6314         -0.02659       2.2
      1.0464      1.0275     1.4477     1.0011     2.8157       3.6314        -0.042849       2.2
      1.0459      1.0257     1.4402    0.98047     2.8157       3.6314        -0.035405       2.2
```

To train a network using categorical features, you must first convert the categorical features to numeric. First, convert the categorical predictors to categorical using the `convertvars` function by specifying a string array containing the names of all the categorical input variables. In this data set, there are two categorical features with names `"SensorCondition"` and `"ShaftCondition"`.

```
categoricalInputNames = ["SensorCondition" "ShaftCondition"];
tbl = convertvars(tbl,categoricalInputNames,'categorical');
```

Loop over the categorical input variables. For each variable:

- Convert the categorical values to one-hot encoded vectors using the `onehotencode` function.
- Add the one-hot vectors to the table using the `addvars` function. Specify to insert the vectors after the column containing the corresponding categorical data.
- Remove the corresponding column containing the categorical data.

```
for i = 1:numel(categoricalInputNames)
    name = categoricalInputNames(i);
    oh = onehotencode(tbl(:,name));
    tbl = addvars(tbl,oh,'After',name);
    tbl(:,name) = [];
end
```

Split the vectors into separate columns using the `splitvars` function.

```
tbl = splitvars(tbl);
```

View the first few rows of the table. Notice that the categorical predictors have been split into multiple columns with the categorical values as the variable names.

```
head(tbl)
```

```

      1.0464      1.0275      1.4477      1.0011      2.8157       3.6314        -0.042849       2.2
      1.0459      1.0257      1.4402     0.98047      2.8157       3.6314        -0.035405       2.2
```

View the class names of the data set.

```
classNames = categories(tbl{:,labelName})
```

```
classNames = 2x1 cell
    {'No Tooth Fault'}
    {'Tooth Fault'   }
```

Split Data Set into Training and Validation Sets

Partition the data set into training, validation, and test partitions. Set aside 15% of the data for validation, and 15% for testing.

View the number of observations in the dataset.

```
numObservations = size(tbl,1)
```

```
numObservations = 208
```

Determine the number of observations for each partition.

```
numObservationsTrain = floor(0.7*numObservations)
```

```
numObservationsTrain = 145
```

```
numObservationsValidation = floor(0.15*numObservations)
```

```
numObservationsValidation = 31
```

```
numObservationsTest = numObservations - numObservationsTrain - numObservationsValidation
```

```
numObservationsTest = 32
```

Create an array of random indices corresponding to the observations and partition it using the partition sizes.

```
idx = randperm(numObservations);
idxTrain = idx(1:numObservationsTrain);
idxValidation = idx(numObservationsTrain+1:numObservationsTrain+numObservationsValidation);
idxTest = idx(numObservationsTrain+numObservationsValidation+1:end);
```

Partition the table of data into training, validation, and testing partitions using the indices.

```
tblTrain = tbl(idxTrain,:);
tblValidation = tbl(idxValidation,:);
tblTest = tbl(idxTest,:);
```

Define Network Architecture

Define the network for classification.

Define a network with a feature input layer and specify the number of features. Also, configure the input layer to normalize the data using Z-score normalization. Next, include a fully connected layer with output size 50 followed by a batch normalization layer and a ReLU layer. For classification, specify another fully connected layer with output size corresponding to the number of classes, followed by a softmax layer and a classification layer.

```
numFeatures = size(tbl,2) - 1;
numClasses = numel(classNames);

layers = [
    featureInputLayer(numFeatures,'Normalization', 'zscore')
    fullyConnectedLayer(50)
    batchNormalizationLayer
    reluLayer
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify Training Options

Specify the training options.

- Train the network using Adam.
- Train using mini-batches of size 16.
- Shuffle the data every epoch.
- Monitor the network accuracy during training by specifying validation data.
- Display the training progress in a plot and suppress the verbose command window output.

The software trains the network on the training data and calculates the accuracy on the validation data at regular intervals during training. The validation data is not used to update the network weights.

```
miniBatchSize = 16;

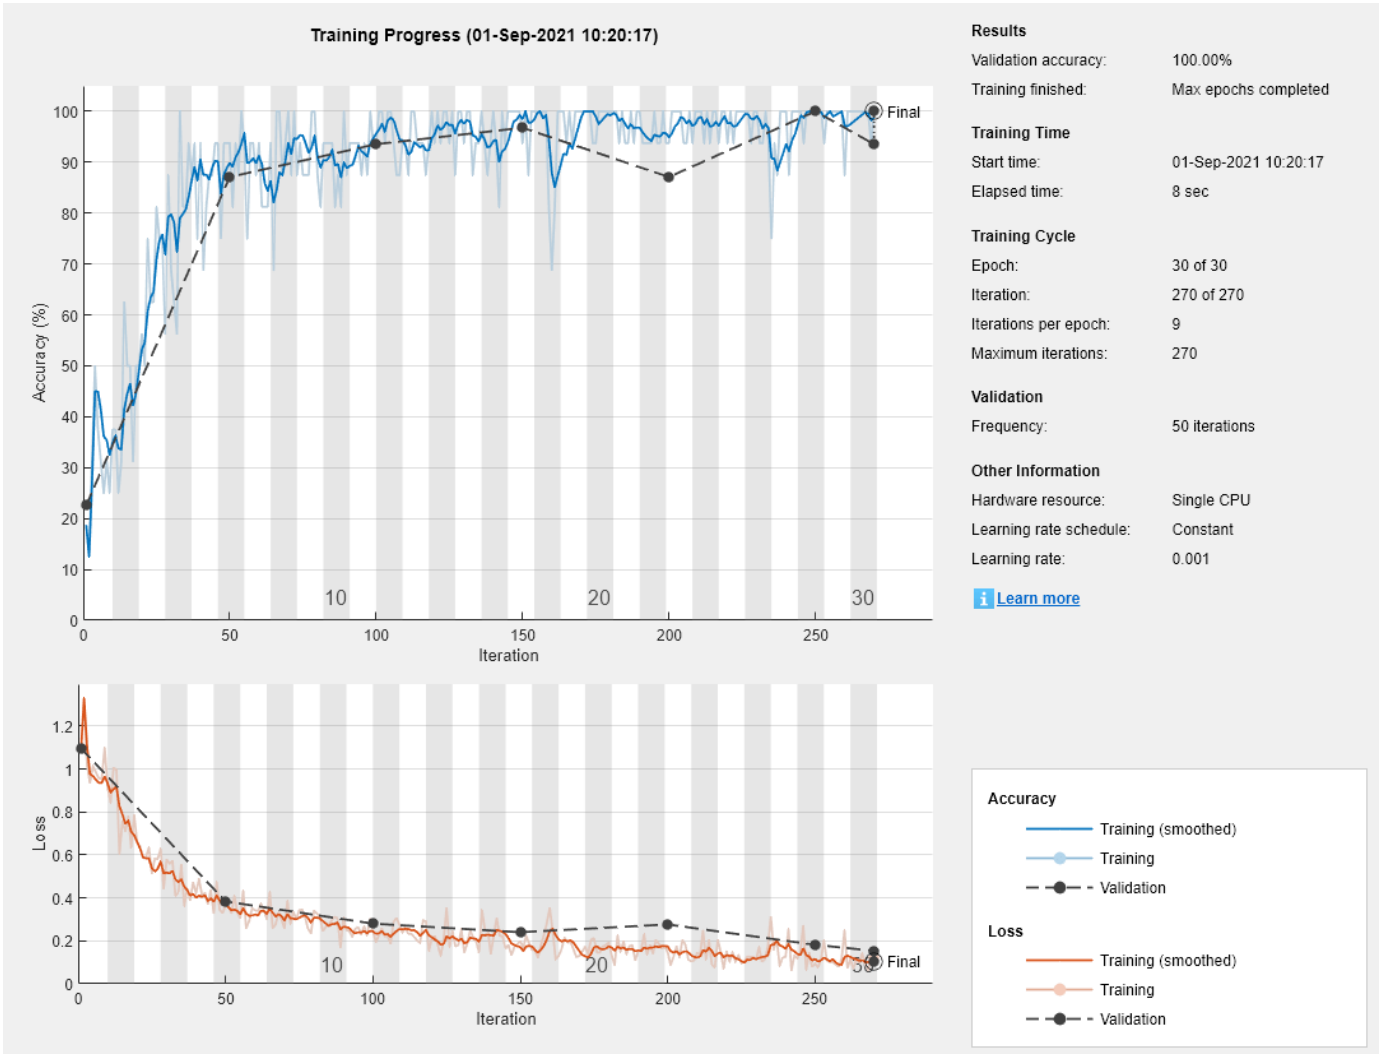
options = trainingOptions('adam', ...
    'MiniBatchSize',miniBatchSize, ...
    'Shuffle','every-epoch', ...
    'ValidationData',tblValidation, ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train Network

Train the network using the architecture defined by `layers`, the training data, and the training options. By default, `trainNetwork` uses a GPU if one is available, otherwise, it uses a CPU. Training on a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`.

The training progress plot shows the mini-batch loss and accuracy and the validation loss and accuracy. For more information on the training progress plot, see “Monitor Deep Learning Training Progress” on page 5-115.

```
net = trainNetwork(tblTrain,labelName,layers,options);
```



Test Network

Predict the labels of the test data using the trained network and calculate the accuracy. Specify the same mini-batch size used for training.

```
YPred = classify(net,tblTest(:,1:end-1),'MiniBatchSize',miniBatchSize);
```

Calculate the classification accuracy. The accuracy is the proportion of the labels that the network predicts correctly.

```
YTest = tblTest{:,labelName};
accuracy = sum(YPred == YTest)/numel(YTest)
```

```
accuracy = 0.9688
```

View the results in a confusion matrix.

```
figure
confusionchart(YTest,YPred)
```

Train Network on Image and Feature Data

This example shows how to train a network that classifies handwritten digits using both image and feature input data.

Load Training Data

Load the digits images `XTrain`, labels `YTrain`, and clockwise rotation angles `anglesTrain`. Create an `arrayDatastore` object for the images, labels, and angles, and then use the `combine` function to make a single datastore that contains all of the training data. Extract the class names and the height, width, number of channels, and number of nondiscrete responses.

```
[XTrain,YTrain,anglesTrain] = digitTrain4DArrayData;

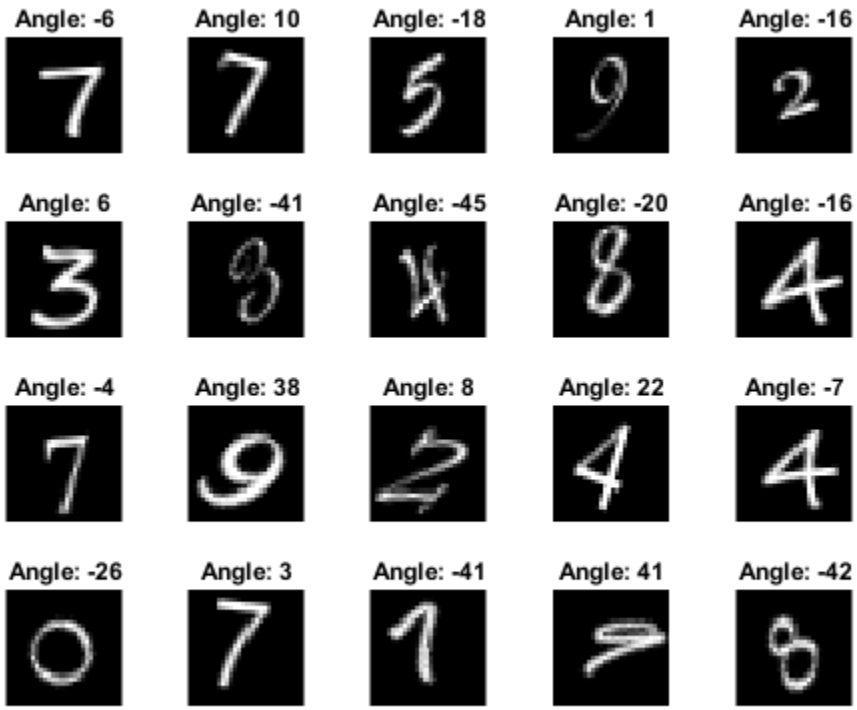
dsXTrain = arrayDatastore(XTrain,'IterationDimension',4);
dsAnglesTrain = arrayDatastore(anglesTrain);
dsYTrain = arrayDatastore(YTrain);

dsTrain = combine(dsXTrain,dsAnglesTrain,dsYTrain);

classes = categories(YTrain);
[h,w,c,numObservations] = size(XTrain);
```

Display 20 random training images.

```
numTrainImages = numel(YTrain);
figure
idx = randperm(numTrainImages,20);
for i = 1:numel(idx)
    subplot(4,5,i)
    imshow(XTrain(:,:,:,idx(i)))
    title("Angle: " + anglesTrain(idx(i)))
end
```



Define Network

Define the size of the input image, the number of features of each observation, the number of classes, and the size and number of filters of the convolution layer.

```
imageInputSize = [h w c];
numFeatures = 1;
numClasses = numel(classes);
filterSize = 5;
numFilters = 16;
```

To create a network with two input layers, you must define the network in two parts and join them, for example, by using a concatenation layer.

Define the first part of the network. Define the image classification layers and include a concatenation layer before the last fully connected layer.

```
layers = [
    imageInputLayer(imageInputSize,'Normalization','none','Name','images')
    convolution2dLayer(filterSize,numFilters,'Name','conv')
    reluLayer('Name','relu')
    fullyConnectedLayer(50,'Name','fc1')
    concatenationLayer(1,2,'Name','concat')
    fullyConnectedLayer(numClasses,'Name','fc2')
    softmaxLayer('Name','softmax')];
```

Convert the layers to a layer graph.

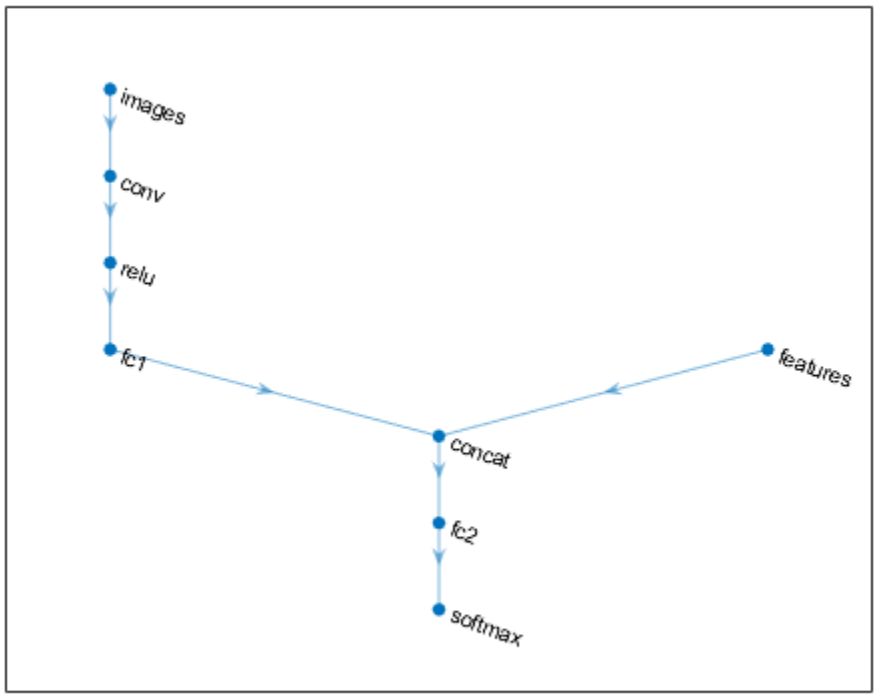
```
lgraph = layerGraph(layers);
```

For the second part of the network, add a feature input layer and connect it to the second input of the concatenation layer.

```
featInput = featureInputLayer(numFeatures,'Name','features');
lgraph = addLayers(lgraph, featInput);
lgraph = connectLayers(lgraph, 'features', 'concat/in2');
```

Visualize the network.

```
figure
plot(lgraph)
```



Create a `dlnetwork` object.

```
dlnet = dlnetwork(lgraph);
```

When you use the functions `predict` and `forward` on a `dlnetwork` object, the input arguments must match the order given by the `InputNames` property of the `dlnetwork` object. Inspect the name and order of the input layers.

```
dlnet.InputNames
```

```
ans = 1×2 cell
    {'images'}    {'features'}
```

Define Model Gradients Function

The `modelGradients` function, listed in the Model Gradients Function on page 1-0 section of the example, takes as input a `dlnetwork` object `dlnet`, a mini-batch of input image data `dlX1`, a mini-batch of input feature data `dlX2`, and the corresponding labels `dlY`, and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, the network state, and the loss.

Specify Training Options

Train with a mini-batch size of 128 for 15 epochs.

```
numEpochs = 15;
miniBatchSize = 128;
```

Specify the options for SGDM optimization. Specify an initial learning rate of 0.01 with a decay of 0.01, and momentum of 0.9.

```
learnRate = 0.01;
decay = 0.01;
momentum = 0.9;
```

To monitor the training progress, you can plot the training loss after each iteration. Create the variable `plots` that contains `"training-progress"`. If you do not want to plot the training progress, then set this value to `"none"`.

```
plots = "training-progress";
```

Train Model

Train the model using a custom training loop. Initialize the velocity parameter for the SGDM solver.

```
velocity = [];
```

Use `minibatchqueue` to process and manage mini-batches of images during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessData` (defined at the end of this example) to one-hot encode the class labels.
- By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Format the images with the dimension labels `'SSCB'` (spatial, spatial, channel, batch), and the angles with the dimension labels `'CB'` (channel, batch). Do not add a format to the class labels.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','CB',''});
```

For each epoch, shuffle the data and loop over mini-batches of data. At the end of each epoch, display the training progress. For each mini-batch:

- Evaluate the model gradients, state, and loss using `dlfeval` and the `modelGradients` function and update the network state.

- Update the network parameters using the `sgdmupdate` function.

Initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Train the model.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches.
    while hasdata(mbq)

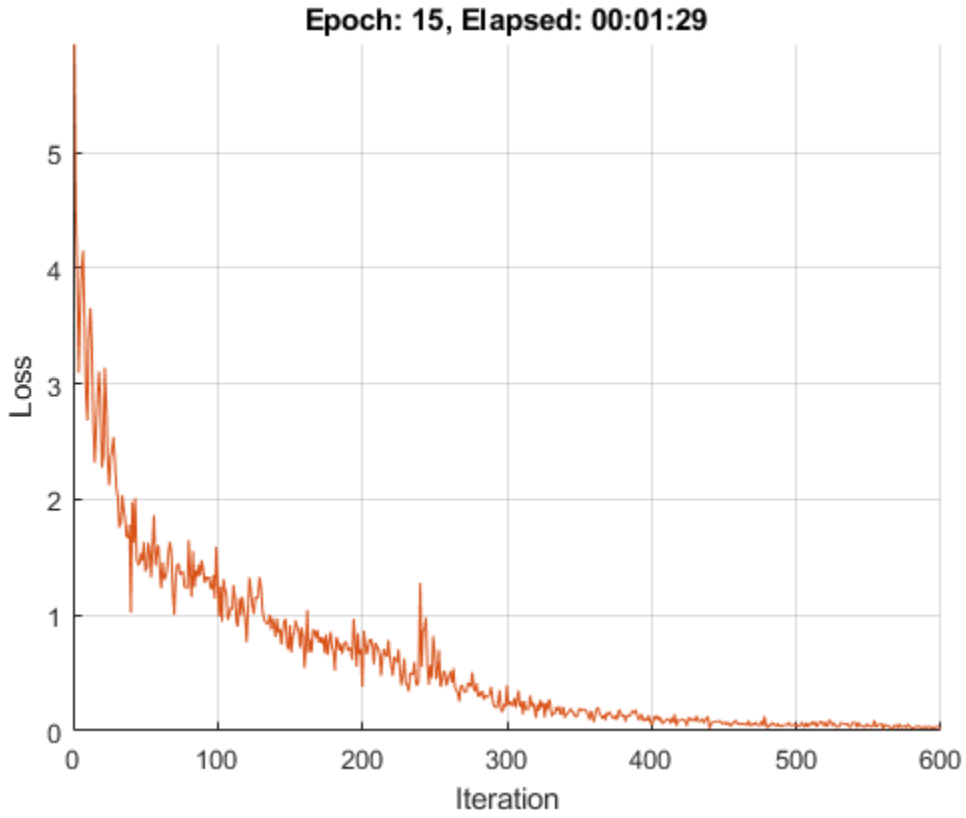
        iteration = iteration + 1;

        % Read mini-batch of data.
        [dlX1,dlX2,dlY] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function and update the network state.
        [gradients,state,loss] = dlfeval(@modelGradients,dlnet,dlX1,dlX2,dlY);
        dlnet.State = state;

        % Update the network parameters using the SGDM optimizer.
        [dlnet, velocity] = sgdmupdate(dlnet, gradients, velocity, learnRate, momentum);

        if plots == "training-progress"
            % Display the training progress.
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            %completionPercentage = round(iteration/numIterations*100,0);
            title("Epoch: " + epoch + ", Elapsed: " + string(D));
            addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
            drawnow
        end
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on a test set with the true labels. Test the classification accuracy of the model by comparing the predictions on a test set with the true labels and angles. Manage the test data set using a `minibatchqueue` object with the same setting as the training data.

```
[XTest,YTest,anglesTest] = digitTest4DArrayData;

dsXTest = arrayDatastore(XTest,'IterationDimension',4);
dsAnglesTest = arrayDatastore(anglesTest);
dsYTest = arrayDatastore(YTest);

dsTest = combine(dsXTest,dsAnglesTest,dsYTest);

mbqTest = minibatchqueue(dsTest,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB','CB',''});
```

Loop over the mini-batches and classify the images using `modelPredictions` function, listed at the end of the example.

```
[predictions,predCorr] = modelPredictions(dlnet,mbqTest,classes);
```

Evaluate the classification accuracy.

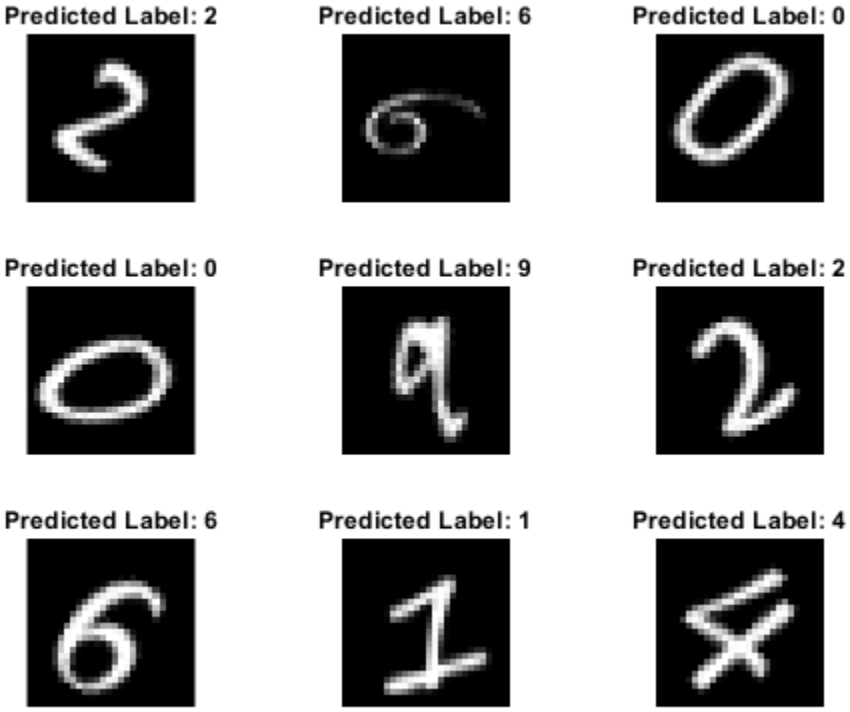
```
accuracy = mean(predCorr)
```

```
accuracy = 0.9818
```

View some of the images with their predictions.

```
idx = randperm(size(XTest,4),9);
figure
for i = 1:9
    subplot(3,3,i)
    I = XTest(:,:,:,idx(i));
    imshow(I)

    label = string(predictions(idx(i)));
    title("Predicted Label: " + label)
end
```



Model Gradients Function

The `modelGradients` function takes as input a `dlnetwork` object `dlnet`, a mini-batch of input image data `dlX1`, a mini-batch of input feature data `dlX2`, and corresponding labels `Y`, and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, the network state, and the loss. To compute the gradients automatically, use the `dlgradient` function.

When you use the `forward` function on a `dlnetwork` object, the input arguments must match the order given by the `InputNames` property of the `dlnetwork` object.

```
function [gradients,state,loss] = modelGradients(dlnet,dlX1,dlX2,Y)
```

```
[dlYPred,state] = forward(dlnet,dlX1,dlX2);

loss = crossentropy(dlYPred,Y);
gradients = dlgradient(loss,dlnet.Learnables);

end
```

Model Predictions Function

The `modelPredictions` function takes as input a `dlnetwork` object `dlnet`, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in the `minibatchqueue` object. The function uses the `onehotdecode` function to find the predicted class with the highest score and then compares the prediction with the true label. The function returns the predictions and a vector of ones and zeros that represents correct and incorrect predictions.

```
function [classesPredictions,classCorr] = modelPredictions(dlnet,mbq,classes)

    classesPredictions = [];
    classCorr = [];

    while hasdata(mbq)
        [dlX1,dlX2,dlY] = next(mbq);

        % Make predictions using the model function.
        dlYPred = predict(dlnet,dlX1,dlX2);

        % Determine predicted classes.
        YPredBatch = onehotdecode(dlYPred,classes,1);
        classesPredictions = [classesPredictions YPredBatch];

        % Compare predicted and true classes.
        Y = onehotdecode(dlY,classes,1);
        classCorr = [classCorr YPredBatch == Y];

    end

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label and angle data from the incoming cell arrays and concatenate along the second dimension into a categorical array and a numeric array, respectively.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,angle,Y] = preprocessMiniBatch(XCell,angleCell,YCell)

    % Extract image data from cell and concatenate.
    X = cat(4,XCell{:});
    % Extract angle data from cell and concatenate.
```

```
    angle = cat(2,angleCell{:});
    % Extract label data from cell and concatenate.
    Y = cat(2,YCell{:});

    % One-hot encode labels.
    Y = onehotencode(Y,1);

end
```

Compare Activation Layers

This example shows how to compare the accuracy of training networks with ReLU, leaky ReLU, ELU, and swish activation layers.

Training deep learning neural networks requires using nonlinear activation functions such as the ReLU and swish operations. Some activation layers can yield better training performance at the cost of extra computation time. When training a neural network, you can try using different activation layers to see if training improves.

This example shows how to compare the validation accuracy of training a SqueezeNet neural network when you use ReLU, leaky ReLU, ELU, or swish activation layers given a validation set of images.

Load Data

Download the Flowers data set.

```
url = 'http://download.tensorflow.org/example_images/flower_photos.tgz';
downloadFolder = tempdir;
filename = fullfile(downloadFolder,'flower_dataset.tgz');

dataFolder = fullfile(downloadFolder,'flower_photos');
if ~exist(dataFolder,'dir')
    fprintf("Downloading Flowers data set (218 MB)... ")
    websave(filename,url);
    untar(filename,downloadFolder)
    fprintf("Done.\n")
end
```

Prepare Data for Training

Load the data as an image datastore using the `imageDatastore` function and specify the folder containing the image data.

```
imds = imageDatastore(dataFolder, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

View the number of classes of the training data.

```
numClasses = numel(categories(imds.Labels))
```

```
numClasses = 5
```

Divide the datastore so that each category in the training set has 80% of the images and the validation set has the remaining images from each label.

```
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.80,'randomize');
```

Specify augmentation options and create an augmented image datastore containing the training images.

- Randomly reflect the images on the horizontal axis.
- Randomly scale the images by up to 20%.
- Randomly rotate the images by up to 45 degrees.

- Randomly translate the images by up to 3 pixels.
- Resize the images to the input size of the network (227-by-227).

```
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandScale',[0.8 1.2], ...
    'RandRotation',[-45,45], ...
    'RandXTranslation',[-3 3], ...
    'RandYTranslation',[-3 3]);

augimdsTrain = augmentedImageDatastore([227 227],imdsTrain,'DataAugmentation',imageAugmenter);
```

Create an augmented image datastore for the validation data that resizes the images to the input size of the network. Do not apply any other image transformations to the validation data.

```
augimdsValidation = augmentedImageDatastore([227 227],imdsValidation);
```

Create Custom Plotting Function

When training multiple networks, to monitor the validation accuracy for each network on the same axis, you can use the `OutputFcn` training option and specify a function that updates a plot with the provided training information.

Create a function that takes the information structure provided by the training process and updates an animated line plot. The `updatePlot` function, listed in the Plotting Function on page 1-0 section of the example, takes the information structure as input and updates the specified animated line.

Specify Training Options

Specify the training options:

- Train using a mini-batch size of 128 for 60 epochs.
- Shuffle the data each epoch.
- Validate the neural network once per epoch using the held-out validation set.

```
miniBatchSize = 128;
numObservationsTrain = numel(imdsTrain.Files);
numIterationsPerEpoch = floor(numObservationsTrain / miniBatchSize);

options = trainingOptions('adam', ...
    'MiniBatchSize',miniBatchSize, ...
    'MaxEpochs',60, ...
    'Shuffle','every-epoch', ...
    'ValidationData',augimdsValidation, ...
    'ValidationFrequency',numIterationsPerEpoch, ...
    'Verbose',false);
```

Train Neural Networks

For each of the activation layer types—ReLU, leaky ReLU, ELU, and swish—train a SqueezeNet network.

Specify the types of activation layers.

```
activationLayerTypes = ["relu" "leaky-relu" "elu" "swish"];
```

Initialize the customized training progress plot by creating animated lines with colors specified by `colororder` function.

```
figure

colors = colororder;

for i = 1:numel(activationLayerTypes)
    line(i) = animatedline('Color',colors(i,:));
end

ylim([0 100])

legend(activationLayerTypes,'Location','southeast');

xlabel("Iteration")
ylabel("Accuracy")
title("Validation Accuracy")
grid on
```

Loop over each of the activation layer types and train the neural network. For each activation layer type:

- Create a function handle `activationLayer` that creates the activation layer.
- Create a new SqueezeNet network without weights and replace the activation layers (the ReLU layers) with layers of the activation layer type using the function handle `activationLayer`.
- Replace the final convolution layer of the neural network with one specifying the number of classes of the input data.
- Update the validation accuracy plot by setting the `OutputFcn` property of the training options object to a function handle representing the `updatePlot` function with the animated line corresponding to the activation layer type.
- Train and time the network using the `trainNetwork` function.

```
for i = 1:numel(activationLayerTypes)
    activationLayerType = activationLayerTypes(i);

    % Determine activation layer type.
    switch activationLayerType
        case "relu"
            activationLayer = @reluLayer;
        case "leaky-relu"
            activationLayer = @leakyReluLayer;
        case "elu"
            activationLayer = @eluLayer;
        case "swish"
            activationLayer = @swishLayer;
    end

    % Create SqueezeNet layer graph.
    lgraph = squeezenet('Weights','none');

    % Replace activation layers.
    if activationLayerType ~= "relu"
        layers = lgraph.Layers;
        for j = 1:numel(layers)
            if isa(layers(j),'nnet.cnn.layer.ReLULayer')
```

```
                layerName = layers(j).Name;
                layer = activationLayer('Name',activationLayerType+"_new_"+j);
                lgraph = replaceLayer(lgraph,layerName,layer);
            end
        end
    end

    % Specify number of classes in final convolution layer.
    layer = convolution2dLayer([1 1],numClasses,'Name','conv10');
    lgraph = replaceLayer(lgraph,'conv10',layer);

    % Specify custom plot function.
    options.OutputFcn = @(info) updatePlot(info,line(i));

    % Train the network.
    start = tic;
    [net{i},info{i}] = trainNetwork(augimdsTrain,lgraph,options);
    elapsed(i) = toc(start);
end
```

Visualize the training times in a bar chart.

```
figure
bar(categorical(activationLayerTypes),elapsed)
title("Training Time")
ylabel("Time (seconds)")
```

In this case, using the different activation layers yields similar final validation accuracies, with the leaky ReLU and swish layers having slightly higher values. Using swish activation layers enables convergence in fewer iterations. When compared to the other activation layers, using ELU layers makes the validation accuracy converge in more iterations and requires more computation time.

Plotting Function

The `updatePlot` function takes as input the information structure `info` and updates the validation plot specified by the animated line `line`.

```
function updatePlot(info,line)

if ~isempty(info.ValidationAccuracy)
    addpoints(line,info.Iteration,info.ValidationAccuracy);
    drawnow limitrate
end

end
```

Deep Learning Tips and Tricks

This page describes various training options and techniques for improving the accuracy of deep learning networks.

Choose Network Architecture

The appropriate network architecture depends on the task and the data available. Consider these suggestions when deciding which architecture to use and whether to use a pretrained network or to train from scratch.

Data	Description of Task	Learn More
Images	Classification of natural images	Try different pretrained networks. For a list of pretrained deep learning networks, see “Pretrained Deep Neural Networks” on page 1-8. To learn how to interactively prepare a network for transfer learning using Deep Network Designer, see “Transfer Learning with Deep Network Designer” on page 2-2.
	Regression of natural images	Try different pretrained networks. For an example showing how to convert a pretrained classification network into a regression network, see “Convert Classification Network into Regression Network” on page 3-70.
	Classification and regression of non-natural images (for example, tiny images and spectrograms	For an example showing how to classify tiny images, see “Train Residual Network for Image Classification” on page 3-13. For an example showing how to classify spectrograms, see “Speech Command Recognition Using Deep Learning” on page 4-23.

Choose Training Options

The `trainingOptions` function provides a variety of options to train your deep learning network.

Tip	More Information
Monitor training progress	To turn on the training progress plot, set the `'Plots'` option in `trainingOptions` to `'training-progress'`.

Tip	More Information
Use validation data	To specify validation data, use the `'ValidationData'` option in `trainingOptions`. **Note** If your validation data set is too small and does not sufficiently represent the data, then the reported metrics might not help you. Using a too large validation data set can result in slower training.
For transfer learning, speed up the learning of new layers and slow down the learning in the transferred layers	Specify higher learning rate factors for new layers by using, for example, the `WeightLearnRateFactor` property of `convolution2dLayer`. Decrease the initial learning rate using the `'InitialLearnRate'` option of `trainingOptions`. When transfer learning, you do not need to train for as many epochs. Decrease the number of epochs using the `'MaxEpochs'` option in `trainingOptions`. To learn how to interactively prepare a network for transfer learning using Deep Network Designer, see “Transfer Learning with Deep Network Designer” on page 2-2.
Shuffle your data every epoch	To shuffle your data every epoch (one full pass of the data), set the `'Shuffle'` option in `trainingOptions` to `'every-epoch'`. **Note** For sequence data, shuffling can have a negative impact on the accuracy as it can increase the amount of padding or truncated data. If you have sequence data, then sorting the data by sequence length can help. To learn more, see “Sequence Padding, Truncation, and Splitting” on page 1-79.
Try different optimizers	To specify different optimizers, use the `solverName` argument in `trainingOptions`.

For more information, see “Set Up Parameters and Train Convolutional Neural Network” on page 1-42.

Improve Training Accuracy

If you notice problems during training, then consider these possible solutions.

Problem	Possible Solution
NaNs or large spikes in the loss	Decrease the initial learning rate using the `'InitialLearnRate'` option of `trainingOptions`. If decreasing the learning rate does not help, then try using gradient clipping. To set the gradient threshold, use the `'GradientThreshold'` option in `trainingOptions`.
Loss is still decreasing at the end of training	Train for longer by increasing the number of epochs using the `'MaxEpochs'` option in `trainingOptions`.
Loss plateaus	If the loss plateaus at an unexpectedly high value, then drop the learning rate at the plateau. To change the learning rate schedule, use the `'LearnRateSchedule'` option in `trainingOptions`. If dropping the learning rate does not help, then the model might be underfitting. Try increasing the number of parameters or layers. You can check if the model is underfitting by monitoring the validation loss.
Validation loss is much higher than the training loss	To prevent overfitting, try one or more of the following: • Use data augmentation. For more information, see “Train Network with Augmented Images”. • Use dropout layers. For more information, see `dropoutLayer`. • Increase the global L2 regularization factor using the `'L2Regularization'` option in `trainingOptions`.
Loss decreases very slowly	Increase the initial learning rate using the `'InitialLearnRate'` option of `trainingOptions`. For image data, try including batch normalization layers in your network. For more information, see `batchNormalizationLayer`.

For more information, see “Set Up Parameters and Train Convolutional Neural Network” on page 1-42.

Fix Errors in Training

If your network does not train at all, then consider the possible solutions.

Error	Description	Possible Solution
Out-of-memory error when training	The available hardware is unable to store the current mini-batch, the network weights, and the computed activations.	Try reducing the mini-batch size using the `'MiniBatchSize'` option of `trainingOptions`. If reducing the mini-batch size does not work, then try using a smaller network, reducing the number of layers, or reducing the number of parameters or filters in the layers.
Custom layer errors	There could be an issue with the implementation of the custom layer.	Check the validity of the custom layer and find potential issues using `checkLayer`. If a test fails when you use `checkLayer`, then the function provides a test diagnostic and a framework diagnostic. The test diagnostic highlights any layer issues, whereas the framework diagnostic provides more detailed information. To learn more about the test diagnostics and get suggestions for possible solutions, see “Diagnostics” on page 18-158.
Training throws the error `'CUDA_ERROR_UNKNOWN'`	Sometimes, the GPU throws this error when it is being used for both compute and display requests from the OS.	Try reducing the mini-batch size using the `'MiniBatchSize'` option of `trainingOptions`. If reducing the mini-batch size does not work, then in Windows®, try adjusting the Timeout Detection and Recovery (TDR) settings. For example, change the `TdrDelay` from 2 seconds (default) to 4 seconds (requires registry edit).

You can analyze your deep learning network using `analyzeNetwork`. The `analyzeNetwork` function displays an interactive visualization of the network architecture, detects errors and issues with the network, and provides detailed information about the network layers. Use the network analyzer to visualize and understand the network architecture, check that you have defined the architecture correctly, and detect problems before training. Problems that `analyzeNetwork` detects include missing or disconnected layers, mismatched or incorrect sizes of layer inputs, an incorrect number of layer inputs, and invalid graph structures.

Prepare and Preprocess Data

You can improve the accuracy by preprocessing your data.

Weight or Balance Classes

Ideally, all classes have an equal number of observations. However, for some tasks, classes can be imbalanced. For example, automotive datasets of street scenes tend to have more sky, building, and road pixels than pedestrian and bicyclist pixels because the sky, buildings, and roads cover more image area. If not handled correctly, this imbalance can be detrimental to the learning process because the learning is biased in favor of the dominant classes.

For classification tasks, you can specify class weights using the `'ClassWeights'` option of `classificationLayer`. For semantic segmentation tasks, you can specify class weights using the `ClassWeights` property of `pixelClassificationLayer`.

Alternatively, you can balance the classes by doing one or more of the following:

- Add new observations from the least frequent classes.
- Remove observations from the most frequent classes.
- Group similar classes. For example, group the classes "car" and "truck" into the single class "vehicle".

Preprocess Image Data

For more information about preprocessing image data, see “Preprocess Images for Deep Learning” on page 19-16.

Task	More Information
Resize images	To use a pretrained network, you must resize images to the input size of the network. To resize images, use `augmentedImageDatastore`. For example, this syntax resizes images in the image datastore `imds`: `auimds = augmentedImageDatastore(inputSize,imds);` **Tip** Use `augmentedImageDatastore` for efficient preprocessing of images for deep learning including image resizing. Do not use the `readFcn` option of `imageDatastore` for preprocessing or resizing as this option is usually significantly slower.
Image augmentation	To avoid overfitting, use image transformation. To learn more, see “Train Network with Augmented Images”.
Normalize regression targets	Normalize the predictors before you input them to the network. If you normalize the responses before training, then you must transform the predictions of the trained network to obtain the predictions of the original responses. For more information, see “Train Convolutional Neural Network for Regression” on page 3-53.

Preprocess Sequence Data

For more information about working with LSTM networks, see “Long Short-Term Memory Networks” on page 1-75.

Task	More Information
Normalize sequence data	To normalize sequence data, first calculate the per-feature mean and standard deviation for all the sequences. Then, for each training observation, subtract the mean value and divide by the standard deviation. To learn more, see “Normalize Sequence Data” on page 1-82.
Reduce sequence padding and truncation	To reduce the amount of padding or discarded data when padding or truncating sequences, try sorting your data by sequence length. To learn more, see “Sequence Padding, Truncation, and Splitting” on page 1-79.
Specify mini-batch size and padding options for prediction	When making predictions with sequences of different lengths, the mini-batch size can impact the amount of padding added to the input data which can result in different predicted values. Try using different values to see which works best with your network. To specify mini-batch size and padding options, use the `'MiniBatchSize'` and `'SequenceLength'` options of the `classify`, `predict`, `classifyAndUpdateState`, and `predictAndUpdateState` functions.

Use Available Hardware

To specify the execution environment, use the `'ExecutionEnvironment'` option in `trainingOptions`.

Problem	More Information
Training on CPU is slow	If training is too slow on a single CPU, try using a pretrained deep learning network as a feature extractor and train a machine learning model. For an example, see “Extract Image Features Using Pretrained Network” on page 3-28.
Training LSTM on GPU is slow	The CPU is better suited for training an LSTM network using mini-batches with short sequences. To use the CPU, set the `'ExecutionEnvironment'` option in `trainingOptions` to `'cpu'`.

Problem	More Information
Software does not use all available GPUs	If you have access to a machine with multiple GPUs, simply set the `'ExecutionEnvironment'` option in `trainingOptions` to `'multi-gpu'`. For more information, see “Deep Learning with MATLAB on Multiple GPUs” on page 7-13.

For more information, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2.

Fix Errors With Loading from MAT-Files

If you are unable to load layers or a network from a MAT-file and get a warning of the form

```
Warning: Unable to load instances of class layerType into a
heterogeneous array.  The definition of layerType could be
missing or contain an error.  Default objects will be
substituted.
Warning: While loading an object of class 'SeriesNetwork':
Error using 'forward' in Layer nnet.cnn.layer.MissingLayer. The
function threw an error and could not be executed.
```

then the network in the MAT-file may contain unavailable layers. This could be due to the following:

- The file contains a custom layer not on the path – To load networks containing custom layers, add the custom layer files to the MATLAB path.
- The file contains a custom layer from a support package – To load networks using layers from support packages, install the required support package at the command line by using the corresponding function (for example, `resnet18`) or using the Add-On Explorer.
- The file contains a custom layer from a documentation example that is not on the path – To load networks containing custom layers from documentation examples, open the example as a Live Script and copy the layer from the example folder to your working directory.
- The file contains a layer from a toolbox that is not installed – To access layers from other toolboxes, for example, Computer Vision Toolbox or Text Analytics Toolbox, install the corresponding toolbox.

After trying the suggested solutions, reload the MAT-file.

Long Short-Term Memory Networks

This topic explains how to work with sequence and time series data for classification and regression tasks using long short-term memory (LSTM) networks. For an example showing how to classify sequence data using an LSTM network, see “Sequence Classification Using Deep Learning” on page 4-2.

An LSTM network is a type of recurrent neural network (RNN) that can learn long-term dependencies between time steps of sequence data.

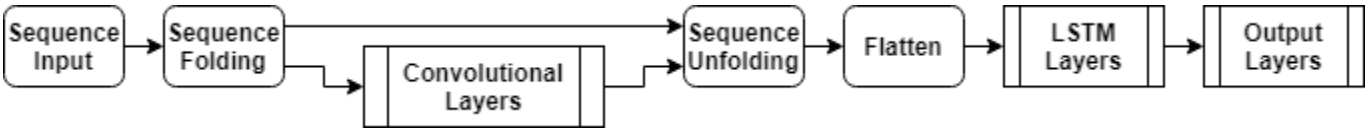
LSTM Network Architecture

The core components of an LSTM network are a sequence input layer and an LSTM layer. A *sequence input layer* inputs sequence or time series data into the network. An *LSTM layer* learns long-term dependencies between time steps of sequence data.

This diagram illustrates the architecture of a simple LSTM network for classification. The network starts with a sequence input layer followed by an LSTM layer. To predict class labels, the network ends with a fully connected layer, a softmax layer, and a classification output layer.

This diagram illustrates the architecture of a simple LSTM network for regression. The network starts with a sequence input layer followed by an LSTM layer. The network ends with a fully connected layer and a regression output layer.

This diagram illustrates the architecture of a network for video classification. To input image sequences to the network, use a sequence input layer. To use convolutional layers to extract features, that is, to apply the convolutional operations to each frame of the videos independently, use a sequence folding layer followed by the convolutional layers, and then a sequence unfolding layer. To use the LSTM layers to learn from sequences of vectors, use a flatten layer followed by the LSTM and output layers.



Classification LSTM Networks

To create an LSTM network for sequence-to-label classification, create a layer array containing a sequence input layer, an LSTM layer, a fully connected layer, a softmax layer, and a classification output layer.

Set the size of the sequence input layer to the number of features of the input data. Set the size of the fully connected layer to the number of classes. You do not need to specify the sequence length.

For the LSTM layer, specify the number of hidden units and the output mode `'last'`.

```
numFeatures = 12;
numHiddenUnits = 100;
numClasses = 9;
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

For an example showing how to train an LSTM network for sequence-to-label classification and classify new data, see “Sequence Classification Using Deep Learning” on page 4-2.

To create an LSTM network for sequence-to-sequence classification, use the same architecture as for sequence-to-label classification, but set the output mode of the LSTM layer to `'sequence'`.

```
numFeatures = 12;
numHiddenUnits = 100;
numClasses = 9;
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','sequence')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Regression LSTM Networks

To create an LSTM network for sequence-to-one regression, create a layer array containing a sequence input layer, an LSTM layer, a fully connected layer, and a regression output layer.

Set the size of the sequence input layer to the number of features of the input data. Set the size of the fully connected layer to the number of responses. You do not need to specify the sequence length.

For the LSTM layer, specify the number of hidden units and the output mode `'last'`.

```
numFeatures = 12;
numHiddenUnits = 125;
numResponses = 1;

layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numResponses)
    regressionLayer];
```

To create an LSTM network for sequence-to-sequence regression, use the same architecture as for sequence-to-one regression, but set the output mode of the LSTM layer to `'sequence'`.

```
numFeatures = 12;
numHiddenUnits = 125;
numResponses = 1;

layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','sequence')
```

```
    fullyConnectedLayer(numResponses)
    regressionLayer];
```

For an example showing how to train an LSTM network for sequence-to-sequence regression and predict on new data, see “Sequence-to-Sequence Regression Using Deep Learning” on page 4-47.

Video Classification Network

To create a deep learning network for data containing sequences of images such as video data and medical images, specify image sequence input using the sequence input layer.

To use convolutional layers to extract features, that is, to apply the convolutional operations to each frame of the videos independently, use a sequence folding layer followed by the convolutional layers, and then a sequence unfolding layer. To use the LSTM layers to learn from sequences of vectors, use a flatten layer followed by the LSTM and output layers.

```
inputSize = [28 28 1];
filterSize = 5;
numFilters = 20;
numHiddenUnits = 200;
numClasses = 10;

layers = [ ...
    sequenceInputLayer(inputSize,'Name','input')

    sequenceFoldingLayer('Name','fold')

    convolution2dLayer(filterSize,numFilters,'Name','conv')
    batchNormalizationLayer('Name','bn')
    reluLayer('Name','relu')

    sequenceUnfoldingLayer('Name','unfold')
    flattenLayer('Name','flatten')

    lstmLayer(numHiddenUnits,'OutputMode','last','Name','lstm')

    fullyConnectedLayer(numClasses, 'Name','fc')
    softmaxLayer('Name','softmax')
    classificationLayer('Name','classification')];
```

Convert the layers to a layer graph and connect the `miniBatchSize` output of the sequence folding layer to the corresponding input of the sequence unfolding layer.

```
lgraph = layerGraph(layers);
lgraph = connectLayers(lgraph,'fold/miniBatchSize','unfold/miniBatchSize');
```

For an example showing how to train a deep learning network for video classification, see “Classify Videos Using Deep Learning” on page 4-54.

Deeper LSTM Networks

You can make LSTM networks deeper by inserting extra LSTM layers with the output mode `'sequence'` before the LSTM layer. To prevent overfitting, you can insert dropout layers after the LSTM layers.

For sequence-to-label classification networks, the output mode of the last LSTM layer must be `'last'`.

```
numFeatures = 12;
numHiddenUnits1 = 125;
numHiddenUnits2 = 100;
numClasses = 9;
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits1,'OutputMode','sequence')
    dropoutLayer(0.2)
    lstmLayer(numHiddenUnits2,'OutputMode','last')
    dropoutLayer(0.2)
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

For sequence-to-sequence classification networks, the output mode of the last LSTM layer must be `'sequence'`.

```
numFeatures = 12;
numHiddenUnits1 = 125;
numHiddenUnits2 = 100;
numClasses = 9;
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits1,'OutputMode','sequence')
    dropoutLayer(0.2)
    lstmLayer(numHiddenUnits2,'OutputMode','sequence')
    dropoutLayer(0.2)
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Layers

Layer	Description
 `sequenceInputLayer`	A sequence input layer inputs sequence data to a network.
 `lstmLayer`	An LSTM layer learns long-term dependencies between time steps in time series and sequence data.
 `bilstmLayer`	A bidirectional LSTM (BiLSTM) layer learns bidirectional long-term dependencies between time steps of time series or sequence data. These dependencies can be useful when you want the network to learn from the complete time series at each time step.
 `gruLayer`	A GRU layer learns dependencies between time steps in time series and sequence data.

Layer	Description
 `convolution1dLayer`	A 1-D convolutional layer applies sliding convolutional filters to 1-D input.
 `maxPooling1dLayer`	A 1-D max pooling layer performs downsampling by dividing the input into 1-D pooling regions, then computing the maximum of each region.
 `averagePooling1dLayer`	A 1-D average pooling layer performs downsampling by dividing the input into 1-D pooling regions, then computing the average of each region.
 `globalMaxPooling1dLayer`	A 1-D global max pooling layer performs downsampling by outputting the maximum of the time or spatial dimensions of the input.
 `sequenceFoldingLayer`	A sequence folding layer converts a batch of image sequences to a batch of images. Use a sequence folding layer to perform convolution operations on time steps of image sequences independently.
 `sequenceUnfoldingLayer`	A sequence unfolding layer restores the sequence structure of the input data after sequence folding.
 `flattenLayer`	A flatten layer collapses the spatial dimensions of the input into the channel dimension.
 `wordEmbeddingLayer`	A word embedding layer maps word indices to vectors.

Classification, Prediction, and Forecasting

To classify or make predictions on new data, use `classify` and `predict`.

LSTM networks can remember the state of the network between predictions. The network state is useful when you do not have the complete time series in advance, or if you want to make multiple predictions on a long time series.

To predict and classify on parts of a time series and update the network state, use `predictAndUpdateState` and `classifyAndUpdateState`. To reset the network state between predictions, use `resetState`.

For an example showing how to forecast future time steps of a sequence, see “Time Series Forecasting Using Deep Learning” on page 4-15.

Sequence Padding, Truncation, and Splitting

LSTM networks support input data with varying sequence lengths. When passing data through the network, the software pads, truncates, or splits sequences so that all the sequences in each mini-batch have the specified length. You can specify the sequence lengths and the value used to pad the sequences using the `SequenceLength` and `SequencePaddingValue` name-value pair arguments in `trainingOptions`.

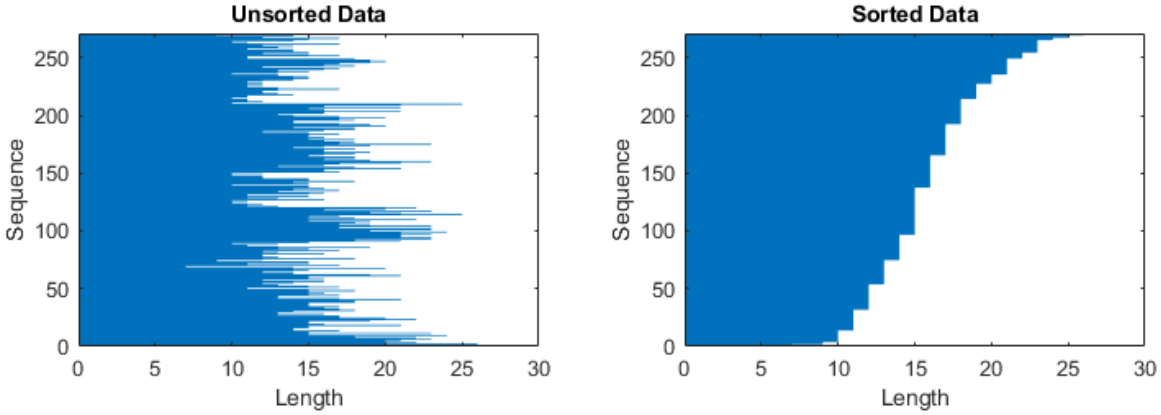
After training the network, use the same mini-batch size and padding options when using the `classify`, `predict`, `classifyAndUpdateState`, `predictAndUpdateState`, and `activations` functions.

Sort Sequences by Length

To reduce the amount of padding or discarded data when padding or truncating sequences, try sorting your data by sequence length. To sort the data by sequence length, first get the number of columns of each sequence by applying `size(X,2)` to every sequence using `cellfun`. Then sort the sequence lengths using `sort`, and use the second output to reorder the original sequences.

```
sequenceLengths = cellfun(@(X) size(X,2), XTrain);
[sequenceLengthsSorted,idx] = sort(sequenceLengths);
XTrain = XTrain(idx);
```

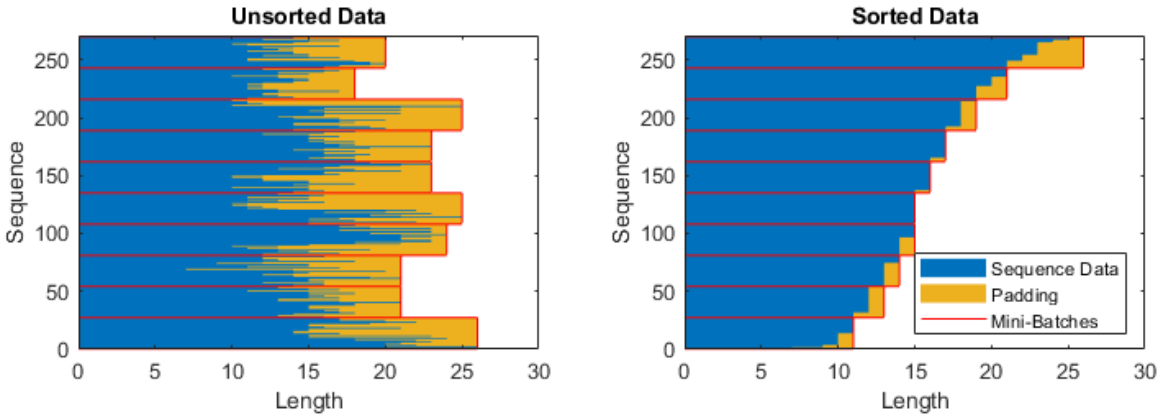
The following figures show the sequence lengths of the sorted and unsorted data in bar charts.



Pad Sequences

If you specify the sequence length `'longest'`, then the software pads the sequences so that all the sequences in a mini-batch have the same length as the longest sequence in the mini-batch. This option is the default.

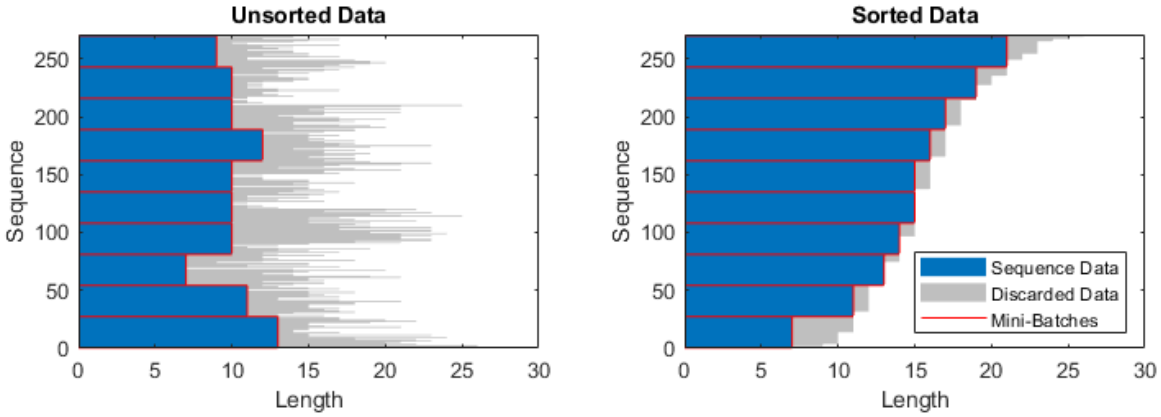
The following figures illustrate the effect of setting `'SequenceLength'` to `'longest'`.



Truncate Sequences

If you specify the sequence length `'shortest'`, then the software truncates the sequences so that all the sequences in a mini-batch have the same length as the shortest sequence in that mini-batch. The remaining data in the sequences is discarded.

The following figures illustrate the effect of setting `'SequenceLength'` to `'shortest'`.



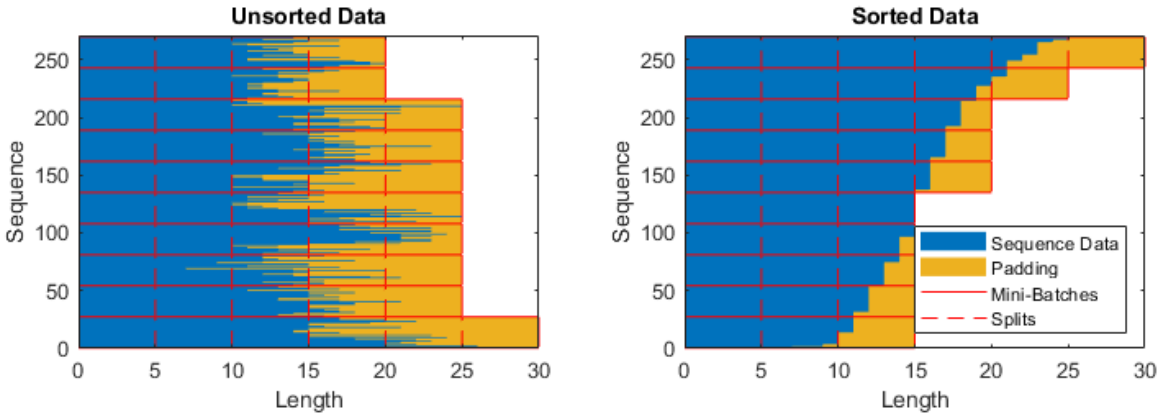
Split Sequences

If you set the sequence length to an integer value, then software pads all the sequences in a mini-batch to the nearest multiple of the specified length that is greater than the longest sequence length in the mini-batch. Then, the software splits each sequence into smaller sequences of the specified length. If splitting occurs, then the software creates extra mini-batches.

Use this option if the full sequences do not fit in memory. Alternatively, you can try reducing the number of sequences per mini-batch by setting the `'MiniBatchSize'` option in `trainingOptions` to a lower value.

If you specify the sequence length as a positive integer, then the software processes the smaller sequences in consecutive iterations. The network updates the network state between the split sequences.

The following figures illustrate the effect of setting `'SequenceLength'` to 5.



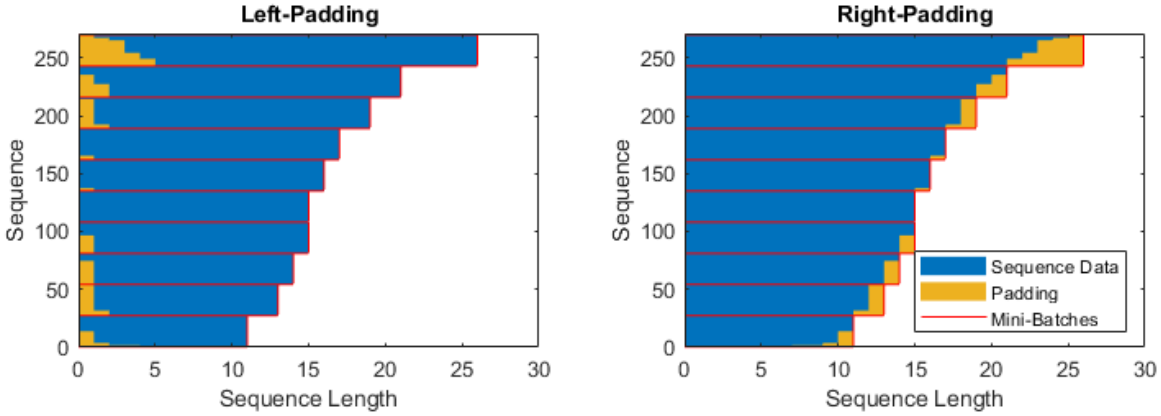
Specify Padding Direction

The location of the padding and truncation can impact training, classification, and prediction accuracy. Try setting the `'SequencePaddingDirection'` option in `trainingOptions` to `'left'` or `'right'` and see which is best for your data.

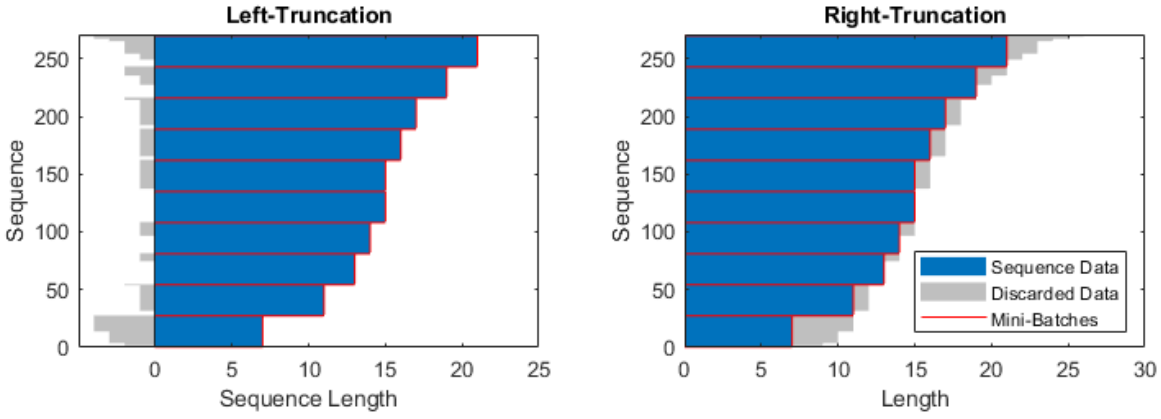
Because LSTM layers process sequence data one time step at a time, when the layer `OutputMode` property is `'last'`, any padding in the final time steps can negatively influence the layer output. To pad or truncate sequence data on the left, set the `'SequencePaddingDirection'` option to `'left'`.

For sequence-to-sequence networks (when the `OutputMode` property is `'sequence'` for each LSTM layer), any padding in the first time steps can negatively influence the predictions for the earlier time steps. To pad or truncate sequence data on the right, set the `'SequencePaddingDirection'` option to `'right'`.

The following figures illustrate padding sequence data on the left and on the right.



The following figures illustrate truncating sequence data on the left and on the right.



Normalize Sequence Data

To recenter training data automatically at training time using zero-center normalization, set the `Normalization` option of `sequenceInputLayer` to `'zerocenter'`. Alternatively, you can normalize sequence data by first calculating the per-feature mean and standard deviation of all the

sequences. Then, for each training observation, subtract the mean value and divide by the standard deviation.

```
mu = mean([XTrain{:}],2);
sigma = std([XTrain{:}],0,2);
XTrain = cellfun(@(X) (X-mu)./sigma,XTrain,'UniformOutput',false);
```

Out-of-Memory Data

Use datastores for sequence, time series, and signal data when data is too large to fit in memory or to perform specific operations when reading batches of data.

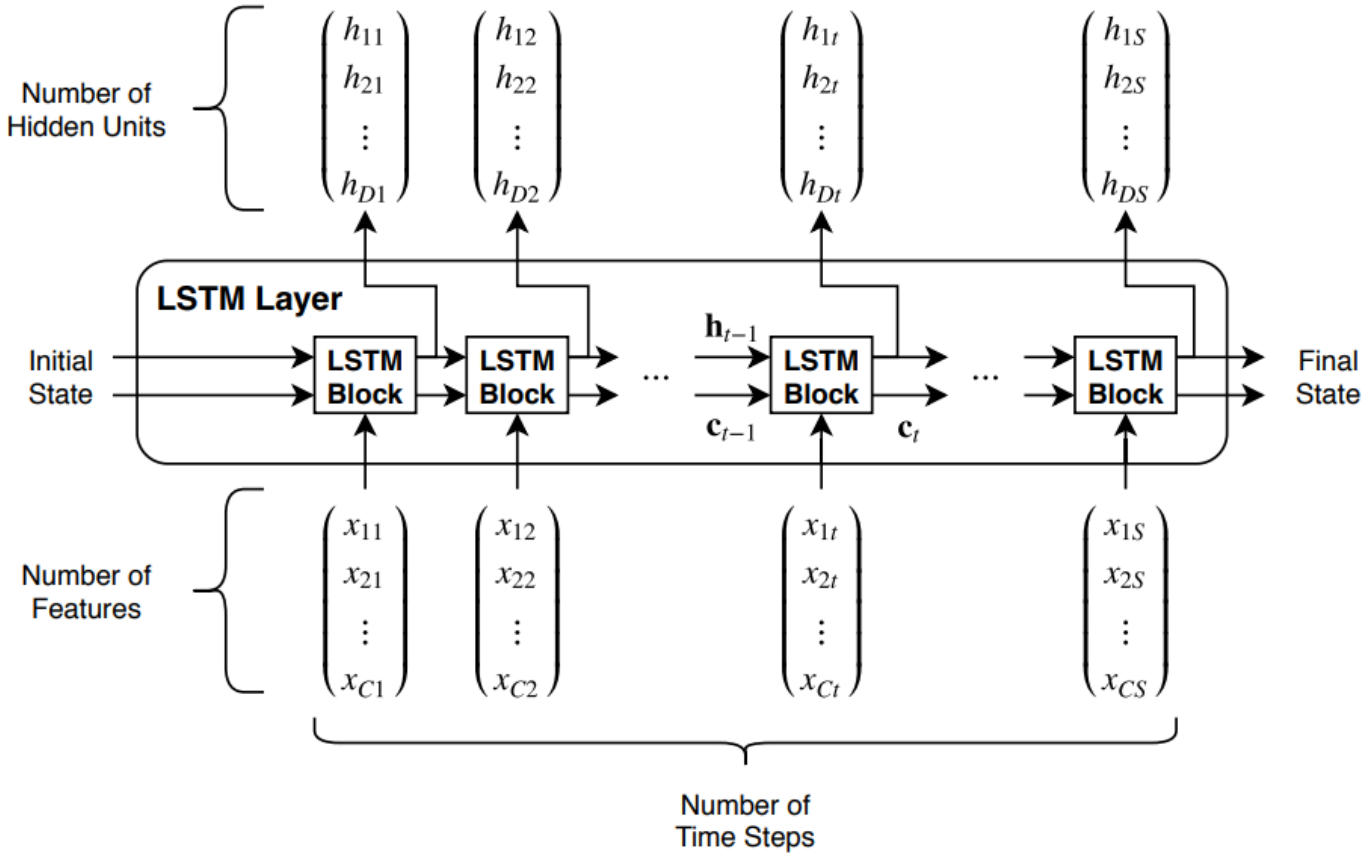
To learn more, see “Train Network Using Out-of-Memory Sequence Data” on page 19-99 and “Classify Out-of-Memory Text Data Using Deep Learning” on page 19-108.

Visualization

Investigate and visualize the features learned by LSTM networks from sequence and time series data by extracting the activations using the `activations` function. To learn more, see “Visualize Activations of LSTM Network” on page 5-152.

LSTM Layer Architecture

This diagram illustrates the flow of a time series X with C features (channels) of length S through an LSTM layer. In the diagram, $\mathbf{h}_t$ and $\mathbf{c}_t$ denote the output (also known as the *hidden state*) and the *cell state* at time step t, respectively.



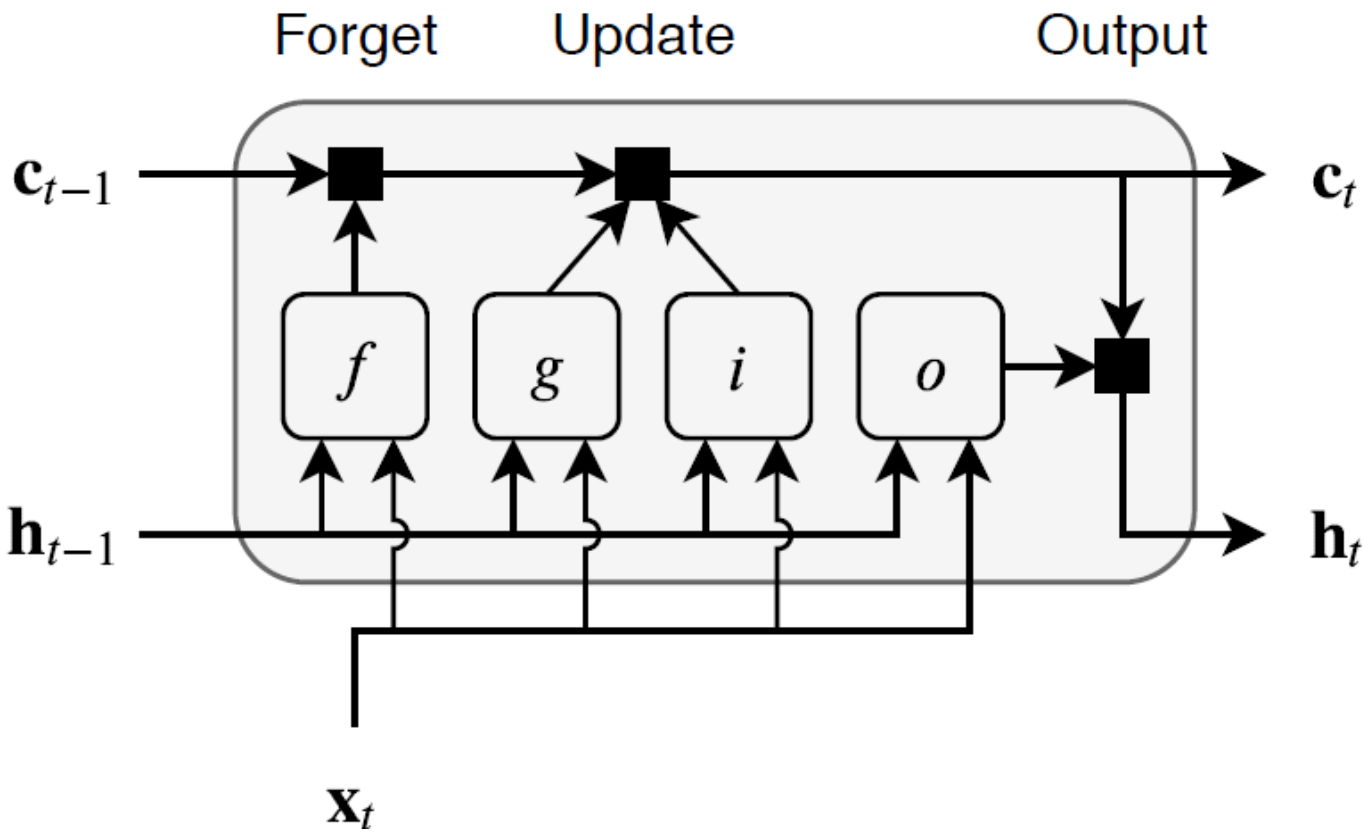
The first LSTM block uses the initial state of the network and the first time step of the sequence to compute the first output and the updated cell state. At time step t, the block uses the current state of the network ($\mathbf{c}_{t-1}, \mathbf{h}_{t-1}$) and the next time step of the sequence to compute the output and the updated cell state $\mathbf{c}_t$.

The state of the layer consists of the *hidden state* (also known as the *output state*) and the *cell state*. The hidden state at time step t contains the output of the LSTM layer for this time step. The cell state contains information learned from the previous time steps. At each time step, the layer adds information to or removes information from the cell state. The layer controls these updates using *gates*.

The following components control the cell state and hidden state of the layer.

Component	Purpose
Input gate (i)	Control level of cell state update
Forget gate (f)	Control level of cell state reset (forget)
Cell candidate (g)	Add information to cell state
Output gate (o)	Control level of cell state added to hidden state

This diagram illustrates the flow of data at time step t. The diagram highlights how the gates forget, update, and output the cell and hidden states.



The learnable weights of an LSTM layer are the input weights W (`InputWeights`), the recurrent weights R (`RecurrentWeights`), and the bias b (`Bias`). The matrices W, R, and b are concatenations of the input weights, the recurrent weights, and the bias of each component, respectively. These matrices are concatenated as follows:

$$W = \begin{bmatrix} W_i \\ W_f \\ W_g \\ W_o \end{bmatrix}, R = \begin{bmatrix} R_i \\ R_f \\ R_g \\ R_o \end{bmatrix}, b = \begin{bmatrix} b_i \\ b_f \\ b_g \\ b_o \end{bmatrix},$$

where i, f, g, and o denote the input gate, forget gate, cell candidate, and output gate, respectively.

The cell state at time step t is given by

$$\mathbf{c}_t = f_t \odot \mathbf{c}_{t-1} + i_t \odot g_t,$$

where $\odot$ denotes the Hadamard product (element-wise multiplication of vectors).

The hidden state at time step t is given by

$$\mathbf{h}_t = o_t \odot \sigma_c(\mathbf{c}_t),$$

where σ_c denotes the state activation function. The `lstmLayer` function, by default, uses the hyperbolic tangent function (tanh) to compute the state activation function.

The following formulas describe the components at time step t.

Component	Formula
Input gate	$i_t = \sigma_g(W_i\mathbf{x}_t + \mathrm{R}_i\mathbf{h}_{t-1} + b_i)$
Forget gate	$f_t = \sigma_g(W_f\mathbf{x}_t + \mathrm{R}_f\mathbf{h}_{t-1} + b_f)$
Cell candidate	$g_t = \sigma_c(W_g\mathbf{x}_t + \mathrm{R}_g\mathbf{h}_{t-1} + b_g)$
Output gate	$o_t = \sigma_g(W_o\mathbf{x}_t + \mathrm{R}_o\mathbf{h}_{t-1} + b_o)$

In these calculations, σ_g denotes the gate activation function. The `lstmLayer` function, by default, uses the sigmoid function given by $\sigma(x) = (1 + e^{-x})^{-1}$ to compute the gate activation function.

Deep Network Designer

Transfer Learning with Deep Network Designer

This example shows how to perform transfer learning interactively using the Deep Network Designer app.

Transfer learning is the process of taking a pretrained deep learning network and fine-tuning it to learn a new task. Using transfer learning is usually faster and easier than training a network from scratch. You can quickly transfer learned features to a new task using a smaller amount of data.

Use Deep Network Designer to perform transfer learning for image classification by following these steps:

1. Open the Deep Network Designer app and choose a pretrained network.
2. Import the new data set.
3. Replace the final layers with new layers adapted to the new data set.
4. Set learning rates so that learning is faster in the new layers than in the transferred layers.
5. Train the network using Deep Network Designer, or export the network for training at the command line.

Extract Data

In the workspace, extract the MathWorks Merch data set. This is a small data set containing 75 images of MathWorks merchandise, belonging to five different classes (*cap*, *cube*, *playing cards*, *screwdriver*, and *torch*).

```
unzip("MerchData.zip");
```

Select a Pretrained Network

To open Deep Network Designer, on the **Apps** tab, under **Machine Learning and Deep Learning**, click the app icon. Alternatively, you can open the app from the command line:

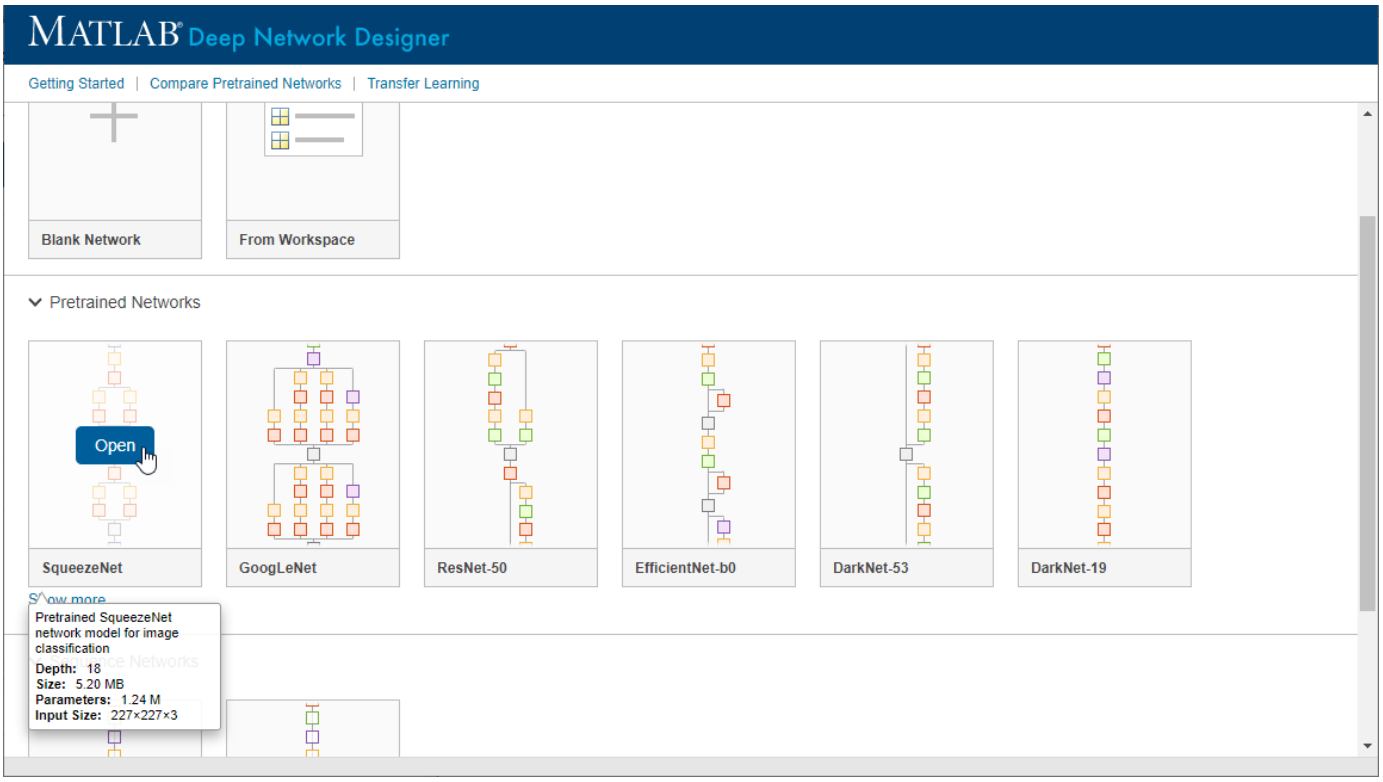
```
deepNetworkDesigner
```

Deep Network Designer provides a selection of pretrained image classification networks that have learned rich feature representations suitable for a wide range of images. Transfer learning works best if your images are similar to the images originally used to train the network. If your training images are natural images like those in the ImageNet database, then any of the pretrained networks is suitable. For a list of available networks and how to compare them, see “Pretrained Deep Neural Networks” on page 1-8.

If your data is very different from the ImageNet data—for example, if you have tiny images, spectrograms, or nonimage data—training a new network might be better. For examples showing how to train a network from scratch, see “Create Simple Sequence Classification Network Using Deep Network Designer” on page 2-51 and “Train Simple Semantic Segmentation Network in Deep Network Designer” on page 8-148.

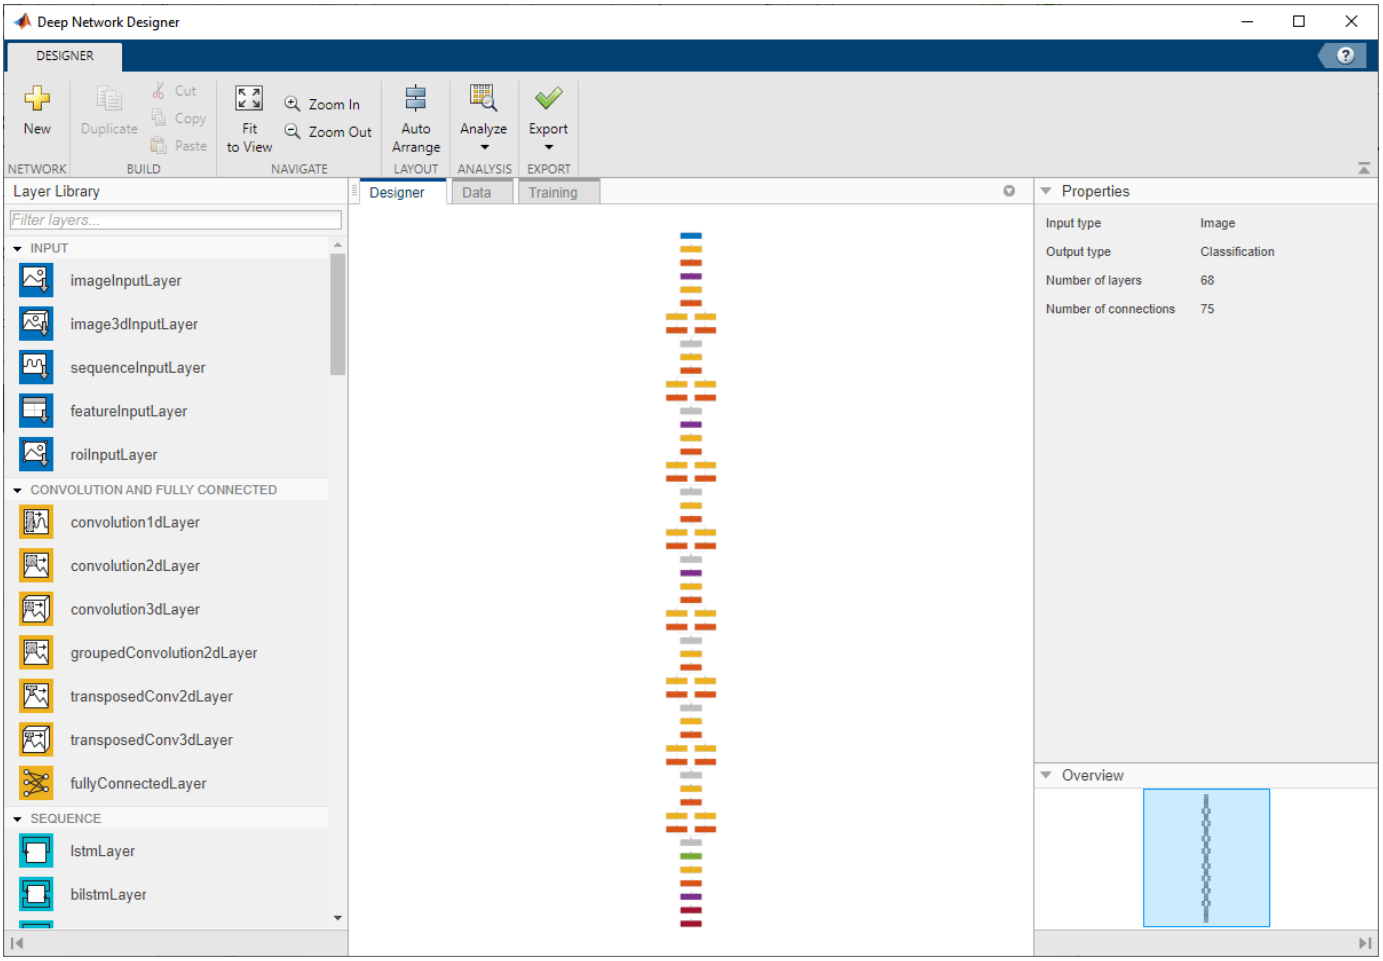
SqueezeNet does not require an additional support package. For other pretrained networks, if you do not have the required support package installed, then the app provides the **Install** option.

Select **SqueezeNet** from the list of pretrained networks and click **Open**.



Explore Network

Deep Network Designer displays a zoomed-out view of the whole network in the **Designer** pane.



Explore the network plot. To zoom in with the mouse, use **Ctrl**+scroll wheel. To pan, use the arrow keys, or hold down the scroll wheel and drag the mouse. Select a layer to view its properties. Deselect all layers to view the network summary in the **Properties** pane.

Import Data

To load the data into Deep Network Designer, on the **Data** tab, click **Import Data** > **Import Image Data**. The Import Image Data dialog box opens.

In the **Data source** list, select **Folder**. Click **Browse** and select the extracted MerchData folder.

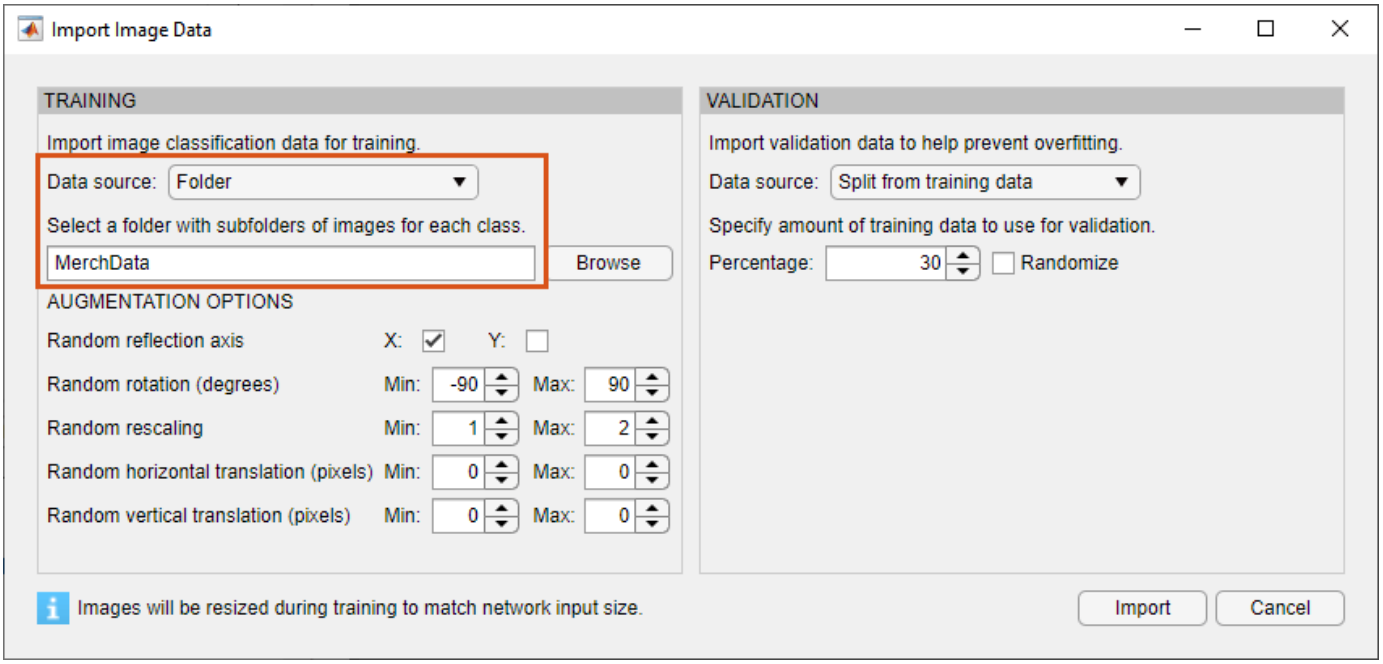


Image Augmentation

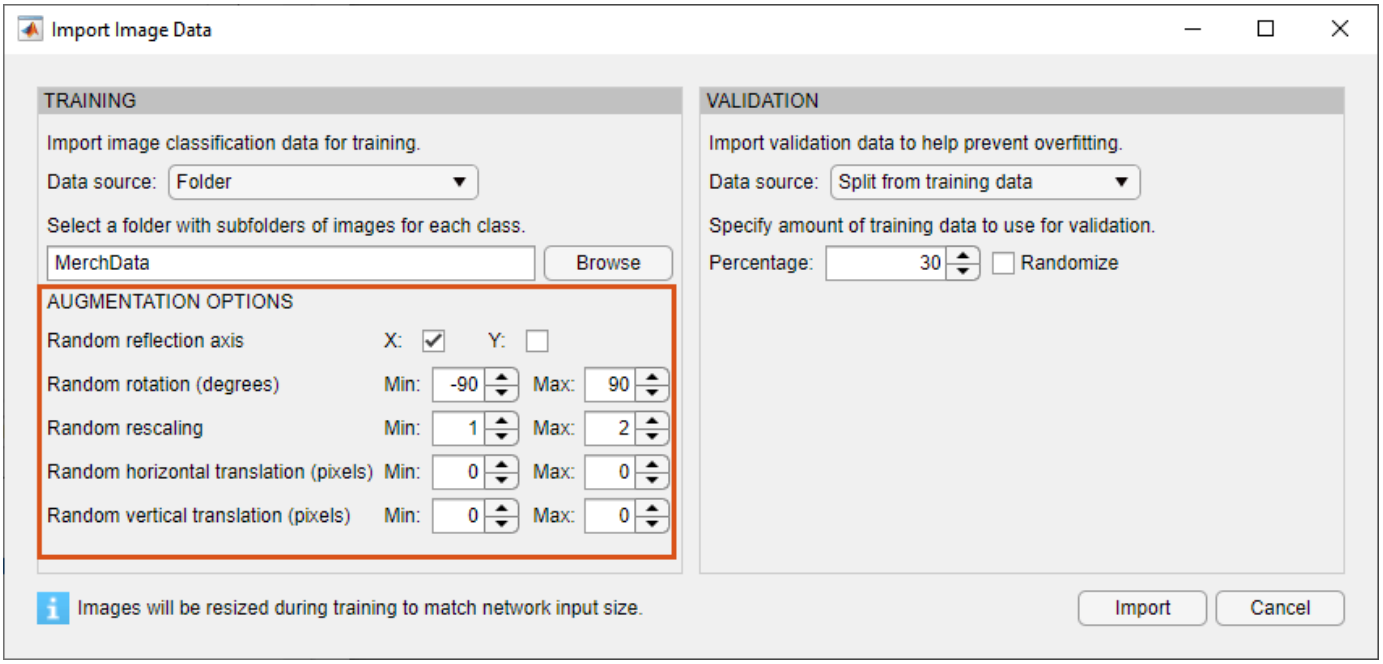
You can choose to apply image augmentation to your training data. The Deep Network Designer app provides the following augmentation options:

- Random reflection in the x-axis
- Random reflection in the y-axis
- Random rotation
- Random rescaling
- Random horizontal translation
- Random vertical translation

You can effectively increase the amount of training data by applying randomized augmentation to your data. Augmentation also enables you to train networks to be invariant to distortions in image data. For example, you can add randomized rotations to input images so that a network is invariant to the presence of rotation in input images.

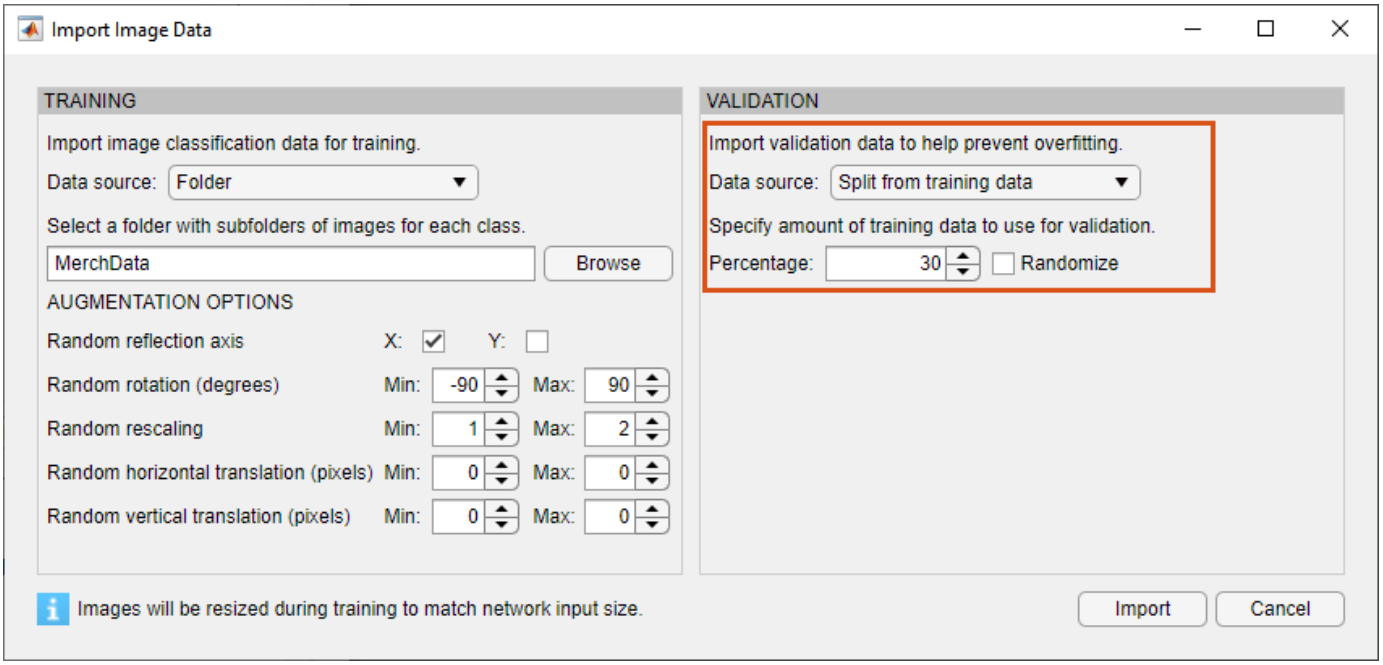
For this example, apply a random reflection in the x-axis, a random rotation from the range [-90,90] degrees, and a random rescaling from the range [1,2].



Validation Data

You can also choose to import validation data either by splitting it from the training data, or by importing it from another source. Validation estimates model performance on new data compared to the training data, and helps you to monitor performance and protect against overfitting.

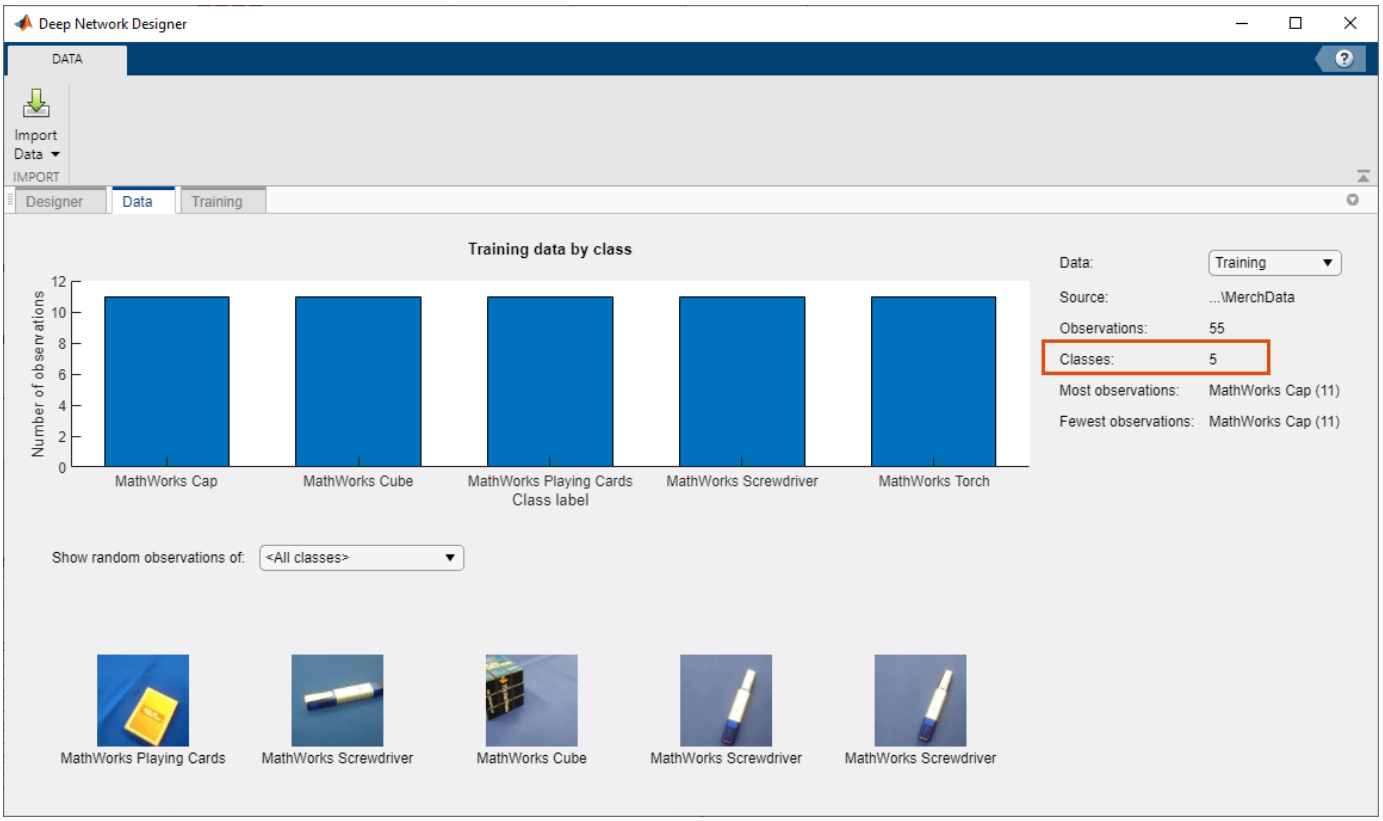
For this example, use 30% of the images for validation.



Click **Import** to import the data into Deep Network Designer.

Visualize Data

Using Deep Network Designer, you can visually inspect the distribution of the training and validation data in the **Data** tab. You can see that, in this example, there are five classes in the data set. You can also see random observations from each class.



Prepare Network for Training

Edit the network in the **Designer** pane to specify a new number of classes in your data. To prepare the network for transfer learning, replace the last learnable layer and the final classification layer.

Replace Last Learnable Layer

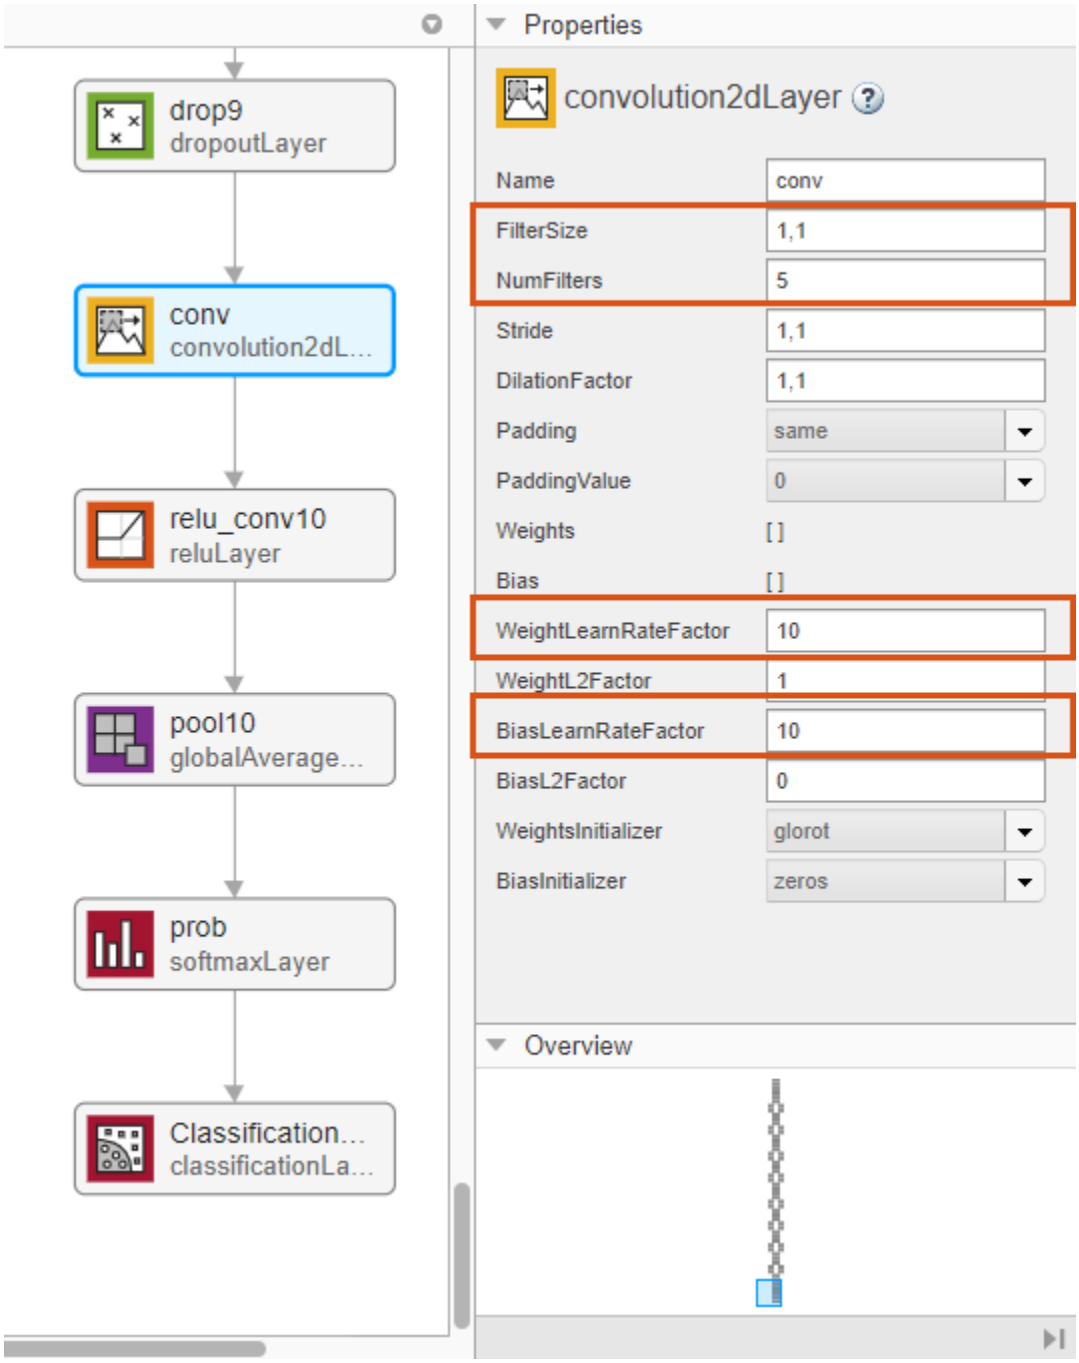
To use a pretrained network for transfer learning, you must change the number of classes to match your new data set. First, find the last learnable layer in the network. For SqueezeNet, the last learnable layer is the last convolutional layer, `'conv10'`. In this case, replace the convolutional layer with a new convolutional layer with the number of filters equal to the number of classes.

Drag a new `convolution2dLayer` onto the canvas. To match the original convolutional layer, set `FilterSize` to `1,1`.

The `NumFilters` property defines the number of classes for classification problems. Change `NumFilters` to the number of classes in the new data, in this example, `5`.

Change the learning rates so that learning is faster in the new layer than in the transferred layers by setting `WeightLearnRateFactor` and `BiasLearnRateFactor` to `10`.

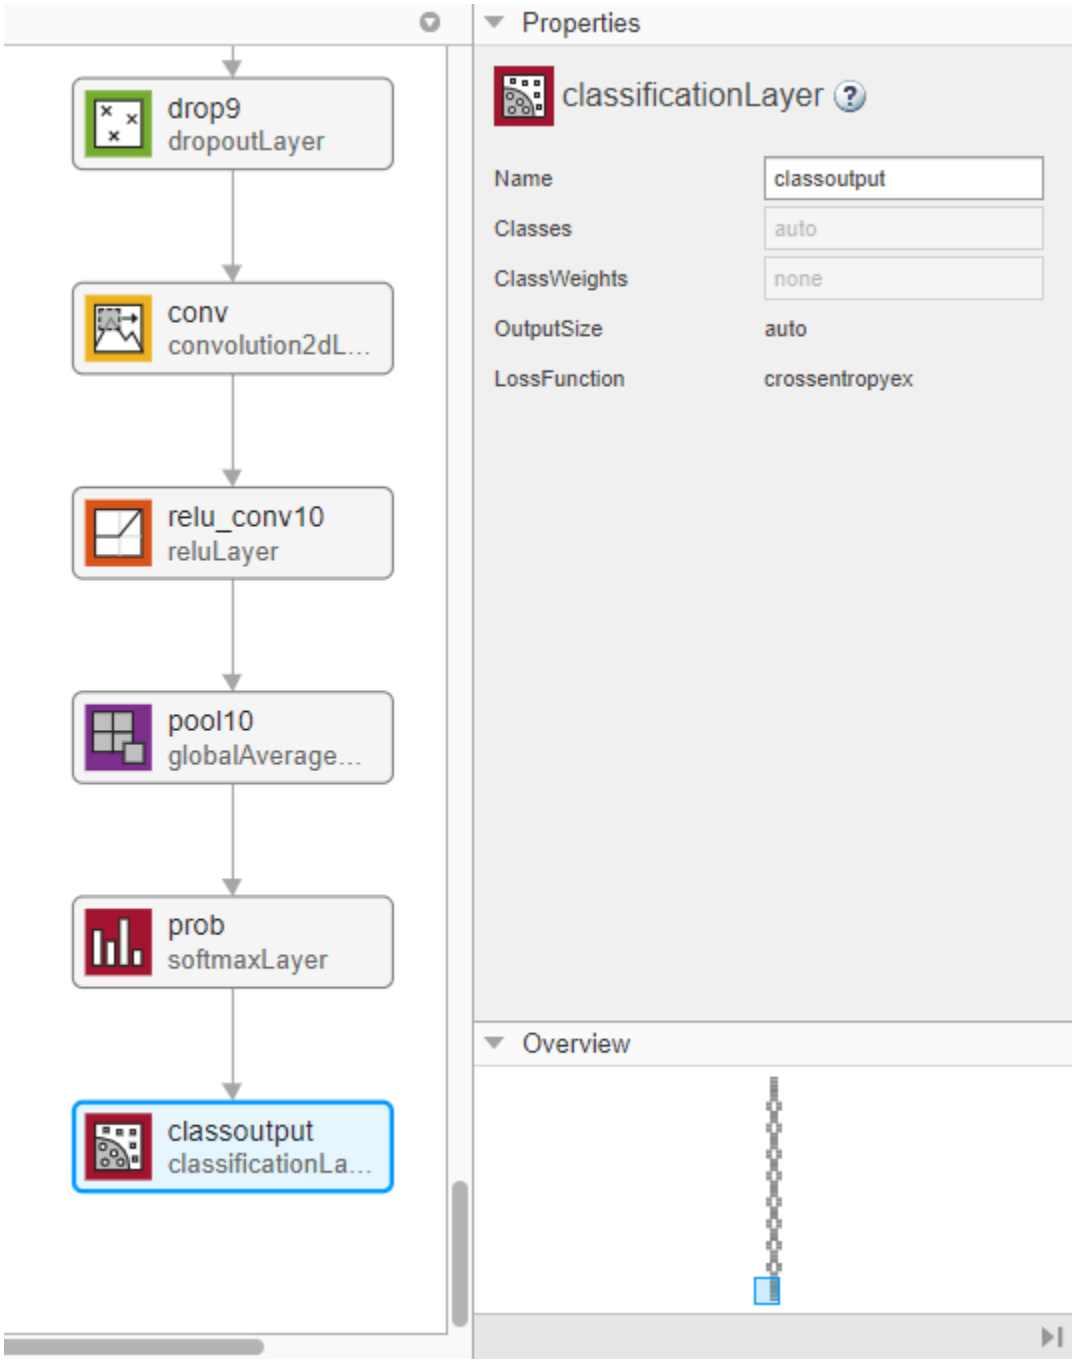
Delete the last 2-D convolutional layer and connect your new layer instead.



Replace Output Layer

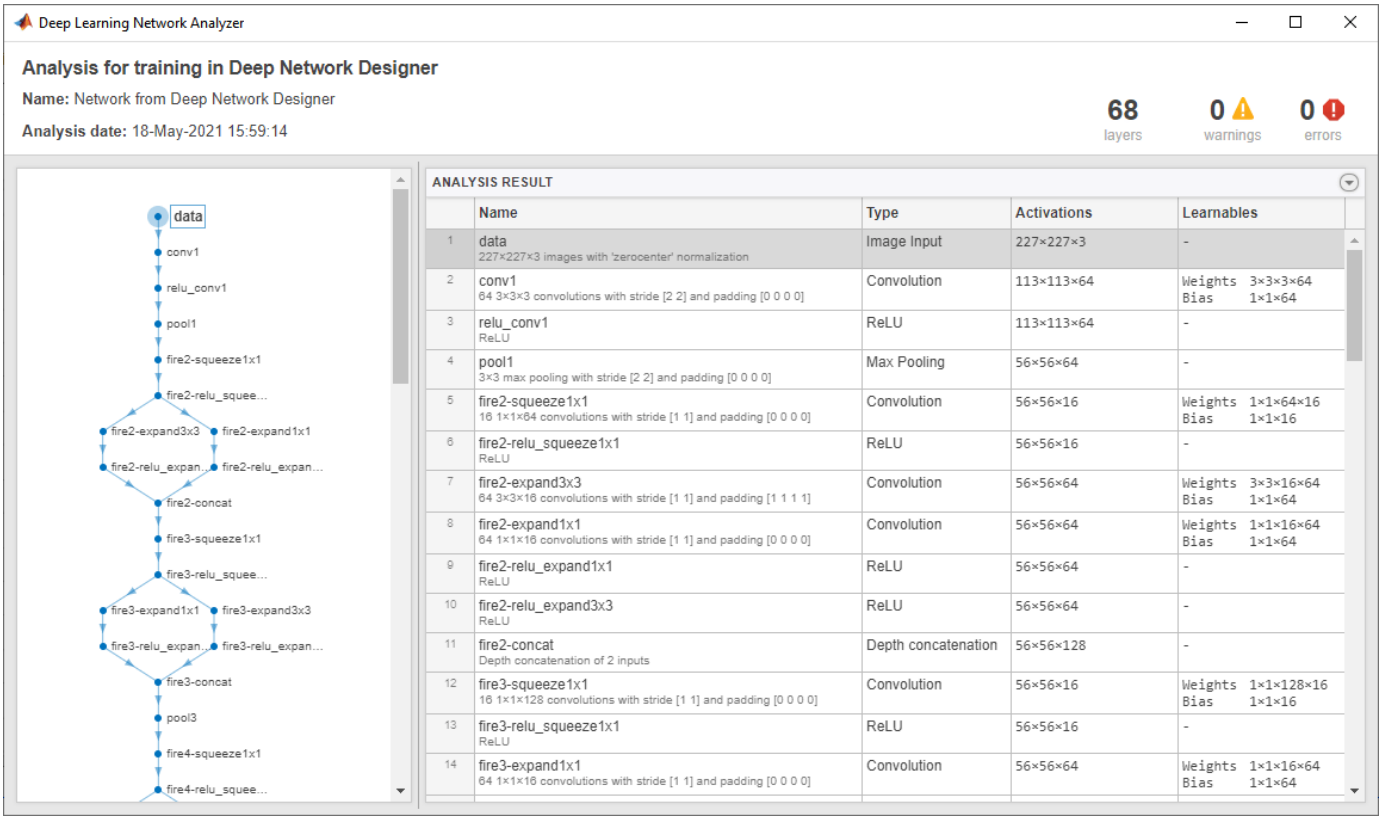
For transfer learning, you need to replace the output layer. Scroll to the end of the **Layer Library** and drag a new `classificationLayer` onto the canvas. Delete the original classification layer and connect your new layer in its place.

For a new output layer, you do not need to set the `OutputSize`. At training time, Deep Network Designer automatically sets the output classes of the layer from the data.



Check Network

To check that the network is ready for training, click **Analyze**. If the Deep Learning Network Analyzer reports zero errors, then the edited network is ready for training.



Train Network

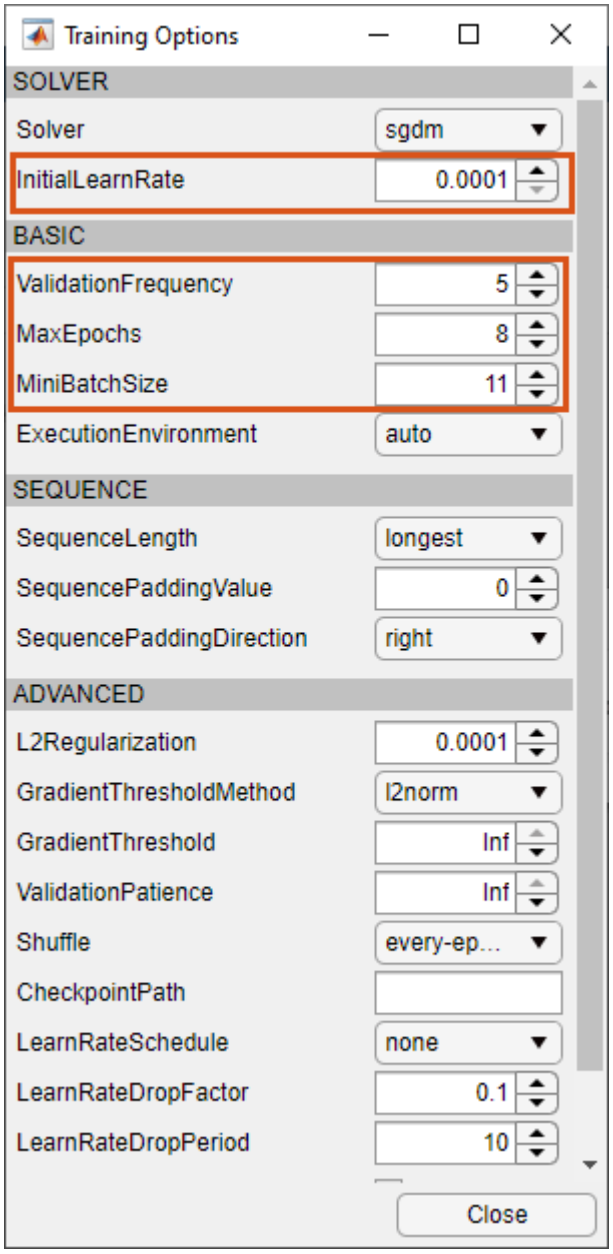
In Deep Network Designer you can train networks imported or created in the app.

To train the network with the default settings, on the **Training** tab, click **Train**. The default training options are better suited for large data sets, for small data sets reduce the mini-batch size and the validation frequency.

If you want greater control over the training, click **Training Options** and choose the settings to train with.

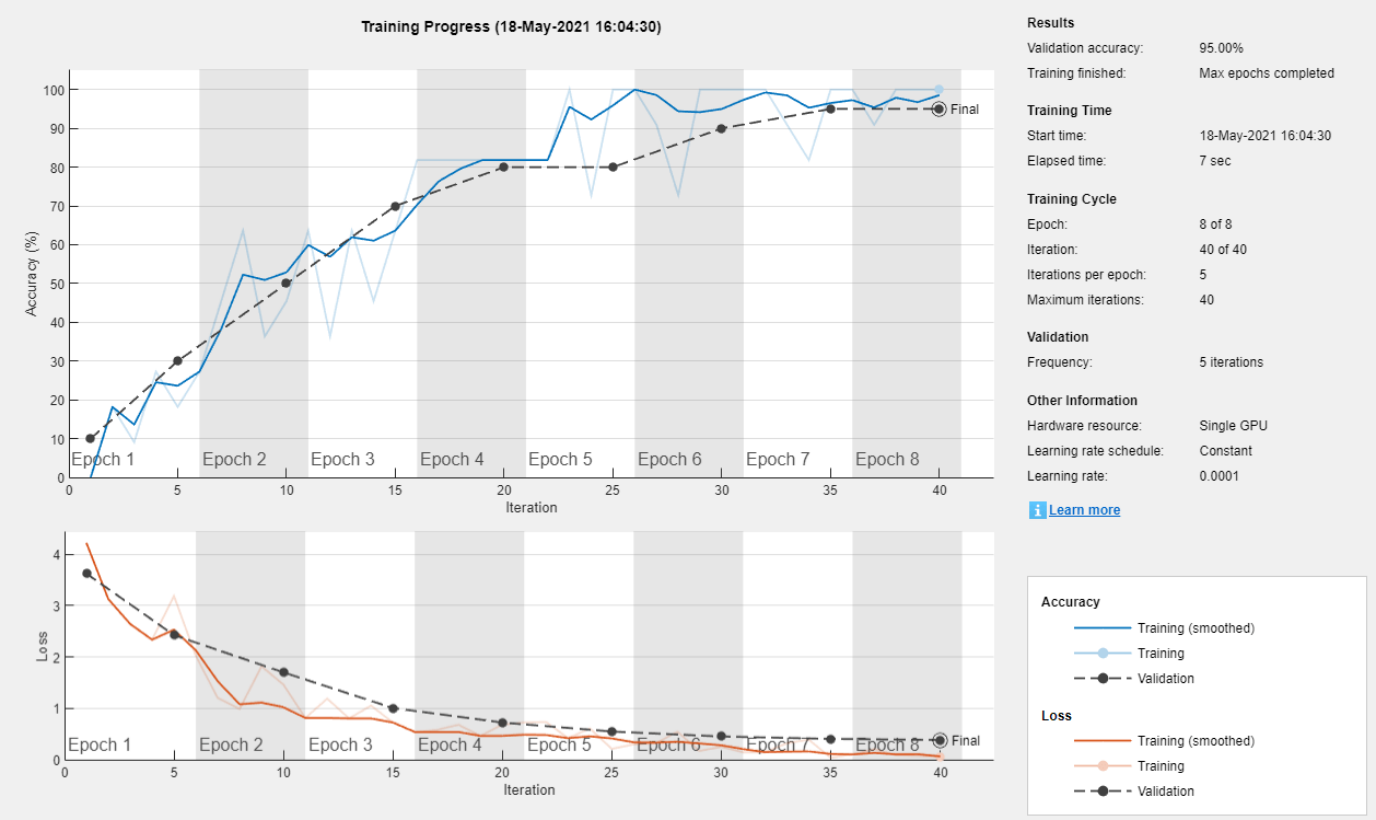
- Set the initial learn rate to a small value to slow down learning in the transferred layers.
- Specify validation frequency so that the accuracy on the validation data is calculated once every epoch.
- Specify a small number of epochs. An epoch is a full training cycle on the entire training data set. For transfer learning, you do not need to train for as many epochs.
- Specify the mini-batch size, that is, how many images to use in each iteration. To ensure the whole data set is used during each epoch, set the mini-batch size to evenly divide the number of training samples.

For this example, set **InitialLearnRate** to `0.0001`, **ValidationFrequency** to `5`, and **MaxEpochs** to `8`. As there are 55 observations, set **MiniBatchSize** to `11` to divide the training data evenly and ensure you use the whole training data set during each epoch. For more information on selecting training options, see `trainingOptions`.



To train the network with the specified training options, click **Close** and then click **Train**.

Deep Network Designer allows you to visualize and monitor training progress. You can then edit the training options and retrain the network, if required.



Export Results and Generate MATLAB Code

To export the network architecture with the trained weights, on the **Training** tab, select **Export** > **Export Trained Network and Results**. Deep Network Designer exports the trained network as the variable `trainedNetwork_1` and the training info as the variable `trainInfoStruct_1`.

```
trainInfoStruct_1
```

```
trainInfoStruct_1 = struct with fields:
              TrainingLoss: [4.2191 3.1255 2.6411 2.3362 3.1848 2.0195 1.2013 0.9902 1.8173 1.46
          TrainingAccuracy: [0 18.1818 9.0909 27.2727 18.1818 27.2727 45.4545 63.6364 36.3636 45
            ValidationLoss: [3.6204 NaN NaN NaN 2.4244 NaN NaN NaN NaN 1.7002 NaN NaN NaN NaN 1
        ValidationAccuracy: [10.0000 NaN NaN NaN 30 NaN NaN NaN NaN 50 NaN NaN NaN NaN 70 NaN Na
            BaseLearnRate: [1.0000e-04 1.0000e-04 1.0000e-04 1.0000e-04 1.0000e-04 1.0000e-04 1
      FinalValidationLoss: 0.3854
  FinalValidationAccuracy: 95
   OutputNetworkIteration: 40
```

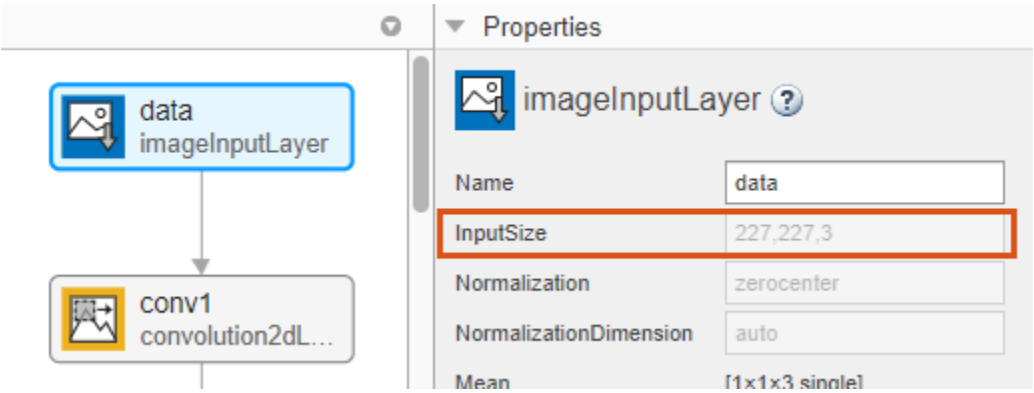
You can also generate MATLAB code, which recreates the network and the training options used. On the **Training** tab, select **Export** > **Generate Code for Training**. Examine the MATLAB code to learn how to programmatically prepare the data for training, create the network architecture, and train the network.

Classify New Image

Load a new image to classify using the trained network.

```
I = imread("MerchDataTest.jpg");
```

Deep Network Designer resizes the images during training to match the network input size. To view the network input size, go to the **Designer** pane and select the `imageInputLayer` (first layer). This network has an input size of 227-by-227.



Resize the test image to match the network input size.

```
I = imresize(I, [227 227]);
```

Classify the test image using the trained network.

```
[YPred,probs] = classify(trainedNetwork_1,I);
imshow(I)
label = YPred;
title(string(label) + ", " + num2str(100*max(probs),3) + "%");
```

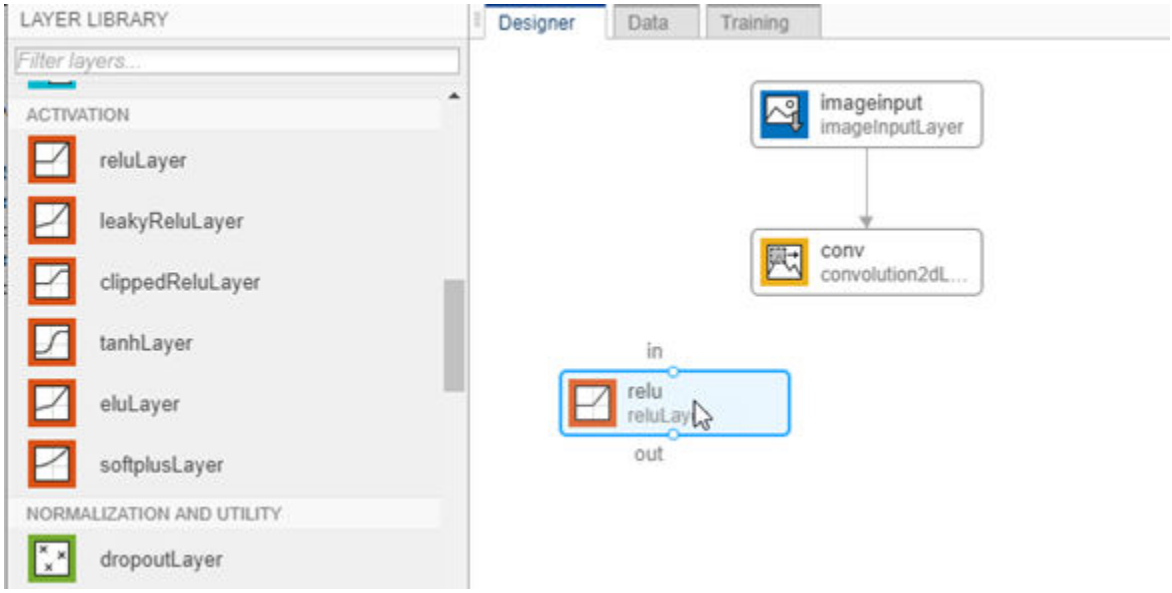
Build Networks with Deep Network Designer

Build and edit deep learning networks interactively using the **Deep Network Designer** app. Using this app, you can import networks or build a network from scratch, view and edit layer properties, combine networks, and generate code to create the network architecture. You can then train your network using Deep Network Designer, or export the network for training at the command line.

You can use Deep Network Designer for a range of network construction tasks:

- “Transfer Learning” on page 2-16
- “Image Classification” on page 2-18
- “Sequence Classification” on page 2-20
- “Numeric Data Classification” on page 2-21
- “Convert Classification Network into Regression Network” on page 2-23
- “Multiple-Input and Multiple-Output Networks” on page 2-23
- “Deep Networks” on page 2-25
- “Advanced Deep Learning Applications” on page 2-26
- “dlnetwork for Custom Training Loops” on page 2-29

Assemble a network by dragging blocks from the **Layer Library** and connecting them. To quickly search for layers, use the **Filter layers** search box in the **Layer Library** pane.

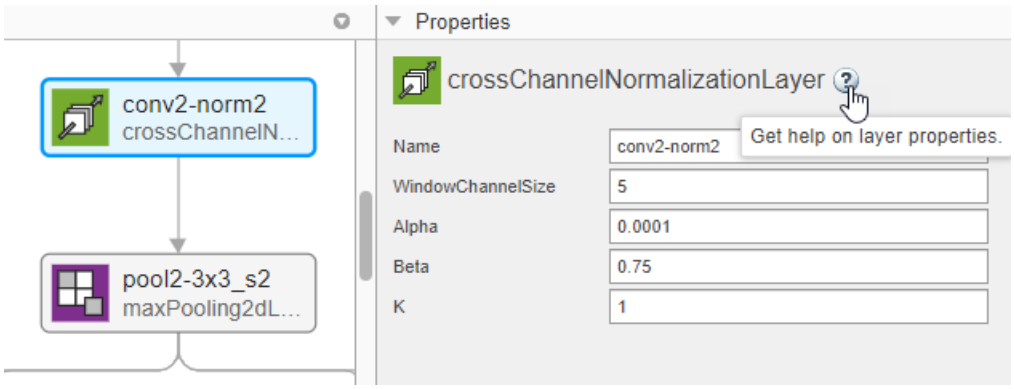


You can add layers from the workspace to the network in the **Designer** pane.

1. Click **New**.
2. Pause on **From Workspace** and click **Import**.
3. Choose the layers or network to import and click **OK**.
4. Click **Add** to add the layers or network to the **Designer** pane.

You can also load pretrained networks by clicking **New** and selecting them from the start page.

To view and edit layer properties, select a layer. Click the help icon next to the layer name for information on the layer properties.



For information on all layer properties, click the layer name in the table on the “List of Deep Learning Layers” on page 1-21 page.

Once you have constructed your network, you can analyze it to check for errors. For more information, see “Check Network” on page 2-29.

Transfer Learning

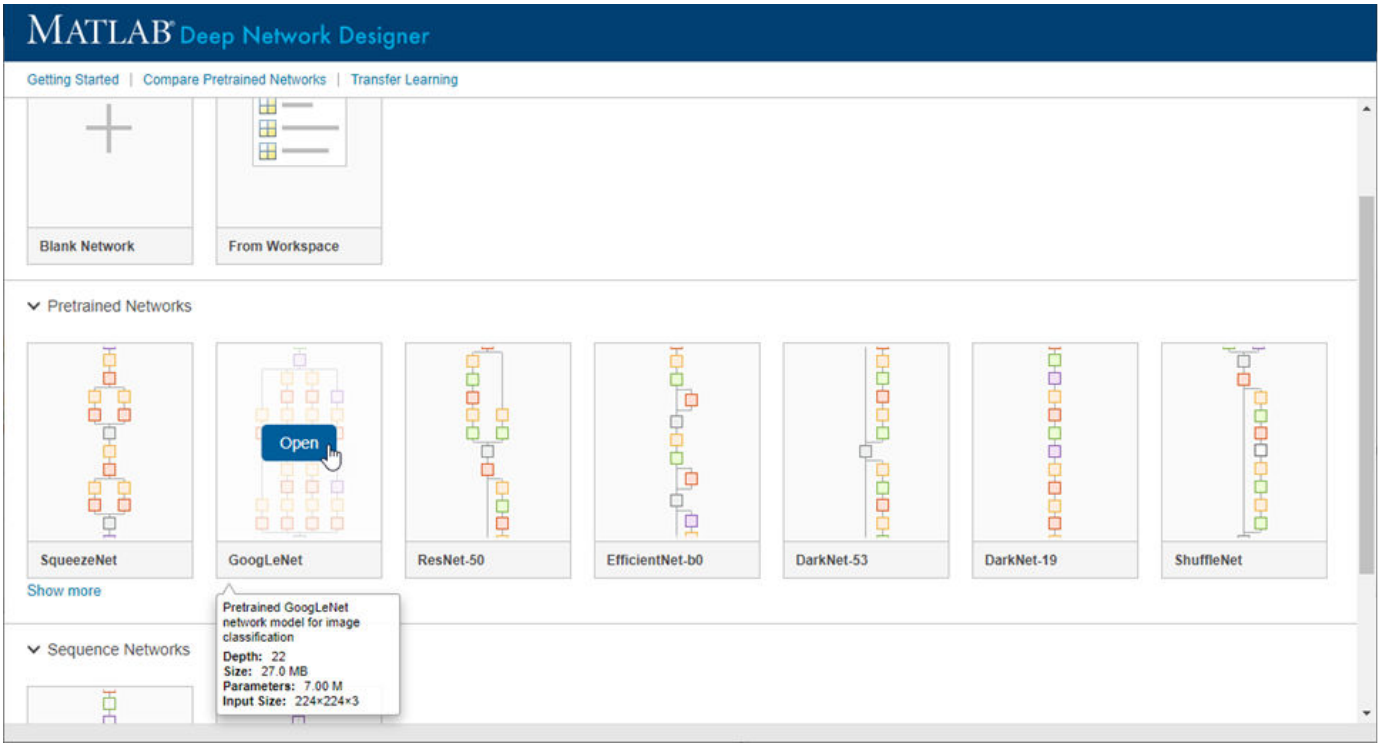
Transfer learning is commonly used in deep learning applications. You can take a pretrained network and use it as a starting point to learn a new task. Fine-tuning a network with transfer learning is usually much faster and easier than training a network with randomly initialized weights from scratch. You can quickly transfer learned features to a new task using a smaller number of training images.

Deep Network Designer has a selection of pretrained networks suitable for transfer learning with image data.

Load Pretrained Network

Open the app and select a pretrained network. You can also load a pretrained network by selecting the **Designer** tab and clicking **New**. If you need to download the network, pause on the network and click **Install** to open the Add-On Explorer.

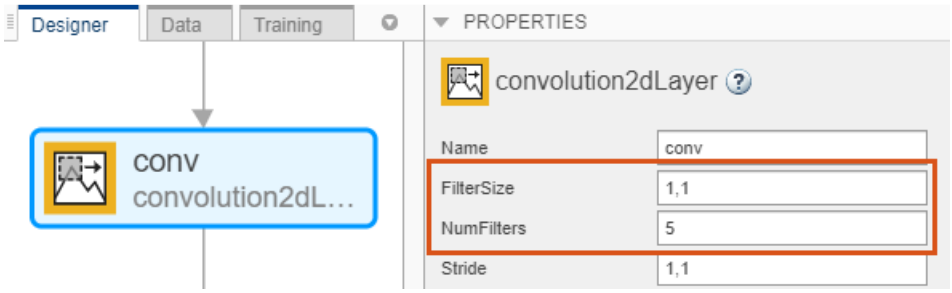
Tip To get started, try choosing one of the faster networks, such as SqueezeNet or GoogLeNet. Once you gain an understanding of which settings work well, try a more accurate network, such as Inception-v3 or a ResNet, and see if that improves your results. For more information on selecting a pretrained network, see “Pretrained Deep Neural Networks” on page 1-8.



Adapt Pretrained Network

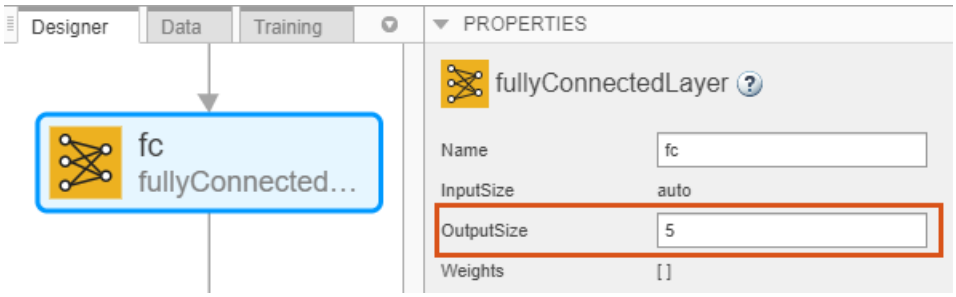
To prepare the network for transfer learning, replace the last learnable layer and the final classification layer.

- If the last learnable layer is a 2-D convolutional layer (for example, the `'conv10'` layer in SqueezeNet):
  - Drag a new **convolution2dLayer** onto the canvas. Set the **NumFilters** property to the new number of classes and **FilterSize** to `1,1`.
  - Change the learning rates so that learning is faster in the new layer than in the transferred layers by increasing the **WeightLearnRateFactor** and **BiasLearnRateFactor** values.
  - Delete the last **convolution2dLayer** and connect your new layer instead.

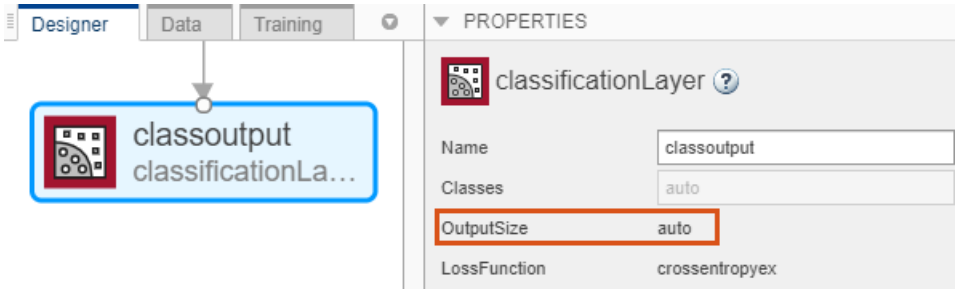


- If the last learnable layer is a fully connected layer (most pretrained networks, for example, GoogLeNet):
  - Drag a new **fullyConnectedLayer** onto the canvas and set the **OutputSize** property to the new number of classes.

- Change the learning rates so that learning is faster in the new layer than in the transferred layers by increasing the **WeightLearnRateFactor** and **BiasLearnRateFactor** values.
- Delete the last **fullyConnectedLayer** and connect your new layer instead.



Next, delete the classification output layer. Then, drag a new **classificationLayer** onto the canvas and connect it instead. The default settings for the output layer mean it will learn the number of classes during training.



To check that the network is ready for training, on the **Designer** tab, click **Analyze**.

For an example showing how to retrain a pretrained network to classify new images, see “Transfer Learning with Deep Network Designer” on page 2-2.

You can also use pretrained networks and transfer learning for regression tasks. For more information, see “Convert Classification Network into Regression Network” on page 2-23.

Image Classification

You can build an image classification network using Deep Network Designer by dragging layers from the **Layer Library** and connecting them. You can also create the network at the command line and then import the network into Deep Network Designer.

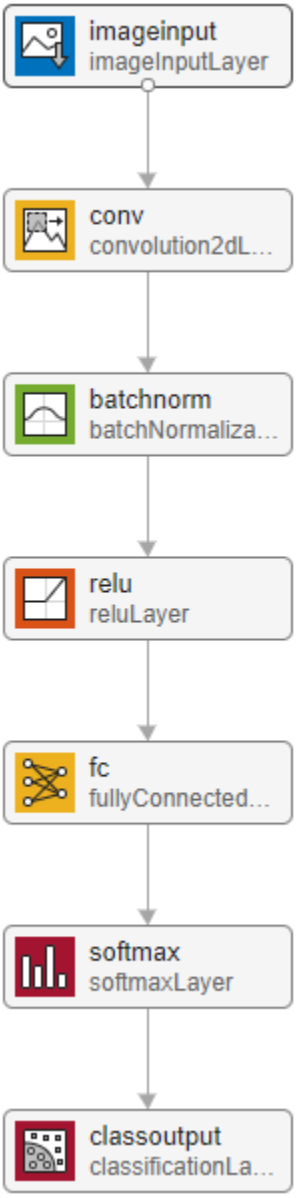
For example, create a network to train for image classification on a data set of 28-by-28 images divided into 10 classes.

```
inputSize = [28 28 1];
numClasses = 10;

layers = [
    imageInputLayer(inputSize)
    convolution2dLayer(5,20)
    batchNormalizationLayer
    reluLayer
```

```
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];

deepNetworkDesigner(layers)
```

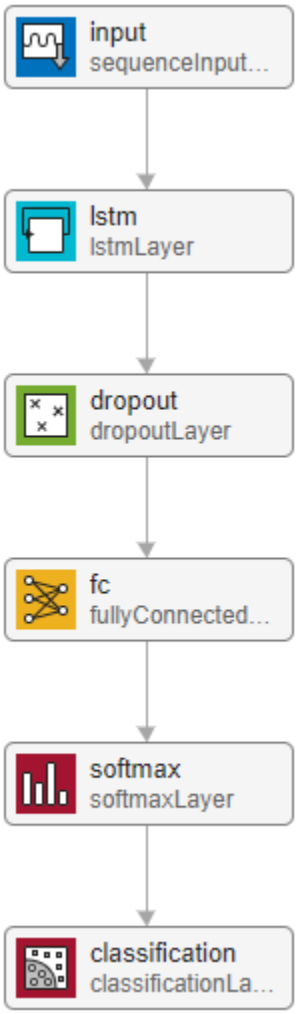


To adapt this network to your own data, set the **InputSize** of the image input layer to match your image input size and set the **OutputSize** of the fully connected layer to the number of classes in your data. For more complex classification tasks, create a deeper network. For more information, see “Deep Networks” on page 2-25.

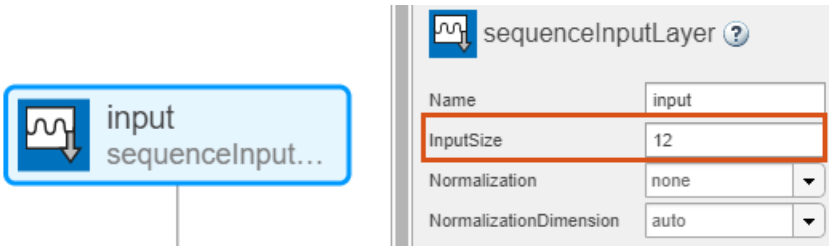
For an example showing how to create and train an image classification network, see “Create Simple Image Classification Network Using Deep Network Designer”.

Sequence Classification

You can use Deep Network Designer to build a sequence network from scratch, or you can use one of the prebuilt untrained networks from the start page. Open the Deep Network Designer start page. Pause on **Sequence-to-Label** and click **Open**. Doing so opens a prebuilt network suitable for sequence classification problems.



You can adapt this sequence network for training with your data. Suppose you have data with 12 features and 9 classes. To adapt this network, select **sequenceInputLayer** and set the **InputSize** to 12.



Then, select the **fullyConnectedLayer** and set the **OutputSize** to 9, the number of classes.

The network is now ready to train. To train the network in Deep Network Designer, create a `CombinedDatastore` containing the predictors and responses. For more information, see “Import Data into Deep Network Designer” on page 2-39. For an example showing how to create a combined datastore and train a sequence-to-sequence regression network using Deep Network Designer, see “Train Network for Time Series Forecasting Using Deep Network Designer” on page 2-57. For an example showing how to export a network built in Deep Network Designer and train using command line functions, see “Create Simple Sequence Classification Network Using Deep Network Designer” on page 2-51.

Numeric Data Classification

If you have a data set of numeric features (for example, a collection of numeric data without spatial or time dimensions), then you can train a deep learning network using a feature input layer. For more information about the feature input layer, see `featureInputLayer`.

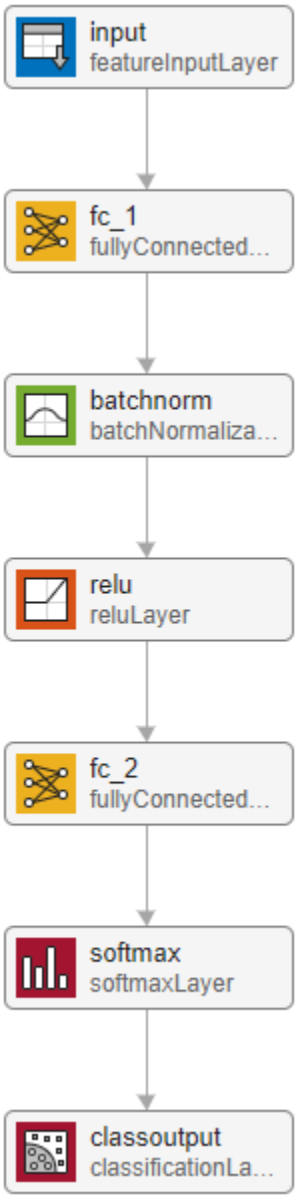
You can construct a suitable network using Deep Network Designer, or you can create the network at the command line and import the network into Deep Network Designer.

For example, create a network for numeric data with 10 classes, where each observation consists of 20 features.

```
inputSize = 20;
numClasses = 10;

layers = [
featureInputLayer(inputSize,'Normalization','zscore')
fullyConnectedLayer(50)
batchNormalizationLayer
reluLayer
fullyConnectedLayer(numClasses)
softmaxLayer
classificationLayer];

deepNetworkDesigner(layers)
```



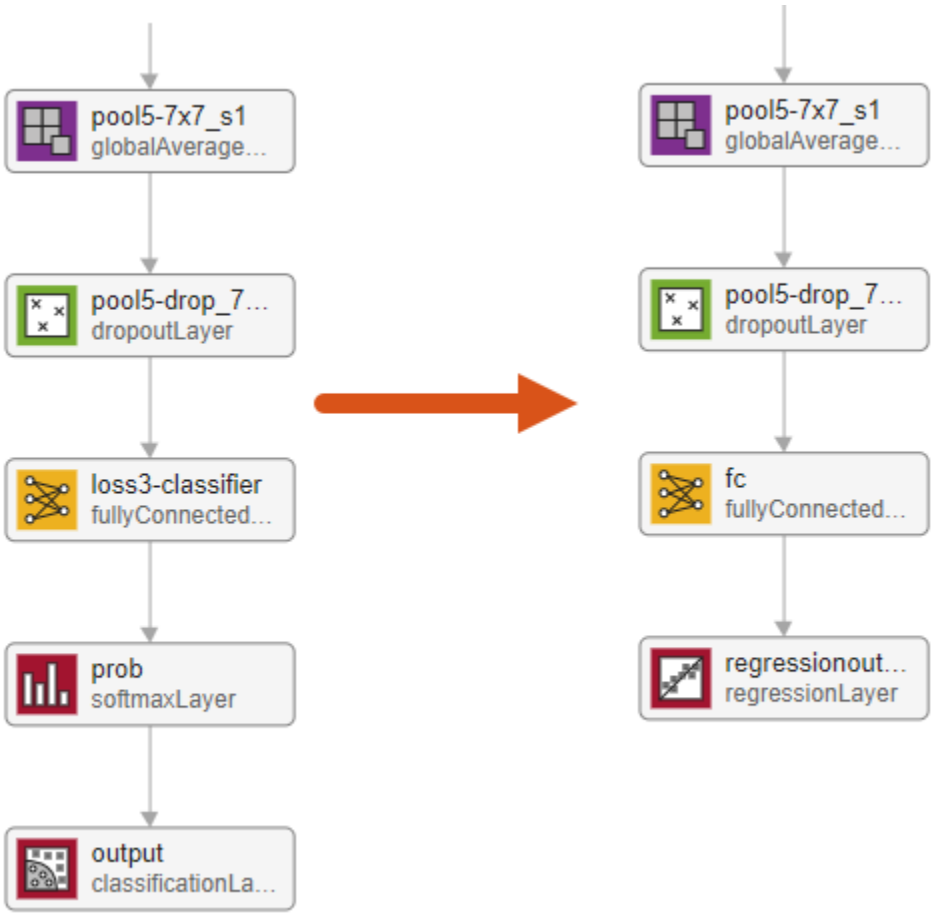
To adapt this network to your own data, set the **InputSize** of the feature input layer to match the number of features in your data and set the **OutputSize** of the fully connected layer to the number of classes in your data. For more complex classification tasks, create a deeper network. For more information, see “Deep Networks” on page 2-25.

To train a network in Deep Network Designer using data in a table, you must first convert your data into a suitable datastore. For example, start by converting your table into arrays containing the predictors and responses. Then, convert the arrays into `arrayDatastore` objects. Finally, combine the predictor and response array datastores into a `CombinedDatastore` object. You can then use the combined datastore to train in Deep Network Designer. For more information, see “Import Data into Deep Network Designer” on page 2-39. You can also train with tabular data and the `trainNetwork` function by exporting the network to the workspace.

Convert Classification Network into Regression Network

You can convert a classification network into a regression network by replacing the final layers of the network. Conversion is useful when you want to take a pretrained classification network and retrain it for regression tasks.

For example, suppose you have a GoogLeNet pretrained network. To convert this network into a regression network with a single response, replace the final fully connected layer, the softmax layer, and the classification output layer with a fully connected layer with **OutputSize** set to 1 (the number of responses) and a regression layer.



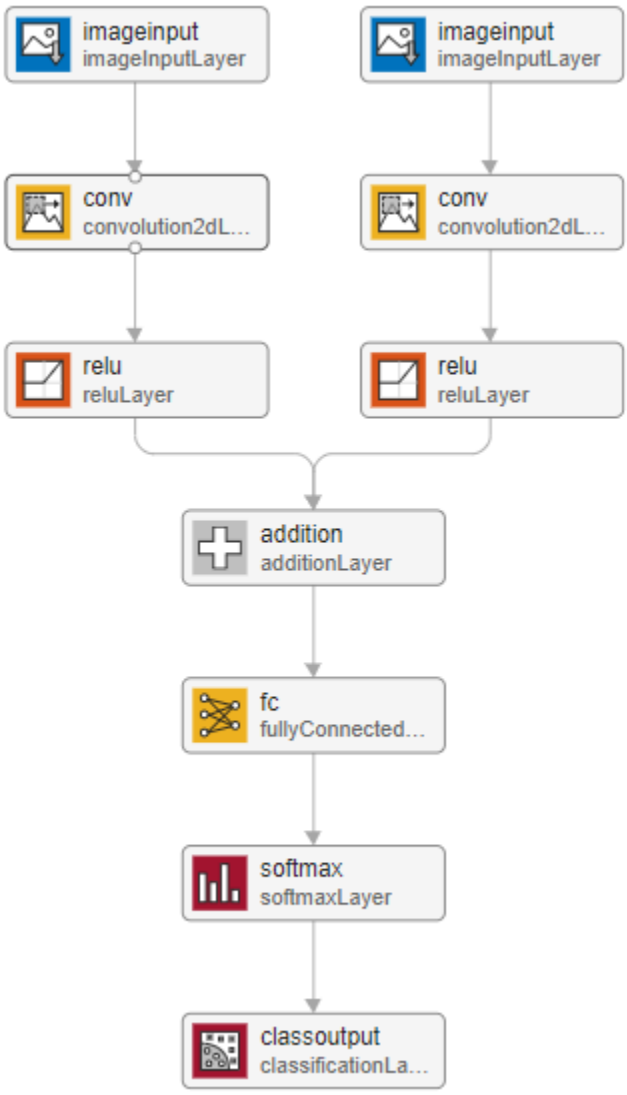
If your output has multiple responses, change the **OutputSize** value of the fully connected layer to the number of responses.

Multiple-Input and Multiple-Output Networks

Multiple Inputs

You can define a network with multiple inputs if the network requires data from multiple sources or in different formats. For example, some networks require image data captured from multiple sensors at different resolutions.

Using Deep Network Designer, you can control the inputs and outputs of each layer. For example, to create a network with multiple image inputs, create two branches, each starting with an image input layer.

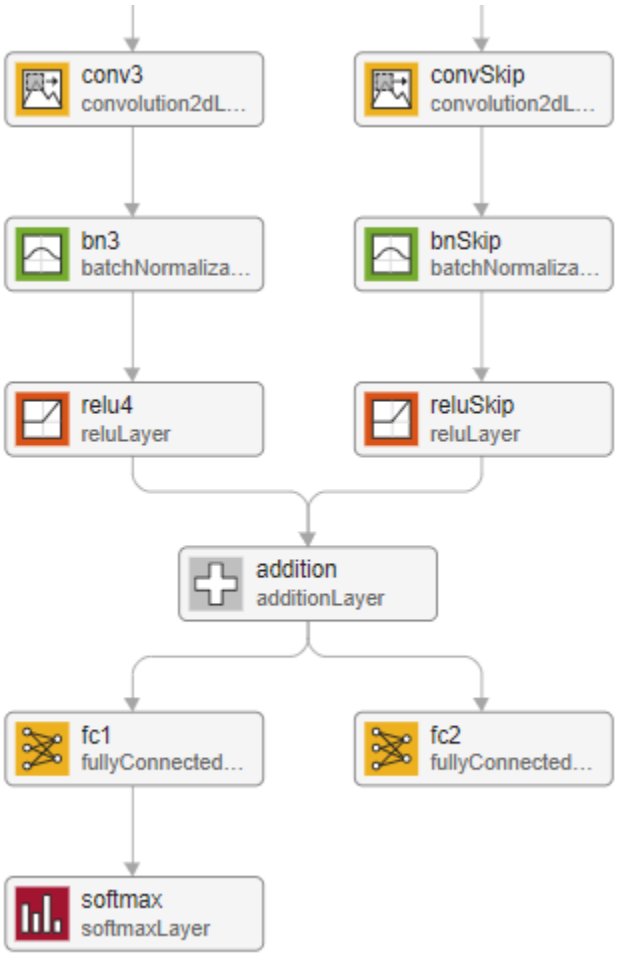


You can train a multi-input network with the same type of input, for example, images from two difference sources, using Deep Network Designer and a datastore object. For networks with data in multiple formats, for example, image and sequence data, train the network using a custom training loop. For more information, see “dlnetwork for Custom Training Loops” on page 2-29.

Multiple Outputs

You can define networks with multiple outputs for tasks requiring multiple responses in different formats, for example, tasks requiring both categorical and numeric output.

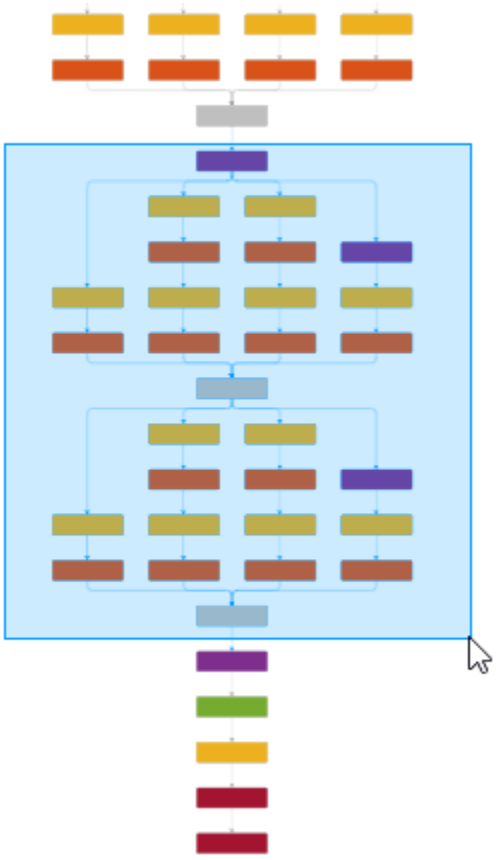
Using Deep Network Designer, you can control the outputs of each layer.



To train a multi-output network, you must use a custom training loop. Custom training loops must use a `dlnetwork` object that does not contain any output layers. For more information, see “dlnetwork for Custom Training Loops” on page 2-29.

Deep Networks

Building large networks can be difficult, you can use Deep Network Designer to speed up construction. You can work with blocks of layers at a time. Select multiple layers, then copy and paste or delete. For example, you can use blocks of layers to create multiple copies of groups of convolution, batch normalization, and ReLU layers.



For trained networks, copying layers also copies the weights and the biases.

You can also copy sub-networks from the workspace to connect up easily using the app. To import a network or layers into the app, click **New > Import from workspace**. Click **Add** to add the layers to the current network.

Advanced Deep Learning Applications

You can use Deep Network Designer to build and train networks for advanced applications, such as computer vision or image processing tasks.

Create Semantic Segmentation Network

Semantic segmentation describes the process of associating each pixel of an image with a class label. Applications for semantic segmentation include road segmentation for autonomous driving and cancer cell segmentation for medical diagnosis.

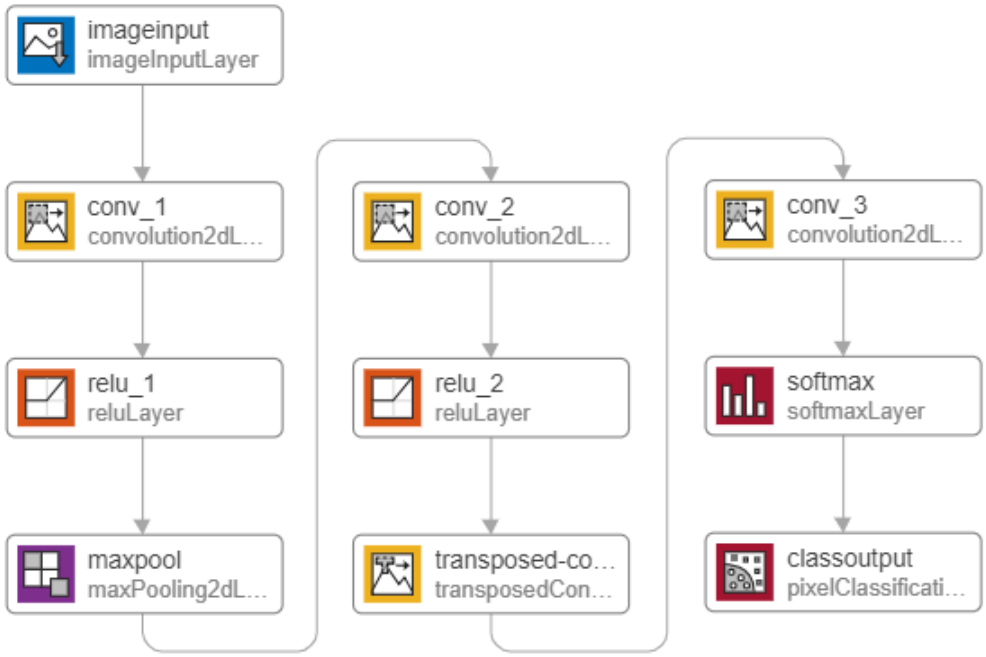
Create a semantic segmentation network by dragging layers from the **Layer Library** to the **Designer** pane or creating the network at the command-line and importing the network into Deep Network Designer.

For example, create a simple semantic segmentation network based on a downsampling and upsampling design.

```
inputSize = [32 32 1];
```

```
layers = [
    imageInputLayer(inputSize)
    convolution2dLayer([3,3],64,'Padding',[1,1,1,1])
    reluLayer
    maxPooling2dLayer([2,2],'Stride',[2,2])
    convolution2dLayer([3,3],64,'Padding',[1,1,1,1])
    reluLayer
    transposedConv2dLayer([4,4],64,'Stride',[2,2],'Cropping',[1,1,1,1])
    convolution2dLayer([1,1],2)
    softmaxLayer
    pixelClassificationLayer
    ];

deepNetworkDesigner(layers)
```



For more information on constructing and training a semantic segmentation network, see “Train Simple Semantic Segmentation Network in Deep Network Designer” (Computer Vision Toolbox).

Create Image-to-Image Regression Network

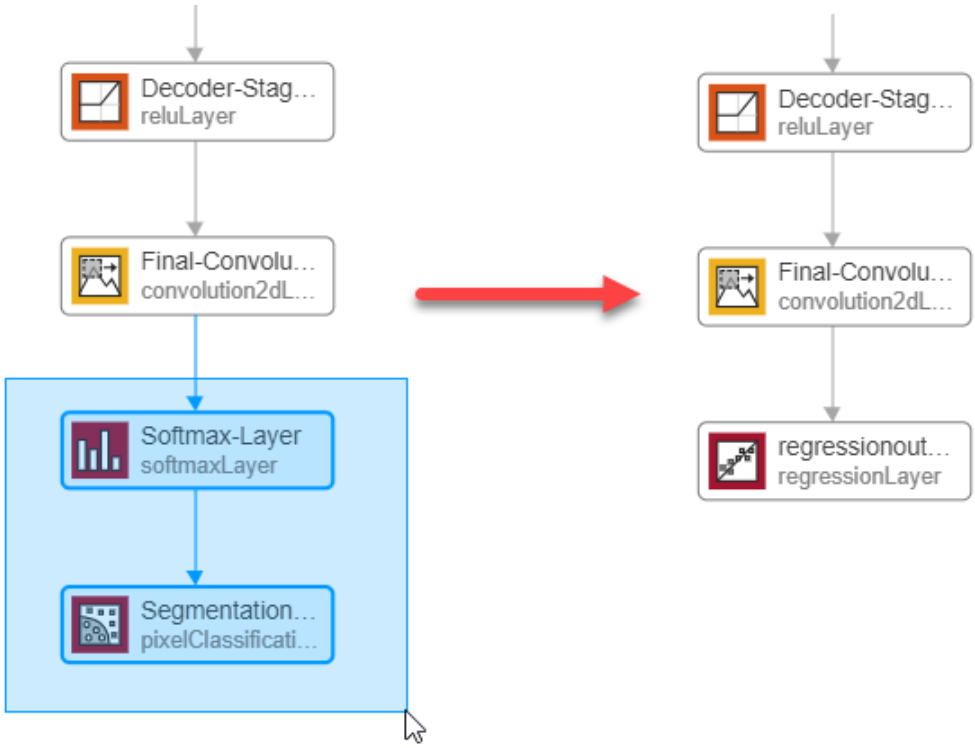
Image-to-image regression involves taking an input image and producing an output image, often of the same size. This type of network is useful for super-resolution, colourization, or image deblurring.

You can create image-to-image regression networks using Deep Network Designer. For example, create a simple network architecture suitable for image-to-image regression using the `unetLayers` function from Computer Vision Toolbox™. This function provides a network suitable for semantic segmentation, that can be easily adapted for image-to-image regression.

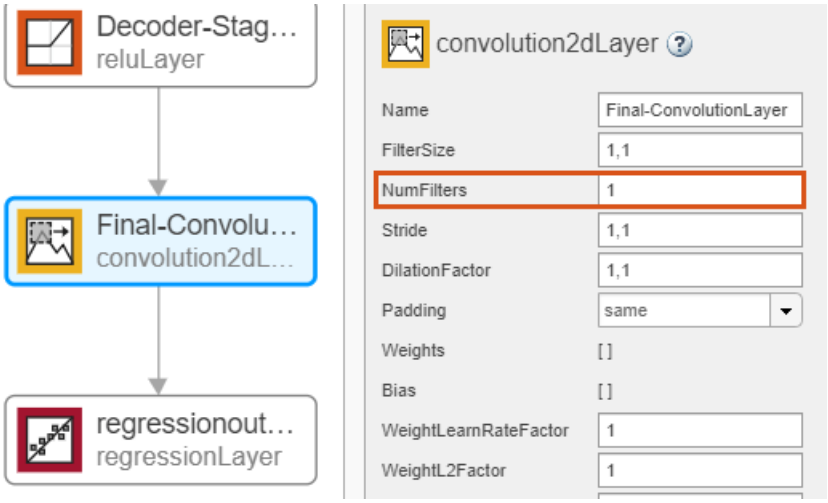
Create a network with input size 28-by-28-by-1 pixels.

```
layers = unetLayers([28,28,1],2,'encoderDepth',2);
deepNetworkDesigner(layers);
```

In the **Designer** pane, replace the softmax and pixel classification layers with a regression layer from the **Layer Library**.



Select the final convolutional layer and set the **NumFilters** property to 1.



For more information on constructing and training an image-to-image regression network, see “Image-to-Image Regression in Deep Network Designer” on page 2-72.

dlnetwork for Custom Training Loops

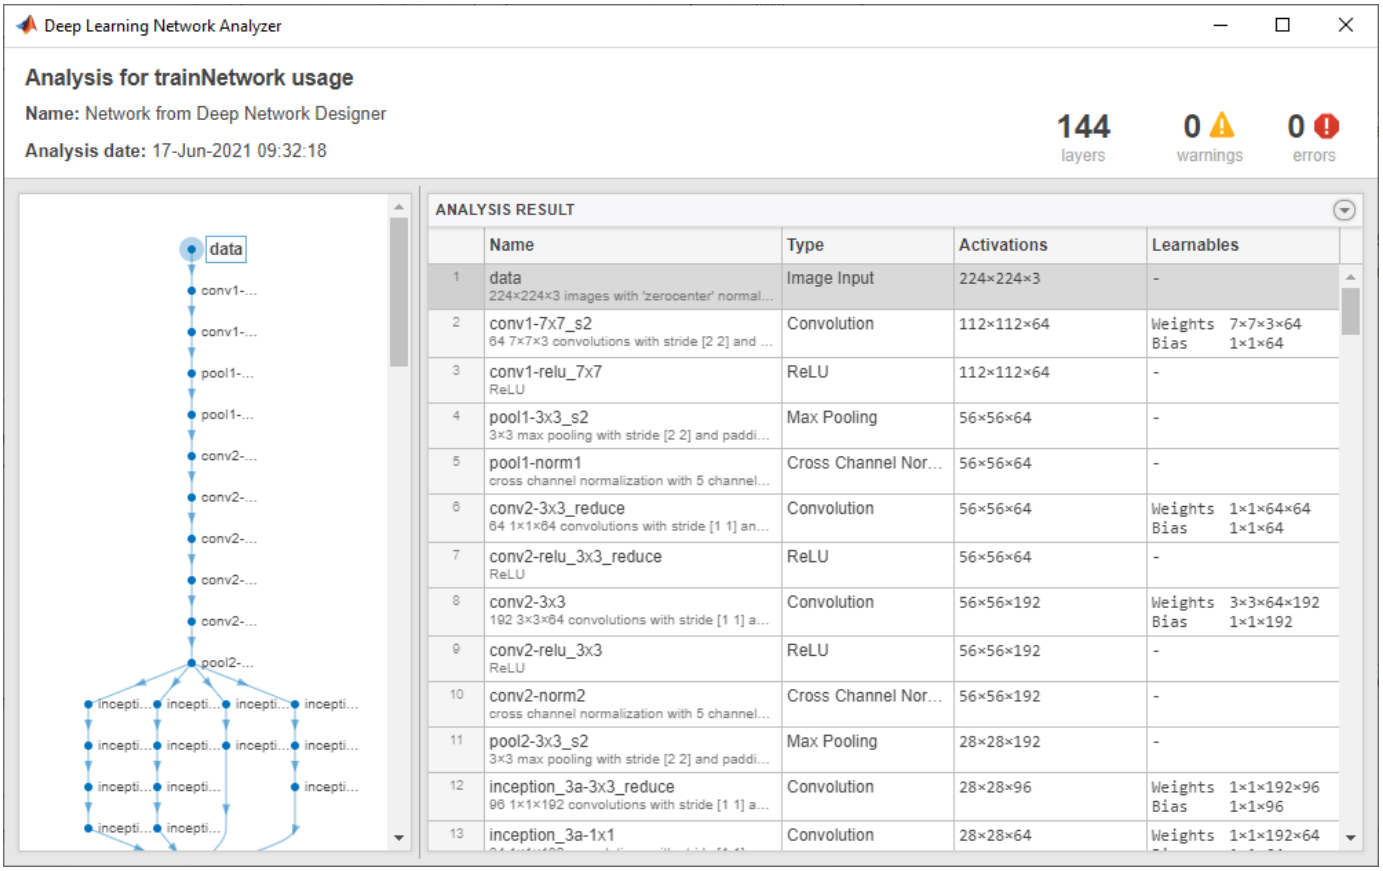
You can build and analyze `dlnetwork` objects using Deep Network Designer. A `dlnetwork` object enables support for custom training loops using automatic differentiation. Use custom training loops when the built-in training options do not provide the training options that you need for your task.

To check that your network is ready for training using a custom training loop, click **Analyze** > **Analyze for dlnetwork**. For more information, see “Check Network” on page 2-29.

Training with a custom training loop is not supported in Deep Network Designer. To train your network using a custom training loop, first export the network to the workspace and convert it to a `dlnetwork` object. You can then train the network using the `dlnetwork` object and a custom training loop. For more information, see “Train Network Using Custom Training Loop” on page 18-225.

Check Network

To check your network and examine the layers in further detail, on the **Designer** tab, click **Analyze**. Investigate problems and examine the layer properties to resolve size mismatches in the network. Return to Deep Network Designer to edit layers, then check the results by clicking **Analyze** again. If Deep Learning Network Analyzer reports zero errors, then the edited network is ready for training.



You can also analyze networks for custom training workflows. Click **Analyze > Analyze for dlnetwork** to analyze the network for usage with `dlnetwork` objects. For example, the Network Analyzer checks that the layer graph does not have any output layers.

- “Deep Learning Tips and Tricks” on page 1-67

Train Networks Using Deep Network Designer

The **Deep Network Designer** app lets you build and train deep neural networks. Deep Network Designer supports `trainNetwork` training using image data or datastore objects. You can also export your untrained network for training at the command line, for example, to train your network using custom training loops.

To train a network, follow these steps:

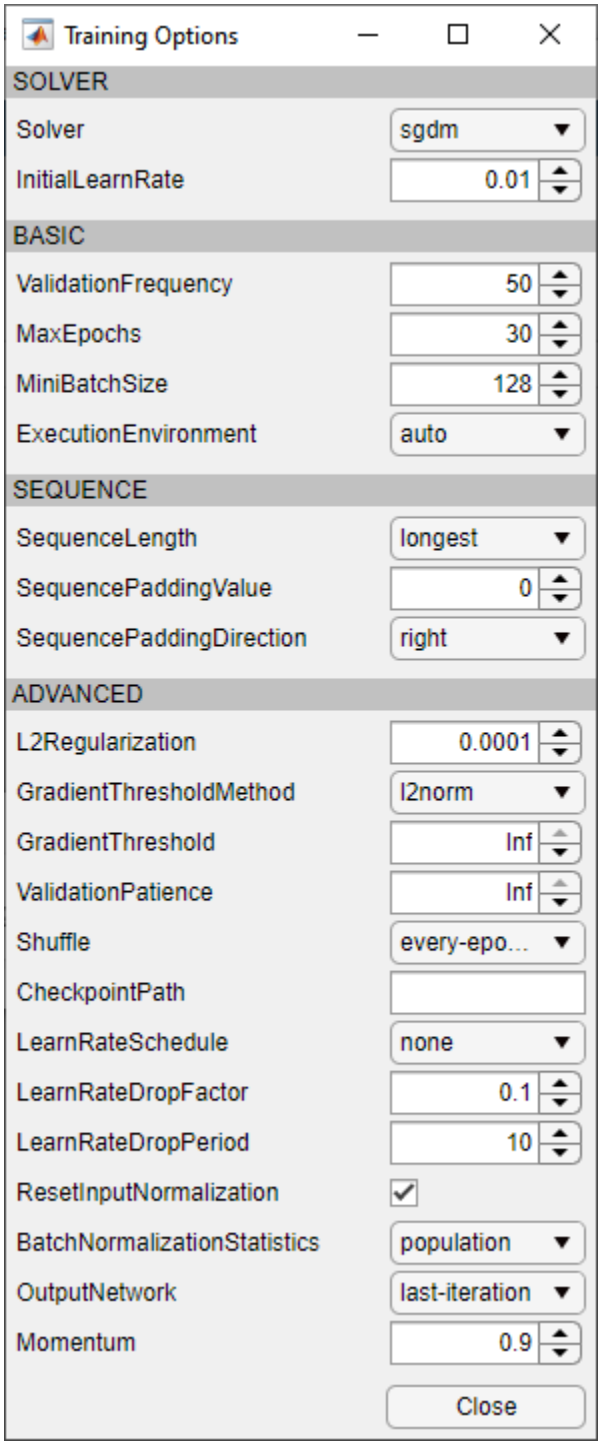
1. Create network
2. Import data
3. Select training options
4. Train network
5. Export network

You can build a network interactively using Deep Network Designer, or import a network from the workspace. You can also select a pretrained network from the Deep Network Designer start page for transfer learning. For more information, see “Build Networks with Deep Network Designer” on page 2-15.

To train a deep learning model, you must have a suitable network and training data. To import image data from a folder containing a subfolder of images for each class, or from an `imageDatastore` object, on the **Data** tab, click **Import Data > Import Image Data**. To import any datastore, on the **Data** tab, click **Import Data > Import Datastore**. After import, Deep Network Designer displays a preview of the imported data so that you can check that the data is as expected prior to training. For more information, see “Import Data into Deep Network Designer” on page 2-39.

Select Training Options

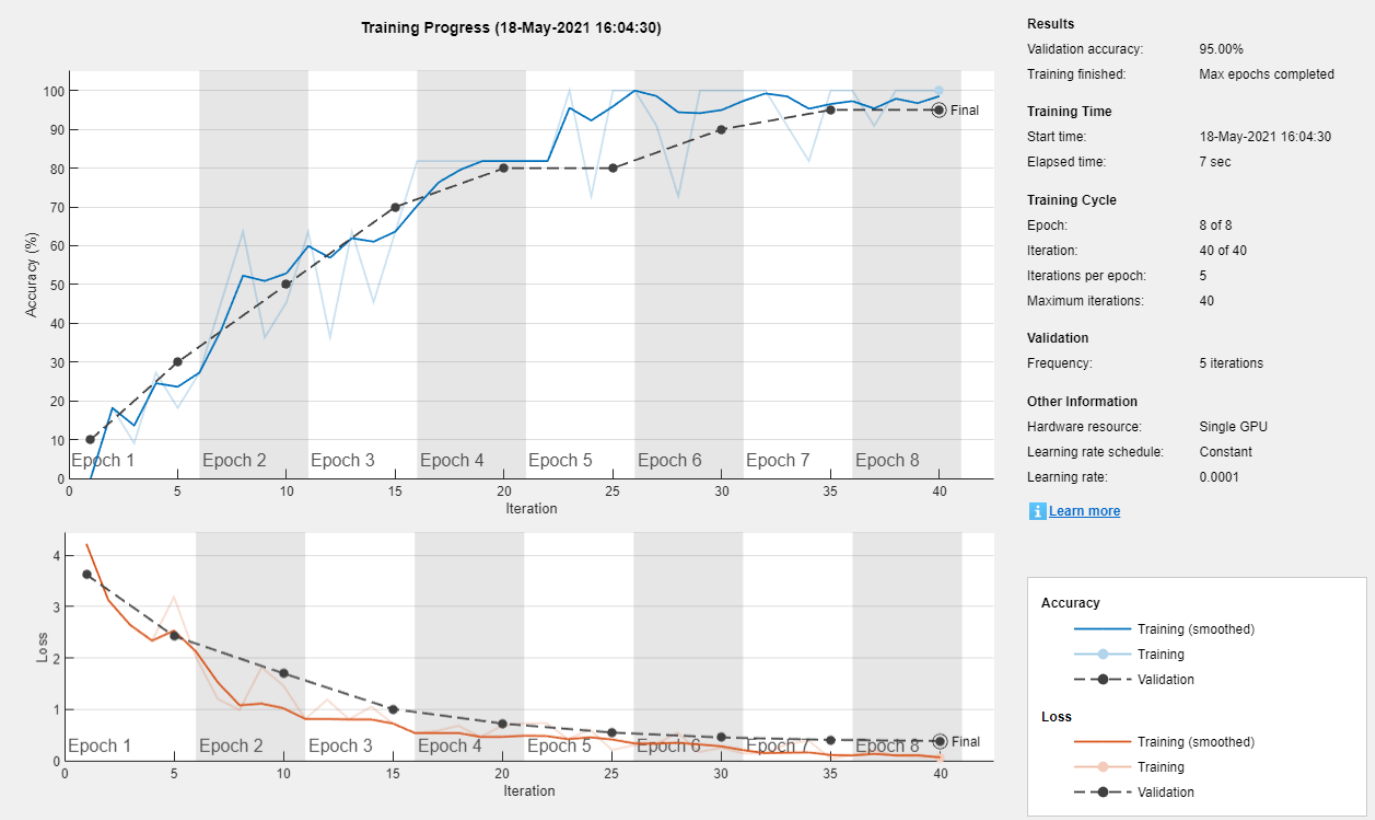
Once you have your network and data, the next step is to select the training options. On the **Training** tab, click **Training Options**. If you do not know which training options to use, try training with the default settings and then adjusting them to suit your network and data. For example, try adjusting the initial learning rate, or train for longer by increasing the number of epochs. For information about techniques for improving the accuracy of deep learning networks, see “Deep Learning Tips and Tricks” on page 1-67. For more information about the training options, see `trainingOptions`.



Train Network

After you select your training options, train the network by clicking **Train**. The Deep Network Designer app displays an animated plot of the training progress. The plot shows mini-batch loss and accuracy, validation loss and accuracy, and additional information on the training progress. The plot

has a stop button in the top-right corner. Click the button to stop training and return the current state of the network. For more information on the training progress plot, see “Monitor Deep Learning Training Progress”.



You can train a variety of networks using Deep Network Designer. For example, image classification or regression networks, sequence networks, numeric data networks, semantic segmentation networks, and image-to-image regression networks. In Deep Network Designer, you can train a network using the `trainNetwork` function on any data that you can express as a datastore object. The following examples show how to build and train a network using Deep Network Designer.

- “Transfer Learning with Deep Network Designer” on page 2-2
- “Train Network for Time Series Forecasting Using Deep Network Designer” on page 2-57
- “Train Simple Semantic Segmentation Network in Deep Network Designer” on page 8-148
- “Image-to-Image Regression in Deep Network Designer” on page 2-72

Once training is complete, on the **Training** tab, click **Export** to export your trained network and results to the workspace.

Deep Network Designer does not support training using custom training loops. To train your network using a custom training loop, first export the network to the workspace and convert it to a `dlnetwork` object. You can then train the network using the `dlnetwork` object and a custom training loop. For more information, see “Train Network Using Custom Training Loop” on page 18-225.

Next Steps

You can learn how to build and train your network using command line functions by clicking **Export > Generate Code for Training** and examining the generated live script. You can also use the generated script as a starting point to create deep learning experiments that sweep through a range of hyperparameter values or use Bayesian optimization to find optimal training options. For an example showing how to use **Experiment Manager** to tune the hyperparameters of a network trained in Deep Network Designer, see “Adapt Code Generated in Deep Network Designer for Use in Experiment Manager” on page 2-79.

Import Custom Layer into Deep Network Designer

This example shows how to import a custom classification output layer with the sum of squares error (SSE) loss and add it to a pretrained network in Deep Network Designer.

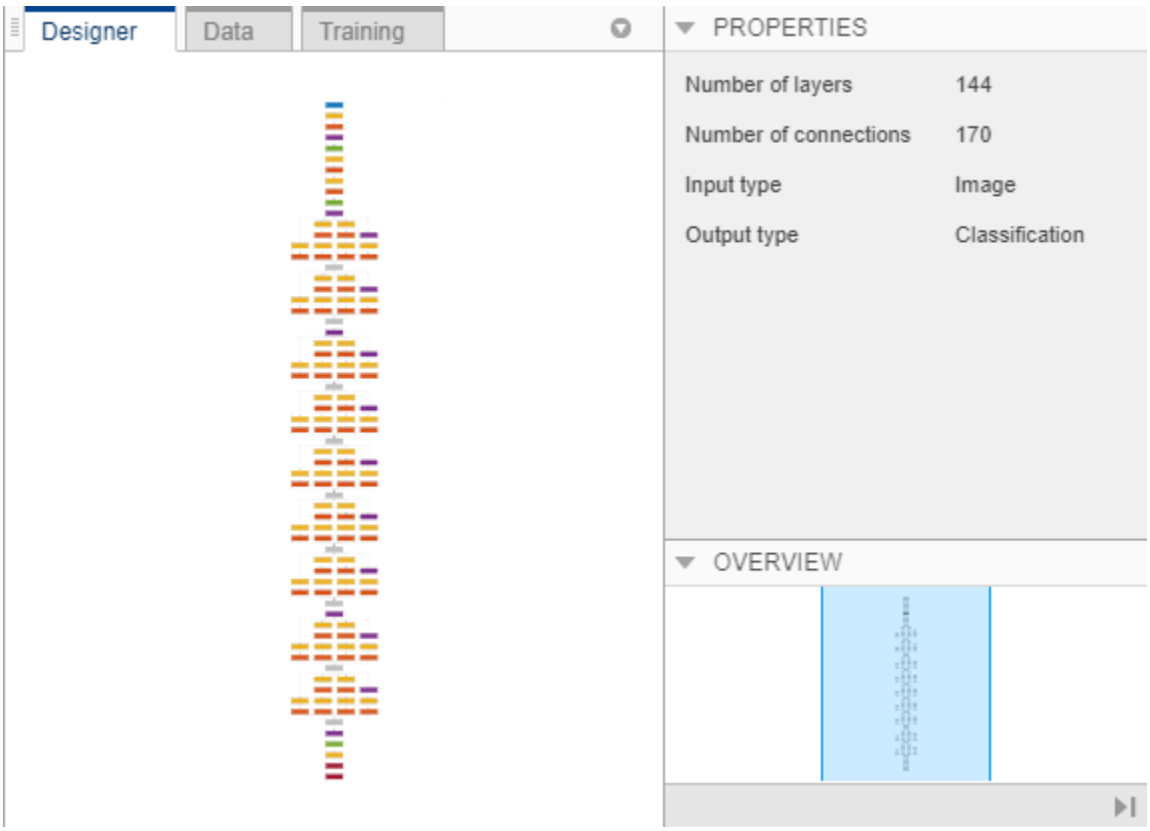
Define a custom classification output layer. To create this layer, save the file `sseClassificationLayer.m` in the current folder. For more information on constructing this layer, see “Define Custom Classification Output Layer” on page 18-91.

Create an instance of the layer.

```
sseClassificationLayer = sseClassificationLayer('sse');
```

Open Deep Network Designer with a pretrained GoogLeNet network.

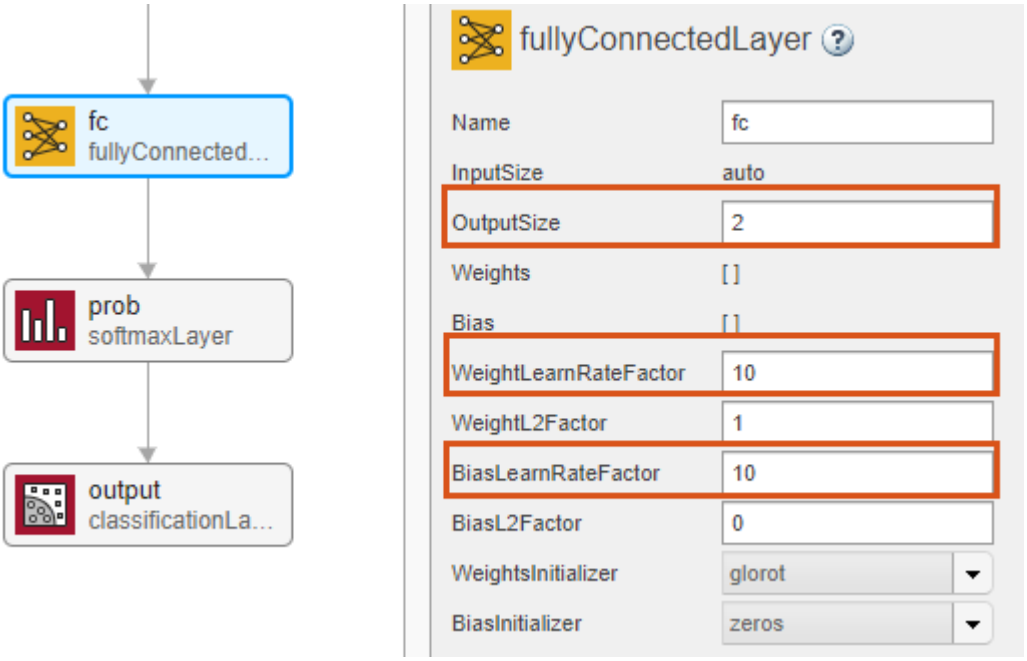
```
deepNetworkDesigner(googlenet);
```



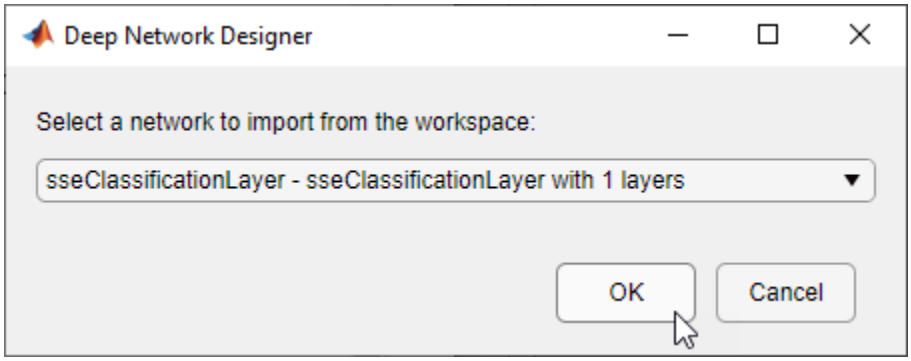
To adapt a pretrained network, replace the last learnable layer and the final classification layer with new layers adapted to the new data set. In GoogLeNet, these layers have the names `'loss3-classifier'` and `'output'`, respectively.

In the **Designer** pane, drag a new `fullyConnectedLayer` from the **Layer Library** onto the canvas. Set `OutputSize` to the new number of classes, in this example, `2`.

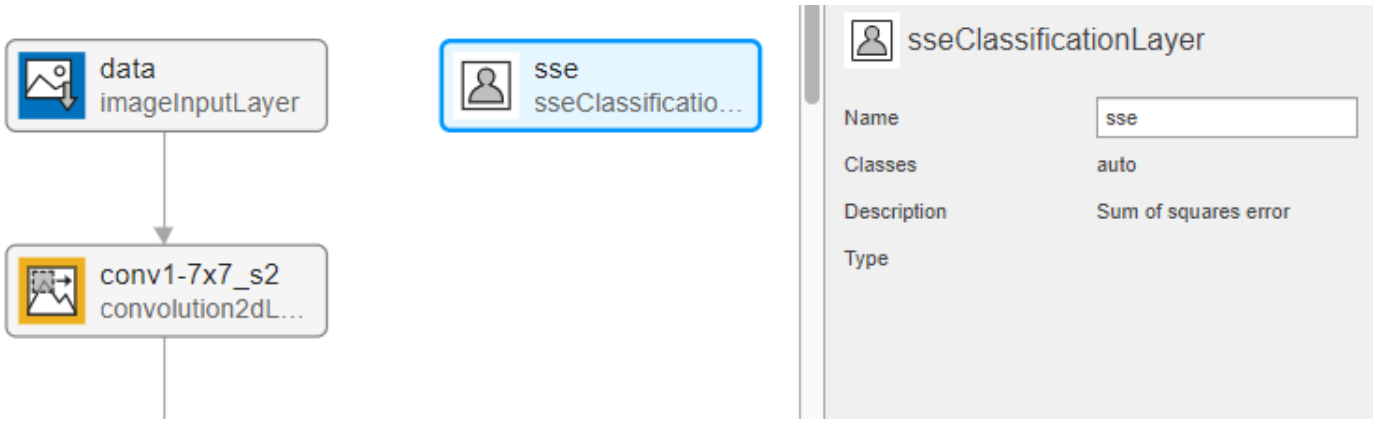
Edit learning rates to learn faster in the new layers than in the transferred layers. Set `WeightLearnRateFactor` and `BiasLearnRateFactor` to `10`. Delete the last fully connected layer and connect your new layer instead.



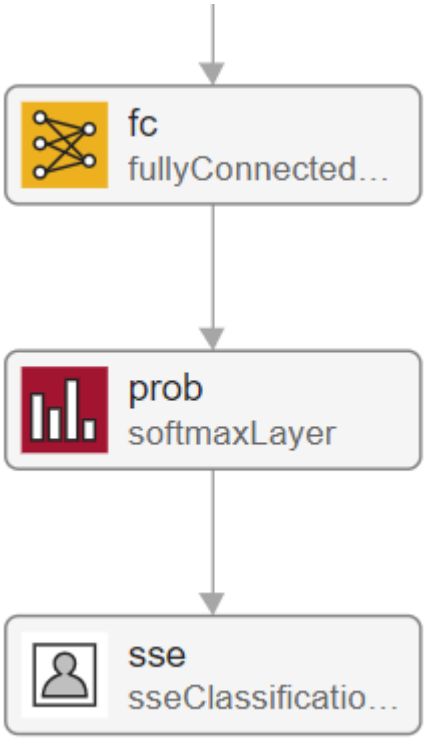
Next, replace the output layer with your custom classification output layer. Click **New** in the **Designer** pane. Pause on **From Workspace** and click **Import**. To import the custom classification layer, select `sseClassificationLayer` and click **OK**.



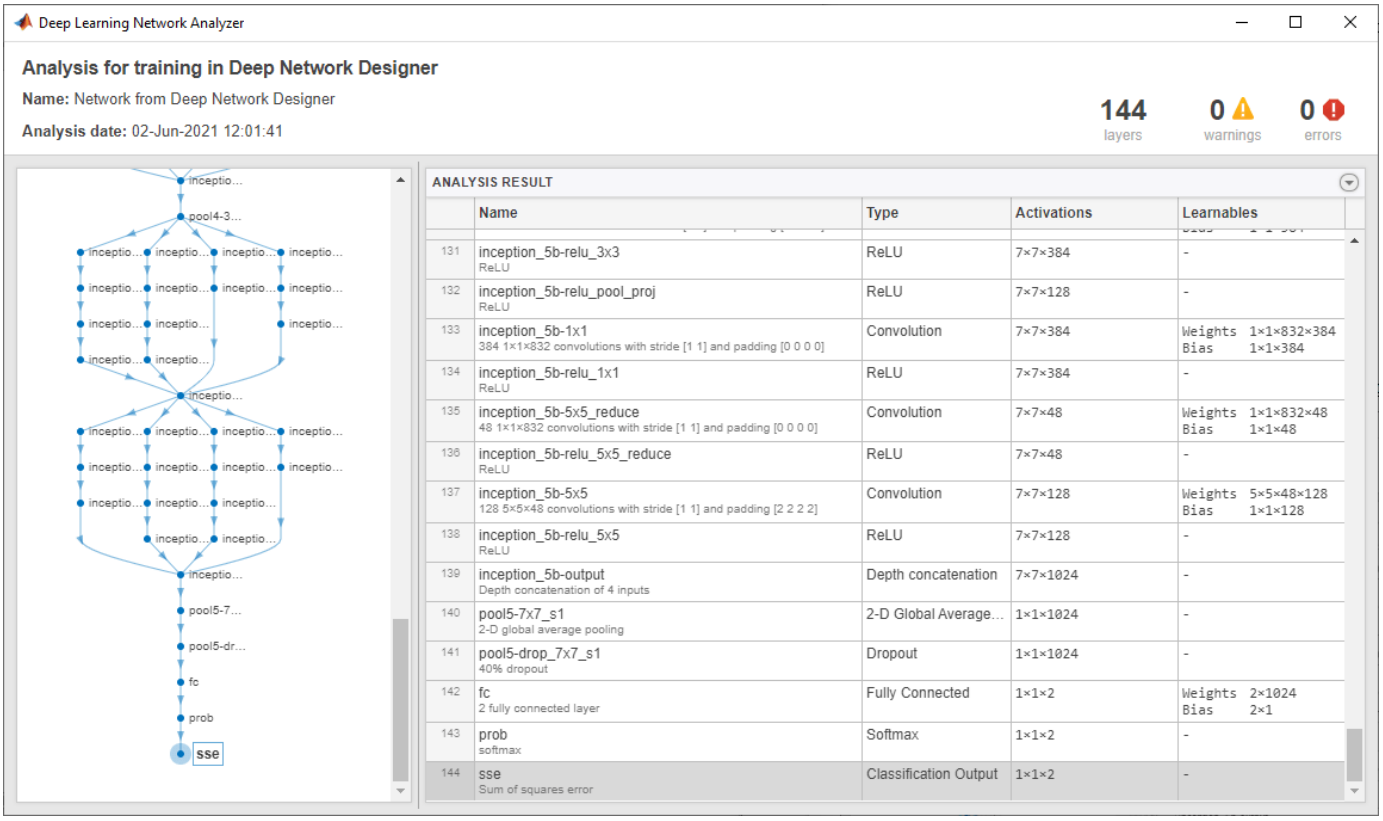
Add the layer to the current GoogLeNet pretrained network by clicking **Add**. The app adds the custom layer to the top of the **Designer** pane. To see the new layer, zoom-in using a mouse or click **Zoom in**.



Drag the custom layer to the bottom of the **Designer** pane. Replace the output layer with the new classification output layer and connect the new layer.



Check your network by clicking **Analyze**. The network is ready for training if Deep Learning Network Analyzer reports zero errors.



After you construct your network, you are ready to import data and train. For more information on importing data and training in Deep Network Designer, see “Transfer Learning with Deep Network Designer” on page 2-2.

Import Data into Deep Network Designer

You can import and visualize training and validation data in **Deep Network Designer**. Using this app you can:

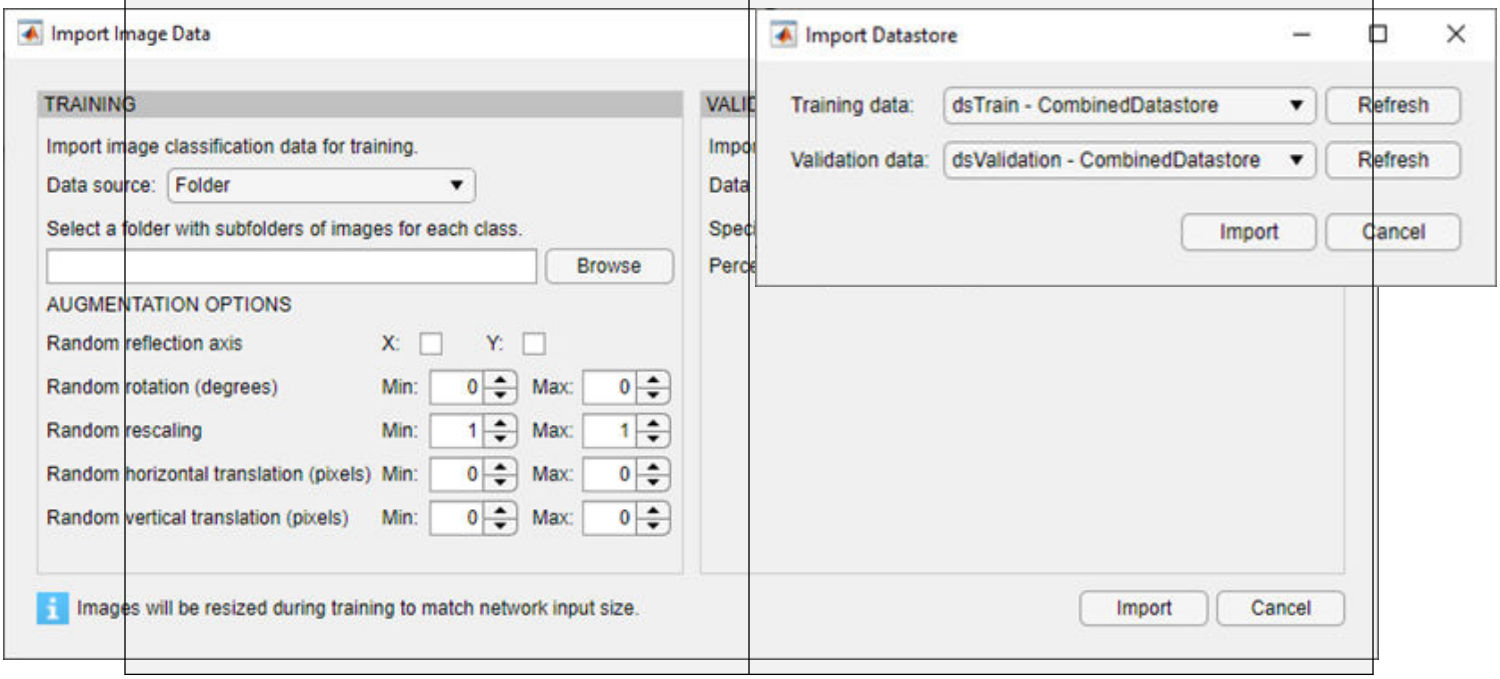
- Import datastore objects for training. After import, Deep Network Designer displays a preview of the data. For more information, see “Import Data” on page 2-39.
- Import training data for image classification problems from an `ImageDatastore` object or a folder containing subfolders of images per class. You can also select built-in options to augment the training images during training. For more information, see “Image Augmentation” on page 2-48.
- Import validation data from a datastore object. For image classification you can also select validation data from a folder containing subfolders of images for each class, or choose to split the validation data from the training data. For more information, see “Validation Data” on page 2-49.

For more information about data sets you can use to get started with deep learning, see “Data Sets for Deep Learning” on page 19-118. For more information on constructing and using datastore objects for deep learning applications, see “Datastores for Deep Learning” on page 19-2.

Import Data

In Deep Network Designer, you can import image classification data from an image datastore or a folder containing subfolders of images from each class. You can also import and train any datastore object that works with the `trainNetwork` function. Select an import method based on the type of datastore you are using.

Import `ImageDatastore` Object	Import Any Other Datastore Object (Not Recommended for `ImageDatastore`)
Select **Import Data** > **Import Image Data**.	Select **Import Data** > **Import Datastore**.

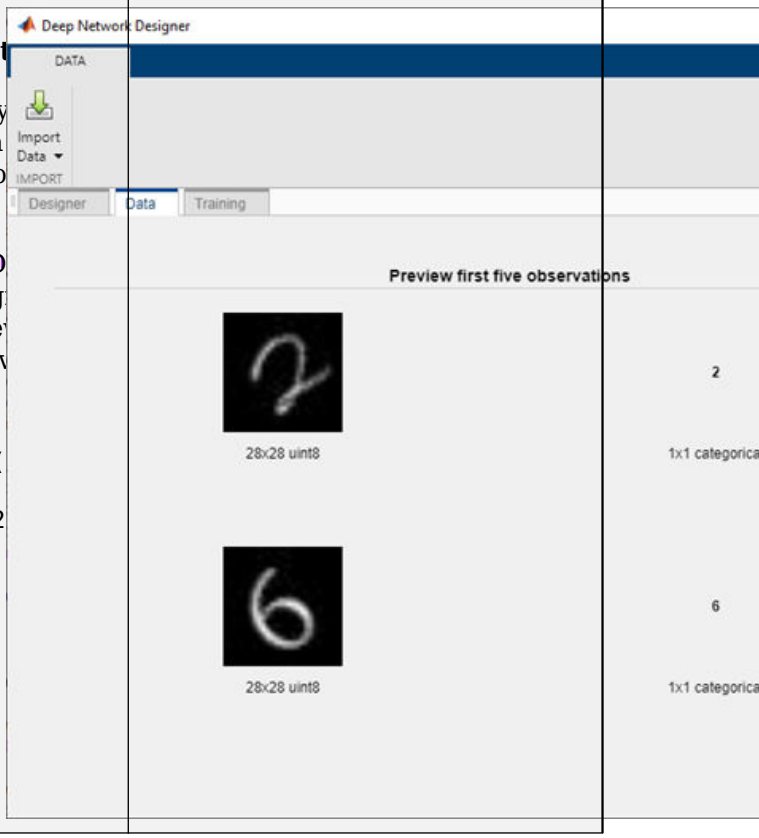


After import, Deep Network Designer provides a preview of the imported data so that you can check that the data is as expected, prior to training. For image classification data, Deep Network Designer also displays a histogram of the class labels and a random selection of images from the imported data. You can also choose to see random images belonging to a specific class.

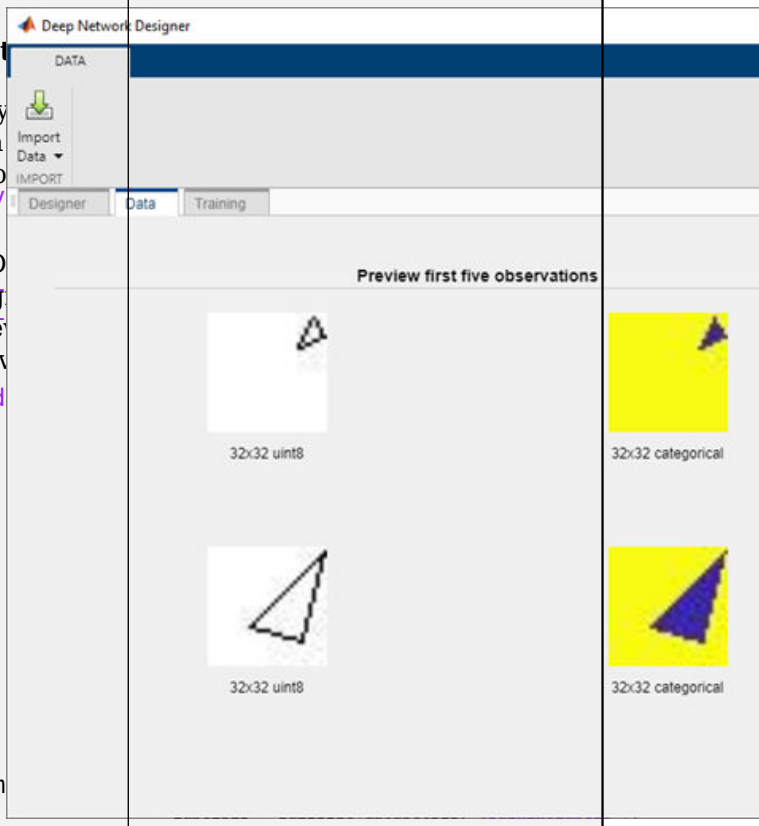
Import Data by Task

Task	Data Type	Data Import Method	Example Visualization
Image classification	Folder with subfolders containing images for each class. The class labels are sourced from the subfolder names. For an example, see "Transfer Learning with Deep Network Designer" on page 2-2.	Select **Import** > **Import Image** You can select augmentation and specify the validation data the Import Ima dialog box. After import, D Network Desig displays a histo the class labels also see rando observations fr class.	
	`ImageDatastore`
	
	For example, create an image datastore containing digits data.
	
	`dataFolder = fullfile(toolboxdir('nnet'),'nndemos', ...`
	`'nndatasets','DigitDataset');`
	
	`imds = imageDatastore(dataFolder, ...`
	`'IncludeSubfolders',true, ...`
	`'LabelSource','foldernames');`
	
	For more information, see "Create Simple Image Classification Network Using Deep Network Designer".		

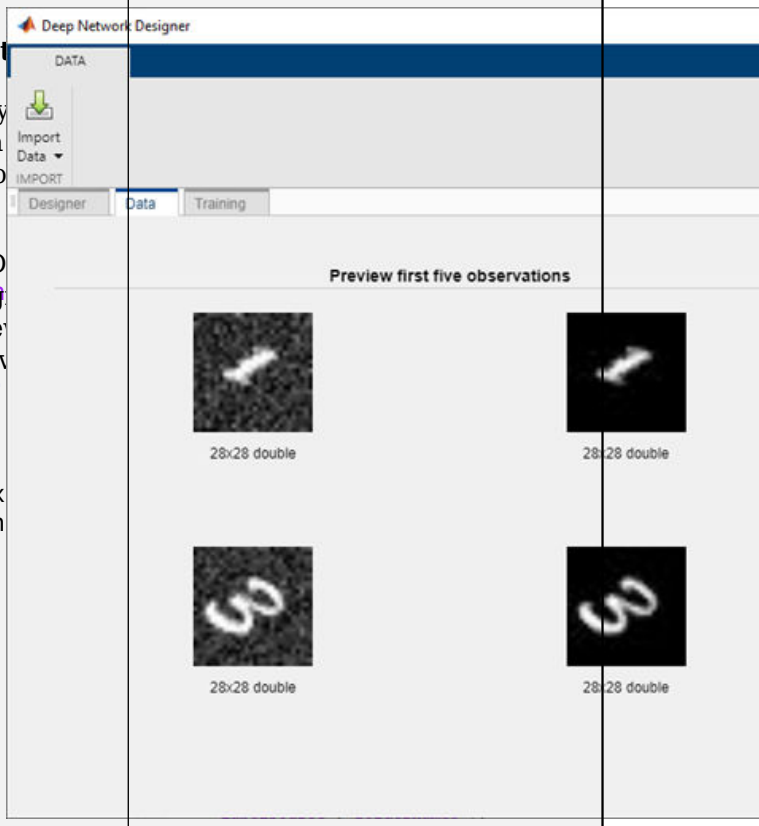
Task	Data Type	Data Import Method	Example Visualization

	`AugmentedImageDatastore`
	
	For example, create an augmented image datastore containing digits data.
	
	`dataFolder = fullfile(toolboxdir('nn','nndatasets','DigitDataset');`
	
	`imds = imageDatastore(dataFolder, ...`
	`'IncludeSubfolders',true, ...`
	`'LabelSource','foldernames');`
	
	`imageAugmenter = imageDataAugmenter(`
	`'RandRotation',[1,2]);`
	`augimds = augmentedImageDatastore([2`
	`'DataAugmentation',imageAugmenter);`
	
	`augimds = shuffle(augimds);`
	
	For more information, see “Transfer Learning Using Pretrained Network” on page 3-33.
		Select **Import** > **Import Datast**
		
		You can specify validation data Import Datasto box.
		
		After import, D Network Desig shows a previe first five observ the datastore.
			


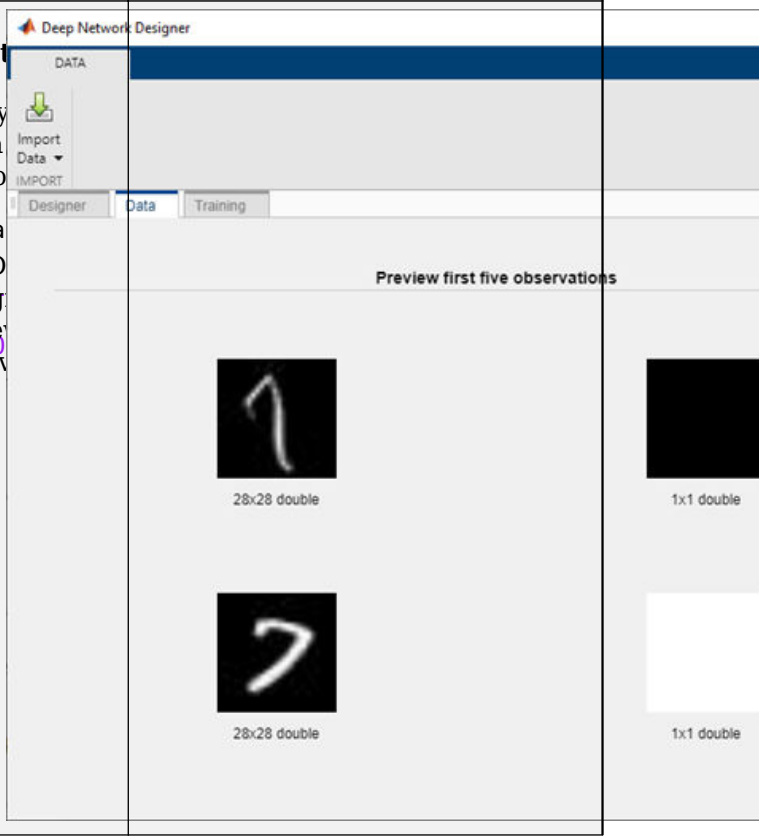
Task	Data Type	Data Import Method	Example Visualization

Semantic segmentation	`CombinedDatastore`
	
	For example, combine an `ImageDatastore` and a `PixelLabelDatastore`.
	
	`dataFolder = fullfile(toolboxdir('v`
	`'visiondata','triangleImages');`
	
	`imageDir = fullfile(dataFolder,'trai`
	`labelDir = fullfile(dataFolder,'trai`
	
	`imds = imageDatastore(imageDir);`
	`classNames = ["triangle","backgrou`
	`labelIDs = [255 0];`
	
	`pxds = pixelLabelDatastore(labelDir,`
	`cds = combine(imds,pxds);`
	
	You can also combine an `ImageDatastore` and a `PixelLabelDatastore` in a `pixelLabelImageDatastore`.
	
	`pximds = pixelLabelImageDatastore(im`
	
	For more information about creating and training a semantic segmentation network, see “Train Simple Semantic Segmentation Network in Deep Network Designer” on page 8-148.
		Select **Import** > **Import Datast**
		
		You can specify validation data Import Datasto box.
		
		After import, D Network Desig shows a previe first five observ the datastore.
			


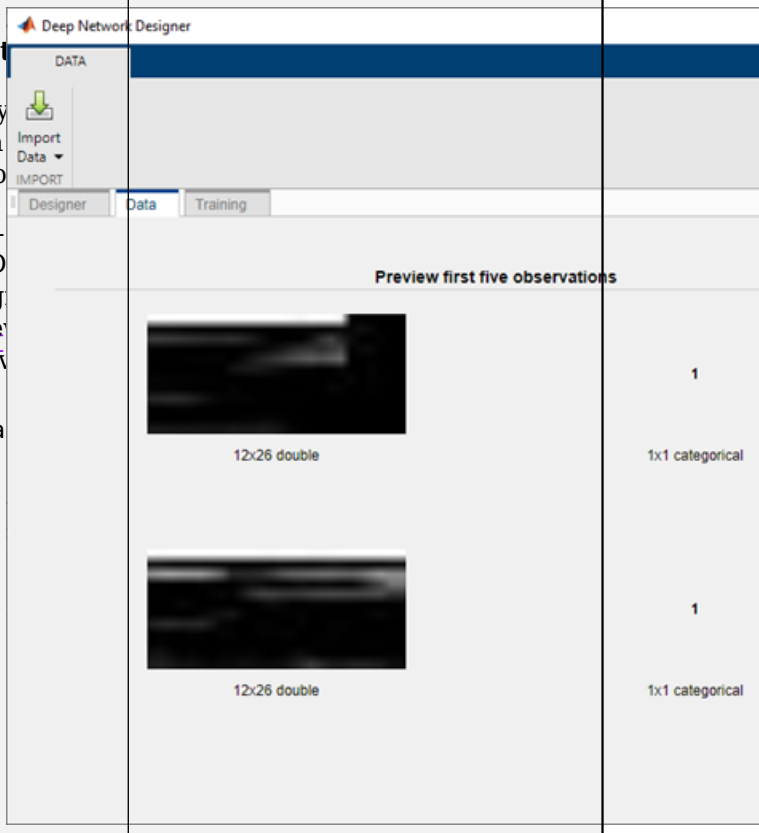
Task	Data Type	Data Import Method	Example Visualization

Image-to-image regression	`CombinedDatastore`
	
	For example, combine noisy input images and pristine output images to create data suitable for image-to-image regression.
	
	`dataFolder = fullfile(toolboxdir('nn','nndatasets','DigitDataset');`
	
	`imds = imageDatastore(dataFolder, ...`
	`    'IncludeSubfolders',true, ...`
	`    'LabelSource','foldernames');`
	
	`imds = transform(imds,@(x) rescale(x`
	`imdsNoise = transform(imds,@(x) {imn`
	
	`cds = combine(imdsNoise,imds);`
	`cds = shuffle(cds);`
	
	For more information about training an image-to-image regression network, see “Image-to-Image Regression in Deep Network Designer” on page 2-72.
		Select **Import** > **Import Datast**
		
		You can specify validation data Import Datasto box.
		
		After import, D Network Desig shows a previe first five observ the datastore.
			


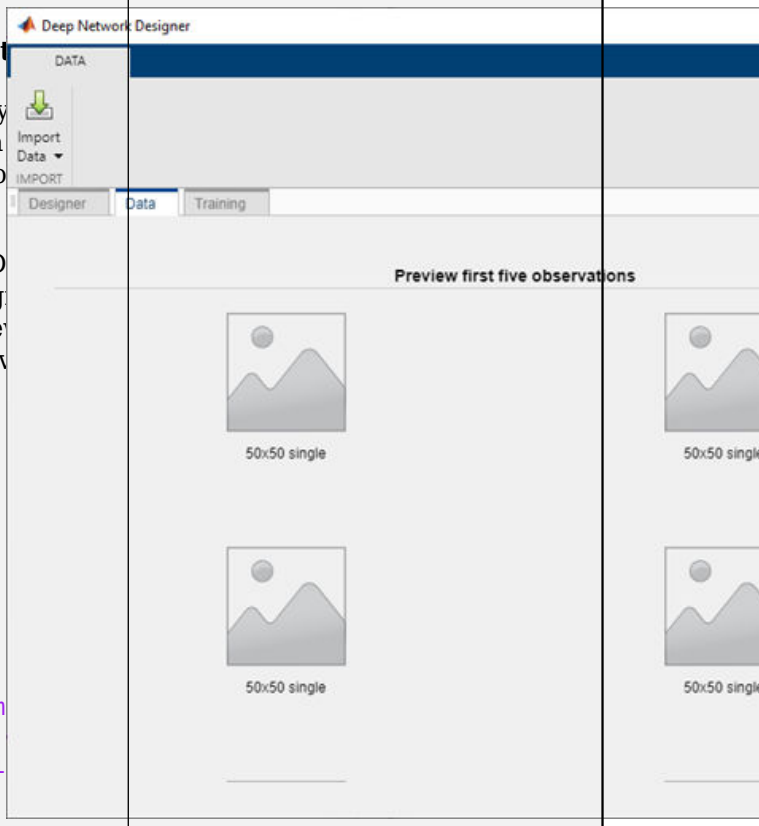
Task	Data Type	Data Import Method	Example Visualization

Regression	`CombinedDatastore`
	
	Create data suitable for training regression networks by combining array datastore objects.
	
	`[XTrain,~,YTrain] = digitTrain4DArra`
	
	`ads = arrayDatastore(XTrain,'Iterati`
	`'OutputType','cell');`
	`adsAngles = arrayDatastore(YTrain,'O`
	
	`cds = combine(ads,adsAngles);`
	
	For more information about training a regression network, see "Train Convolutional Neural Network for Regression" on page 3-53.
		Select **Import** > **Import Datast**
		
		You can specify validation data Import Datasto box.
		After import, D Network Desig shows a previe first five observ the datastore.
			


Task	Data Type	Data Import Method	Example Visualization

Sequences and time series	`CombinedDatastore`
	
	For in-memory data, create data suitable for training by combining array datastore objects.
	
	`[XTrain,YTrain] = japaneseVowelsTrai`
	
	`XTrain = padsequences(XTrain,2);`
	
	`adsXTrain = arrayDatastore(XTrain,'I`
	`adsYTrain = arrayDatastore(YTrain);`
	
	`cdsTrain = combine(adsXTrain,adsYTra`
	
	For information about training a network on time series data, see "Train Network for Time Series Forecasting Using Deep Network Designer" on page 2-57.
	
	For out-of-memory data, use a custom datastore object. For an example showing how to create a custom sequence datastore, see "Train Network Using Custom Mini-Batch Datastore for Sequence Data" on page 19-104.
		Select **Import** > **Import Datast**
		
		You can specify validation data Import Datasto box.
		
		After import, D Network Desig shows a previe first five obser the datastore.
			


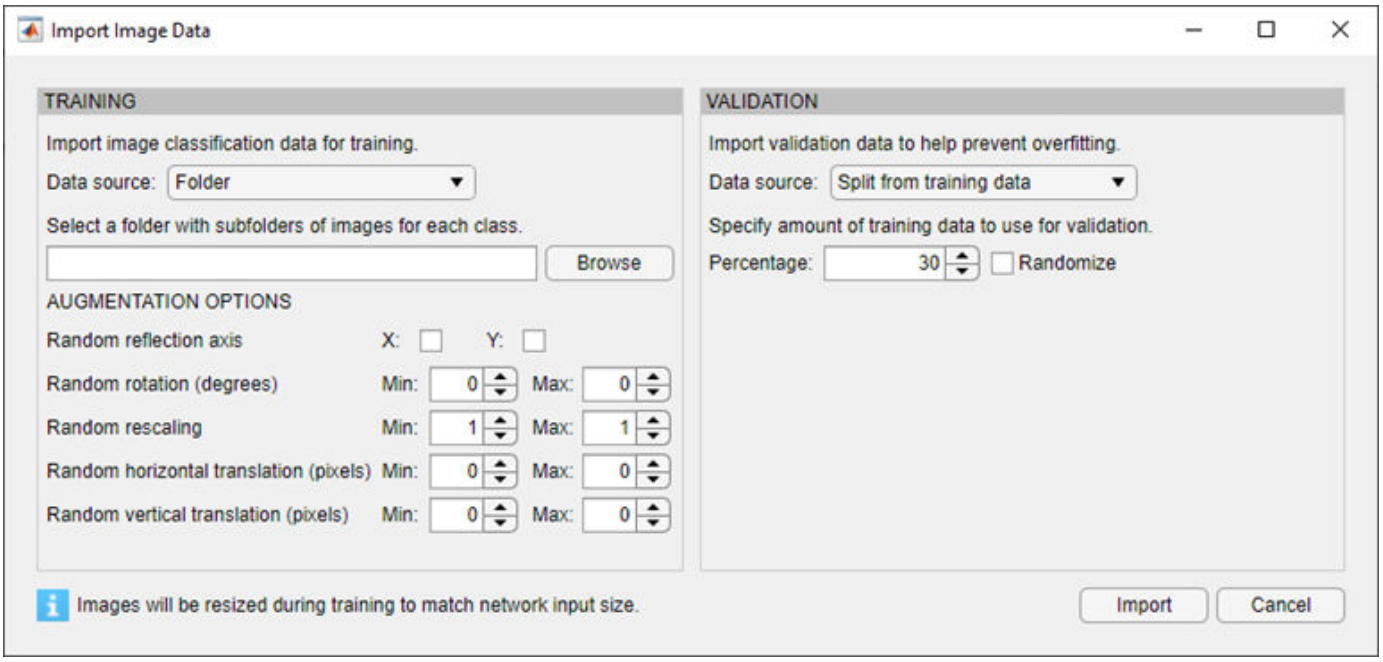
Task	Data Type	Data Import Method	Example Visualization

Other extended workflows (such as numeric feature input, out-of-memory data, image processing, and audio and speech processing)	Datastore
	
	For other extended workflows, use a suitable datastore object. For example, custom datastore, `randomPatchExtractionDatastore`, `denoisingImageDatastore`, or `audioDatastore`. For more information, see "Datastores for Deep Learning" on page 19-2.
	
	For example, create a `denoisingImageDatastore` object using Image Processing Toolbox™.
	
	`dataFolder = fullfile(toolboxdir('im`
	
	`imds = imageDatastore(dataFolder,'Fi`
	
	`dnds = denoisingImageDatastore(imds,...`
	`    'PatchesPerImage',512,...`
	`    'PatchSize',50,...`
	`    'GaussianNoiseLevel',[0.01 0.1]);`
	
	For table array data, you must convert your data into a suitable datastore to train using Deep Network Designer. For example, start by converting your table into arrays containing the predictors and responses. Then, convert the arrays into `arrayDatastore` objects. Finally, combine the predictor and response array datastores into a `CombinedDatastore` object. You can then use the combined datastore to train in Deep Network Designer. For more information on suitable
		Select **Import** > **Import Datast**
		
		You can specify validation data Import Datasto box.
		
		After import, D Network Desig shows a previe first five observ the datastore.
			


Task	Data Type	Data Import Method	Example Visualization
	datastores, see "Datastores for Deep Learning" on page 19-2.		

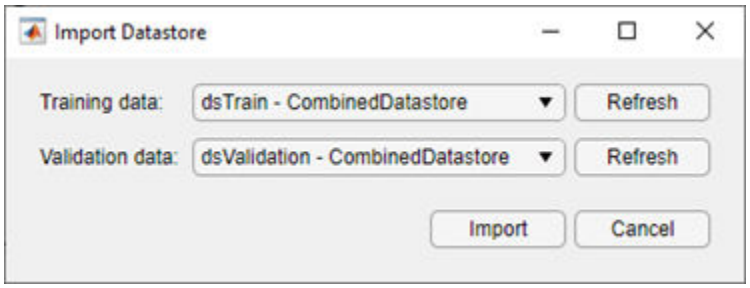
Image Augmentation

For image classification problems, Deep Network Designer provides simple augmentation options to apply to the training data. Open the Import Image Data dialog box by selecting **Import Data** > **Import Image Data**. You can select options to apply a random combination of reflection, rotation, rescaling, and translation operations to the training data.



You can effectively increase the amount of training data by applying randomized augmentation to your data. Augmentation also enables you to train networks to be invariant to distortions in image data. For example, you can add randomized rotations to input images so that a network is invariant to the presence of rotation in input images. Data augmentation can also help prevent the network from overfitting and memorizing the exact details of the training images. When you use data augmentation, one randomly augmented version of each image is used during each epoch of training, where an epoch is a full pass of the training algorithm over the entire training data set. Therefore, each epoch uses a slightly different data set, but the actual number of training images in each epoch does not change. For more information, see "Create and Explore Datastore for Image Classification" on page 19-10.

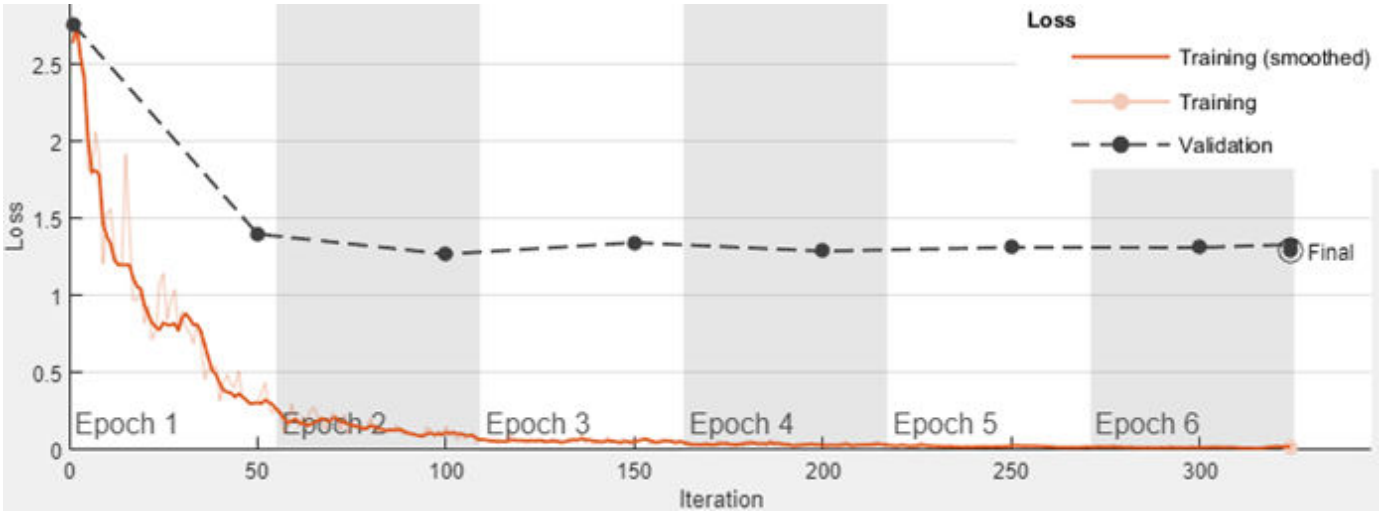
To perform more general and complex image preprocessing operations than those offered by Deep Network Designer, use `TransformedDatastore` and `CombinedDatastore` objects. To import `CombinedDatastore` and `TransformedDatastore` objects, select **Import Data** > **Import Datastore**.



For more information on image augmentation, see “Preprocess Images for Deep Learning” on page 19-16.

Validation Data

In Deep Network Designer, you can import validation data to use during training. Validation data is data that the network does not use to update the weights and biases during training. As the network does not directly use this data, it is useful for assessing the true accuracy of the network during training. You can monitor validation metrics, such as loss and accuracy, to assess if the network is overfitting or underfitting and adjust the training options as required. For example, if the validation loss is much higher than the training loss, then the network might be overfitting.



For more information on improving the accuracy of deep learning networks, see “Deep Learning Tips and Tricks” on page 1-67.

In Deep Network Designer, you can import validation data:

- From a datastore in the workspace.
- From a folder containing subfolders of images for each class (image classification data only).
- By splitting a portion of the training data to use as validation data (image classification data only).

Split Validation Data from Training Data

When splitting the validation data from the training data, Deep Network Designer splits a percentage of the training data from each class. For example, suppose you have a data set with two classes, cat

and dog, and choose to use 30% of the training data for validation. Deep Network Designer uses the last 30% of images with the label "cat" and the last 30% with the label "dog" as the validation set.

Rather than using the last 30% of the training data as validation data, you can choose to randomly allocate the observations to the training and validation sets by selecting the **Randomize** check box in the Import Image Data dialog box. Randomizing the images can improve the accuracy of networks trained on data stored in a nonrandom order. For example, the digits data set consists of 10,000 synthetic grayscale images of handwritten digits. This data set has an underlying order in which images with the same handwriting style appear next to each other within each class. An example of the display follows.

Randomizing ensures that when you split the data, the images are shuffled so that the training and validation sets contain random images from each class. Using training and validation data that consists of a similar distribution of images can help prevent overfitting. Not randomizing the data ensures that the training and validation data split is the same each time, and can help improve the reproducibility of results. For more information, see `splitEachLabel`.

Create Simple Sequence Classification Network Using Deep Network Designer

This example shows how to create a simple long short-term memory (LSTM) classification network using Deep Network Designer.

To train a deep neural network to classify sequence data, you can use an LSTM network. An LSTM network is a type of recurrent neural network (RNN) that learns long-term dependencies between time steps of sequence data.

The example demonstrates how to:

- Load sequence data.
- Construct the network architecture.
- Specify training options.
- Train the network.
- Predict the labels of new data and calculate the classification accuracy.

Load Data

Load the Japanese Vowels data set, as described in [1] on page 2-0 and [2] on page 2-0 . The predictors are cell arrays containing sequences of varying length with a feature dimension of 12. The labels are categorical vectors of labels 1,2,...,9.

```
[XTrain,YTrain] = japaneseVowelsTrainData;
[XValidation,YValidation] = japaneseVowelsTestData;
```

View the sizes of the first few training sequences. The sequences are matrices with 12 rows (one row for each feature) and a varying number of columns (one column for each time step).

```
XTrain(1:5)
```

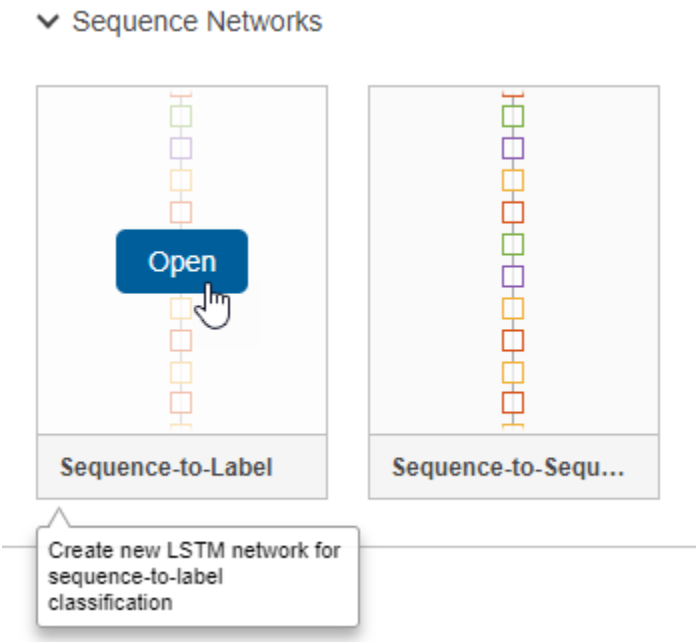
```
ans=5×1 cell array
    {12×20 double}
    {12×26 double}
    {12×22 double}
    {12×20 double}
    {12×21 double}
```

Define Network Architecture

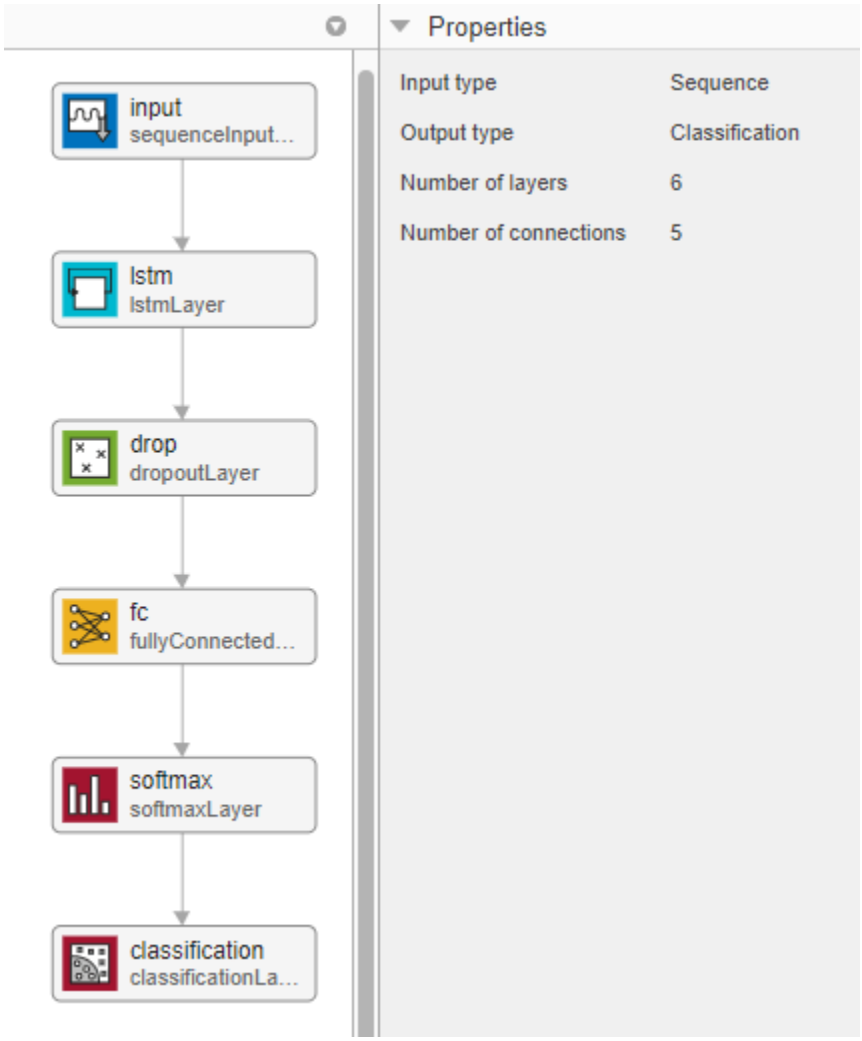
Open Deep Network Designer.

```
deepNetworkDesigner
```

Pause on **Sequence-to-Label** and click **Open**. This opens a prebuilt network suitable for sequence classification problems.

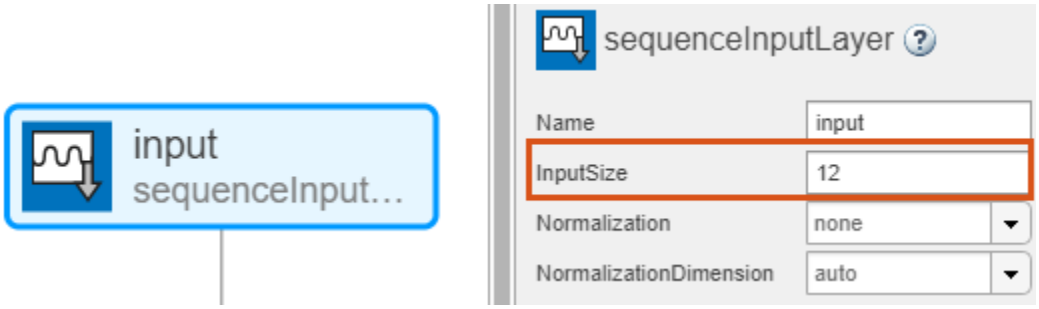


Deep Network Designer displays the prebuilt network.

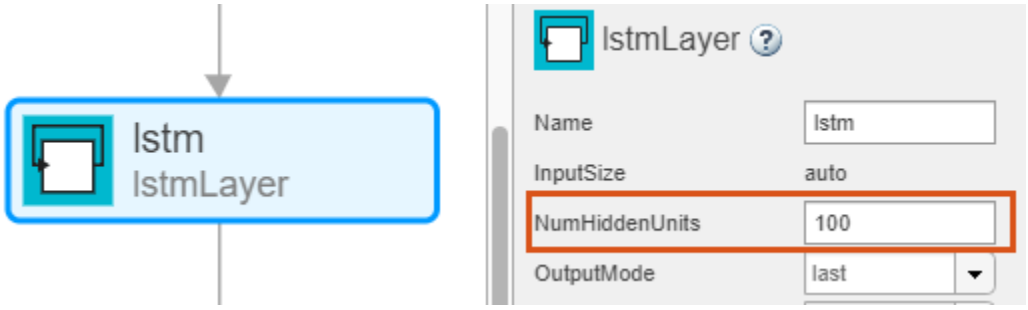


You can easily adapt this sequence network for the Japanese Vowels data set.

Select **sequenceInputLayer** and check that **InputSize** is set to 12 to match the feature dimension.



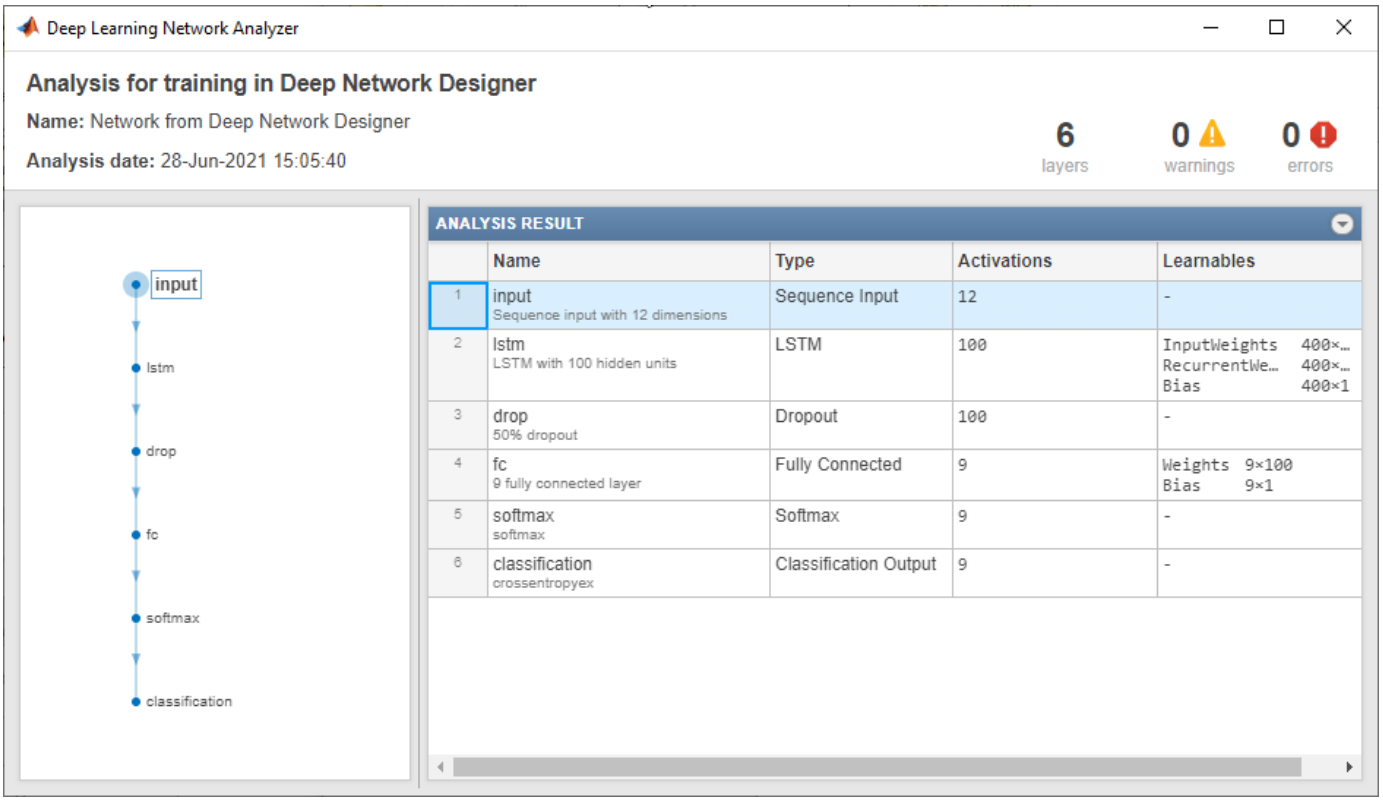
Select **lstmLayer** and set **NumHiddenUnits** to 100.



Select **fullyConnectedLayer** and check that **OutputSize** is set to 9, the number of classes.

Check Network Architecture

To check the network and examine more details of the layers, click **Analyze**.



Export Network Architecture

To export the network architecture to the workspace, on the **Designer** tab, click **Export**. Deep Network Designer saves the network as the variable `layers_1`.

You can also generate code to construct the network architecture by selecting **Export** > **Generate Code**.

Train Network

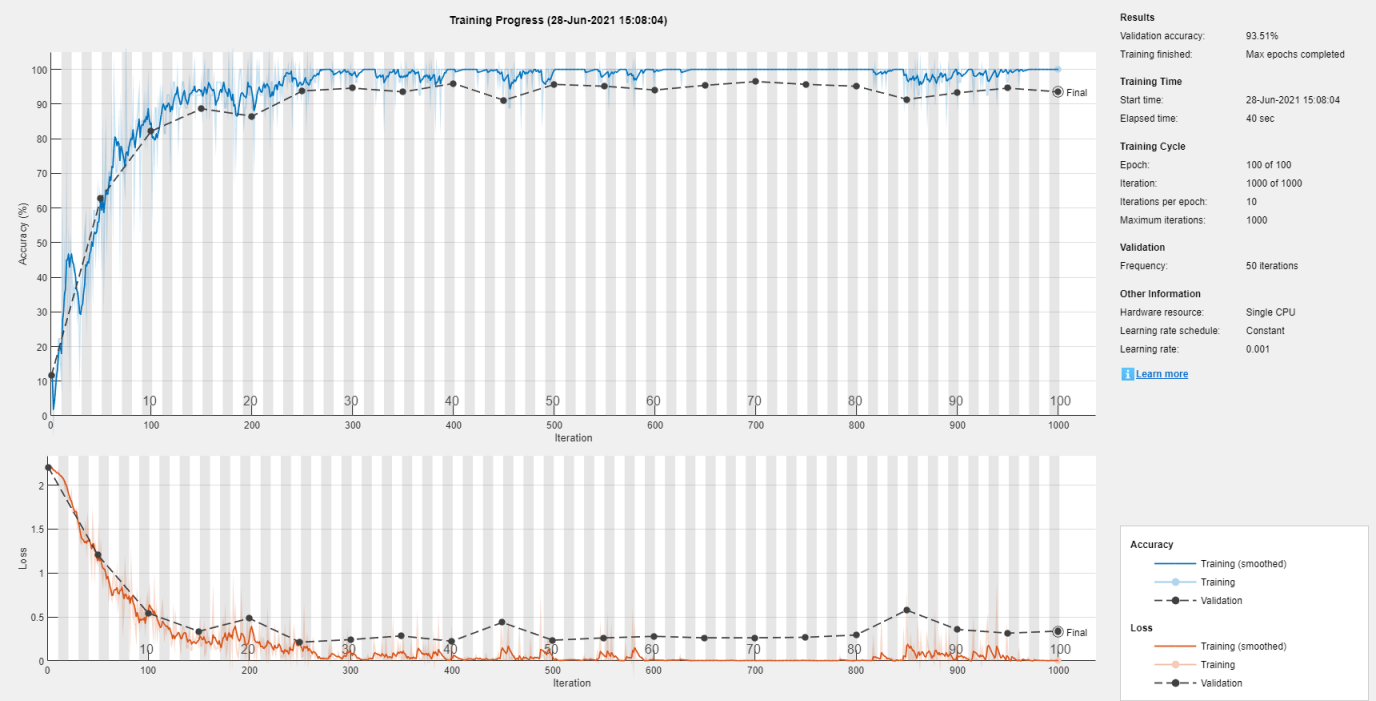
Specify the training options and train the network.

Because the mini-batches are small with short sequences, the CPU is better suited for training. Set `'ExecutionEnvironment'` to `'cpu'`. To train on a GPU, if available, set `'ExecutionEnvironment'` to `'auto'` (the default value).

```
miniBatchSize = 27;
options = trainingOptions('adam', ...
    'ExecutionEnvironment','cpu', ...
    'MaxEpochs',100, ...
    'MiniBatchSize',miniBatchSize, ...
    'ValidationData',{XValidation,YValidation}, ...
    'GradientThreshold',2, ...
    'Shuffle','every-epoch', ...
    'Verbose',false, ...
    'Plots','training-progress');
```

Train the network.

```
net = trainNetwork(XTrain,YTrain,layers_1,options);
```



You can also train this network using Deep Network Designer and datastore objects. For an example showing how to train a sequence-to-sequence regression network in Deep Network Designer, see “Train Network for Time Series Forecasting Using Deep Network Designer” on page 2-57.

Test Network

Classify the test data and calculate the classification accuracy. Specify the same mini-batch size as for training.

```
YPred = classify(net,XValidation,'MiniBatchSize',miniBatchSize);
acc = mean(YPred == YValidation)
```

```
acc = 0.9405
```

For next steps, you can try improving the accuracy by using bidirectional LSTM (BiLSTM) layers or by creating a deeper network. For more information, see “Long Short-Term Memory Networks” on page 1-75.

For an example showing how to use convolutional networks to classify sequence data, see “Speech Command Recognition Using Deep Learning” on page 4-23.

Train Network for Time Series Forecasting Using Deep Network Designer

This example shows how to forecast time series data by training a long short-term memory (LSTM) network in **Deep Network Designer**.

Deep Network Designer allows you to interactively create and train deep neural networks for sequence classification and regression tasks.

To forecast the values of future time steps of a sequence, you can train a sequence-to-sequence regression LSTM network, where the responses are the training sequences with values shifted by one time step. That is, at each time step of the input sequence, the LSTM network learns to predict the value of the next time step.

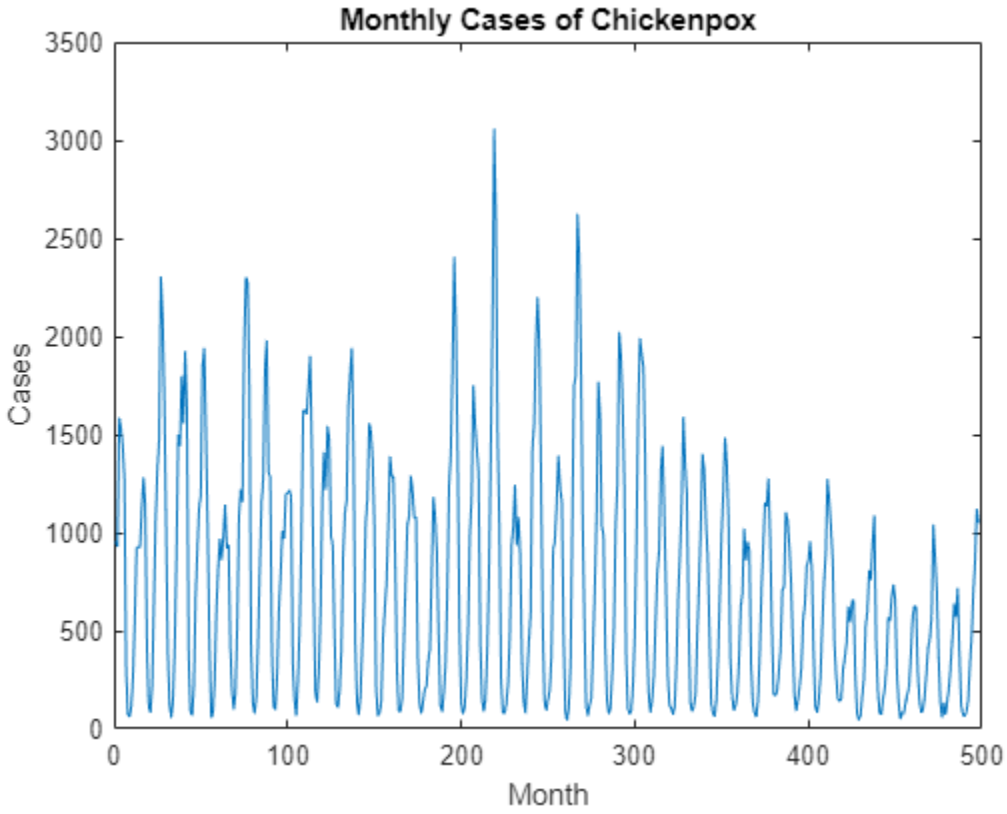
This example uses the data set `chickenpox_dataset`. The example creates and trains an LSTM network to forecast the number of chickenpox cases given the number of cases in previous months.

Load Sequence Data

Load the example data. `chickenpox_dataset` contains a single time series, with time steps corresponding to months and values corresponding to the number of cases. The output is a cell array, where each element is a single time step. Reshape the data to be a row vector.

```
data = chickenpox_dataset;
data = [data{:}];

figure
plot(data)
xlabel("Month")
ylabel("Cases")
title("Monthly Cases of Chickenpox")
```



Partition the training and test data. Train on the first 90% of the sequence and test on the last 10%.

```
numTimeStepsTrain = floor(0.9*numel(data))
```

```
numTimeStepsTrain = 448
```

```
dataTrain = data(1:numTimeStepsTrain+1);
dataTest = data(numTimeStepsTrain+1:end);
```

Standardize Data

For a better fit and to prevent the training from diverging, standardize the training data to have zero mean and unit variance. For prediction, you must standardize the test data using the same parameters as the training data.

```
mu = mean(dataTrain);
sig = std(dataTrain);

dataTrainStandardized = (dataTrain - mu) / sig;
```

Prepare Predictors and Responses

To forecast the values of future time steps of a sequence, specify the responses as the training sequences with values shifted by one time step. That is, at each time step of the input sequence, the LSTM network learns to predict the value of the next time step. The predictors are the training sequences without the final time step.

```
XTrain = dataTrainStandardized(1:end-1);
YTrain = dataTrainStandardized(2:end);
```

To train the network using Deep Network Designer, convert the training data to a datastore object. Use `arrayDatastore` to convert the training data predictors and responses into `ArrayDatastore` objects. Use `combine` to combine the two datastores.

```
adsXTrain = arrayDatastore(XTrain);
adsYTrain = arrayDatastore(YTrain);

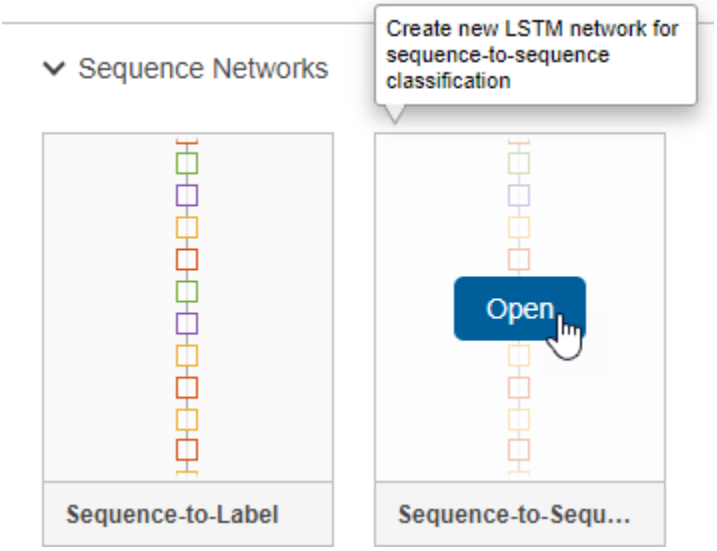
cdsTrain = combine(adsXTrain,adsYTrain);
```

Define LSTM Network Architecture

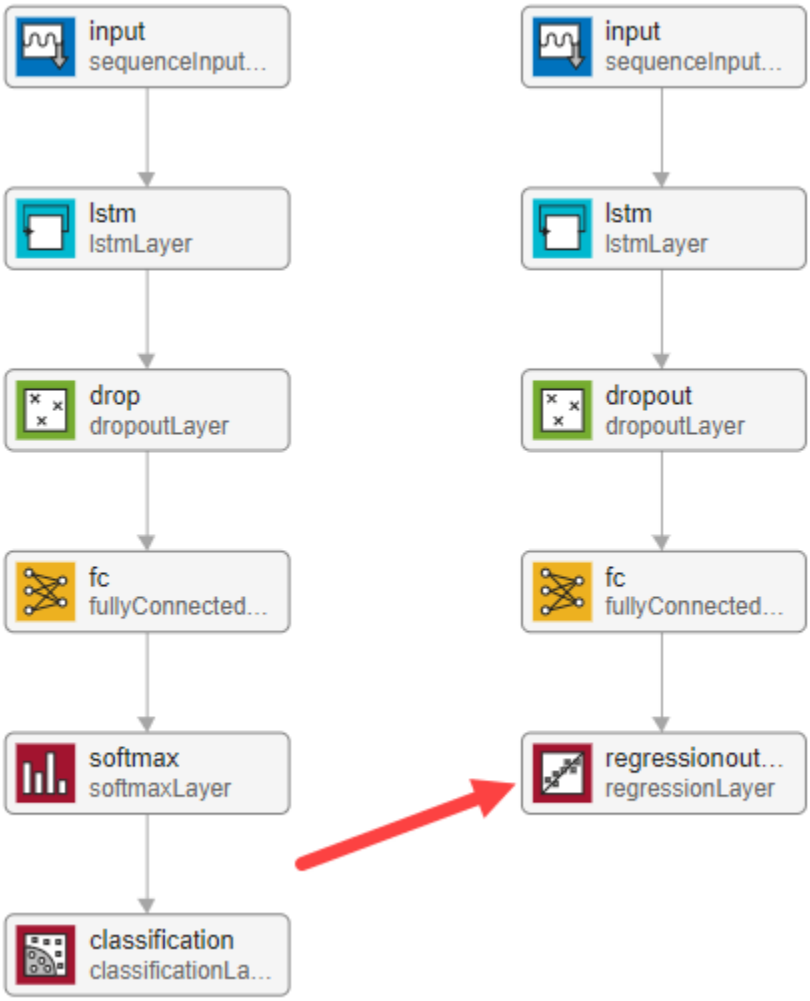
To create the LSTM network architecture, use **Deep Network Designer**. The **Deep Network Designer** app lets you build, visualize, edit, and train deep learning networks.

```
deepNetworkDesigner
```

On the **Deep Network Designer** start page, pause on **Sequence-to-Sequence** and click **Open**. Doing so opens a prebuilt network suitable for sequence-to-sequence classification tasks. You can convert the classification network into a regression network by replacing the final layers.

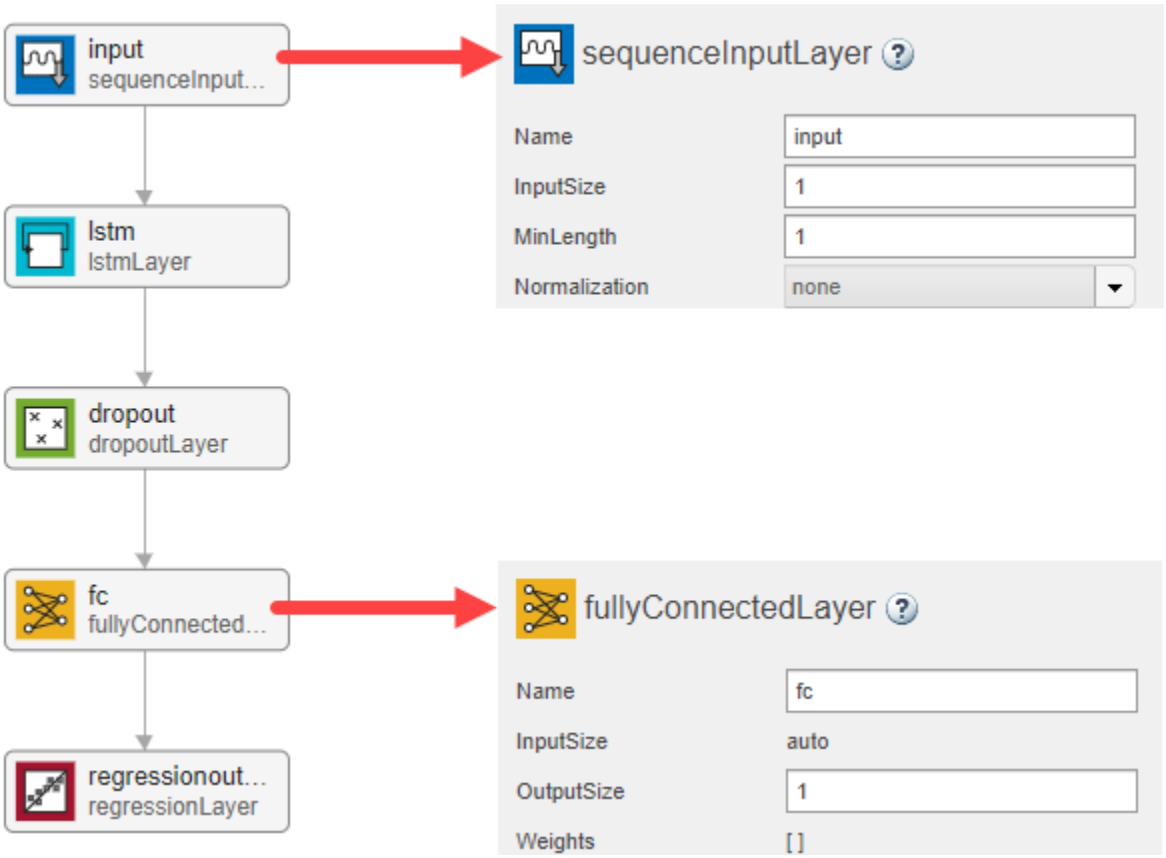


Delete the softmax layer and the classification layer and replace them with a regression layer.

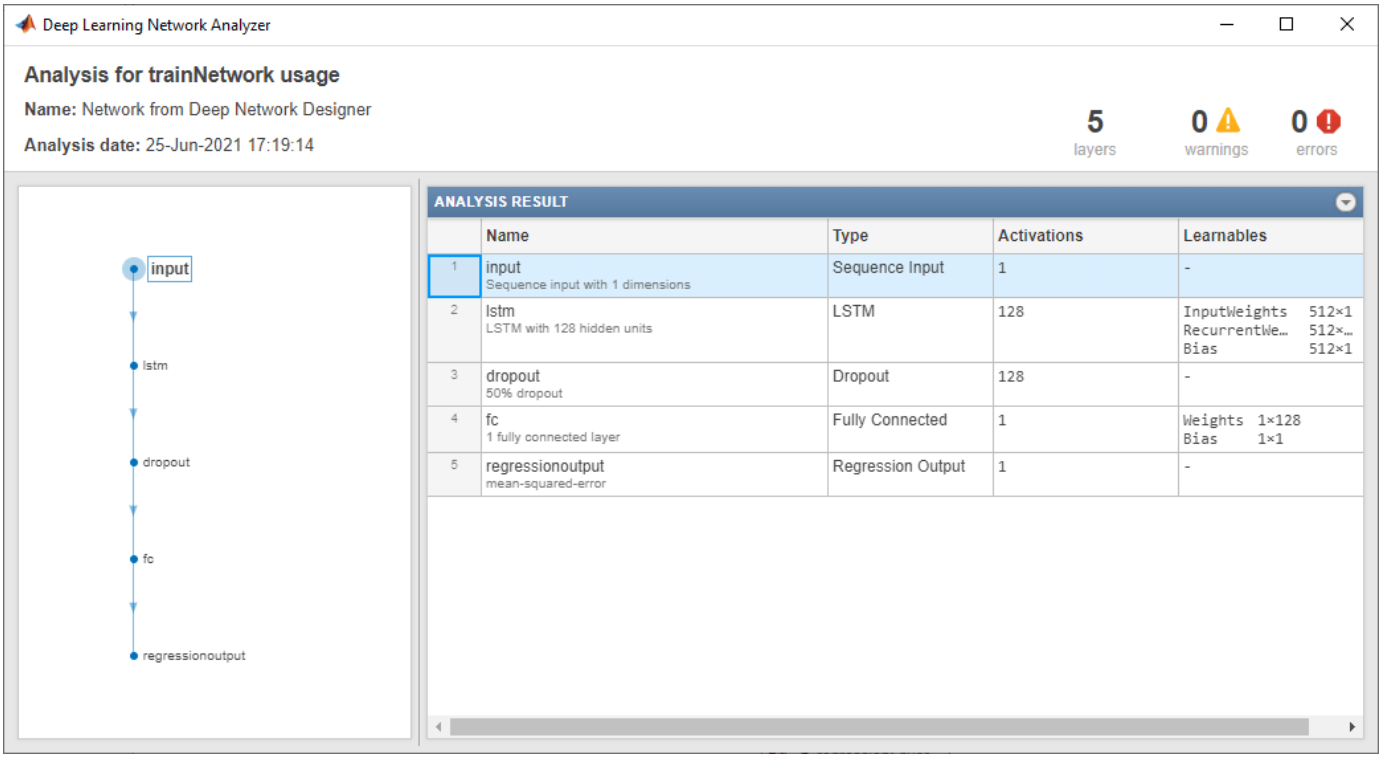


Adjust the properties of the layers so that they are suitable for the chickenpox data set. This data has a single input feature and a single output feature. Select **sequenceInputLayer** and set the

InputSize to 1. Select **fullyConnectedLayer** and set the **OutputSize** to 1.

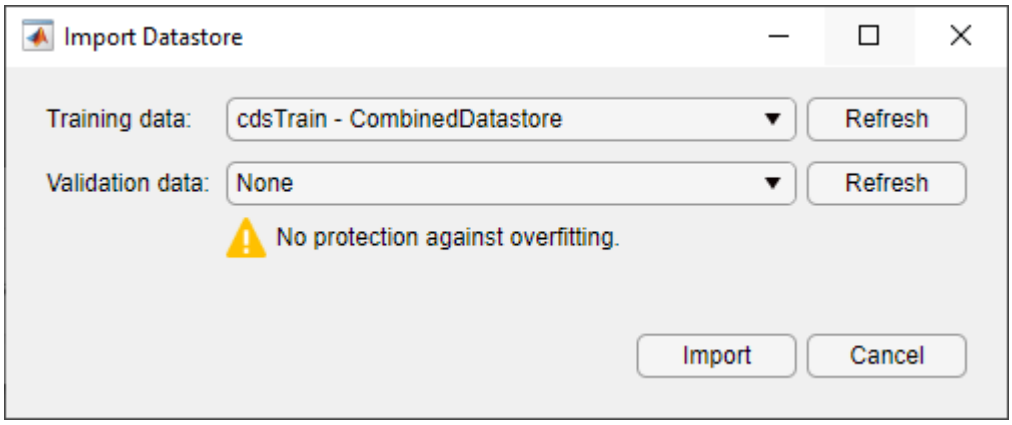


Check your network by clicking **Analyze**. The network is ready for training if **Deep Learning Network Analyzer** reports zero errors.

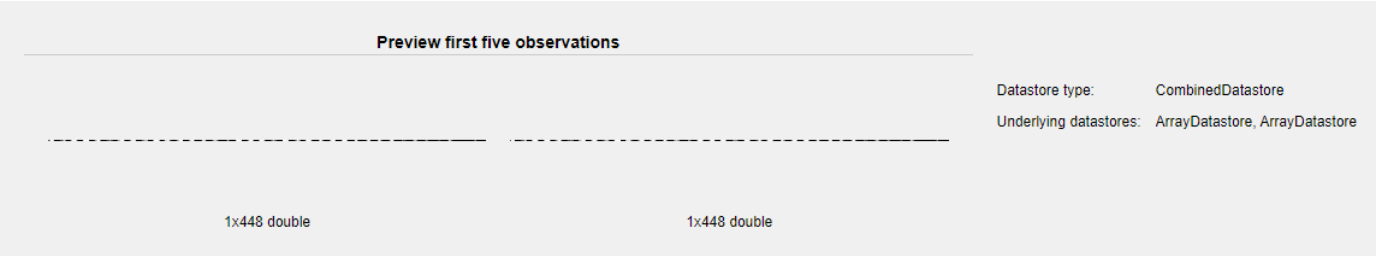


Import Data

To import the training datastore, select the **Data** tab and click **Import Data** > **Import Datastore**. Select `cdsTrain` as the training data and `None` as the validation data. Click **Import**.

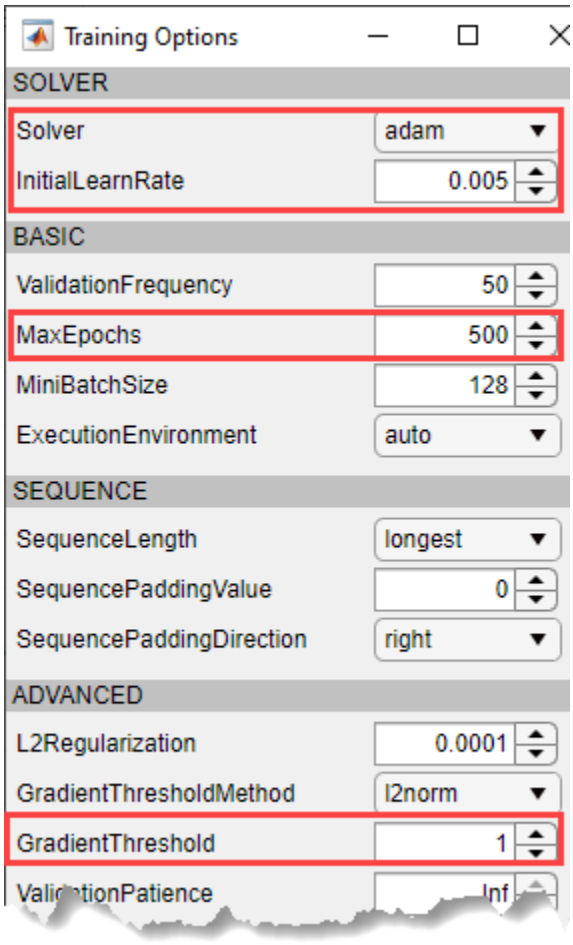


The data preview shows a single input time series and a single response time series, each with 448 time steps.



Specify Training Options

On the **Training** tab, click **Training Options**. Set **Solver** to `adam`, **InitialLearnRate** to `0.005`, and **MaxEpochs** to `500`. To prevent the gradients from exploding, set the **GradientThreshold** to `1`.

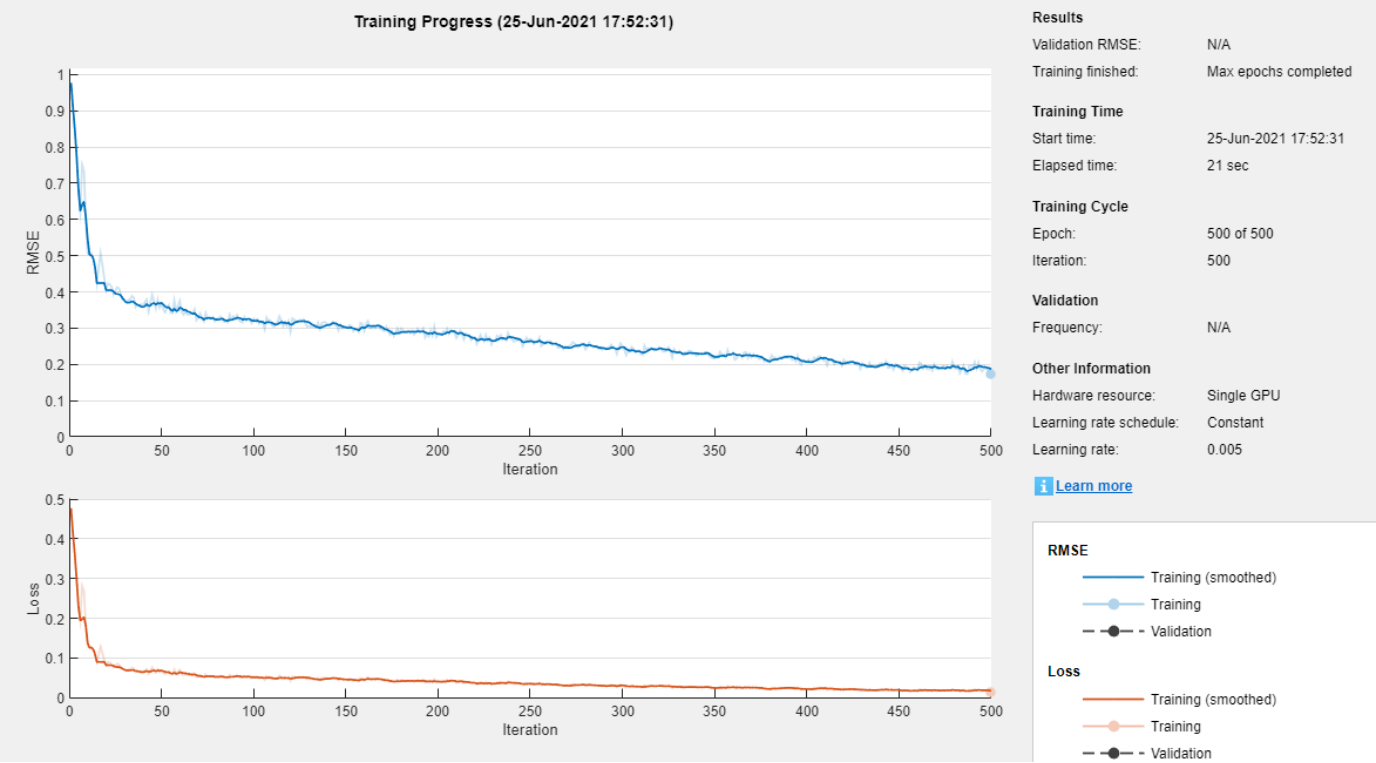


For more information about setting the training options, see `trainingOptions`.

Train Network

Click **Train**.

Deep Network Designer displays an animated plot showing the training progress. The plot shows mini-batch loss and accuracy, validation loss and accuracy, and additional information on the training progress.



Once training is complete, export the trained network by clicking **Export** in the **Training** tab. The trained network is saved as the `trainedNetwork_1` variable.

Forecast Future Time Steps

Test the trained network by forecasting multiple time steps in the future. Use the `predictAndUpdateState` function to predict time steps one at a time and update the network state at each prediction. For each prediction, use the previous prediction as input to the function.

Standardize the test data using the same parameters as the training data.

```
dataTestStandardized = (dataTest - mu) / sig;

XTest = dataTestStandardized(1:end-1);
YTest = dataTest(2:end);
```

To initialize the network state, first predict on the training data `XTrain`. Next, make the first prediction using the last time step of the training response `YTrain(end)`. Loop over the remaining predictions and input the previous prediction to `predictAndUpdateState`.

For large collections of data, long sequences, or large networks, predictions on the GPU are usually faster to compute than predictions on the CPU. Otherwise, predictions on the CPU are usually faster to compute. For single time step predictions, use the CPU. To use the CPU for prediction, set the `'ExecutionEnvironment'` option of `predictAndUpdateState` to `'cpu'`.

```
net = predictAndUpdateState(trainedNetwork_1,XTrain);

[net,YPred] = predictAndUpdateState(net,YTrain(end));
```

```
numTimeStepsTest = numel(XTest);
for i = 2:numTimeStepsTest
    [net,YPred(:,i)] = predictAndUpdateState(net,YPred(:,i-1),'ExecutionEnvironment','cpu');
end
```

Unstandardize the predictions using the parameters calculated earlier.

```
YPred = sig*YPred + mu;
```

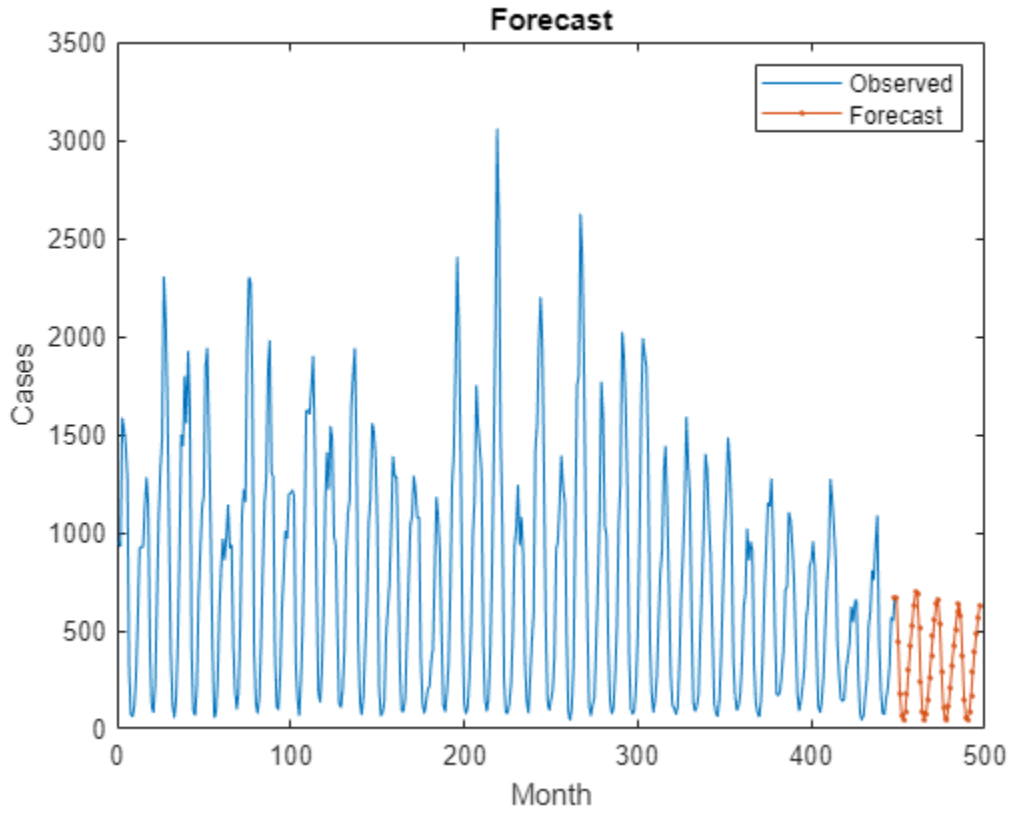
The training progress plot reports the root-mean-square error (RMSE) calculated from the standardized data. Calculate the RMSE from the unstandardized predictions.

```
rmse = sqrt(mean((YPred-YTest).^2))
```

```
rmse = single
    175.9693
```

Plot the training time series with the forecasted values.

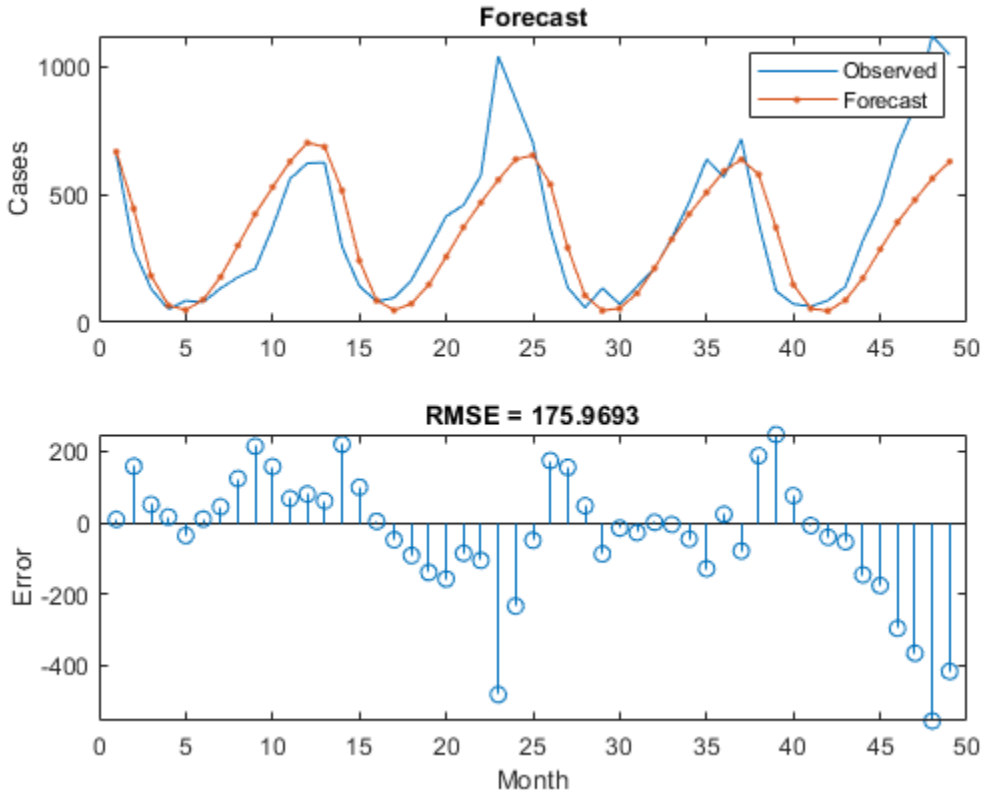
```
figure
plot(dataTrain(1:end-1))
hold on
idx = numTimeStepsTrain:(numTimeStepsTrain+numTimeStepsTest);
plot(idx,[data(numTimeStepsTrain) YPred],'.-')
hold off
xlabel("Month")
ylabel("Cases")
title("Forecast")
legend(["Observed" "Forecast"])
```



Compare the forecasted values with the test data.

```
figure
subplot(2,1,1)
plot(YTest)
hold on
plot(YPred,'.-')
hold off
legend(["Observed" "Forecast"])
ylabel("Cases")
title("Forecast")

subplot(2,1,2)
stem(YPred - YTest)
xlabel("Month")
ylabel("Error")
title("RMSE = " + rmse)
```



Update Network State with Observed Values

If you have access to the actual values of time steps between predictions, then you can update the network state with the observed values instead of the predicted values.

First, initialize the network state. To make predictions on a new sequence, reset the network state using `resetState`. Resetting the network state prevents previous predictions from affecting the predictions on the new data. Reset the network state, and then initialize the network state by predicting on the training data.

```
net = resetState(net);
net = predictAndUpdateState(net,XTrain);
```

Predict on each time step. For each prediction, predict the next time step using the observed value of the previous time step. Set the `'ExecutionEnvironment'` option of `predictAndUpdateState` to `'cpu'`.

```
YPred = [];
numTimeStepsTest = numel(XTest);
for i = 1:numTimeStepsTest
    [net,YPred(:,i)] = predictAndUpdateState(net,XTest(:,i),'ExecutionEnvironment','cpu');
end
```

Unstandardize the predictions using the parameters calculated earlier.

```
YPred = sig*YPred + mu;
```

Calculate the root-mean-square error (RMSE).

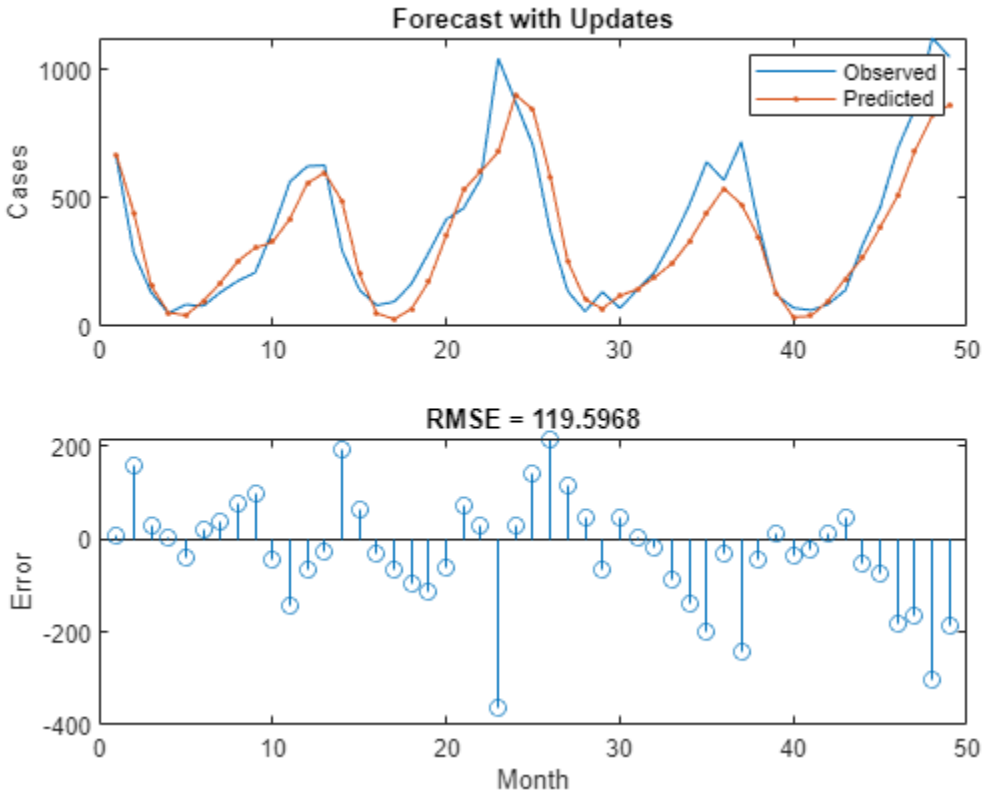
```
rmse = sqrt(mean((YPred-YTest).^2))
```

```
rmse = 119.5968
```

Compare the forecasted values with the test data.

```
figure
subplot(2,1,1)
plot(YTest)
hold on
plot(YPred,'.-')
hold off
legend(["Observed" "Predicted"])
ylabel("Cases")
title("Forecast with Updates")

subplot(2,1,2)
stem(YPred - YTest)
xlabel("Month")
ylabel("Error")
title("RMSE = " + rmse)
```



Here, the predictions are more accurate when updating the network state with the observed values instead of the predicted values.

- “Generate MATLAB Code from Deep Network Designer” on page 2-69
- “Deep Learning Tips and Tricks” on page 1-67

Generate MATLAB Code from Deep Network Designer

The Deep Network Designer app enables you to generate MATLAB code that recreates the building, editing, and training of a network in the app.

In the **Designer** tab, you can generate a live script to:

- Recreate the layers in your network. Select **Export > Generate Code**.
- Recreate the layers in your network, including any initial parameters. Select **Export > Generate Code with Initial Parameters**.

In the **Training** tab, you can generate a live script to:

- Recreate the building and training of a network you construct in Deep Network Designer. Select **Export > Generate Code for Training**.

Generate MATLAB Code to Recreate Network Layers

Generate MATLAB code for recreating the network constructed in Deep Network Designer. In the **Designer** tab, choose one of these options:

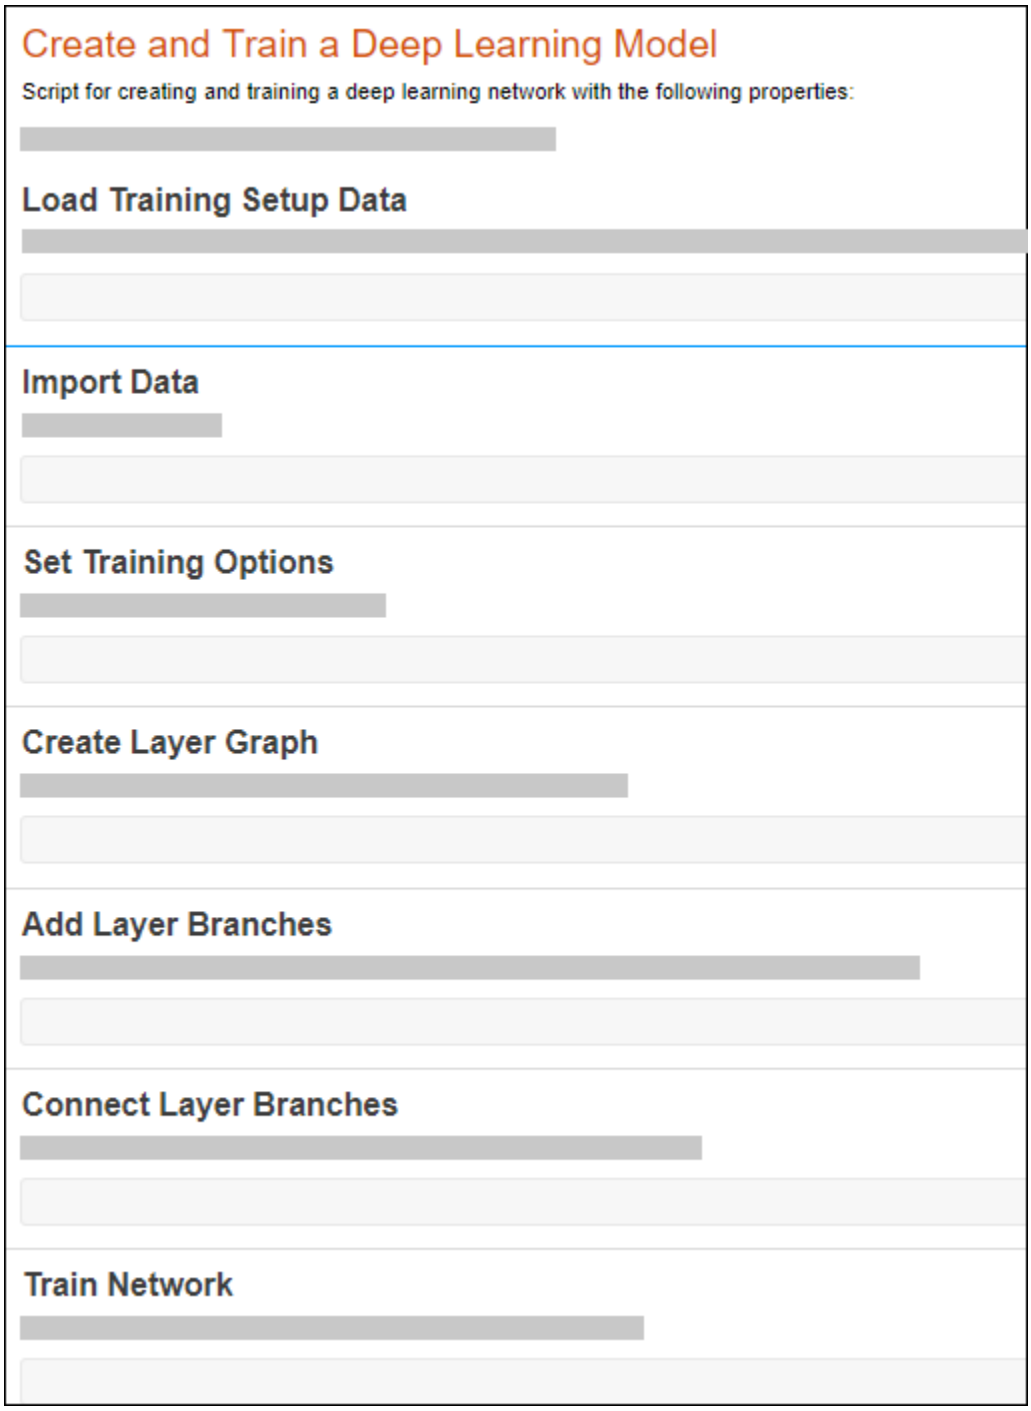
- To recreate the layers in your network, select **Export > Generate Code**. This network does not contain initial parameters, such as pretrained weights.
- To recreate the layers in your network, including any initial parameters, select **Export > Generate Code with Initial Parameters**. The app creates a live script and a MAT-file containing the initial parameters (weights and biases) from your network. Run the script to recreate the network layers, including the learnable parameters from the MAT-file. Use this option to preserve the weights if you want to perform transfer learning.

Running the generated script returns the network architecture as a variable in the workspace. Depending on the network architecture, the variable is a layer graph named `lgraph` or a layer array named `layers`. For an example of training a network exported from Deep Network Designer, see “Create Simple Sequence Classification Network Using Deep Network Designer” on page 2-51.

Generate MATLAB Code to Train Network

To recreate the construction and training of a network in Deep Network Designer, generate MATLAB code after training. For an example of using Deep Network Designer to train an image classification network, see “Transfer Learning with Deep Network Designer” on page 2-2.

Once training is complete, on the **Training** tab, select **Export > Generate Code for Training**. The app creates a live script and a MAT-file containing the initial parameters (weights and biases) from your network. If you import data from the workspace into Deep Network Designer then this is also contained in the generated MAT-file.



Running the generated script builds the network (including the learnable parameters from the MAT-file), imports the data, sets the training options, and trains the network. Examine the generated script to learn how to construct and train a network at the command line.

Note If you change the network, training and validation data, or training options, click **Train** before generating the live script.

You can also use the generated script as a starting point to create deep learning experiments which sweep through a range of hyperparameter values or use Bayesian optimization to find optimal training options. For an example showing how to use **Experiment Manager** to tune the hyperparameters of a network trained in Deep Network Designer, see “Adapt Code Generated in Deep Network Designer for Use in Experiment Manager” on page 2-79.

Use Network for Prediction

Suppose that the trained network is contained in the variable `net`. To use the trained network for prediction, use the `predict` function. For example, suppose you have a trained image classification network. Use the exported network to predict the class of `peppers.png`.

```
img = imread("peppers.png");
img = imresize(img, net.Layers(1).InputSize(1:2));
label = predict(net, img);
imshow(img);
title(label);
```

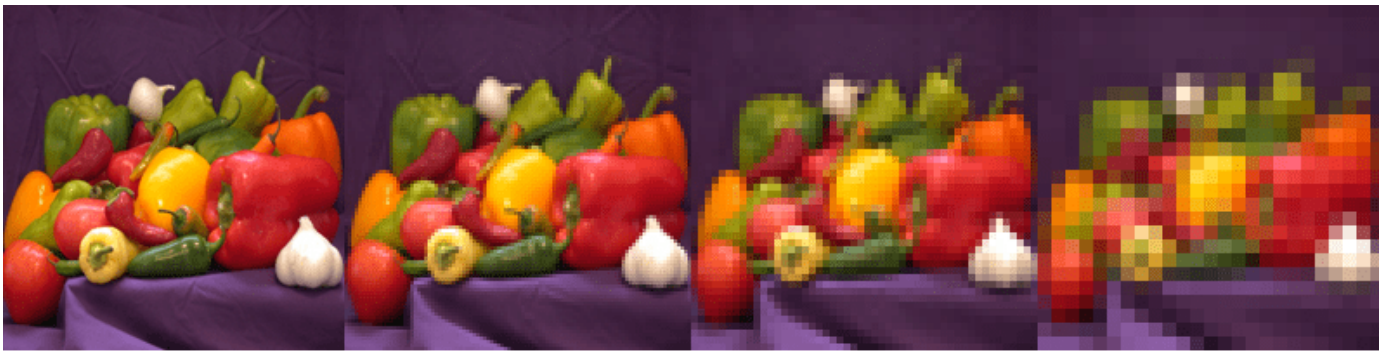
Image-to-Image Regression in Deep Network Designer

This example shows how to use Deep Network Designer to construct and train an image-to-image regression network for super resolution.

Spatial resolution is the number of pixels used to construct a digital image. An image with a high spatial resolution is composed of a greater number of pixels and as a result the image contains greater detail. Super resolution is the process of taking as input a low resolution image and upscaling it into a higher resolution image. When you work with image data, you might reduce the spatial resolution to decrease the size of the data, at the cost of losing information. To recover this lost information, you can train a deep learning network to predict the missing details of an image. In this example, you recover 28-by-28 pixel images from images that were compressed to 7-by-7 pixels.



Load Data

This example uses the digits data set, which consists of 10,000 synthetic grayscale images of handwritten digits. Each image is 28-by-28-by-1 pixels.

Load the data and create an image datastore.

```
dataFolder = fullfile(toolboxdir('nnet'),'nndemos','nndatasets','DigitDataset');

imds = imageDatastore(dataFolder, ...
    'IncludeSubfolders',true, ....
    'LabelSource','foldernames');
```

Use the `shuffle` function to shuffle the data prior to training.

```
imds = shuffle(imds);
```

Use the `splitEachLabel` function to divide the image datastore into three image datastores containing images for training, validation, and testing.

```
[imdsTrain,imdsVal,imdsTest] = splitEachLabel(imds,0.7,0.15,0.15,'randomized');
```

Normalize the data in each image to the range [0,1]. Normalization helps stabilize and speed up network training using gradient descent. If your data is poorly scaled, then the loss can become NaN and the network parameters can diverge during training.

```
imdsTrain = transform(imdsTrain,@(x) rescale(x));
imdsVal = transform(imdsVal,@(x) rescale(x));
imdsTest = transform(imdsTest,@(x) rescale(x));
```

Generate Training Data

Create a training data set by generating pairs of images consisting of upsampled low resolution images and the corresponding high resolution images.

To train a network to perform image-to-image regression, the images need to be pairs consisting of an input and a response where both images are the same size. Generate the training data by downsampling each image to 7-by-7 pixels and then upsampling to 28-by-28 pixels. Using the pairs of transformed and original images, the network can learn how to map between the two different resolutions.

Generate the input data using the helper function `upsampLowRes`, which uses `imresize` to produce lower resolution images.

```
imdsInputTrain = transform(imdsTrain,@upsampLowRes);
imdsInputVal= transform(imdsVal,@upsampLowRes);
imdsInputTest = transform(imdsTest,@upsampLowRes);
```

Use the `combine` function to combine the low and high resolution images into a single datastore. The output of the `combine` function is a `CombinedDatastore` object.

```
dsTrain = combine(imdsInputTrain,imdsTrain);
dsVal = combine(imdsInputVal,imdsVal);
dsTest = combine(imdsInputTest,imdsTest);
```

Create Network Architecture

Create the network architecture using the `unetLayers` function from Computer Vision Toolbox™. This function provides a network suitable for semantic segmentation that can be easily adapted for image-to-image regression.

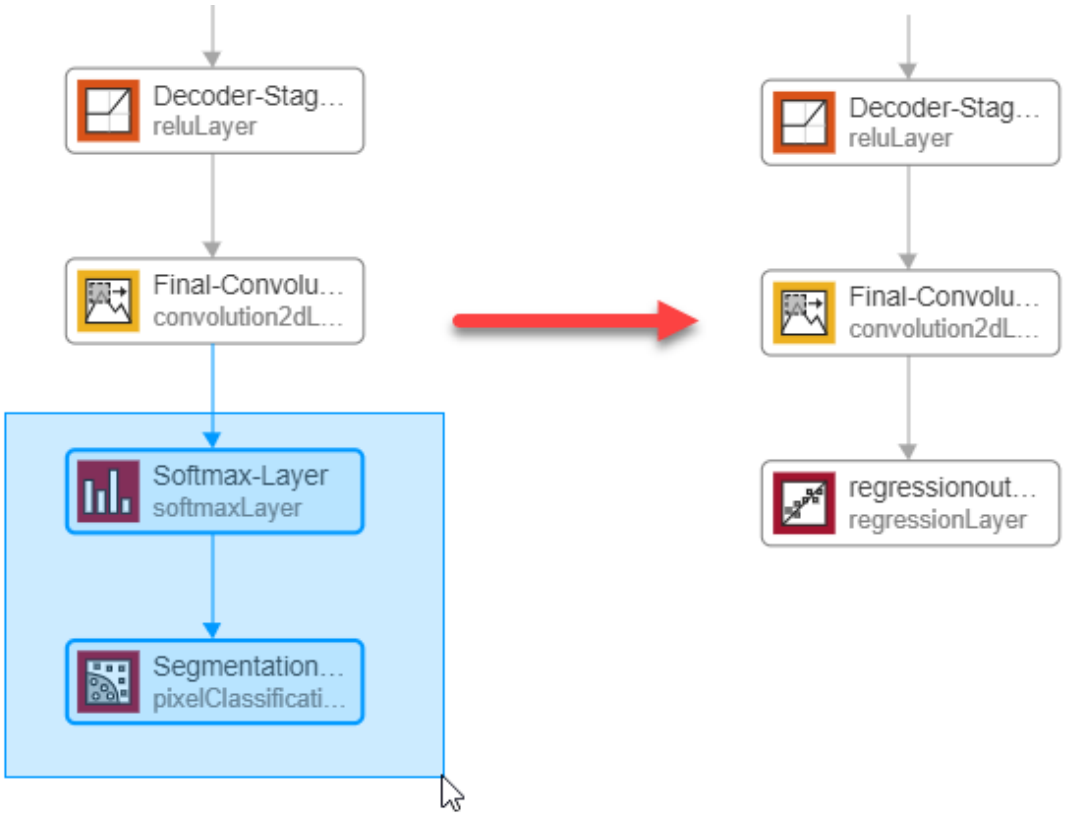
Create a network with input size 28-by-28-by-1 pixels.

```
layers = unetLayers([28,28,1],2,'encoderDepth',2);
```

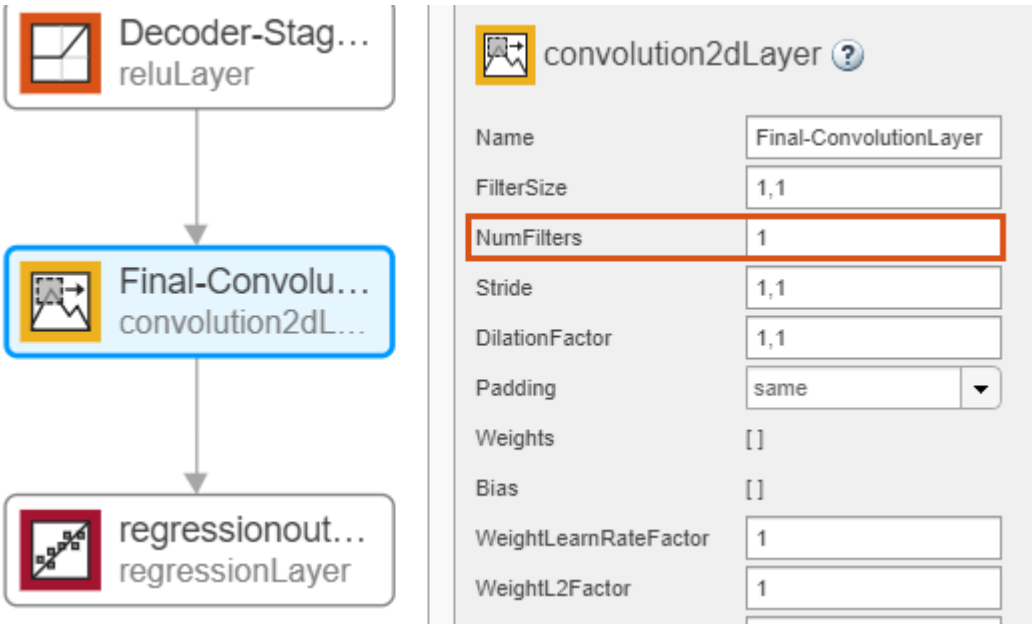
Edit the network for image-to-image regression using Deep Network Designer.

```
deepNetworkDesigner(layers);
```

In the **Designer** pane, replace the softmax and pixel classification layers with a regression layer from the **Layer Library**.



Select the final convolutional layer and set the `NumFilters` property to `1`.

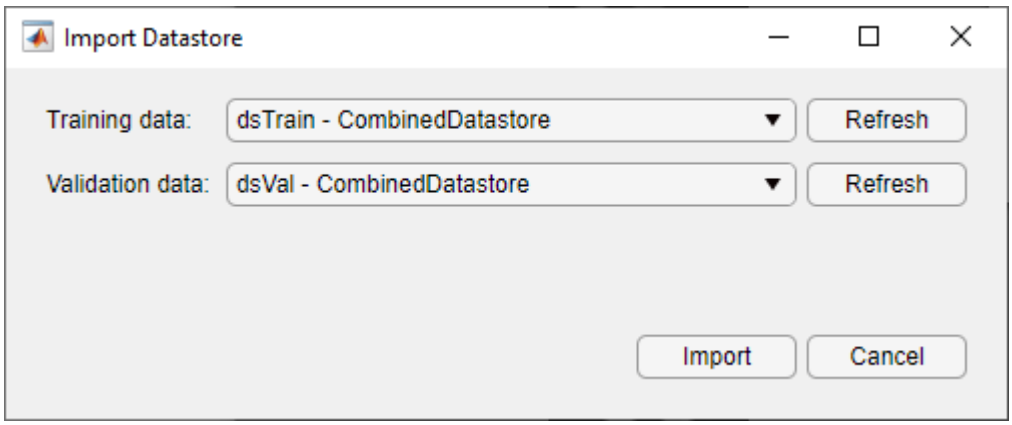


The network is now ready for training.

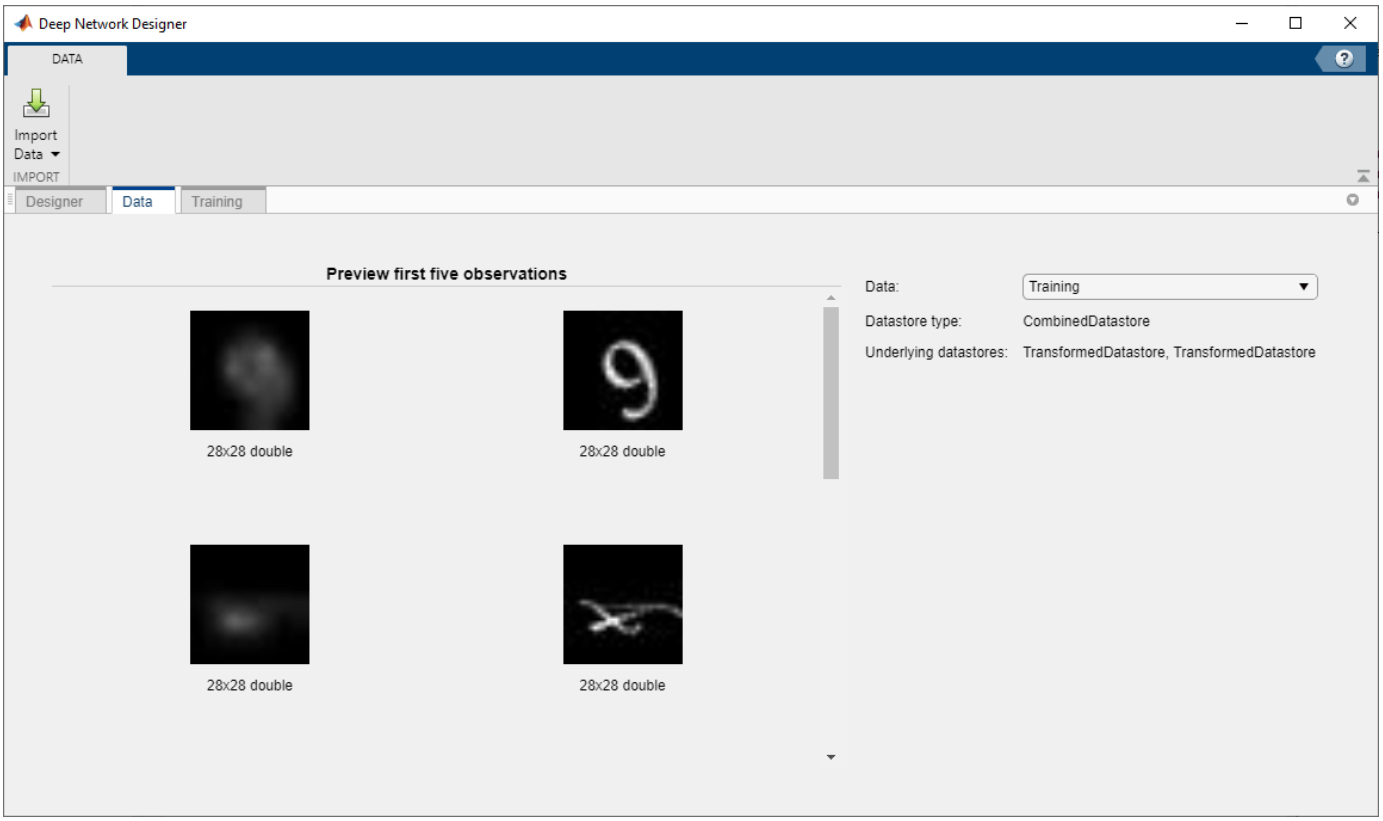
Import Data

Import the training and validation data into Deep Network Designer.

In the **Data** tab, click **Import Data** > **Import Datastore** and select `dsTrain` as the training data and `dsVal` as the validation data. Import both datastores by clicking **Import**.



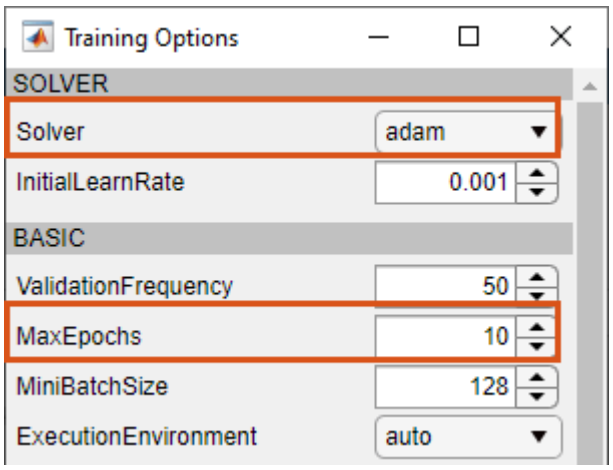
Deep Network Designer displays the pairs of images in the combined datastore. The upscaled low resolution input images are on the left, and the original high resolution response images are on the right. The network learns how to map between the input and the response images.



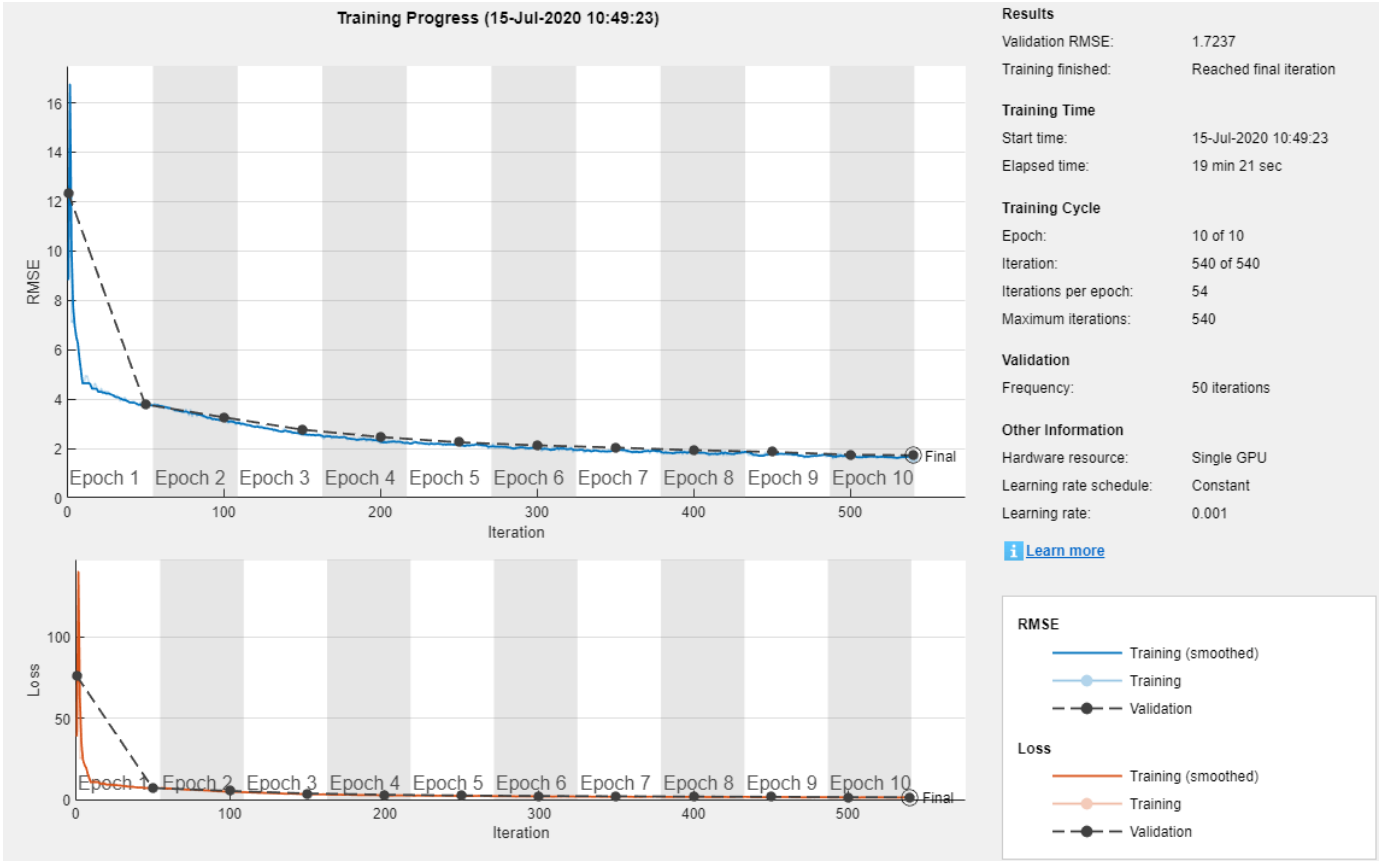
Train Network

Select the training options and train the network.

In the **Training** tab, select **Training Options**. From the **Solver** list, select `adam`. Set **MaxEpochs** to `10`. Confirm the training options by clicking **Close**.



Train the network on the combined datastore by clicking **Train**.



As the network learns how to map between the two images the validation root mean squared error (RMSE) decreases.

Once training is complete, click **Export** to export the trained network to the workspace. The trained network is stored in the variable `trainedNetwork_1`.

Test Network

Evaluate the performance of the network using the test data.

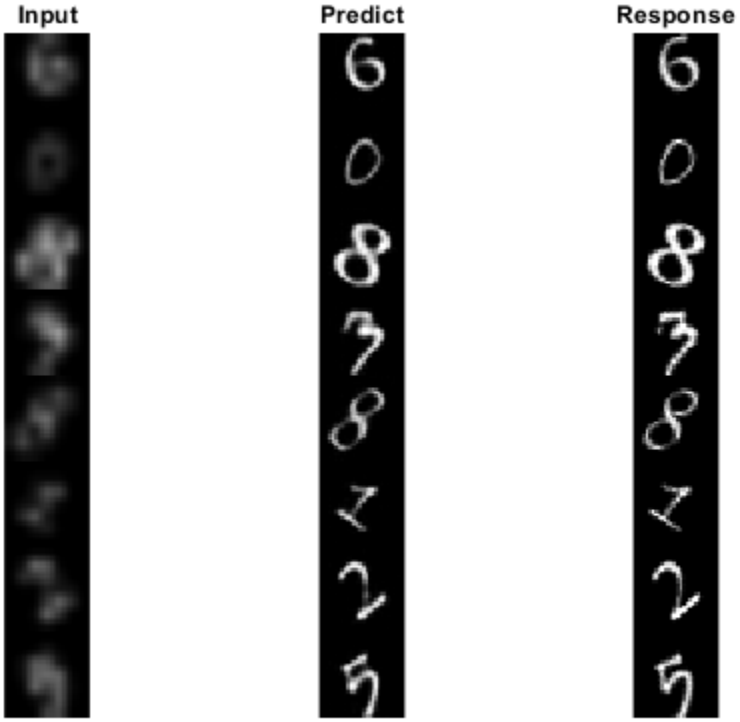
Using `predict`, you can test if the network can produce a high resolution image from a low resolution input image that was not included in the training set.

```
ypred = predict(trainedNetwork_1,dsTest);

for i = 1:8
    I(1:2,i) = read(dsTest);
    I(3,i) = {ypred(:,:,:,i)};
end
```

Compare the input, predicted, and response images.

```
subplot(1,3,1)
imshow(imtile(I(1,:),'GridSize',[8,1]))
title('Input')
subplot(1,3,2)
imshow(imtile(I(3,:),'GridSize',[8,1]))
title('Predict')
subplot(1,3,3)
imshow(imtile(I(2,:),'GridSize',[8,1]))
title('Response')
```



The network successfully produces high resolution images from low resolution inputs.

The network in this example is very simple and highly tailored to the digits data set. For an example showing how to create a more complex image-to-image regression network for everyday images, see “Single Image Super-Resolution Using Deep Learning” on page 9-8.

Supporting Functions

```
function dataOut = upsampLowRes(dataIn)
        temp = dataIn;
        temp = imresize(temp,[7,7],'method','bilinear');
        dataOut = {imresize(temp,[28,28],'method','bilinear')};
end
```

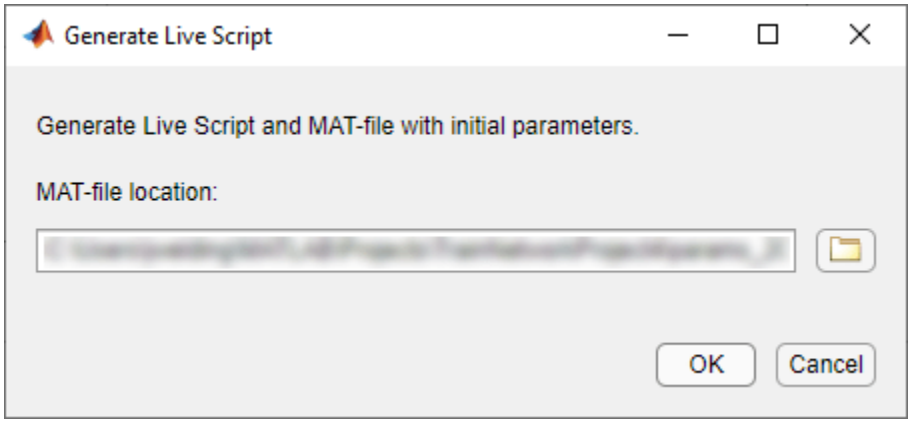
Adapt Code Generated in Deep Network Designer for Use in Experiment Manager

This example shows how to use Experiment Manager to tune the hyperparameters of a network trained in Deep Network Designer.

You can use Deep Network Designer to create a network, import data, and train the network. You can then use Experiment Manager to sweep through a range of hyperparameter values to find optimal training options.

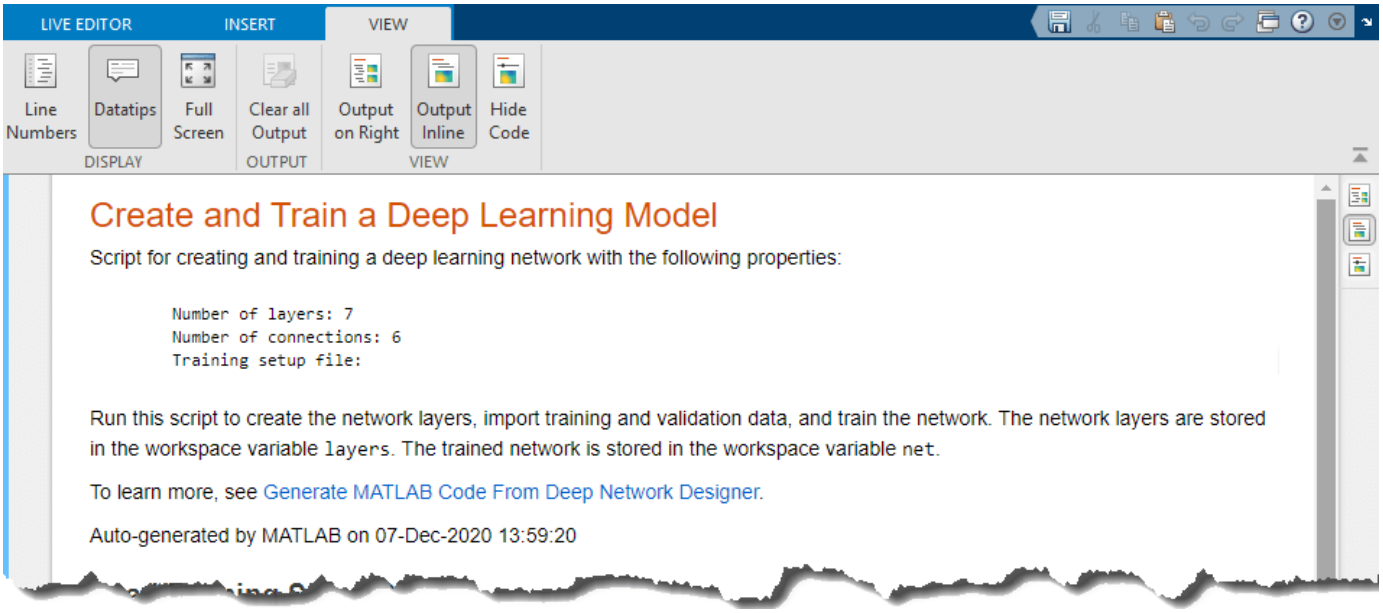
Generate Training Script

To generate a live script to recreate the building and training of a network you construct in Deep Network Designer, on the **Training** tab, select **Export > Generate Code for Training**. Select a MAT file location and click **OK**. For an example showing how to train a classification network in Deep Network Designer, see “Create Simple Image Classification Network Using Deep Network Designer”.



Deep Network Designer creates a live script and a MAT file containing the initial parameters (weights and biases) from your network. If you import data from the workspace into Deep Network Designer, then the generated MAT file contains the data as well.

Running the generated script builds the network (including the learnable parameters from the MAT file), imports the data, sets the training options, and trains the network.



Open Experiment Manager

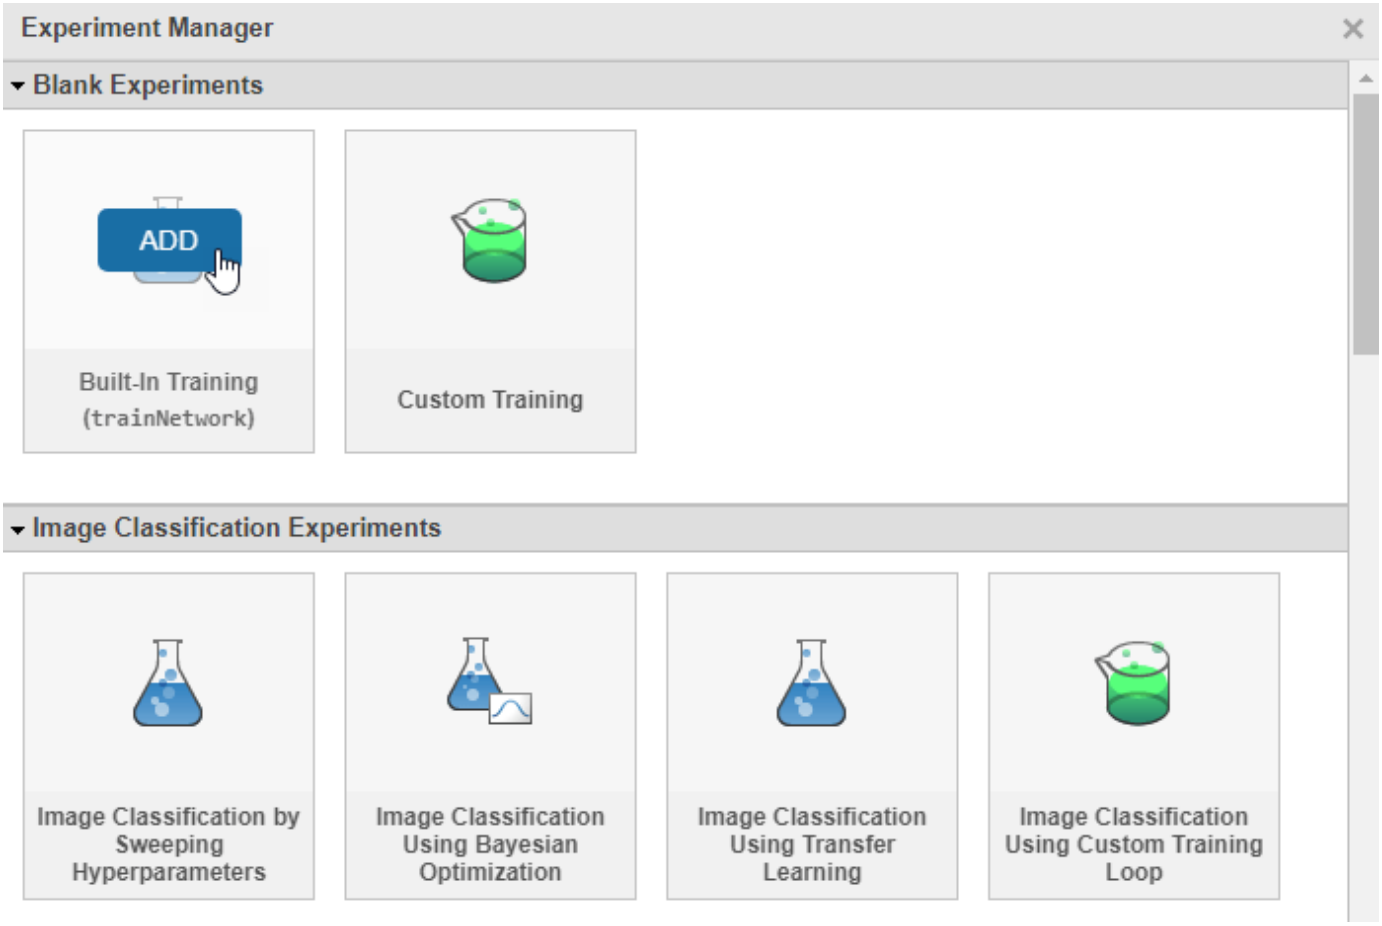
Experiment Manager enables you to create deep learning experiments to train networks under various initial conditions and compare the results. You can use Experiment Manager to tune a network you initially train in Deep Network Designer.

Open Experiment Manager.

```
experimentManager
```

Pause on **Project** and click **Create**. Experiment Manager provides several templates that support many deep learning workflows, including image classification, image regression, sequence classification, semantic segmentation, and custom training loops.

Pause on **Built-In Training** and click **ADD**.



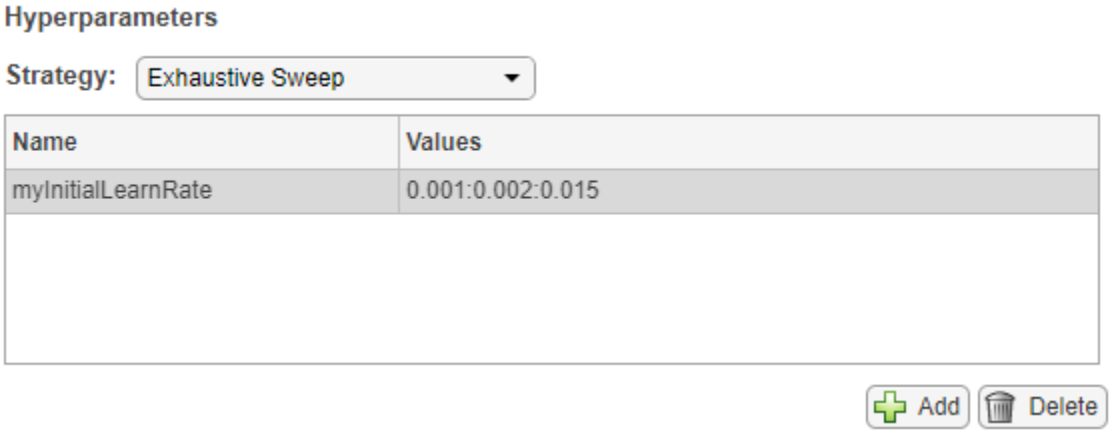
Specify the name and location for the new project and click **Save**. Experiment Manager opens a new experiment in the project. The **Experiment** pane displays the description, hyperparameters, setup function, and metrics that define the experiment.

Add Hyperparameters

In the hyperparameter table, specify the values of the hyperparameters to use in the experiment. When you run the experiment, Experiment Manager trains the network using every combination of the hyperparameter values specified in the table. For this example, sweep over the initial learning rate.

Under **Hyperparameters**, click **Add** to add a new hyperparameter to sweep over.

Add the hyperparameter `myInitialLearnRate`. Set the hyperparameter to sweep the sequence of values `0.001:0.002:0.015`.



Create Setup Function Using Generated Script

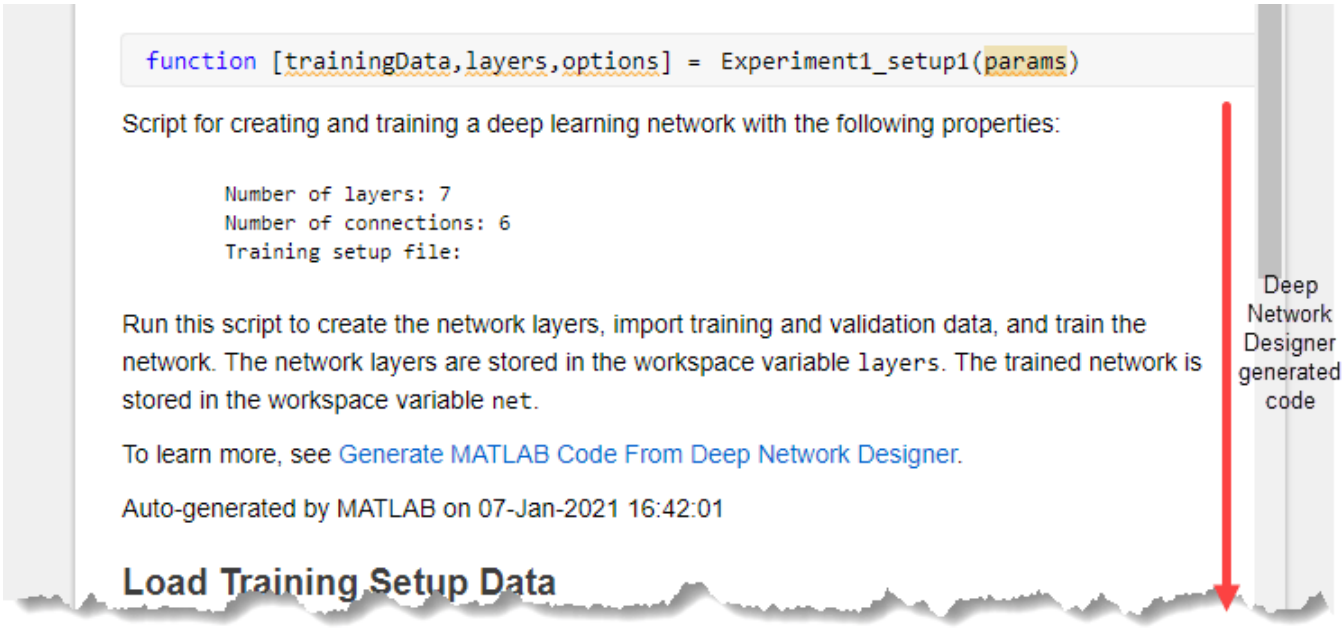
When you create an experiment, Experiment Manager creates a setup function template. To edit this function, under **Setup Function**, click **Edit**.

The empty setup function `Experiment1_setup1` opens in MATLAB Editor. Experiment Manager uses the outputs of this function to call the `trainNetwork` function.

```
function [trainingData,layers,options] = Experiment1_setup1(params)
end
```

The setup function is where you specify the training data, network architecture, and training options for the experiment.

Copy and paste the live script generated by Deep Network Designer inside the setup function.



Adapt Setup Function Input Arguments

Adapt the script for use in Experiment Manager by changing the function input arguments to match the variable names in the generated script. The input arguments to `Experiment1_setup1` must match those the generated script uses in the call to `trainNetwork`.

In the script generated by Deep Network Designer, find the variable names of the data, network, and training options at the bottom of the generated live script in the call to `trainNetwork`. Change the setup function input arguments to match. For example, if your generated live script calls `trainNetwork` with data `imdsTrain`, network `lgraph`, and training options `opts`, then you must make the following changes in the experiment setup function input arguments:

- Change `trainingData` to `imdsTrain`.
- Change `layers` to `lgraph`.
- Change `options` to `opts`.

```
function [trainingData,layers,options] = Experiment1_setup1(params)
```

```
function [imdsTrain,lgraph,opts] = Experiment1_setup1(params)
```

You can check to see if your input arguments need changing by looking for the yellow underline in the setup function input arguments.

Adapt Training Options

Change the training options so that Experiment Manager conducts a hyperparameter sweep of the learning rate.

- Set the initial learning rate to `params.myInitialLearnRate`.

- Optionally, hide the output information by adding the additional name-value argument `"Verbose",false`.

```
opts = trainingOptions("sgdm",...
    "ExecutionEnvironment","auto",...
    "InitialLearnRate",params.myInitialLearnRate,...
    "MaxEpochs",5,...
    "Shuffle","every-epoch",...
    "Plots","training-progress",...
    "ValidationData",augimdsValidation, ...
    "Verbose",false);
```

Remove Call to `trainNetwork`

Experiment Manager uses the outputs of the setup function to call the `trainNetwork` function. Remove the call to `trainNetwork` from the copied and pasted generated code.

The setup function is now ready. Click **Save** to save your edited setup function.

Run Experiment

In Experiment Manager, run the experiment by clicking **Run**. When you run the experiment, Experiment Manager trains the network defined by the setup function. Each trial uses one of the learning rates specified in the hyperparameter table.

While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial.

A table of results displays the accuracy and loss for each trial. When the experiment finishes, you can sort the trials by the accuracy or loss metrics to see which trial performs the best. In this experiment, Trial 6, with an initial learning rate of 0.0110, has the highest validation accuracy.

Trial	Status	Progress	Elapsed Time	myInitialLearnRate	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss
6	Complete	100.0%	0 hr 3 min 39 sec	0.0110	100.0000	0.0200	99.3500	0.0429
8	Complete	100.0%	0 hr 3 min 33 sec	0.0150	100.0000	0.0191	99.3000	0.0418
7	Complete	100.0%	0 hr 3 min 37 sec	0.0130	100.0000	0.0197	99.2500	0.0418
5	Complete	100.0%	0 hr 3 min 19 sec	0.0090	100.0000	0.0255	99.2000	0.0488
4	Complete	100.0%	0 hr 2 min 55 sec	0.0070	100.0000	0.0354	98.9500	0.0594
3	Complete	100.0%	0 hr 2 min 57 sec	0.0050	100.0000	0.0566	98.7500	0.0794
2	Complete	100.0%	0 hr 2 min 49 sec	0.0030	98.4375	0.1081	98.1500	0.1243
1	Complete	100.0%	0 hr 2 min 50 sec	0.0010	92.1875	0.3411	94.4000	0.3220

To close the experiment, in the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Deep Learning with Images

Classify Webcam Images Using Deep Learning

This example shows how to classify images from a webcam in real time using the pretrained deep convolutional neural network GoogLeNet.

Use MATLAB®, a simple webcam, and a deep neural network to identify objects in your surroundings. This example uses GoogLeNet, a pretrained deep convolutional neural network (CNN or ConvNet) that has been trained on over a million images and can classify images into 1000 object categories (such as keyboard, coffee mug, pencil, and many animals). You can download GoogLeNet and use MATLAB to continuously process the camera images in real time.

GoogLeNet has learned rich feature representations for a wide range of images. It takes the image as input and provides a label for the object in the image and the probabilities for each of the object categories. You can experiment with objects in your surroundings to see how accurately GoogLeNet classifies images. To learn more about the network's object classification, you can show the scores for the top five classes in real time, instead of just the final class decision.

Load Camera and Pretrained Network

Connect to the camera and load a pretrained GoogLeNet network. You can use any pretrained network at this step. The example requires MATLAB Support Package for USB Webcams, and Deep Learning Toolbox™ Model *for GoogLeNet Network*. If you do not have the required support packages installed, then the software provides a download link.

```
camera = webcam;
net = googlenet;
```

If you want to run the example again, first run the command `clear camera` where `camera` is the connection to the webcam. Otherwise, you see an error because you cannot create another connection to the same webcam.

Classify Snapshot from Camera

To classify an image, you must resize it to the input size of the network. Get the first two elements of the `InputSize` property of the image input layer of the network. The image input layer is the first layer of the network.

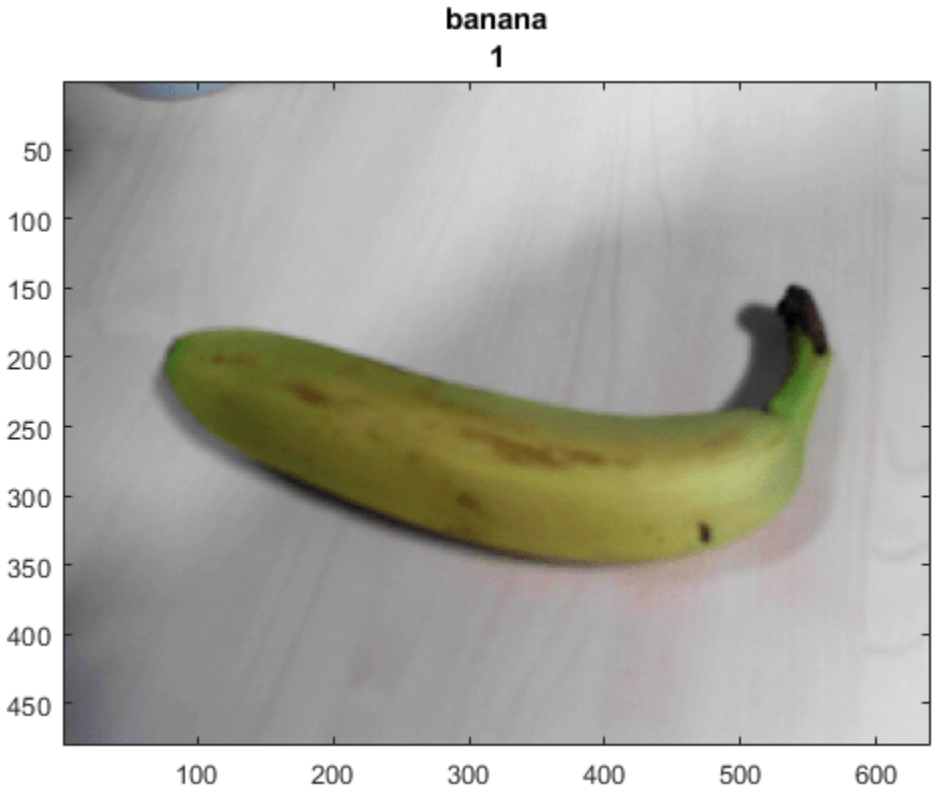
```
inputSize = net.Layers(1).InputSize(1:2)
```

```
inputSize =

   224   224
```

Display the image from the camera with the predicted label and its probability. You must resize the image to the input size of the network before calling `classify`.

```
figure
im = snapshot(camera);
image(im)
im = imresize(im,inputSize);
[label,score] = classify(net,im);
title({char(label),num2str(max(score),2)});
```



Continuously Classify Images from Camera

To classify images from the camera continuously, include the previous steps inside a loop. Run the loop while the figure is open. To stop the live prediction, simply close the figure. Use `drawnow` at the end of each iteration to update the figure.

```
h = figure;

while ishandle(h)
    im = snapshot(camera);
    image(im)
    im = imresize(im,inputSize);
    [label,score] = classify(net,im);
    title({char(label), num2str(max(score),2)});
    drawnow
end
```

Display Top Predictions

The predicted classes can change rapidly. Therefore, it can be helpful to display the top predictions together. You can display the top five predictions and their probabilities by plotting the classes with the highest prediction scores.

Classify a snapshot from the camera. Display the image from the camera with the predicted label and its probability. Display a histogram of the probabilities of the top five predictions by using the `score` output of the `classify` function.

Create the figure window. First, resize the window to have twice the width, and create two subplots.

```
h = figure;
h.Position(3) = 2*h.Position(3);
ax1 = subplot(1,2,1);
ax2 = subplot(1,2,2);
```

In the left subplot, display the image and classification together.

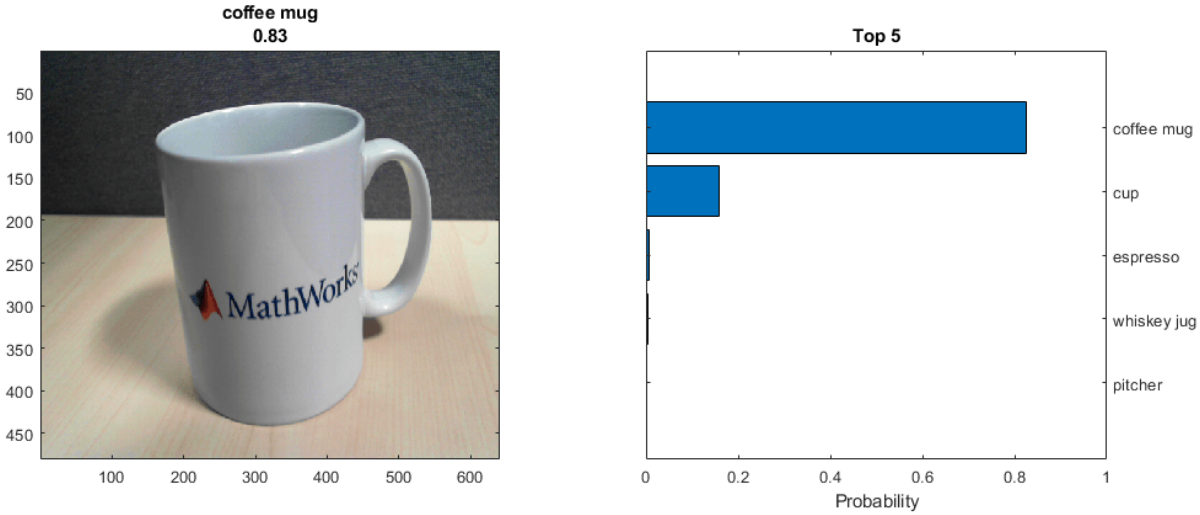
```
im = snapshot(camera);
image(ax1,im)
im = imresize(im,inputSize);
[label,score] = classify(net,im);
title(ax1,{char(label),num2str(max(score),2)});
```

Select the top five predictions by selecting the classes with the highest scores.

```
[~,idx] = sort(score,'descend');
idx = idx(5:-1:1);
classes = net.Layers(end).Classes;
classNamesTop = string(classes(idx));
scoreTop = score(idx);
```

Display the top five predictions as a histogram.

```
barh(ax2,scoreTop)
xlim(ax2,[0 1])
title(ax2,'Top 5')
xlabel(ax2,'Probability')
yticklabels(ax2,classNamesTop)
ax2.YAxisLocation = 'right';
```



Continuously Classify Images and Display Top Predictions

To classify images from the camera continuously and display the top predictions, include the previous steps inside a loop. Run the loop while the figure is open. To stop the live prediction, simply close the figure. Use `drawnow` at the end of each iteration to update the figure.

Create the figure window. First resize the window, to have twice the width, and create two subplots. To prevent the axes from resizing, set `PositionConstraint` property to `'innerposition'`.

```
h = figure;
h.Position(3) = 2*h.Position(3);
ax1 = subplot(1,2,1);
ax2 = subplot(1,2,2);
ax2.PositionConstraint = 'innerposition';
```

Continuously display and classify images together with a histogram of the top five predictions.

```
while ishandle(h)
    % Display and classify the image
    im = snapshot(camera);
    image(ax1,im)
    im = imresize(im,inputSize);
    [label,score] = classify(net,im);
    title(ax1,{char(label),num2str(max(score),2)});

    % Select the top five predictions
    [~,idx] = sort(score,'descend');
    idx = idx(5:-1:1);
    scoreTop = score(idx);
    classNamesTop = string(classes(idx));

    % Plot the histogram
    barh(ax2,scoreTop)
    title(ax2,'Top 5')
    xlabel(ax2,'Probability')
    xlim(ax2,[0 1])
    yticklabels(ax2,classNamesTop)
    ax2.YAxisLocation = 'right';

    drawnow
end
```

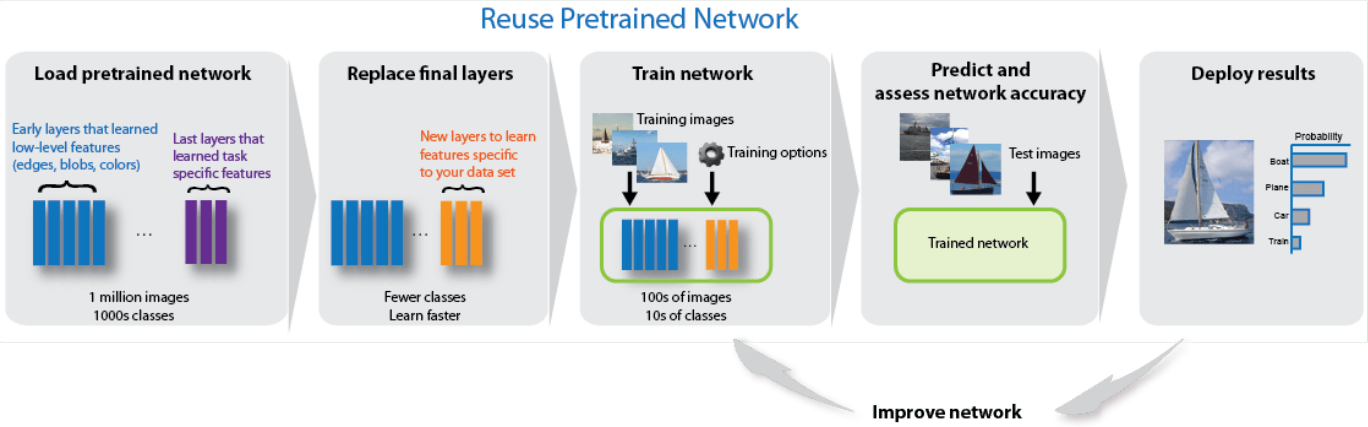
Train Deep Learning Network to Classify New Images

This example shows how to use transfer learning to retrain a convolutional neural network to classify a new set of images.

Pretrained image classification networks have been trained on over a million images and can classify images into 1000 object categories, such as keyboard, coffee mug, pencil, and many animals. The networks have learned rich feature representations for a wide range of images. The network takes an image as input, and then outputs a label for the object in the image together with the probabilities for each of the object categories.

Transfer learning is commonly used in deep learning applications. You can take a pretrained network and use it as a starting point to learn a new task. Fine-tuning a network with transfer learning is usually much faster and easier than training a network from scratch with randomly initialized weights. You can quickly transfer learned features to a new task using a smaller number of training images.



Load Data

Unzip and load the new images as an image datastore. This very small data set contains only 75 images. Divide the data into training and validation data sets. Use 70% of the images for training and 30% for validation.

```
unzip('MerchData.zip');
imds = imageDatastore('MerchData', ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.7);
```

Load Pretrained Network

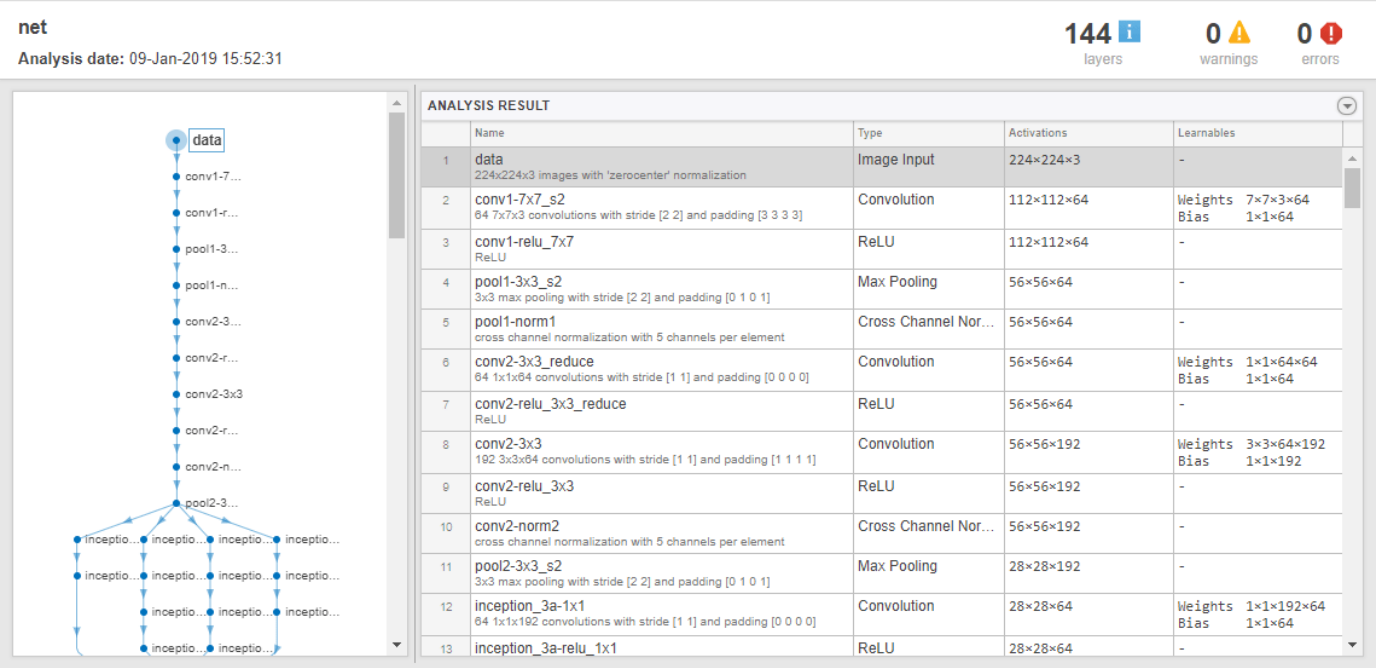
Load a pretrained GoogLeNet network. If the Deep Learning Toolbox™ Model *for GoogLeNet Network* support package is not installed, then the software provides a download link.

To try a different pretrained network, open this example in MATLAB® and select a different network. For example, you can try `squeezenet`, a network that is even faster than `googlenet`. You can run this example with other pretrained networks. For a list of all available networks, see “Load Pretrained Networks” on page 1-10.

```
net = googlenet;
```

Use `analyzeNetwork` to display an interactive visualization of the network architecture and detailed information about the network layers.

```
analyzeNetwork(net)
```



The first element of the `Layers` property of the network is the image input layer. For a GoogLeNet network, this layer requires input images of size 224-by-224-by-3, where 3 is the number of color channels. Other networks can require input images with different sizes. For example, the Xception network requires images of size 299-by-299-by-3.

```
net.Layers(1)
```

```
ans =
  ImageInputLayer with properties:

                     Name: 'data'
                InputSize: [224 224 3]

   Hyperparameters
          DataAugmentation: 'none'
             Normalization: 'zerocenter'
    NormalizationDimension: 'auto'
                     Mean: [224×224×3 single]
```

```
inputSize = net.Layers(1).InputSize;
```

Replace Final Layers

The convolutional layers of the network extract image features that the last learnable layer and the final classification layer use to classify the input image. These two layers, `'loss3-classifier'` and `'output'` in GoogLeNet, contain information on how to combine the features that the network extracts into class probabilities, a loss value, and predicted labels. To retrain a pretrained network to classify new images, replace these two layers with new layers adapted to the new data set.

Convert the trained network to a layer graph.

```
lgraph = layerGraph(net);
```

Find the names of the two layers to replace. You can do this manually or you can use the supporting function findLayersToReplace to find these layers automatically.

```
[learnableLayer,classLayer] = findLayersToReplace(lgraph);
[learnableLayer,classLayer]
```

```
ans =
  1×2 Layer array with layers:

     1   'loss3-classifier'   Fully Connected         1000 fully connected layer
     2   'output'             Classification Output   crossentropyex with 'tench' and 999 other c
```

In most networks, the last layer with learnable weights is a fully connected layer. Replace this fully connected layer with a new fully connected layer with the number of outputs equal to the number of classes in the new data set (5, in this example). In some networks, such as SqueezeNet, the last learnable layer is a 1-by-1 convolutional layer instead. In this case, replace the convolutional layer with a new convolutional layer with the number of filters equal to the number of classes. To learn faster in the new layer than in the transferred layers, increase the learning rate factors of the layer.

```
numClasses = numel(categories(imdsTrain.Labels));

if isa(learnableLayer,'nnet.cnn.layer.FullyConnectedLayer')
    newLearnableLayer = fullyConnectedLayer(numClasses, ...
        'Name','new_fc', ...
        'WeightLearnRateFactor',10, ...
        'BiasLearnRateFactor',10);

elseif isa(learnableLayer,'nnet.cnn.layer.Convolution2DLayer')
    newLearnableLayer = convolution2dLayer(1,numClasses, ...
        'Name','new_conv', ...
        'WeightLearnRateFactor',10, ...
        'BiasLearnRateFactor',10);
end

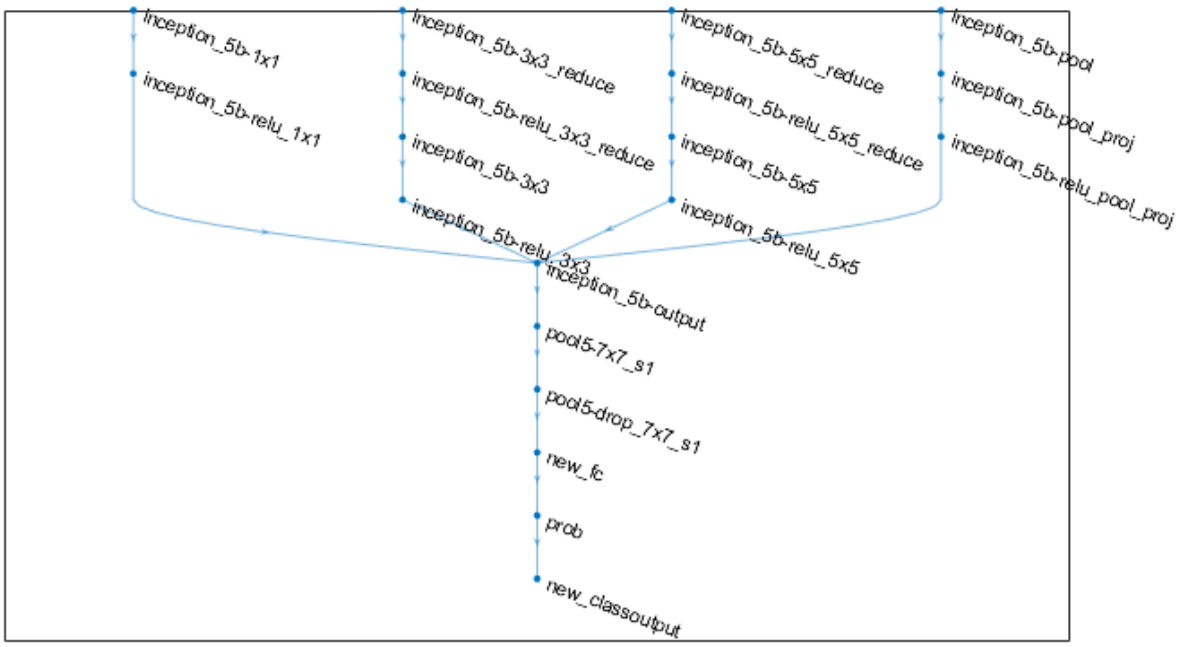
lgraph = replaceLayer(lgraph,learnableLayer.Name,newLearnableLayer);
```

The classification layer specifies the output classes of the network. Replace the classification layer with a new one without class labels. `trainNetwork` automatically sets the output classes of the layer at training time.

```
newClassLayer = classificationLayer('Name','new_classoutput');
lgraph = replaceLayer(lgraph,classLayer.Name,newClassLayer);
```

To check that the new layers are connected correctly, plot the new layer graph and zoom in on the last layers of the network.

```
figure('Units','normalized','Position',[0.3 0.3 0.4 0.4]);
plot(lgraph)
ylim([0,10])
```



Freeze Initial Layers

The network is now ready to be retrained on the new set of images. Optionally, you can "freeze" the weights of earlier layers in the network by setting the learning rates in those layers to zero. During training, `trainNetwork` does not update the parameters of the frozen layers. Because the gradients of the frozen layers do not need to be computed, freezing the weights of many initial layers can significantly speed up network training. If the new data set is small, then freezing earlier network layers can also prevent those layers from overfitting to the new data set.

Extract the layers and connections of the layer graph and select which layers to freeze. In GoogLeNet, the first 10 layers make out the initial 'stem' of the network. Use the supporting function freezeWeights to set the learning rates to zero in the first 10 layers. Use the supporting function createLgraphUsingConnections to reconnect all the layers in the original order. The new layer graph contains the same layers, but with the learning rates of the earlier layers set to zero.

```
layers = lgraph.Layers;
connections = lgraph.Connections;

layers(1:10) = freezeWeights(layers(1:10));
lgraph = createLgraphUsingConnections(layers,connections);
```

Train Network

The network requires input images of size 224-by-224-by-3, but the images in the image datastore have different sizes. Use an augmented image datastore to automatically resize the training images. Specify additional augmentation operations to perform on the training images: randomly flip the training images along the vertical axis and randomly translate them up to 30 pixels and scale them up to 10% horizontally and vertically. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
pixelRange = [-30 30];
scaleRange = [0.9 1.1];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange, ...
    'RandXScale',scaleRange, ...
    'RandYScale',scaleRange);
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain, ...
    'DataAugmentation',imageAugmenter);
```

To automatically resize the validation images without performing further data augmentation, use an augmented image datastore without specifying any additional preprocessing operations.

```
augimdsValidation = augmentedImageDatastore(inputSize(1:2),imdsValidation);
```

Specify the training options. Set `InitialLearnRate` to a small value to slow down learning in the transferred layers that are not already frozen. In the previous step, you increased the learning rate factors for the last learnable layer to speed up learning in the new final layers. This combination of learning rate settings results in fast learning in the new layers, slower learning in the middle layers, and no learning in the earlier, frozen layers.

Specify the number of epochs to train for. When performing transfer learning, you do not need to train for as many epochs. An epoch is a full training cycle on the entire training data set. Specify the mini-batch size and validation data. Compute the validation accuracy once per epoch.

```
miniBatchSize = 10;
valFrequency = floor(numel(augimdsTrain.Files)/miniBatchSize);
options = trainingOptions('sgdm', ...
    'MiniBatchSize',miniBatchSize, ...
    'MaxEpochs',6, ...
    'InitialLearnRate',3e-4, ...
    'Shuffle','every-epoch', ...
    'ValidationData',augimdsValidation, ...
    'ValidationFrequency',valFrequency, ...
    'Verbose',false, ...
    'Plots','training-progress');
```

Train the network using the training data. By default, `trainNetwork` uses a GPU if one is available. This requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Otherwise, `trainNetwork` uses a CPU. You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`. Because the data set is so small, training is fast.

```
net = trainNetwork(augimdsTrain,lgraph,options);
```

Classify Validation Images

Classify the validation images using the fine-tuned network, and calculate the classification accuracy.

```
[YPred,probs] = classify(net,augimdsValidation);
accuracy = mean(YPred == imdsValidation.Labels)
```

```
accuracy = 0.9000
```

Display four sample validation images with predicted labels and the predicted probabilities of the images having those labels.

```
idx = randperm(numel(imdsValidation.Files),4);
figure
for i = 1:4
    subplot(2,2,i)
    I = readimage(imdsValidation,idx(i));
    imshow(I)
    label = YPred(idx(i));
    title(string(label) + ", " + num2str(100*max(probs(idx(i),:)),3) + "%");
end
```

Train Residual Network for Image Classification

This example shows how to create a deep learning neural network with residual connections and train it on CIFAR-10 data. Residual connections are a popular element in convolutional neural network architectures. Using residual connections improves gradient flow through the network and enables training of deeper networks.

For many applications, using a network that consists of a simple sequence of layers is sufficient. However, some applications require networks with a more complex graph structure in which layers can have inputs from multiple layers and outputs to multiple layers. These types of networks are often called directed acyclic graph (DAG) networks. A residual network is a type of DAG network that has residual (or shortcut) connections that bypass the main network layers. Residual connections enable the parameter gradients to propagate more easily from the output layer to the earlier layers of the network, which makes it possible to train deeper networks. This increased network depth can result in higher accuracies on more difficult tasks.

To create and train a network with a graph structure, follow these steps.

- Create a `LayerGraph` object using `layerGraph`. The layer graph specifies the network architecture. You can create an empty layer graph and then add layers to it. You can also create a layer graph directly from an array of network layers. In this case, `layerGraph` connects the layers in the array one after the other.
- Add layers to the layer graph using `addLayers`, and remove layers from the graph using `removeLayers`.
- Connect layers to other layers using `connectLayers`, and disconnect layers from other layers using `disconnectLayers`.
- Plot the network architecture using `plot`.
- Train the network using `trainNetwork`. The trained network is a `DAGNetwork` object.
- Perform classification and prediction on new data using `classify` and `predict`.

This example shows how to build a residual network from scratch. You can also create residual networks using the `resnetLayers` function. This function allows you to quickly construct residual networks for image classification tasks.

You can also load pretrained networks for image classification. For more information, see “Pretrained Deep Neural Networks” on page 1-8.

Prepare Data

Download the CIFAR-10 data set [1]. The data set contains 60,000 images. Each image is 32-by-32 in size and has three color channels (RGB). The size of the data set is 175 MB. Depending on your internet connection, the download process can take time.

```
datadir = tempdir;
downloadCIFARData(datadir);
```

Load the CIFAR-10 training and test images as 4-D arrays. The training set contains 50,000 images and the test set contains 10,000 images. Use the CIFAR-10 test images for network validation.

```
[XTrain,YTrain,XValidation,YValidation] = loadCIFARData(datadir);
```

You can display a random sample of the training images using the following code.

```
figure;
idx = randperm(size(XTrain,4),20);
im = imtile(XTrain(:,:,:,idx),'ThumbnailSize',[96,96]);
imshow(im)
```

Create an `augmentedImageDatastore` object to use for network training. During training, the datastore randomly flips the training images along the vertical axis and randomly translates them up to four pixels horizontally and vertically. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
imageSize = [32 32 3];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augimdsTrain = augmentedImageDatastore(imageSize,XTrain,YTrain, ...
    'DataAugmentation',imageAugmenter, ...
    'OutputSizeMode','randcrop');
```

Define Network Architecture

The residual network architecture consists of these components:

- A main branch with convolutional, batch normalization, and ReLU layers connected sequentially.
- *Residual connections* that bypass the convolutional units of the main branch. The outputs of the residual connections and convolutional units are added element-wise. When the size of the activations changes, the residual connections must also contain 1-by-1 convolutional layers. Residual connections enable the parameter gradients to flow more easily from the output layer to the earlier layers of the network, which makes it possible to train deeper networks.

Create Main Branch

Start by creating the main branch of the network. The main branch contains five sections.

- An initial section containing the image input layer and an initial convolution with activation.
- Three stages of convolutional layers with different feature sizes (32-by-32, 16-by-16, and 8-by-8). Each stage contains N convolutional units. In this part of the example, $N = 2$. Each convolutional unit contains two 3-by-3 convolutional layers with activations. The `netWidth` parameter is the network width, defined as the number of filters in the convolutional layers in the first stage of the network. The first convolutional units in the second and third stages downsample the spatial dimensions by a factor of two. To keep the amount of computation required in each convolutional layer roughly the same throughout the network, increase the number of filters by a factor of two each time you perform spatial downsampling.
- A final section with global average pooling, fully connected, softmax, and classification layers.

Use `convolutionalUnit(numF,stride,tag)` to create a convolutional unit. `numF` is the number of convolutional filters in each layer, `stride` is the stride of the first convolutional layer of the unit, and `tag` is a character array to prepend to the layer names. The `convolutionalUnit` function is defined at the end of the example.

Give unique names to all the layers. The layers in the convolutional units have names starting with `'SjUk'`, where `j` is the stage index and `k` is the index of the convolutional unit within that stage. For example, `'S2U1'` denotes stage 2, unit 1.

```
netWidth = 16;
layers = [
    imageInputLayer([32 32 3],'Name','input')
    convolution2dLayer(3,netWidth,'Padding','same','Name','convInp')
    batchNormalizationLayer('Name','BNInp')
    reluLayer('Name','reluInp')

    convolutionalUnit(netWidth,1,'S1U1')
    additionLayer(2,'Name','add11')
    reluLayer('Name','relu11')
    convolutionalUnit(netWidth,1,'S1U2')
    additionLayer(2,'Name','add12')
    reluLayer('Name','relu12')

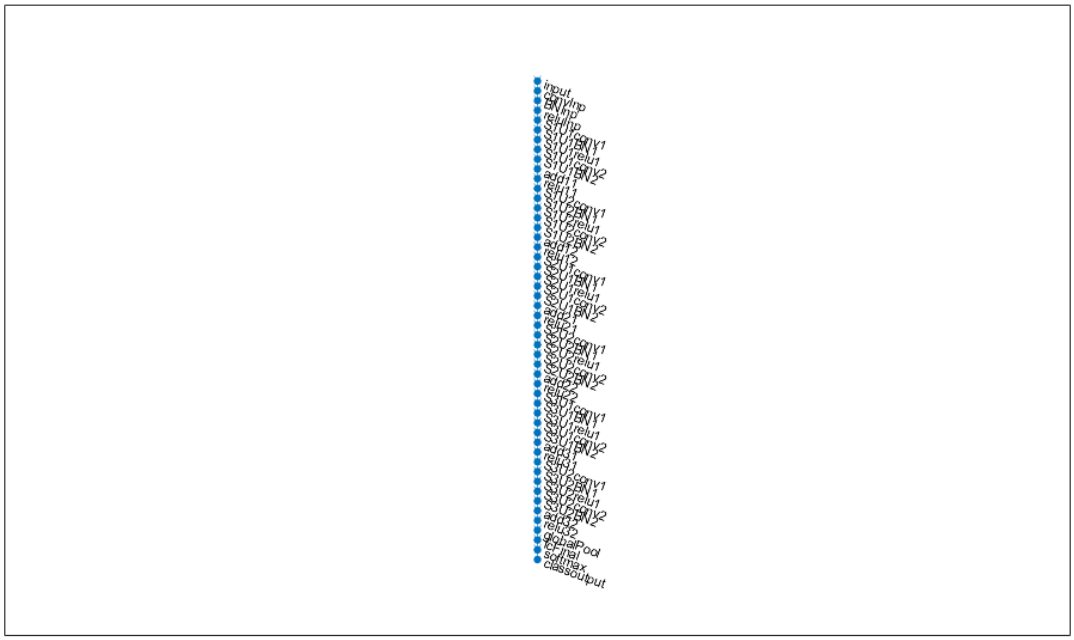
    convolutionalUnit(2*netWidth,2,'S2U1')
    additionLayer(2,'Name','add21')
    reluLayer('Name','relu21')
    convolutionalUnit(2*netWidth,1,'S2U2')
    additionLayer(2,'Name','add22')
    reluLayer('Name','relu22')

    convolutionalUnit(4*netWidth,2,'S3U1')
    additionLayer(2,'Name','add31')
    reluLayer('Name','relu31')
    convolutionalUnit(4*netWidth,1,'S3U2')
    additionLayer(2,'Name','add32')
    reluLayer('Name','relu32')

    averagePooling2dLayer(8,'Name','globalPool')
    fullyConnectedLayer(10,'Name','fcFinal')
    softmaxLayer('Name','softmax')
    classificationLayer('Name','classoutput')
    ];
```

Create a layer graph from the layer array. `layerGraph` connects all the layers in `layers` sequentially. Plot the layer graph.

```
lgraph = layerGraph(layers);
figure('Units','normalized','Position',[0.2 0.2 0.6 0.6]);
plot(lgraph);
```



Create Residual Connections

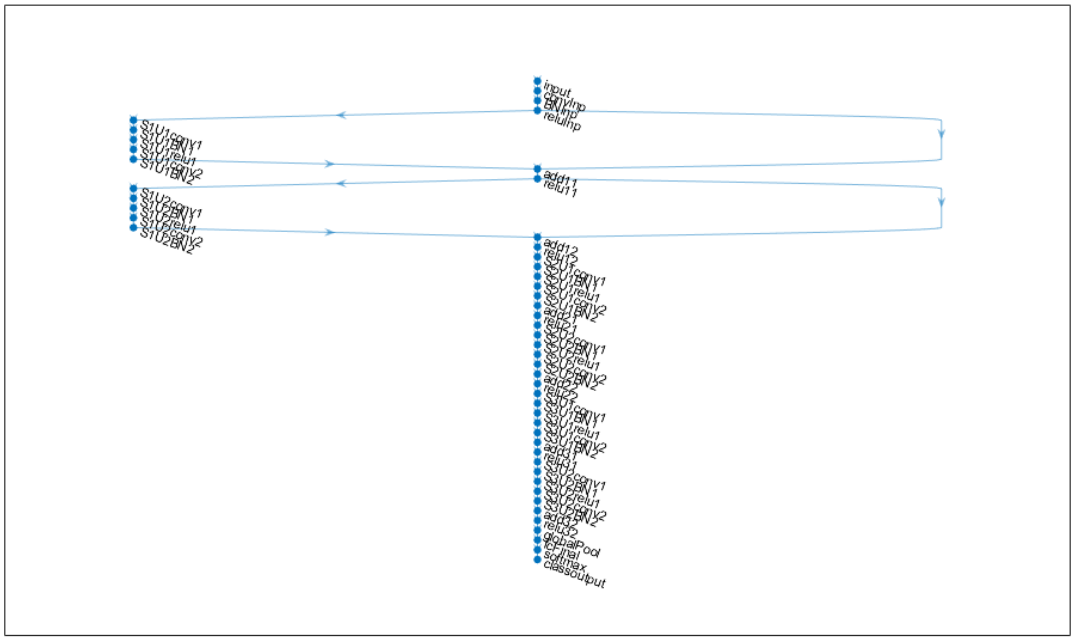
Add residual connections around the convolutional units. Most residual connections perform no operations and simply add element-wise to the outputs of the convolutional units.

Create the residual connection from the `'reluInp'` to the `'add11'` layer. Because you specified the number of inputs to the addition layer to be two when you created the layer, the layer has two inputs with the names `'in1'` and `'in2'`. The final layer of the first convolutional unit is already connected to the `'in1'` input. The addition layer then sums the outputs of the first convolutional unit and the `'reluInp'` layer.

In the same way, connect the `'relu11'` layer to the second input of the `'add12'` layer. Check that you have connected the layers correctly by plotting the layer graph.

```
lgraph = connectLayers(lgraph,'reluInp','add11/in2');
lgraph = connectLayers(lgraph,'relu11','add12/in2');

figure('Units','normalized','Position',[0.2 0.2 0.6 0.6]);
plot(lgraph);
```



When the layer activations in the convolutional units change size (that is, when they are downsampled spatially and upsampled in the channel dimension), the activations in the residual connections must also change size. Change the activation sizes in the residual connections by using a 1-by-1 convolutional layer together with its batch normalization layer.

```
skip1 = [
    convolution2dLayer(1,2*netWidth,'Stride',2,'Name','skipConv1')
    batchNormalizationLayer('Name','skipBN1')];
lgraph = addLayers(lgraph,skip1);
lgraph = connectLayers(lgraph,'relu12','skipConv1');
lgraph = connectLayers(lgraph,'skipBN1','add21/in2');
```

Add the identity connection in the second stage of the network.

```
lgraph = connectLayers(lgraph,'relu21','add22/in2');
```

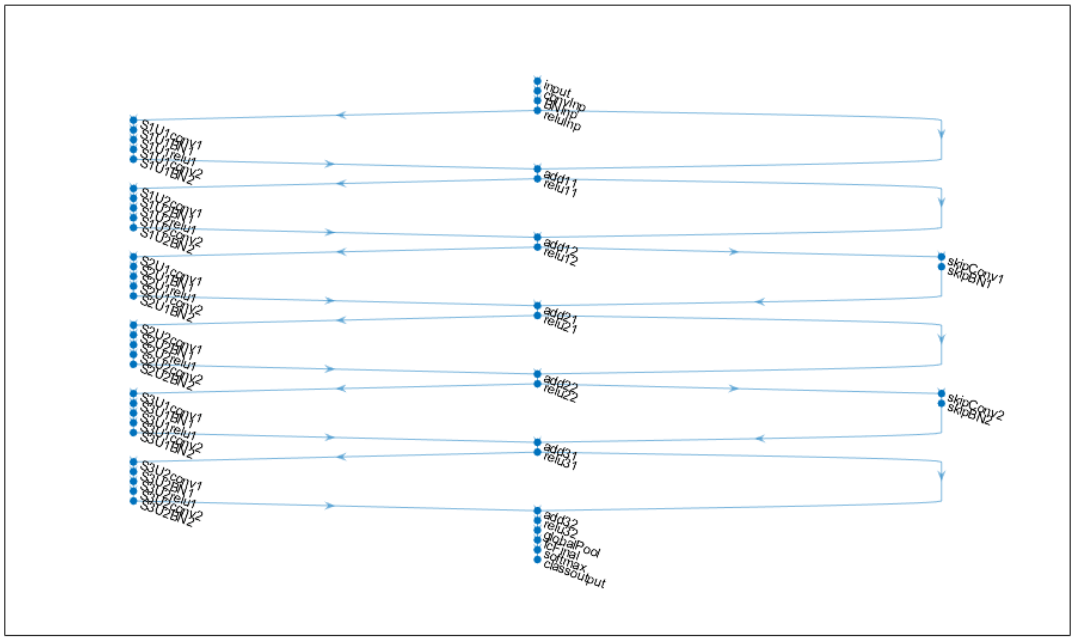
Change the activation size in the residual connection between the second and third stages by another 1-by-1 convolutional layer together with its batch normalization layer.

```
skip2 = [
    convolution2dLayer(1,4*netWidth,'Stride',2,'Name','skipConv2')
    batchNormalizationLayer('Name','skipBN2')];
lgraph = addLayers(lgraph,skip2);
lgraph = connectLayers(lgraph,'relu22','skipConv2');
lgraph = connectLayers(lgraph,'skipBN2','add31/in2');
```

Add the last identity connection and plot the final layer graph.

```
lgraph = connectLayers(lgraph,'relu31','add32/in2');
```

```
figure('Units','normalized','Position',[0.2 0.2 0.6 0.6]);
plot(lgraph)
```



Create Deeper Network

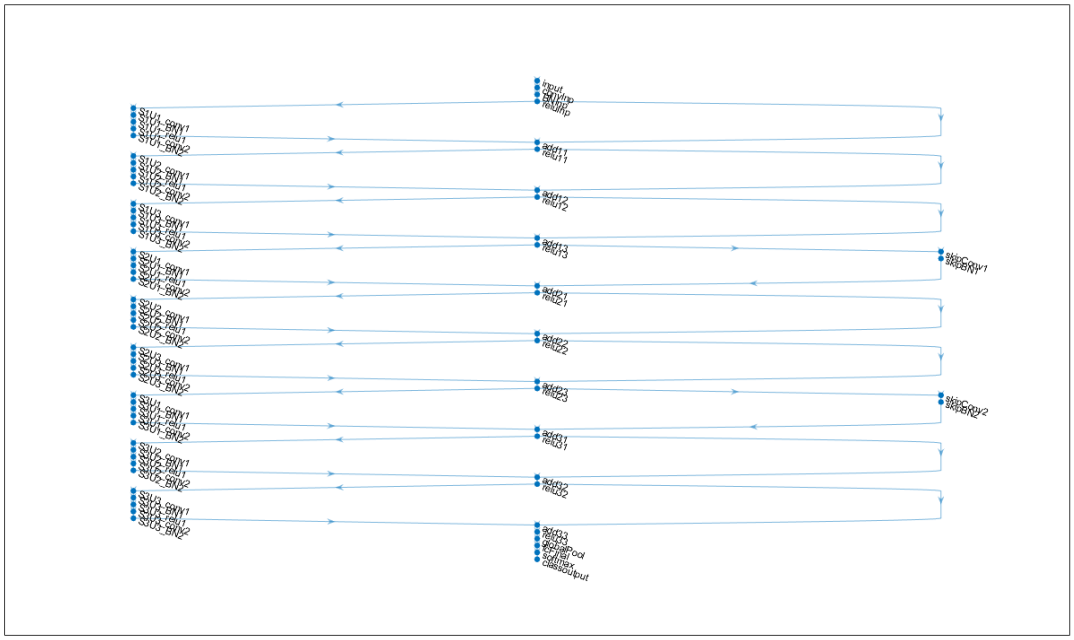
To create a layer graph with residual connections for CIFAR-10 data of arbitrary depth and width, use the supporting function residualCIFARlgraph.

`lgraph = residualCIFARlgraph(netWidth,numUnits,unitType)` creates a layer graph for CIFAR-10 data with residual connections.

- `netWidth` is the network width, defined as the number of filters in the first 3-by-3 convolutional layers of the network.
- `numUnits` is the number of convolutional units in the main branch of network. Because the network consists of three stages where each stage has the same number of convolutional units, `numUnits` must be an integer multiple of 3.
- `unitType` is the type of convolutional unit, specified as `"standard"` or `"bottleneck"`. A standard convolutional unit consists of two 3-by-3 convolutional layers. A bottleneck convolutional unit consists of three convolutional layers: a 1-by-1 layer for downsampling in the channel dimension, a 3-by-3 convolutional layer, and a 1-by-1 layer for upsampling in the channel dimension. Hence, a bottleneck convolutional unit has 50% more convolutional layers than a standard unit, but only half the number of spatial 3-by-3 convolutions. The two unit types have similar computational complexity, but the total number of features propagating in the residual connections is four times larger when using the bottleneck units. The total depth, defined as the maximum number of sequential convolutional and fully connected layers, is 2*`numUnits` + 2 for networks with standard units and 3*`numUnits` + 2 for networks with bottleneck units.

Create a residual network with nine standard convolutional units (three units per stage) and a width of 16. The total network depth is 2*9+2 = 20.

```
numUnits = 9;
netWidth = 16;
lgraph = residualCIFARlgraph(netWidth,numUnits,"standard");
figure('Units','normalized','Position',[0.1 0.1 0.8 0.8]);
plot(lgraph)
```



Train Network

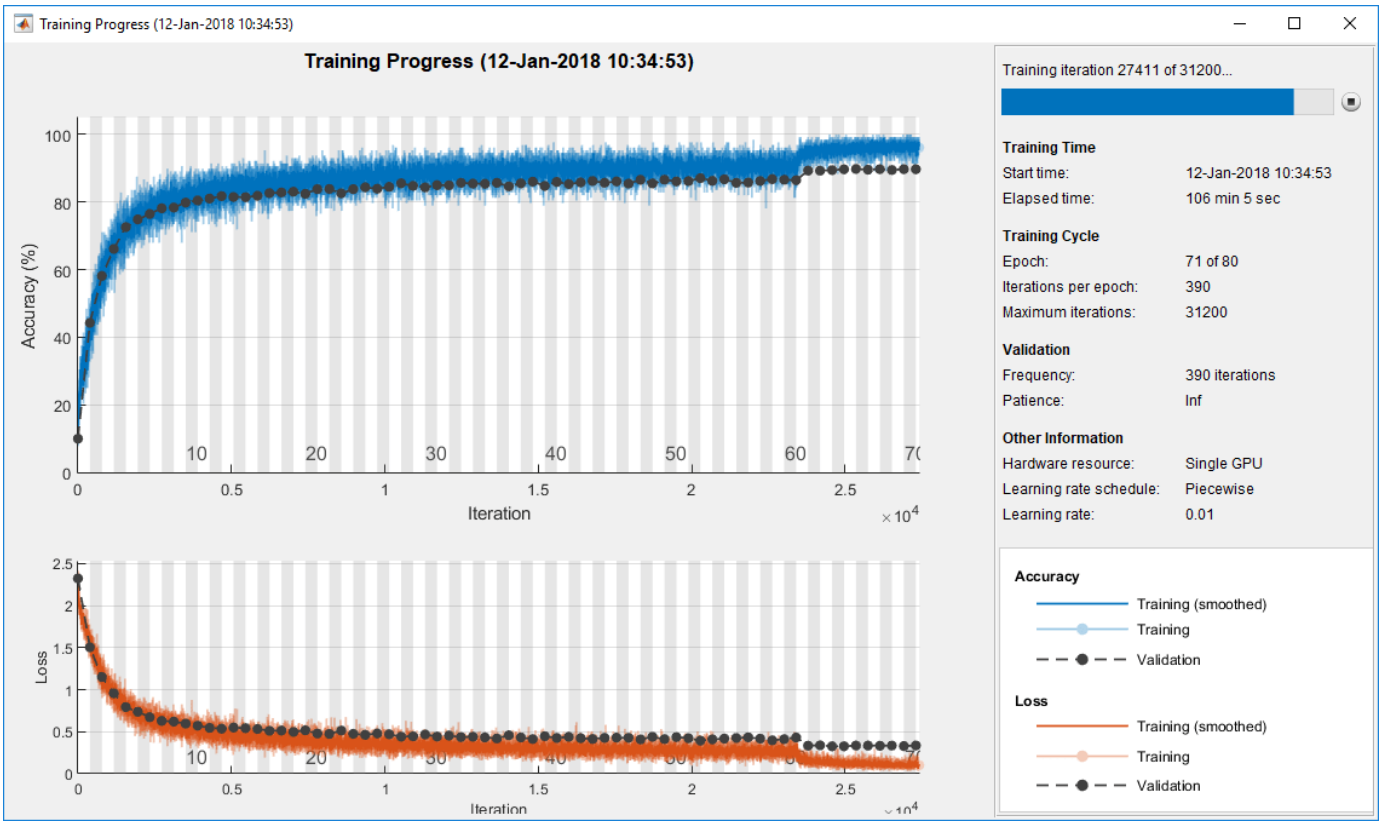
Specify training options. Train the network for 80 epochs. Select a learning rate that is proportional to the mini-batch size and reduce the learning rate by a factor of 10 after 60 epochs. Validate the network once per epoch using the validation data.

```
miniBatchSize = 128;
learnRate = 0.1*miniBatchSize/128;
valFrequency = floor(size(XTrain,4)/miniBatchSize);
options = trainingOptions('sgdm', ...
    'InitialLearnRate',learnRate, ...
    'MaxEpochs',80, ...
    'MiniBatchSize',miniBatchSize, ...
    'VerboseFrequency',valFrequency, ...
    'Shuffle','every-epoch', ...
    'Plots','training-progress', ...
    'Verbose',false, ...
    'ValidationData',{XValidation,YValidation}, ...
    'ValidationFrequency',valFrequency, ...
    'LearnRateSchedule','piecewise', ...
```

```
    'LearnRateDropFactor',0.1, ...
    'LearnRateDropPeriod',60);
```

To train the network using `trainNetwork`, set the `doTraining` flag to `true`. Otherwise, load a pretrained network. Training the network on a good GPU takes about two hours. If you do not have a GPU, then training takes much longer.

```
doTraining = false;
if doTraining
    trainedNet = trainNetwork(augimdsTrain,lgraph,options);
else
    load('CIFARNet-20-16.mat','trainedNet');
end
```



Evaluate Trained Network

Calculate the final accuracy of the network on the training set (without data augmentation) and validation set.

```
[YValPred,probs] = classify(trainedNet,XValidation);
validationError = mean(YValPred ~= YValidation);
YTrainPred = classify(trainedNet,XTrain);
trainError = mean(YTrainPred ~= YTrain);
disp("Training error: " + trainError*100 + "%")
```

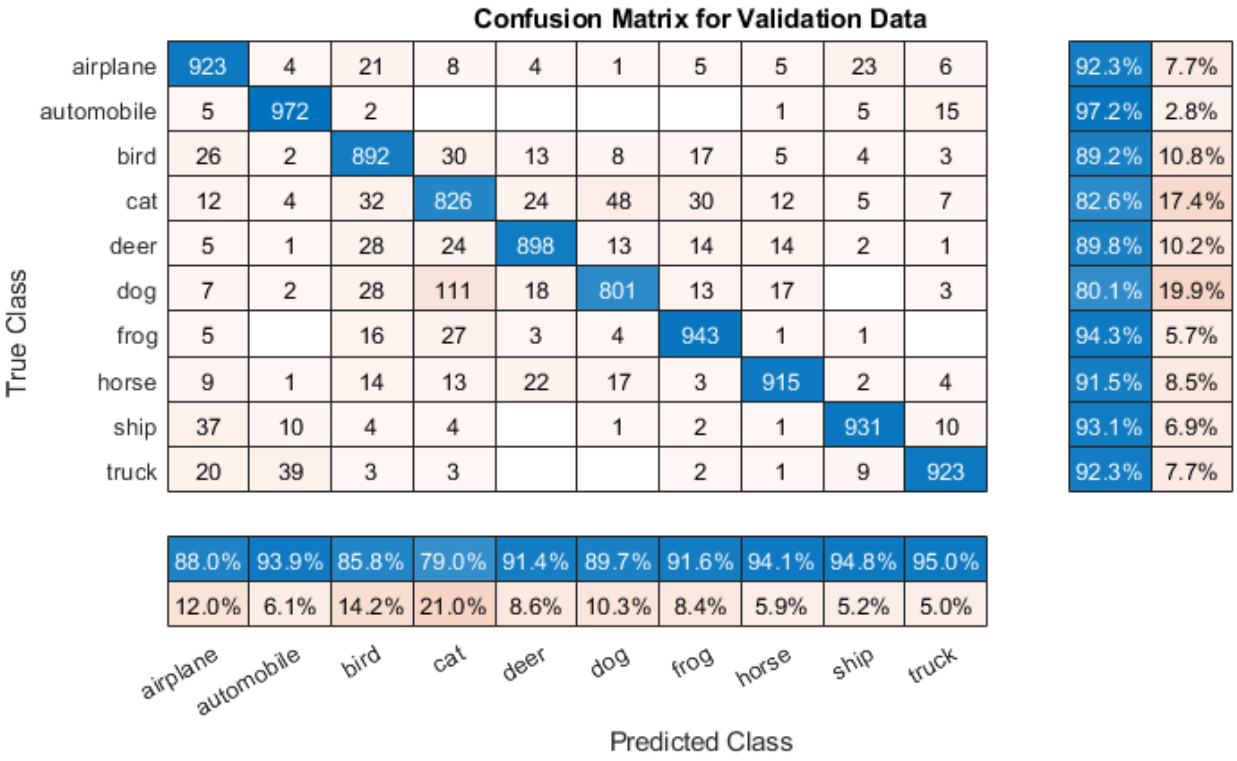
```
Training error: 2.862%
```

```
disp("Validation error: " + validationError*100 + "%")
```

```
Validation error: 9.76%
```

Plot the confusion matrix. Display the precision and recall for each class by using column and row summaries. The network most commonly confuses cats with dogs.

```
figure('Units','normalized','Position',[0.2 0.2 0.4 0.4]);
cm = confusionchart(YValidation,YValPred);
cm.Title = 'Confusion Matrix for Validation Data';
cm.ColumnSummary = 'column-normalized';
cm.RowSummary = 'row-normalized';
```



You can display a random sample of nine test images together with their predicted classes and the probabilities of those classes using the following code.

```
figure
idx = randperm(size(XValidation,4),9);
for i = 1:numel(idx)
    subplot(3,3,i)
    imshow(XValidation(:,:,:,idx(i)));
    prob = num2str(100*max(probs(idx(i),:)),3);
    predClass = char(YValPred(idx(i)));
    title([predClass,', ',prob,'%'])
end
```

`convolutionalUnit(numF,stride,tag)` creates an array of layers with two convolutional layers and corresponding batch normalization and ReLU layers. `numF` is the number of convolutional filters, `stride` is the stride of the first convolutional layer, and `tag` is a tag that is prepended to all layer names.

```
function layers = convolutionalUnit(numF,stride,tag)
layers = [
    convolution2dLayer(3,numF,'Padding','same','Stride',stride,'Name',[tag,'conv1'])
    batchNormalizationLayer('Name',[tag,'BN1'])
    reluLayer('Name',[tag,'relu1'])
    convolution2dLayer(3,numF,'Padding','same','Name',[tag,'conv2'])
    batchNormalizationLayer('Name',[tag,'BN2'])];
end
```

Classify Image Using GoogLeNet

This example shows how to classify an image using the pretrained deep convolutional neural network GoogLeNet.

GoogLeNet has been trained on over a million images and can classify images into 1000 object categories (such as keyboard, coffee mug, pencil, and many animals). The network has learned rich feature representations for a wide range of images. The network takes an image as input, and then outputs a label for the object in the image together with the probabilities for each of the object categories.

Load Pretrained Network

Load the pretrained GoogLeNet network. This step requires the Deep Learning Toolbox™ Model *for GoogLeNet Network* support package. If you do not have the required support packages installed, then the software provides a download link.

You can also choose to load a different pretrained network for image classification. To try a different pretrained network, open this example in MATLAB® and select a different network. For example, you can try `squeezenet`, a network that is even faster than `googlenet`. You can run this example with other pretrained networks. For a list of all available networks, see “Load Pretrained Networks” on page 1-10.

```
net = googlenet;
```

The image that you want to classify must have the same size as the input size of the network. For GoogLeNet, the first element of the `Layers` property of the network is the image input layer. The network input size is the `InputSize` property of the image input layer.

```
inputSize = net.Layers(1).InputSize
```

```
inputSize = 1×3

   224   224     3
```

The final element of the `Layers` property is the classification output layer. The `ClassNames` property of this layer contains the names of the classes learned by the network. View 10 random class names out of the total of 1000.

```
classNames = net.Layers(end).ClassNames;
numClasses = numel(classNames);
disp(classNames(randperm(numClasses,10)))
```

```
    'papillon'
    'eggnog'
    'jackfruit'
    'castle'
    'sleeping bag'
    'redshank'
    'Band Aid'
    'wok'
    'seat belt'
    'orange'
```

Read and Resize Image

Read and show the image that you want to classify.

```
I = imread('peppers.png');
figure
imshow(I)
```

Display the size of the image. The image is 384-by-512 pixels and has three color channels (RGB).

```
size(I)
```

```
ans = 1×3

   384   512     3
```

Resize the image to the input size of the network by using `imresize`. This resizing slightly changes the aspect ratio of the image.

```
I = imresize(I,inputSize(1:2));
figure
imshow(I)
```

Depending on your application, you might want to resize the image in a different way. For example, you can crop the top left corner of the image by using `I(1:inputSize(1),1:inputSize(2),:)`. If you have Image Processing Toolbox™, then you can use the `imcrop` function.

Classify Image

Classify the image and calculate the class probabilities using `classify`. The network correctly classifies the image as a bell pepper. A network for classification is trained to output a single label for each input image, even when the image contains multiple objects.

```
[label,scores] = classify(net,I);
label
```

```
label = categorical
     bell pepper
```

Display the image with the predicted label and the predicted probability of the image having that label.

```
figure
imshow(I)
title(string(label) + ", " + num2str(100*scores(classNames == label),3) + "%");
```

Display Top Predictions

Display the top five predicted labels and their associated probabilities as a histogram. Because the network classifies images into so many object categories, and many categories are similar, it is common to consider the top-five accuracy when evaluating networks. The network classifies the image as a bell pepper with a high probability.

```
[~,idx] = sort(scores,'descend');
idx = idx(5:-1:1);
classNamesTop = net.Layers(end).ClassNames(idx);
scoresTop = scores(idx);

figure
barh(scoresTop)
xlim([0 1])
title('Top 5 Predictions')
xlabel('Probability')
yticklabels(classNamesTop)
```

Extract Image Features Using Pretrained Network

This example shows how to extract learned image features from a pretrained convolutional neural network and use those features to train an image classifier. Feature extraction is the easiest and fastest way to use the representational power of pretrained deep networks. For example, you can train a support vector machine (SVM) using `fitcecoc` (Statistics and Machine Learning Toolbox™) on the extracted features. Because feature extraction only requires a single pass through the data, it is a good starting point if you do not have a GPU to accelerate network training with.

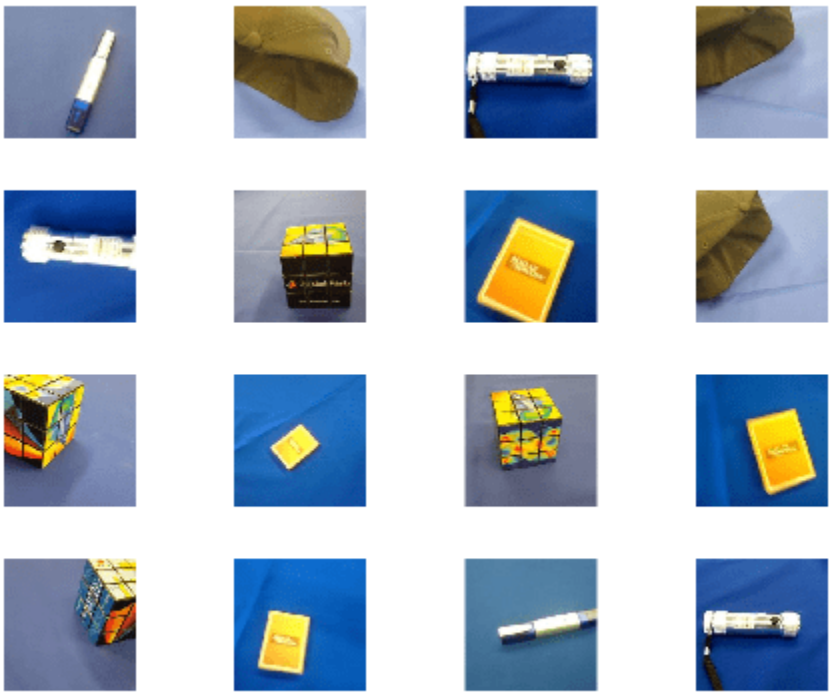
Load Data

Unzip and load the sample images as an image datastore. `imageDatastore` automatically labels the images based on folder names and stores the data as an `ImageDatastore` object. An image datastore lets you store large image data, including data that does not fit in memory. Split the data into 70% training and 30% test data.

```
unzip('MerchData.zip');
imds = imageDatastore('MerchData','IncludeSubfolders',true,'LabelSource','foldernames');
[imdsTrain,imdsTest] = splitEachLabel(imds,0.7,'randomized');
```

There are now 55 training images and 20 validation images in this very small data set. Display some sample images.

```
numTrainImages = numel(imdsTrain.Labels);
idx = randperm(numTrainImages,16);
figure
for i = 1:16
    subplot(4,4,i)
    I = readimage(imdsTrain,idx(i));
    imshow(I)
end
```



Load Pretrained Network

Load a pretrained ResNet-18 network. If the Deep Learning Toolbox Model *for ResNet-18 Network* support package is not installed, then the software provides a download link. ResNet-18 is trained on more than a million images and can classify images into 1000 object categories, such as keyboard, mouse, pencil, and many animals. As a result, the model has learned rich feature representations for a wide range of images.

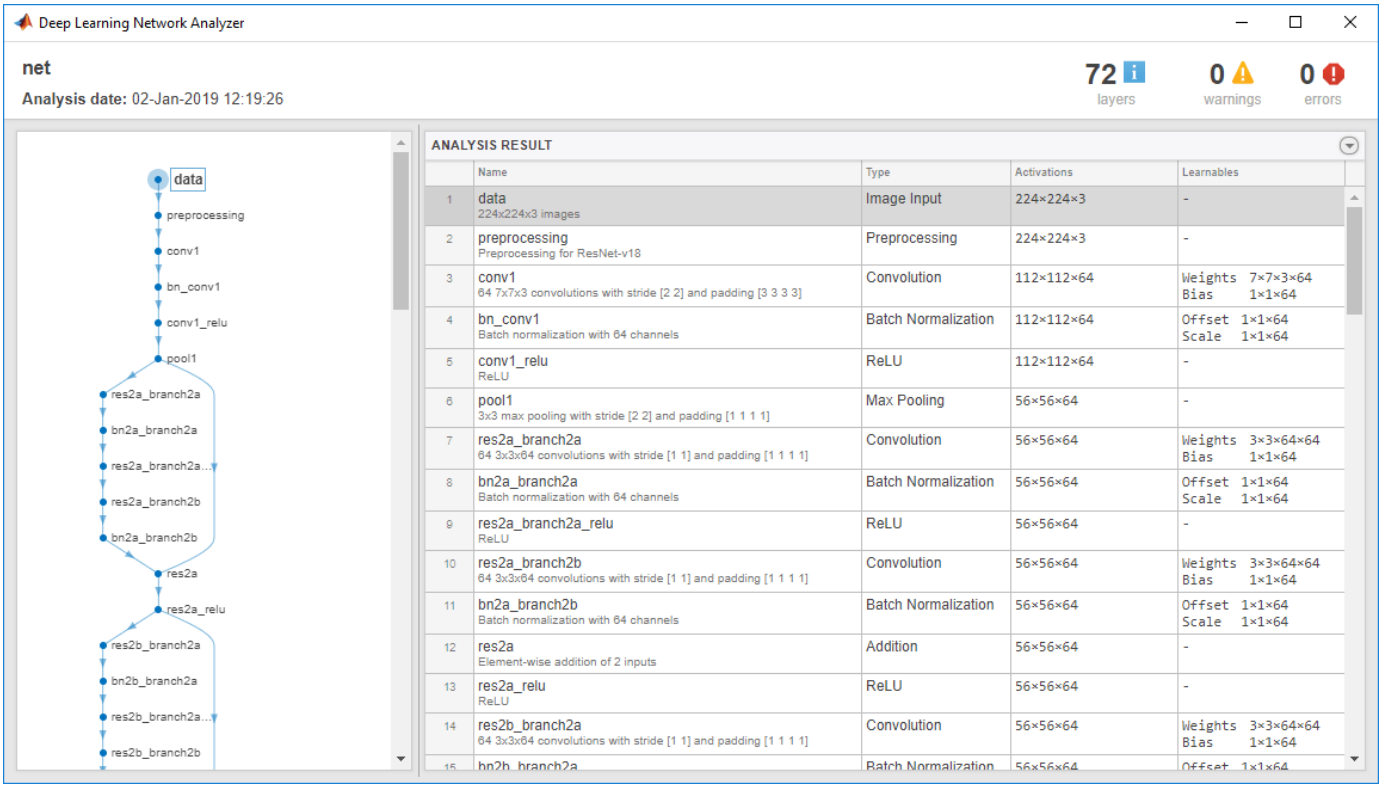
```
net = resnet18
```

```
net =
  DAGNetwork with properties:

         Layers: [71x1 nnet.cnn.layer.Layer]
    Connections: [78x2 table]
     InputNames: {'data'}
    OutputNames: {'ClassificationLayer_predictions'}
```

Analyze the network architecture. The first layer, the image input layer, requires input images of size 224-by-224-by-3, where 3 is the number of color channels.

```
inputSize = net.Layers(1).InputSize;
analyzeNetwork(net)
```



Extract Image Features

The network requires input images of size 224-by-224-by-3, but the images in the image datastores have different sizes. To automatically resize the training and test images before they are input to the network, create augmented image datastores, specify the desired image size, and use these datastores as input arguments to `activations`.

```
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain);
augimdsTest = augmentedImageDatastore(inputSize(1:2),imdsTest);
```

The network constructs a hierarchical representation of input images. Deeper layers contain higher-level features, constructed using the lower-level features of earlier layers. To get the feature representations of the training and test images, use `activations` on the global pooling layer, `'pool5'`, at the end of the network. The global pooling layer pools the input features over all spatial locations, giving 512 features in total.

```
layer = 'pool5';
featuresTrain = activations(net,augimdsTrain,layer,'OutputAs','rows');
featuresTest = activations(net,augimdsTest,layer,'OutputAs','rows');

whos featuresTrain
```

```
  Name                Size              Bytes  Class     Attributes

  featuresTrain      55x512            112640  single
```

Extract the class labels from the training and test data.

```
YTrain = imdsTrain.Labels;
YTest = imdsTest.Labels;
```

Fit Image Classifier

Use the features extracted from the training images as predictor variables and fit a multiclass support vector machine (SVM) using `fitcecoc` (Statistics and Machine Learning Toolbox).

```
classifier = fitcecoc(featuresTrain,YTrain);
```

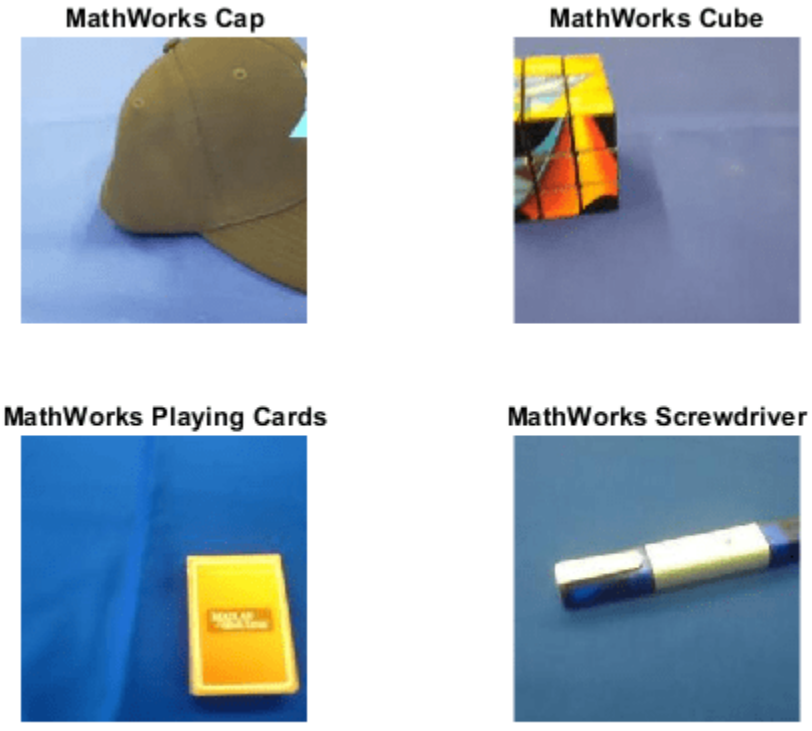
Classify Test Images

Classify the test images using the trained SVM model using the features extracted from the test images.

```
YPred = predict(classifier,featuresTest);
```

Display four sample test images with their predicted labels.

```
idx = [1 5 10 15];
figure
for i = 1:numel(idx)
    subplot(2,2,i)
    I = readimage(imdsTest,idx(i));
    label = YPred(idx(i));
    imshow(I)
    title(char(label))
end
```



Calculate the classification accuracy on the test set. Accuracy is the fraction of labels that the network predicts correctly.

```
accuracy = mean(YPred == YTest)
```

```
accuracy = 1
```

Train Classifier on Shallower Features

You can also extract features from an earlier layer in the network and train a classifier on those features. Earlier layers typically extract fewer, shallower features, have higher spatial resolution, and a larger total number of activations. Extract the features from the `'res3b_relu'` layer. This is the final layer that outputs 128 features and the activations have a spatial size of 28-by-28.

```
layer = 'res3b_relu';
featuresTrain = activations(net,augimdsTrain,layer);
featuresTest = activations(net,augimdsTest,layer);
whos featuresTrain
```

```
  Name                Size                       Bytes  Class     Attributes

  featuresTrain      28x28x128x55            22077440  single
```

The extracted features used in the first part of this example were pooled over all spatial locations by the global pooling layer. To achieve the same result when extracting features in earlier layers, manually average the activations over all spatial locations. To get the features on the form *N*-by-*C*, where *N* is the number of observations and *C* is the number of features, remove the singleton dimensions and transpose.

```
featuresTrain = squeeze(mean(featuresTrain,[1 2]))';
featuresTest = squeeze(mean(featuresTest,[1 2]))';
whos featuresTrain
```

```
  Name                Size              Bytes  Class     Attributes

  featuresTrain      55x128             28160  single
```

Train an SVM classifier on the shallower features. Calculate the test accuracy.

```
classifier = fitcecoc(featuresTrain,YTrain);
YPred = predict(classifier,featuresTest);
accuracy = mean(YPred == YTest)
```

```
accuracy = 0.9500
```

Both trained SVMs have high accuracies. If the accuracy is not high enough using feature extraction, then try transfer learning instead. For an example, see “Train Deep Learning Network to Classify New Images” on page 3-6. For a list and comparison of the pretrained networks, see “Pretrained Deep Neural Networks” on page 1-8.

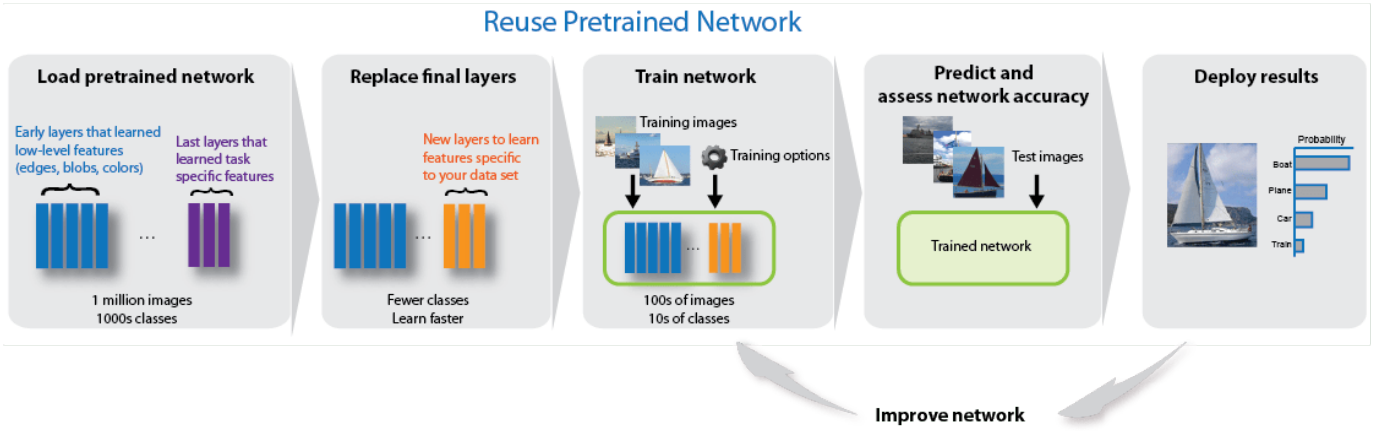
Transfer Learning Using Pretrained Network

This example shows how to fine-tune a pretrained GoogLeNet convolutional neural network to perform classification on a new collection of images.

GoogLeNet has been trained on over a million images and can classify images into 1000 object categories (such as keyboard, coffee mug, pencil, and many animals). The network has learned rich feature representations for a wide range of images. The network takes an image as input and outputs a label for the object in the image together with the probabilities for each of the object categories.

Transfer learning is commonly used in deep learning applications. You can take a pretrained network and use it as a starting point to learn a new task. Fine-tuning a network with transfer learning is usually much faster and easier than training a network with randomly initialized weights from scratch. You can quickly transfer learned features to a new task using a smaller number of training images.



Load Data

Unzip and load the new images as an image datastore. `imageDatastore` automatically labels the images based on folder names and stores the data as an `ImageDatastore` object. An image datastore enables you to store large image data, including data that does not fit in memory, and efficiently read batches of images during training of a convolutional neural network.

```
unzip('MerchData.zip');
imds = imageDatastore('MerchData', ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

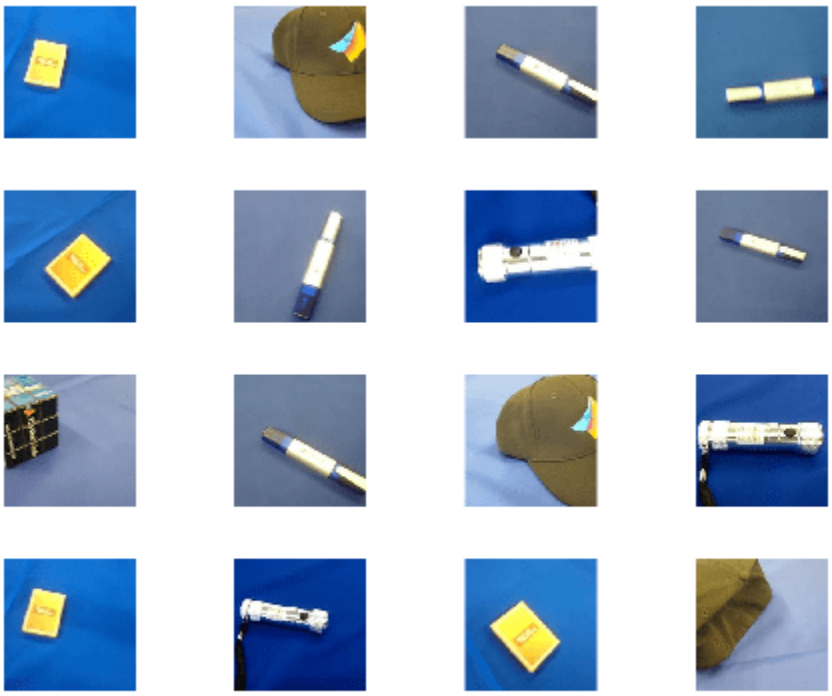
Divide the data into training and validation data sets. Use 70% of the images for training and 30% for validation. `splitEachLabel` splits the image datastore into two new datastores.

```
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.7,'randomized');
```

This very small data set now contains 55 training images and 20 validation images. Display some sample images.

```
numTrainImages = numel(imdsTrain.Labels);
idx = randperm(numTrainImages,16);
figure
for i = 1:16
```

```
    subplot(4,4,i)
    I = readimage(imdsTrain,idx(i));
    imshow(I)
end
```



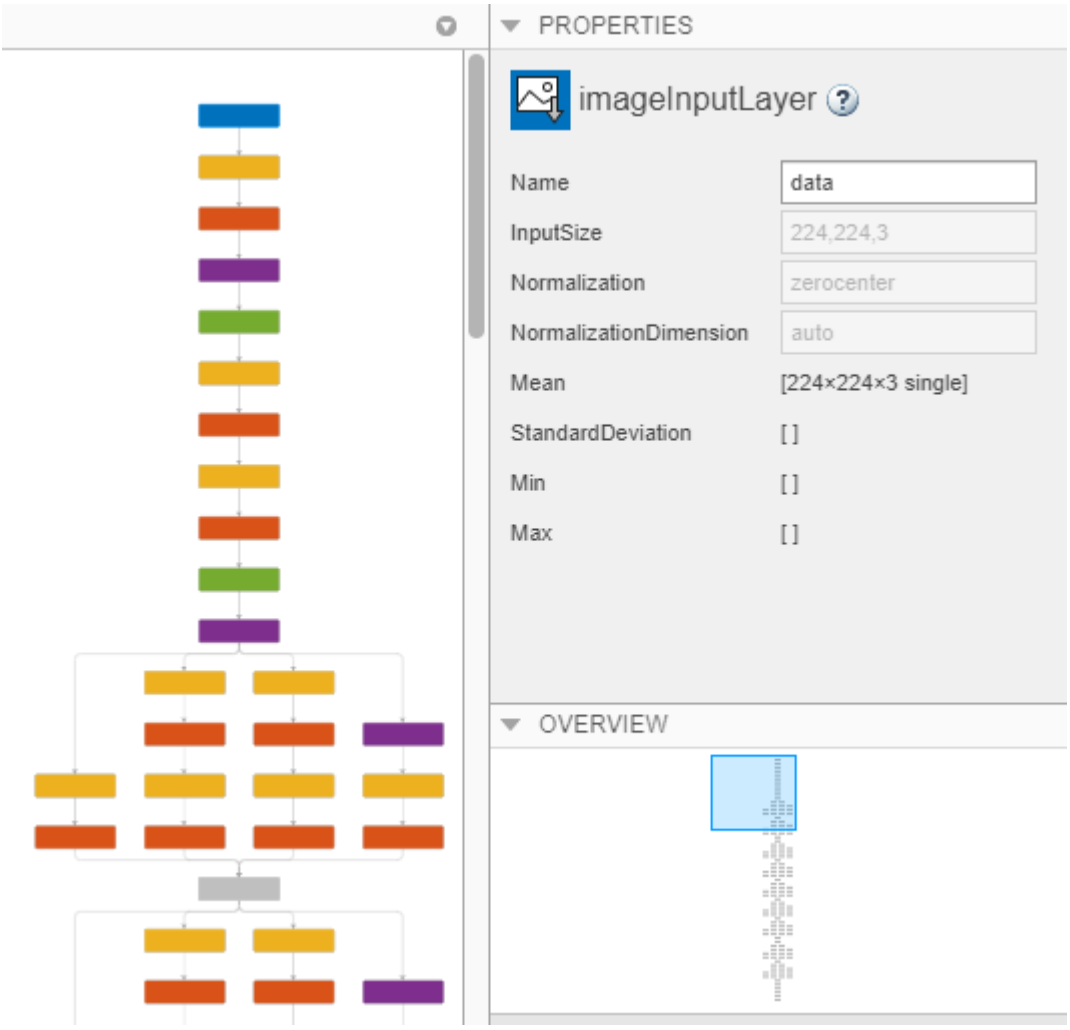
Load Pretrained Network

Load the pretrained GoogLeNet neural network. If Deep Learning Toolbox™ Model *for GoogLeNet Network* is not installed, then the software provides a download link.

```
net = googlenet;
```

Use `deepNetworkDesigner` to display an interactive visualization of the network architecture and detailed information about the network layers.

```
deepNetworkDesigner(net)
```



The first layer, which is the image input layer, requires input images of size 224-by-224-by-3, where 3 is the number of color channels.

```
inputSize = net.Layers(1).InputSize
```

```
inputSize = 1×3

   224   224     3
```

Replace Final Layers

The fully connected layer and classification layer of the pretrained network `net` are configured for 1000 classes. These two layers, `loss3-classifier` and `output` in GoogLeNet, contain information on how to combine the features that the network extracts into class probabilities, a loss value, and predicted labels. To retrain a pretrained network to classify new images, replace these two layers with new layers adapted to the new data set.

Extract the layer graph from the trained network.

```
lgraph = layerGraph(net);
```

Replace the fully connected layer with a new fully connected layer that has number of outputs equal to the number of classes. To make learning faster in the new layers than in the transferred layers, increase the `WeightLearnRateFactor` and `BiasLearnRateFactor` values of the fully connected layer.

```
numClasses = numel(categories(imdsTrain.Labels))
```

```
numClasses = 5
```

```
newLearnableLayer = fullyConnectedLayer(numClasses, ...
    'Name','new_fc', ...
    'WeightLearnRateFactor',10, ...
    'BiasLearnRateFactor',10);

lgraph = replaceLayer(lgraph,'loss3-classifier',newLearnableLayer);
```

The classification layer specifies the output classes of the network. Replace the classification layer with a new one without class labels. `trainNetwork` automatically sets the output classes of the layer at training time.

```
newClassLayer = classificationLayer('Name','new_classoutput');
lgraph = replaceLayer(lgraph,'output',newClassLayer);
```

Train Network

The network requires input images of size 224-by-224-by-3, but the images in the image datastores have different sizes. Use an augmented image datastore to automatically resize the training images. Specify additional augmentation operations to perform on the training images: randomly flip the training images along the vertical axis, and randomly translate them up to 30 pixels horizontally and vertically. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
pixelRange = [-30 30];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain, ...
    'DataAugmentation',imageAugmenter);
```

To automatically resize the validation images without performing further data augmentation, use an augmented image datastore without specifying any additional preprocessing operations.

```
augimdsValidation = augmentedImageDatastore(inputSize(1:2),imdsValidation);
```

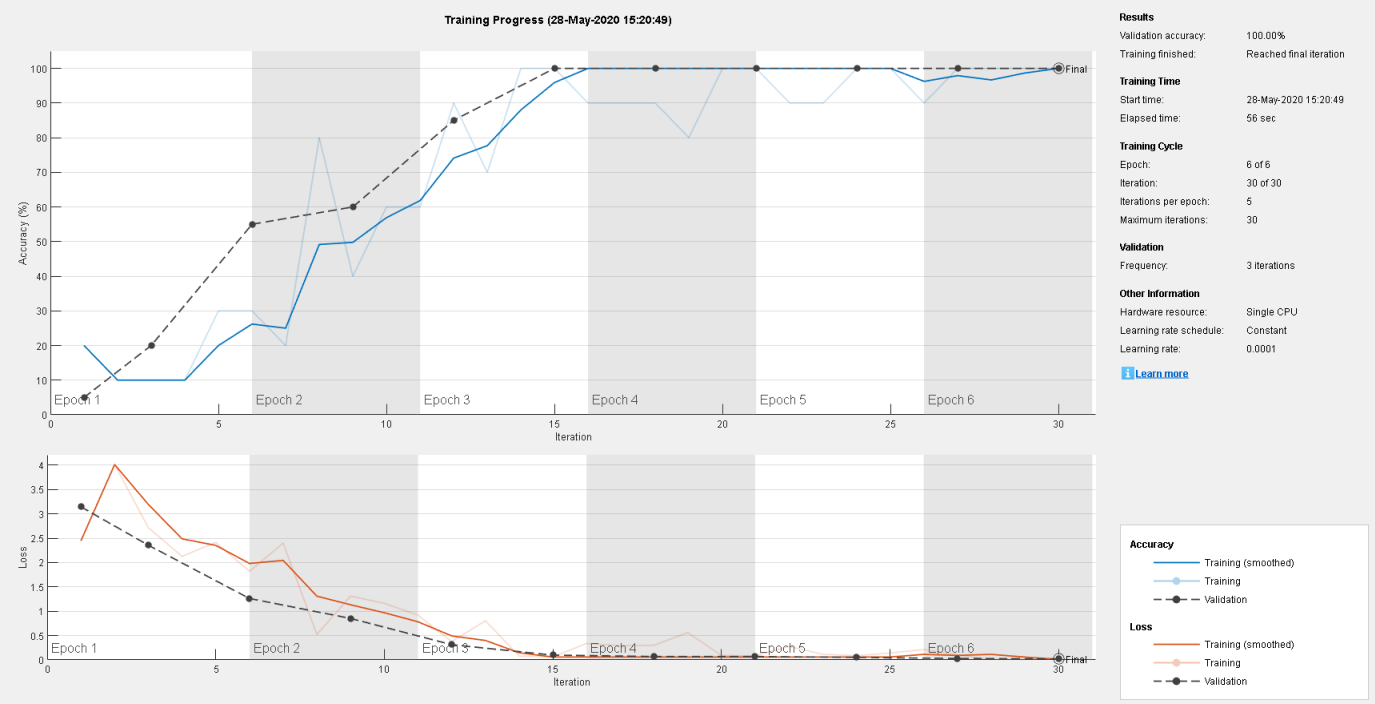
Specify the training options. For transfer learning, keep the features from the early layers of the pretrained network (the transferred layer weights). To slow down learning in the transferred layers, set the initial learning rate to a small value. In the previous step, you increased the learning rate factors for the fully connected layer to speed up learning in the new final layers. This combination of learning rate settings results in fast learning only in the new layers and slower learning in the other layers. When performing transfer learning, you do not need to train for as many epochs. An epoch is a full training cycle on the entire training data set. Specify the mini-batch size and validation data. The software validates the network every `ValidationFrequency` iterations during training.

```
options = trainingOptions('sgdm', ...
    'MiniBatchSize',10, ...
    'MaxEpochs',6, ...
```

```
    'InitialLearnRate',1e-4, ...
    'Shuffle','every-epoch', ...
    'ValidationData',augimdsValidation, ...
    'ValidationFrequency',3, ...
    'Verbose',false, ...
    'Plots','training-progress');
```

Train the network consisting of the transferred and new layers. By default, `trainNetwork` uses a GPU if one is available. This requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Otherwise, it uses a CPU. You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`.

```
netTransfer = trainNetwork(augimdsTrain,lgraph,options);
```



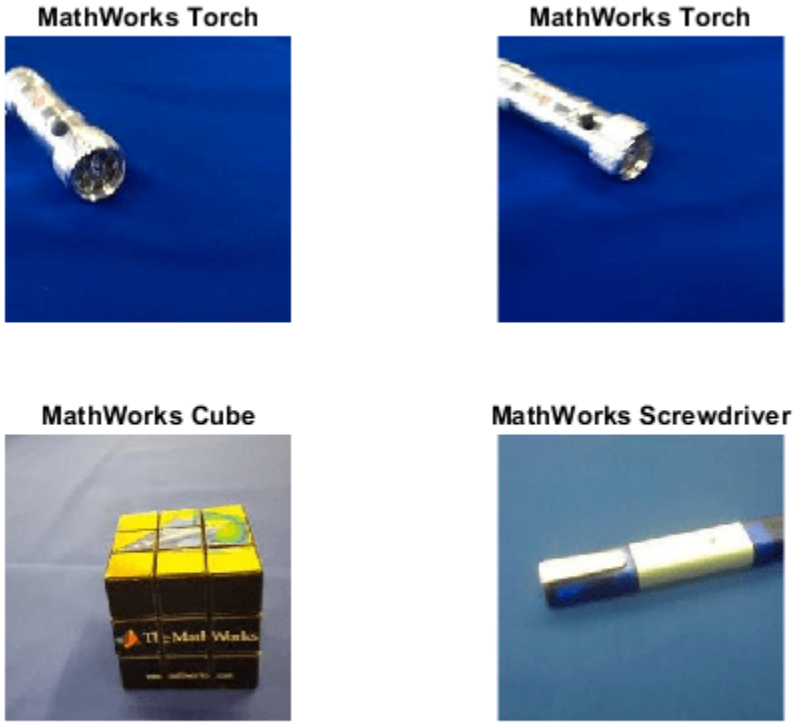
Classify Validation Images

Classify the validation images using the fine-tuned network.

```
[YPred,scores] = classify(netTransfer,augimdsValidation);
```

Display four sample validation images with their predicted labels.

```
idx = randperm(numel(imdsValidation.Files),4);
figure
for i = 1:4
    subplot(2,2,i)
    I = readimage(imdsValidation,idx(i));
    imshow(I)
    label = YPred(idx(i));
    title(string(label));
end
```



Calculate the classification accuracy on the validation set. Accuracy is the fraction of labels that the network predicts correctly.

```
YValidation = imdsValidation.Labels;
accuracy = mean(YPred == YValidation)
```

```
accuracy = 1
```

For tips on improving classification accuracy, see “Deep Learning Tips and Tricks” on page 1-67.

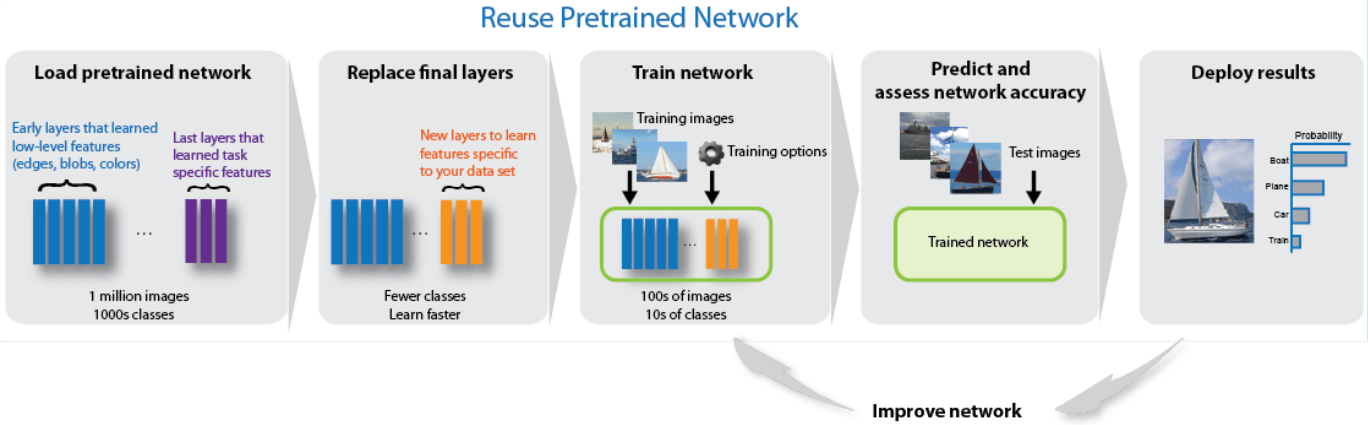
Transfer Learning Using AlexNet

This example shows how to fine-tune a pretrained AlexNet convolutional neural network to perform classification on a new collection of images.

AlexNet has been trained on over a million images and can classify images into 1000 object categories (such as keyboard, coffee mug, pencil, and many animals). The network has learned rich feature representations for a wide range of images. The network takes an image as input and outputs a label for the object in the image together with the probabilities for each of the object categories.

Transfer learning is commonly used in deep learning applications. You can take a pretrained network and use it as a starting point to learn a new task. Fine-tuning a network with transfer learning is usually much faster and easier than training a network with randomly initialized weights from scratch. You can quickly transfer learned features to a new task using a smaller number of training images.



Load Data

Unzip and load the new images as an image datastore. `imageDatastore` automatically labels the images based on folder names and stores the data as an `ImageDatastore` object. An image datastore enables you to store large image data, including data that does not fit in memory, and efficiently read batches of images during training of a convolutional neural network.

```
unzip('MerchData.zip');
imds = imageDatastore('MerchData', ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');
```

Divide the data into training and validation data sets. Use 70% of the images for training and 30% for validation. `splitEachLabel` splits the `images` datastore into two new datastores.

```
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.7,'randomized');
```

This very small data set now contains 55 training images and 20 validation images. Display some sample images.

```
numTrainImages = numel(imdsTrain.Labels);
idx = randperm(numTrainImages,16);
figure
for i = 1:16
```

```
    subplot(4,4,i)
    I = readimage(imdsTrain,idx(i));
    imshow(I)
end
```

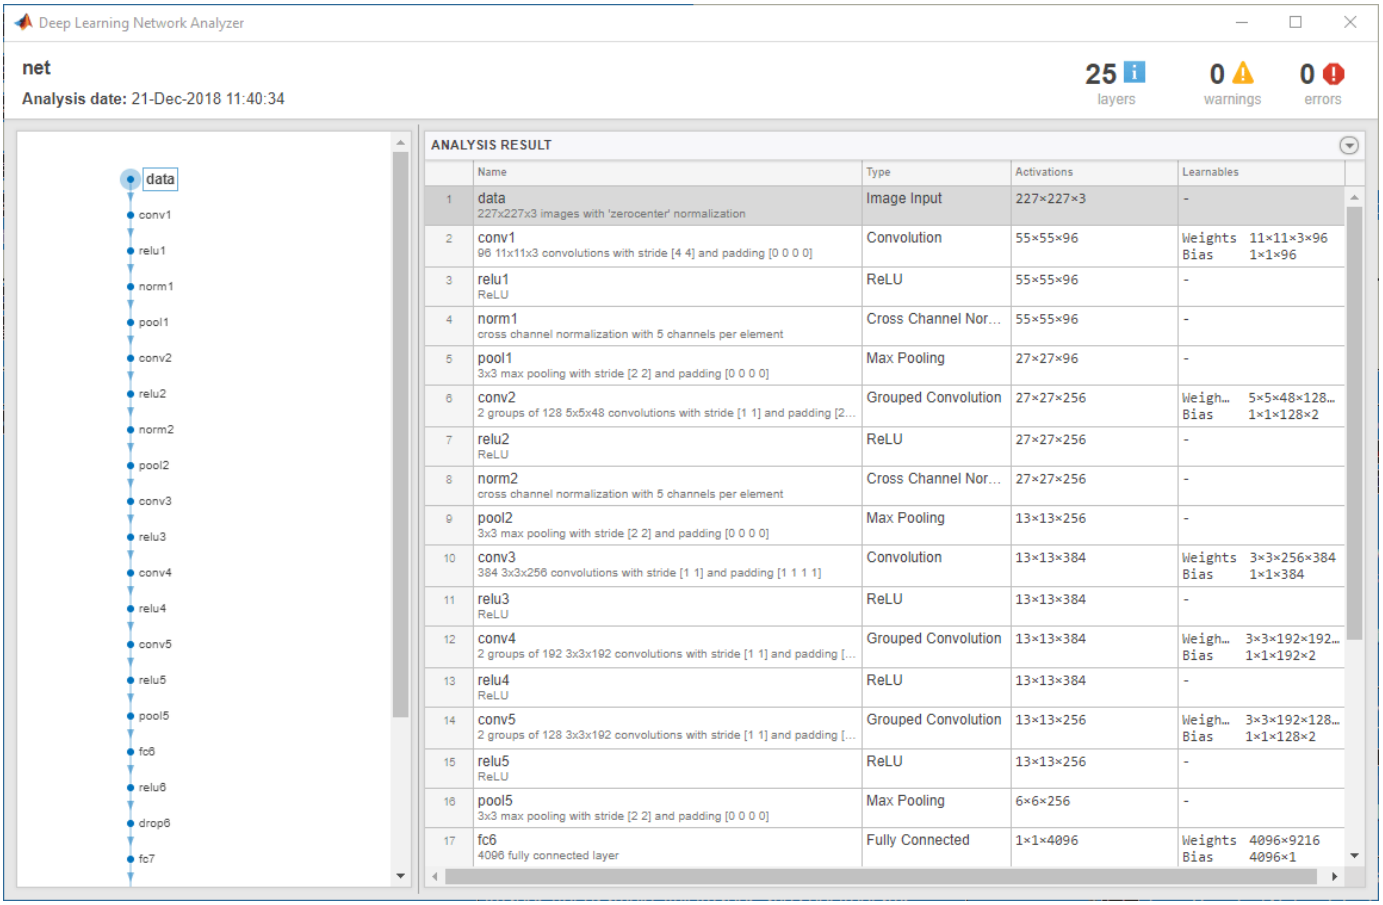
Load Pretrained Network

Load the pretrained AlexNet neural network. If Deep Learning Toolbox™ Model *for AlexNet Network* is not installed, then the software provides a download link. AlexNet is trained on more than one million images and can classify images into 1000 object categories, such as keyboard, mouse, pencil, and many animals. As a result, the model has learned rich feature representations for a wide range of images.

```
net = alexnet;
```

Use `analyzeNetwork` to display an interactive visualization of the network architecture and detailed information about the network layers.

```
analyzeNetwork(net)
```



The first layer, the image input layer, requires input images of size 227-by-227-by-3, where 3 is the number of color channels.

```
inputSize = net.Layers(1).InputSize
```

```
inputSize = 1×3

   227   227     3
```

Replace Final Layers

The last three layers of the pretrained network `net` are configured for 1000 classes. These three layers must be fine-tuned for the new classification problem. Extract all layers, except the last three, from the pretrained network.

```
layersTransfer = net.Layers(1:end-3);
```

Transfer the layers to the new classification task by replacing the last three layers with a fully connected layer, a softmax layer, and a classification output layer. Specify the options of the new fully connected layer according to the new data. Set the fully connected layer to have the same size as the number of classes in the new data. To learn faster in the new layers than in the transferred layers, increase the `WeightLearnRateFactor` and `BiasLearnRateFactor` values of the fully connected layer.

```
numClasses = numel(categories(imdsTrain.Labels))
```

```
numClasses = 5

layers = [
    layersTransfer
    fullyConnectedLayer(numClasses,'WeightLearnRateFactor',20,'BiasLearnRateFactor',20)
    softmaxLayer
    classificationLayer];
```

Train Network

The network requires input images of size 227-by-227-by-3, but the images in the image datastores have different sizes. Use an augmented image datastore to automatically resize the training images. Specify additional augmentation operations to perform on the training images: randomly flip the training images along the vertical axis, and randomly translate them up to 30 pixels horizontally and vertically. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
pixelRange = [-30 30];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain, ...
    'DataAugmentation',imageAugmenter);
```

To automatically resize the validation images without performing further data augmentation, use an augmented image datastore without specifying any additional preprocessing operations.

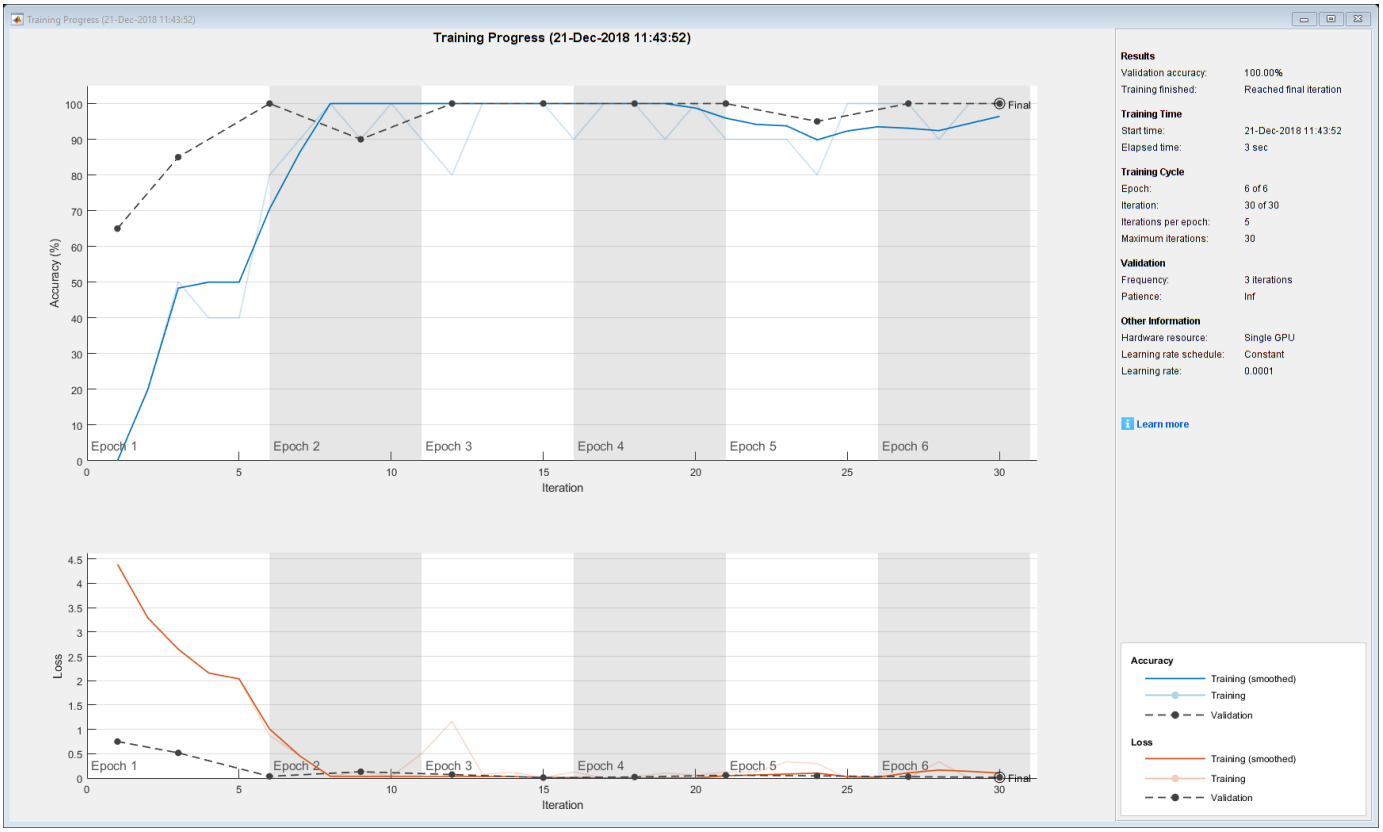
```
augimdsValidation = augmentedImageDatastore(inputSize(1:2),imdsValidation);
```

Specify the training options. For transfer learning, keep the features from the early layers of the pretrained network (the transferred layer weights). To slow down learning in the transferred layers, set the initial learning rate to a small value. In the previous step, you increased the learning rate factors for the fully connected layer to speed up learning in the new final layers. This combination of learning rate settings results in fast learning only in the new layers and slower learning in the other layers. When performing transfer learning, you do not need to train for as many epochs. An epoch is a full training cycle on the entire training data set. Specify the mini-batch size and validation data. The software validates the network every `ValidationFrequency` iterations during training.

```
options = trainingOptions('sgdm', ...
    'MiniBatchSize',10, ...
    'MaxEpochs',6, ...
    'InitialLearnRate',1e-4, ...
    'Shuffle','every-epoch', ...
    'ValidationData',augimdsValidation, ...
    'ValidationFrequency',3, ...
    'Verbose',false, ...
    'Plots','training-progress');
```

Train the network that consists of the transferred and new layers. By default, `trainNetwork` uses a GPU if one is available, otherwise, it uses a CPU. Training on a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`.

```
netTransfer = trainNetwork(augimdsTrain,layers,options);
```



Classify Validation Images

Classify the validation images using the fine-tuned network.

```
[YPred,scores] = classify(netTransfer,augimdsValidation);
```

Display four sample validation images with their predicted labels.

```
idx = randperm(numel(imdsValidation.Files),4);
figure
for i = 1:4
    subplot(2,2,i)
    I = readimage(imdsValidation,idx(i));
    imshow(I)
    label = YPred(idx(i));
    title(string(label));
end
```

Calculate the classification accuracy on the validation set. Accuracy is the fraction of labels that the network predicts correctly.

```
YValidation = imdsValidation.Labels;
accuracy = mean(YPred == YValidation)
```

```
accuracy = 1
```

For tips on improving classification accuracy, see “Deep Learning Tips and Tricks” on page 1-67.

Create Simple Deep Learning Network for Classification

This example shows how to create and train a simple convolutional neural network for deep learning classification. Convolutional neural networks are essential tools for deep learning, and are especially suited for image recognition.

The example demonstrates how to:

- Load and explore image data.
- Define the network architecture.
- Specify training options.
- Train the network.
- Predict the labels of new data and calculate the classification accuracy.

For an example showing how to interactively create and train a simple image classification network, see “Create Simple Image Classification Network Using Deep Network Designer”.

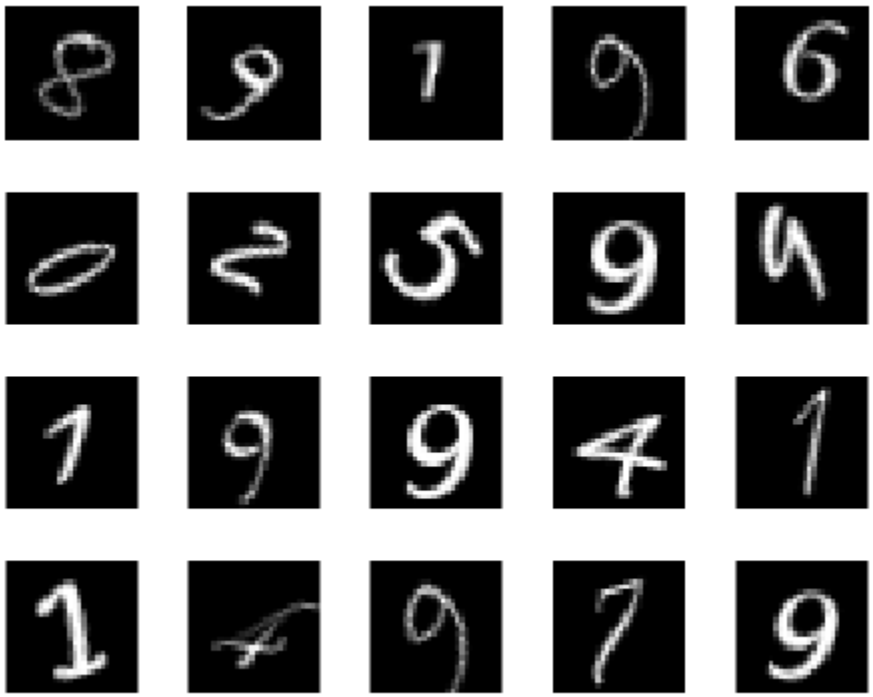
Load and Explore Image Data

Load the digit sample data as an image datastore. `imageDatastore` automatically labels the images based on folder names and stores the data as an `ImageDatastore` object. An image datastore enables you to store large image data, including data that does not fit in memory, and efficiently read batches of images during training of a convolutional neural network.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet','nndemos', ...
    'nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true,'LabelSource','foldernames');
```

Display some of the images in the datastore.

```
figure;
perm = randperm(10000,20);
for i = 1:20
    subplot(4,5,i);
    imshow(imds.Files{perm(i)});
end
```



Calculate the number of images in each category. `labelCount` is a table that contains the labels and the number of images having each label. The datastore contains 1000 images for each of the digits 0-9, for a total of 10000 images. You can specify the number of classes in the last fully connected layer of your network as the `OutputSize` argument.

```
labelCount = countEachLabel(imds)
```

```
labelCount=10×2 table
    Label    Count
    _____    _____

      0      1000
      1      1000
      2      1000
      3      1000
      4      1000
      5      1000
      6      1000
      7      1000
      8      1000
      9      1000
```

You must specify the size of the images in the input layer of the network. Check the size of the first image in `digitData`. Each image is 28-by-28-by-1 pixels.

```
img = readimage(imds,1);
size(img)
```

```
ans = 1×2

    28    28
```

Specify Training and Validation Sets

Divide the data into training and validation data sets, so that each category in the training set contains 750 images, and the validation set contains the remaining images from each label. `splitEachLabel` splits the datastore `digitData` into two new datastores, `trainDigitData` and `valDigitData`.

```
numTrainFiles = 750;
[imdsTrain,imdsValidation] = splitEachLabel(imds,numTrainFiles,'randomize');
```

Define Network Architecture

Define the convolutional neural network architecture.

```
layers = [
    imageInputLayer([28 28 1])

    convolution2dLayer(3,8,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,16,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,32,'Padding','same')
    batchNormalizationLayer
    reluLayer

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer];
```

Image Input Layer An `imageInputLayer` is where you specify the image size, which, in this case, is 28-by-28-by-1. These numbers correspond to the height, width, and the channel size. The digit data consists of grayscale images, so the channel size (color channel) is 1. For a color image, the channel size is 3, corresponding to the RGB values. You do not need to shuffle the data because `trainNetwork`, by default, shuffles the data at the beginning of training. `trainNetwork` can also automatically shuffle the data at the beginning of every epoch during training.

Convolutional Layer In the convolutional layer, the first argument is `filterSize`, which is the height and width of the filters the training function uses while scanning along the images. In this example, the number 3 indicates that the filter size is 3-by-3. You can specify different sizes for the height and width of the filter. The second argument is the number of filters, `numFilters`, which is the number of neurons that connect to the same region of the input. This parameter determines the number of feature maps. Use the `'Padding'` name-value pair to add padding to the input feature map. For a convolutional layer with a default stride of 1, `'same'` padding ensures that the spatial

output size is the same as the input size. You can also define the stride and learning rates for this layer using name-value pair arguments of `convolution2dLayer`.

Batch Normalization Layer Batch normalization layers normalize the activations and gradients propagating through a network, making network training an easier optimization problem. Use batch normalization layers between convolutional layers and nonlinearities, such as ReLU layers, to speed up network training and reduce the sensitivity to network initialization. Use `batchNormalizationLayer` to create a batch normalization layer.

ReLU Layer The batch normalization layer is followed by a nonlinear activation function. The most common activation function is the rectified linear unit (ReLU). Use `reluLayer` to create a ReLU layer.

Max Pooling Layer Convolutional layers (with activation functions) are sometimes followed by a down-sampling operation that reduces the spatial size of the feature map and removes redundant spatial information. Down-sampling makes it possible to increase the number of filters in deeper convolutional layers without increasing the required amount of computation per layer. One way of down-sampling is using a max pooling, which you create using `maxPooling2dLayer`. The max pooling layer returns the maximum values of rectangular regions of inputs, specified by the first argument, `poolSize`. In this example, the size of the rectangular region is [2,2]. The `'Stride'` name-value pair argument specifies the step size that the training function takes as it scans along the input.

Fully Connected Layer The convolutional and down-sampling layers are followed by one or more fully connected layers. As its name suggests, a fully connected layer is a layer in which the neurons connect to all the neurons in the preceding layer. This layer combines all the features learned by the previous layers across the image to identify the larger patterns. The last fully connected layer combines the features to classify the images. Therefore, the `OutputSize` parameter in the last fully connected layer is equal to the number of classes in the target data. In this example, the output size is 10, corresponding to the 10 classes. Use `fullyConnectedLayer` to create a fully connected layer.

Softmax Layer The softmax activation function normalizes the output of the fully connected layer. The output of the softmax layer consists of positive numbers that sum to one, which can then be used as classification probabilities by the classification layer. Create a softmax layer using the `softmaxLayer` function after the last fully connected layer.

Classification Layer The final layer is the classification layer. This layer uses the probabilities returned by the softmax activation function for each input to assign the input to one of the mutually exclusive classes and compute the loss. To create a classification layer, use `classificationLayer`.

Specify Training Options

After defining the network structure, specify the training options. Train the network using stochastic gradient descent with momentum (SGDM) with an initial learning rate of 0.01. Set the maximum number of epochs to 4. An epoch is a full training cycle on the entire training data set. Monitor the network accuracy during training by specifying validation data and validation frequency. Shuffle the data every epoch. The software trains the network on the training data and calculates the accuracy on the validation data at regular intervals during training. The validation data is not used to update the network weights. Turn on the training progress plot, and turn off the command window output.

```
options = trainingOptions('sgdm', ...
    'InitialLearnRate',0.01, ...
    'MaxEpochs',4, ...
    'Shuffle','every-epoch', ...
```

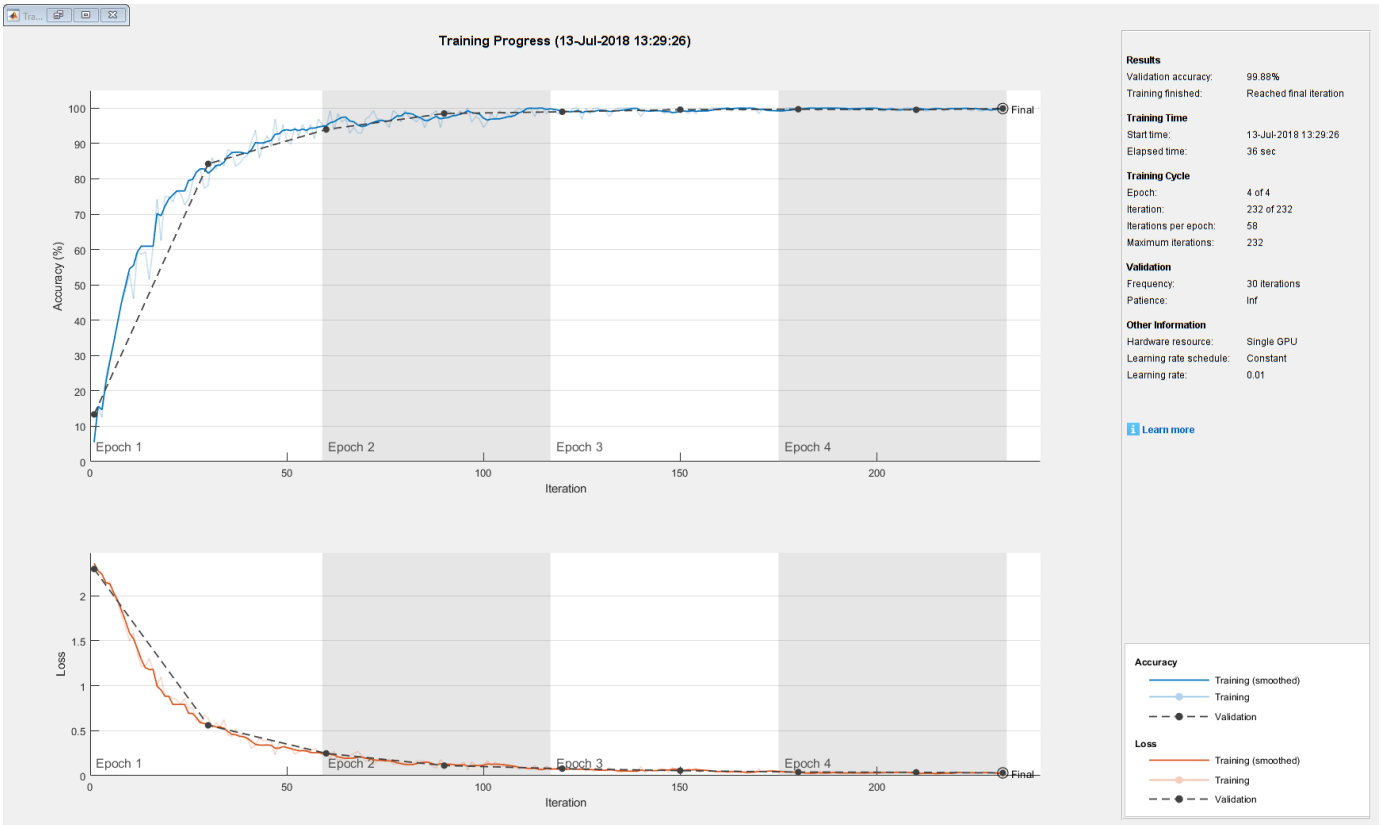
```
    'ValidationData',imdsValidation, ...
    'ValidationFrequency',30, ...
    'Verbose',false, ...
    'Plots','training-progress');
```

Train Network Using Training Data

Train the network using the architecture defined by `layers`, the training data, and the training options. By default, `trainNetwork` uses a GPU if one is available, otherwise, it uses a CPU. Training on a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see "GPU Support by Release" (Parallel Computing Toolbox). You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`.

The training progress plot shows the mini-batch loss and accuracy and the validation loss and accuracy. For more information on the training progress plot, see "Monitor Deep Learning Training Progress" on page 5-115. The loss is the cross-entropy loss. The accuracy is the percentage of images that the network classifies correctly.

```
net = trainNetwork(imdsTrain,layers,options);
```



Classify Validation Images and Compute Accuracy

Predict the labels of the validation data using the trained network, and calculate the final validation accuracy. Accuracy is the fraction of labels that the network predicts correctly. In this case, more than 99% of the predicted labels match the true labels of the validation set.

```
YPred = classify(net,imdsValidation);
YValidation = imdsValidation.Labels;

accuracy = sum(YPred == YValidation)/numel(YValidation)
```

```
accuracy = 0.9988
```

Train Convolutional Neural Network for Regression

This example shows how to fit a regression model using convolutional neural networks to predict the angles of rotation of handwritten digits.

Convolutional neural networks (CNNs, or ConvNets) are essential tools for deep learning, and are especially suited for analyzing image data. For example, you can use CNNs to classify images. To predict continuous data, such as angles and distances, you can include a regression layer at the end of the network.

The example constructs a convolutional neural network architecture, trains a network, and uses the trained network to predict angles of rotated handwritten digits. These predictions are useful for optical character recognition.

Optionally, you can use `imrotate` (Image Processing Toolbox™) to rotate the images, and `boxplot` (Statistics and Machine Learning Toolbox™) to create a residual box plot.

Load Data

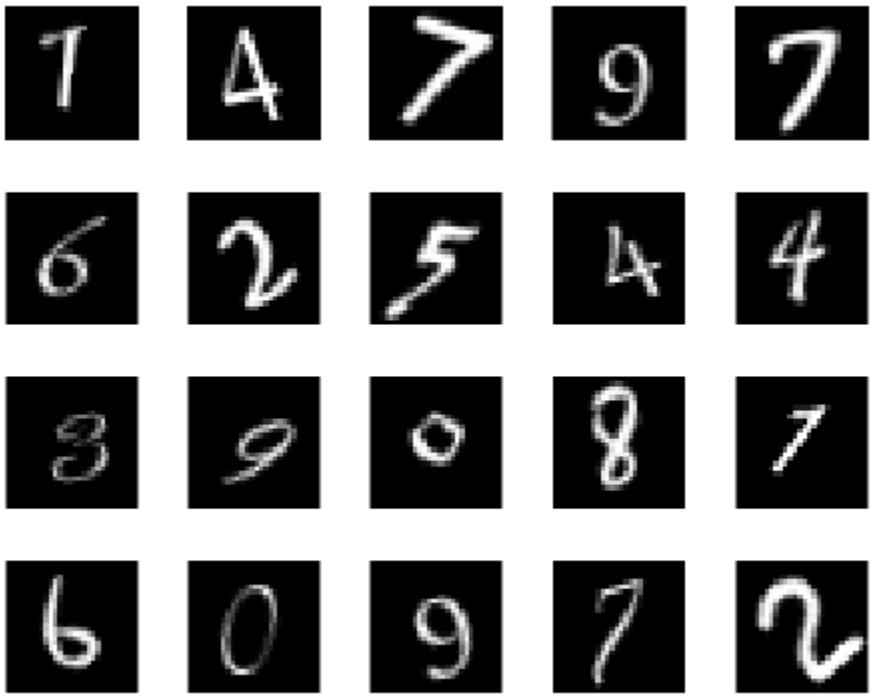
The data set contains synthetic images of handwritten digits together with the corresponding angles (in degrees) by which each image is rotated.

Load the training and validation images as 4-D arrays using `digitTrain4DArrayData` and `digitTest4DArrayData`. The outputs `YTrain` and `YValidation` are the rotation angles in degrees. The training and validation data sets each contain 5000 images.

```
[XTrain,~,YTrain] = digitTrain4DArrayData;
[XValidation,~,YValidation] = digitTest4DArrayData;
```

Display 20 random training images using `imshow`.

```
numTrainImages = numel(YTrain);
figure
idx = randperm(numTrainImages,20);
for i = 1:numel(idx)
    subplot(4,5,i)
    imshow(XTrain(:,:,:,idx(i)))
end
```



Check Data Normalization

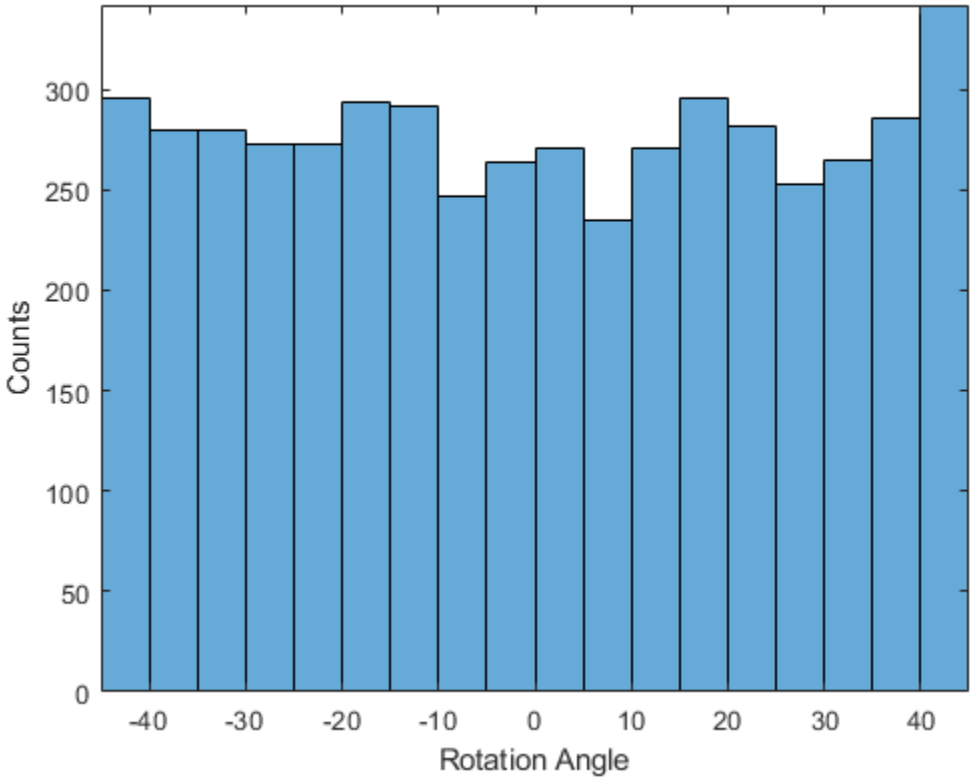
When training neural networks, it often helps to make sure that your data is normalized in all stages of the network. Normalization helps stabilize and speed up network training using gradient descent. If your data is poorly scaled, then the loss can become `NaN` and the network parameters can diverge during training. Common ways of normalizing data include rescaling the data so that its range becomes [0,1] or so that it has a mean of zero and standard deviation of one. You can normalize the following data:

- Input data. Normalize the predictors before you input them to the network. In this example, the input images are already normalized to the range [0,1].
- Layer outputs. You can normalize the outputs of each convolutional and fully connected layer by using a batch normalization layer.
- Responses. If you use batch normalization layers to normalize the layer outputs in the end of the network, then the predictions of the network are normalized when training starts. If the response has a very different scale from these predictions, then network training can fail to converge. If your response is poorly scaled, then try normalizing it and see if network training improves. If you normalize the response before training, then you must transform the predictions of the trained network to obtain the predictions of the original response.

Plot the distribution of the response. The response (the rotation angle in degrees) is approximately uniformly distributed between -45 and 45, which works well without needing normalization. In classification problems, the outputs are class probabilities, which are always normalized.

```
figure
histogram(YTrain)
```

```
axis tight
ylabel('Counts')
xlabel('Rotation Angle')
```



In general, the data does not have to be exactly normalized. However, if you train the network in this example to predict `100*YTrain` or `YTrain+500` instead of `YTrain`, then the loss becomes `NaN` and the network parameters diverge when training starts. These results occur even though the only difference between a network predicting $aY + b$ and a network predicting Y is a simple rescaling of the weights and biases of the final fully connected layer.

If the distribution of the input or response is very uneven or skewed, you can also perform nonlinear transformations (for example, taking logarithms) to the data before training the network.

Create Network Layers

To solve the regression problem, create the layers of the network and include a regression layer at the end of the network.

The first layer defines the size and type of the input data. The input images are 28-by-28-by-1. Create an image input layer of the same size as the training images.

The middle layers of the network define the core architecture of the network, where most of the computation and learning take place.

The final layers define the size and type of output data. For regression problems, a fully connected layer must precede the regression layer at the end of the network. Create a fully connected output layer of size 1 and a regression layer.

Combine all the layers together in a `Layer` array.

```
layers = [
    imageInputLayer([28 28 1])
    convolution2dLayer(3,8,'Padding','same')
    batchNormalizationLayer
    reluLayer
    averagePooling2dLayer(2,'Stride',2)
    convolution2dLayer(3,16,'Padding','same')
    batchNormalizationLayer
    reluLayer
    averagePooling2dLayer(2,'Stride',2)
    convolution2dLayer(3,32,'Padding','same')
    batchNormalizationLayer
    reluLayer
    convolution2dLayer(3,32,'Padding','same')
    batchNormalizationLayer
    reluLayer
    dropoutLayer(0.2)
    fullyConnectedLayer(1)
    regressionLayer];
```

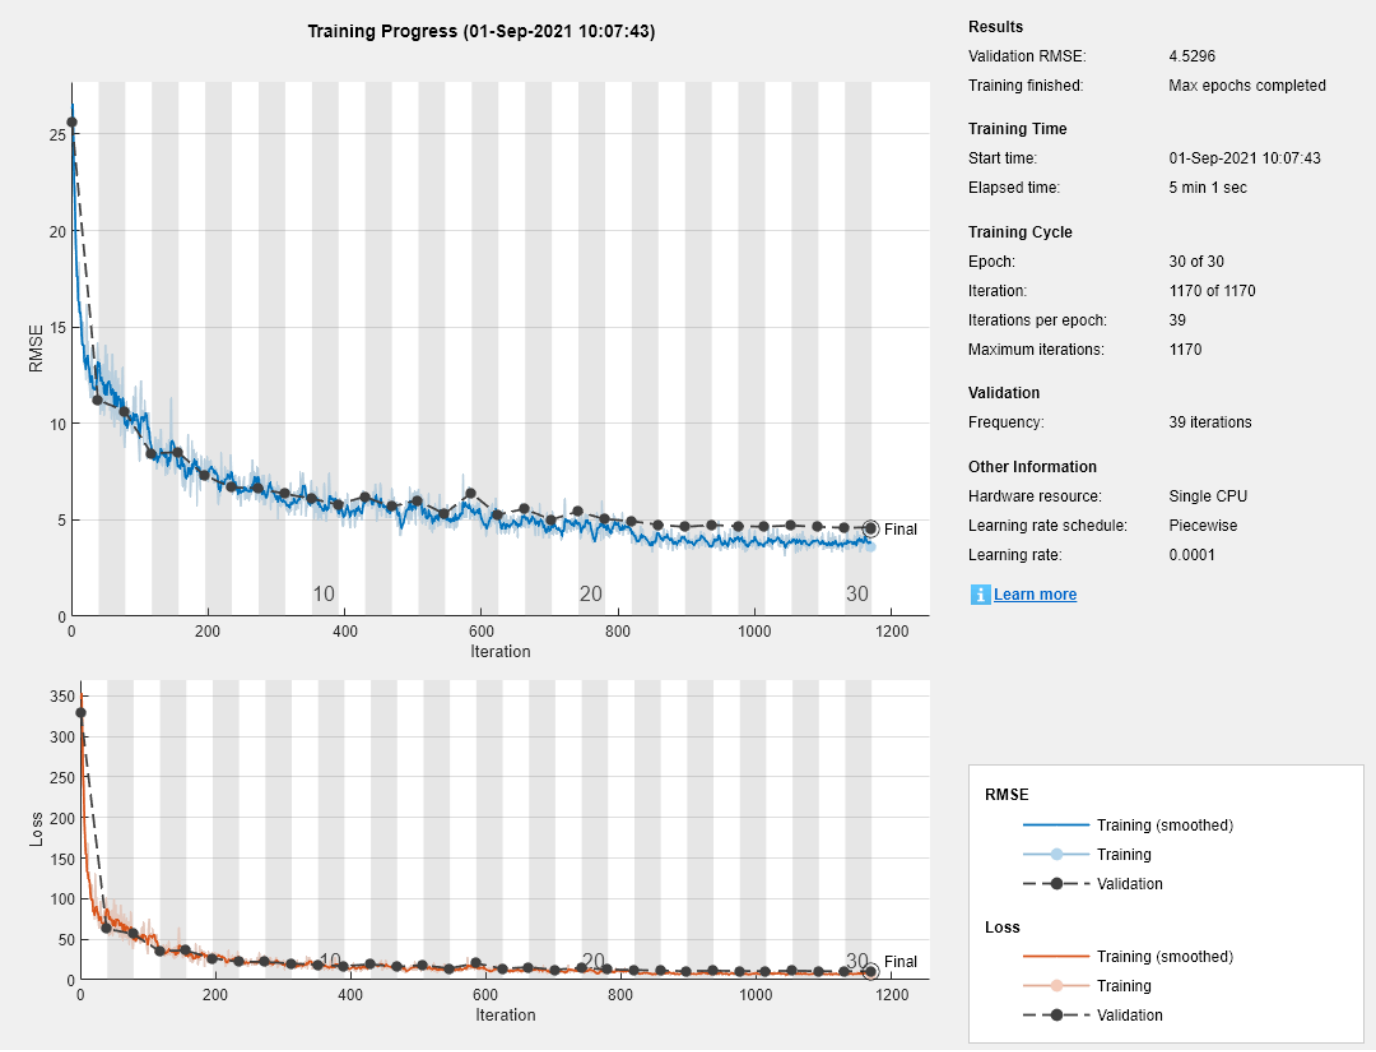
Train Network

Create the network training options. Train for 30 epochs. Set the initial learn rate to 0.001 and lower the learning rate after 20 epochs. Monitor the network accuracy during training by specifying validation data and validation frequency. The software trains the network on the training data and calculates the accuracy on the validation data at regular intervals during training. The validation data is not used to update the network weights. Turn on the training progress plot, and turn off the command window output.

```
miniBatchSize  = 128;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
options = trainingOptions('sgdm', ...
    'MiniBatchSize',miniBatchSize, ...
    'MaxEpochs',30, ...
    'InitialLearnRate',1e-3, ...
    'LearnRateSchedule','piecewise', ...
    'LearnRateDropFactor',0.1, ...
    'LearnRateDropPeriod',20, ...
    'Shuffle','every-epoch', ...
    'ValidationData',{XValidation,YValidation}, ...
    'ValidationFrequency',validationFrequency, ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Create the network using `trainNetwork`. This command uses a compatible GPU if available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Otherwise, `trainNetwork` uses the CPU.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```



Examine the details of the network architecture contained in the `Layers` property of `net`.

```
net.Layers
```

```
ans =
  18x1 Layer array with layers:

    13   'conv_4'            Convolution           32 3x3x32 convolutions with stride [1  1] and
```

```
    14   'batchnorm_4'        Batch Normalization   Batch normalization with 32 channels
    15   'relu_4'             ReLU                  ReLU
    16   'dropout'            Dropout               20% dropout
    17   'fc'                 Fully Connected       1 fully connected layer
    18   'regressionoutput'   Regression Output     mean-squared-error with response 'Response'
```

Test Network

Test the performance of the network by evaluating the accuracy on the validation data.

Use `predict` to predict the angles of rotation of the validation images.

```
YPredicted = predict(net,XValidation);
```

Evaluate Performance

Evaluate the performance of the model by calculating:

1. The percentage of predictions within an acceptable error margin
2. The root-mean-square error (RMSE) of the predicted and actual angles of rotation

Calculate the prediction error between the predicted and actual angles of rotation.

```
predictionError = YValidation - YPredicted;
```

Calculate the number of predictions within an acceptable error margin from the true angles. Set the threshold to be 10 degrees. Calculate the percentage of predictions within this threshold.

```
thr = 10;
numCorrect = sum(abs(predictionError) < thr);
numValidationImages = numel(YValidation);

accuracy = numCorrect/numValidationImages
```

```
accuracy = 0.9700
```

Use the root-mean-square error (RMSE) to measure the differences between the predicted and actual angles of rotation.

```
squares = predictionError.^2;
rmse = sqrt(mean(squares))
```

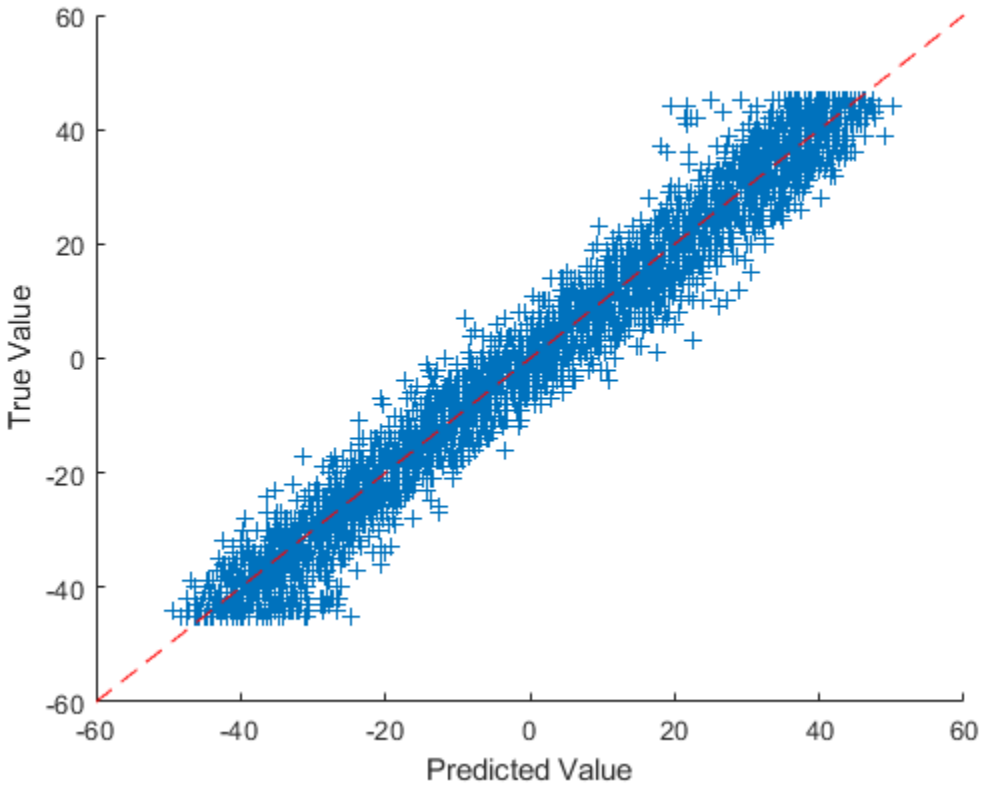
```
rmse = single
    4.5296
```

Visualize Predictions

Visualize the predictions in a scatter plot. Plot the predicted values against the true values.

```
figure
scatter(YPredicted,YValidation,'+')
xlabel("Predicted Value")
ylabel("True Value")

hold on
plot([-60 60], [-60 60],'r--')
```



Correct Digit Rotations

You can use functions from Image Processing Toolbox to straighten the digits and display them together. Rotate 49 sample digits according to their predicted angles of rotation using `imrotate` (Image Processing Toolbox).

```
idx = randperm(numValidationImages,49);
for i = 1:numel(idx)
    image = XValidation(:,:,:,idx(i));
    predictedAngle = YPredicted(idx(i));
    imagesRotated(:,:,:,i) = imrotate(image,predictedAngle,'bicubic','crop');
end
```

Display the original digits with their corrected rotations. You can use `montage` (Image Processing Toolbox) to display the digits together in a single image.

```
figure
subplot(1,2,1)
montage(XValidation(:,:,:,idx))
title('Original')

subplot(1,2,2)
montage(imagesRotated)
title('Corrected')
```

Train Network with Multiple Outputs

This example shows how to train a deep learning network with multiple outputs that predict both labels and angles of rotations of handwritten digits.

To train a network with multiple outputs, you must train the network using a custom training loop.

Load Training Data

The `digitTrain4DArrayData` function loads the images, their digit labels, and their angles of rotation from the vertical. Create an `arrayDatastore` object for the images, labels, and the angles, and then use the `combine` function to make a single datastore that contains all of the training data. Extract the class names and number of nondiscrete responses.

```
[XTrain,YTrain,anglesTrain] = digitTrain4DArrayData;

dsXTrain = arrayDatastore(XTrain,'IterationDimension',4);
dsYTrain = arrayDatastore(YTrain);
dsAnglesTrain = arrayDatastore(anglesTrain);

dsTrain = combine(dsXTrain,dsYTrain,dsAnglesTrain);

classNames = categories(YTrain);
numClasses = numel(classNames);
numObservations = numel(YTrain);
```

View some images from the training data.

```
idx = randperm(numObservations,64);
I = imtile(XTrain(:,:,:,idx));
figure
imshow(I)
```

Define Deep Learning Model

Define the following network that predicts both labels and angles of rotation.

- A convolution-batchnorm-ReLU block with 16 5-by-5 filters.
- Two convolution-batchnorm-ReLU blocks each with 32 3-by-3 filters.
- A skip connection around the previous two blocks containing a convolution-batchnorm-ReLU block with 32 1-by-1 convolutions.
- Merge the skip connection using addition.
- For classification output, a branch with a fully connected operation of size 10 (the number of classes) and a softmax operation.
- For the regression output, a branch with a fully connected operation of size 1 (the number of responses).

Define the main block of layers as a layer graph.

```
layers = [
    imageInputLayer([28 28 1],'Normalization','none','Name','in')

    convolution2dLayer(5,16,'Padding','same','Name','conv1')
    batchNormalizationLayer('Name','bn1')
    reluLayer('Name','relu1')

    convolution2dLayer(3,32,'Padding','same','Stride',2,'Name','conv2')
    batchNormalizationLayer('Name','bn2')
    reluLayer('Name','relu2')
    convolution2dLayer(3,32,'Padding','same','Name','conv3')
    batchNormalizationLayer('Name','bn3')
    reluLayer('Name','relu4')

    additionLayer(2,'Name','addition')

    fullyConnectedLayer(numClasses,'Name','fc1')
    softmaxLayer('Name','softmax')];

lgraph = layerGraph(layers);
```

Add the skip connection.

```
layers = [
    convolution2dLayer(1,32,'Stride',2,'Name','convSkip')
    batchNormalizationLayer('Name','bnSkip')
    reluLayer('Name','reluSkip')];

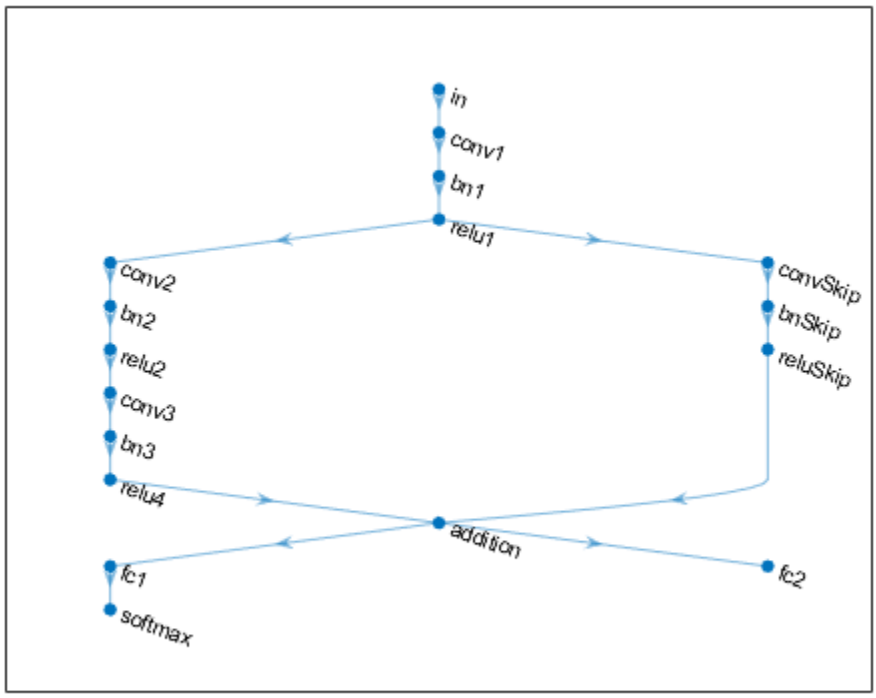
lgraph = addLayers(lgraph,layers);
lgraph = connectLayers(lgraph,'relu1','convSkip');
lgraph = connectLayers(lgraph,'reluSkip','addition/in2');
```

Add the fully connected layer for regression.

```
layers = fullyConnectedLayer(1,'Name','fc2');
lgraph = addLayers(lgraph,layers);
lgraph = connectLayers(lgraph,'addition','fc2');
```

View the layer graph in a plot.

```
figure
plot(lgraph)
```



Create a `dlnetwork` object from the layer graph.

```
dlnet = dlnetwork(lgraph)
```

```
dlnet =
  dlnetwork with properties:

         Layers: [17×1 nnet.cnn.layer.Layer]
    Connections: [17×2 table]
     Learnables: [20×3 table]
          State: [8×3 table]
     InputNames: {'in'}
    OutputNames: {'softmax'  'fc2'}
```

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, that takes as input, the `dlnetwork` object `dlnet`, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

Specify Training Options

Specify the training options. Train for 30 epochs using a mini-batch size of 128.

```
numEpochs = 30;
miniBatchSize = 128;
```

Visualize the training progress in a plot.

```
plots = "training-progress";
```

Train Model

Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to one-hot encode the class labels.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels or angles.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessData,...
    'MiniBatchFormat',{'SSCB','',''});
```

Train the model using a custom training loop. For each epoch, shuffle the data and loop over mini-batches of data. At the end of each iteration, display the training progress. For each mini-batch:

- Evaluate the model gradients and loss using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.

Initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Initialize parameters for Adam.

```
trailingAvg = [];
trailingAvgSq = [];
```

Train the model.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
```

```
        shuffle(mbq)

        % Loop over mini-batches
        while hasdata(mbq)

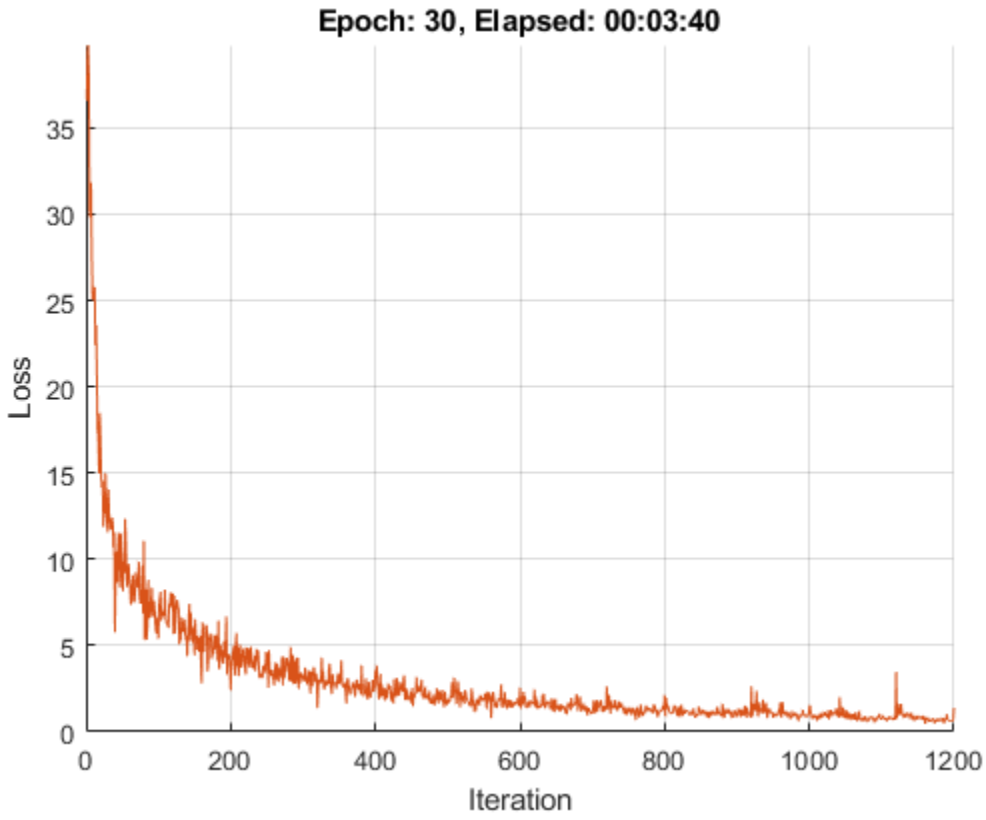
            iteration = iteration + 1;

            [dlX,dlY1,dlY2] = next(mbq);

            % Evaluate the model gradients, state, and loss using dlfeval and the
            % modelGradients function.
            [gradients,state,loss] = dlfeval(@modelGradients, dlnet, dlX, dlY1, dlY2);
            dlnet.State = state;

            % Update the network parameters using the Adam optimizer.
            [dlnet,trailingAvg,trailingAvgSq] = adamupdate(dlnet,gradients, ...
                trailingAvg,trailingAvgSq,iteration);

            % Display the training progress.
            if plots == "training-progress"
                D = duration(0,0,toc(start),'Format','hh:mm:ss');
                addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
                title("Epoch: " + epoch + ", Elapsed: " + string(D))
                drawnow
            end
        end
    end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on a test set with the true labels and angles. Manage the test data set using a `minibatchqueue` object with the same setting as the training data.

```
[XTest,Y1Test,anglesTest] = digitTest4DArrayData;

dsXTest = arrayDatastore(XTest,'IterationDimension',4);
dsYTest = arrayDatastore(Y1Test);
dsAnglesTest = arrayDatastore(anglesTest);

dsTest = combine(dsXTest,dsYTest,dsAnglesTest);

mbqTest = minibatchqueue(dsTest,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessData,...
    'MiniBatchFormat',{'SSCB','',''});
```

To predict the labels and angles of the validation data, loop over the mini-batches and use the `predict` function. Store the predicted classes and angles. Compare the predicted and true classes and angles and store the results.

```
classesPredictions = [];
anglesPredictions = [];
classCorr = [];
angleDiff = [];

% Loop over mini-batches.
while hasdata(mbqTest)

    % Read mini-batch of data.
    [dlXTest,dlY1Test,dlY2Test] = next(mbqTest);

    % Make predictions using the predict function.
    [dlY1Pred,dlY2Pred] = predict(dlnet,dlXTest,'Outputs',["softmax" "fc2"]);

    % Determine predicted classes.
    Y1PredBatch = onehotdecode(dlY1Pred,classNames,1);
    classesPredictions = [classesPredictions Y1PredBatch];

    % Dermine predicted angles
    Y2PredBatch = extractdata(dlY2Pred);
    anglesPredictions = [anglesPredictions Y2PredBatch];

    % Compare predicted and true classes
    Y1Test = onehotdecode(dlY1Test,classNames,1);
    classCorr = [classCorr Y1PredBatch == Y1Test];

    % Compare predicted and true angles
    angleDiffBatch = Y2PredBatch - dlY2Test;
    angleDiff = [angleDiff extractdata(gather(angleDiffBatch))];

end
```

Evaluate the classification accuracy.

```
accuracy = mean(classCorr)
```

```
accuracy = 0.9814
```

Evaluate the regression accuracy.

```
angleRMSE = sqrt(mean(angleDiff.^2))
```

```
angleRMSE = single
    7.7431
```

View some of the images with their predictions. Display the predicted angles in red and the correct labels in green.

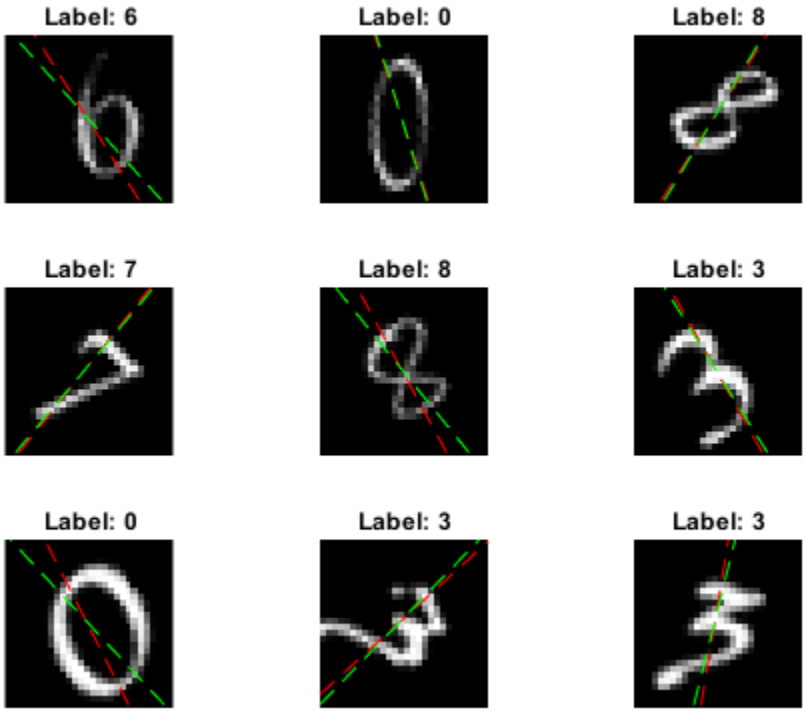
```
idx = randperm(size(XTest,4),9);
figure
for i = 1:9
    subplot(3,3,i)
    I = XTest(:,:,:,idx(i));
    imshow(I)
    hold on

    sz = size(I,1);
    offset = sz/2;

    thetaPred = anglesPredictions(idx(i));
    plot(offset*[1-tand(thetaPred) 1+tand(thetaPred)],[sz 0],'r--')

    thetaValidation = anglesTest(idx(i));
    plot(offset*[1-tand(thetaValidation) 1+tand(thetaValidation)],[sz 0],'g--')

    hold off
    label = string(classesPredictions(idx(i)));
    title("Label: " + label)
end
```



Model Gradients Function

The `modelGradients` function, takes as input, the `dlnetwork` object `dlnet`, a mini-batch of input data `dlX` with corresponding targets `T1` and `T2` containing the labels and angles, respectively, and returns the gradients of the loss with respect to the learnable parameters, the updated network state, and the corresponding loss.

```
function [gradients,state,loss] = modelGradients(dlnet,dlX,T1,T2)

[dlY1,dlY2,state] = forward(dlnet,dlX,'Outputs',["softmax" "fc2"]);

lossLabels = crossentropy(dlY1,T1);
lossAngles = mse(dlY2,T2);

loss = lossLabels + 0.1*lossAngles;
gradients = dlgradient(loss,dlnet.Learnables);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.

2. Extract the label and angle data from the incoming cell arrays and concatenate along the second dimension into a categorical array and a numeric array, respectively.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y,angle] = preprocessData(XCell,YCell,angleCell)

    % Extract image data from cell and concatenate
    X = cat(4,XCell{:});
    % Extract label data from cell and concatenate
    Y = cat(2,YCell{:});
    % Extract angle data from cell and concatenate
    angle = cat(2,angleCell{:});

    % One-hot encode labels
    Y = onehotencode(Y,1);

end
```

Convert Classification Network into Regression Network

This example shows how to convert a trained classification network into a regression network.

Pretrained image classification networks have been trained on over a million images and can classify images into 1000 object categories, such as keyboard, coffee mug, pencil, and many animals. The networks have learned rich feature representations for a wide range of images. The network takes an image as input, and then outputs a label for the object in the image together with the probabilities for each of the object categories.

Transfer learning is commonly used in deep learning applications. You can take a pretrained network and use it as a starting point to learn a new task. This example shows how to take a pretrained classification network and retrain it for regression tasks.

The example loads a pretrained convolutional neural network architecture for classification, replaces the layers for classification and retrains the network to predict angles of rotated handwritten digits. Optionally, you can use `imrotate` (Image Processing Toolbox™) to correct the image rotations using the predicted values.

Load Pretrained Network

Load the pretrained network from the supporting file `digitsNet.mat`. This file contains a classification network that classifies handwritten digits.

```
load digitsNet
layers = net.Layers
```

```
layers =
  15x1 Layer array with layers:

     1   'imageinput'    Image Input             28x28x1 images with 'zerocenter' normalization
     2   'conv_1'        Convolution             8 3x3x1 convolutions with stride [1  1] and pado
     3   'batchnorm_1'   Batch Normalization     Batch normalization with 8 channels
     4   'relu_1'        ReLU                    ReLU
     5   'maxpool_1'     Max Pooling             2x2 max pooling with stride [2  2] and padding
     6   'conv_2'        Convolution             16 3x3x8 convolutions with stride [1  1] and pad
     7   'batchnorm_2'   Batch Normalization     Batch normalization with 16 channels
     8   'relu_2'        ReLU                    ReLU
     9   'maxpool_2'     Max Pooling             2x2 max pooling with stride [2  2] and padding

```

Load Data

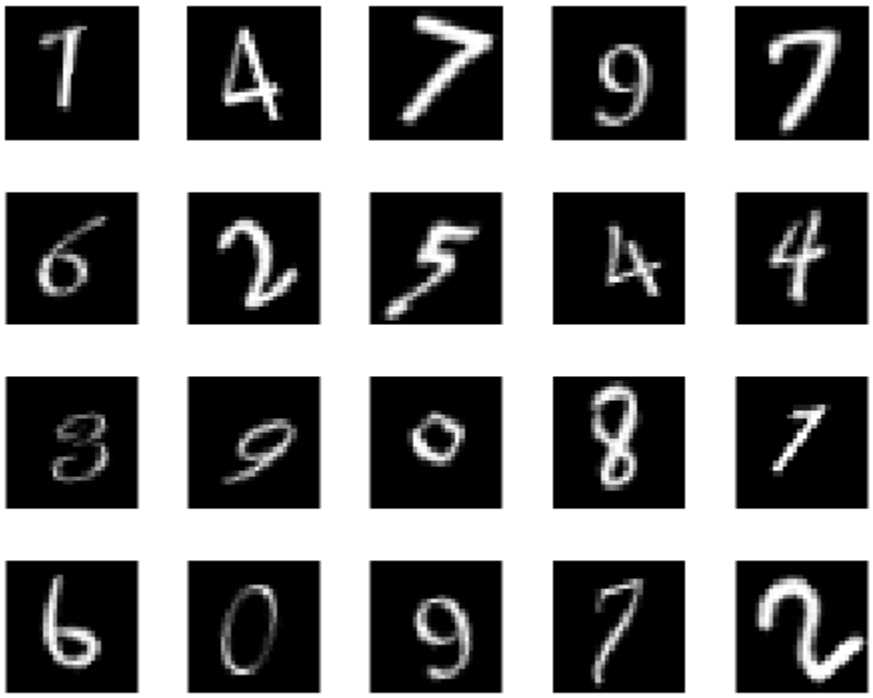
The data set contains synthetic images of handwritten digits together with the corresponding angles (in degrees) by which each image is rotated.

Load the training and validation images as 4-D arrays using `digitTrain4DArrayData` and `digitTest4DArrayData`. The outputs `YTrain` and `YValidation` are the rotation angles in degrees. The training and validation data sets each contain 5000 images.

```
[XTrain,~,YTrain] = digitTrain4DArrayData;
[XValidation,~,YValidation] = digitTest4DArrayData;
```

Display 20 random training images using `imshow`.

```
numTrainImages = numel(YTrain);
figure
idx = randperm(numTrainImages,20);
for i = 1:numel(idx)
    subplot(4,5,i)
    imshow(XTrain(:,:,:,idx(i)))
end
```



Replace Final Layers

The convolutional layers of the network extract image features that the last learnable layer and the final classification layer use to classify the input image. These two layers, `'fc'` and `'classoutput'` in `digitsNet`, contain information on how to combine the features that the network extracts into class probabilities, a loss value, and predicted labels. To retrain a pretrained network for regression, replace these two layers with new layers adapted to the task.

Replace the final fully connected layer, the softmax layer, and the classification output layer with a fully connected layer of size 1 (the number of responses) and a regression layer.

```
numResponses = 1;
layers = [
    layers(1:12)
    fullyConnectedLayer(numResponses)
    regressionLayer];
```

Freeze Initial Layers

The network is now ready to be retrained on the new data. Optionally, you can "freeze" the weights of earlier layers in the network by setting the learning rates in those layers to zero. During training, `trainNetwork` does not update the parameters of the frozen layers. Because the gradients of the frozen layers do not need to be computed, freezing the weights of many initial layers can significantly speed up network training. If the new data set is small, then freezing earlier network layers can also prevent those layers from overfitting to the new data set.

Use the supporting function `freezeWeights` to set the learning rates to zero in the first 12 layers.

```
layers(1:12) = freezeWeights(layers(1:12));
```

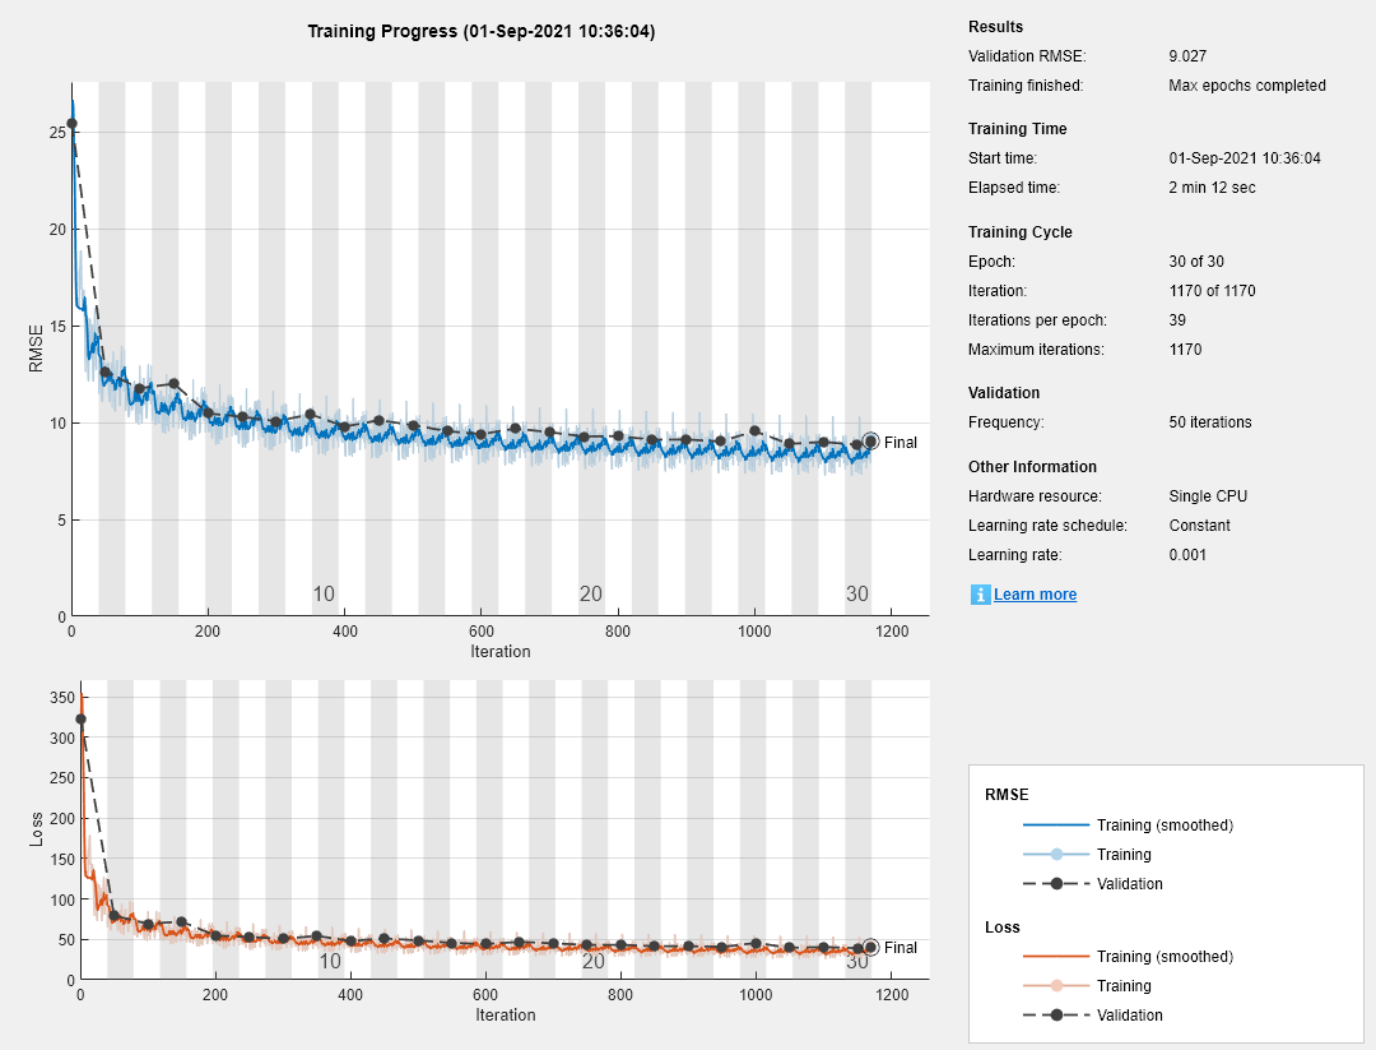
Train Network

Create the network training options. Set the initial learn rate to 0.001. Monitor the network accuracy during training by specifying validation data. Turn on the training progress plot, and turn off the command window output.

```
options = trainingOptions('sgdm',...
    'InitialLearnRate',0.001, ...
    'ValidationData',{XValidation,YValidation},...
    'Plots','training-progress',...
    'Verbose',false);
```

Create the network using `trainNetwork`. This command uses a compatible GPU if available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Otherwise, `trainNetwork` uses the CPU.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```



Test Network

Test the performance of the network by evaluating the accuracy on the validation data.

Use `predict` to predict the angles of rotation of the validation images.

```
YPred = predict(net,XValidation);
```

Evaluate the performance of the model by calculating:

1. The percentage of predictions within an acceptable error margin
2. The root-mean-square error (RMSE) of the predicted and actual angles of rotation

Calculate the prediction error between the predicted and actual angles of rotation.

```
predictionError = YValidation - YPred;
```

Calculate the number of predictions within an acceptable error margin from the true angles. Set the threshold to be 10 degrees. Calculate the percentage of predictions within this threshold.

```
thr = 10;
numCorrect = sum(abs(predictionError) < thr);
numImagesValidation = numel(YValidation);

accuracy = numCorrect/numImagesValidation
```

```
accuracy = 0.7532
```

Use the root-mean-square error (RMSE) to measure the differences between the predicted and actual angles of rotation.

```
 rmse = sqrt(mean(predictionError.^2))
```

```
rmse = single
    9.0271
```

Correct Digit Rotations

You can use functions from Image Processing Toolbox to straighten the digits and display them together. Rotate 49 sample digits according to their predicted angles of rotation using `imrotate` (Image Processing Toolbox).

```
idx = randperm(numImagesValidation,49);
for i = 1:numel(idx)
    I = XValidation(:,:,:,idx(i));
    Y = YPred(idx(i));
    XValidationCorrected(:,:,:,i) = imrotate(I,Y,'bicubic','crop');
end
```

Display the original digits with their corrected rotations. Use `montage` (Image Processing Toolbox) to display the digits together in a single image.

```
figure
subplot(1,2,1)
montage(XValidation(:,:,:,idx))
title('Original')

subplot(1,2,2)
montage(XValidationCorrected)
title('Corrected')
```

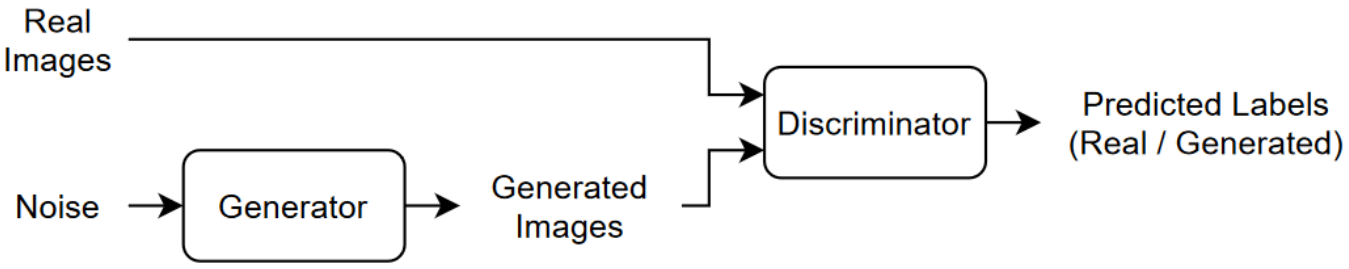
Train Generative Adversarial Network (GAN)

This example shows how to train a generative adversarial network to generate images.

A generative adversarial network (GAN) is a type of deep learning network that can generate data with similar characteristics as the input real data.

A GAN consists of two networks that train together:

1. Generator — Given a vector of random values (latent inputs) as input, this network generates data with the same structure as the training data.
2. Discriminator — Given batches of data containing observations from both the training data, and generated data from the generator, this network attempts to classify the observations as `"real"` or `"generated"`.



To train a GAN, train both networks simultaneously to maximize the performance of both:

- Train the generator to generate data that "fools" the discriminator.
- Train the discriminator to distinguish between real and generated data.

To optimize the performance of the generator, maximize the loss of the discriminator when given generated data. That is, the objective of the generator is to generate data that the discriminator classifies as `"real"`.

To optimize the performance of the discriminator, minimize the loss of the discriminator when given batches of both real and generated data. That is, the objective of the discriminator is to not be "fooled" by the generator.

Ideally, these strategies result in a generator that generates convincingly realistic data and a discriminator that has learned strong feature representations that are characteristic of the training data.

Load Training Data

Download and extract the Flowers data set [1].

```
url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");

imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
    disp("Downloading Flowers data set (218 MB)...")
    websave(filename,url);
```

```
    untar(filename,downloadFolder)
end
```

Create an image datastore containing the photos of the flowers.

```
datasetFolder = fullfile(imageFolder);

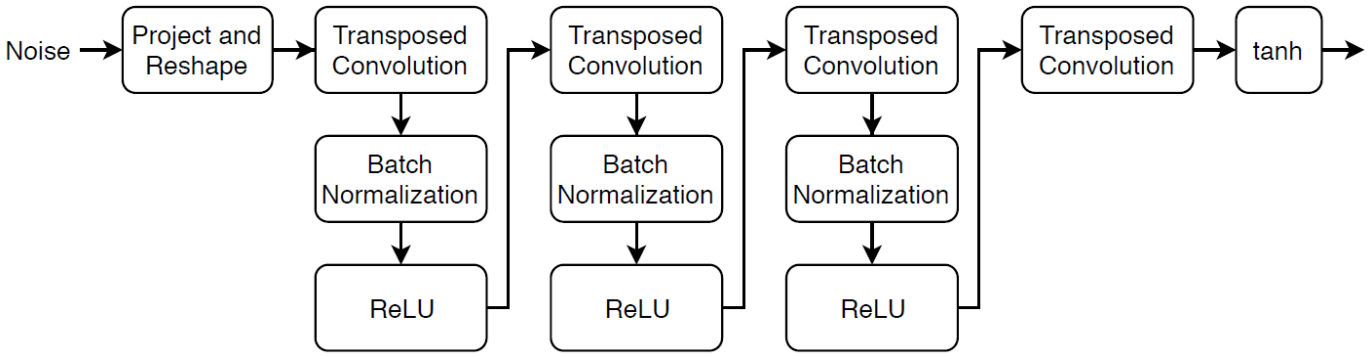
imds = imageDatastore(datasetFolder,IncludeSubfolders=true);
```

Augment the data to include random horizontal flipping and resize the images to have size 64-by-64.

```
augmenter = imageDataAugmenter(RandXReflection=true);
augimds = augmentedImageDatastore([64 64],imds,DataAugmentation=augmenter);
```

Define Generator Network

Define the following network architecture, which generates images from random vectors of size 100.



This network:

- Converts the random vectors of size 100 to 7-by-7-by-128 arrays using a fully connected layer followed by a reshape operation.
- Upscales the resulting arrays to 64-by-64-by-3 arrays using a series of transposed convolution layers with batch normalization and ReLU layers.

Define this network architecture as a layer graph and specify the following network properties.

- For the transposed convolution layers, specify 5-by-5 filters with a decreasing number of filters for each layer, a stride of 2, and cropping of the output on each edge.
- For the final transposed convolution layer, specify three 5-by-5 filters corresponding to the three RGB channels of the generated images, and the output size of the previous layer.
- At the end of the network, include a tanh layer.

To project and reshape the noise input, use a fully connected layer followed by a reshape operation specifed as a function layer with function given by the `feature2image` function, attached to this example as a supporting file. To access this function, open this example as a live script.

```
filterSize = 5;
numFilters = 64;
numLatentInputs = 100;

projectionSize = [4 4 512];
```

```
layersGenerator = [
    featureInputLayer(numLatentInputs)
    fullyConnectedLayer(prod(projectionSize))
    functionLayer(@(X) feature2image(X,projectionSize),Formattable=true)
    transposedConv2dLayer(filterSize,4*numFilters)
    batchNormalizationLayer
    reluLayer
    transposedConv2dLayer(filterSize,2*numFilters,Stride=2,Cropping="same")
    batchNormalizationLayer
    reluLayer
    transposedConv2dLayer(filterSize,numFilters,Stride=2,Cropping="same")
    batchNormalizationLayer
    reluLayer
    transposedConv2dLayer(filterSize,3,Stride=2,Cropping="same")
    tanhLayer];

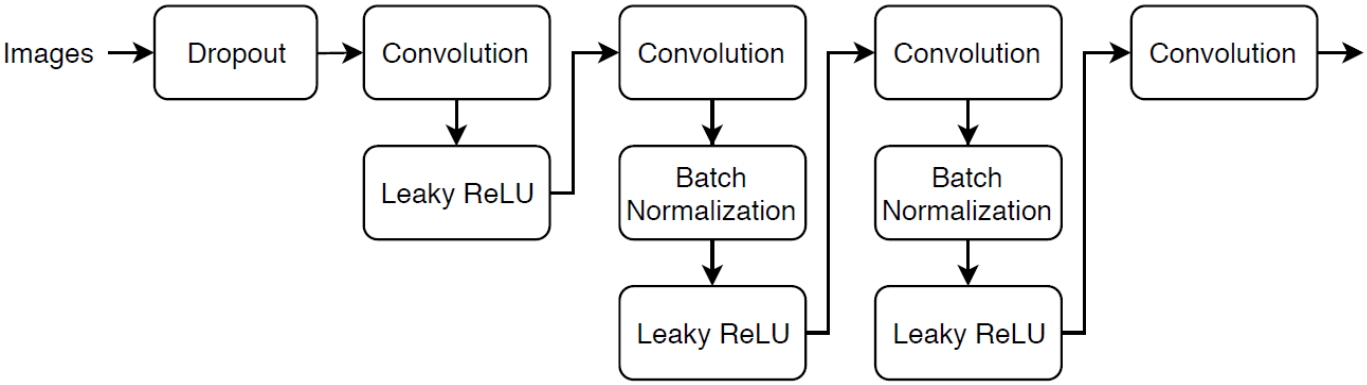
lgraphGenerator = layerGraph(layersGenerator);
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

```
dlnetGenerator = dlnetwork(lgraphGenerator);
```

Define Discriminator Network

Define the following network, which classifies real and generated 64-by-64 images.



Create a network that takes 64-by-64-by-3 images and returns a scalar prediction score using a series of convolution layers with batch normalization and leaky ReLU layers. Add noise to the input images using dropout.

- For the dropout layer, specify a dropout probability of 0.5.
- For the convolution layers, specify 5-by-5 filters with an increasing number of filters for each layer. Also specify a stride of 2 and padding of the output.
- For the leaky ReLU layers, specify a scale of 0.2.
- For the final layer, specify a convolutional layer with one 4-by-4 filter.

To output the probabilities in the range [0,1], use the `sigmoid` function in the `modelGradients` function, listed in the Model Gradients Function on page 3-0 section of the example.

```
dropoutProb = 0.5;
numFilters = 64;
```

```
scale = 0.2;

inputSize = [64 64 3];
filterSize = 5;

layersDiscriminator = [
    imageInputLayer(inputSize,Normalization="none")
    dropoutLayer(dropoutProb)
    convolution2dLayer(filterSize,numFilters,Stride=2,Padding="same")
    leakyReluLayer(scale)
    convolution2dLayer(filterSize,2*numFilters,Stride=2,Padding="same")
    batchNormalizationLayer
    leakyReluLayer(scale)
    convolution2dLayer(filterSize,4*numFilters,Stride=2,Padding="same")
    batchNormalizationLayer
    leakyReluLayer(scale)
    convolution2dLayer(filterSize,8*numFilters,Stride=2,Padding="same")
    batchNormalizationLayer
    leakyReluLayer(scale)
    convolution2dLayer(4,1)];

lgraphDiscriminator = layerGraph(layersDiscriminator);
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

```
dlnetDiscriminator = dlnetwork(lgraphDiscriminator);
```

Define Model Gradients and Loss Functions

Create the function `modelGradients`, listed in the Model Gradients Function on page 3-0 section of the example, which takes as input the generator and discriminator networks, a mini-batch of input data, an array of random values, and the flip factor, and returns the gradients of the loss with respect to the learnable parameters in the networks and the scores of the two networks.

Specify Training Options

Train with a mini-batch size of 128 for 500 epochs. For larger data sets, you might not need to train for as many epochs.

```
numEpochs = 500;
miniBatchSize = 128;
```

Specify the options for Adam optimization. For both networks, specify:

- A learning rate of 0.0002
- A gradient decay factor of 0.5
- A squared gradient decay factor of 0.999

```
learnRate = 0.0002;
gradientDecayFactor = 0.5;
squaredGradientDecayFactor = 0.999;
```

If the discriminator learns to discriminate between real and generated images too quickly, then the generator can fail to train. To better balance the learning of the discriminator and the generator, add noise to the real data by randomly flipping the labels.

Specify a `flipFactor` value of 0.3 to flip 30% of the real labels (15% of the total labels). Note that this does not impair the generator as all the generated images are still labeled correctly.

```
flipFactor = 0.3;
```

Display the generated validation images every 100 iterations.

```
validationFrequency = 100;
```

Train Model

Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to rescale the images in the range `[-1,1]`.
- Discard any partial mini-batches with less than 128 observations.
- Format the image data with the dimension labels `"SSCB"` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`.
- Train on a GPU if one is available. When the `OutputEnvironment` option of `minibatchqueue` is `"auto"`, `minibatchqueue` converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a CUDA® enabled NVIDIA® GPU with compute capability 3.0 or higher.

```
augimds.MiniBatchSize = miniBatchSize;

executionEnvironment = "auto";

mbq = minibatchqueue(augimds,...
    MiniBatchSize=miniBatchSize,...
    PartialMiniBatch="discard",...
    MiniBatchFcn=@preprocessMiniBatch,...
    MiniBatchFormat="SSCB",...
    OutputEnvironment=executionEnvironment);
```

Train the model using a custom training loop. Loop over the training data and update the network parameters at each iteration. To monitor the training progress, display a batch of generated images using a held-out array of random values to input to the generator as well as a plot of the scores.

Initialize the parameters for Adam.

```
trailingAvgGenerator = [];
trailingAvgSqGenerator = [];
trailingAvgDiscriminator = [];
trailingAvgSqDiscriminator = [];
```

To monitor the training progress, display a batch of generated images using a held-out batch of fixed random vectors fed into the generator and plot the network scores.

Create an array of held-out random values.

```
numValidationImages = 25;
ZValidation = randn(numLatentInputs,numValidationImages,"single");
```

Convert the data to `dlarray` objects and specify the dimension labels `"CB"` (channel, batch).

```
dlZValidation = dlarray(ZValidation,"CB");
```

For GPU training, convert the data to `gpuArray` objects.

```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZValidation = gpuArray(dlZValidation);
end
```

Initialize the training progress plots. Create a figure and resize it to have twice the width.

```
f = figure;
f.Position(3) = 2*f.Position(3);
```

Create a subplot for the generated images and the network scores.

```
imageAxes = subplot(1,2,1);
scoreAxes = subplot(1,2,2);
```

Initialize the animated lines for the scores plot.

```
lineScoreGenerator = animatedline(scoreAxes,Color=[0 0.447 0.741]);
lineScoreDiscriminator = animatedline(scoreAxes,Color=[0.85 0.325 0.098]);
legend("Generator","Discriminator");
ylim([0 1])
xlabel("Iteration")
ylabel("Score")
grid on
```

Train the GAN. For each epoch, shuffle the datastore and loop over mini-batches of data.

For each mini-batch:

- Evaluate the model gradients using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.
- Plot the scores of the two networks.
- After every `validationFrequency` iterations, display a batch of generated images for a fixed held-out generator input.

Training can take some time to run.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Reset and shuffle datastore.
    shuffle(mbq);

    % Loop over mini-batches.
    while hasdata(mbq)
        iteration = iteration + 1;

        % Read mini-batch of data.
        dlX = next(mbq);

        % Generate latent inputs for the generator network. Convert to
        % dlarray and specify the dimension labels "CB" (channel, batch).
        % If training on a GPU, then convert latent inputs to gpuArray.
```

```
Z = randn(numLatentInputs,miniBatchSize,"single");
dlZ = dlarray(Z,"CB");

if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZ = gpuArray(dlZ);
end

% Evaluate the model gradients and the generator state using
% dlfeval and the modelGradients function listed at the end of the
% example.
[gradientsGenerator, gradientsDiscriminator, stateGenerator, scoreGenerator, scoreDiscri
    dlfeval(@modelGradients, dlnetGenerator, dlnetDiscriminator, dlX, dlZ, flipFactor);
dlnetGenerator.State = stateGenerator;

% Update the discriminator network parameters.
[dlnetDiscriminator,trailingAvgDiscriminator,trailingAvgSqDiscriminator] = ...
    adamupdate(dlnetDiscriminator, gradientsDiscriminator, ...
    trailingAvgDiscriminator, trailingAvgSqDiscriminator, iteration, ...
    learnRate, gradientDecayFactor, squaredGradientDecayFactor);

% Update the generator network parameters.
[dlnetGenerator,trailingAvgGenerator,trailingAvgSqGenerator] = ...
    adamupdate(dlnetGenerator, gradientsGenerator, ...
    trailingAvgGenerator, trailingAvgSqGenerator, iteration, ...
    learnRate, gradientDecayFactor, squaredGradientDecayFactor);

% Every validationFrequency iterations, display batch of generated images using the
% held-out generator input.
if mod(iteration,validationFrequency) == 0 || iteration == 1
    % Generate images using the held-out generator input.
    dlXGeneratedValidation = predict(dlnetGenerator,dlZValidation);

    % Tile and rescale the images in the range [0 1].
    I = imtile(extractdata(dlXGeneratedValidation));
    I = rescale(I);

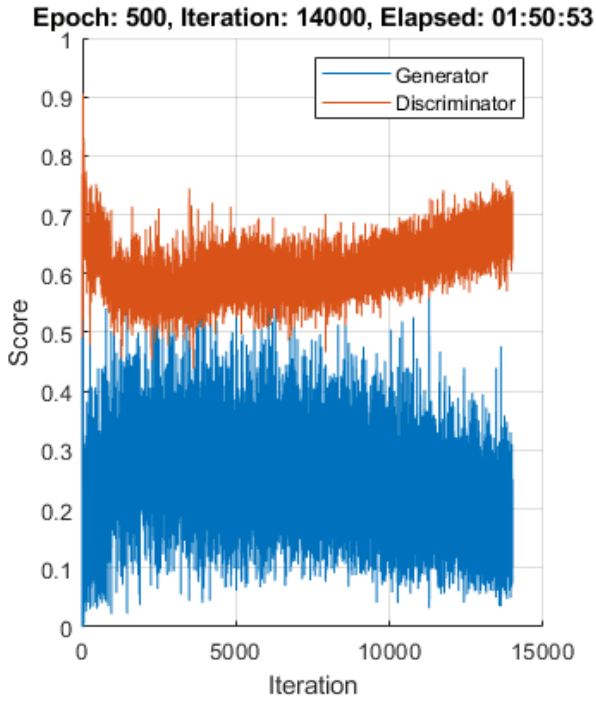
    % Display the images.
    subplot(1,2,1);
    image(imageAxes,I)
    xticklabels([]);
    yticklabels([]);
    title("Generated Images");
end

% Update the scores plot.
subplot(1,2,2)
addpoints(lineScoreGenerator,iteration,...
    double(gather(extractdata(scoreGenerator))));

addpoints(lineScoreDiscriminator,iteration,...
    double(gather(extractdata(scoreDiscriminator))));

% Update the title with training progress information.
D = duration(0,0,toc(start),Format="hh:mm:ss");
title(...
    "Epoch: " + epoch + ", " + ...
    "Iteration: " + iteration + ", " + ...
    "Elapsed: " + string(D))
```

```
        drawnow
    end
end
```



Here, the discriminator has learned a strong feature representation that identifies real images among generated images. In turn, the generator has learned a similarly strong feature representation that allows it to generate images similar to the training data.

The training plot shows the scores of the generator and discriminator networks. To learn more about how to interpret the network scores, see “Monitor GAN Training Progress and Identify Common Failure Modes” on page 5-182.

Generate New Images

To generate new images, use the `predict` function on the generator with a `dlarray` object containing a batch of random vectors. To display the images together, use the `imtile` function and rescale the images using the `rescale` function.

Create a `dlarray` object containing a batch of 25 random vectors to input to the generator network.

```
numObservations = 25;
ZNew = randn(numLatentInputs,numObservations,"single");
dlZNew = dlarray(ZNew,"CB");
```

To generate images using the GPU, also convert the data to `gpuArray` objects.

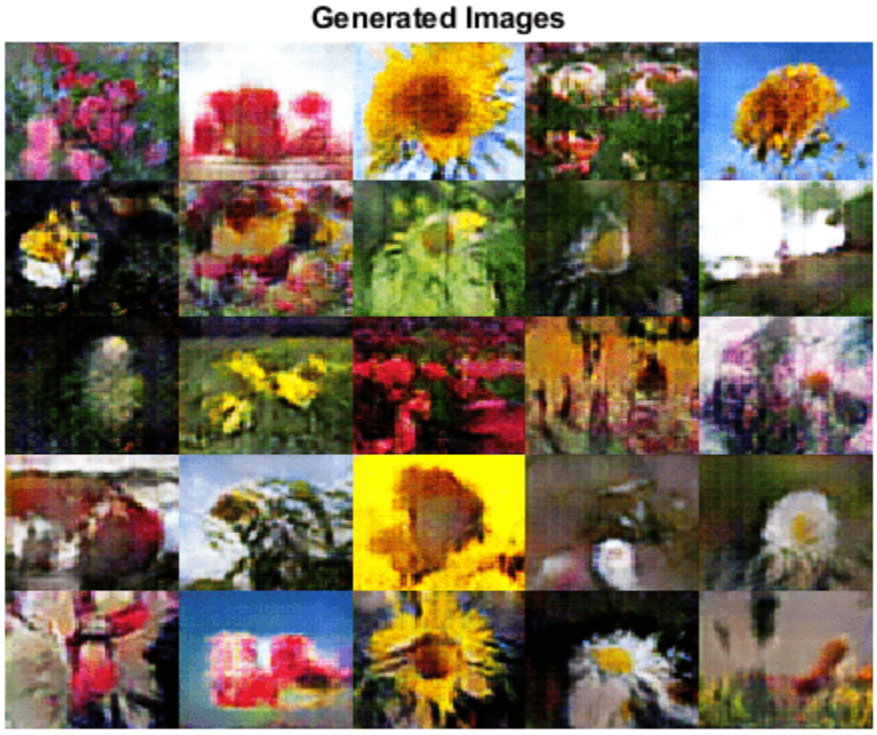
```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZNew = gpuArray(dlZNew);
end
```

Generate new images using the `predict` function with the generator and the input data.

```
dlXGeneratedNew = predict(dlnetGenerator,dlZNew);
```

Display the images.

```
I = imtile(extractdata(dlXGeneratedNew));
I = rescale(I);
figure
image(I)
axis off
title("Generated Images")
```



Model Gradients Function

The function `modelGradients` takes as input the generator and discriminator `dlnetwork` objects `dlnetGenerator` and `dlnetDiscriminator`, a mini-batch of input data `dlX`, an array of random values `dlZ`, and the percentage of real labels to flip `flipFactor`, and returns the gradients of the loss with respect to the learnable parameters in the networks, the generator state, and the scores of the two networks. Because the discriminator output is not in the range [0,1], the `modelGradients` function applies the sigmoid function to convert it into probabilities.

```
function [gradientsGenerator, gradientsDiscriminator, stateGenerator, scoreGenerator, scoreDiscr
    modelGradients(dlnetGenerator, dlnetDiscriminator, dlX, dlZ, flipFactor)

% Calculate the predictions for real data with the discriminator network.
dlYPred = forward(dlnetDiscriminator, dlX);

% Calculate the predictions for generated data with the discriminator network.
```

```
[dlXGenerated,stateGenerator] = forward(dlnetGenerator,dlZ);
dlYPredGenerated = forward(dlnetDiscriminator, dlXGenerated);

% Convert the discriminator outputs to probabilities.
probGenerated = sigmoid(dlYPredGenerated);
probReal = sigmoid(dlYPred);

% Calculate the score of the discriminator.
scoreDiscriminator = (mean(probReal) + mean(1-probGenerated)) / 2;

% Calculate the score of the generator.
scoreGenerator = mean(probGenerated);

% Randomly flip a fraction of the labels of the real images.
numObservations = size(probReal,4);
idx = randperm(numObservations,floor(flipFactor * numObservations));

% Flip the labels.
probReal(:,:,:,idx) = 1 - probReal(:,:,:,idx);

% Calculate the GAN loss.
[lossGenerator, lossDiscriminator] = ganLoss(probReal,probGenerated);

% For each network, calculate the gradients with respect to the loss.
gradientsGenerator = dlgradient(lossGenerator, dlnetGenerator.Learnables,RetainData=true);
gradientsDiscriminator = dlgradient(lossDiscriminator, dlnetDiscriminator.Learnables);

end
```

GAN Loss Function and Scores

The objective of the generator is to generate data that the discriminator classifies as `"real"`. To maximize the probability that images from the generator are classified as real by the discriminator, minimize the negative log likelihood function.

Given the output Y of the discriminator:

- $\widehat{Y} = \sigma(Y)$ is the probability that the input image belongs to the class `"real"`.
- $1 - \widehat{Y}$ is the probability that the input image belongs to the class `"generated"`.

Note that the sigmoid operation σ happens in the `modelGradients` function. The loss function for the generator is given by

$$\text{lossGenerator} = -\text{mean}\left(\log\left(\widehat{Y}_{\text{Generated}}\right)\right),$$

where $\widehat{Y}_{Generated}$ contains the discriminator output probabilities for the generated images.

The objective of the discriminator is to not be "fooled" by the generator. To maximize the probability that the discriminator successfully discriminates between the real and generated images, minimize the sum of the corresponding negative log likelihood functions.

The loss function for the discriminator is given by

$$\text{lossDiscriminator} = -\text{mean}\left(\log\left(\widehat{Y}_{\text{Real}}\right)\right) - \text{mean}\left(\log\left(1 - \widehat{Y}_{\text{Generated}}\right)\right),$$

where $\widehat{Y}_{Real}$ contains the discriminator output probabilities for the real images.

To measure on a scale from 0 to 1 how well the generator and discriminator achieve their respective goals, you can use the concept of score.

The generator score is the average of the probabilities corresponding to the discriminator output for the generated images:

$$\text{scoreGenerator} = \text{mean}\left(\widehat{Y}_{\text{Generated}}\right).$$

The discriminator score is the average of the probabilities corresponding to the discriminator output for both the real and generated images:

$$\text{scoreDiscriminator} = \frac{1}{2}\text{mean}\left(\widehat{Y}_{\text{Real}}\right) + \frac{1}{2}\text{mean}\left(1 - \widehat{Y}_{\text{Generated}}\right).$$

The score is inversely proportional to the loss but effectively contains the same information.

```
function [lossGenerator, lossDiscriminator] = ganLoss(probReal,probGenerated)

% Calculate the loss for the discriminator network.
lossDiscriminator = -mean(log(probReal)) - mean(log(1-probGenerated));

% Calculate the loss for the generator network.
lossGenerator = -mean(log(probGenerated));

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array.
2. Rescale the images to be in the range `[-1,1]`.

```
function X = preprocessMiniBatch(data)

% Concatenate mini-batch
X = cat(4,data{:});

% Rescale the images in the range [-1 1].
X = rescale(X,-1,1,InputMin=0,InputMax=255);

end
```

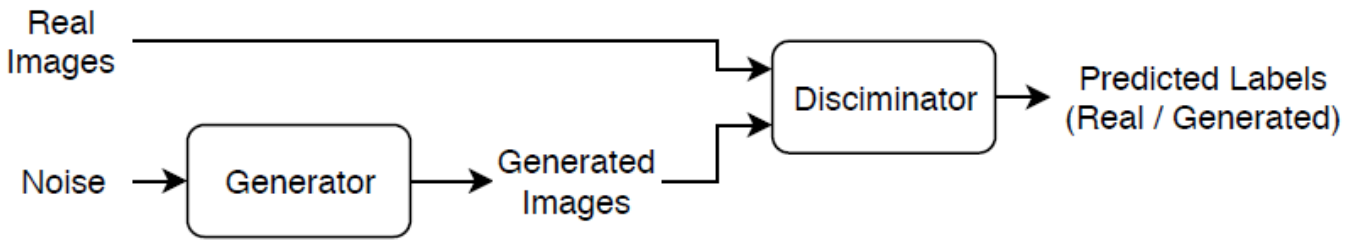
Train Conditional Generative Adversarial Network (CGAN)

This example shows how to train a conditional generative adversarial network to generate images.

A generative adversarial network (GAN) is a type of deep learning network that can generate data with similar characteristics as the input training data.

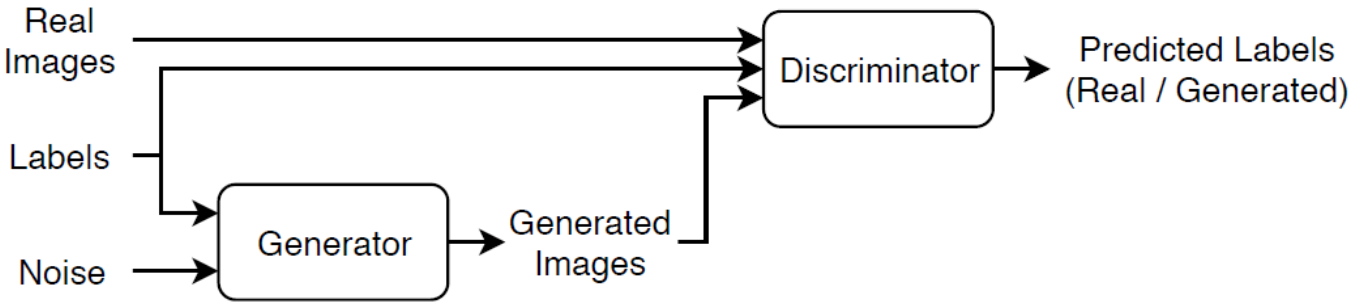
A GAN consists of two networks that train together:

1. Generator — Given a vector of random values as input, this network generates data with the same structure as the training data.
2. Discriminator — Given batches of data containing observations from both the training data, and generated data from the generator, this network attempts to classify the observations as `"real"` or `"generated"`.



A *conditional* generative adversarial network (CGAN) is a type of GAN that also takes advantage of labels during the training process.

1. Generator — Given a label and random array as input, this network generates data with the same structure as the training data observations corresponding to the same label.
2. Discriminator — Given batches of labeled data containing observations from both the training data and generated data from the generator, this network attempts to classify the observations as `"real"` or `"generated"`.



To train a conditional GAN, train both networks simultaneously to maximize the performance of both:

- Train the generator to generate data that "fools" the discriminator.
- Train the discriminator to distinguish between real and generated data.

To maximize the performance of the generator, maximize the loss of the discriminator when given generated labeled data. That is, the objective of the generator is to generate labeled data that the discriminator classifies as `"real"`.

To maximize the performance of the discriminator, minimize the loss of the discriminator when given batches of both real and generated labeled data. That is, the objective of the discriminator is to not be "fooled" by the generator.

Ideally, these strategies result in a generator that generates convincingly realistic data that corresponds to the input labels and a discriminator that has learned strong feature representations that are characteristic of the training data for each label.

Load Training Data

Download and extract the Flowers data set [1].

```
url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");

imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
    disp("Downloading Flowers data set (218 MB)...")
    websave(filename,url);
    untar(filename,downloadFolder)
end
```

Create an image datastore containing the photos of the flowers.

```
datasetFolder = fullfile(imageFolder);

imds = imageDatastore(datasetFolder,IncludeSubfolders=true,LabelSource="foldernames");
```

View the number of classes.

```
classes = categories(imds.Labels);
numClasses = numel(classes)
```

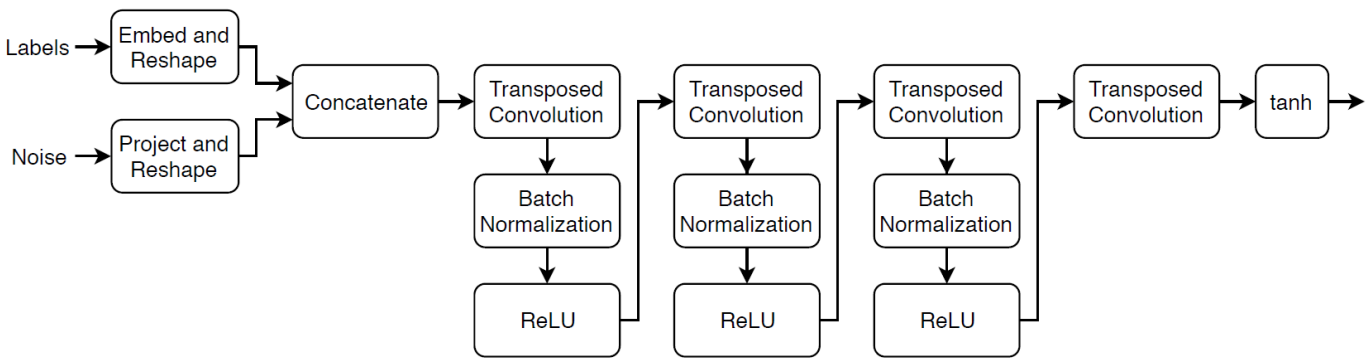
```
numClasses = 5
```

Augment the data to include random horizontal flipping and resize the images to have size 64-by-64.

```
augmenter = imageDataAugmenter(RandXReflection=true);
augimds = augmentedImageDatastore([64 64],imds,DataAugmentation=augmenter);
```

Define Generator Network

Define the following two-input network, which generates images given random vectors of size 100 and corresponding labels.



This network:

- Converts the random vectors of size 100 to 4-by-4-by-1024 arrays using a fully connected layer followed by a reshape operation.
- Converts the categorical labels to embedding vectors and reshapes them to a 4-by-4 array.
- Concatenates the resulting images from the two inputs along the channel dimension. The output is a 4-by-4-by-1025 array.
- Upscales the resulting arrays to 64-by-64-by-3 arrays using a series of transposed convolution layers with batch normalization and ReLU layers.

Define this network architecture as a layer graph and specify the following network properties.

- For the categorical inputs, use an embedding dimension of 50.
- For the transposed convolution layers, specify 5-by-5 filters with a decreasing number of filters for each layer, a stride of 2, and `"same"` cropping of the output.
- For the final transposed convolution layer, specify a three 5-by-5 filter corresponding to the three RGB channels of the generated images.
- At the end of the network, include a tanh layer.

To project and reshape the noise input, use a fully connected layer followed by a reshape operation specifed as a function layer with function given by the `feature2image` function, attached to this example as a supporting file. To embed the categorical labels, use the custom layer `embeddingLayer` attached to this example as a supporting file. To access these supporting files, open the example as a live script.

```
numLatentInputs = 100;
embeddingDimension = 50;
numFilters = 64;

filterSize = 5;
projectionSize = [4 4 1024];

layersGenerator = [
    featureInputLayer(numLatentInputs)
    fullyConnectedLayer(prod(projectionSize))
    functionLayer(@(X) feature2image(X,projectionSize),Formattable=true)
    concatenationLayer(3,2,Name="cat");
    transposedConv2dLayer(filterSize,4*numFilters)
    batchNormalizationLayer
    reluLayer
    transposedConv2dLayer(filterSize,2*numFilters,Stride=2,Cropping="same")
    batchNormalizationLayer
    reluLayer
    transposedConv2dLayer(filterSize,numFilters,Stride=2,Cropping="same")
    batchNormalizationLayer
    reluLayer
    transposedConv2dLayer(filterSize,3,Stride=2,Cropping="same")
    tanhLayer];

lgraphGenerator = layerGraph(layersGenerator);

layers = [
    featureInputLayer(1)
    embeddingLayer(embeddingDimension,numClasses)
```

```
    fullyConnectedLayer(prod(projectionSize(1:2)))
    functionLayer(@(X) feature2image(X,[projectionSize(1:2) 1]),Formattable=true,Name="emb_reshap
```

```
lgraphGenerator = addLayers(lgraphGenerator,layers);
lgraphGenerator = connectLayers(lgraphGenerator,"emb_reshape","cat/in2");
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

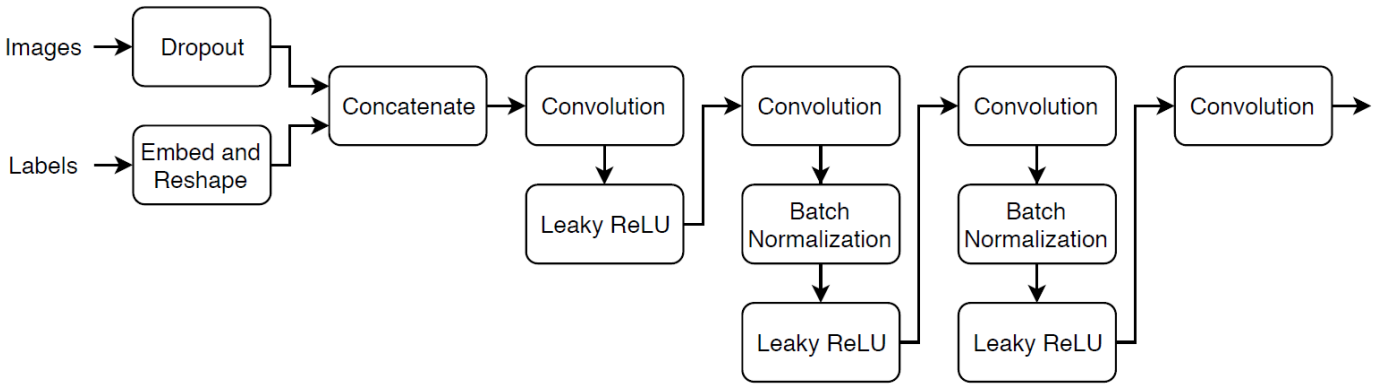
```
dlnetGenerator = dlnetwork(lgraphGenerator)
```

```
dlnetGenerator =
  dlnetwork with properties:

         Layers: [19×1 nnet.cnn.layer.Layer]
    Connections: [18×2 table]
     Learnables: [19×3 table]
          State: [6×3 table]
     InputNames: {'input'  'input_1'}
    OutputNames: {'layer_2'}
    Initialized: 1
```

Define Discriminator Network

Define the following two-input network, which classifies real and generated 64-by-64 images given a set of images and the corresponding labels.



Create a network that takes as input 64-by-64-by-1 images and the corresponding labels and outputs a scalar prediction score using a series of convolution layers with batch normalization and leaky ReLU layers. Add noise to the input images using dropout.

- For the dropout layer, specify a dropout probability of 0.75.
- For the convolution layers, specify 5-by-5 filters with an increasing number of filters for each layer. Also specify a stride of 2 and padding of the output on each edge.
- For the leaky ReLU layers, specify a scale of 0.2.
- For the final layer, specify a convolution layer with one 4-by-4 filter.

```
dropoutProb = 0.75;
numFilters = 64;
scale = 0.2;
```

```
inputSize = [64 64 3];
filterSize = 5;

layersDiscriminator = [
    imageInputLayer(inputSize,Normalization="none")
    dropoutLayer(dropoutProb)
    concatenationLayer(3,2,Name="cat")
    convolution2dLayer(filterSize,numFilters,Stride=2,Padding="same")
    leakyReluLayer(scale)
    convolution2dLayer(filterSize,2*numFilters,Stride=2,Padding="same")
    batchNormalizationLayer
    leakyReluLayer(scale)
    convolution2dLayer(filterSize,4*numFilters,Stride=2,Padding="same")
    batchNormalizationLayer
    leakyReluLayer(scale)
    convolution2dLayer(filterSize,8*numFilters,Stride=2,Padding="same")
    batchNormalizationLayer
    leakyReluLayer(scale)
    convolution2dLayer(4,1)];

lgraphDiscriminator = layerGraph(layersDiscriminator);

layers = [
    featureInputLayer(1)
    embeddingLayer(embeddingDimension,numClasses)
    fullyConnectedLayer(prod(inputSize(1:2)))
    functionLayer(@(X) feature2image(X,[inputSize(1:2) 1]),Formattable=true,Name="emb_reshape")];

lgraphDiscriminator = addLayers(lgraphDiscriminator,layers);
lgraphDiscriminator = connectLayers(lgraphDiscriminator,"emb_reshape","cat/in2");
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

```
dlnetDiscriminator = dlnetwork(lgraphDiscriminator)
```

```
dlnetDiscriminator =
  dlnetwork with properties:

         Layers: [19×1 nnet.cnn.layer.Layer]
    Connections: [18×2 table]
     Learnables: [19×3 table]
          State: [6×3 table]
     InputNames: {'imageinput'  'input'}
    OutputNames: {'conv_5'}
    Initialized: 1
```

Define Model Gradients and Loss Functions

Create the function `modelGradients`, listed in the Model Gradients Function on page 3-0 section of the example, which takes as input the generator and discriminator networks, a mini-batch of input data, and an array of random values, and returns the gradients of the loss with respect to the learnable parameters in the networks and an array of generated images.

Specify Training Options

Train with a mini-batch size of 128 for 500 epochs.

```
numEpochs = 500;
miniBatchSize = 128;
```

Specify the options for Adam optimization. For both networks, use:

- A learning rate of 0.0002
- A gradient decay factor of 0.5
- A squared gradient decay factor of 0.999

```
learnRate = 0.0002;
gradientDecayFactor = 0.5;
squaredGradientDecayFactor = 0.999;
```

Update the training progress plots every 100 iterations.

```
validationFrequency = 100;
```

If the discriminator learns to discriminate between real and generated images too quickly, then the generator can fail to train. To better balance the learning of the discriminator and the generator, randomly flip the labels of a proportion of the real images. Specify a flip factor of 0.5.

```
flipFactor = 0.5;
```

Train Model

Train the model using a custom training loop. Loop over the training data and update the network parameters at each iteration. To monitor the training progress, display a batch of generated images using a held-out array of random values to input into the generator and the network scores.

Use `minibatchqueue` to process and manage the mini-batches of images during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to rescale the images in the range `[-1,1]`.
- Discard any partial mini-batches with less than 128 observations.
- Format the image data with the dimension labels `"SSCB"` (spatial, spatial, channel, batch).
- Format the label data with the dimension labels `"BC"` (batch, channel).
- Train on a GPU if one is available. When the `OutputEnvironment` option of `minibatchqueue` is `"auto"`, `minibatchqueue` converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

The `minibatchqueue` object, by default, converts the data to `dlarray` objects with underlying type `single`.

```
augimds.MiniBatchSize = miniBatchSize;
executionEnvironment = "auto";

mbq = minibatchqueue(augimds, ...
    MiniBatchSize=miniBatchSize, ...
    PartialMiniBatch="discard", ...
    MiniBatchFcn=@preprocessData, ...
    MiniBatchFormat=["SSCB" "BC"], ...
    OutputEnvironment=executionEnvironment);
```

Initialize the parameters for the Adam optimizer.

```
velocityDiscriminator = [];
trailingAvgGenerator = [];
trailingAvgSqGenerator = [];
trailingAvgDiscriminator = [];
trailingAvgSqDiscriminator = [];
```

Initialize the plot of the training progress. Create a figure and resize it to have twice the width.

```
f = figure;
f.Position(3) = 2*f.Position(3);
```

Create subplots of the generated images and of the scores plot.

```
imageAxes = subplot(1,2,1);
scoreAxes = subplot(1,2,2);
```

Initialize animated lines for the scores plot.

```
lineScoreGenerator = animatedline(scoreAxes,Color=[0 0.447 0.741]);
lineScoreDiscriminator = animatedline(scoreAxes,Color=[0.85 0.325 0.098]);
```

Customize the appearance of the plots.

```
legend("Generator","Discriminator");
ylim([0 1])
xlabel("Iteration")
ylabel("Score")
grid on
```

To monitor training progress, create a held-out batch of 25 random vectors and a corresponding set of labels 1 through 5 (corresponding to the classes) repeated five times.

```
numValidationImagesPerClass = 5;
ZValidation = randn(numLatentInputs,numValidationImagesPerClass*numClasses,"single");

TValidation = single(repmat(1:numClasses,[1 numValidationImagesPerClass]));
```

Convert the data to `dlarray` objects and specify the dimension labels `"CB"` (channel, batch).

```
dlZValidation = dlarray(ZValidation,"CB");
dlTValidation = dlarray(TValidation,"CB");
```

For GPU training, convert the data to `gpuArray` objects.

```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZValidation = gpuArray(dlZValidation);
    dlTValidation = gpuArray(dlTValidation);
end
```

Train the conditional GAN. For each epoch, shuffle the data and loop over mini-batches of data.

For each mini-batch:

- Evaluate the model gradients using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.

- Plot the scores of the two networks.
- After every `validationFrequency` iterations, display a batch of generated images for a fixed held-out generator input.

Training can take some time to run.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Reset and shuffle data.
    shuffle(mbq);

    % Loop over mini-batches.
    while hasdata(mbq)
        iteration = iteration + 1;

        % Read mini-batch of data.
        [dlX,dlT] = next(mbq);

        % Generate latent inputs for the generator network. Convert to
        % dlarray and specify the dimension labels "CB" (channel, batch).
        % If training on a GPU, then convert latent inputs to gpuArray.
        Z = randn(numLatentInputs,miniBatchSize,"single");
        dlZ = dlarray(Z,"CB");
        if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
            dlZ = gpuArray(dlZ);
        end

        % Evaluate the model gradients and the generator state using
        % dlfeval and the modelGradients function listed at the end of the
        % example.
        [gradientsGenerator, gradientsDiscriminator, stateGenerator, scoreGenerator, scoreDiscri
            dlfeval(@modelGradients, dlnetGenerator, dlnetDiscriminator, dlX, dlT, dlZ, flipFacto
        dlnetGenerator.State = stateGenerator;

        % Update the discriminator network parameters.
        [dlnetDiscriminator,trailingAvgDiscriminator,trailingAvgSqDiscriminator] = ...
            adamupdate(dlnetDiscriminator, gradientsDiscriminator, ...
            trailingAvgDiscriminator, trailingAvgSqDiscriminator, iteration, ...
            learnRate, gradientDecayFactor, squaredGradientDecayFactor);

        % Update the generator network parameters.
        [dlnetGenerator,trailingAvgGenerator,trailingAvgSqGenerator] = ...
            adamupdate(dlnetGenerator, gradientsGenerator, ...
            trailingAvgGenerator, trailingAvgSqGenerator, iteration, ...
            learnRate, gradientDecayFactor, squaredGradientDecayFactor);

        % Every validationFrequency iterations, display batch of generated images using the
        % held-out generator input.
        if mod(iteration,validationFrequency) == 0 || iteration == 1

            % Generate images using the held-out generator input.
            dlXGeneratedValidation = predict(dlnetGenerator,dlZValidation,dlTValidation);
```

```
            % Tile and rescale the images in the range [0 1].
            I = imtile(extractdata(dlXGeneratedValidation), ...
                GridSize=[numValidationImagesPerClass numClasses]);
            I = rescale(I);

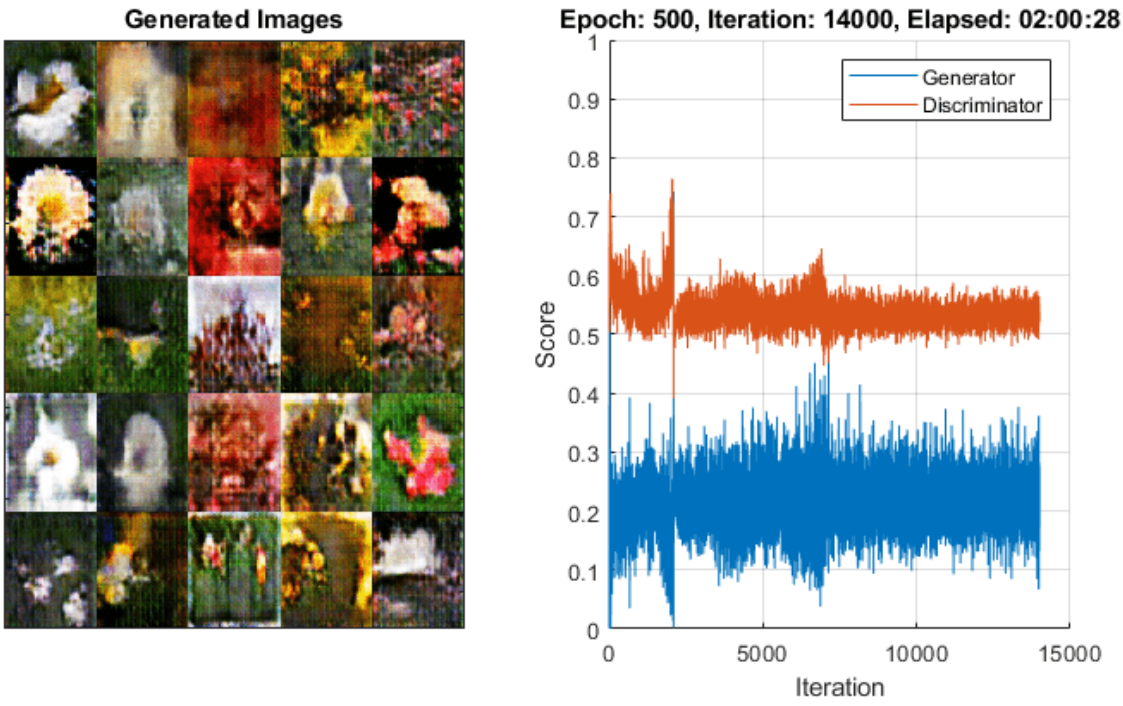
            % Display the images.
            subplot(1,2,1);
            image(imageAxes,I)
            xticklabels([]);
            yticklabels([]);
            title("Generated Images");
        end

        % Update the scores plot.
        subplot(1,2,2)
        addpoints(lineScoreGenerator,iteration,...
            double(gather(extractdata(scoreGenerator))));

        addpoints(lineScoreDiscriminator,iteration,...
            double(gather(extractdata(scoreDiscriminator))));

        % Update the title with training progress information.
        D = duration(0,0,toc(start),Format="hh:mm:ss");
        title(...
            "Epoch: " + epoch + ", " + ...
            "Iteration: " + iteration + ", " + ...
            "Elapsed: " + string(D))

        drawnow
    end
end
```



Here, the discriminator has learned a strong feature representation that identifies real images among generated images. In turn, the generator has learned a similarly strong feature representation that allows it to generate images similar to the training data. Each column corresponds to a single class.

The training plot shows the scores of the generator and discriminator networks. To learn more about how to interpret the network scores, see “Monitor GAN Training Progress and Identify Common Failure Modes” on page 5-182.

Generate New Images

To generate new images of a particular class, use the `predict` function on the generator with a `dlarray` object containing a batch of random vectors and an array of labels corresponding to the desired classes. Convert the data to `dlarray` objects and specify the dimension labels `"CB"` (channel, batch). For GPU prediction, convert the data to `gpuArray` objects. To display the images together, use the `imtile` function and rescale the images using the `rescale` function.

Create an array of 36 vectors of random values corresponding to the first class.

```
numObservationsNew = 36;
idxClass = 1;
Z = randn(numLatentInputs,numObservationsNew,"single");
T = repmat(single(idxClass),[1 numObservationsNew]);
```

Convert the data to `dlarray` objects with the dimension labels `"SSCB"` (spatial, spatial, channels, batch).

```
dlZ = dlarray(Z,"CB");
dlT = dlarray(T,"CB");
```

To generate images using the GPU, also convert the data to `gpuArray` objects.

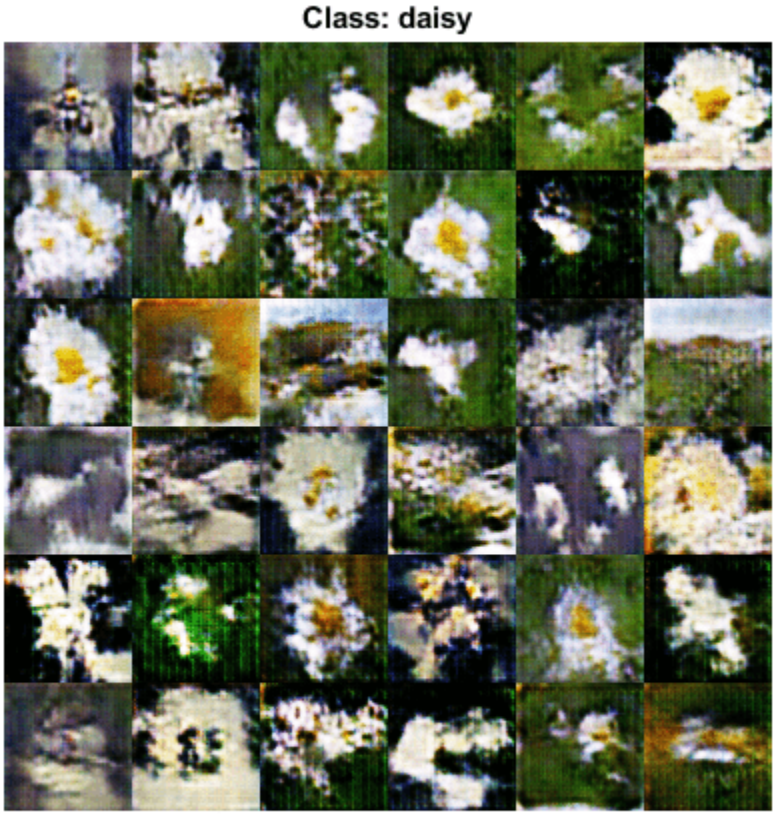
```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZ = gpuArray(dlZ);
    dlT = gpuArray(dlT);
end
```

Generate images using the `predict` function with the generator network.

```
dlXGenerated = predict(dlnetGenerator,dlZ,dlT);
```

Display the generated images in a plot.

```
figure
I = imtile(extractdata(dlXGenerated));
I = rescale(I);
imshow(I)
title("Class: " + classes(idxClass))
```



Here, the generator network generates images conditioned on the specified class.

Model Gradients Function

The function `modelGradients` takes as input the generator and discriminator `dlnetwork` objects `dlnetGenerator` and `dlnetDiscriminator`, a mini-batch of input data `dlX`, the corresponding labels `dlT`, and an array of random values `dlZ`, and returns the gradients of the loss with respect to the learnable parameters in the networks, the generator state, and the network scores.

If the discriminator learns to discriminate between real and generated images too quickly, then the generator can fail to train. To better balance the learning of the discriminator and the generator, randomly flip the labels of a proportion of the real images.

```
function [gradientsGenerator, gradientsDiscriminator, stateGenerator, scoreGenerator, scoreDiscr
    modelGradients(dlnetGenerator, dlnetDiscriminator, dlX, dlT, dlZ, flipFactor)

% Calculate the predictions for real data with the discriminator network.
dlYPred = forward(dlnetDiscriminator, dlX, dlT);

% Calculate the predictions for generated data with the discriminator network.
[dlXGenerated,stateGenerator] = forward(dlnetGenerator, dlZ, dlT);
dlYPredGenerated = forward(dlnetDiscriminator, dlXGenerated, dlT);
```

```
% Calculate probabilities.
probGenerated = sigmoid(dlYPredGenerated);
probReal = sigmoid(dlYPred);

% Calculate the generator and discriminator scores.
scoreGenerator = mean(probGenerated);
scoreDiscriminator = (mean(probReal) + mean(1-probGenerated)) / 2;

% Flip labels.
numObservations = size(dlYPred,4);
idx = randperm(numObservations,floor(flipFactor * numObservations));
probReal(:,:,:,idx) = 1 - probReal(:,:,:,idx);

% Calculate the GAN loss.
[lossGenerator, lossDiscriminator] = ganLoss(probReal, probGenerated);

% For each network, calculate the gradients with respect to the loss.
gradientsGenerator = dlgradient(lossGenerator, dlnetGenerator.Learnables,RetainData=true);
gradientsDiscriminator = dlgradient(lossDiscriminator, dlnetDiscriminator.Learnables);

end
```

GAN Loss Function

The objective of the generator is to generate data that the discriminator classifies as `"real"`. To maximize the probability that images from the generator are classified as real by the discriminator, minimize the negative log likelihood function.

Given the output Y of the discriminator:

- $\widehat{Y} = \sigma(Y)$ is the probability that the input image belongs to the class `"real"`.
- $1 - \widehat{Y}$ is the probability that the input image belongs to the class `"generated"`.

Note the sigmoid operation σ happens in the `modelGradients` function. The loss function for the generator is given by

$$\text{lossGenerator} = -\text{mean}\left(\log\left(\widehat{Y}_{\text{Generated}}\right)\right),$$

where $\widehat{Y}_{Generated}$ contains the discriminator output probabilities for the generated images.

The objective of the discriminator is to not be "fooled" by the generator. To maximize the probability that the discriminator successfully discriminates between the real and generated images, minimize the sum of the corresponding negative log likelihood functions. The loss function for the discriminator is given by

$$\text{lossDiscriminator} = -\text{mean}\left(\log\left(\widehat{Y}_{\text{Real}}\right)\right) - \text{mean}\left(\log\left(1 - \widehat{Y}_{\text{Generated}}\right)\right),$$

where $\widehat{Y}_{Real}$ contains the discriminator output probabilities for the real images.

```
function [lossGenerator, lossDiscriminator] = ganLoss(scoresReal,scoresGenerated)

% Calculate losses for the discriminator network.
lossGenerated = -mean(log(1 - scoresGenerated));
lossReal = -mean(log(scoresReal));
```

```
% Combine the losses for the discriminator network.
lossDiscriminator = lossReal + lossGenerated;

% Calculate the loss for the generator network.
lossGenerator = -mean(log(scoresGenerated));

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image and label data from the input cell arrays and concatenate them into numeric arrays.
2. Rescale the images to be in the range `[-1,1]`.

```
function [X,T] = preprocessData(XCell,TCell)

% Extract image data from cell and concatenate
X = cat(4,XCell{:});

% Extract label data from cell and concatenate
T = cat(1,TCell{:});

% Rescale the images in the range [-1 1].
X = rescale(X,-1,1,InputMin=0,InputMax=255);

end
```

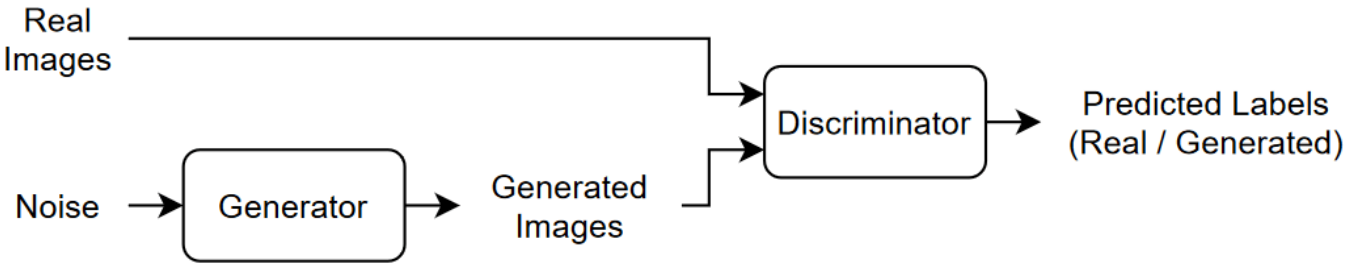
Train Wasserstein GAN with Gradient Penalty (WGAN-GP)

This example shows how to train a Wasserstein generative adversarial network with a gradient penalty (WGAN-GP) to generate images.

A generative adversarial network (GAN) is a type of deep learning network that can generate data with similar characteristics as the input real data.

A GAN consists of two networks that train together:

1. Generator — Given a vector of random values (latent inputs) as input, this network generates data with the same structure as the training data.
2. Discriminator — Given batches of data containing observations from both the training data, and generated data from the generator, this network attempts to classify the observations as "real" or "generated".



To train a GAN, train both networks simultaneously to maximize the performance of both:

- Train the generator to generate data that "fools" the discriminator.
- Train the discriminator to distinguish between real and generated data.

To optimize the performance of the generator, maximize the loss of the discriminator when given generated data. That is, the objective of the generator is to generate data that the discriminator classifies as "real". To optimize the performance of the discriminator, minimize the loss of the discriminator when given batches of both real and generated data. That is, the objective of the discriminator is to not be "fooled" by the generator.

Ideally, these strategies result in a generator that generates convincingly realistic data and a discriminator that has learned strong feature representations that are characteristic of the training data. However, [2] argues that the divergences which GANs typically minimize are potentially not continuous with respect to the generator's parameters, leading to training difficulty and introduces the Wasserstein GAN (WGAN) model that uses the Wasserstein loss to help stabilize training. A WGAN model can still produce poor samples or fail to converge because interactions between the weight constraint and the cost function can result in vanishing or exploding gradients. To address these issues, [3] introduces a gradient penalty which improves stability by penalizing gradients with large norm values at the cost of longer computational time. This type of model is known as a WGAN-GP model.

This example shows how to train a WGAN-GP model that can generate images with similar characteristics to a training set of images.

Load Training Data

Download and extract the Flowers data set [1].

```
url = 'http://download.tensorflow.org/example_images/flower_photos.tgz';
downloadFolder = tempdir;
filename = fullfile(downloadFolder,'flower_dataset.tgz');

imageFolder = fullfile(downloadFolder,'flower_photos');
if ~exist(imageFolder,'dir')
    disp('Downloading Flowers data set (218 MB)...')
    websave(filename,url);
    untar(filename,downloadFolder)
end
```

Create an image datastore containing the photos of the flowers.

```
datasetFolder = fullfile(imageFolder);

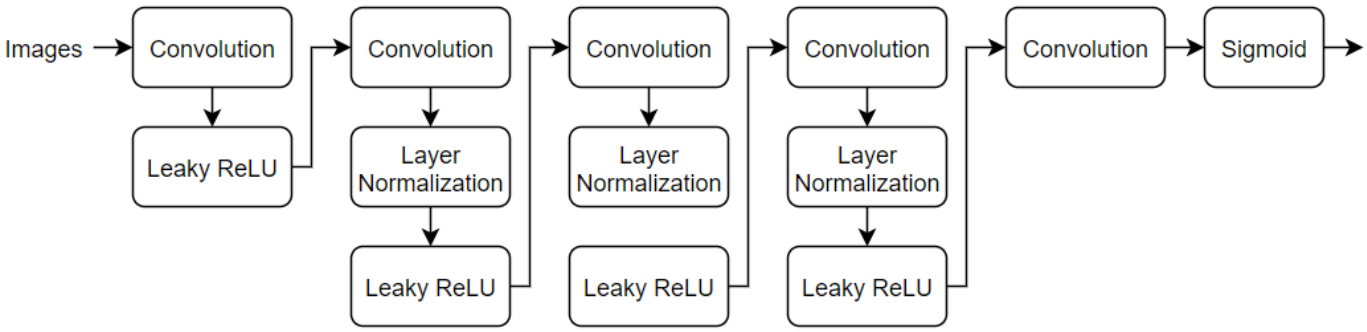
imds = imageDatastore(datasetFolder, ...
    'IncludeSubfolders',true);
```

Augment the data to include random horizontal flipping and resize the images to have size 64-by-64.

```
augmenter = imageDataAugmenter('RandXReflection',true);
augimds = augmentedImageDatastore([64 64],imds,'DataAugmentation',augmenter);
```

Define Discriminator Network

Define the following network, which classifies real and generated 64-by-64 images.



Create a network that takes 64-by-64-by-3 images and returns a scalar prediction score using a series of convolution layers with batch normalization and leaky ReLU layers. To output the probabilities in the range [0,1], use a sigmoid layer.

- For the convolution layers, specify 5-by-5 filters with an increasing number of filters for each layer. Also specify a stride of 2 and padding of the output.
- For the leaky ReLU layers, specify a scale of 0.2.
- For the final convolution layer, specify one 4-by-4 filter.

```
numFilters = 64;
scale = 0.2;

inputSize = [64 64 3];
filterSize = 5;

layersD = [
    imageInputLayer(inputSize,'Normalization','none','Name','in')
```

```
    convolution2dLayer(filterSize,numFilters,'Stride',2,'Padding','same','Name','conv1')
    leakyReluLayer(scale,'Name','lrelu1')
    convolution2dLayer(filterSize,2*numFilters,'Stride',2,'Padding','same','Name','conv2')
    layerNormalizationLayer('Name','bn2')
    leakyReluLayer(scale,'Name','lrelu2')
    convolution2dLayer(filterSize,4*numFilters,'Stride',2,'Padding','same','Name','conv3')
    layerNormalizationLayer('Name','bn3')
    leakyReluLayer(scale,'Name','lrelu3')
    convolution2dLayer(filterSize,8*numFilters,'Stride',2,'Padding','same','Name','conv4')
    layerNormalizationLayer('Name','bn4')
    leakyReluLayer(scale,'Name','lrelu4')
    convolution2dLayer(4,1,'Name','conv5')
    sigmoidLayer('Name','sigmoid')];

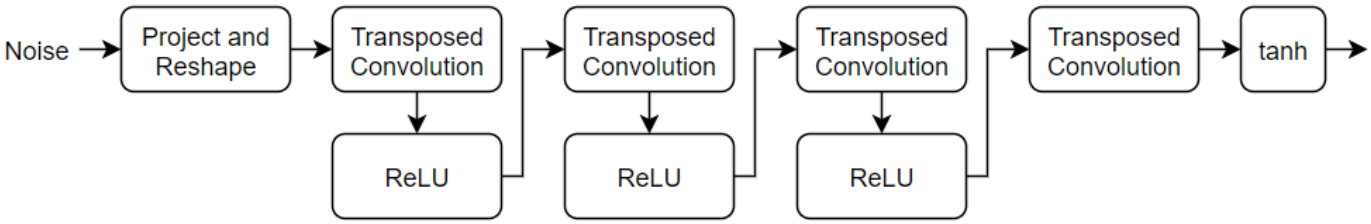
lgraphD = layerGraph(layersD);
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

```
dlnetD = dlnetwork(lgraphD);
```

Define Generator Network

Define the following network architecture, which generates images from 1-by-1-by-100 arrays of random values:



This network:

- Converts the random vectors of size 100 to 7-by-7-by-128 arrays using a *project and reshape* layer.
- Upscales the resulting arrays to 64-by-64-by-3 arrays using a series of transposed convolution layers and ReLU layers.

Define this network architecture as a layer graph and specify the following network properties.

- For the transposed convolution layers, specify 5-by-5 filters with a decreasing number of filters for each layer, a stride of 2, and cropping of the output on each edge.
- For the final transposed convolution layer, specify three 5-by-5 filters corresponding to the three RGB channels of the generated images, and the output size of the previous layer.
- At the end of the network, include a tanh layer.

To project and reshape the noise input, use the custom layer `projectAndReshapeLayer`, attached to this example as a supporting file. The `projectAndReshape` layer upscales the input using a fully connected operation and reshapes the output to the specified size.

```
filterSize = 5;
numFilters = 64;
numLatentInputs = 100;
```

```
projectionSize = [4 4 512];

layersG = [
    featureInputLayer(numLatentInputs,'Normalization','none','Name','in')
    projectAndReshapeLayer(projectionSize,numLatentInputs,'Name','proj');
    transposedConv2dLayer(filterSize,4*numFilters,'Name','tconv1')
    reluLayer('Name','relu1')
    transposedConv2dLayer(filterSize,2*numFilters,'Stride',2,'Cropping','same','Name','tconv2')
    reluLayer('Name','relu2')
    transposedConv2dLayer(filterSize,numFilters,'Stride',2,'Cropping','same','Name','tconv3')
    reluLayer('Name','relu3')
    transposedConv2dLayer(filterSize,3,'Stride',2,'Cropping','same','Name','tconv4')
    tanhLayer('Name','tanh')];

lgraphG = layerGraph(layersG);
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

```
dlnetG = dlnetwork(lgraphG);
```

Define Model Gradients Functions

Create the functions `modelGradientsD` and `modelGradientsG` listed in the Model Gradients Function on page 3-0 section of the example, that calculate the gradients of the discriminator and generator loss with respect to the learnable parameters of the discriminator and generator networks, respectively.

The function `modelGradientsD` takes as input the generator and discriminator `dlnetG` and `dlnetD`, a mini-batch of input data `dlX`, an array of random values `dlZ`, and the `lambda` value used for the gradient penalty, and returns the gradients of the loss with respect to the learnable parameters in the discriminator, and the loss.

The function `modelGradientsG` takes as input the generator and discriminator `dlnetG` and `dlnetD`, and an array of random values `dlZ`, and returns the gradients of the loss with respect to the learnable parameters in the generator, and the loss.

Specify Training Options

To train a WGAN-GP model, you must train the discriminator for more iterations than the generator. In other words, for each generator iteration, you must train the discriminator for multiple iterations.

Train with a mini-batch size of 64 for 10,000 generator iterations. For larger datasets, you might need to train for more iterations.

```
miniBatchSize = 64;
numIterationsG = 10000;
```

For each generator iteration, train the discriminator for 5 iterations.

```
numIterationsDPerG = 5;
```

For the WGAN-GP loss, specify a lambda value of 10. The lambda value controls the magnitude of the gradient penalty added to the discriminator loss.

```
lambda = 10;
```

Specify the options for Adam optimization:

- For the discriminator network, specify a learning rate of 0.0002.
- For the generator network, specify a learning rate of 0.001.
- For both networks, specify a gradient decay factor of 0 and a squared gradient decay factor of 0.9.

```
learnRateD = 2e-4;
learnRateG = 1e-3;
gradientDecayFactor = 0;
squaredGradientDecayFactor = 0.9;
```

Display the generated validation images every 20 generator iterations.

```
validationFrequency = 20;
```

Train Model

Use `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to rescale the images in the range `[-1,1]`.
- Discard any partial mini-batches.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch).
- Train on a GPU if one is available. When the `'OutputEnvironment'` option of `minibatchqueue` is `'auto'`, `minibatchqueue` converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox) (Parallel Computing Toolbox).

The `minibatchqueue` object, by default, converts the data to `dlarray` objects with underlying type `single`.

```
augimds.MiniBatchSize = miniBatchSize;
executionEnvironment = "auto";

mbq = minibatchqueue(augimds,...
    'MiniBatchSize',miniBatchSize,...
    'PartialMiniBatch','discard',...
    'MiniBatchFcn', @preprocessMiniBatch,...
    'MiniBatchFormat','SSCB',...
    'OutputEnvironment',executionEnvironment);
```

Train the model using a custom training loop. Loop over the training data and update the network parameters at each iteration. To monitor the training progress, display a batch of generated images using a held-out array of random values to input into the generator as well as a plot of the scores.

Initialize the parameters for Adam.

```
trailingAvgD = [];
trailingAvgSqD = [];
trailingAvgG = [];
trailingAvgSqG = [];
```

To monitor training progress, display a batch of generated images using a held-out batch of fixed arrays of random values fed into the generator and plot the network scores.

Create an array of held-out random values.

```
numValidationImages = 25;
ZValidation = randn(numLatentInputs,numValidationImages,'single');
```

Convert the data to `dlarray` objects and specify the dimension labels `'SSCB'` (spatial, spatial, channel, batch).

```
dlZValidation = dlarray(ZValidation,'CB');
```

For GPU training, convert the data to `gpuArray` objects.

```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZValidation = gpuArray(dlZValidation);
end
```

Initialize the training progress plots. Create a figure and resize it to have twice the width.

```
f = figure;
f.Position(3) = 2*f.Position(3);
```

Create a subplot for the generated images and the network scores.

```
imageAxes = subplot(1,2,1);
scoreAxes = subplot(1,2,2);
```

Initialize the animated lines for the loss plot.

```
C = colororder;
lineLossD = animatedline(scoreAxes,'Color',C(1,:));
lineLossDUnregularized = animatedline(scoreAxes,'Color',C(2,:));
legend('With Gradient Penalty','Unregularized')
xlabel("Generator Iteration")
ylabel("Discriminator Loss")
grid on
```

Train the WGAN-GP model by looping over mini-batches of data.

For `numIterationsDPerG` iterations, train the discriminator only. For each mini-batch:

- Evaluate the discriminator model gradients using `dlfeval` and the `modelGradientsD` function.
- Update the discriminator network parameters using the `adamupdate` function.

After training the discriminator for `numIterationsDPerG` iterations, train the generator on a single mini-batch.

- Evaluate the generator model gradients using `dlfeval` and the `modelGradientsG` function.
- Update the generator network parameters using the `adamupdate` function.

After updating the generator network:

- Plot the losses of the two networks.
- After every `validationFrequency` generator iterations, display a batch of generated images for a fixed held-out generator input.

After passing through the data set, shuffle the mini-batch queue.

Training can take some time to run and may require many iterations to output good images.

```
iterationG = 0;
iterationD = 0;
start = tic;

% Loop over mini-batches
while iterationG < numIterationsG
    iterationG = iterationG + 1;

    % Train discriminator only
    for n = 1:numIterationsDPerG
        iterationD = iterationD + 1;

        % Reset and shuffle mini-batch queue when there is no more data.
        if ~hasdata(mbq)
            shuffle(mbq);
        end

        % Read mini-batch of data.
        dlX = next(mbq);

        % Generate latent inputs for the generator network. Convert to
        % dlarray and specify the dimension labels 'CB' (channel, batch).
        Z = randn([numLatentInputs size(dlX,4)],'like',dlX);
        dlZ = dlarray(Z,'CB');

        % Evaluate the discriminator model gradients using dlfeval and the
        % modelGradientsD function listed at the end of the example.
        [gradientsD, lossD, lossDUnregularized] = dlfeval(@modelGradientsD, dlnetD, dlnetG, dlX,

        % Update the discriminator network parameters.
        [dlnetD,trailingAvgD,trailingAvgSqD] = adamupdate(dlnetD, gradientsD, ...
            trailingAvgD, trailingAvgSqD, iterationD, ...
            learnRateD, gradientDecayFactor, squaredGradientDecayFactor);
    end

    % Generate latent inputs for the generator network. Convert to dlarray
    % and specify the dimension labels 'CB' (channel, batch).
    Z = randn([numLatentInputs size(dlX,4)],'like',dlX);
    dlZ = dlarray(Z,'CB');

    % Evaluate the generator model gradients using dlfeval and the
    % modelGradientsG function listed at the end of the example.
    gradientsG = dlfeval(@modelGradientsG, dlnetG, dlnetD, dlZ);

    % Update the generator network parameters.
    [dlnetG,trailingAvgG,trailingAvgSqG] = adamupdate(dlnetG, gradientsG, ...
        trailingAvgG, trailingAvgSqG, iterationG, ...
        learnRateG, gradientDecayFactor, squaredGradientDecayFactor);

    % Every validationFrequency generator iterations, display batch of
    % generated images using the held-out generator input
    if mod(iterationG,validationFrequency) == 0 || iterationG == 1
        % Generate images using the held-out generator input.
        dlXGeneratedValidation = predict(dlnetG,dlZValidation);

        % Tile and rescale the images in the range [0 1].
```

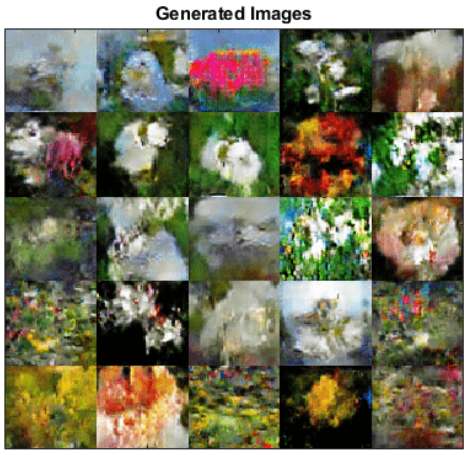
```
        I = imtile(extractdata(dlXGeneratedValidation));
        I = rescale(I);

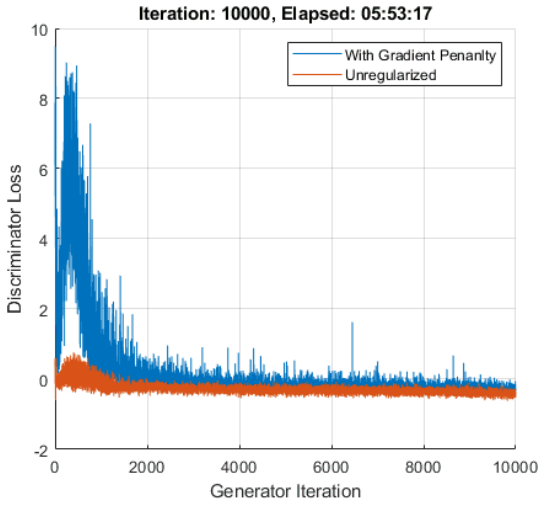
        % Display the images.
        subplot(1,2,1);
        image(imageAxes,I)
        xticklabels([]);
        yticklabels([]);
        title("Generated Images");
    end

    % Update the scores plot
    subplot(1,2,2)

    lossD = double(gather(extractdata(lossD)));
    lossDUnregularized = double(gather(extractdata(lossDUnregularized)));
    addpoints(lineLossD,iterationG,lossD);
    addpoints(lineLossDUnregularized,iterationG,lossDUnregularized);

    D = duration(0,0,toc(start),'Format','hh:mm:ss');
    title( ...
        "Iteration: " + iterationG + ", " + ...
        "Elapsed: " + string(D))
    drawnow
end
```





Here, the discriminator has learned a strong feature representation that identifies real images among generated images. In turn, the generator has learned a similarly strong feature representation that allows it to generate images similar to the training data.

Generate New Images

To generate new images, use the `predict` function on the generator with a `dlarray` object containing a batch of random vectors. To display the images together, use the `imtile` function and rescale the images using the `rescale` function.

Create a `dlarray` object containing a batch of 25 random vectors to input to the generator network.

```
ZNew = randn(numLatentInputs,25,'single');
dlZNew = dlarray(ZNew,'CB');
```

To generate images using the GPU, also convert the data to `gpuArray` objects.

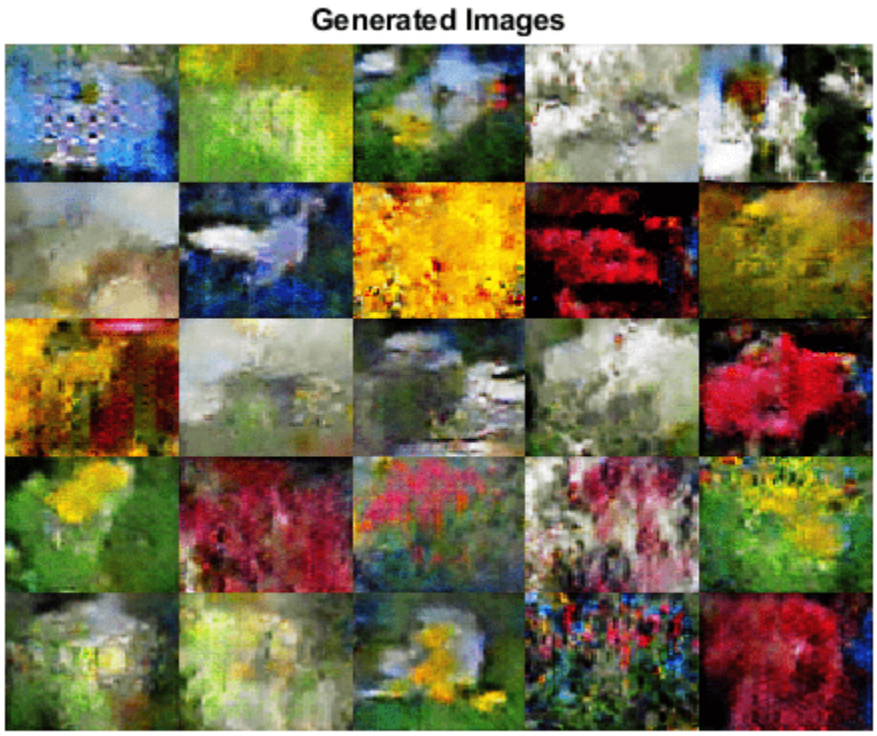
```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZNew = gpuArray(dlZNew);
end
```

Generate new images using the `predict` function with the generator and the input data.

```
dlXGeneratedNew = predict(dlnetG,dlZNew);
```

Display the images.

```
I = imtile(extractdata(dlXGeneratedNew));
I = rescale(I);
figure
image(I)
axis off
title("Generated Images")
```



Discriminator Model Gradients Function

The function `modelGradientsD` takes as input the generator and discriminator `dlnetwork` objects `dlnetG` and `dlnetD`, a mini-batch of input data `dlX`, an array of random values `dlZ`, and the `lambda` value used for the gradient penalty, and returns the gradients of the loss with respect to the learnable parameters in the discriminator, and the loss.

Given an image X, a generated image $\widetilde{X}$, define $\widehat{X} = \epsilon X + (1-\epsilon)\widetilde{X}$ for some random $\epsilon \in U(0,1)$.

For the WGAN-GP model, given the lambda value λ, the discriminator loss is given by

$$\text{loss}_D = \widetilde{Y} - Y + \lambda\left(\left\|\nabla_{\widehat{X}}\widehat{Y}\right\|_2 - 1\right)^2,$$

where Y, $\widetilde{Y}$, and $\widehat{Y}$ denote the output of the discriminator for the inputs X, $\widetilde{X}$, and $\widehat{X}$, respectively, and $\nabla_{\widehat{X}}\widehat{Y}$ denotes the gradients of the output $\widehat{Y}$ with respect to $\widehat{X}$. For a mini-batch of data, use a different value of ϵ for each obersvation and calculate the mean loss.

The gradient penalty $\lambda\left(\left\|\nabla_{\widehat{X}}\widehat{Y}\right\|_2 - 1\right)^2$ improves stability by penalizing gradients with large norm values. The lambda value controls the magnitude of the gradient penalty added to the discriminator loss.

```
function [gradientsD, lossD, lossDUnregularized] = modelGradientsD(dlnetD, dlnetG, dlX, dlZ, lamb

% Calculate the predictions for real data with the discriminator network.
dlYPred = forward(dlnetD, dlX);

% Calculate the predictions for generated data with the discriminator
% network.
dlXGenerated = forward(dlnetG,dlZ);
dlYPredGenerated = forward(dlnetD, dlXGenerated);

% Calculate the loss.
lossDUnregularized = mean(dlYPredGenerated - dlYPred);

% Calculate and add the gradient penalty.
epsilon = rand([1 1 1 size(dlX,4)],'like',dlX);
dlXHat = epsilon.*dlX + (1-epsilon).*dlXGenerated;
dlYHat = forward(dlnetD, dlXHat);

% Calculate gradients. To enable computing higher-order derivatives, set
% 'EnableHigherDerivatives' to true.
gradientsHat = dlgradient(sum(dlYHat),dlXHat,'EnableHigherDerivatives',true);
gradientsHatNorm = sqrt(sum(gradientsHat.^2,1:3) + 1e-10);
gradientPenalty = lambda.*mean((gradientsHatNorm - 1).^2);

% Penalize loss.
lossD = lossDUnregularized + gradientPenalty;

% Calculate the gradients of the penalized loss with respect to the
% learnable parameters.
gradientsD = dlgradient(lossD, dlnetD.Learnables);

end
```

Generator Model Gradients Function

The function `modelGradientsG` takes as input the generator and discriminator `dlnetwork` objects `dlnetG` and `dlnetD`, and an array of random values `dlZ`, and returns the gradients of the loss with respect to the learnable parameters in the generator.

Given a generated image $\widetilde{X}$, the loss for the generator network is given by

$$\text{loss}_G = -\widetilde{Y},$$

where $\widetilde{Y}$ denotes the output of the discriminator for the generated image $\widetilde{X}$. For a mini-batch of generated images, calculate the mean loss.

```
function gradientsG =  modelGradientsG(dlnetG, dlnetD, dlZ)

% Calculate the predictions for generated data with the discriminator
% network.
dlXGenerated = forward(dlnetG,dlZ);
dlYPredGenerated = forward(dlnetD, dlXGenerated);

% Calculate the loss.
lossG = -mean(dlYPredGenerated);

% Calculate the gradients of the loss with respect to the learnable
% parameters.
gradientsG = dlgradient(lossG, dlnetG.Learnables);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses the data using the following steps:

1. Extract the image data from the input cell array and concatenate into a numeric array.
2. Rescale the images to be in the range `[-1,1]`.

```
function X = preprocessMiniBatch(data)

% Concatenate mini-batch
X = cat(4,data{:});

% Rescale the images in the range [-1 1].
X = rescale(X,-1,1,'InputMin',0,'InputMax',255);

end
```

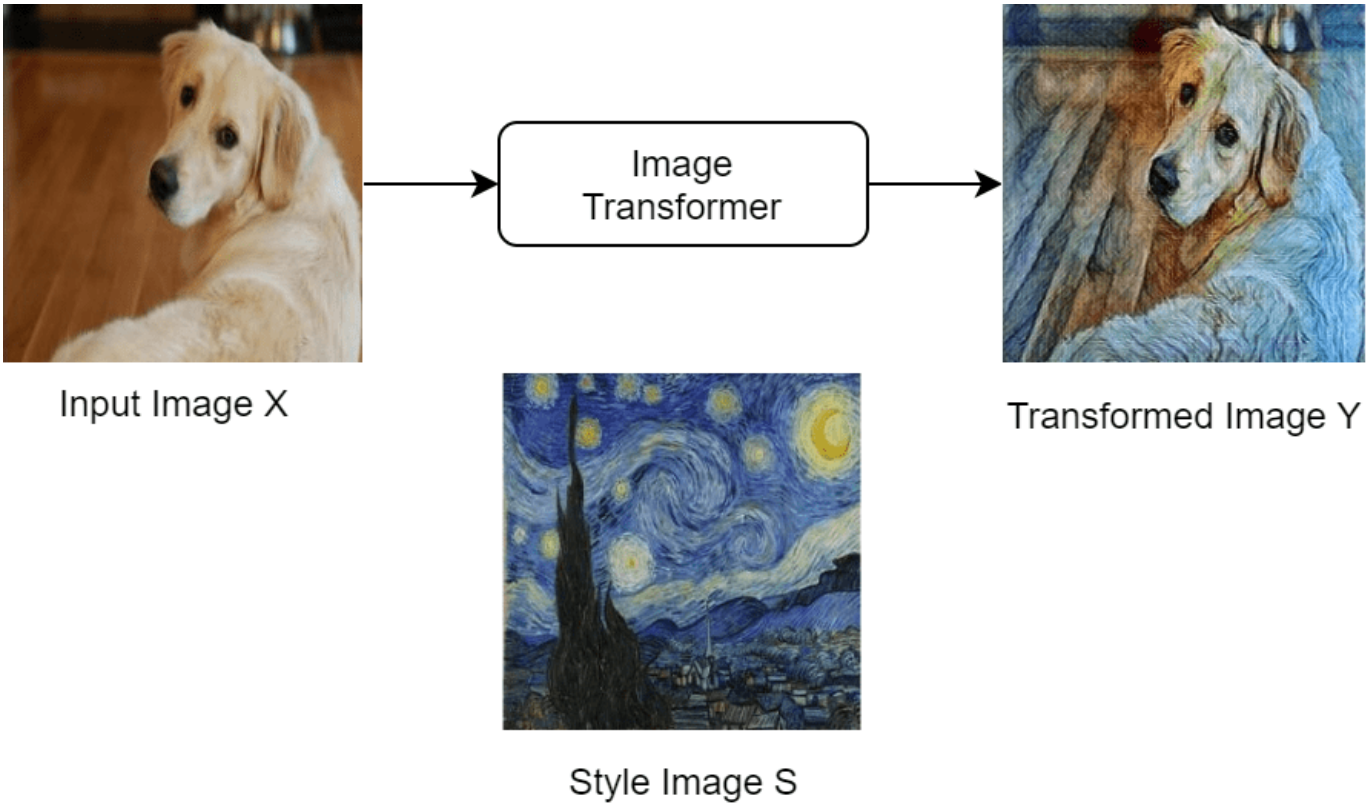
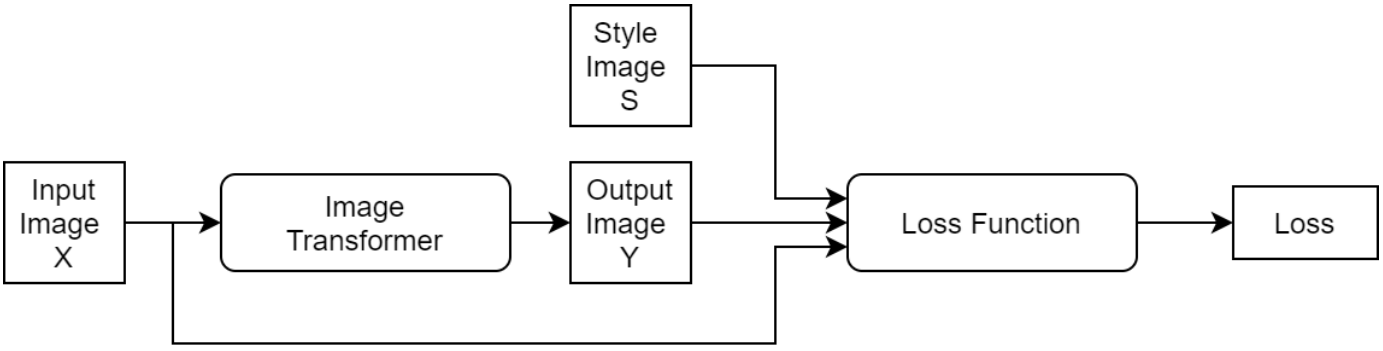
Train Fast Style Transfer Network

This example shows how to train a network to transfer the style of an image to a second image. It is based on the architecture defined in [1].

This example is similar to “Neural Style Transfer Using Deep Learning” on page 9-121, but it works faster once you have trained the network on a style image S. This is because, to obtain the stylized image Y you only need to do a forward pass of the input image X to the network.



Find a high-level diagram of the training algorithm below. This uses three images to calculate the loss: the input image X, the transformed image Y and the style image S.



Note that the loss function uses the pretrained network VGG-16 to extract features from the images. You can find its implementation and mathematical definition in the Style Transfer Loss on page 3-0 section of this example.

Load Training Data

Download and extract the COCO 2014 train images and captions from https://cocodataset.org/#download by clicking the "2014 Train images". Save the data in the folder specified by `imageFolder`. Extract the images into `imageFolder`. The COCO 2014 was collected by the Coco Consortium.

Create directories to store the COCO data set.

```
imageFolder = fullfile(tempdir,"coco");
if ~exist(imageFolder,'dir')
    mkdir(imageFolder);
end
```

Create an image datastore containing the COCO images.

```
imds = imageDatastore(imageFolder,'IncludeSubfolders',true);
```

Training can take a long time to run. If you want to decrease the training time at the cost of accuracy of the resulting network, then select a subset of the image datastore by setting `fraction` to a smaller value.

```
fraction = 1;
numObservations = numel(imds.Files);
imds = subset(imds,1:floor(numObservations*fraction));
```

To resize the images and convert them all to RGB, create an augmented image datastore.

```
augimds = augmentedImageDatastore([256 256],imds,'ColorPreprocessing',"gray2rgb");
```

Read the style image.

```
styleImage = imread('starryNight.jpg');
styleImage = imresize(styleImage,[256 256]);
```

Display the chosen style image.

```
figure
imshow(styleImage)
title("Style Image")
```

Define Image Transformer Network

Define the image transformer network. This is an image-to-image network. The network consists of 3 parts:

1. The first part of the network takes as input an RGB image of size [256x256x3] and downsamples it to a feature map of size [64x64x128].
2. The second part of the network consists of five identical residual blocks defined in the supporting function `residualBlock`.
3. The third and final part of the network upsamples the feature map to the original size of the image and returns the transformed image. This last part uses the `upsampleLayer`, which is a custom layer attached to this example as a supporting file.

```
layers = [

    % First part.
    imageInputLayer([256 256 3], 'Name', 'input', 'Normalization','none')

    convolution2dLayer([9 9], 32, 'Padding','same','Name', 'conv1')
    groupNormalizationLayer('channel-wise','Name','norm1')
    reluLayer('Name', 'relu1')

    convolution2dLayer([3 3], 64, 'Stride', 2,'Padding','same','Name', 'conv2')
    groupNormalizationLayer('channel-wise' ,'Name','norm2')
    reluLayer('Name', 'relu2')

    convolution2dLayer([3 3], 128, 'Stride', 2, 'Padding','same','Name', 'conv3')
    groupNormalizationLayer('channel-wise' ,'Name','norm3')
    reluLayer('Name', 'relu3')
```

```
    % Second part.
    residualBlock("1")
    residualBlock("2")
    residualBlock("3")
    residualBlock("4")
    residualBlock("5")

    % Third part.
    upsampleLayer('up1')
    convolution2dLayer([3 3], 64, 'Stride', 1, 'Padding','same','Name', 'upconv1')
    groupNormalizationLayer('channel-wise' ,'Name','norm6')
    reluLayer('Name', 'relu5')

    upsampleLayer('up2')
    convolution2dLayer([3 3], 32, 'Stride', 1, 'Padding','same','Name', 'upconv2')
    groupNormalizationLayer('channel-wise' ,'Name','norm7')
    reluLayer('Name', 'relu6')

    convolution2dLayer(9,3,'Padding','same','Name','conv_out')];

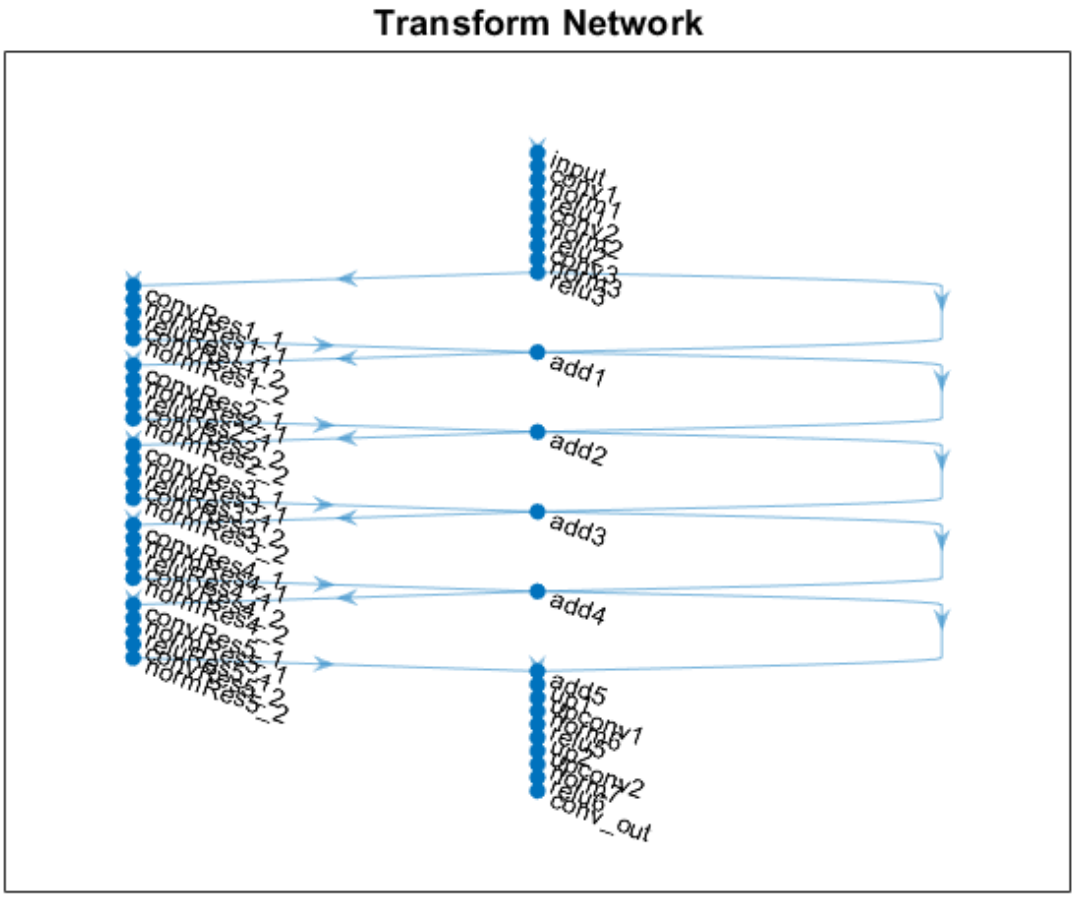
lgraph = layerGraph(layers);
```

Add missing connections in residual blocks.

```
lgraph = connectLayers(lgraph,"relu3","add1/in2");
lgraph = connectLayers(lgraph,"add1","add2/in2");
lgraph = connectLayers(lgraph,"add2","add3/in2");
lgraph = connectLayers(lgraph,"add3","add4/in2");
lgraph = connectLayers(lgraph,"add4","add5/in2");
```

Visualize the image transformer network in a plot.

```
figure
plot(lgraph)
title("Transform Network")
```



Create a `dlnetwork` object from the layer graph.

```
dlnetTransform = dlnetwork(lgraph);
```

Style Loss Network

This example uses a pretrained VGG-16 deep neural network to extract the features of the content and style images at different layers. These multilayer features are used to compute respective content and style losses.

To get a pretrained VGG-16 network, use the `vgg16` function. If you do not have the required support packages installed, then the software provides a download link.

```
netLoss = vgg16;
```

To extract the feature necessary to calculate the loss you need the first 24 layers only. Extract and convert to a layer graph.

```
lossLayers = netLoss.Layers(1:24);
lgraph = layerGraph(lossLayers);
```

Convert to a `dlnetwork`.

```
dlnetLoss = dlnetwork(lgraph);
```

Define the Loss Function and Gram Matrix

Create the `styleTransferLoss` function defined in the Style Transfer Loss on page 3-0 section of this example.

The function `styleTransferLoss` takes as input the loss network `dlnetLoss`, a mini-batch of input transformed images `dlX`, a mini-batch of transformed images `dlY`, an array containing the Gram matrices of the style image `dlSGram`, the weight associated with the content loss `contentWeight` and the weight associated with the style loss `styleWeight`. The function returns the total loss `loss` and the individual components: the content loss `lossContent` and the style loss `lossStyle`.

The `styleTransferLoss` function uses the supporting function `createGramMatrix` in the computation of the style loss.

The `createGramMatrix` function takes as an input the features extracted by the loss network and returns a stylistic representation for each image in a mini-batch. You can find the implementation and mathematical definition of the Gram matrix in the section Gram Matrix on page 3-0 .

Define the Model Gradients Function

Create the function `modelGradients`, listed in the Model Gradients Function on page 3-0 section of the example. This function takes as input the loss network `dlnetLoss`, the image transformer network `dlnetTransform`, a mini-batch of input images `dlX`, an array containing the Gram matrices of the style image `dlSGram`, the weight associated with the content loss `contentWeight` and the weight associated with the style loss `styleWeight`. The function returns the `gradients` of the loss with respect to the learnable parameters of the image transformer, the state of the image transformer network, the transformed images `dlY`, the total loss `loss`, the loss associated with the content `lossContent` and the loss associated with the style `lossStyle`.

Specify Training Options

Train with a mini-batch size of 4 for 2 epochs as in [1].

```
numEpochs = 2;
miniBatchSize = 4;
```

Set the read size of the augmented image datastore to the mini-batch size.

```
augimds.MiniBatchSize = miniBatchSize;
```

Specify the options for ADAM optimization. Specify a learn rate of 0.001 with a gradient decay factor of 0.01, and a squared gradient decay factor of 0.999.

```
learnRate = 0.001;
gradientDecayFactor = 0.9;
squaredGradientDecayFactor = 0.999;
```

Train on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
executionEnvironment = "auto";
```

Specify the weight given to the style loss and the one given to the content loss in the calculation of the total loss.

Note that, in order to find a good balance between content and style loss, you might need to experiment with different combinations of weights.

```
weightContent = 1e-4;
weightStyle = 3e-8;
```

Choose the plot frequency of the training progress. This specifies how many iterations there are between each plot update.

```
plotFrequency = 10;
```

Train Model

In order to be able to compute the loss during training, calculate the Gram matrices for the style image.

Convert the style image to `dlarray`.

```
dlS = dlarray(single(styleImage),'SSC');
```

In order to calculate the Gram matrix, feed the style image to the VGG-16 network and extract the activations at four different layers.

```
[dlSActivations1,dlSActivations2,dlSActivations3,dlSActivations4] = forward(dlnetLoss,dlS, ...
    'Outputs',["relu1_2" "relu2_2" "relu3_3" "relu4_3"]);
```

Calculate the Gram matrix for each set of activations using the supporting function `createGramMatrix`.

```
dlSGram{1} = createGramMatrix(dlSActivations1);
dlSGram{2} = createGramMatrix(dlSActivations2);
dlSGram{3} = createGramMatrix(dlSActivations3);
dlSGram{4} = createGramMatrix(dlSActivations4);
```

The training plots consists of two figures:

1. A figure showing a plot of the losses during training
2. A figure containing an input and an output image of the image transformer network

Initialize the training plots. You can check the details of the initialization in the supporting function `initializeFigures.` This function returns: the axis `ax1` where you plot the loss, the axis `ax2` where you plot the validation images, the animated line `lineLossContent` which contains the content loss, the animated line `lineLossStyle` which contains the style loss and the animated line `lineLossTotal` which contains the total loss.

```
[ax1,ax2,lineLossContent,lineLossStyle,lineLossTotal]=initializeStyleTransferPlots();
```

Initialize the average gradient and average squared gradient hyperparameters for the ADAM optimizer.

```
averageGrad = [];
averageSqGrad = [];
```

Calculate total number of training iterations.

```
numIterations = floor(augimds.NumObservations*numEpochs/miniBatchSize);
```

Initialize iteration number and timer before training.

```
iteration = 0;
start = tic;
```

Train the model. This could take a long time to run.

```
% Loop over epochs.
for i = 1:numEpochs

    % Reset and shuffle datastore.
    reset(augimds);
    augimds = shuffle(augimds);

    % Loop over mini-batches.
    while hasdata(augimds)
        iteration = iteration + 1;

        % Read mini-batch of data.
        data = read(augimds);

        % Ignore last partial mini-batch of epoch.
        if size(data,1) < miniBatchSize
            continue
        end

        % Extract the images from data store into a cell array.
        images = data{:,1};

        % Concatenate the images along the 4th dimension.
        X = cat(4,images{:});
        X = single(X);

        % Convert mini-batch of data to dlarray and specify the dimension labels
        % 'SSCB' (spatial, spatial, channel, batch).
        dlX = dlarray(X, 'SSCB');

        % If training on a GPU, then convert data to gpuArray.
        if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
            dlX = gpuArray(dlX);
        end

        % Evaluate the model gradients and the network state using
        % dlfeval and the modelGradients function listed at the end of the
        % example.
        [gradients,state,dlY,loss,lossContent,lossStyle] = dlfeval(@modelGradients, ...
            dlnetLoss,dlnetTransform,dlX,dlSGram,weightContent,weightStyle);

        dlnetTransform.State = state;

        % Update the network parameters.
        [dlnetTransform,averageGrad,averageSqGrad] = ...
            adamupdate(dlnetTransform,gradients,averageGrad,averageSqGrad,iteration,...
            learnRate, gradientDecayFactor, squaredGradientDecayFactor);
```

```
        % Every plotFequency iterations, plot the training progress.
        if mod(iteration,plotFrequency) == 0
            addpoints(lineLossTotal,iteration,double(gather(extractdata(loss))))
            addpoints(lineLossContent,iteration,double(gather(extractdata(lossContent))))
            addpoints(lineLossStyle,iteration,double(gather(extractdata(lossStyle))))

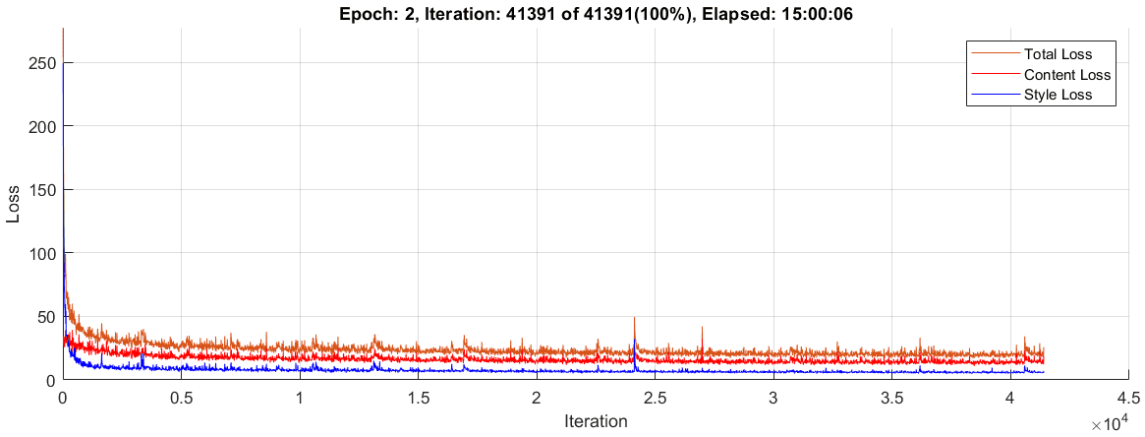
            % Use the first image of the mini-batch as a validation image.
            dlV = dlX(:,:,:,1);
            % Use the transformed validation image computed previously.
            dlVY = dlY(:,:,:,1);

            % To use the function imshow, convert to uint8.
            validationImage = uint8(gather(extractdata(dlV)));
            transformedValidationImage = uint8(gather(extractdata(dlVY)));

            % Plot the input image and the output image and increase size
            imshow(imtile({validationImage,transformedValidationImage}),'Parent',ax2);
        end

        % Display time elapsed since start of training and training completion percentage.
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        completionPercentage = round(iteration/numIterations*100,2);
        title(ax1,"Epoch: " + i + ", Iteration: " + iteration +" of "+ numIterations + "(" + comp
        drawnow

    end
end
```



Stylize an Image

Once training has finished, you can use the image transformer on any image of your choice.

Load the image you would like to transform.

```
imFilename = 'peppers.png';
im = imread(imFilename);
```

Resize the input image to the input dimensions of the image transformer.

```
im = imresize(im,[256,256]);
```

Convert it to `dlarray`.

```
dlX = dlarray(single(im),'SSCB');
```

To use the GPU convert to `gpuArray` if one is available.

```
if canUseGPU
    dlX = gpuArray(dlX);
end
```

To apply the style to the image, forward pass it to the image transformer using the function `predict.`

```
dlY = predict(dlnetTransform,dlX);
```

Rescale the image into the range [0 255]. First, use the function `tanh` to rescale `dlY` to the range [-1 1]. Then, shift and scale the output to rescale into the [0 255] range.

```
Y = 255*(tanh(dlY)+1)/2;
```

Prepare `Y` for plotting. Use the function `extractdata` to extract the data from `dlarray.` Use the function gather to transfer Y from the GPU to the local workspace.

```
Y = uint8(gather(extractdata(Y)));
```

Show the input image (left) next to the stylized image (right).

```
figure
m = imtile({im,Y});
imshow(m)
```

Model Gradients Function

The function `modelGradients` takes as input the loss network `dlnetLoss`, the image transformer network `dlnetTransform`, a mini-batch of input images `dlX`, an array containing the Gram matrices of the style image `dlSGram`, the weight associated with the content loss `contentWeight` and the weight associated with the style loss `styleWeight`. It returns the `gradients` of the loss with respect to the learnable parameters of the image transformer, the state of the image transformer network, the transformed images `dlY`, the total loss `loss`, the loss associated with the content `lossContent` and the loss associated with the style `lossStyle.`

```
function [gradients,state,dlY,loss,lossContent,lossStyle] = ...
    modelGradients(dlnetLoss,dlnetTransform,dlX,dlSGram,contentWeight,styleWeight)

[dlY,state] = forward(dlnetTransform,dlX);

dlY = 255*(tanh(dlY)+1)/2;

[loss,lossContent,lossStyle] = styleTransferLoss(dlnetLoss,dlY,dlX,dlSGram,contentWeight,styleWe

gradients = dlgradient(loss,dlnetTransform.Learnables);

end
```

Style Transfer Loss

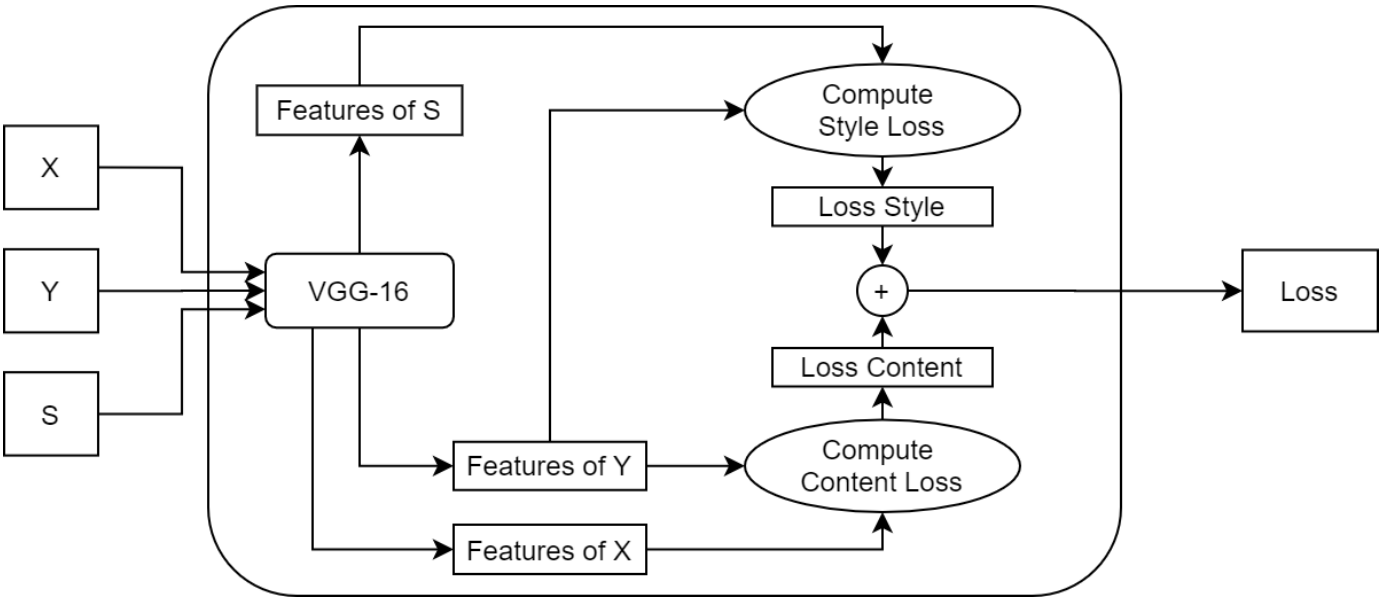
The function `styleTransferLoss` takes as input the loss network `dlnetLoss`, a mini-batch of input images `dlX`, a mini-batch of transformed images `dlY`, an array containing the Gram matrices of the style image `dlSGram`, the weights associated with the content and style `contentWeight` and `styleWeight`, respectively. It returns the total loss `loss` and the individual components: the content loss `lossContent` and the style loss `lossStyle`.

The content loss is a measure of how much difference in spatial structure there is between the input image X and the output images Y.

On the other hand, the style loss tells you how much difference in the stylistic appearance there is between the style image S and the output image Y.

The graph below explains the algorithm that `styleTransferLoss` implements to calculate the total loss.

First, the function passes the input images X, the transformed images Y and the style image S to the pretrained network VGG-16. This pretrained network extracts several features from these images. The algorithm then calculates the content loss by using the spatial features of the input image X and of the output image Y. Moreover, it calculates the style loss by using the stylistic features of the output image Y and of the style image S. Finally, it obtains the total loss by adding the content and style losses.



Content Loss

For each image in the mini-batch, the content loss function compares the features of the original image and of the transformed image output by the layer `relu_3_3`. In particular, it calculates the mean square error between the activations and returns the average loss for the mini-batch:

$$\text{lossContent} = \frac{1}{N}\sum_{n=1}^{N} \text{mean}([\phi(X_n) - \phi(Y_n)]^2),$$

where X contains the input images, Y contains the transformed images, N is the mini-batch size, and $\phi()$ represents the activations extracted at layer `relu_3_3`.

Style Loss

To calculate the style loss, for each single image in the mini-batch:

1. Extract the activations at the layers `relu1_2`, `relu2_2`, `relu3_3` and `relu4_3`.
2. For each of the four activations ϕ_j compute the Gram matrix $G(\phi_j)$.
3. Calculate the squared difference between the corresponding Gram matrices.
4. Add up the four outputs for each layer j from the previous step.

To obtain the style loss for the whole mini-batch, compute the average of the style loss for each image n in the mini-batch:

$$\text{lossStyle} = \frac{1}{N}\sum_{n=1}^{N}\sum_{j=1}^{4} [G(\phi_j(X_n)) - G(\phi_j(S))]^2,$$

where j is the index of the layer, and $G()$ is the Gram Matrix.

Total Loss

```
function [loss,lossContent,lossStyle] = styleTransferLoss(dlnetLoss,dlY,dlX, ...
    dlSGram,weightContent,weightStyle)
```

```
% Extract activations.
dlYActivations = cell(1,4);
[dlYActivations{1},dlYActivations{2},dlYActivations{3},dlYActivations{4}] = ...
    forward(dlnetLoss,dlY,'Outputs',["relu1_2" "relu2_2" "relu3_3" "relu4_3"]);

dlXActivations = forward(dlnetLoss,dlX,'Outputs','relu3_3');

% Calculate the mean square error between activations.
lossContent = mean((dlYActivations{3} - dlXActivations).^2,'all');

% Add up the losses for all the four activations.
lossStyle = 0;
for j = 1:4
    G = createGramMatrix(dlYActivations{j});
    lossStyle = lossStyle + sum((G - dlSGram{j}).^2,'all');
end

% Average the loss over the mini-batch.
miniBatchSize = size(dlX,4);
lossStyle = lossStyle/miniBatchSize;

% Apply weights.
lossContent = weightContent * lossContent;
lossStyle = weightStyle * lossStyle;

% Calculate the total loss.
loss = lossContent + lossStyle;

end
```

Residual Block

The `residualBlock` function returns an array of six layers. It consists of convolution layers, instance normalization layers, a ReLu layer and an addition layer. Note that `groupNormalizationLayer('channel-wise')` is simply an instance normalization layer.

```
function layers = residualBlock(name)

layers = [
    convolution2dLayer([3 3], 128, 'Stride', 1,'Padding','same','Name', "convRes"+name+"_1")
    groupNormalizationLayer('channel-wise','Name',"normRes"+name+"_1")
    reluLayer('Name', "reluRes"+name+"_1")
    convolution2dLayer([3 3], 128, 'Stride', 1,'Padding','same', 'Name', "convRes"+name+"_2")
    groupNormalizationLayer('channel-wise','Name',"normRes"+name+"_2")
    additionLayer(2,'Name',"add"+name)];

end
```

Gram Matrix

The function `createGramMatrix` takes as an input the activations of a single layer and returns a stylistic representation for each image in a mini-batch. The input is a feature map of size [H, W, C, N], where H is the height, W is the width, C is the number of channels and N is the mini-batch size. The function outputs an array `G` of size [C,C,N]. Each subarray `G(:,:,k)` is the Gram matrix corresponding to the k^{th} image in the mini-batch. Each entry $G(i, j, k)$ of the Gram matrix represents

the correlation between channels c_i and c_j, because each entry in channel c_i multiplies the entry in the corresponding position in channel c_j:

$$G(i,j,k) = \frac{1}{C \times H \times W} \sum_{h=1}^{H} \sum_{w=1}^{W} \phi_k(h,w,c_i)\phi_k(h,w,c_j),$$

where ϕ_k are the activations for the k^{th} image in the mini-batch.

The Gram matrix contains information about which features activate together but has no information about where the features occur in the image. This is because the summation over height and width loses the information about the spatial structure. The loss function uses this matrix as a stylistic representation of the image.

```
function G = createGramMatrix(activations)

[h,w,numChannels] = size(activations,1:3);

features = reshape(activations,h*w,numChannels,[]);
featuresT = permute(features,[2 1 3]);

G = dlmtimes(featuresT,features) / (h*w*numChannels);

end
```

Train a Siamese Network to Compare Images

This example shows how to train a Siamese network to identify similar images of handwritten characters.

A Siamese network is a type of deep learning network that uses two or more identical subnetworks that have the same architecture and share the same parameters and weights. Siamese networks are typically used in tasks that involve finding the relationship between two comparable things. Some common applications for Siamese networks include facial recognition, signature verification [1], or paraphrase identification [2]. Siamese networks perform well in these tasks because their shared weights mean there are fewer parameters to learn during training and they can produce good results with a relatively small amount of training data.

Siamese networks are particularly useful in cases where there are large numbers of classes with small numbers of observations of each. In such cases, there is not enough data to train a deep convolutional neural network to classify images into these classes. Instead, the Siamese network can determine if two images are in the same class.

This example use the Omniglot dataset [3] to train a Siamese network to compare images of handwritten characters [4]. The Omniglot dataset contains character sets for 50 alphabets, divided into 30 used for training and 20 for testing. Each alphabet contains a number of characters from 14 for Ojibwe (Canadia Aboriginal Sullabics) to 55 for Tifinagh. Finally, each character has 20 handwritten observations. This example trains a network to identify whether two handwritten observations are different instances of the same character.

You can also use Siamese networks to identify similar images using dimensionality reduction. For an example, see “Train a Siamese Network for Dimensionality Reduction” on page 3-142.

Load and Preprocess Training Data

Download and extract the Omniglot training dataset.

```
url = "https://github.com/brendenlake/omniglot/raw/master/python/images_background.zip";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"images_background.zip");

dataFolderTrain = fullfile(downloadFolder,'images_background');
if ~exist(dataFolderTrain,"dir")
    disp("Downloading Omniglot training data (4.5 MB)...")
    websave(filename,url);
    unzip(filename,downloadFolder);
end
disp("Training data downloaded.")
```

```
Training data downloaded.
```

Load the training data as a image datastore using the `imageDatastore` function. Specify the labels manually by extracting the labels from the file names and setting the `Labels` property.

```
imdsTrain = imageDatastore(dataFolderTrain, ...
    'IncludeSubfolders',true, ...
    'LabelSource','none');

files = imdsTrain.Files;
parts = split(files,filesep);
```

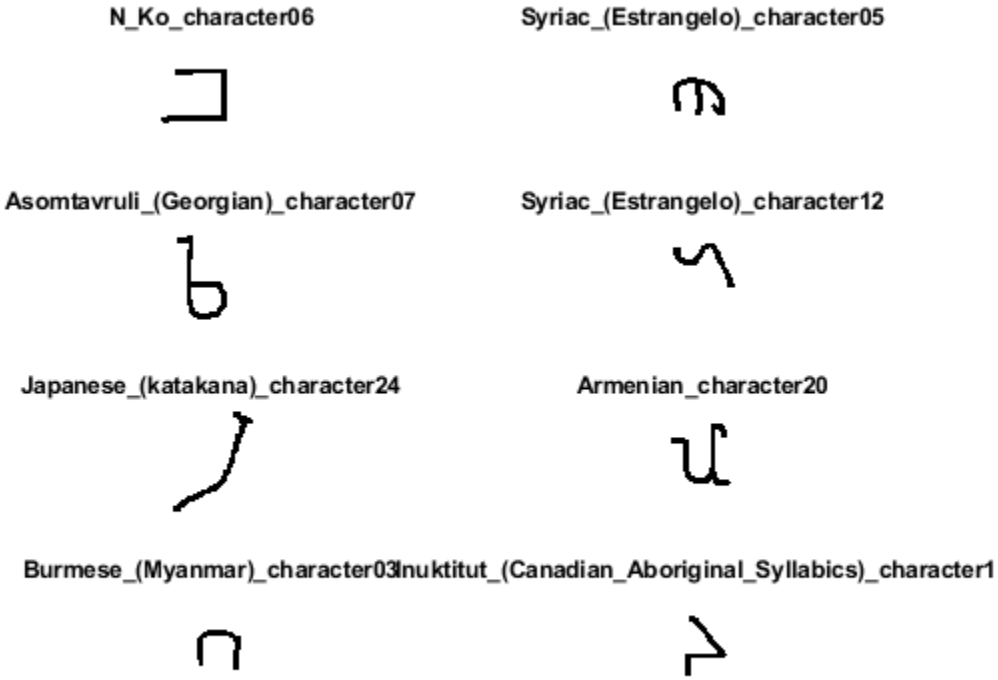
```
labels = join(parts(:,(end-2):(end-1)),'_');
imdsTrain.Labels = categorical(labels);
```

The Omniglot training dataset consists of black and white handwritten characters from 30 alphabets, with 20 observations of each character. The images are of size 105-by-105-by-1, and the values of each pixel are between `0` and `1`.

Display a random selection of the images.

```
idxs = randperm(numel(imdsTrain.Files),8);

for i = 1:numel(idxs)
    subplot(4,2,i)
    imshow(readimage(imdsTrain,idxs(i)))
    title(imdsTrain.Labels(idxs(i)), "Interpreter","none");
end
```



Create Pairs of Similar and Dissimilar Images

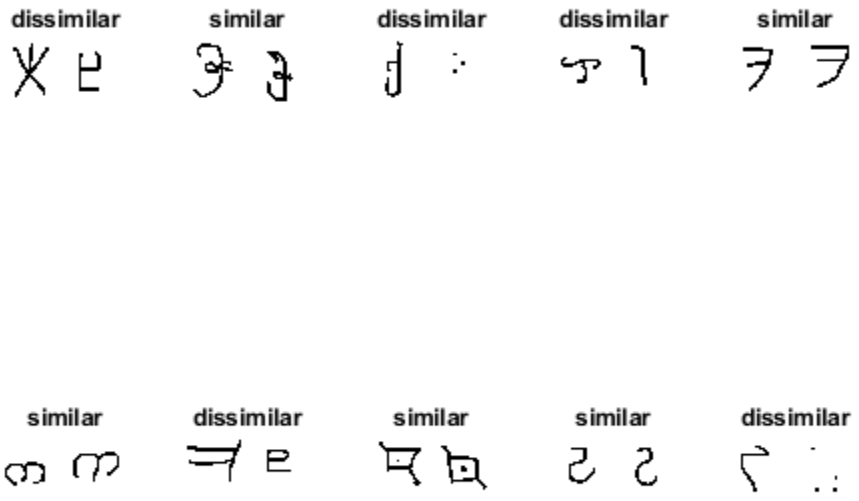
To train the network, the data must be grouped into pairs of images that are either similar or dissimilar. Here, similar images are different handwritten instances of the same character, which have the same label, while dissimilar images of different characters have different labels. The function `getSiameseBatch` (defined in the Supporting Functions on page 3-0 section of this example) creates randomized pairs of similar or dissimilar images, `pairImage1` and `pairImage2`. The function also returns the label `pairLabel`, which identifies if the pair of images is similar or dissimilar to each other. Similar pairs of images have `pairLabel = 1`, while dissimilar pairs have `pairLabel = 0`.

As an example, create a small representative set of five pairs of images

```
batchSize = 10;
[pairImage1,pairImage2,pairLabel] = getSiameseBatch(imdsTrain,batchSize);
```

Display the generated pairs of images.

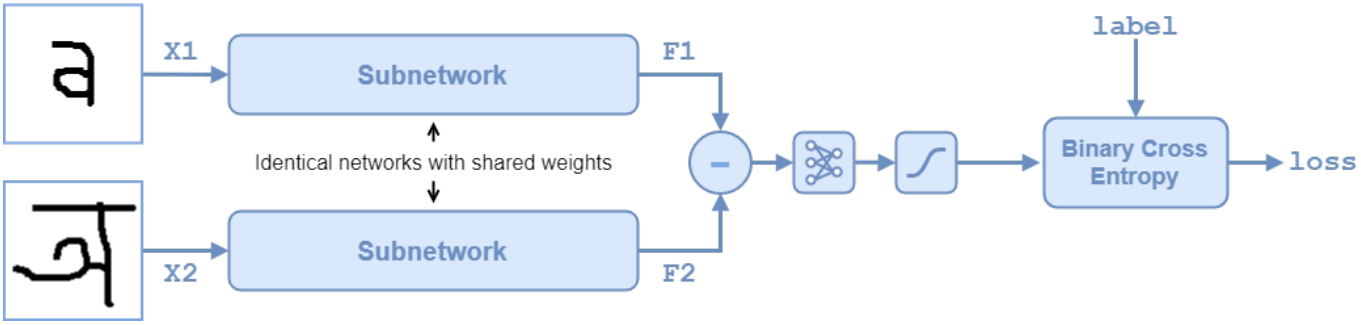
```
for i = 1:batchSize
    if pairLabel(i) == 1
        s = "similar";
    else
        s = "dissimilar";
    end
    subplot(2,5,i)
    imshow([pairImage1(:,:,:,i) pairImage2(:,:,:,i)]);
    title(s)
end
```



In this example, a new batch of 180 paired images is created for each iteration of the training loop. This ensures that the network is trained on a large number of random pairs of images with approximately equal proportions of similar and dissimilar pairs.

Define Network Architecture

The Siamese network architecture is illustrated in the following diagram.



To compare two images, each image is passed through one of two identical subnetworks that share weights. The subnetworks convert each 105-by-105-by-1 image to a 4096-dimensional feature vector. Images of the same class have similar 4096-dimensional representations. The output feature vectors from each subnetwork are combined through subtraction and the result is passed through a `fullyconnect` operation with a single output. A `sigmoid` operation converts this value to a probability between `0` and `1`, indicating the network's prediction of whether the images are similar or dissimilar. The binary cross-entropy loss between the network prediction and the true label is used to update the network during training.

In this example, the two identical subnetworks are defined as a `dlnetwork` object. The final `fullyconnect` and `sigmoid` operations are performed as functional operations on the subnetwork outputs.

Create the subnetwork as a series of layers that accepts 105-by-105-by-1 images and outputs a feature vector of size 4096.

For the `convolution2dLayer` objects, use the narrow normal distribution to initialize the weights and bias.

For the `maxPooling2dLayer` objects, set the stride to 2.

For the final `fullyConnectedLayer` object, specify an output size of 4096 and use the narrow normal distribution to initialize the weights and bias.

```
layers = [
    imageInputLayer([105 105 1],'Name','input1','Normalization','none')
    convolution2dLayer(10,64,'Name','conv1','WeightsInitializer','narrow-normal','BiasInitialize
    reluLayer('Name','relu1')
    maxPooling2dLayer(2,'Stride',2,'Name','maxpool1')
    convolution2dLayer(7,128,'Name','conv2','WeightsInitializer','narrow-normal','BiasInitialize
    reluLayer('Name','relu2')
    maxPooling2dLayer(2,'Stride',2,'Name','maxpool2')
    convolution2dLayer(4,128,'Name','conv3','WeightsInitializer','narrow-normal','BiasInitialize
    reluLayer('Name','relu3')
    maxPooling2dLayer(2,'Stride',2,'Name','maxpool3')
    convolution2dLayer(5,256,'Name','conv4','WeightsInitializer','narrow-normal','BiasInitialize
    reluLayer('Name','relu4')
    fullyConnectedLayer(4096,'Name','fc1','WeightsInitializer','narrow-normal','BiasInitializer'
```

```
lgraph = layerGraph(layers);
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

```
dlnet = dlnetwork(lgraph);
```

Create the weights for the final `fullyconnect` operation. Initialize the weights by sampling a random selection from a narrow normal distribution with standard deviation of 0.01.

```
fcWeights = dlarray(0.01*randn(1,4096));
fcBias = dlarray(0.01*randn(1,1));

fcParams = struct(...
    "FcWeights",fcWeights,...
    "FcBias",fcBias);
```

To use the network, create the function `forwardSiamese` (defined in the Supporting Functions on page 3-0 section of this example) that defines how the two subnetworks and the subtraction, `fullyconnect`, and `sigmoid` operations are combined. The function `forwardSiamese` accepts the network, the structure containing the parameters for the `fullyconnect` operation, and two training images. The `forwardSiamese` function outputs a prediction about the similarity of the two images.

Define Model Gradients Function

Create the function `modelGradients` (defined in the Supporting Functions on page 3-0 section of this example). The `modelGradients` function takes the Siamese subnetwork `dlnet`, the parameter structure for the `fullyconnect` operation, and a mini-batch of input data `X1` and `X2` with their labels `pairLabels`. The function returns the loss values and the gradients of the loss with respect to the learnable parameters of the network.

The objective of the Siamese network is to discriminate between the two inputs `X1` and `X2`. The output of the network is a probability between `0` and `1`, where a value closer to `0` indicates a prediction that the images are dissimilar, and a value closer to `1` that the images are similar. The loss is given by the binary cross-entropy between the predicted score and the true label value:

$$\text{loss} = -t\log(y) - (1-t)\log(1-y),$$

where the true label t can be 0 or 1 and y is the predicted label.

Specify Training Options

Specify the options to use during training. Train for 10000 iterations.

```
numIterations = 10000;
miniBatchSize = 180;
```

Specify the options for ADAM optimization:

- Set the learning rate to `0.00006`.
- Initialize the trailing average gradient and trailing average gradient-square decay rates with `[]` for both `dlnet` and `fcParams`.
- Set the gradient decay factor to `0.9` and the squared gradient decay factor to `0.99`.

```
learningRate = 6e-5;
trailingAvgSubnet = [];
trailingAvgSqSubnet = [];
trailingAvgParams = [];
trailingAvgSqParams = [];
gradDecay = 0.9;
gradDecaySq = 0.99;
```

Train on a GPU, if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel

Computing Toolbox). To automatically detect if you have a GPU available and place the relevant data on the GPU, set the value of `executionEnvironment` to `"auto"`. If you don't have a GPU, or don't want to use one for training, set the value of `executionEnvironment` to `"cpu"`. To ensure you use a GPU for training, set the value of `executionEnvironment` to `"gpu"`.

```
executionEnvironment = "auto";
```

To monitor the training progress, you can plot the training loss after each iteration. Create the variable `plots` that contains `"training-progress"`. If you don't want to plot the training progress, set this value to `"none"`.

```
plots = "training-progress";
```

Initialize the plot parameters for the training loss progress plot.

```
plotRatio = 16/9;

if plots == "training-progress"
    trainingPlot = figure;
    trainingPlot.Position(3) = plotRatio*trainingPlot.Position(4);
    trainingPlot.Visible = 'on';

    trainingPlotAxes = gca;

    lineLossTrain = animatedline(trainingPlotAxes);
    xlabel(trainingPlotAxes,"Iteration")
    ylabel(trainingPlotAxes,"Loss")
    title(trainingPlotAxes,"Loss During Training")
end
```

Train Model

Train the model using a custom training loop. Loop over the training data and update the network parameters at each iteration.

For each iteration:

- Extract a batch of image pairs and labels using the `getSiameseBatch` function defined in the section Create Batches of Image Pairs on page 3-0 .
- Convert the data to `dlarray` objects with underlying type `single` and specify the dimension labels `'SSCB'` (spatial, spatial, channel, batch) for the image data and `'CB'` (channel, batch) for the labels.
- For GPU training, convert the data to `gpuArray` objects.
- Evaluate the model gradients using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.

```
% Loop over mini-batches.
for iteration = 1:numIterations

    % Extract mini-batch of image pairs and pair labels
    [X1,X2,pairLabels] = getSiameseBatch(imdsTrain,miniBatchSize);

    % Convert mini-batch of data to dlarray. Specify the dimension labels
    % 'SSCB' (spatial, spatial, channel, batch) for image data
    dlX1 = dlarray(single(X1),'SSCB');
    dlX2 = dlarray(single(X2),'SSCB');
```

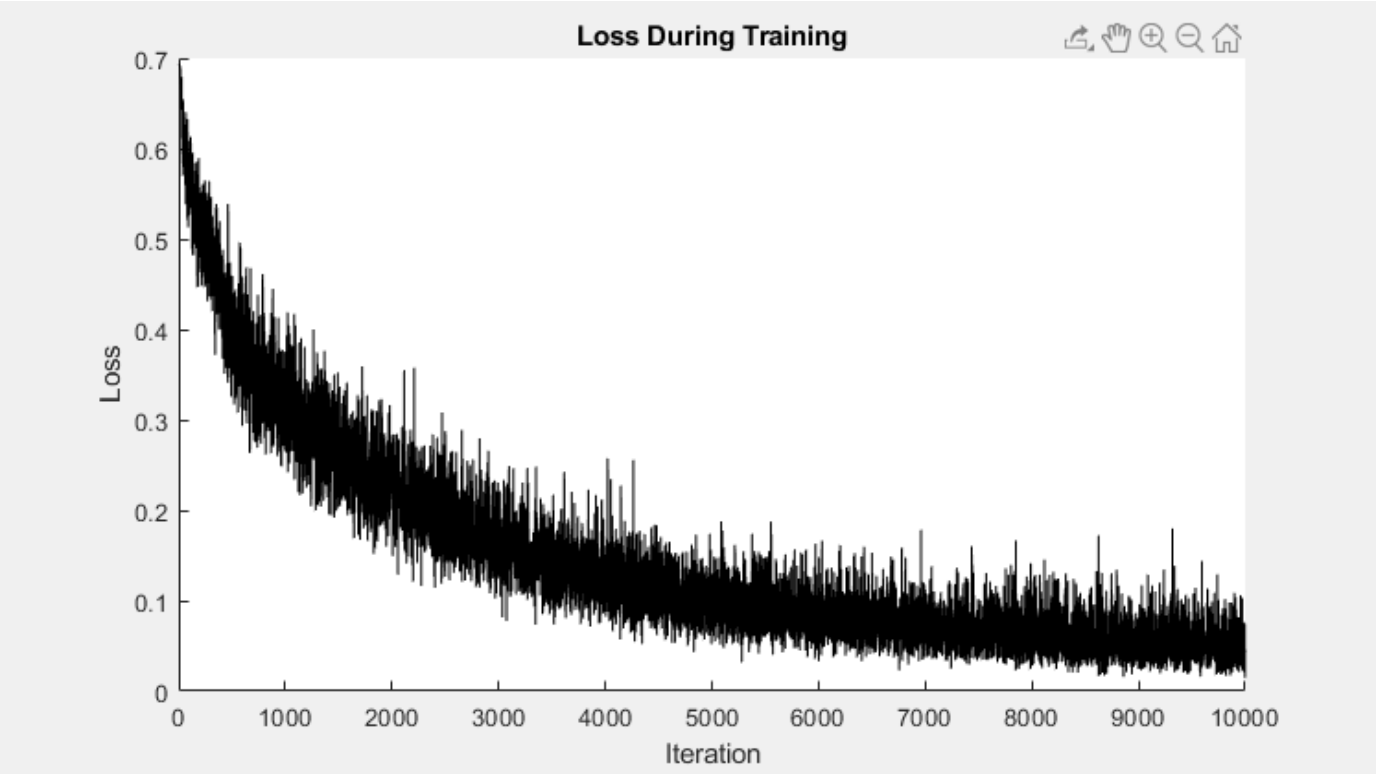
```
        % If training on a GPU, then convert data to gpuArray.
        if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
            dlX1 = gpuArray(dlX1);
            dlX2 = gpuArray(dlX2);
        end

        % Evaluate the model gradients and the generator state using
        % dlfeval and the modelGradients function listed at the end of the
        % example.
        [gradientsSubnet, gradientsParams,loss] = dlfeval(@modelGradients,dlnet,fcParams,dlX1,dlX2,pa
        lossValue = double(gather(extractdata(loss)));

        % Update the Siamese subnetwork parameters.
        [dlnet,trailingAvgSubnet,trailingAvgSqSubnet] = ...
            adamupdate(dlnet,gradientsSubnet, ...
            trailingAvgSubnet,trailingAvgSqSubnet,iteration,learningRate,gradDecay,gradDecaySq);

        % Update the fullyconnect parameters.
        [fcParams,trailingAvgParams,trailingAvgSqParams] = ...
            adamupdate(fcParams,gradientsParams, ...
            trailingAvgParams,trailingAvgSqParams,iteration,learningRate,gradDecay,gradDecaySq);

        % Update the training loss progress plot.
        if plots == "training-progress"
            addpoints(lineLossTrain,iteration,lossValue);
        end
        drawnow;
    end
```



Evaluate the Accuracy of the Network

Download and extract the Omniglot test dataset.

```
url = 'https://github.com/brendenlake/omniglot/raw/master/python/images_evaluation.zip';
downloadFolder = tempdir;
filename = fullfile(downloadFolder,'images_evaluation.zip');

dataFolderTest = fullfile(downloadFolder,'images_evaluation');
if ~exist(dataFolderTest,'dir')
    disp('Downloading Omniglot test data (3.2 MB)...')
    websave(filename,url);
    unzip(filename,downloadFolder);
end
disp("Test data downloaded.")
```

```
Test data downloaded.
```

Load the test data as a image datastore using the `imageDatastore` function. Specify the labels manually by extracting the labels from the file names and setting the `Labels` property.

```
imdsTest = imageDatastore(dataFolderTest, ...
    'IncludeSubfolders',true, ...
    'LabelSource','none');

files = imdsTest.Files;
parts = split(files,filesep);
labels = join(parts(:,(end-2):(end-1)),'_');
imdsTest.Labels = categorical(labels);
```

The test dataset contains 20 alphabets that are different to those that the network was trained on. In total, there 659 different classes in the test dataset.

```
numClasses = numel(unique(imdsTest.Labels))
```

```
numClasses = 659
```

To calculate the accuracy of the network, create a set of five random mini-batches of test pairs. Use the `predictSiamese` function (defined in the Supporting Functions on page 3-0 section of this example) to evaluate the network predictions and calculate the average accuracy over the mini-batches.

```
accuracy = zeros(1,5);
accuracyBatchSize = 150;

for i = 1:5

    % Extract mini-batch of image pairs and pair labels
    [XAcc1,XAcc2,pairLabelsAcc] = getSiameseBatch(imdsTest,accuracyBatchSize);

    % Convert mini-batch of data to dlarray. Specify the dimension labels
    % 'SSCB' (spatial, spatial, channel, batch) for image data.
    dlXAcc1 = dlarray(single(XAcc1),'SSCB');
    dlXAcc2 = dlarray(single(XAcc2),'SSCB');

    % If using a GPU, then convert data to gpuArray.
    if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
       dlXAcc1 = gpuArray(dlXAcc1);
```

```
        dlXAcc2 = gpuArray(dlXAcc2);
    end

    % Evaluate predictions using trained network
    dlY = predictSiamese(dlnet,fcParams,dlXAcc1,dlXAcc2);

    % Convert predictions to binary 0 or 1
    Y = gather(extractdata(dlY));
    Y = round(Y);

    % Compute average accuracy for the minibatch
    accuracy(i) = sum(Y == pairLabelsAcc)/accuracyBatchSize;
end

% Compute accuracy over all minibatches
averageAccuracy = mean(accuracy)*100
```

```
averageAccuracy = 88.6667
```

Display a Test Set of Images with Predictions

To visually check if the network correctly identifies similar and dissimilar pairs, create a small batch of image pairs to test. Use the predictSiamese function to get the prediction for each test pair. Display the pair of images with the prediction, the probability score, and a label indicating whether the prediction was correct or incorrect.

```
testBatchSize = 10;

[XTest1,XTest2,pairLabelsTest] = getSiameseBatch(imdsTest,testBatchSize);

% Convert test batch of data to dlarray. Specify the dimension labels
% 'SSCB' (spatial, spatial, channel, batch) for image data and 'CB'
% (channel, batch) for labels
dlXTest1 = dlarray(single(XTest1),'SSCB');
dlXTest2 = dlarray(single(XTest2),'SSCB');

% If using a GPU, then convert data to gpuArray
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
   dlXTest1 = gpuArray(dlXTest1);
   dlXTest2 = gpuArray(dlXTest2);
end

% Calculate the predicted probability
dlYScore = predictSiamese(dlnet,fcParams,dlXTest1,dlXTest2);
YScore = gather(extractdata(dlYScore));

% Convert predictions to binary 0 or 1
YPred = round(YScore);

% Extract data to plot
XTest1 = extractdata(dlXTest1);
XTest2 = extractdata(dlXTest2);

% Plot images with predicted label and predicted score
testingPlot = figure;
testingPlot.Position(3) = plotRatio*testingPlot.Position(4);
testingPlot.Visible = 'on';
```

```
for i = 1:numel(pairLabelsTest)

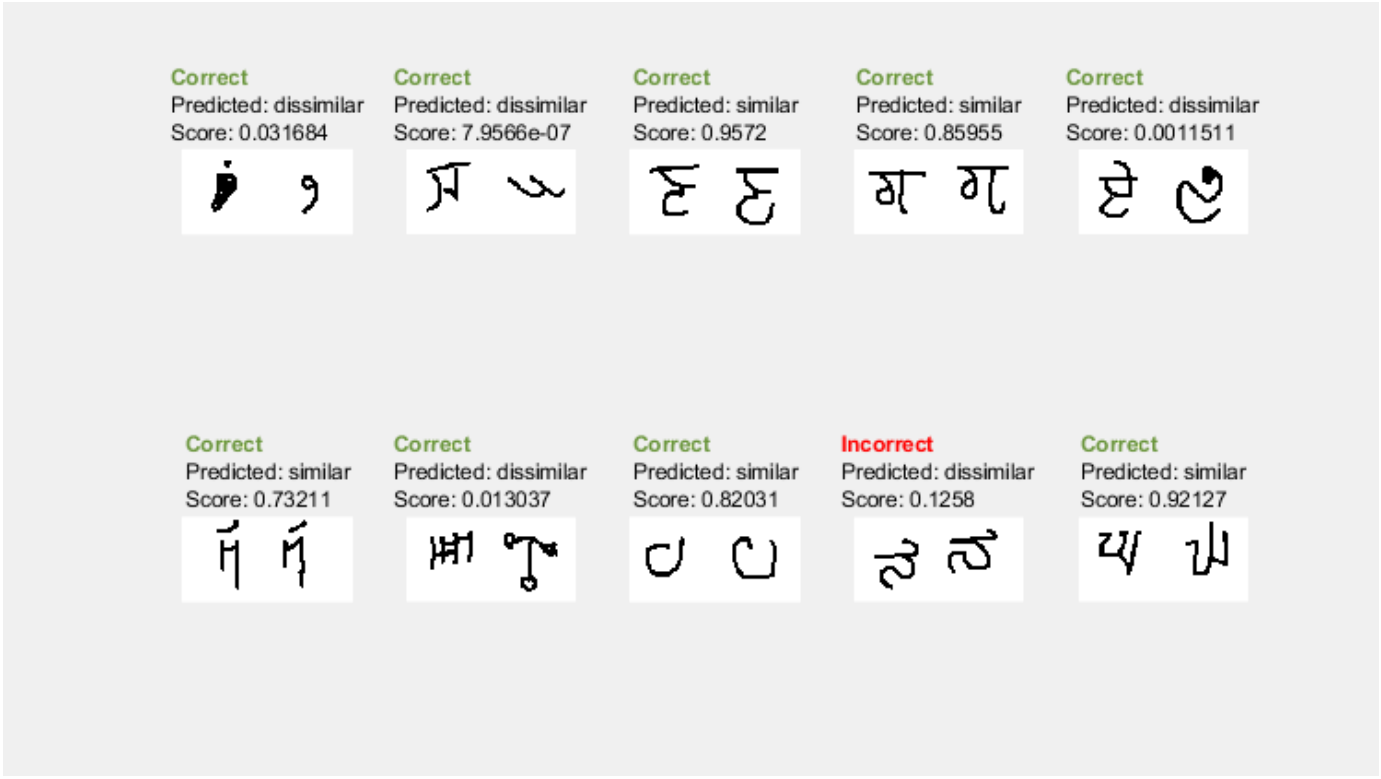
    if YPred(i) == 1
        predLabel = "similar";
    else
        predLabel = "dissimilar" ;
    end

    if pairLabelsTest(i) == YPred(i)
        testStr = "\bf\color{darkgreen}Correct\rm\newline";

    else
        testStr = "\bf\color{red}Incorrect\rm\newline";
    end

    subplot(2,5,i)
    imshow([XTest1(:,:,:,i) XTest2(:,:,:,i)]);

    title(testStr + "\color{black}Predicted: " + predLabel + "\newlineScore: " + YScore(i));
end
```



The network is able to compare the test images to determine their similarity, even though none of these images were in the training dataset.

Supporting Functions

Model Functions for Training and Prediction

The function `forwardSiamese` is used during network training. The function defines how the subnetworks and the `fullyconnect` and `sigmoid` operations combine to form the complete

Siamese network. forwardSiamese accepts the network structure and two training images and outputs a prediction about the similarity of the two images. Within this example, the function `forwardSiamese` is introduced in the section Define Network Architecture on page 3-0 .

```
function Y = forwardSiamese(dlnet,fcParams,dlX1,dlX2)
% forwardSiamese accepts the network and pair of training images, and returns a
% prediction of the probability of the pair being similar (closer to 1) or
% dissimilar (closer to 0). Use forwardSiamese during training.

    % Pass the first image through the twin subnetwork
    F1 = forward(dlnet,dlX1);
    F1 = sigmoid(F1);

    % Pass the second image through the twin subnetwork
    F2 = forward(dlnet,dlX2);
    F2 = sigmoid(F2);

    % Subtract the feature vectors
    Y = abs(F1 - F2);

    % Pass the result through a fullyconnect operation
    Y = fullyconnect(Y,fcParams.FcWeights,fcParams.FcBias);

    % Convert to probability between 0 and 1.
    Y = sigmoid(Y);
end
```

The function `predictSiamese` uses the trained network to make predictions about the similarity of two images. The function is similar to the function `forwardSiamese`, defined previously. However, `predictSiamese` uses the `predict` function with the network instead of the `forward` function, because some deep learning layers behave differently during training and prediction. Within this example, the function `predictSiamese` is introduced in the section Evaluate the Accuracy of the Network on page 3-0 .

```
function Y = predictSiamese(dlnet,fcParams,dlX1,dlX2)
% predictSiamese accepts the network and pair of images, and returns a
% prediction of the probability of the pair being similar (closer to 1)
% or dissimilar (closer to 0). Use predictSiamese during prediction.

    % Pass the first image through the twin subnetwork
    F1 = predict(dlnet,dlX1);
    F1 = sigmoid(F1);

    % Pass the second image through the twin subnetwork
    F2 = predict(dlnet,dlX2);
    F2 = sigmoid(F2);

    % Subtract the feature vectors
    Y = abs(F1 - F2);

    % Pass result through a fullyconnect operation
    Y = fullyconnect(Y,fcParams.FcWeights,fcParams.FcBias);

    % Convert to probability between 0 and 1.
    Y = sigmoid(Y);
end
```

Model Gradients Function

The function `modelGradients` takes the Siamese `dlnetwork` object `net`, a pair of mini-batch input data `X1` and `X2`, and the label indicating whether they are similar or dissimilar. The function returns the gradients of the loss with respect to the learnable parameters in the network and the binary cross-entropy loss between the prediction and the ground truth. Within this example, the function `modelGradients` is introduced in the section Define Model Gradients Function on page 3-0 .

```
function [gradientsSubnet,gradientsParams,loss] = modelGradients(dlnet,fcParams,dlX1,dlX2,pairLa
% The modelGradients function calculates the binary cross-entropy loss between the
% paired images and returns the loss and the gradients of the loss with respect to
% the network learnable parameters

    % Pass the image pair through the network
    Y = forwardSiamese(dlnet,fcParams,dlX1,dlX2);

    % Calculate binary cross-entropy loss
    loss = binarycrossentropy(Y,pairLabels);

    % Calculate gradients of the loss with respect to the network learnable
    % parameters
    [gradientsSubnet,gradientsParams] = dlgradient(loss,dlnet.Learnables,fcParams);
end

function loss = binarycrossentropy(Y,pairLabels)
    % binarycrossentropy accepts the network's prediction Y, the true
    % label, and pairLabels, and returns the binary cross-entropy loss value.

    % Get precision of prediction to prevent errors due to floating
    % point precision
    precision = underlyingType(Y);

    % Convert values less than floating point precision to eps.
    Y(Y < eps(precision)) = eps(precision);
    %convert values between 1-eps and 1 to 1-eps.
    Y(Y > 1 - eps(precision)) = 1 - eps(precision);

    % Calculate binary cross-entropy loss for each pair
    loss = -pairLabels.*log(Y) - (1 - pairLabels).*log(1 - Y);

    % Sum over all pairs in minibatch and normalize.
    loss = sum(loss)/numel(pairLabels);
end
```

Create Batches of Image Pairs

The following functions create randomized pairs of images that are similar or dissimilar, based on their labels. Within this example, the function `getSiameseBatch` is introduced in the section Create Pairs of Similar and Dissimilar Images. on page 3-0

```
function [X1,X2,pairLabels] = getSiameseBatch(imds,miniBatchSize)
% getSiameseBatch returns a randomly selected batch or paired images. On
% average, this function produces a balanced set of similar and dissimilar
% pairs.

    pairLabels = zeros(1,miniBatchSize);
    imgSize = size(readimage(imds,1));
    X1 = zeros([imgSize 1 miniBatchSize]);
```

```
        X2 = zeros([imgSize 1 miniBatchSize]);

        for i = 1:miniBatchSize
            choice = rand(1);
            if choice < 0.5
                [pairIdx1,pairIdx2,pairLabels(i)] = getSimilarPair(imds.Labels);
            else
                [pairIdx1,pairIdx2,pairLabels(i)] = getDissimilarPair(imds.Labels);
            end
            X1(:,:,:,i) = imds.readimage(pairIdx1);
            X2(:,:,:,i) = imds.readimage(pairIdx2);
        end
    end

    function [pairIdx1,pairIdx2,pairLabel] = getSimilarPair(classLabel)
    % getSimilarSiamesePair returns a random pair of indices for images
    % that are in the same class and the similar pair label = 1.

        % Find all unique classes.
        classes = unique(classLabel);

        % Choose a class randomly which will be used to get a similar pair.
        classChoice = randi(numel(classes));

        % Find the indices of all the observations from the chosen class.
        idxs = find(classLabel==classes(classChoice));

        % Randomly choose two different images from the chosen class.
        pairIdxChoice = randperm(numel(idxs),2);
        pairIdx1 = idxs(pairIdxChoice(1));
        pairIdx2 = idxs(pairIdxChoice(2));
        pairLabel = 1;
    end

    function  [pairIdx1,pairIdx2,label] = getDissimilarPair(classLabel)
    % getDissimilarSiamesePair returns a random pair of indices for images
    % that are in different classes and the dissimilar pair label = 0.

        % Find all unique classes.
        classes = unique(classLabel);

        % Choose two different classes randomly which will be used to get a dissimilar pair.
        classesChoice = randperm(numel(classes),2);

        % Find the indices of all the observations from the first and second classes.
        idxs1 = find(classLabel==classes(classesChoice(1)));
        idxs2 = find(classLabel==classes(classesChoice(2)));

        % Randomly choose one image from each class.
        pairIdx1Choice = randi(numel(idxs1));
        pairIdx2Choice = randi(numel(idxs2));
        pairIdx1 = idxs1(pairIdx1Choice);
        pairIdx2 = idxs2(pairIdx2Choice);
        label = 0;
    end
```

Train a Siamese Network for Dimensionality Reduction

This example shows how to train a Siamese network to compare handwritten digits using dimensionality reduction.

A Siamese network is a type of deep learning network that uses two or more identical subnetworks that have the same architecture and share the same parameters and weights. Siamese networks are typically used in tasks that involve finding the relationship between two comparable things. Some common applications for Siamese networks include facial recognition, signature verification [1], or paraphrase identification [2]. Siamese networks perform well in these tasks because their shared weights mean there are fewer parameters to learn during training and they can produce good results with a relatively small amount of training data.

Siamese networks are particularly useful in cases where there are large numbers of classes with small numbers of observations of each. In such cases, there is not enough data to train a deep convolutional neural network to classify images into these classes. Instead, the Siamese network can determine if two images are in the same class. The network does this by reducing the dimensionality of the training data and using a distance-based cost function to differentiate between the classes.

This example uses a Siamese network for dimensionality reduction of a collection of images of handwritten digits. The Siamese architecture reduces the dimensionality by mapping images with the same class to nearby points in a low-dimensional space. The reduced-feature representation is then used to extract images from the dataset that are most similar to a test image. The training data in this example are images of size 28-by-28-by-1, giving an initial feature dimensionality of 784. The Siamese network reduces the dimensionality of the input images to two features and is trained to output similar reduced features for images with the same label.

You can also use Siamese networks to identify similar images by directly comparing them. For an example, see “Train a Siamese Network to Compare Images” on page 3-128.

Load and Preprocess Training Data

Load the training data, which consists of images of handwritten digits. The function `digitTrain4DArrayData` loads the digit images and their labels.

```
[XTrain,YTrain] = digitTrain4DArrayData;
```

`XTrain` is a 28-by-28-by-1-by-5000 array containing 5000 single-channel images, each of size 28-by-28. The values of each pixel are between `0` and `1`. `YTrain` is a categorical vector containing the labels for each observation, which are the numbers from 0 to 9 corresponding to the value of the written digit.

Display a random selection of the images.

```
perm = randperm(numel(YTrain), 9);
imshow(imtile(XTrain(:,:,:,perm),"ThumbnailSize",[100 100]));
```

Create Pairs of Similar and Dissimilar Images

To train the network, the data must be grouped into pairs of images that are either similar or dissimilar. Here, similar images are defined as having the same label, while dissimilar images have different labels. The function `getSiameseBatch` (defined in the Supporting Functions on page 3-0 section of this example) creates randomized pairs of similar or dissimilar images, `pairImage1` and `pairImage2`. The function also returns the label `pairLabel`, which identifies if the pair of images is similar or dissimilar to each other. Similar pairs of images have `pairLabel = 1`, while dissimilar pairs have `pairLabel = 0`.

As an example, create a small representative set of five pairs of images

```
batchSize = 10;
[pairImage1,pairImage2,pairLabel] = getSiameseBatch(XTrain,YTrain,batchSize);
```

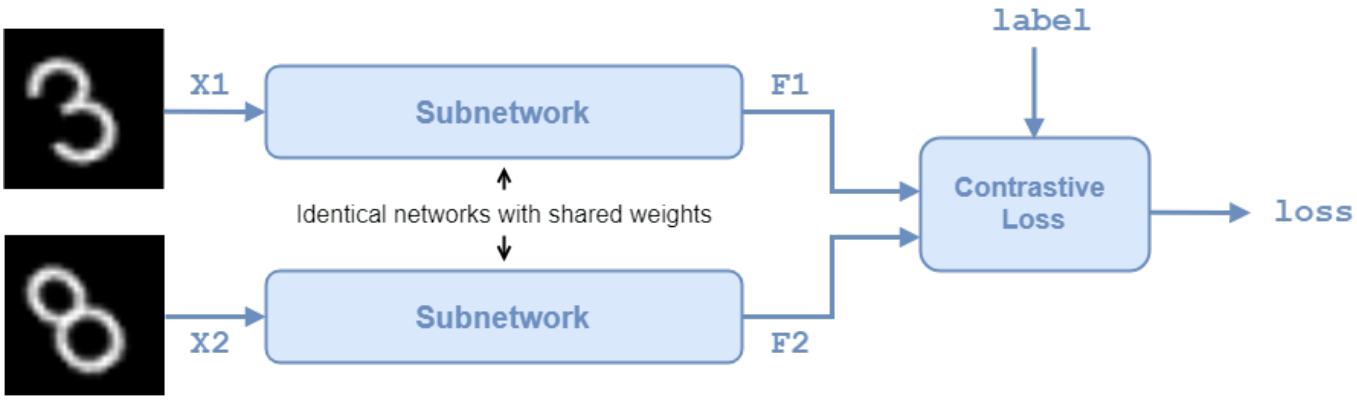
Display the generated pairs of images.

```
for i = 1:batchSize
subplot(2,5,i)
imshow([pairImage1(:,:,:,i) pairImage2(:,:,:,i)]);
if pairLabel(i) == 1
    s = "similar";
else
    s = "dissimilar";
end
title(s)
end
```

In this example, a new batch of 180 paired images is created for each iteration of the training loop. This ensures that the network is trained on a large number of random pairs of images with approximately equal proportions of similar and dissimilar pairs.

Define Network Architecture

The Siamese network architecture is illustrated in the following diagram.



In this example, the two identical subnetworks are defined as a series of fully connected layers with ReLU layers. Create a network that accepts 28-by-28-by-1 images and outputs the two feature vectors used for the reduced feature representation. The network reduces the dimensionality of the input images to two, a value that is easier to plot and visualize than the initial dimensionality of 784.

For the first two fully connected layers, specify an output size of 1024 and use the He weight initializer.

For the final fully connected layer, specify an output size of two and use the He weights initializer.

```
layers = [
    imageInputLayer([28 28],'Name','input1','Normalization','none')
    fullyConnectedLayer(1024,'Name','fc1','WeightsInitializer','he')
    reluLayer('Name','relu1')
    fullyConnectedLayer(1024,'Name','fc2','WeightsInitializer','he')
    reluLayer('Name','relu2')
    fullyConnectedLayer(2,'Name','fc3','WeightsInitializer','he')];

lgraph = layerGraph(layers);
```

To train the network with a custom training loop and enable automatic differentiation, convert the layer graph to a `dlnetwork` object.

```
dlnet = dlnetwork(lgraph);
```

Define Model Gradients Function

Create the function `modelGradients` (defined in the Supporting Functions on page 3-0 section of this example). The `modelGradients` function takes the Siamese `dlnetwork` object `dlnet` and a mini-batch of input data `dlX1` and `dlX2` with their labels `pairLabels`. The function returns the loss values and the gradients of the loss with respect to the learnable parameters of the network.

The objective of the Siamese network is to output a feature vector for each image such that the feature vectors are similar for similar images, and notably different for dissimilar images. In this way, the network can discriminate between the two inputs.

Find the contrastive loss between the outputs from the last fully connected layer, the feature vectors `features1` and `features1` from `pairImage1` and `pairImage2`, respectively. The contrastive loss for a pair is given by [3]

$$\text{loss} = \frac{1}{2} y d^2 + \frac{1}{2}\left(1 - y\right)\max(margin - d, 0)^2,$$

where y is the value of the pair label ($y = 1$ for similar images;$y = 0$ for dissimilar images), and d is the Euclidean distance between two features vectors $f1$ and $f2$: $d = \|f1 - f2\|_2$.

The *margin* parameter is used for constraint: if two images in a pair are dissimilar, then their distance should be at least *margin*, or a loss will be incurred.

The contrastive loss has two terms, but only one is ever non-zero for a given image pair. In the case of similar images, the first term can be non-zero and is minimized by reducing the distance between the image features $f1$ and $f2$. In the case of dissimilar images, the second term can be non-zero, and is minimized by increasing the distance between the image features, to at least a distance of *margin*. The smaller the value of *margin*, the less constraining it is over how close a dissimilar pair can be before a loss is incurred.

Specify Training Options

Specify the value of *margin* to use during training.

```
margin = 0.3;
```

Specify the options to use during training. Train for 3000 iterations.

```
numIterations = 3000;
miniBatchSize = 180;
```

Specify the options for ADAM optimization:

- Set the learning rate to `0.0001`.
- Initialize the trailing average gradient and trailing average gradient-square decay rates with `[]`.
- Set the gradient decay factor to `0.9` and the squared gradient decay factor to `0.99`.

```
learningRate = 1e-4;
trailingAvg = [];
trailingAvgSq = [];
gradDecay = 0.9;
gradDecaySq = 0.99;
```

Train on a GPU, if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). To automatically detect if you have a GPU available and place the relevant data on the GPU, set the value of `executionEnvironment` to `"auto"`. If you don't have a GPU, or don't want to use one for training, set the value of `executionEnvironment` to `"cpu"`. To ensure you use a GPU for training, set the value of `executionEnvironment` to `"gpu"`.

```
executionEnvironment = "auto";
```

To monitor the training progress, you can plot the training loss after each iteration. Create the variable `plots` that contains `"training-progress"`. If you don't want to plot the training progress, set this value to `"none"`.

```
plots = "training-progress";
```

Initialize the plot parameters for the training loss progress plot.

```
plotRatio = 16/9;

if plots == "training-progress"
    trainingPlot = figure;
    trainingPlot.Position(3) = plotRatio*trainingPlot.Position(4);
    trainingPlot.Visible = 'on';

    trainingPlotAxes = gca;

    lineLossTrain = animatedline(trainingPlotAxes);
    xlabel(trainingPlotAxes,"Iteration")
    ylabel(trainingPlotAxes,"Loss")
    title(trainingPlotAxes,"Loss During Training")
end
```

To evaluate how well the network is doing at dimensionality reduction, compute and plot the reduced features of a set of test data after each iteration. Load the test data, which consists of images of handwritten digits similar to the training data. Convert the test data to `dlarray` and specify the dimension labels `'SSCB'` (spatial, spatial, channel, batch). If you are using a GPU, convert the test data to `gpuArray`.

```
[XTest,YTest] = digitTest4DArrayData;
dlXTest = dlarray(single(XTest),'SSCB');
```

```
% If training on a GPU, then convert data to gpuArray.
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlXTest = gpuArray(dlXTest);
end
```

Initialize the plot parameters for the reduced-feature plot of the test data.

```
dimensionPlot = figure;
dimensionPlot.Position(3) = plotRatio*dimensionPlot.Position(4);
dimensionPlot.Visible = 'on';

dimensionPlotAxes = gca;

uniqueGroups = unique(YTest);
colors = hsv(length(uniqueGroups));
```

Initialize a counter to keep track of the total number of iterations.

```
iteration = 1;
```

Train Model

Train the model using a custom training loop. Loop over the training data and update the network parameters at each iteration.

For each iteration:

- Extract a batch of image pairs and labels using the `getSiameseBatch` function defined in the section Create Batches of Image Pairs on page 3-0 .
- Convert the image data to `dlarray` objects with underlying type `single` and specify the dimension labels `'SSCB'` (spatial, spatial, channel, batch).
- For GPU training, convert the image data to `gpuArray` objects.
- Evaluate the model gradients using `dlfeval` and the `modelGradients` function.
- Update the network parameters using the `adamupdate` function.

```
% Loop over mini-batches.
for iteration = 1:numIterations

    % Extract mini-batch of image pairs and pair labels
    [X1,X2,pairLabels] = getSiameseBatch(XTrain,YTrain,miniBatchSize);

    % Convert mini-batch of data to dlarray. Specify the dimension labels
    % 'SSCB' (spatial, spatial, channel, batch) for image data
    dlX1 = dlarray(single(X1),'SSCB');
    dlX2 = dlarray(single(X2),'SSCB');

    % If training on a GPU, then convert data to gpuArray.
    if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
        dlX1 = gpuArray(dlX1);
        dlX2 = gpuArray(dlX2);
    end

    % Evaluate the model gradients and the generator state using
    % dlfeval and the modelGradients function listed at the end of the
    % example.
```

```
        [gradients,loss] = dlfeval(@modelGradients,dlnet,dlX1,dlX2,pairLabels,margin);
        lossValue = double(gather(extractdata(loss)));

        % Update the Siamese network parameters.
        [dlnet.Learnables,trailingAvg,trailingAvgSq] = ...
            adamupdate(dlnet.Learnables,gradients, ...
            trailingAvg,trailingAvgSq,iteration,learningRate,gradDecay,gradDecaySq);

        % Update the training loss progress plot.
        if plots == "training-progress"
            addpoints(lineLossTrain,iteration,lossValue);
        end

        % Update the reduced-feature plot of the test data.
        % Compute reduced features of the test data:
        dlFTest = predict(dlnet,dlXTest);
        FTest = extractdata(dlFTest);

        figure(dimensionPlot);
        for k = 1:length(uniqueGroups)
            % Get indices of each image in test data with the same numeric
            % label (defined by the unique group):
            ind = YTest==uniqueGroups(k);
            % Plot this group:
            plot(dimensionPlotAxes,gather(FTest(1,ind)'),gather(FTest(2,ind)'),'.','color',...
                colors(k,:));
            hold on
        end

        legend(uniqueGroups)

        % Update title of reduced-feature plot with training progress information.
        title(dimensionPlotAxes,"2-D Feature Representation of Digits Images. Iteration = " +...
            iteration);
        legend(dimensionPlotAxes,'Location','eastoutside');
        xlabel(dimensionPlotAxes,"Feature 1")
        ylabel(dimensionPlotAxes,"Feature 2")

        hold off
        drawnow
    end
```

The network has now learned to represent each image as a 2-D vector. As you can see from the reduced-feature plot of the test data, images of similar digits are clustered close to each other in this 2-D representation.

Use the Trained Network to Find Similar Images

You can use the trained network to find a selection of images that are similar to each other out of a group. In this case, use the test data as the group of images. Convert the group of images to `dlarray` objects and `gpuArray` objects, if you are using a GPU.

```
groupX = XTest;

dlGroupX = dlarray(single(groupX),'SSCB');

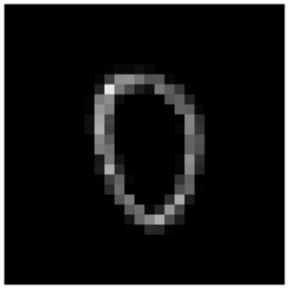
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlGroupX = gpuArray(dlGroupX);
end
```

Extract a single test image from the group and display it. Remove the test image from the group so that it does not appear in the set of similar images.

```
testIdx = randi(5000);
testImg = dlGroupX(:,:,:,testIdx);

trialImgDisp = extractdata(testImg);

figure
imshow(trialImgDisp, 'InitialMagnification', 500);
```



```
dlGroupX(:,:,:,testIdx) = [];
```

Find the reduced features of the test image using `predict`.

```
trialF = predict(dlnet,testImg);
```

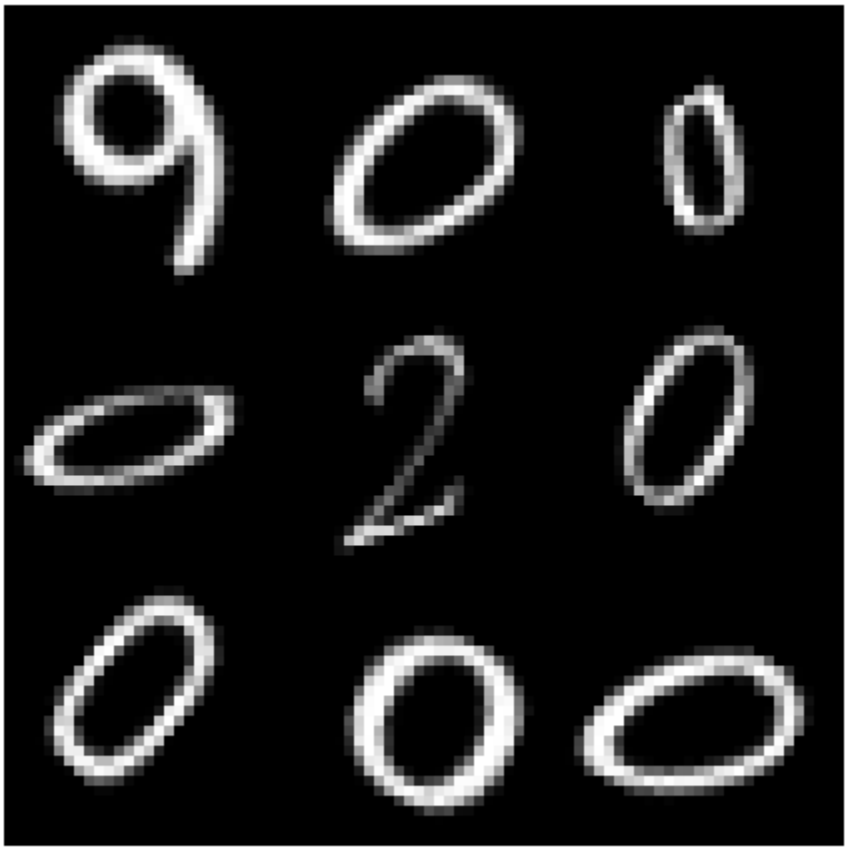
Find the 2-D reduced feature representation of each of the images in the group using the trained network.

```
FGroupX = predict(dlnet,dlGroupX);
```

Use the reduced feature representation to find the nine images in the group that are closest to the test image, using the Euclidean distance metric. Display the images.

```
distances = vecnorm(extractdata(trialF - FGroupX));
[~,idx] = sort(distances);
sortedImages = groupX(:,:,:,idx);

figure
imshow(imtile(sortedImages(:,:,:,1:9)), 'InitialMagnification', 500);
```



By reducing the images to a lower dimensionality, the network is able to identify images that are similar to the trial image. The reduced feature representation allows the network to discriminate between images that are similar and dissimilar. Siamese networks are often used in the context of facial or signature recognition. For example, you can train a Siamese network to accept an image of a face as an input, and return a set of the most similar faces from a database.

Supporting Functions

Model Gradients Function

The function `modelGradients` takes the Siamese `dlnetwork` object `dlnet`, a pair of mini-batch input data `X1` and `X2`, and the label `pairLabels`. The function returns the gradients of the loss with respect to the learnable parameters in the network as well as the contrastive loss between the reduced dimensionality features of the paired images. Within this example, the function `modelGradients` is introduced in the section Define Model Gradients Function on page 3-0 .

```
function [gradients, loss] = modelGradients(net,X1,X2,pairLabel,margin)
% The modelGradients function calculates the contrastive loss between the
% paired images and returns the loss and the gradients of the loss with
% respect to the network learnable parameters
```

```
    % Pass first half of image pairs forward through the network
    F1 = forward(net,X1);
    % Pass second set of image pairs forward through the network
    F2 = forward(net,X2);

    % Calculate contrastive loss
    loss = contrastiveLoss(F1,F2,pairLabel,margin);

    % Calculate gradients of the loss with respect to the network learnable
    % parameters
    gradients = dlgradient(loss, net.Learnables);

end

function loss = contrastiveLoss(F1,F2,pairLabel,margin)
% The contrastiveLoss function calculates the contrastive loss between
% the reduced features of the paired images

    % Define small value to prevent taking square root of 0
    delta = 1e-6;

    % Find Euclidean distance metric
    distances = sqrt(sum((F1 - F2).^2,1) + delta);

    % label(i) = 1 if features1(:,i) and features2(:,i) are features
    % for similar images, and 0 otherwise
    lossSimilar = pairLabel.*(distances.^2);

    lossDissimilar = (1 - pairLabel).*(max(margin - distances, 0).^2);

    loss = 0.5*sum(lossSimilar + lossDissimilar,'all');
end
```

Create Batches of Image Pairs

The following functions create randomized pairs of images that are similar or dissimilar, based on their labels. Within this example, the function `getSiameseBatch` is introduced in the section Create Pairs of Similar and Dissimilar Images on page 3-0 .

```
function [X1,X2,pairLabels] = getSiameseBatch(X,Y,miniBatchSize)
% getSiameseBatch returns a randomly selected batch of paired images.
% On average, this function produces a balanced set of similar and
% dissimilar pairs.
    pairLabels = zeros(1, miniBatchSize);
    imgSize = size(X(:,:,:,1));
    X1 = zeros([imgSize 1 miniBatchSize]);
    X2 = zeros([imgSize 1 miniBatchSize]);

    for i = 1:miniBatchSize
        choice = rand(1);
        if choice < 0.5
            [pairIdx1, pairIdx2, pairLabels(i)] = getSimilarPair(Y);
        else
            [pairIdx1, pairIdx2, pairLabels(i)] = getDissimilarPair(Y);
        end
        X1(:,:,:,i) = X(:,:,:,pairIdx1);
        X2(:,:,:,i) = X(:,:,:,pairIdx2);
```

```
    end

end

function [pairIdx1,pairIdx2,pairLabel] = getSimilarPair(classLabel)
% getSimilarPair returns a random pair of indices for images
% that are in the same class and the similar pair label = 1.

    % Find all unique classes.
    classes = unique(classLabel);

    % Choose a class randomly which will be used to get a similar pair.
    classChoice = randi(numel(classes));

    % Find the indices of all the observations from the chosen class.
    idxs = find(classLabel==classes(classChoice));

    % Randomly choose two different images from the chosen class.
    pairIdxChoice = randperm(numel(idxs),2);
    pairIdx1 = idxs(pairIdxChoice(1));
    pairIdx2 = idxs(pairIdxChoice(2));
    pairLabel = 1;
end

function  [pairIdx1,pairIdx2,pairLabel] = getDissimilarPair(classLabel)
% getDissimilarPair returns a random pair of indices for images
% that are in different classes and the dissimilar pair label = 0.

    % Find all unique classes.
    classes = unique(classLabel);

    % Choose two different classes randomly which will be used to get a dissimilar pair.
    classesChoice = randperm(numel(classes), 2);

    % Find the indices of all the observations from the first and second classes.
    idxs1 = find(classLabel==classes(classesChoice(1)));
    idxs2 = find(classLabel==classes(classesChoice(2)));

    % Randomly choose one image from each class.
    pairIdx1Choice = randi(numel(idxs1));
    pairIdx2Choice = randi(numel(idxs2));
    pairIdx1 = idxs1(pairIdx1Choice);
    pairIdx2 = idxs2(pairIdx2Choice);
    pairLabel = 0;
end
```

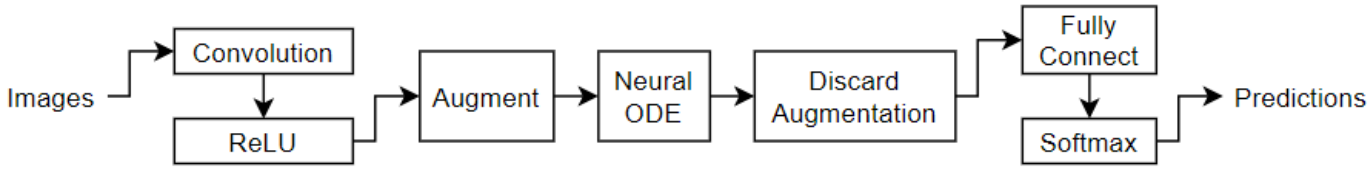
Train Neural ODE Network

This example shows how to train an augmented neural ordinary differential equation (ODE) network.

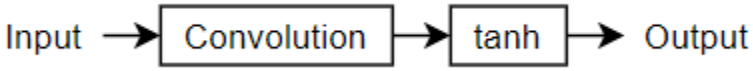
A neural ODE [1 on page 3-0] is a deep learning operation that returns the solution of an ODE. In particular, given an input, a neural ODE operation outputs the numerical solution of the ODE $y' = f(t, y, \theta)$ for the time horizon (t_0, t_1) and the initial condition $y(t_0) = y_0$, where t and y denote the ODE function inputs and θ is a set of learnable parameters. Typically, the initial condition y_0 is either the network input or, as in the case of this example, the output of another deep learning operation.

An *augmented* neural ODE [2 on page 3-0] operation improves upon a standard neural ODE by augmenting the input data with extra channels and then discarding the augmentation after the neural ODE operation. Empirically, augmented neural ODEs are more stable, generalize better, and have a lower computational cost than neural ODEs.

This example trains a simple convolutional neural network with an augmented neural ODE operation.



The ODE function can be a collection of deep learning operations. In this example, the model uses a convolution-tanh block as the ODE function:



The example shows how to train a neural network to classify images of digits using an augmented neural ODE operation.

Load Training Data

Load the training images and labels using the `digitTrain4DArrayData` function.

```
[XTrain,TTrain] = digitTrain4DArrayData;
```

View the number of classes of the training data.

```
classNames = categories(TTrain);
numClasses = numel(classNames)
```

```
numClasses = 10
```

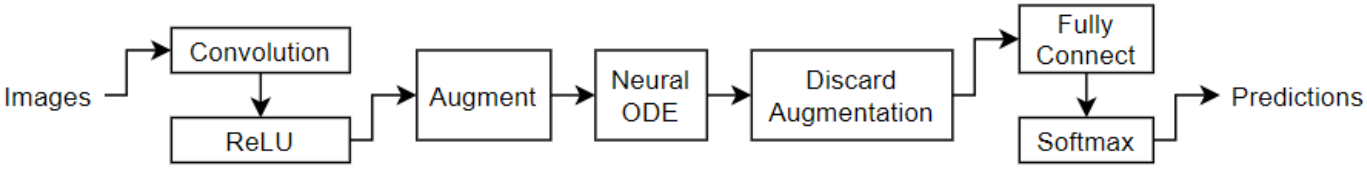
View some images from the training data.

```
numObservations = size(XTrain,4);
idx = randperm(numObservations,64);
I = imtile(XTrain(:,:,:,idx));
figure
imshow(I)
```

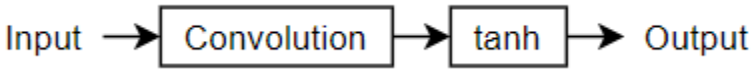
Define Deep Learning Model

Define the following network, which classifies images.

- A convolution-ReLU block with 8 3-by-3 filters with a stride of 2
- An augmentation step that concatenates an array of zeros to the input such that the number of channels is doubled
- A neural ODE operation with ODE function containing a convolution-tanh block with 16 3-by-3 filters
- For classification output, a fully connect operation of size 10 (the number of classes) and a softmax operation



A neural ODE operation outputs the solution of a specified ODE function. For this example, specify a convolution-tanh block as the ODE function.



That is, specify the ODE function given by $y' = f(t, y, \theta)$, where f denotes the convolution-tanh operation, y is the input data, and θ contains the learnable parameters for the convolution operation. In this case, the variable t is unused.

Define and Initialize Model Parameters

Define the learnable parameters for each of the operations and include them in a structure. Use the format `parameters.OperationName.ParameterName`, where `parameters` is the structure, `OperationName` is the name of the operation (for example, "conv1"), and `ParameterName` is the name of the parameter (for example, "Weights"). Initialize the learnable layer weights and biases using the `initializeGlorot` and `initializeZeros` example functions, respectively. The initialization example functions are attached to this example as supporting files. To access these functions, open this example as a live script. For more information about initializing learnable parameters for model functions, see “Initialize Learnable Parameters for Model Function” on page 18-292.

Initialize the parameters structure.

```
parameters = struct;
```

Initialize the parameters for the first convolutional layer. Specify 8 3-by-3 filters. If you change these dimensions, then you must manually calculate the input size of the fully connect operation for its Glorot weights initialization.

```
filterSize = [3 3];
numFilters = 8;

numChannels = size(XTrain,3);
sz = [filterSize numChannels numFilters];
numOut = prod(filterSize) * numFilters;
numIn = prod(filterSize) * numFilters;

parameters.conv1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.conv1.Bias = initializeZeros([numFilters 1]);
```

Initialize the parameters for the convolution operation used in the neural ODE function. Because the augmentation step augments the input data with an array of zeros, the number of input channels is given by `numFilters + numExtraChannels`, where `numExtraChannels` is the number of channels in the augmentation. Similarly, because the model discards channels of the output of the neural ODE operation corresponding to the augmentation, the convolution operation in the neural ODE must have (`numChannels + numExtraChannels`) filters, where `numChannels` is the desired number of output channels.

Specify the same number of filters as the first convolution layer and a matching augmentation size.

```
numChannels = numFilters;
numExtraChannels = numFilters;

numFiltersAugmented = numChannels + numExtraChannels;
sz = [filterSize numFiltersAugmented numFiltersAugmented];

numOut = prod(filterSize) * numFiltersAugmented;
numIn = prod(filterSize) * numFiltersAugmented;

parameters.neuralode.Weights = initializeGlorot(sz,numOut,numIn);
parameters.neuralode.Bias = initializeZeros([numFiltersAugmented 1]);
```

Initialize the parameters for the fully connect operation. To initialize the weights of the fully connect operation using the Glorot initializer, first calculate the number of input elements to the operation.

For each operation in the model that changes the size of the data flowing through, consider the output sizes when you pass 28-by-28 images through the model:

- The first convolution has 8 filters with `"same"` padding and a stride of 2. This operation outputs 14-by-14 images with 8 channels.
- The model then augments the data with an 8-channel array of zeros. This operation outputs 14-by-14 images with 16 channels.
- The neural ODE operation has a convolution operation with 16 filters and `"same"` padding. This operation outputs 14-by-14 images with 16 channels.
- The model then discards the channels corresponding to the augmentation. This operation outputs 14-by-14 images with 8 channels.

This means that the number of input elements to the fully connect operation is 14*14*8 = 1568.

```
sz =  [14 14];
inputSize = prod(sz)*numChannels;
outputSize = numClasses;

sz = [outputSize inputSize];
numOut = outputSize;
numIn = inputSize;

parameters.fc1.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fc1.Bias = initializeZeros([outputSize 1]);
```

View the structure of parameters.

```
parameters
```

```
parameters = struct with fields:
        conv1: [1×1 struct]
    neuralode: [1×1 struct]
          fc1: [1×1 struct]
```

View the parameters for the neural ODE operation.

```
parameters.neuralode
```

```
ans = struct with fields:
    Weights: [3×3×16×16 dlarray]
       Bias: [16×1 dlarray]
```

Define Model Hyper Parameters

Define the hyperparameters for the operations and include them in a structure. Use the format `hyperparameters.OperationName.ParameterName` where `hyperparameters` is the structure, `OperationName` is the name of the operation (for example "neuralode") and `ParameterName` is the name of the hyperparameter (for example, "tspan").

Initialize the hyperparameters structure.

```
hyperparameters = struct;
```

For the neural ODE, specify an interval of integration of [0 0.1].

```
hyperparameters.neuralode.tspan = [0 0.1];
```

Define Neural ODE Function

Create the function `odeModel`, listed in the ODE Function on page 3-0 section of the example, which takes as input the time input (unused), the initial conditions, and the ODE function parameters. The function applies a convolution operation followed by a tanh operation to the input data using the weights and biases given by the parameters.

Define Model Function

Create the function `model`, listed in the Model Function on page 3-0 section of the example, which computes the outputs of the deep learning model. The function `model` takes as input the model parameters and the input data. The function outputs the predictions for the labels.

Define Model Gradients Function

Create the function `modelGradients`, listed in the Model Gradients on page 3-0 section of the example, which takes as input the model parameters and a mini-batch of input data with corresponding targets containing the labels, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss.

Specify Training Options

Specify the training options. Train with a mini-batch size of 64 for 30 epochs.

```
miniBatchSize = 64;
numEpochs = 30;
```

Train Model

Train the model using a custom training loop.

Create a `minibatchqueue` object that processes and manages mini-batches of images during training. To create a `minibatchqueue` object, first create a datastore that returns the images and labels by creating array datastores and then combining them.

```
dsXTrain = arrayDatastore(XTrain,IterationDimension=4);
dsTTrain = arrayDatastore(TTrain);
dsTrain = combine(dsXTrain,dsTTrain);
```

Create the mini-batch queue. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch`, defined in the Mini-Batch Preprocessing Function on page 3-0 section of the example, to convert the labels to one-hot encoded variables.
- Format the image data with the dimension labels `"SSCB"` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`.
- Discard partial mini-batches.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain, ...
    MiniBatchSize=miniBatchSize, ...
    MiniBatchFcn=@preprocessMiniBatch, ...
    MiniBatchFormat=["SSCB" "CB"]);
```

Initialize the moving average of the parameter gradients and the element-wise squares of the gradients used by the Adam optimizer.

```
trailingAvg = [];
trailingAvgSq = [];
```

Initialize the training plot.

```
figure
C = colororder;
lineLossTrain = animatedline(Color=C(2,:));
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Train the model using a custom training loop. For each epoch, shuffle the data. For each mini-batch:

- Evaluate the model gradients using the `dlfeval` and `modelGradients` functions.
- Update the network parameters using the `adamupdate` function.
- Update the training progress plot.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches.
    while hasdata(mbq)

        iteration = iteration + 1;

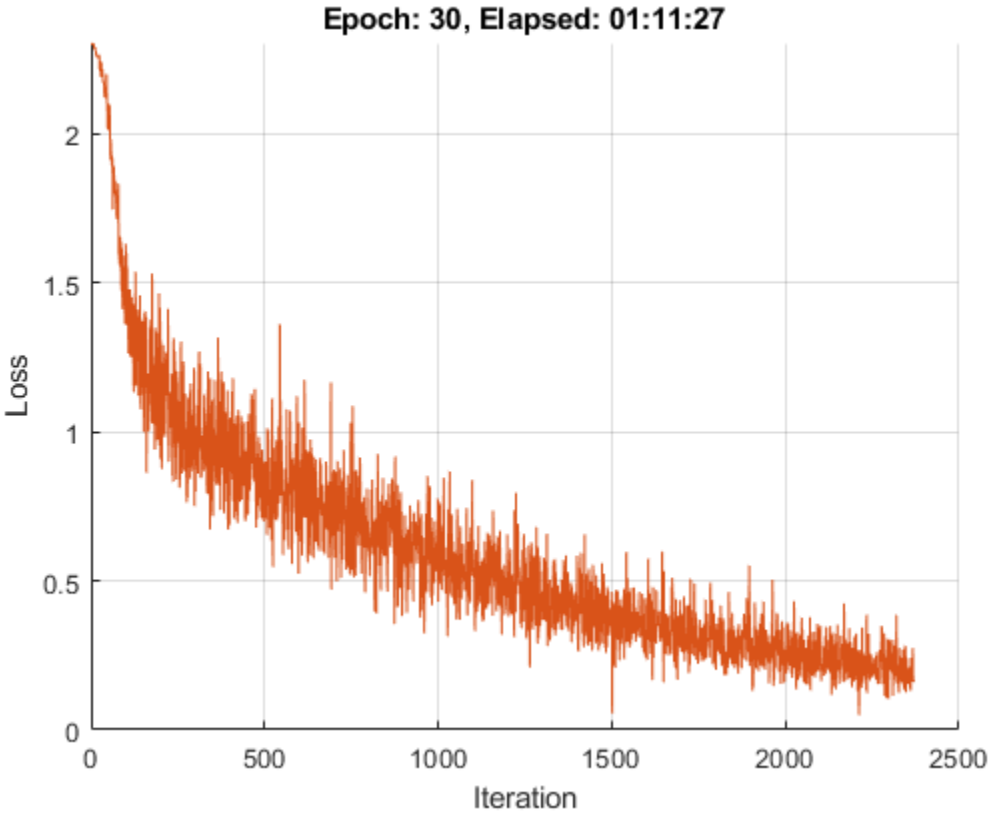
        [dlX,dlT] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function.
        [gradients,loss] = dlfeval(@modelGradients, parameters, dlX, dlT, hyperparameters);

        % Update the network parameters using the Adam optimizer.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
            trailingAvg,trailingAvgSq,iteration);

        % Display the training progress.
        D = duration(0,0,toc(start),Format="hh:mm:ss");
        loss = double(gather(extractdata(loss)));
        addpoints(lineLossTrain,iteration,loss)
        title("Epoch: " + epoch + ", Elapsed: " + string(D))
        drawnow
```

```
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on a held-out test set with the true labels.

Load the test data.

```
[XTest,TTest] = digitTest4DArrayData;
```

After training, making predictions on new data does not require the labels. Create a `minibatchqueue` object containing only the predictors of the test data:

- Set the number of outputs of the mini-batch queue to 1.
- Specify the same mini-batch size used for training.
- Preprocess the predictors using the `preprocessPredictors` function, listed in the Mini-Batch Predictors Preprocessing Function on page 3-0 section of the example.
- For the single output of the datastore, specify the mini-batch format `"SSCB"` (spatial, spatial, channel, batch).

```
dsTest = arrayDatastore(XTest,IterationDimension=4);

mbqTest = minibatchqueue(dsTest,1, ...
    MiniBatchSize=miniBatchSize, ...
```

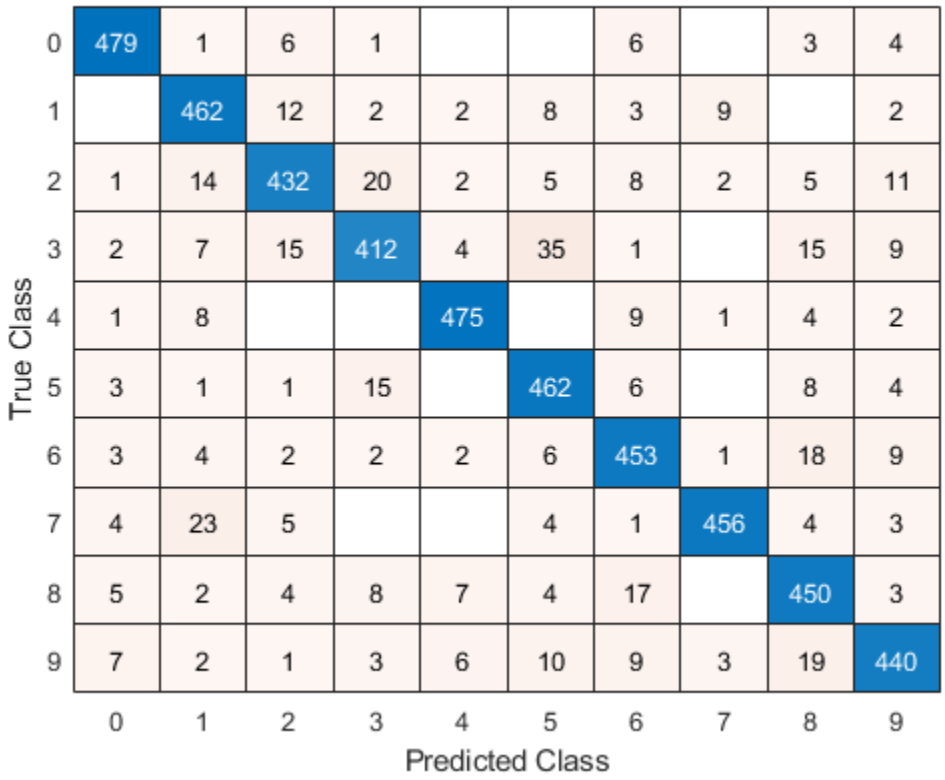
```
    MiniBatchFormat="SSCB", ...
    MiniBatchFcn=@preprocessPredictors);
```

Loop over the mini-batches and classify the sequences using `modelPredictions` function, listed in the Model Predictions Function on page 3-0 section of the example.

```
YPred = modelPredictions(parameters,hyperparameters,mbqTest,classNames);
```

Visualize the predictions in a confusion matrix.

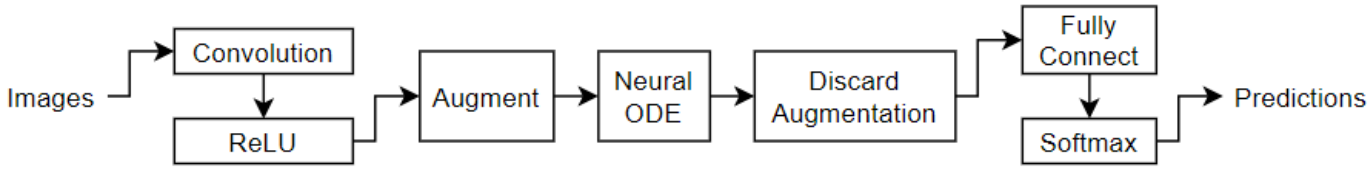
```
figure
confusionchart(TTest,YPred)
```



Model Function

The function `model` takes as input the model parameters, the input data `dlX`, the model hyperparameters, and outputs the predictions for the labels.

This diagram outlines the model structure.



For the neural ODE operation, use the `dlode45` function and specify the `odeModel` function, listed in the ODE Function on page 3-0 section of the example. Increase the absolute and relative tolerance using the `AbsoluteTolerance` and `RelativeTolerance` name-value arguments, respectively. To calculate the gradients by solving the associated adjoint ODE system, set the `GradientMode` option to `"adjoint"`.

```
function dlY = model(parameters,dlX,hyperparameters)

% Convolution, ReLU.
weights = parameters.conv1.Weights;
bias = parameters.conv1.Bias;
dlY = dlconv(dlX,weights,bias,Padding="same",Stride=2);

dlY = relu(dlY);

% Augment.
weights = parameters.neuralode.Weights;

numChannels = size(dlY,3);
szAugmented = size(dlY);
szAugmented(3) = size(weights,3) - numChannels;

dlY0 = cat(3, dlY, zeros(szAugmented,"like",dlY));

% Neural ODE.
tspan = hyperparameters.neuralode.tspan;
dlY = dlode45(@odeModel,tspan,dlY0,parameters.neuralode, ...
    GradientMode="adjoint", ...
    AbsoluteTolerance=1e-3, ...
    RelativeTolerance=1e-4);

% Discard augmentation.
dlY(:,:,numChannels+1:end,:) = [];

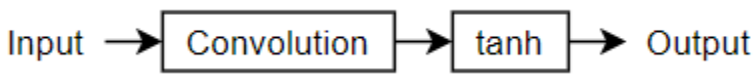
% Fully connect, softmax.
weights = parameters.fc1.Weights;
bias = parameters.fc1.Bias;
dlY = fullyconnect(dlY,weights,bias);

dlY = softmax(dlY);

end
```

ODE Function

The neural ODE operation consists of a convolution operation followed by a tanh operation.



The ODE function `odeModel` takes as input the function inputs `t` (unused) and `y` and the ODE function parameters `p` containing the convolution weights and biases, and returns the output of the convolution-tanh block operation.

```
function z = odeModel(t,y,p)
```

```
weights = p.Weights;
bias = p.Bias;

z = dlconv(y,weights,bias,Padding="same");
z = tanh(z);

end
```

Model Gradients Function

The `modelGradients` function takes as input the model parameters, a mini-batch of input data `dlX` with corresponding targets `dlT`, and model hyperparameters, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss. To compute the gradients using automatic differentiation, use the `dlgradient` function.

```
function [gradients,loss] = modelGradients(parameters,dlX,dlT,hyperparameters)

dlY = model(parameters,dlX,hyperparameters);

loss = crossentropy(dlY,dlT);

gradients = dlgradient(loss,parameters);

end
```

Model Predictions Function

The `modelPredictions` function takes as input the model parameters, model hyperparameters, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in the `minibatchqueue` object. The function uses the `onehotdecode` function to find the predicted classes with the highest score.

```
function predictions = modelPredictions(parameters,hyperparameters,mbq,classNames)

predictions = [];

while hasdata(mbq)
    dlX = next(mbq);
    dlYPred = model(parameters,dlX,hyperparameters);
    YPred = onehotdecode(dlYPred,classNames,1)';
    predictions = [predictions; YPred];
end

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses a mini-batch of predictors and labels using the following steps:

1. Preprocess the images using the `preprocessPredictors` function.
2. Extract the label data from the incoming cell array and concatenate into a categorical array along the second dimension.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y] = preprocessMiniBatch(XCell,YCell)
```

```
% Preprocess predictors.
X = preprocessPredictors(XCell);

% Extract label data from cell and concatenate.
Y = cat(2,YCell{:});

% One-hot encode labels.
Y = onehotencode(Y,1);

end
```

Predictors Preprocessing Function

The `preprocessPredictors` function preprocesses a mini-batch of predictors by extracting the image data from the input cell array and concatenating the data into a numeric array. For grayscale input, concatenating over the fourth dimension adds a third dimension to each image to use as a singleton channel dimension.

```
function X = preprocessPredictors(XCell)

X = cat(4,XCell{:});

end
```

Train Variational Autoencoder (VAE) to Generate Images

This example shows how to create a variational autoencoder (VAE) in MATLAB to generate digit images. The VAE generates hand-drawn digits in the style of the MNIST data set.

VAEs differ from regular autoencoders in that they do not use the encoding-decoding process to reconstruct an input. Instead, they impose a probability distribution on the latent space, and learn the distribution so that the distribution of outputs from the decoder matches that of the observed data. Then, they sample from this distribution to generate new data.

In this example, you construct a VAE network, train it on the MNIST data set, and generate new images that closely resemble those in the data set.

Load Data

Download the MNIST files from http://yann.lecun.com/exdb/mnist/ and load the MNIST data set into the workspace [1]. Call the `processImagesMNIST` and `processLabelsMNIST` helper functions attached to this example to load the data from the files into MATLAB arrays.

Because the VAE compares the reconstructed digits against the inputs and not against the categorical labels, you do not need to use the training labels in the MNIST data set.

```
trainImagesFile = 'train-images-idx3-ubyte.gz';
testImagesFile = 't10k-images-idx3-ubyte.gz';
testLabelsFile = 't10k-labels-idx1-ubyte.gz';

XTrain = processImagesMNIST(trainImagesFile);
```

```
Read MNIST image data...
Number of images in the dataset:  60000 ...
```

```
numTrainImages = size(XTrain,4);
XTest = processImagesMNIST(testImagesFile);
```

```
Read MNIST image data...
Number of images in the dataset:  10000 ...
```

```
YTest = processLabelsMNIST(testLabelsFile);
```

```
Read MNIST label data...
Number of labels in the dataset:  10000 ...
```

Construct Network

Autoencoders have two parts: the encoder and the decoder. The encoder takes an image input and outputs a compressed representation (the encoding), which is a vector of size `latentDim`, equal to 20 in this example. The decoder takes the compressed representation, decodes it, and recreates the original image.

To make calculations more numerically stable, increase the range of possible values from [0,1] to [-inf, 0] by making the network learn from the logarithm of the variances. Define two vectors of size `latent_dim`: one for the means μ and one for the logarithm of the variances $\log\left(\sigma^2\right)$. Then use these two vectors to create the distribution to sample from.

Use 2-D convolutions followed by a fully connected layer to downsample from the 28-by-28-by-1 MNIST image to the encoding in the latent space. Then, use transposed 2-D convolutions to scale up the 1-by-1-by-20 encoding back into a 28-by-28-by-1 image.

```
latentDim = 20;
imageSize = [28 28 1];

encoderLG = layerGraph([
    imageInputLayer(imageSize,'Name','input_encoder','Normalization','none')
    convolution2dLayer(3, 32, 'Padding','same', 'Stride', 2, 'Name', 'conv1')
    reluLayer('Name','relu1')
    convolution2dLayer(3, 64, 'Padding','same', 'Stride', 2, 'Name', 'conv2')
    reluLayer('Name','relu2')
    fullyConnectedLayer(2 * latentDim, 'Name', 'fc_encoder')
    ]);

decoderLG = layerGraph([
    imageInputLayer([1 1 latentDim],'Name','i','Normalization','none')
    transposedConv2dLayer(7, 64, 'Cropping', 'same', 'Stride', 7, 'Name', 'transpose1')
    reluLayer('Name','relu1')
    transposedConv2dLayer(3, 64, 'Cropping', 'same', 'Stride', 2, 'Name', 'transpose2')
    reluLayer('Name','relu2')
    transposedConv2dLayer(3, 32, 'Cropping', 'same', 'Stride', 2, 'Name', 'transpose3')
    reluLayer('Name','relu3')
    transposedConv2dLayer(3, 1, 'Cropping', 'same', 'Name', 'transpose4')
    ]);
```

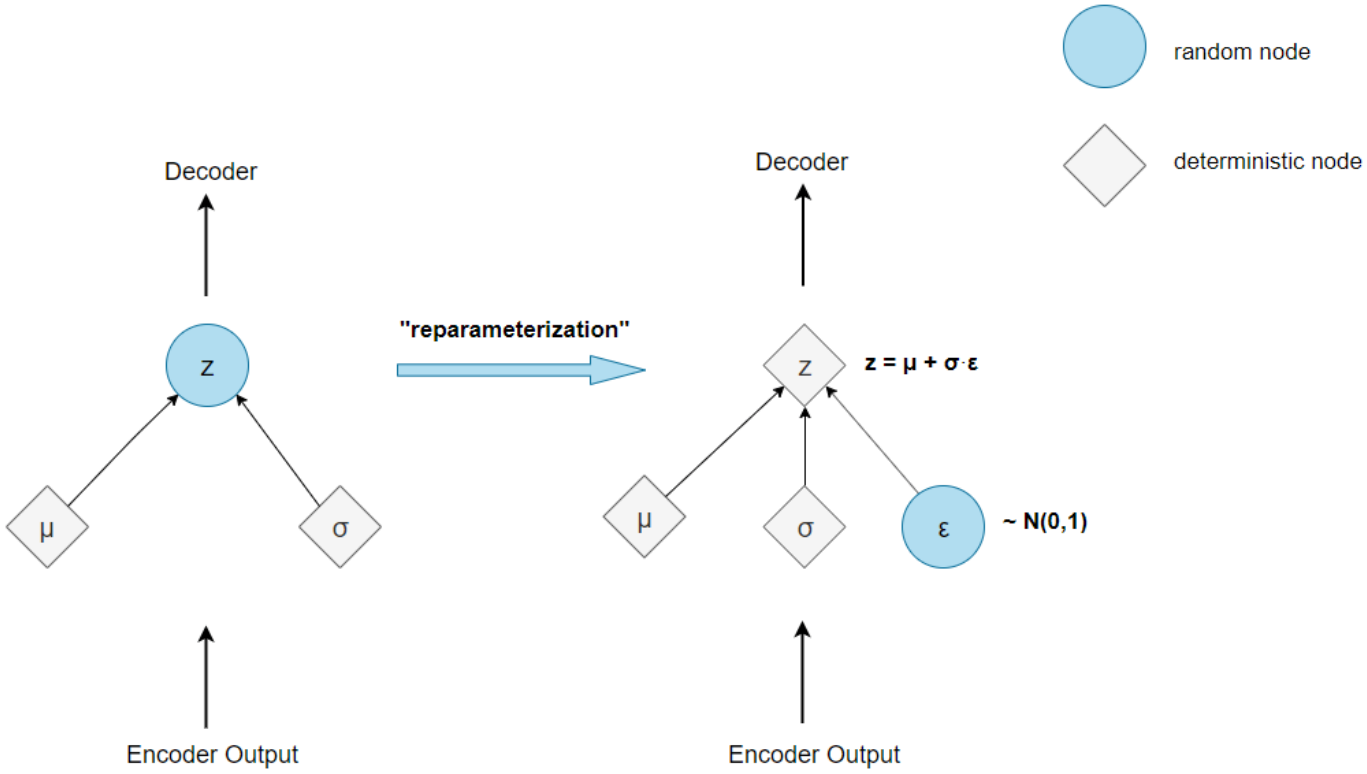
To train both networks with a custom training loop and enable automatic differentiation, convert the layer graphs to `dlnetwork` objects.

```
encoderNet = dlnetwork(encoderLG);
decoderNet = dlnetwork(decoderLG);
```

Define Model Gradients Function

The helper function modelGradients on page 3-0 takes in the encoder and decoder `dlnetwork` objects and a mini-batch of input data `X`, and returns the gradients of the loss with respect to the learnable parameters in the networks. This helper function is defined at the end of this example.

The function performs this process in two steps: sampling and loss on page 3-0 . The sampling step samples the mean and the variance vectors to create the final encoding to be passed to the decoder network. However, because backpropagation through a random sampling operation is not possible, you must use the *reparameterization trick*. This trick moves the random sampling operation to an auxiliary variable ε, which is then shifted by the mean μ_i and scaled by the standard deviation σ_i. The idea is that sampling from $N\left(\mu_i, \sigma_i^2\right)$ is the same as sampling from $\mu_i + \varepsilon \cdot \sigma_i$, where $\varepsilon \sim N(0, 1)$. The following figure depicts this idea graphically.



The loss step passes the encoding generated by the sampling step through the decoder network, and determines the loss, which is then used to compute the gradients. The loss in VAEs, also called the evidence lower bound (ELBO) loss, is defined as a sum of two separate loss terms:

ELBO loss = reconstruction loss + KL loss.

The *reconstruction loss* measures how close the decoder output is to the original input by using the mean-squared error (MSE):

reconstruction loss = MSE(decoder output, original image).

The *KL loss*, or Kullback–Leibler divergence, measures the difference between two probability distributions. Minimizing the KL loss in this case means ensuring that the learned means and variances are as close as possible to those of the target (normal) distribution. For a latent dimension of size n, the KL loss is obtained as

$$\text{KL loss} = -0.5 \cdot \sum_{i=1}^{n} \left(1 + \log\left(\sigma_i^2\right) - \mu_i^2 - \sigma_i^2\right).$$

The practical effect of including a KL loss term is to pack the clusters learned due to the reconstruction loss tightly around the center of the latent space, forming a continuous space to sample from.

Specify Training Options

Train on a GPU if one is available (requires Parallel Computing Toolbox™).

```
executionEnvironment = "auto";
```

Set the training options for the network. When using the Adam optimizer, you need to initialize for each network the trailing average gradient and the trailing average gradient-square decay rates with empty arrays.

```
numEpochs = 50;
miniBatchSize = 512;
lr = 1e-3;
numIterations = floor(numTrainImages/miniBatchSize);
iteration = 0;

avgGradientsEncoder = [];
avgGradientsSquaredEncoder = [];
avgGradientsDecoder = [];
avgGradientsSquaredDecoder = [];
```

Train Model

Train the model using a custom training loop.

For each iteration in an epoch:

- Obtain the next mini-batch from the training set.
- Convert the mini-batch to a `dlarray` object, making sure to specify the dimension labels `'SSCB'` (spatial, spatial, channel, batch).
- For GPU training, convert the `dlarray` to a `gpuArray` object.
- Evaluate the model gradients using the `dlfeval` and `modelGradients` functions.
- Update the network learnables and the average gradients for both networks, using the `adamupdate` function.

At the end of each epoch, pass the test set images through the autoencoder, and display the loss and the training time for that epoch.

```
for epoch = 1:numEpochs
    tic;
    for i = 1:numIterations
        iteration = iteration + 1;
        idx = (i-1)*miniBatchSize+1:i*miniBatchSize;
        XBatch = XTrain(:,:,:,idx);
        XBatch = dlarray(single(XBatch), 'SSCB');

        if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
            XBatch = gpuArray(XBatch);
        end

        [infGrad, genGrad] = dlfeval(...
            @modelGradients, encoderNet, decoderNet, XBatch);

        [decoderNet.Learnables, avgGradientsDecoder, avgGradientsSquaredDecoder] = ...
            adamupdate(decoderNet.Learnables, ...
                genGrad, avgGradientsDecoder, avgGradientsSquaredDecoder, iteration, lr);
        [encoderNet.Learnables, avgGradientsEncoder, avgGradientsSquaredEncoder] = ...
            adamupdate(encoderNet.Learnables, ...
                infGrad, avgGradientsEncoder, avgGradientsSquaredEncoder, iteration, lr);
    end
    elapsedTime = toc;
```

```
    [z, zMean, zLogvar] = sampling(encoderNet, XTest);
    xPred = sigmoid(forward(decoderNet, z));
    elbo = ELBOloss(XTest, xPred, zMean, zLogvar);
    disp("Epoch : "+epoch+" Test ELBO loss = "+gather(extractdata(elbo))+...
        ". Time taken for epoch = "+ elapsedTime + "s")
end
```

```

Visualize Results

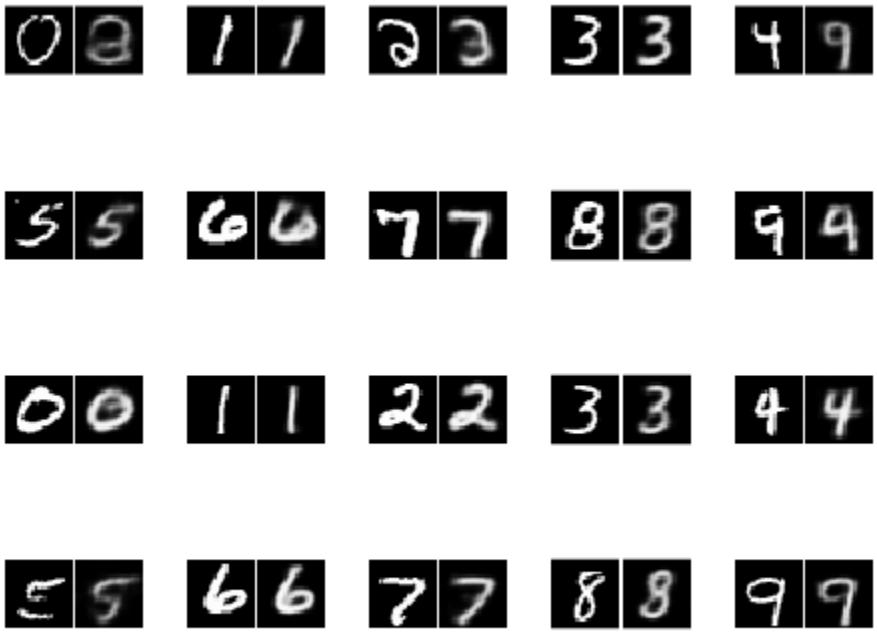
To visualize and interpret the results, use the helper Visualization functions on page 3-0 . These helper functions are defined at the end of this example.

The `VisualizeReconstruction` function shows a randomly chosen digit from each class accompanied by its reconstruction after passing through the autoencoder.

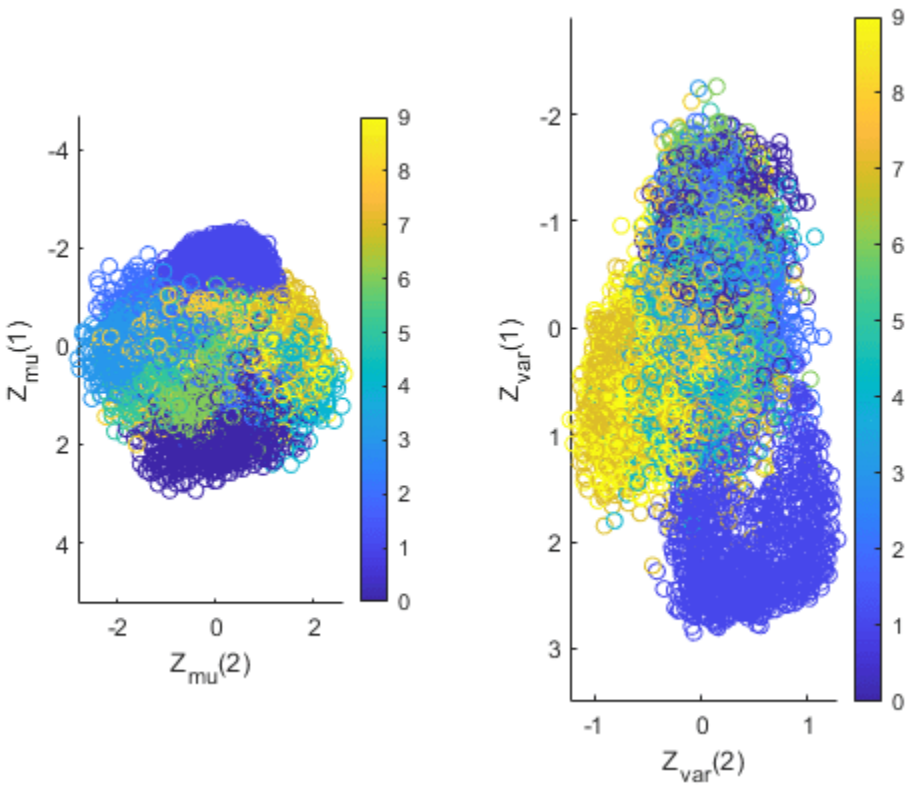
The `VisualizeLatentSpace` function takes the mean and the variance encodings (each of dimension 20) generated after passing the test images through the encoder network, and performs principal component analysis (PCA) on the matrix containing the encodings for each of the images. You can then visualize the latent space defined by the means and the variances in the two dimensions characterized by the two first principal components.

The `Generate` function initializes new encodings sampled from a normal distribution, and outputs the images generated when these encodings pass through the decoder network.

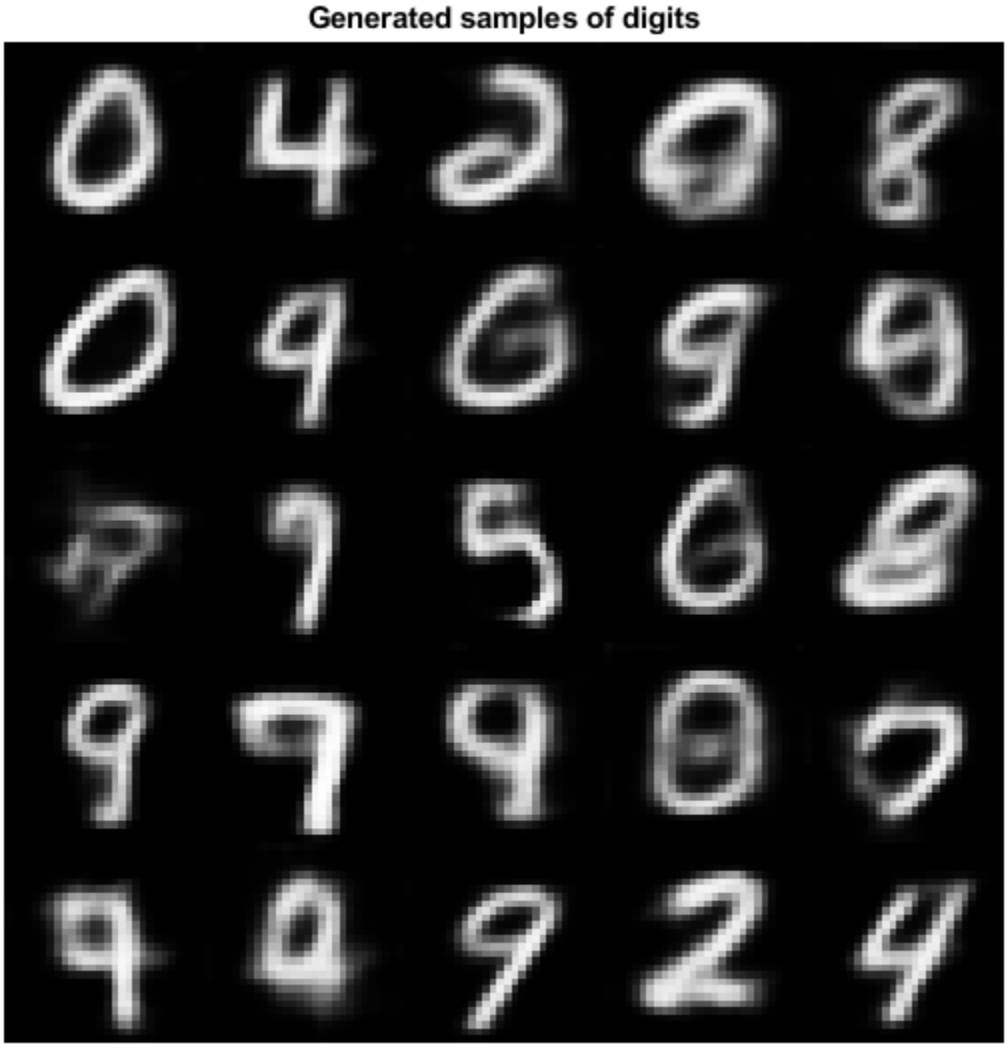
```
visualizeReconstruction(XTest, YTest, encoderNet, decoderNet)
```



```
visualizeLatentSpace(XTest, YTest, encoderNet)
```



```
generate(decoderNet, latentDim)
```



Next Steps

Variational autoencoders are only one of the many available models used to perform generative tasks. They work well on data sets where the images are small and have clearly defined features (such as MNIST). For more complex data sets with larger images, generative adversarial networks (GANs) tend to perform better and generate images with less noise. For an example showing how to implement GANs to generate 64-by-64 RGB images, see “Train Generative Adversarial Network (GAN)” on page 3-76.

Helper Functions

Model Gradients Function

The `modelGradients` function takes the encoder and decoder `dlnetwork` objects and a mini-batch of input data `X`, and returns the gradients of the loss with respect to the learnable parameters in the networks. The function performs three operations:

1. Obtain the encodings by calling the `sampling` function on the mini-batch of images that passes through the encoder network.
2. Obtain the loss by passing the encodings through the decoder network and calling the `ELBOloss` function.
3. Compute the gradients of the loss with respect to the learnable parameters of both networks by calling the `dlgradient` function.

```
function [infGrad, genGrad] = modelGradients(encoderNet, decoderNet, x)
[z, zMean, zLogvar] = sampling(encoderNet, x);
xPred = sigmoid(forward(decoderNet, z));
loss = ELBOloss(x, xPred, zMean, zLogvar);
[genGrad, infGrad] = dlgradient(loss, decoderNet.Learnables, ...
    encoderNet.Learnables);
end
```

Sampling and Loss Functions

The `sampling` function obtains encodings from input images. Initially, it passes a mini-batch of images through the encoder network and splits the output of size `(2*latentDim)*miniBatchSize` into a matrix of means and a matrix of variances, each of size `latentDim*batchSize`. Then, it uses these matrices to implement the reparameterization trick and to compute the encoding. Finally, it converts this encoding to a `dlarray` object in SSCB format.

```
function [zSampled, zMean, zLogvar] = sampling(encoderNet, x)
compressed = forward(encoderNet, x);
d = size(compressed,1)/2;
zMean = compressed(1:d,:);
zLogvar = compressed(1+d:end,:);

sz = size(zMean);
epsilon = randn(sz);
sigma = exp(.5 * zLogvar);
z = epsilon .* sigma + zMean;
z = reshape(z, [1,1,sz]);
zSampled = dlarray(z, 'SSCB');
end
```

The `ELBOloss` function takes the encodings of the means and the variances returned by the `sampling` function, and uses them to compute the ELBO loss.

```
function elbo = ELBOloss(x, xPred, zMean, zLogvar)
squares = 0.5*(xPred-x).^2;
reconstructionLoss  = sum(squares, [1,2,3]);

KL = -.5 * sum(1 + zLogvar - zMean.^2 - exp(zLogvar), 1);

elbo = mean(reconstructionLoss + KL);
end
```

Visualization Functions

The `VisualizeReconstruction` function randomly chooses two images for each digit of the MNIST data set, passes them through the VAE, and plots the reconstruction side by side with the original input. Note that to plot the information contained inside a `dlarray` object, you need to extract it first using the `extractdata` and `gather` functions.

```
function visualizeReconstruction(XTest,YTest, encoderNet, decoderNet)
f = figure;
figure(f)
title("Example ground truth image vs. reconstructed image")
for i = 1:2
    for c=0:9
        idx = iRandomIdxOfClass(YTest,c);
        X = XTest(:,:,:,idx);

        [z, ~, ~] = sampling(encoderNet, X);
        XPred = sigmoid(forward(decoderNet, z));

        X = gather(extractdata(X));
        XPred = gather(extractdata(XPred));

        comparison = [X, ones(size(X,1),1), XPred];
        subplot(4,5,(i-1)*10+c+1), imshow(comparison,[]),
    end
end
end

function idx = iRandomIdxOfClass(T,c)
idx = T == categorical(c);
idx = find(idx);
idx = idx(randi(numel(idx),1));
end
```

The `VisualizeLatentSpace` function visualizes the latent space defined by the mean and the variance matrices that form the output of the encoder network, and locates the clusters formed by the latent space representations of each digit.

The function starts by extracting the mean and the variance matrices from the `dlarray` objects. Because transposing a matrix with channel/batch dimensions (C and B) is not possible, the function calls `stripdims` before transposing the matrices. Then, it carries out a principal component analysis (PCA) on both matrices. To visualize the latent space in two dimensions, the function keeps the first two principal components and plots them against each other. Finally, the function colors the digit classes so that you can observe clusters.

```
function visualizeLatentSpace(XTest, YTest, encoderNet)
[~, zMean, zLogvar] = sampling(encoderNet, XTest);

zMean = stripdims(zMean)';
zMean = gather(extractdata(zMean));

zLogvar = stripdims(zLogvar)';
zLogvar = gather(extractdata(zLogvar));

[~,scoreMean] = pca(zMean);
[~,scoreLogvar] = pca(zLogvar);
```

```
c = parula(10);
f1 = figure;
figure(f1)
title("Latent space")

ah = subplot(1,2,1);
scatter(scoreMean(:,2),scoreMean(:,1),[],c(double(YTest),:));
ah.YDir = 'reverse';
axis equal
xlabel("Z_m_u(2)")
ylabel("Z_m_u(1)")
cb = colorbar; cb.Ticks = 0:(1/9):1; cb.TickLabels = string(0:9);

ah = subplot(1,2,2);
scatter(scoreLogvar(:,2),scoreLogvar(:,1),[],c(double(YTest),:));
ah.YDir = 'reverse';
xlabel("Z_v_a_r(2)")
ylabel("Z_v_a_r(1)")
cb = colorbar;  cb.Ticks = 0:(1/9):1; cb.TickLabels = string(0:9);
axis equal
end
```

The `generate` function tests the generative capabilities of the VAE. It initializes a `dlarray` object containing 25 randomly generated encodings, passes them through the decoder network, and plots the outputs.

```
function generate(decoderNet, latentDim)
randomNoise = dlarray(randn(1,1,latentDim,25),'SSCB');
generatedImage = sigmoid(predict(decoderNet, randomNoise));
generatedImage = extractdata(generatedImage);

f3 = figure;
figure(f3)
imshow(imtile(generatedImage, "ThumbnailSize", [100,100]))
title("Generated samples of digits")
drawnow
end
```

Lane and Vehicle Detection in Simulink Using Deep Learning

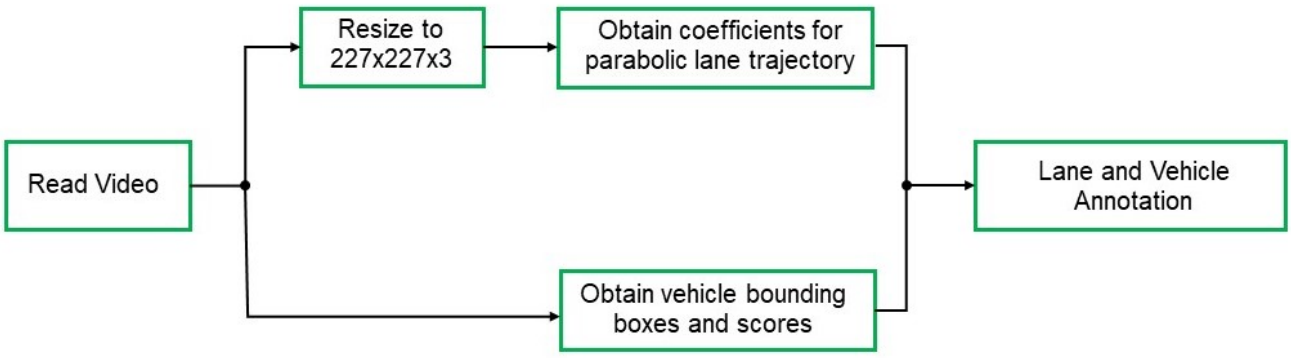
This example shows how to use deep convolutional neural networks inside a Simulink® model to perform lane and vehicle detection. This example takes the frames from a traffic video as an input, outputs two lane boundaries that correspond to the left and right lanes of the ego vehicle, and detects vehicles in the frame.

This example uses the pretrained lane detection network from the *Lane Detection Optimized with GPU Coder* example of the GPU Coder Toolbox™. For more information, see "Lane Detection Optimized with GPU Coder" (GPU Coder).

This example also uses the pretrained vehicle detection network from the *Object Detection Using YOLO v2 Deep Learning* example of the Computer Vision toolbox™. For more information, see "Object Detection Using YOLO v2 Deep Learning" (Computer Vision Toolbox).

Algorithmic Workflow

The block diagram for the algorithmic workflow of the Simulink model is shown.



Get Pretrained Lane and Vehicle Detection Networks

This example uses the `trainedLaneNet` and `yolov2ResNet50VehicleExample` MAT-files containing the pretrained networks. The files are approximately 143MB and 98MB in size, respectively. Download the files from the MathWorks website.

```
lanenetFile = matlab.internal.examples.downloadSupportFile('gpucoder/cnn_models/lane_detection',
vehiclenetFile = matlab.internal.examples.downloadSupportFile('vision/data','yolov2ResNet50Vehic
```

Download Test Traffic Video

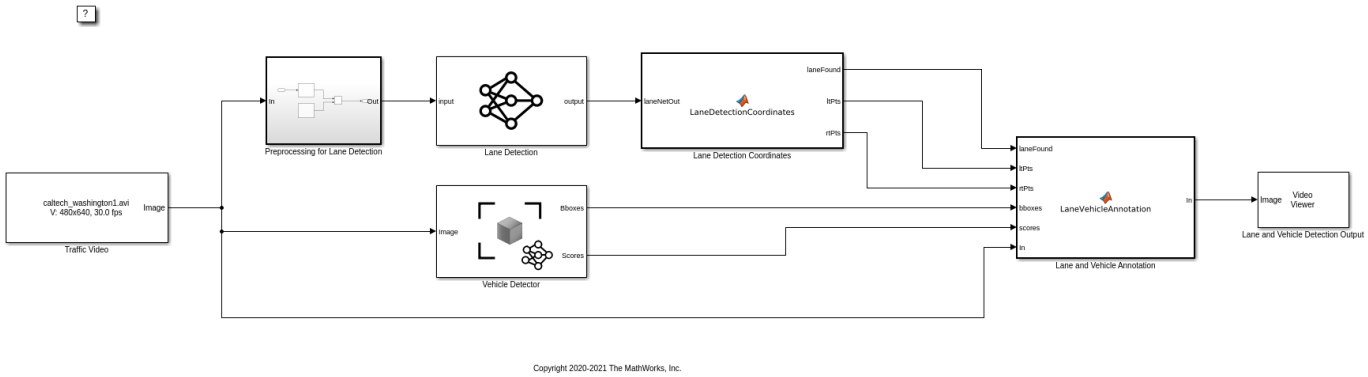
To test the model, the example uses the Caltech lanes dataset. The file is approximately 16 MB in size. Download the files from the MathWorks website.

```
mediaFile = matlab.internal.examples.downloadSupportFile('gpucoder/media','caltech_washington1.av
```

Lane and Vehicle Detection Simulink Model

The Simulink model for performing lane and vehicle detection on the traffic video is shown. When the model runs, the `Video Viewer` block displays the traffic video with lane and vehicle annotations.

```
open_system('laneAndVehicleDetectionMDL');
```



Set the file paths of the dowloaded network model in the predict and detector blocks of the Simulink model. Set the location of the test video to be loaded by the Simulink model.

```
set_param('laneAndVehicleDetectionMDL/Lane Detection','NetworkFilePath',lanenetFile)
set_param('laneAndVehicleDetectionMDL/Vehicle Detector','DetectorFilePath',vehiclenetFile)
set_param('laneAndVehicleDetectionMDL/Traffic Video','inputFileName',mediaFile)
```

Lane Detection

For lane detection, the traffic video is preprocessed by resizing each frame of the video to 227-by-227-by-3 and then scaled by a factor of 255. The preprocessed frames are then input to the `trainedLaneNet.mat` network loaded in the `Predict` block from the Deep Learning Toolbox™. This network takes an image as an input and outputs two lane boundaries that correspond to the left and right lanes of the ego vehicle. Each lane boundary is represented by the parabolic equation:

$$y = ax^2 + bx + c$$

Here y is the lateral offset and x is the longitudinal distance from the vehicle. The network outputs the three parameters a, b, and c per lane. The network architecture is similar to `AlexNet` except that the last few layers are replaced by a smaller fully connected layer and regression output layer. The `Lane Detection Coordinates` MATLAB function block defines a function `lane_detection_coordinates` that takes the output from the predict block and outputs three parameters; `laneFound`, `ltPts`, and `rtPts`. Thresholding is used to determine if both left and right lane boundaries are both found. If both are found, `laneFound` is set to be true and the trajectories of the boundaries are calculated and stored in `ltPts` and `rtPts` respectively.

```
type lane_detection_coordinates
```

```
function [laneFound,ltPts,rtPts] = lane_detection_coordinates(laneNetOut)

% Copyright 2020-2021 The MathWorks, Inc.

persistent laneCoeffMeans;
if isempty(laneCoeffMeans)
    laneCoeffMeans = [-0.0002,0.0002,1.4740,-0.0002,0.0045,-1.3787];
end

persistent laneCoeffStds;
if isempty(laneCoeffStds)
    laneCoeffStds = [0.0030,0.0766,0.6313,0.0026,0.0736,0.9846];
end
```

```
params = laneNetOut .* laneCoeffStds + laneCoeffMeans;

% 'c' should be more than 0.5 for it to be a right lane
isRightLaneFound = abs(params(6)) > 0.5;
isLeftLaneFound =  abs(params(3)) > 0.5;

persistent vehicleXPoints;
if isempty(vehicleXPoints)
    vehicleXPoints = 3:30; %meters, ahead of the sensor
end

ltPts = coder.nullcopy(zeros(28,2,'single'));
rtPts = coder.nullcopy(zeros(28,2,'single'));

if isRightLaneFound && isLeftLaneFound
    rtBoundary = params(4:6);
    rt_y = computeBoundaryModel(rtBoundary, vehicleXPoints);
    ltBoundary = params(1:3);
    lt_y = computeBoundaryModel(ltBoundary, vehicleXPoints);

    % Visualize lane boundaries of the ego vehicle
    tform = get_tformToImage;
    % Map vehicle to image coordinates
    ltPts =  tform.transformPointsInverse([vehicleXPoints', lt_y']);
    rtPts =  tform.transformPointsInverse([vehicleXPoints', rt_y']);
    laneFound = true;
else
    laneFound = false;
end

end
```

Vehicle Detection

This example uses a YOLO v2 based network for vehicle detection. A YOLO v2 object detection network is composed of two subnetworks: a feature extraction network followed by a detection network. This pretrained network uses a `ResNet-50` for feature extraction. The detection sub-network is a small CNN compared to the feature extraction network and is composed of a few convolutional layers and layers specific to YOLO v2.

The Simulink model performs vehicle detection using the `Object Detector` block from the Computer Vision Toolbox. This block takes an image as input and outputs the bounding box coordinates along with the confidence scores for vehicles in the image.

Annotation of Vehicle Bounding Boxes and Lane Trajectory in Traffic Video

The `Lane and Vehicle Annotation` MATLAB function block defines a function `lane_vehicle_annotation` which annotates the vehicle bounding boxes along with the confidence scores. If `laneFound` is true, then the left and right lane boundaries stored in `ltPts` and `rtPts` are overlayed on the traffic video.

```
type lane_vehicle_annotation
```

```
function In = lane_vehicle_annotation(laneFound,ltPts,rtPts,bboxes,scores,In)
```

```
% Copyright 2020-2021 The MathWorks, Inc.

if ~isempty(bboxes)
    In = insertObjectAnnotation(In, 'rectangle',bboxes,scores);
end

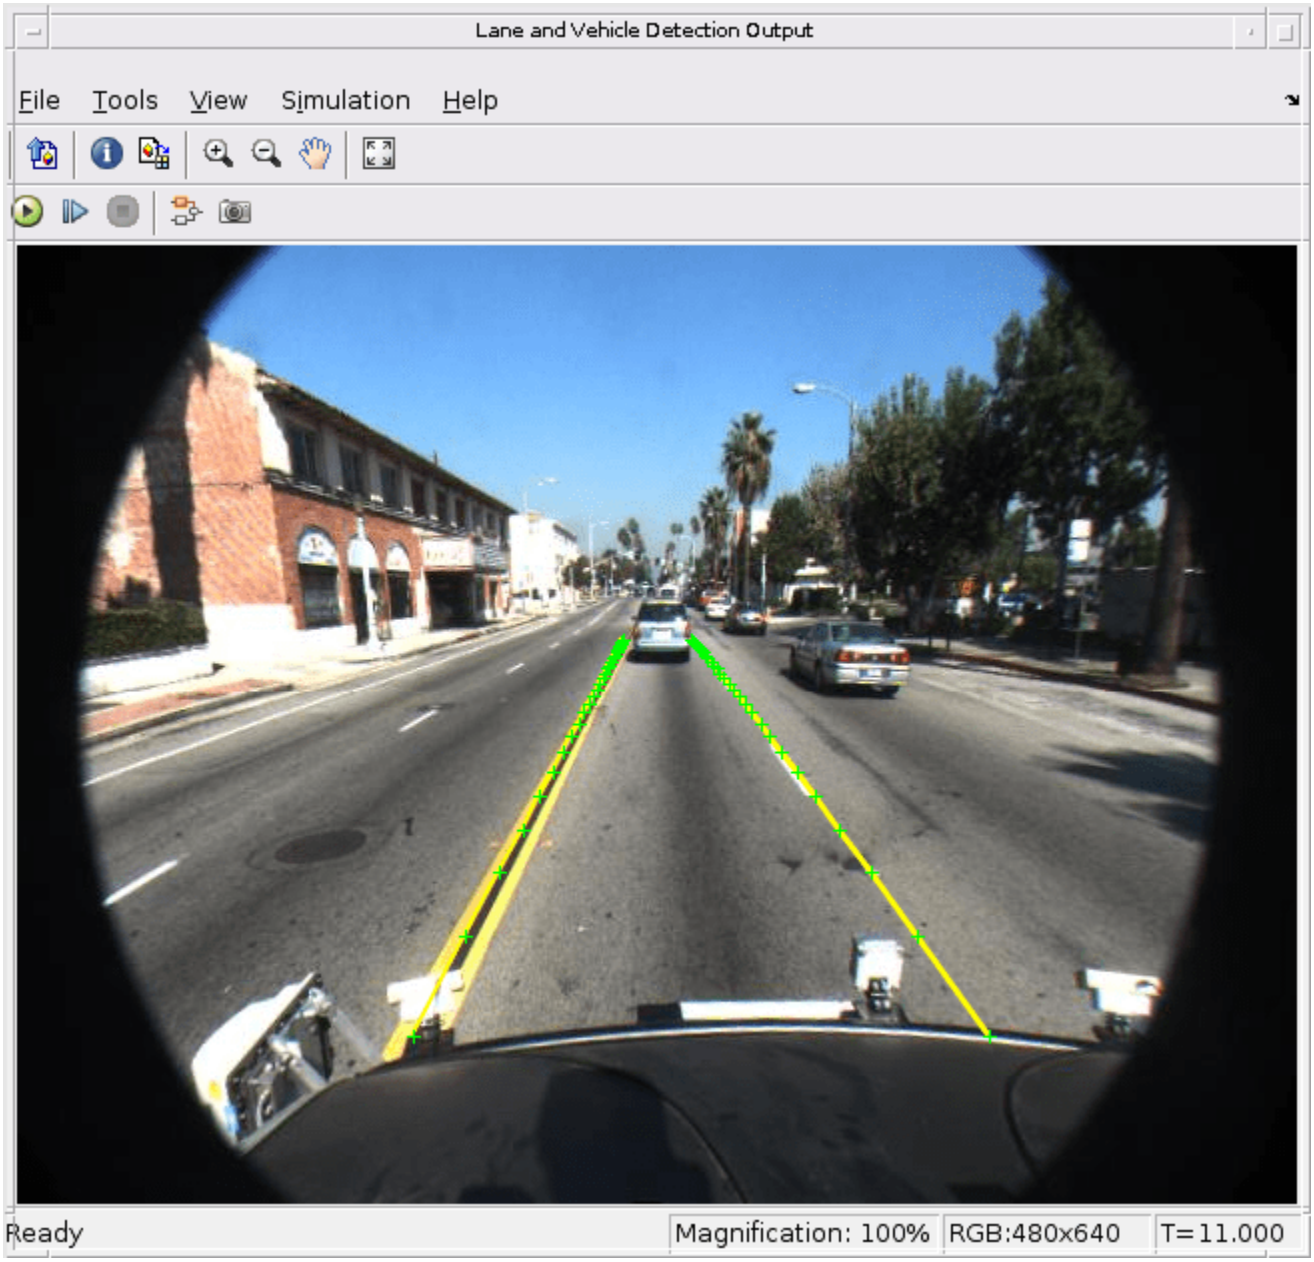
pts = coder.nullcopy(zeros(28, 4, 'single'));
if laneFound
    prevpt =  [ltPts(1,1) ltPts(1,2)];
    for k = 2:1:28
        pts(k,1:4) = [prevpt ltPts(k,1) ltPts(k,2)];
        prevpt = [ltPts(k,1) ltPts(k,2)];
    end
    In = insertShape(In, 'Line', pts, 'LineWidth', 2);
    prevpt =  [rtPts(1,1) rtPts(1,2)];
    for k = 2:1:28
        pts(k,1:4) = [prevpt rtPts(k,1) rtPts(k,2)];
        prevpt = [rtPts(k,1) rtPts(k,2)];
    end
    In = insertShape(In, 'Line', pts, 'LineWidth', 2);
    In = insertMarker(In, ltPts);
    In = insertMarker(In, rtPts);
end

end
```

Run the Simulation

To verify the lane and vehicle detection algorithms and display the lane trajectories, vehicle bounding boxes and scores for the traffic video loaded in the Simulink model, run the simulation.

```
set_param('laneAndVehicleDetectionMDL', 'SimulationMode', 'Normal');
sim('laneAndVehicleDetectionMDL');
```



On Windows®, the maximum path length of 260 characters can cause `"File not found"` errors when running the simulation. In such cases, move the example folder to a different location or enable long paths in Windows. For more information, see Maximum Path Length Limitation (Microsoft).

Use Deep Learning Accelerator Libraries

If you have an Intel® CPU that supports AVX2 instructions, you can use the *MATLAB Coder Interface for Deep Learning Libraries* to accelerate the simulation using Intel MKL-DNN libraries. In the Model Configuration Parameters window, on the Simulation Target pane, set the Language to `C++` and the Target library to `MKL-DNN`.

Code Generation

With GPU Coder, you can accelerate the execution of model on NVIDIA® GPUs and generate CUDA® code for model. For more information, see “Code Generation for a Deep Learning Simulink Model that Performs Lane and Vehicle Detection” (GPU Coder).

Classify ECG Signals in Simulink Using Deep Learning

This example shows how to use wavelet transforms and a deep learning network within a Simulink (R) model to classify ECG signals. This example uses the pretrained convolutional neural network from the *Classify Time Series Using Wavelet Analysis and Deep Learning* example of the Wavelet Toolbox™ to classify ECG signals based on images from the CWT of the time series data. For information on training, see “Classify Time Series Using Wavelet Analysis and Deep Learning” (Wavelet Toolbox).

ECG Data Description

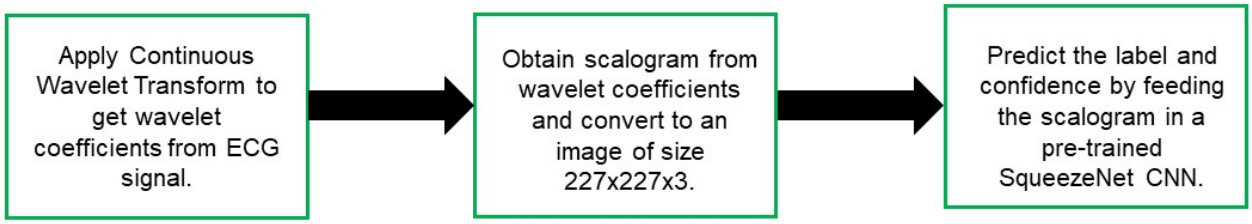
This example uses ECG data from PhysioNet database. It contains data from three groups of people:

1. Persons with cardiac arrhythmia (ARR)
2. Persons with congestive heart failure (CHF)
3. Persons with normal sinus rhythms (NSR)

It includes 96 recordings from persons with ARR, 30 recordings from persons with CHF, and 36 recordings from persons with NSR. The `ecg_signals` MAT-file contains the test ECG data in time series format. The image classifier in this example distinguishes between ARR, CHF, and NSR.

Algorithmic Workflow

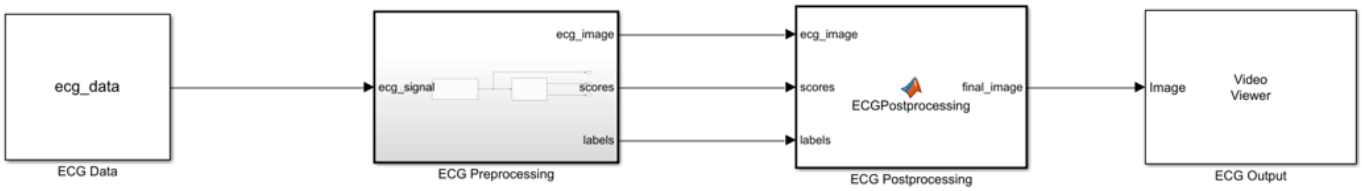
The block diagram for the algorithmic workflow of the Simulink model is shown.



ECG Deep Learning Simulink Model

The Simulink model for classifying the ECG signals is shown. When the model runs, the `Video Viewer` block displays the classified ECG signal.

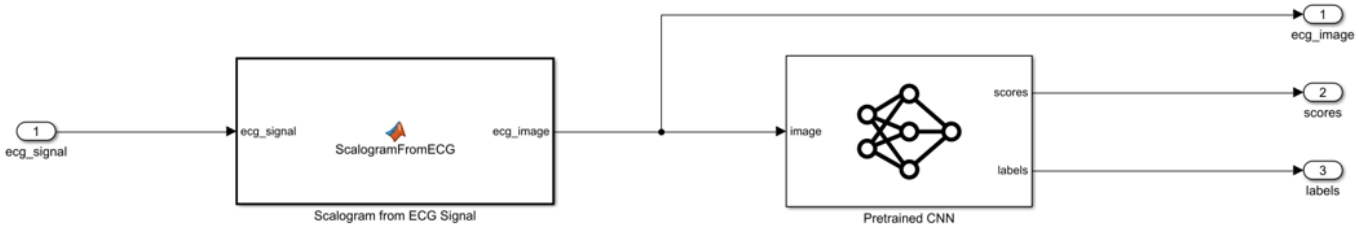
```
open_system('ecg_dl_cwtMDL');
```



ECG Preprocessing Subsystem

The `ECG Preprocessing` subsystem contains a `MATLAB Function` block that performs CWT to obtain scalogram of the ECG signal and then processes the scalogram to obtain an image. It also contains an `Image Classifier` block from the Deep Learning Toolbox™ that loads the pretrained network from `trainedNet.mat` and performs prediction for image classification based on SqueezeNet deep learning CNN.

```
open_system('ecg_dl_cwtMDL/ECG Preprocessing');
```



The `ScalogramFromECG` function block defines a function called `ecg_to_scalogram` that:

- Uses 65536 samples of double-precision ECG data as input.
- Create time frequency representation from the ECG data by applying Wavelet transform.
- Obtain scalogram from the wavelet coefficients.
- Convert the scalogram to image of size (227-by-227-by-3).

The function signature of `ecg_to_scalogram` is shown.

```
type ecg_to_scalogram
```

```
function ecg_image  = ecg_to_scalogram(ecg_signal)

% Copyright 2020 The MathWorks, Inc.

persistent jetdata;
if(isempty(jetdata))
    jetdata = colourmap(128,'single');
end
% Obtain wavelet coefficients from ECG signal
cfs = cwt_ecg(ecg_signal);
% Obtain scalogram from wavelet coefficients
image = ind2rgb(im2uint8(rescale(cfs)),jetdata);
ecg_image = im2uint8(imresize(image,[227,227]));

end
```

ECG Postprocessing

The `ECG Postprocessing` MATLAB function block defines the `label_prob_image` function that finds the label for the scalogram image based on the highest score from the scores outputed by the image classifier. It outputs the scalogram image with the label and confidence overlayed.

```
type label_prob_image
```

```
function final_image = label_prob_image(ecg_image, scores, labels)
```

```
% Copyright 2020 The MathWorks, Inc.

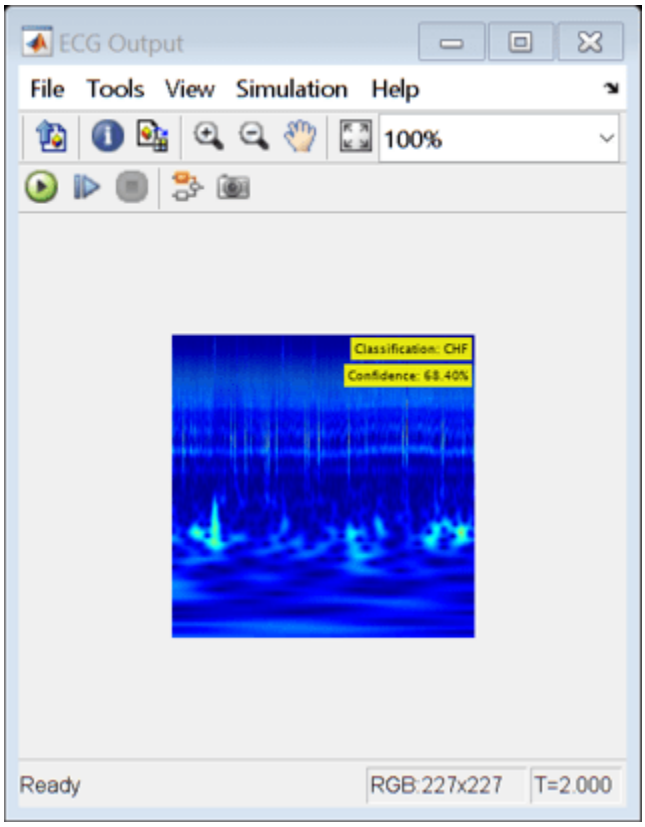
scores = double(scores);
% Obtain maximum confidence
[prob,index] = max(scores);
confidence = prob*100;
% Obtain label corresponding to maximum confidence
label = erase(char(labels(index)),'_label');
text = cell(2,1);
text{1} = ['Classification: ' label];
text{2} = ['Confidence: ' sprintf('%0.2f',confidence) '%'];
position = [135 20 0 0; 130 40 0 0];
final_image = insertObjectAnnotation(ecg_image,'rectangle',position,text,'TextBoxOpacity',0.9,'Fo

end
```

Run the Simulation

To verify the algorithm and display the labels and confidence score of the test ECG signal loaded in the workspace, run the simulation.

```
set_param('ecg_dl_cwtMDL', 'SimulationMode', 'Normal');
sim('ecg_dl_cwtMDL');
```



Code Generation

With GPU Coder™, you can accelerate the execution of model on NVIDIA® GPUs and generate CUDA® code for model. See the “Code Generation for a Deep Learning Simulink Model to Classify ECG Signals” (GPU Coder) for more details.

Cleanup

Close the Simulink model.

```
close_system('ecg_dl_cwtMDL/ECG Preprocessing');
close_system('ecg_dl_cwtMDL');
```

Classify Images in Simulink Using GoogLeNet

This example shows how to classify an image in Simulink® using the `Image Classifier` block. The example uses the pretrained deep convolutional neural network GoogLeNet to perform the classification.

Pretrained GoogLeNet Network

GoogLeNet has been trained on over a million images and can classify images into 1000 object categories (such as keyboard, coffee mug, pencil, and many animals). The network has learned rich feature representations for a wide range of images. The network takes an image as input, and then outputs a label for the object in the image together with the probabilities for each of the object categories.

```
net = googlenet;
inputSize = net.Layers(1).InputSize;
classNames = net.Layers(end).ClassNames;
numClasses = numel(classNames);
disp(classNames(randperm(numClasses,10)))
```

```
    {'speedboat'    }
    {'window screen'}
    {'isopod'       }
    {'wooden spoon' }
    {'lipstick'     }
    {'drake'        }
    {'hyena'        }
    {'dumbbell'     }
    {'strawberry'   }
    {'custard apple'}
```

Read and Resize Image

Read and show the image that you want to classify.

```
I = imread('peppers.png');
figure
imshow(I)
```

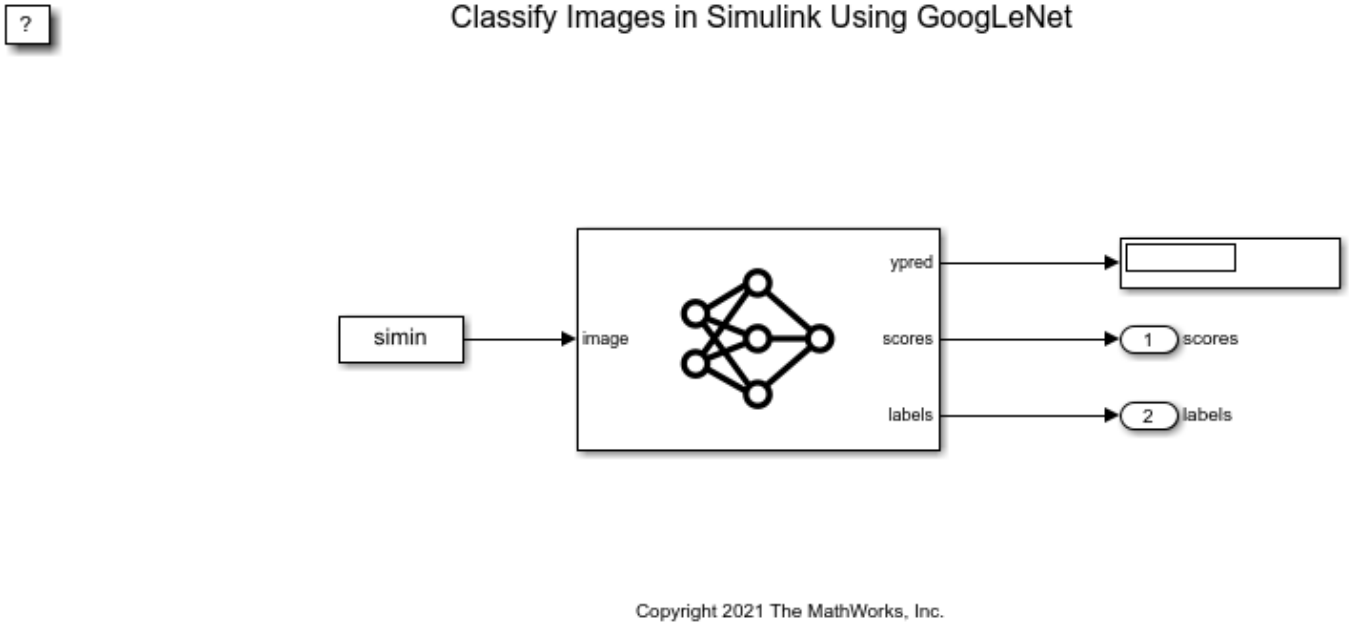
To import this data into the Simulink model, specify a structure variable containing the input image data and an empty time vector.

```
simin.time = [];
simin.signals.values = I;
simin.signals.dimensions = size(I);
```

Simulink Model for Prediction

The Simulink model for classifying images is shown. The model uses a `From Workspace` block to load the input image, an `Image Classifier` block from the Deep Neural Networks library that classifies the input, and `Display` block to show the predicted output.

```
model = 'googlenet_classifier';
open_system(model);
```

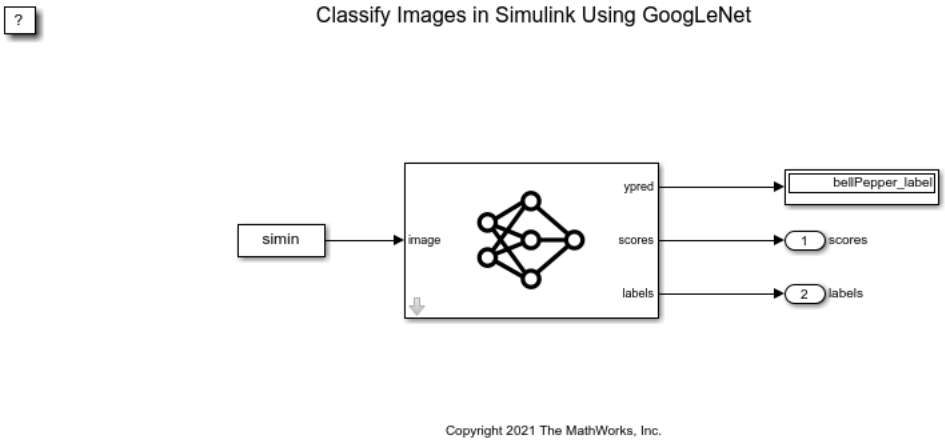


Run the Simulation

To validate the Simulink model, run the simulation.

```
set_param(model,'SimulationMode','Normal');
sim(model);
```

The network classifies the image as a bell pepper.



Display Top Predictions

Display the top five predicted labels and their associated probabilities as a histogram. Because the network classifies images into so many object categories, and many categories are similar, it is common to consider the top-five accuracy when evaluating networks. The network classifies the image as a bell pepper with a high probability.

```
scores = yout.signals(1).values(:,:,1);
labels = yout.signals(2).values(:,:,1);
[~,idx] = sort(scores,'descend');
idx = idx(5:-1:1);
scoresTop = scores(idx);
labelsTop = split(string(labels(idx)),'_');
labelsTop = labelsTop(:,:,1);

figure
imshow(I)
title(labelsTop(5) + ", " + num2str(100*scoresTop(5) + "%"));

figure
barh(scoresTop)
xlim([0 1])
title('Top 5 Predictions')
xlabel('Probability')
yticklabels(labelsTop)

Deep Learning with Time Series, Sequences, and Text

Sequence Classification Using Deep Learning

This example shows how to classify sequence data using a long short-term memory (LSTM) network.

To train a deep neural network to classify sequence data, you can use an LSTM network. An LSTM network enables you to input sequence data into a network, and make predictions based on the individual time steps of the sequence data.

This example uses the Japanese Vowels data set as described in [1] and [2]. This example trains an LSTM network to recognize the speaker given time series data representing two Japanese vowels spoken in succession. The training data contains time series data for nine speakers. Each sequence has 12 features and varies in length. The data set contains 270 training observations and 370 test observations.

Load Sequence Data

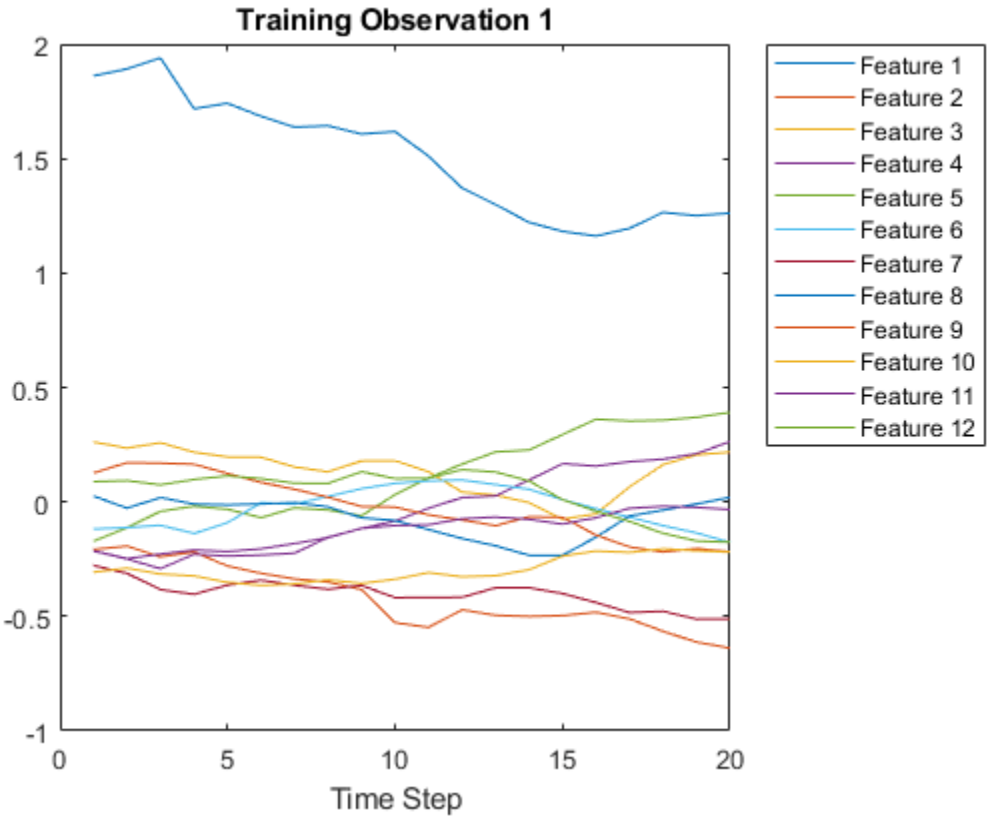
Load the Japanese Vowels training data. `XTrain` is a cell array containing 270 sequences of dimension 12 of varying length. `Y` is a categorical vector of labels "1","2",...,"9", which correspond to the nine speakers. The entries in `XTrain` are matrices with 12 rows (one row for each feature) and varying number of columns (one column for each time step).

```
[XTrain,YTrain] = japaneseVowelsTrainData;
XTrain(1:5)
```

```
ans=5×1 cell array
    {12x20 double}
    {12x26 double}
    {12x22 double}
    {12x20 double}
    {12x21 double}
```

Visualize the first time series in a plot. Each line corresponds to a feature.

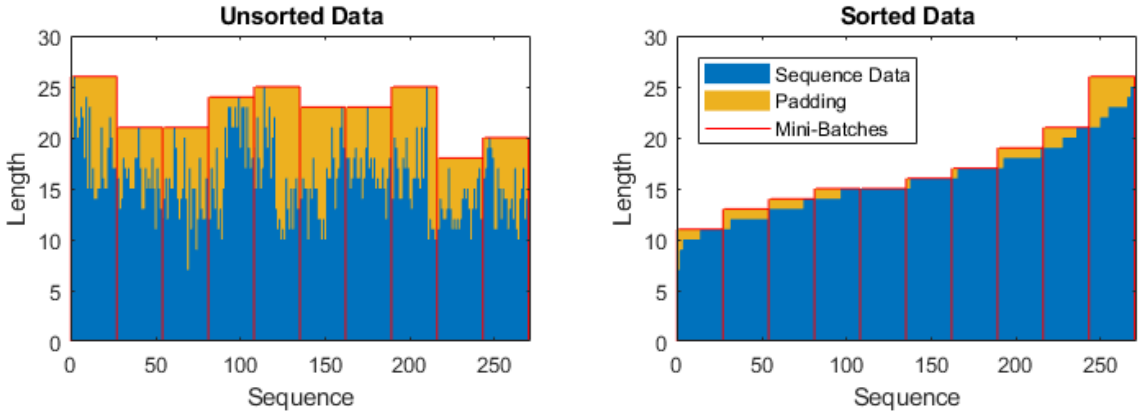
```
figure
plot(XTrain{1}')
xlabel("Time Step")
title("Training Observation 1")
numFeatures = size(XTrain{1},1);
legend("Feature " + string(1:numFeatures),'Location','northeastoutside')
```



Prepare Data for Padding

During training, by default, the software splits the training data into mini-batches and pads the sequences so that they have the same length. Too much padding can have a negative impact on the network performance.

To prevent the training process from adding too much padding, you can sort the training data by sequence length, and choose a mini-batch size so that sequences in a mini-batch have a similar length. The following figure shows the effect of padding sequences before and after sorting data.



Get the sequence lengths for each observation.

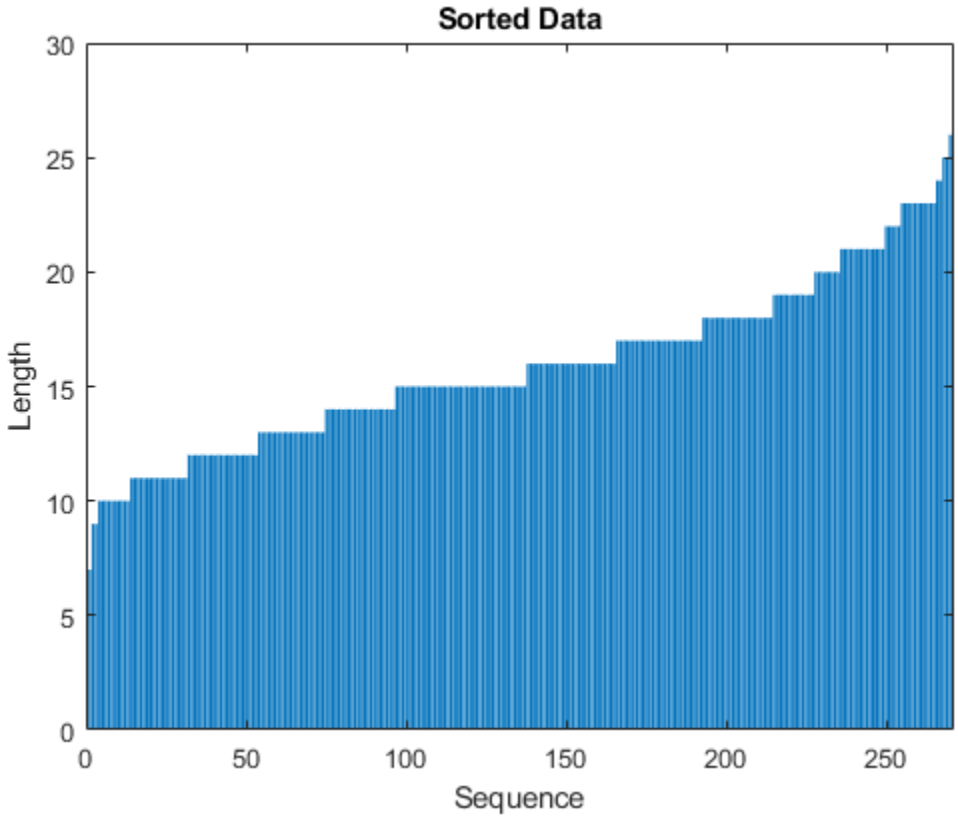
```
numObservations = numel(XTrain);
for i=1:numObservations
    sequence = XTrain{i};
    sequenceLengths(i) = size(sequence,2);
end
```

Sort the data by sequence length.

```
[sequenceLengths,idx] = sort(sequenceLengths);
XTrain = XTrain(idx);
YTrain = YTrain(idx);
```

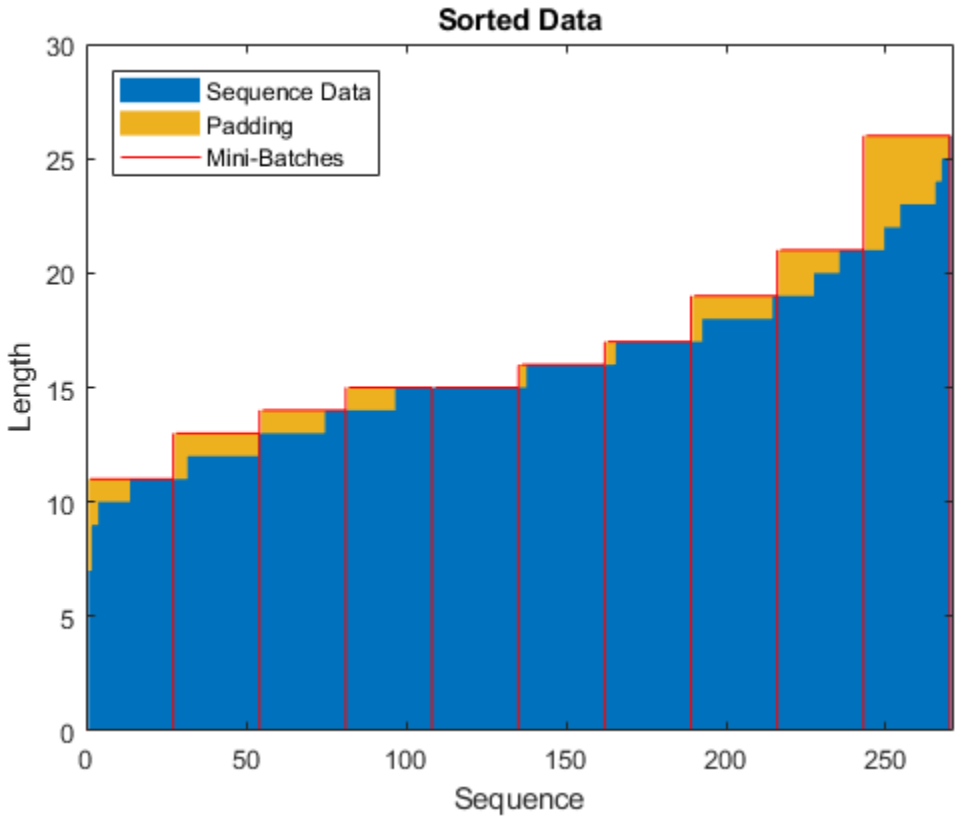
View the sorted sequence lengths in a bar chart.

```
figure
bar(sequenceLengths)
ylim([0 30])
xlabel("Sequence")
ylabel("Length")
title("Sorted Data")
```



Choose a mini-batch size of 27 to divide the training data evenly and reduce the amount of padding in the mini-batches. The following figure illustrates the padding added to the sequences.

```
miniBatchSize = 27;
```



Define LSTM Network Architecture

Define the LSTM network architecture. Specify the input size to be sequences of size 12 (the dimension of the input data). Specify an bidirectional LSTM layer with 100 hidden units, and output the last element of the sequence. Finally, specify nine classes by including a fully connected layer of size 9, followed by a softmax layer and a classification layer.

If you have access to full sequences at prediction time, then you can use a bidirectional LSTM layer in your network. A bidirectional LSTM layer learns from the full sequence at each time step. If you do not have access to the full sequence at prediction time, for example, if you are forecasting values or predicting one time step at a time, then use an LSTM layer instead.

```
inputSize = 12;
numHiddenUnits = 100;
numClasses = 9;

layers = [ ...
    sequenceInputLayer(inputSize)
    bilstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer]
```

```
layers =
  5x1 Layer array with layers:

     1   ''   Sequence Input          Sequence input with 12 dimensions
```

```
     2   ''   BiLSTM                  BiLSTM with 100 hidden units
     3   ''   Fully Connected         9 fully connected layer
     4   ''   Softmax                 softmax
     5   ''   Classification Output   crossentropyex
```

Now, specify the training options. Specify the solver to be `'adam'`, the gradient threshold to be 1, and the maximum number of epochs to be 100. To reduce the amount of padding in the mini-batches, choose a mini-batch size of 27. To pad the data to have the same length as the longest sequences, specify the sequence length to be `'longest'`. To ensure that the data remains sorted by sequence length, specify to never shuffle the data.

Since the mini-batches are small with short sequences, training is better suited for the CPU. Specify `'ExecutionEnvironment'` to be `'cpu'`. To train on a GPU, if available, set `'ExecutionEnvironment'` to `'auto'` (this is the default value).

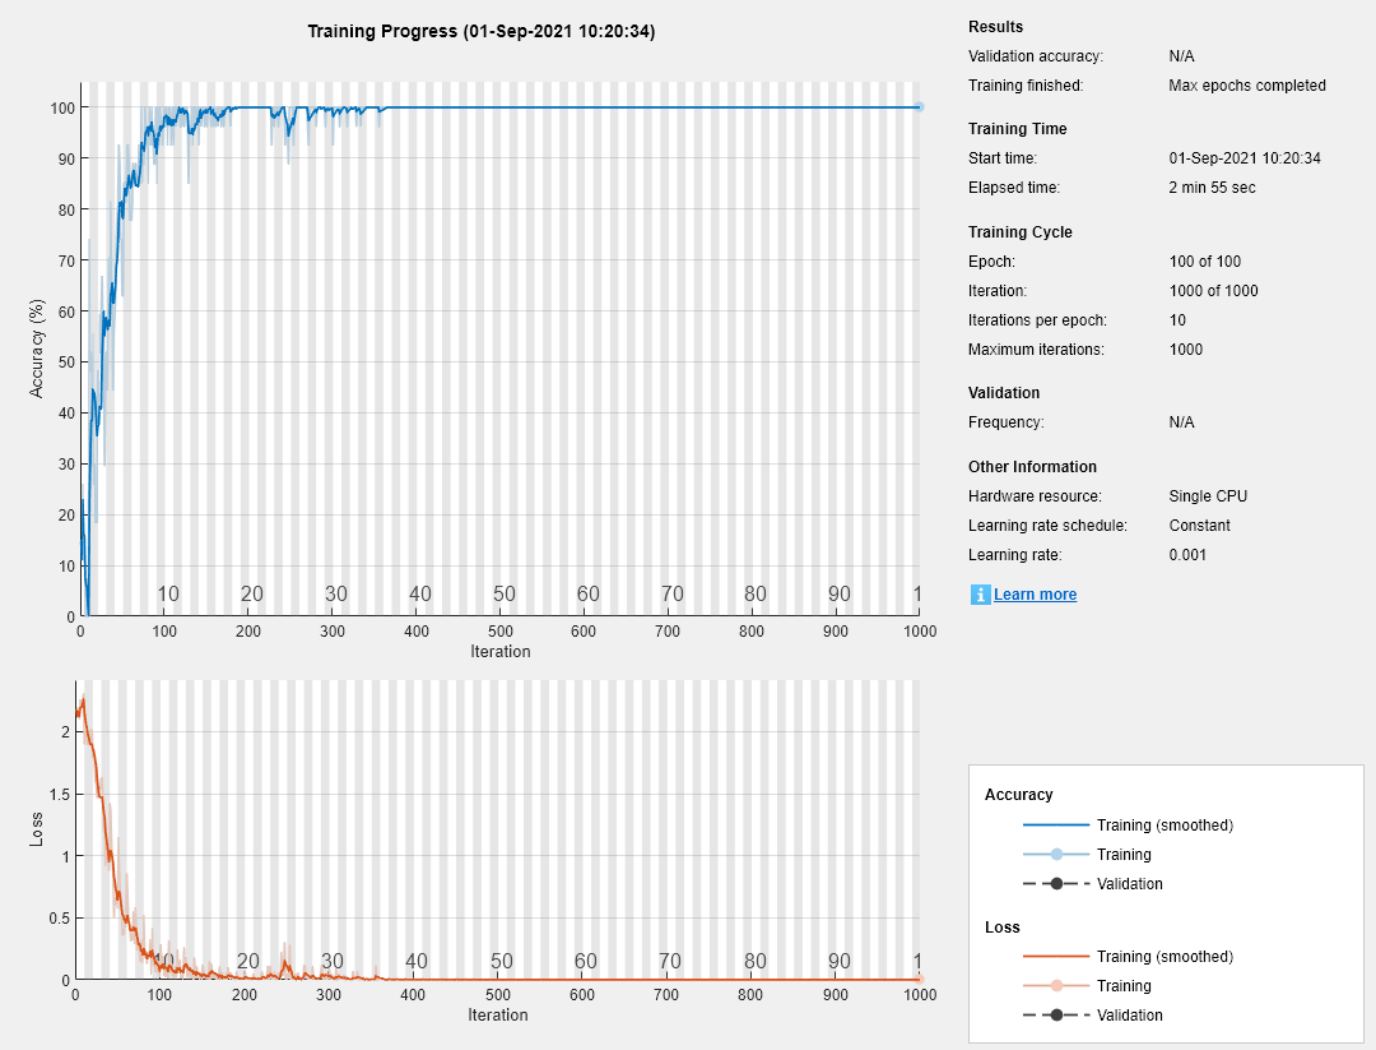
```
maxEpochs = 100;
miniBatchSize = 27;

options = trainingOptions('adam', ...
    'ExecutionEnvironment','cpu', ...
    'GradientThreshold',1, ...
    'MaxEpochs',maxEpochs, ...
    'MiniBatchSize',miniBatchSize, ...
    'SequenceLength','longest', ...
    'Shuffle','never', ...
    'Verbose',0, ...
    'Plots','training-progress');
```

Train LSTM Network

Train the LSTM network with the specified training options by using `trainNetwork`.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```



Test LSTM Network

Load the test set and classify the sequences into speakers.

Load the Japanese Vowels test data. `XTest` is a cell array containing 370 sequences of dimension 12 of varying length. `YTest` is a categorical vector of labels "1","2",..."9", which correspond to the nine speakers.

```
[XTest,YTest] = japaneseVowelsTestData;
XTest(1:3)
```

```
ans=3×1 cell array
    {12x19 double}
    {12x17 double}
    {12x19 double}
```

The LSTM network `net` was trained using mini-batches of sequences of similar length. Ensure that the test data is organized in the same way. Sort the test data by sequence length.

```
numObservationsTest = numel(XTest);
for i=1:numObservationsTest
    sequence = XTest{i};
    sequenceLengthsTest(i) = size(sequence,2);
end
[sequenceLengthsTest,idx] = sort(sequenceLengthsTest);
XTest = XTest(idx);
YTest = YTest(idx);
```

Classify the test data. To reduce the amount of padding introduced by the classification process, set the mini-batch size to 27. To apply the same padding as the training data, specify the sequence length to be `'longest'`.

```
miniBatchSize = 27;
YPred = classify(net,XTest, ...
    'MiniBatchSize',miniBatchSize, ...
    'SequenceLength','longest');
```

Calculate the classification accuracy of the predictions.

```
acc = sum(YPred == YTest)./numel(YTest)
```

```
acc = 0.9730
```

Sequence Classification Using 1-D Convolutions

This example shows how to classify sequence data using a 1-D convolutional neural network.

To train a deep neural network to classify sequence data, you can use a 1-D convolutional neural network. A 1-D convolutional layer learns features by applying sliding convolutional filters to 1-D input. Using 1-D convolutional layers can be faster than using recurrent layers because convolutional layers can process the input with a single operation. By contrast, recurrent layers must iterate over the time steps of the input. However, depending on the network architecture and filter sizes, 1-D convolutional layers might not perform as well as recurrent layers, which can learn long-term dependencies between time steps.

This example uses the Japanese Vowels data set described in [1] and [2]. This example trains a 1-D convolutional neural network to recognize the speaker given time series data representing two Japanese vowels spoken in succession. The training data contains time series data for nine speakers. Each sequence has 12 features and varies in length. The data set contains 270 training observations and 370 test observations.

Load Sequence Data

Load the Japanese Vowels training data. The predictor data is a cell array containing sequences of varying length with 12 features. The target data is a categorical vector of labels "1","2",...,"9", which correspond to the nine speakers. The predictor sequences are matrices with 12 rows (one row for each feature) and a varying number of columns (one column for each time step).

```
[XTrain,TTrain] = japaneseVowelsTrainData;
[XValidation,TValidation] = japaneseVowelsTestData;
```

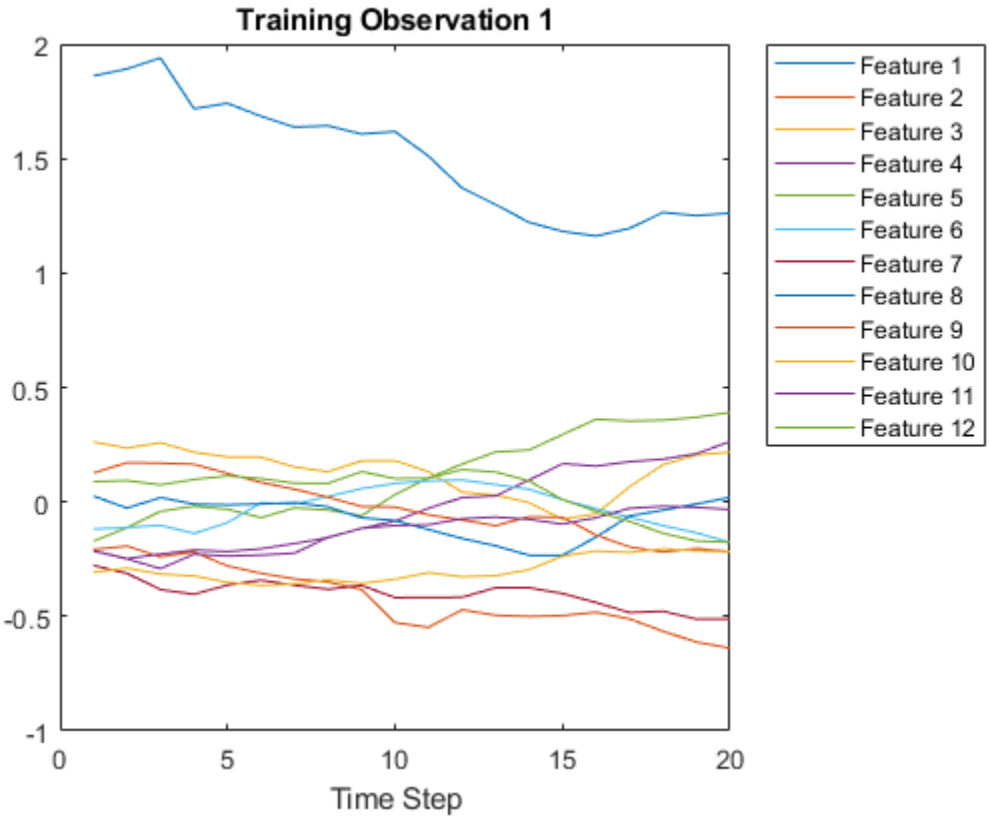
View the first few training sequences.

```
XTrain(1:5)
```

```
ans=5×1 cell array
    {12x20 double}
    {12x26 double}
    {12x22 double}
    {12x20 double}
    {12x21 double}
```

Visualize the first time series in a plot. Each line corresponds to a feature.

```
figure
plot(XTrain{1}')
xlabel("Time Step")
title("Training Observation 1")
numFeatures = size(XTrain{1},1);
legend("Feature " + string(1:numFeatures),Location="northeastoutside")
```



View the number of classes in the training data.

```
classes = categories(TTrain);
numClasses = numel(classes)
```

```
numClasses = 9
```

Define 1-D Convolutional Network Architecture

Define the 1-D convolutional neural network architecture.

- Specify the input size as the number of features of the input data.
- Specify two blocks of 1-D convolution, ReLU, and layer normalization layers, where the convolutional layer has a filter size of 3. Specify 32 and 64 filters for the first and second convolutional layers, respectively. For both convolutional layers, left-pad the inputs such that the outputs have the same length (causal padding).
- To reduce the output of the convolutional layers to a single vector, use a 1-D global average pooling layer.
- To map the output to a vector of probabilities, specify a fully connected layer with an output size matching the number of classes, followed by a softmax layer and a classification layer.

```
filterSize = 3;
numFilters = 32;

layers = [ ...
    sequenceInputLayer(numFeatures)
```

```
    convolution1dLayer(filterSize,numFilters,Padding="causal")
    reluLayer
    layerNormalizationLayer
    convolution1dLayer(filterSize,2*numFilters,Padding="causal")
    reluLayer
    layerNormalizationLayer
    globalAveragePooling1dLayer
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify Training Options

Specify the training options:

- Train using the Adam optimizer.
- Train with a mini-batch size of 27 for 15 epochs.
- Left-pad the sequences.
- Validate the network using the validation data.
- Monitor the training progress in a plot and suppress the verbose output.

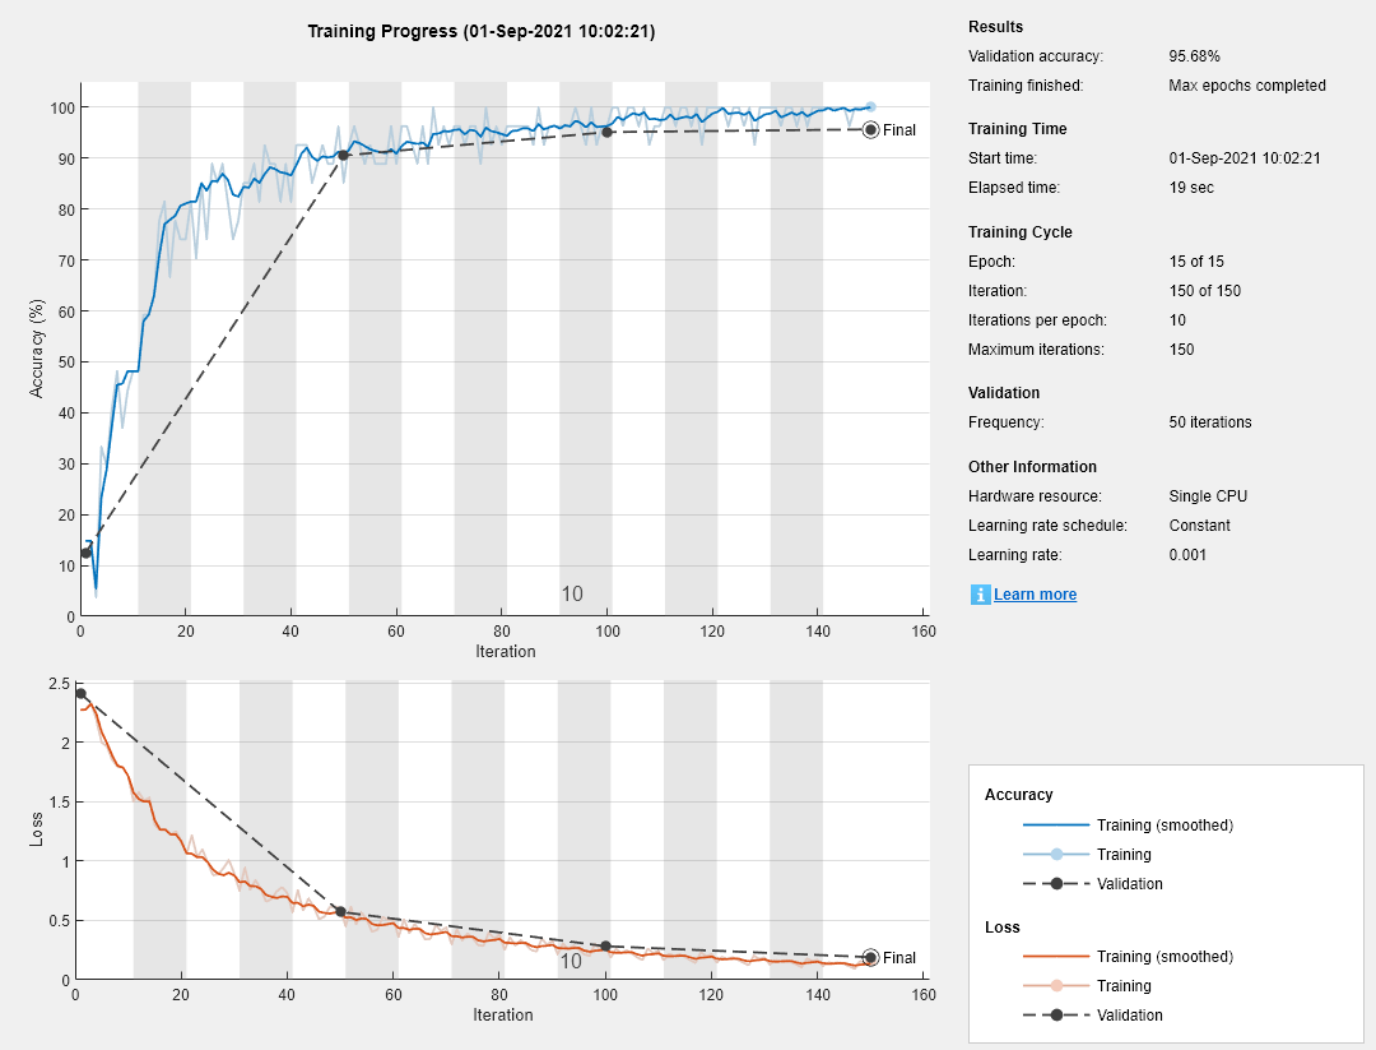
```
miniBatchSize = 27;

options = trainingOptions("adam", ...
    MiniBatchSize=miniBatchSize, ...
    MaxEpochs=15, ...
    SequencePaddingDirection="left", ...
    ValidationData={XValidation,TValidation}, ...
    Plots="training-progress", ...
    Verbose=0);
```

Train Network

Train the network with the specified training options using the `trainNetwork` function.

```
net = trainNetwork(XTrain,TTrain,layers,options);
```



Test Network

Classify the validation data using the same mini-batch size and sequence padding options used for training.

```
YPred = classify(net,XValidation, ...
    MiniBatchSize=miniBatchSize, ...
    SequencePaddingDirection="left");
```

Calculate the classification accuracy of the predictions.

```
acc = mean(YPred == TValidation)
```

```
acc = 0.9568
```

Visualize the predictions in a confusion matrix.

```
confusionchart(TValidation,YPred)
```

Time Series Forecasting Using Deep Learning

This example shows how to forecast time series data using a long short-term memory (LSTM) network.

To forecast the values of future time steps of a sequence, you can train a sequence-to-sequence regression LSTM network, where the responses are the training sequences with values shifted by one time step. That is, at each time step of the input sequence, the LSTM network learns to predict the value of the next time step.

To forecast the values of multiple time steps in the future, use the `predictAndUpdateState` function to predict time steps one at a time and update the network state at each prediction.

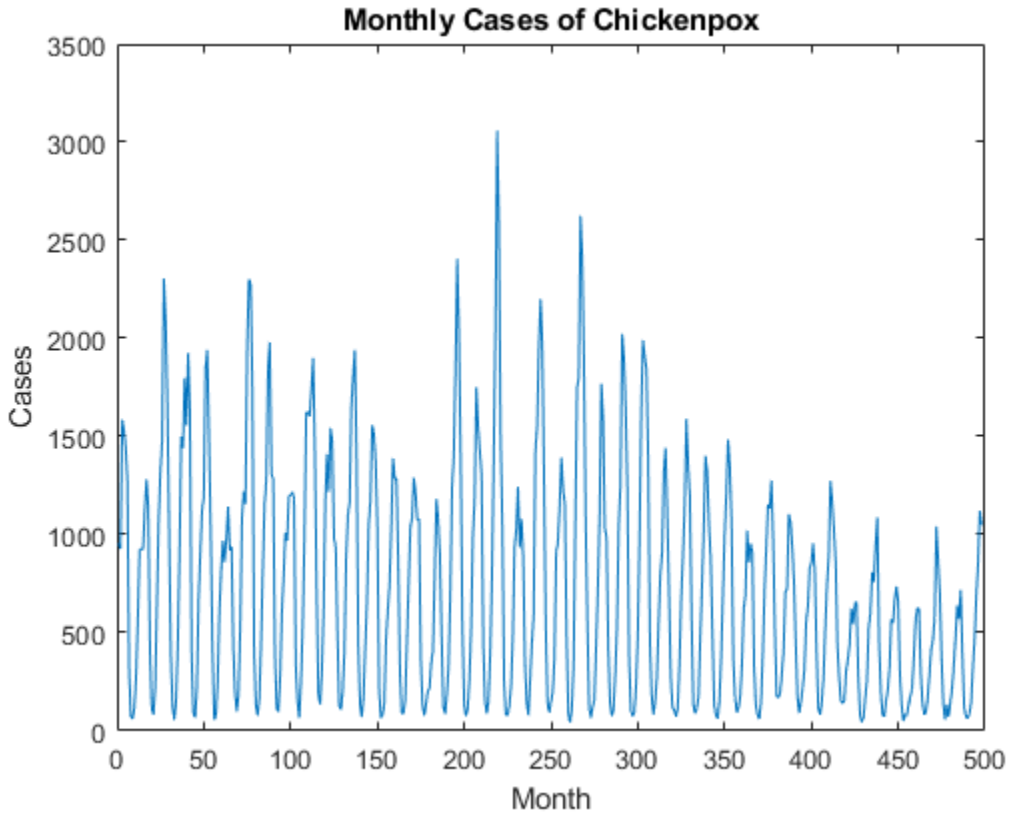
This example uses the data set `chickenpox_dataset`. The example trains an LSTM network to forecast the number of chickenpox cases given the number of cases in previous months.

Load Sequence Data

Load the example data. `chickenpox_dataset` contains a single time series, with time steps corresponding to months and values corresponding to the number of cases. The output is a cell array, where each element is a single time step. Reshape the data to be a row vector.

```
data = chickenpox_dataset;
data = [data{:}];

figure
plot(data)
xlabel("Month")
ylabel("Cases")
title("Monthly Cases of Chickenpox")
```



Partition the training and test data. Train on the first 90% of the sequence and test on the last 10%.

```
numTimeStepsTrain = floor(0.9*numel(data));

dataTrain = data(1:numTimeStepsTrain+1);
dataTest = data(numTimeStepsTrain+1:end);
```

Standardize Data

For a better fit and to prevent the training from diverging, standardize the training data to have zero mean and unit variance. At prediction time, you must standardize the test data using the same parameters as the training data.

```
mu = mean(dataTrain);
sig = std(dataTrain);

dataTrainStandardized = (dataTrain - mu) / sig;
```

Prepare Predictors and Responses

To forecast the values of future time steps of a sequence, specify the responses to be the training sequences with values shifted by one time step. That is, at each time step of the input sequence, the LSTM network learns to predict the value of the next time step. The predictors are the training sequences without the final time step.

```
XTrain = dataTrainStandardized(1:end-1);
YTrain = dataTrainStandardized(2:end);
```

Define LSTM Network Architecture

Create an LSTM regression network. Specify the LSTM layer to have 200 hidden units.

```
numFeatures = 1;
numResponses = 1;
numHiddenUnits = 200;

layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits)
    fullyConnectedLayer(numResponses)
    regressionLayer];
```

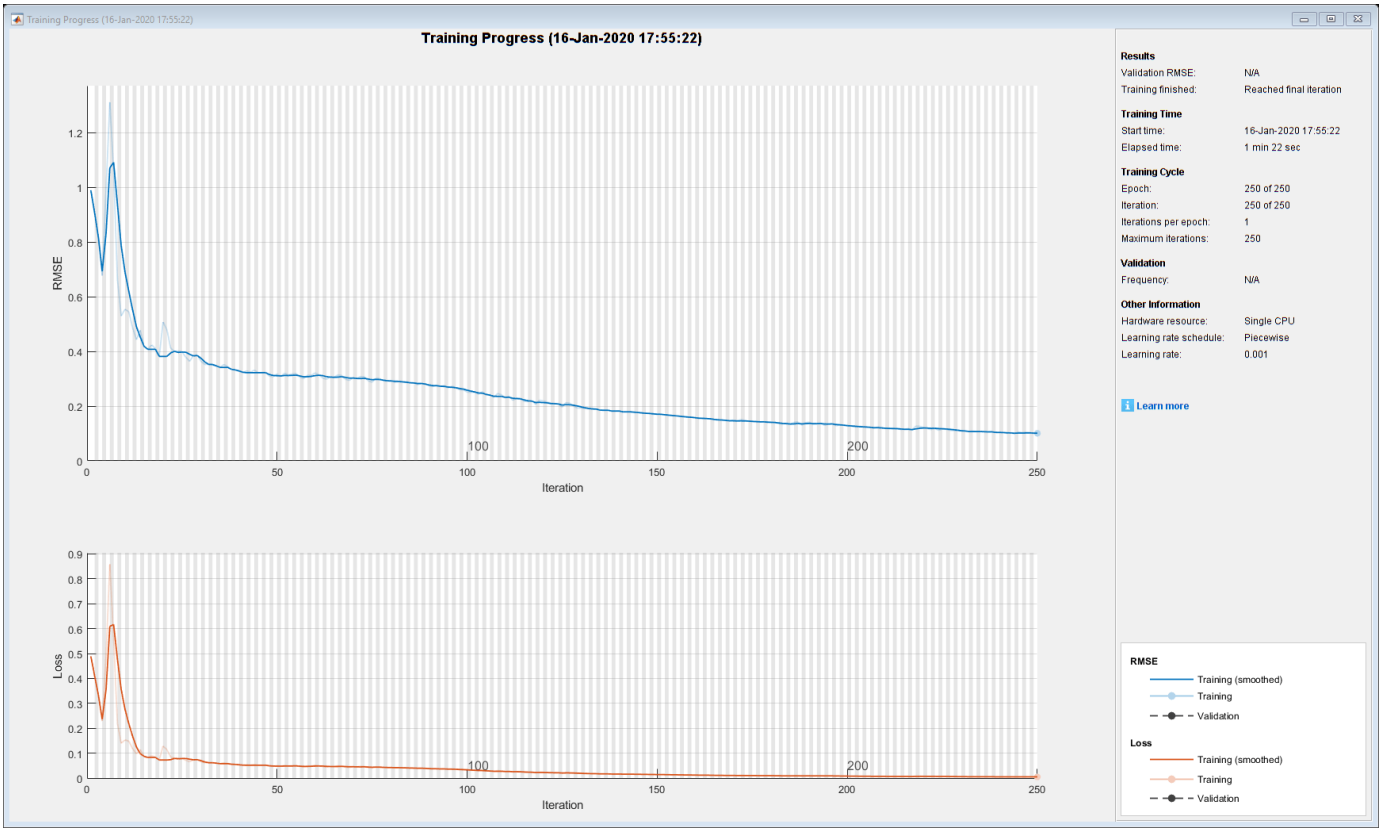
Specify the training options. Set the solver to `'adam'` and train for 250 epochs. To prevent the gradients from exploding, set the gradient threshold to 1. Specify the initial learn rate 0.005, and drop the learn rate after 125 epochs by multiplying by a factor of 0.2.

```
options = trainingOptions('adam', ...
    'MaxEpochs',250, ...
    'GradientThreshold',1, ...
    'InitialLearnRate',0.005, ...
    'LearnRateSchedule','piecewise', ...
    'LearnRateDropPeriod',125, ...
    'LearnRateDropFactor',0.2, ...
    'Verbose',0, ...
    'Plots','training-progress');
```

Train LSTM Network

Train the LSTM network with the specified training options by using `trainNetwork`.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```



Forecast Future Time Steps

To forecast the values of multiple time steps in the future, use the `predictAndUpdateState` function to predict time steps one at a time and update the network state at each prediction. For each prediction, use the previous prediction as input to the function.

Standardize the test data using the same parameters as the training data.

```
dataTestStandardized = (dataTest - mu) / sig;
XTest = dataTestStandardized(1:end-1);
```

To initialize the network state, first predict on the training data `XTrain`. Next, make the first prediction using the last time step of the training response `YTrain(end)`. Loop over the remaining predictions and input the previous prediction to `predictAndUpdateState`.

For large collections of data, long sequences, or large networks, predictions on the GPU are usually faster to compute than predictions on the CPU. Otherwise, predictions on the CPU are usually faster to compute. For single time step predictions, use the CPU. To use the CPU for prediction, set the `'ExecutionEnvironment'` option of `predictAndUpdateState` to `'cpu'`.

```
net = predictAndUpdateState(net,XTrain);
[net,YPred] = predictAndUpdateState(net,YTrain(end));

numTimeStepsTest = numel(XTest);
for i = 2:numTimeStepsTest
    [net,YPred(:,i)] = predictAndUpdateState(net,YPred(:,i-1),'ExecutionEnvironment','cpu');
end
```

Unstandardize the predictions using the parameters calculated earlier.

```
YPred = sig*YPred + mu;
```

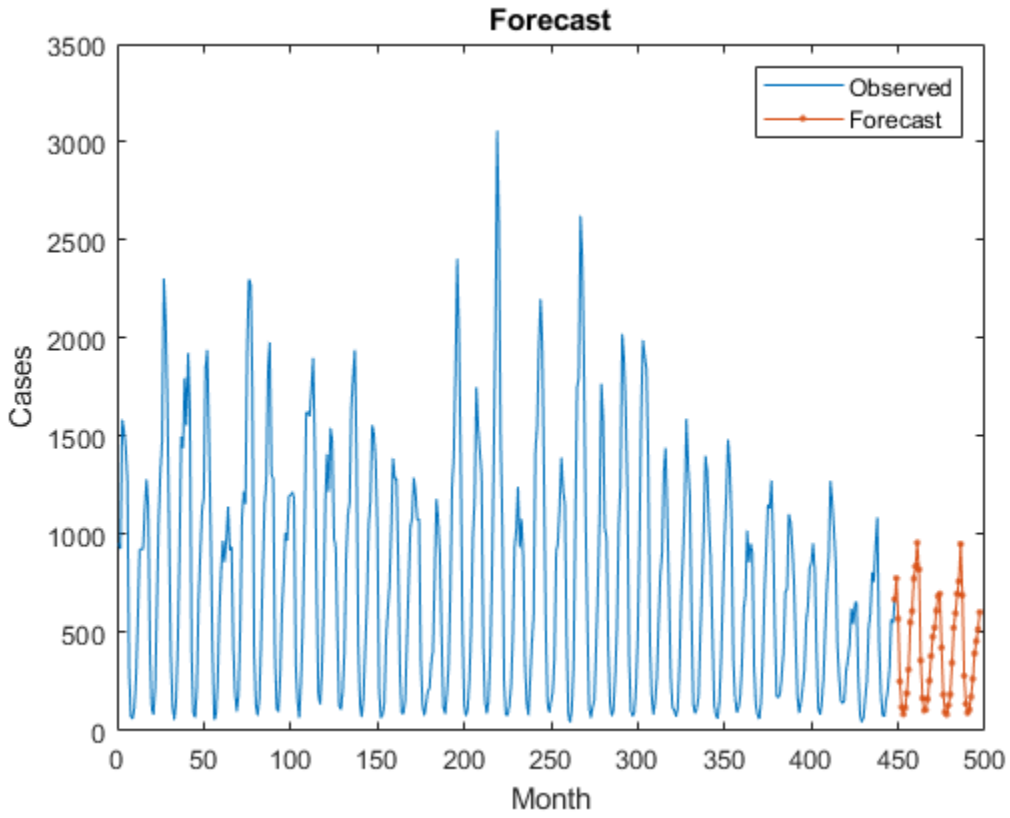
The training progress plot reports the root-mean-square error (RMSE) calculated from the standardized data. Calculate the RMSE from the unstandardized predictions.

```
YTest = dataTest(2:end);
rmse = sqrt(mean((YPred-YTest).^2))
```

```
rmse = single
    248.5531
```

Plot the training time series with the forecasted values.

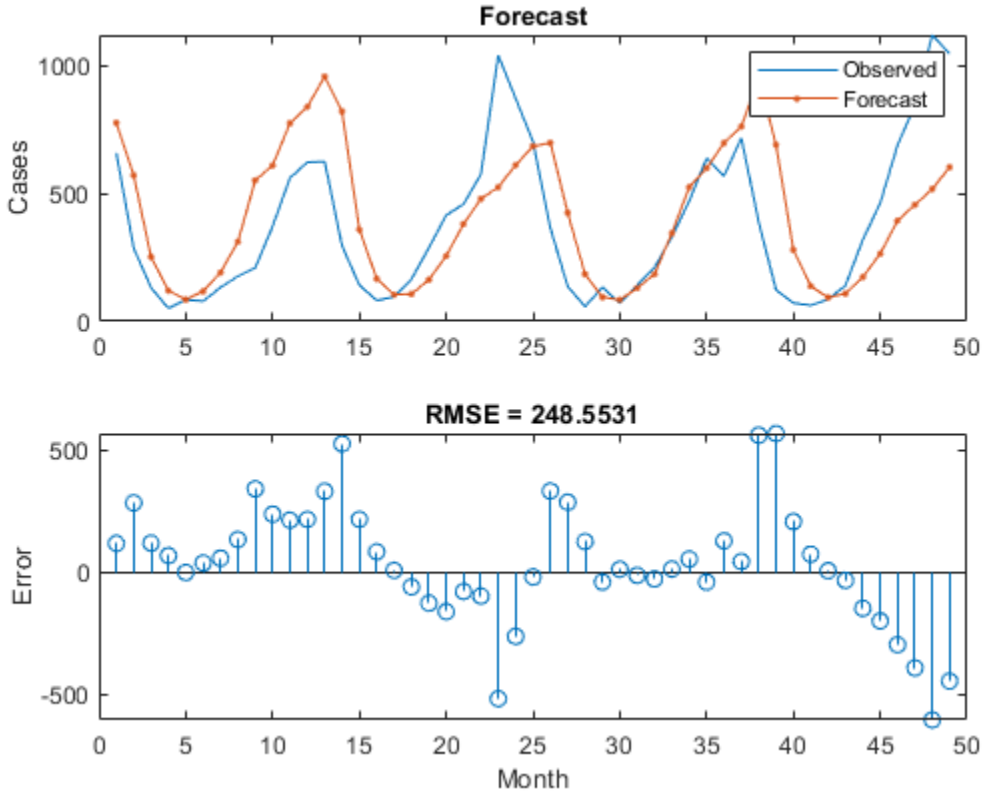
```
figure
plot(dataTrain(1:end-1))
hold on
idx = numTimeStepsTrain:(numTimeStepsTrain+numTimeStepsTest);
plot(idx,[data(numTimeStepsTrain) YPred],'.-')
hold off
xlabel("Month")
ylabel("Cases")
title("Forecast")
legend(["Observed" "Forecast"])
```



Compare the forecasted values with the test data.

```
figure
subplot(2,1,1)
plot(YTest)
hold on
plot(YPred,'.-')
hold off
legend(["Observed" "Forecast"])
ylabel("Cases")
title("Forecast")

subplot(2,1,2)
stem(YPred - YTest)
xlabel("Month")
ylabel("Error")
title("RMSE = " + rmse)
```



Update Network State with Observed Values

If you have access to the actual values of time steps between predictions, then you can update the network state with the observed values instead of the predicted values.

First, initialize the network state. To make predictions on a new sequence, reset the network state using `resetState`. Resetting the network state prevents previous predictions from affecting the predictions on the new data. Reset the network state, and then initialize the network state by predicting on the training data.

```
net = resetState(net);
net = predictAndUpdateState(net,XTrain);
```

Predict on each time step. For each prediction, predict the next time step using the observed value of the previous time step. Set the `'ExecutionEnvironment'` option of `predictAndUpdateState` to `'cpu'`.

```
YPred = [];
numTimeStepsTest = numel(XTest);
for i = 1:numTimeStepsTest
    [net,YPred(:,i)] = predictAndUpdateState(net,XTest(:,i),'ExecutionEnvironment','cpu');
end
```

Unstandardize the predictions using the parameters calculated earlier.

```
YPred = sig*YPred + mu;
```

Calculate the root-mean-square error (RMSE).

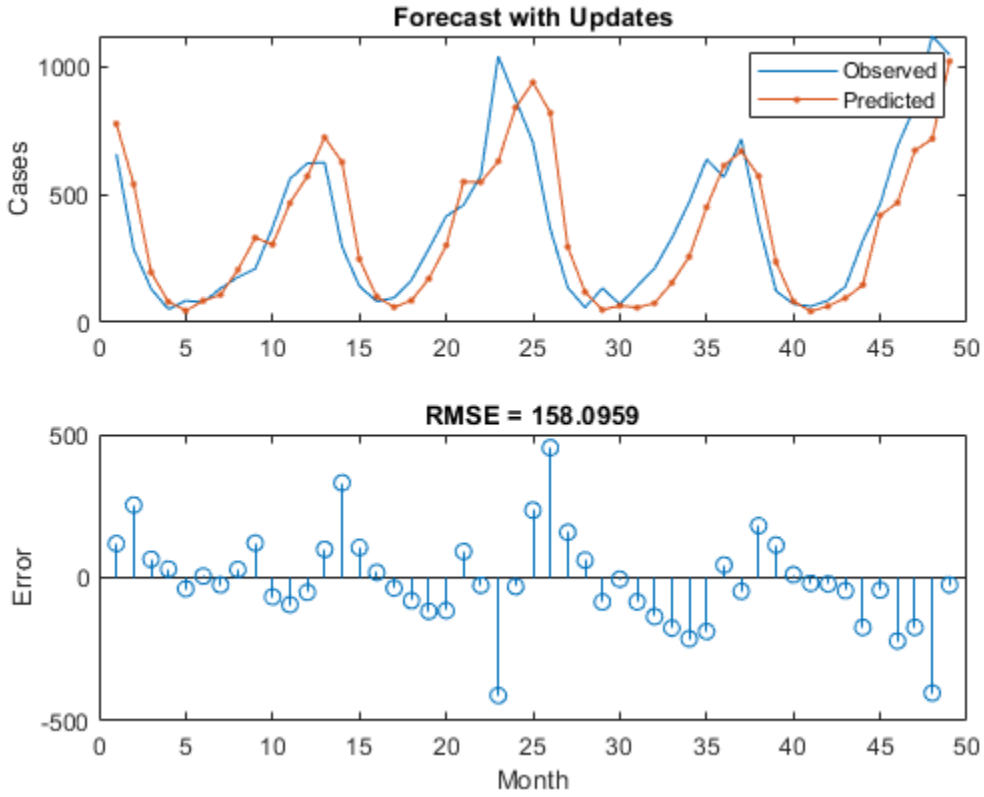
```
rmse = sqrt(mean((YPred-YTest).^2))
```

```
rmse = 158.0959
```

Compare the forecasted values with the test data.

```
figure
subplot(2,1,1)
plot(YTest)
hold on
plot(YPred,'.-')
hold off
legend(["Observed" "Predicted"])
ylabel("Cases")
title("Forecast with Updates")

subplot(2,1,2)
stem(YPred - YTest)
xlabel("Month")
ylabel("Error")
title("RMSE = " + rmse)
```



Here, the predictions are more accurate when updating the network state with the observed values instead of the predicted values.

Speech Command Recognition Using Deep Learning

This example shows how to train a deep learning model that detects the presence of speech commands in audio. The example uses the Speech Commands Dataset [1] to train a convolutional neural network to recognize a given set of commands.

To train a network from scratch, you must first download the data set. If you do not want to download the data set or train the network, then you can load a pretrained network provided with this example and execute the next two sections of the example: *Recognize Commands with a Pre-Trained Network* and *Detect Commands Using Streaming Audio from Microphone*.

Recognize Commands with a Pre-Trained Network

Before going into the training process in detail, you will use a pre-trained speech recognition network to identify speech commands.

Load the pre-trained network.

```
load('commandNet.mat')
```

The network is trained to recognize the following speech commands:

- "yes"
- "no"
- "up"
- "down"
- "left"
- "right"
- "on"
- "off"
- "stop"
- "go"

Load a short speech signal where a person says "stop".

```
[x,fs] = audioread('stop_command.flac');
```

Listen to the command.

```
sound(x,fs)
```

The pre-trained network takes auditory-based spectrograms as inputs. You will first convert the speech waveform to an auditory-based spectrogram.

Use the function `extractAuditoryFeature` to compute the auditory spectrogram. You will go through the details of feature extraction later in the example.

```
auditorySpect = helperExtractAuditoryFeatures(x,fs);
```

Classify the command based on its auditory spectrogram.

```
command = classify(trainedNet,auditorySpect)
```

```
command =

  categorical

     stop
```

The network is trained to classify words not belonging to this set as "unknown".

You will now classify a word ("play") that was not included in the list of command to identify.

Load the speech signal and listen to it.

```
x = audioread('play_command.flac');
sound(x,fs)
```

Compute the auditory spectrogram.

```
auditorySpect = helperExtractAuditoryFeatures(x,fs);
```

Classify the signal.

```
command = classify(trainedNet,auditorySpect)
```

```
command =

  categorical

     unknown
```

The network is trained to classify background noise as "background".

Create a one-second signal consisting of random noise.

```
x = pinknoise(16e3);
```

Compute the auditory spectrogram.

```
auditorySpect = helperExtractAuditoryFeatures(x,fs);
```

Classify the background noise.

```
command = classify(trainedNet,auditorySpect)
```

```
command =

  categorical

     background
```

Detect Commands Using Streaming Audio from Microphone

Test your pre-trained command detection network on streaming audio from your microphone. Try saying one of the commands, for example, *yes*, *no*, or *stop*. Then, try saying one of the unknown words such as *Marvin*, *Sheila*, *bed*, *house*, *cat*, *bird*, or any number from zero to nine.

Specify the classification rate in Hz and create an audio device reader that can read audio from your microphone.

```
classificationRate = 20;
adr = audioDeviceReader('SampleRate',fs,'SamplesPerFrame',floor(fs/classificationRate));
```

Initialize a buffer for the audio. Extract the classification labels of the network. Initialize buffers of half a second for the labels and classification probabilities of the streaming audio. Use these buffers to compare the classification results over a longer period of time and by that build 'agreement' over when a command is detected. Specify thresholds for the decision logic.

```
audioBuffer = dsp.AsyncBuffer(fs);

labels = trainedNet.Layers(end).Classes;
YBuffer(1:classificationRate/2) = categorical("background");

probBuffer = zeros([numel(labels),classificationRate/2]);

countThreshold = ceil(classificationRate*0.2);
probThreshold = 0.7;
```

Create a figure and detect commands as long as the created figure exists. To run the loop indefinitely, set `timeLimit` to `Inf`. To stop the live detection, simply close the figure.

```
h = figure('Units','normalized','Position',[0.2 0.1 0.6 0.8]);

timeLimit = 20;

tic
while ishandle(h) && toc < timeLimit

    % Extract audio samples from the audio device and add the samples to
    % the buffer.
    x = adr();
    write(audioBuffer,x);
    y = read(audioBuffer,fs,fs-adr.SamplesPerFrame);

    spec = helperExtractAuditoryFeatures(y,fs);

    % Classify the current spectrogram, save the label to the label buffer,
    % and save the predicted probabilities to the probability buffer.
    [YPredicted,probs] = classify(trainedNet,spec,'ExecutionEnvironment','cpu');
    YBuffer = [YBuffer(2:end),YPredicted];
    probBuffer = [probBuffer(:,2:end),probs(:)];

    % Plot the current waveform and spectrogram.
    subplot(2,1,1)
    plot(y)
    axis tight
    ylim([-1,1])
```

```
        subplot(2,1,2)
        pcolor(spec')
        caxis([-4 2.6445])
        shading flat

        % Now do the actual command detection by performing a very simple
        % thresholding operation. Declare a detection and display it in the
        % figure title if all of the following hold: 1) The most common label
        % is not background. 2) At least countThreshold of the latest frame
        % labels agree. 3) The maximum probability of the predicted label is at
        % least probThreshold. Otherwise, do not declare a detection.
        [YMode,count] = mode(YBuffer);

        maxProb = max(probBuffer(labels == YMode,:));
        subplot(2,1,1)
        if YMode == "background" || count < countThreshold || maxProb < probThreshold
            title(" ")
        else
            title(string(YMode),'FontSize',20)
        end

        drawnow
    end
```

Load Speech Commands Data Set

This example uses the Google Speech Commands Dataset [1]. Download the dataset and untar the downloaded file. Set PathToDatabase to the location of the data.

```
url = 'https://ssd.mathworks.com/supportfiles/audio/google_speech.zip';
downloadFolder = tempdir;
dataFolder = fullfile(downloadFolder,'google_speech');

if ~exist(dataFolder,'dir')
    disp('Downloading data set (1.4 GB) ...')
    unzip(url,downloadFolder)
end
```

Create Training Datastore

Create an `audioDatastore` (Audio Toolbox) that points to the training data set.

```
ads = audioDatastore(fullfile(dataFolder, 'train'), ...
    'IncludeSubfolders',true, ...
    'FileExtensions','.wav', ...
    'LabelSource','foldernames')
```

```
ads =

  audioDatastore with properties:

                      Files: {
                             ' ...\AppData\Local\Temp\google_speech\train\bed\00176480_nohash_0
                             ' ...\AppData\Local\Temp\google_speech\train\bed\004ae714_nohash_0
                             ' ...\AppData\Local\Temp\google_speech\train\bed\004ae714_nohash_1
                              ... and 51085 more
                             }
                    Folders: {
                             'C:\Users\jibrahim\AppData\Local\Temp\google_speech\train'
                             }
                     Labels: [bed; bed; bed ... and 51085 more categorical]
    AlternateFileSystemRoots: {}
              OutputDataType: 'double'
      SupportedOutputFormats: ["wav"    "flac"    "ogg"    "mp4"    "m4a"]
         DefaultOutputFormat: "wav"
```

Choose Words to Recognize

Specify the words that you want your model to recognize as commands. Label all words that are not commands as `unknown`. Labeling words that are not commands as `unknown` creates a group of words that approximates the distribution of all words other than the commands. The network uses this group to learn the difference between commands and all other words.

To reduce the class imbalance between the known and unknown words and speed up processing, only include a fraction of the unknown words in the training set.

Use `subset` (Audio Toolbox) to create a datastore that contains only the commands and the subset of unknown words. Count the number of examples belonging to each category.

```
commands = categorical(["yes","no","up","down","left","right","on","off","stop","go"]);

isCommand = ismember(ads.Labels,commands);
isUnknown = ~isCommand;

includeFraction = 0.2;
mask = rand(numel(ads.Labels),1) < includeFraction;
isUnknown = isUnknown & mask;
ads.Labels(isUnknown) = categorical("unknown");

adsTrain = subset(ads,isCommand|isUnknown);
countEachLabel(adsTrain)
```

```
ans =

  11×2 table

     Label     Count
    _______    _____

    down       1842
    go         1861
    left       1839
```

```
    no         1853
    off        1839
    on         1864
    right      1852
    stop       1885
    unknown    6483
    up         1843
    yes        1860
```

Create Validation Datastore

Create an `audioDatastore` (Audio Toolbox) that points to the validation data set. Follow the same steps used to create the training datastore.

```
ads = audioDatastore(fullfile(dataFolder, 'validation'), ...
    'IncludeSubfolders',true, ...
    'FileExtensions','.wav', ...
    'LabelSource','foldernames')

isCommand = ismember(ads.Labels,commands);
isUnknown = ~isCommand;

includeFraction = 0.2;
mask = rand(numel(ads.Labels),1) < includeFraction;
isUnknown = isUnknown & mask;
ads.Labels(isUnknown) = categorical("unknown");

adsValidation = subset(ads,isCommand|isUnknown);
countEachLabel(adsValidation)
```

```
ads =

  audioDatastore with properties:

                      Files: {
                             ' ...\AppData\Local\Temp\google_speech\validation\bed\026290a7_noha
                             ' ...\AppData\Local\Temp\google_speech\validation\bed\060cd039_noha
                             ' ...\AppData\Local\Temp\google_speech\validation\bed\060cd039_noha
                              ... and 6795 more
                             }
                    Folders: {
                             'C:\Users\jibrahim\AppData\Local\Temp\google_speech\validation'
                             }
                     Labels: [bed; bed; bed ... and 6795 more categorical]
    AlternateFileSystemRoots: {}
              OutputDataType: 'double'
      SupportedOutputFormats: ["wav"    "flac"    "ogg"    "mp4"    "m4a"]
         DefaultOutputFormat: "wav"

ans =

  11×2 table

     Label     Count
    _______    _____
```

```
    down         264
    go           260
    left         247
    no           270
    off          256
    on           257
    right        256
    stop         246
    unknown      850
    up           260
    yes          261
```

To train the network with the entire dataset and achieve the highest possible accuracy, set `reduceDataset` to `false`. To run this example quickly, set `reduceDataset` to `true`.

```
reduceDataset = false;
if reduceDataset
    numUniqueLabels = numel(unique(adsTrain.Labels));
    % Reduce the dataset by a factor of 20
    adsTrain = splitEachLabel(adsTrain,round(numel(adsTrain.Files) / numUniqueLabels / 20));
    adsValidation = splitEachLabel(adsValidation,round(numel(adsValidation.Files) / numUniqueLabe
end
```

Compute Auditory Spectrograms

To prepare the data for efficient training of a convolutional neural network, convert the speech waveforms to auditory-based spectrograms.

Define the parameters of the feature extraction. `segmentDuration` is the duration of each speech clip (in seconds). `frameDuration` is the duration of each frame for spectrum calculation. `hopDuration` is the time step between each spectrum. `numBands` is the number of filters in the auditory spectrogram.

Create an `audioFeatureExtractor` (Audio Toolbox) object to perform the feature extraction.

```
fs = 16e3; % Known sample rate of the data set.

segmentDuration = 1;
frameDuration = 0.025;
hopDuration = 0.010;

segmentSamples = round(segmentDuration*fs);
frameSamples = round(frameDuration*fs);
hopSamples = round(hopDuration*fs);
overlapSamples = frameSamples - hopSamples;

FFTLength = 512;
numBands = 50;

afe = audioFeatureExtractor( ...
    'SampleRate',fs, ...
    'FFTLength',FFTLength, ...
    'Window',hann(frameSamples,'periodic'), ...
    'OverlapLength',overlapSamples, ...
    'barkSpectrum',true);
setExtractorParams(afe,'barkSpectrum','NumBands',numBands,'WindowNormalization',false);
```

Read a file from the dataset. Training a convolutional neural network requires input to be a consistent size. Some files in the data set are less than 1 second long. Apply zero-padding to the front and back of the audio signal so that it is of length `segmentSamples`.

```
x = read(adsTrain);

numSamples = size(x,1);

numToPadFront = floor( (segmentSamples - numSamples)/2 );
numToPadBack = ceil( (segmentSamples - numSamples)/2 );

xPadded = [zeros(numToPadFront,1,'like',x);x;zeros(numToPadBack,1,'like',x)];
```

To extract audio features, call `extract`. The output is a Bark spectrum with time across rows.

```
features = extract(afe,xPadded);
[numHops,numFeatures] = size(features)
```

```
numHops =

    98

numFeatures =

    50
```

In this example, you post-process the auditory spectrogram by applying a logarithm. Taking a log of small numbers can lead to roundoff error.

To speed up processing, you can distribute the feature extraction across multiple workers using `parfor`.

First, determine the number of partitions for the dataset. If you do not have Parallel Computing Toolbox™, use a single partition.

```
if ~isempty(ver('parallel')) && ~reduceDataset
    pool = gcp;
    numPar = numpartitions(adsTrain,pool);
else
    numPar = 1;
end
```

For each partition, read from the datastore, zero-pad the signal, and then extract the features.

```
parfor ii = 1:numPar
    subds = partition(adsTrain,numPar,ii);
    XTrain = zeros(numHops,numBands,1,numel(subds.Files));
    for idx = 1:numel(subds.Files)
        x = read(subds);
        xPadded = [zeros(floor((segmentSamples-size(x,1))/2),1);x;zeros(ceil((segmentSamples-size
        XTrain(:,:,:,idx) = extract(afe,xPadded);
    end
    XTrainC{ii} = XTrain;
end
```

Convert the output to a 4-dimensional array with auditory spectrograms along the fourth dimension.

```
XTrain = cat(4,XTrainC{:});

[numHops,numBands,numChannels,numSpec] = size(XTrain)
```

```
numHops =

    98

numBands =

    50

numChannels =

     1

numSpec =

       25021
```

Scale the features by the window power and then take the log. To obtain data with a smoother distribution, take the logarithm of the spectrograms using a small offset.

```
epsil = 1e-6;
XTrain = log10(XTrain + epsil);
```

Perform the feature extraction steps described above to the validation set.

```
if ~isempty(ver('parallel'))
    pool = gcp;
    numPar = numpartitions(adsValidation,pool);
else
    numPar = 1;
end
parfor ii = 1:numPar
    subds = partition(adsValidation,numPar,ii);
    XValidation = zeros(numHops,numBands,1,numel(subds.Files));
    for idx = 1:numel(subds.Files)
        x = read(subds);
        xPadded = [zeros(floor((segmentSamples-size(x,1))/2),1);x;zeros(ceil((segmentSamples-size
        XValidation(:,:,:,idx) = extract(afe,xPadded);
    end
    XValidationC{ii} = XValidation;
end
XValidation = cat(4,XValidationC{:});
XValidation = log10(XValidation + epsil);
```

Isolate the train and validation labels. Remove empty categories.

```
YTrain = removecats(adsTrain.Labels);
YValidation = removecats(adsValidation.Labels);
```

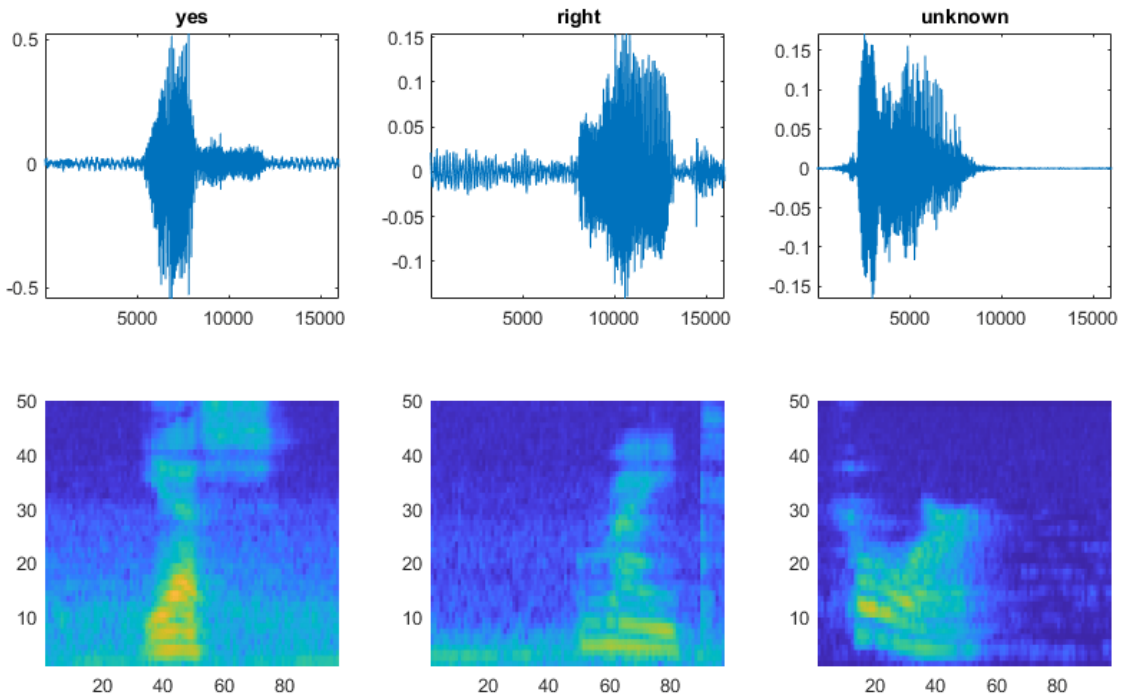
Visualize Data

Plot the waveforms and auditory spectrograms of a few training samples. Play the corresponding audio clips.

```
specMin = min(XTrain,[],'all');
specMax = max(XTrain,[],'all');
idx = randperm(numel(adsTrain.Files),3);
figure('Units','normalized','Position',[0.2 0.2 0.6 0.6]);
for i = 1:3
    [x,fs] = audioread(adsTrain.Files{idx(i)});
    subplot(2,3,i)
    plot(x)
    axis tight
    title(string(adsTrain.Labels(idx(i))))

    subplot(2,3,i+3)
    spect = (XTrain(:,:,1,idx(i))');
    pcolor(spect)
    caxis([specMin specMax])
    shading flat

    sound(x,fs)
    pause(2)
end
```



Add Background Noise Data

The network must be able not only to recognize different spoken words but also to detect if the input contains silence or background noise.

Use the audio files in the `_background_` folder to create samples of one-second clips of background noise. Create an equal number of background clips from each background noise file. You can also create your own recordings of background noise and add them to the `_background_` folder. Before calculating the spectrograms, the function rescales each audio clip with a factor sampled from a log-uniform distribution in the range given by `volumeRange`.

```
adsBkg = audioDatastore(fullfile(dataFolder, 'background'))
numBkgClips = 4000;
if reduceDataset
    numBkgClips = numBkgClips/20;
end
volumeRange = log10([1e-4,1]);

numBkgFiles = numel(adsBkg.Files);
numClipsPerFile = histcounts(1:numBkgClips,linspace(1,numBkgClips,numBkgFiles+1));
Xbkg = zeros(size(XTrain,1),size(XTrain,2),1,numBkgClips,'single');
bkgAll = readall(adsBkg);
ind = 1;

for count = 1:numBkgFiles
    bkg = bkgAll{count};
    idxStart = randi(numel(bkg)-fs,numClipsPerFile(count),1);
    idxEnd = idxStart+fs-1;
    gain = 10.^((volumeRange(2)-volumeRange(1))*rand(numClipsPerFile(count),1) + volumeRange(1))
    for j = 1:numClipsPerFile(count)

        x = bkg(idxStart(j):idxEnd(j))*gain(j);

        x = max(min(x,1),-1);

        Xbkg(:,:,:,ind) = extract(afe,x);

        if mod(ind,1000)==0
            disp("Processed " + string(ind) + " background clips out of " + string(numBkgClips))
        end
        ind = ind + 1;
    end
end
Xbkg = log10(Xbkg + epsil);
```

```
adsBkg =

  audioDatastore with properties:

                      Files: {
                             ' ...\AppData\Local\Temp\google_speech\background\doing_the_dishes
                             ' ...\AppData\Local\Temp\google_speech\background\dude_miaowing.wav
                             ' ...\AppData\Local\Temp\google_speech\background\exercise_bike.wav
                              ... and 3 more
                             }
                    Folders: {
                             'C:\Users\jibrahim\AppData\Local\Temp\google_speech\background'
                             }
    AlternateFileSystemRoots: {}
              OutputDataType: 'double'
                      Labels: {}
      SupportedOutputFormats: ["wav"    "flac"    "ogg"    "mp4"    "m4a"]
```

```
         DefaultOutputFormat: "wav"

Processed 1000 background clips out of 4000
Processed 2000 background clips out of 4000
Processed 3000 background clips out of 4000
Processed 4000 background clips out of 4000
```

Split the spectrograms of background noise between the training, validation, and test sets. Because the `_background_noise_` folder contains only about five and a half minutes of background noise, the background samples in the different data sets are highly correlated. To increase the variation in the background noise, you can create your own background files and add them to the folder. To increase the robustness of the network to noise, you can also try mixing background noise into the speech files.

```
numTrainBkg = floor(0.85*numBkgClips);
numValidationBkg = floor(0.15*numBkgClips);

XTrain(:,:,:,end+1:end+numTrainBkg) = Xbkg(:,:,:,1:numTrainBkg);
YTrain(end+1:end+numTrainBkg) = "background";

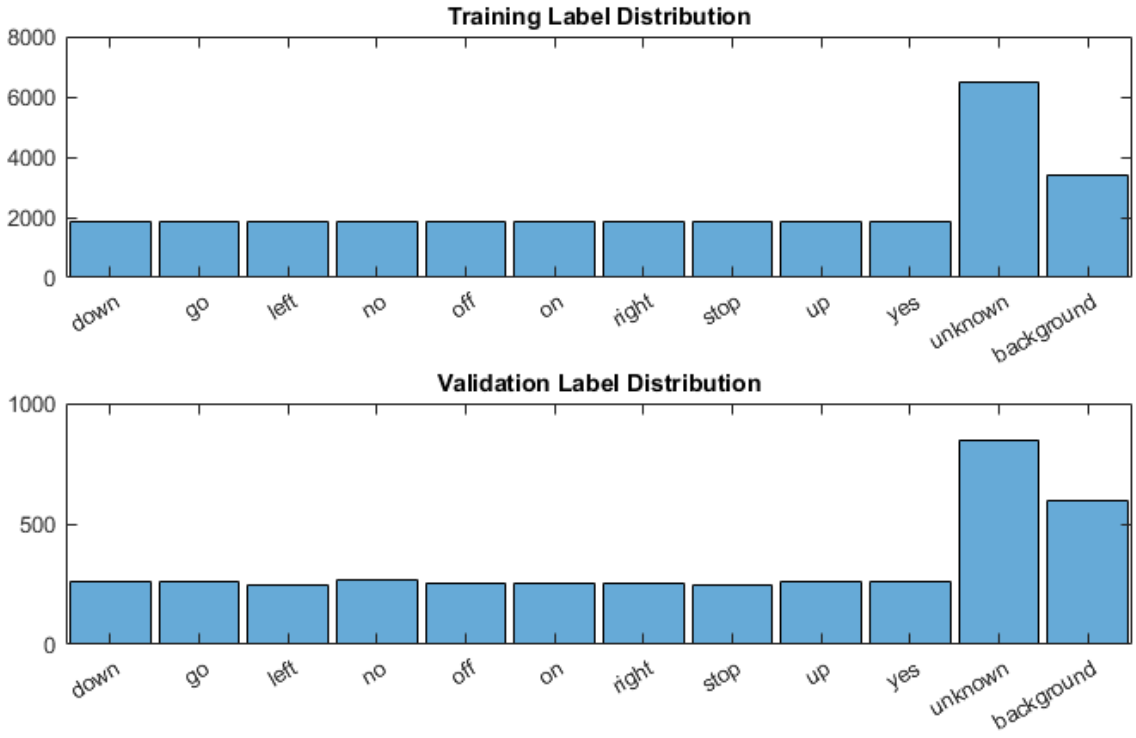
XValidation(:,:,:,end+1:end+numValidationBkg) = Xbkg(:,:,:,numTrainBkg+1:end);
YValidation(end+1:end+numValidationBkg) = "background";
```

Plot the distribution of the different class labels in the training and validation sets.

```
figure('Units','normalized','Position',[0.2 0.2 0.5 0.5])

subplot(2,1,1)
histogram(YTrain)
title("Training Label Distribution")

subplot(2,1,2)
histogram(YValidation)
title("Validation Label Distribution")
```



Define Neural Network Architecture

Create a simple network architecture as an array of layers. Use convolutional and batch normalization layers, and downsample the feature maps "spatially" (that is, in time and frequency) using max pooling layers. Add a final max pooling layer that pools the input feature map globally over time. This enforces (approximate) time-translation invariance in the input spectrograms, allowing the network to perform the same classification independent of the exact position of the speech in time. Global pooling also significantly reduces the number of parameters in the final fully connected layer. To reduce the possibility of the network memorizing specific features of the training data, add a small amount of dropout to the input to the last fully connected layer.

The network is small, as it has only five convolutional layers with few filters. `numF` controls the number of filters in the convolutional layers. To increase the accuracy of the network, try increasing the network depth by adding identical blocks of convolutional, batch normalization, and ReLU layers. You can also try increasing the number of convolutional filters by increasing `numF`.

Use a weighted cross entropy classification loss. `weightedClassificationLayer(classWeights)` creates a custom classification layer that calculates the cross entropy loss with observations weighted by `classWeights`. Specify the class weights in the same order as the classes appear in `categories(YTrain)`. To give each class equal total weight in the loss, use class weights that are inversely proportional to the number of training examples in each class. When using the Adam optimizer to train the network, the training algorithm is independent of the overall normalization of the class weights.

```
classWeights = 1./countcats(YTrain);
classWeights = classWeights'/mean(classWeights);
numClasses = numel(categories(YTrain));
```

```
timePoolSize = ceil(numHops/8);

dropoutProb = 0.2;
numF = 12;
layers = [
    imageInputLayer([numHops numBands])

    convolution2dLayer(3,numF,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(3,'Stride',2,'Padding','same')

    convolution2dLayer(3,2*numF,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(3,'Stride',2,'Padding','same')

    convolution2dLayer(3,4*numF,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(3,'Stride',2,'Padding','same')

    convolution2dLayer(3,4*numF,'Padding','same')
    batchNormalizationLayer
    reluLayer
    convolution2dLayer(3,4*numF,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer([timePoolSize,1])

    dropoutLayer(dropoutProb)
    fullyConnectedLayer(numClasses)
    softmaxLayer
    weightedClassificationLayer(classWeights)];
```

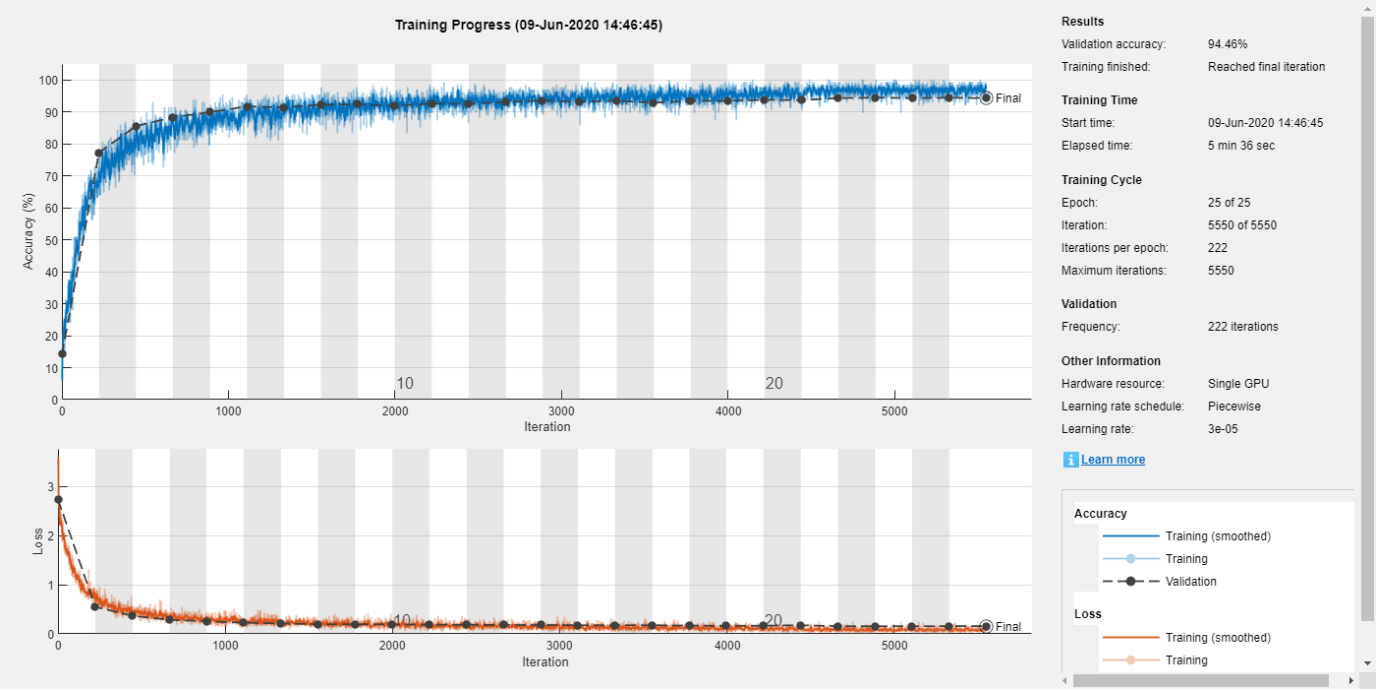
Train Network

Specify the training options. Use the Adam optimizer with a mini-batch size of 128. Train for 25 epochs and reduce the learning rate by a factor of 10 after 20 epochs.

```
miniBatchSize = 128;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
options = trainingOptions('adam', ...
    'InitialLearnRate',3e-4, ...
    'MaxEpochs',25, ...
    'MiniBatchSize',miniBatchSize, ...
    'Shuffle','every-epoch', ...
    'Plots','training-progress', ...
    'Verbose',false, ...
    'ValidationData',{XValidation,YValidation}, ...
    'ValidationFrequency',validationFrequency, ...
    'LearnRateSchedule','piecewise', ...
    'LearnRateDropFactor',0.1, ...
    'LearnRateDropPeriod',20);
```

Train the network. If you do not have a GPU, then training the network can take time.

```
trainedNet = trainNetwork(XTrain,YTrain,layers,options);
```



Evaluate Trained Network

Calculate the final accuracy of the network on the training set (without data augmentation) and validation set. The network is very accurate on this data set. However, the training, validation, and test data all have similar distributions that do not necessarily reflect real-world environments. This limitation particularly applies to the `unknown` category, which contains utterances of only a small number of words.

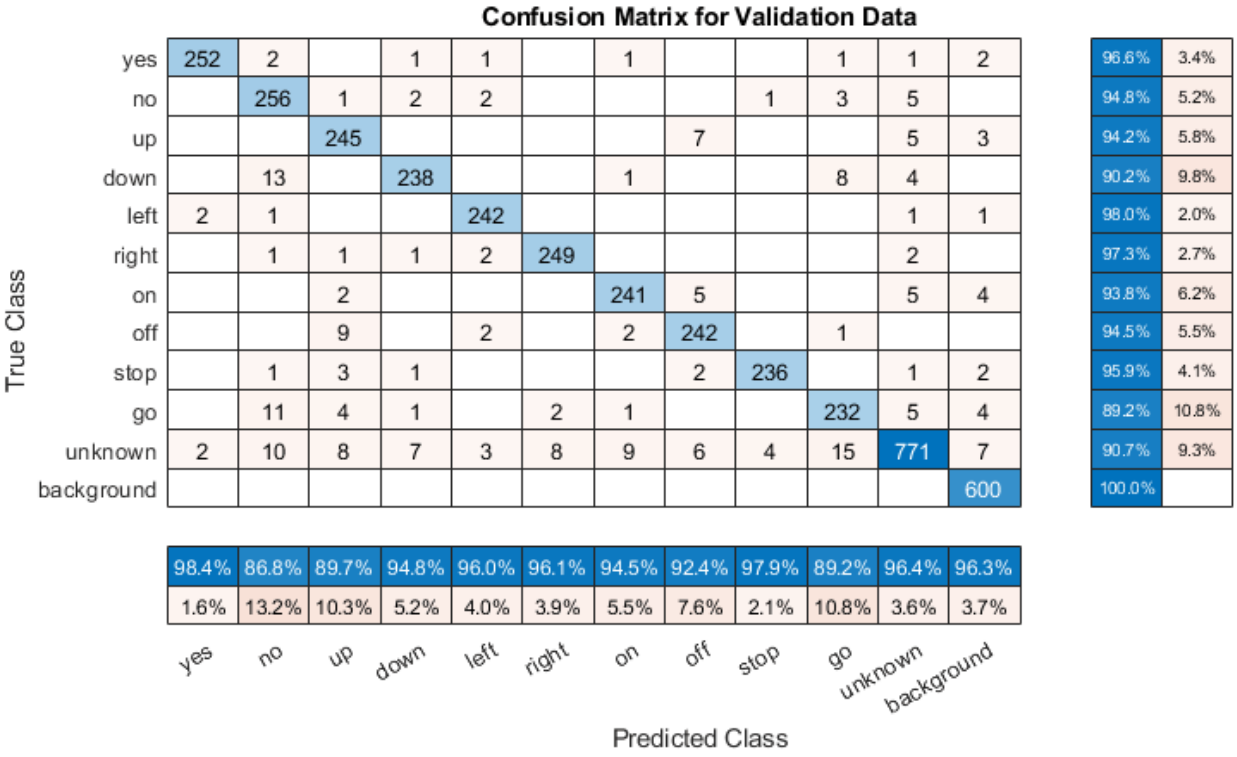
```
if reduceDataset
    load('commandNet.mat','trainedNet');
end
YValPred = classify(trainedNet,XValidation);
validationError = mean(YValPred ~= YValidation);
YTrainPred = classify(trainedNet,XTrain);
trainError = mean(YTrainPred ~= YTrain);
disp("Training error: " + trainError*100 + "%")
disp("Validation error: " + validationError*100 + "%")
```

```
Training error: 1.907%
Validation error: 5.5376%
```

Plot the confusion matrix. Display the precision and recall for each class by using column and row summaries. Sort the classes of the confusion matrix. The largest confusion is between unknown words and commands, *up* and *off*, *down* and *no*, and *go* and *no*.

```
figure('Units','normalized','Position',[0.2 0.2 0.5 0.5]);
cm = confusionchart(YValidation,YValPred);
cm.Title = 'Confusion Matrix for Validation Data';
cm.ColumnSummary = 'column-normalized';
```

```
cm.RowSummary = 'row-normalized';
sortClasses(cm, [commands,"unknown","background"])
```



When working on applications with constrained hardware resources such as mobile applications, consider the limitations on available memory and computational resources. Compute the total size of the network in kilobytes and test its prediction speed when using a CPU. The prediction time is the time for classifying a single input image. If you input multiple images to the network, these can be classified simultaneously, leading to shorter prediction times per image. When classifying streaming audio, however, the single-image prediction time is the most relevant.

```
info = whos('trainedNet');
disp("Network size: " + info.bytes/1024 + " kB")

for i = 1:100
    x = randn([numHops,numBands]);
    tic
    [YPredicted,probs] = classify(trainedNet,x,"ExecutionEnvironment",'cpu');
    time(i) = toc;
end
disp("Single-image prediction time on CPU: " + mean(time(11:end))*1000 + " ms")

Network size: 286.7402 kB
Single-image prediction time on CPU: 2.5119 ms
```

More About

- “Deep Learning in MATLAB” on page 1-2

Sequence-to-Sequence Classification Using Deep Learning

This example shows how to classify each time step of sequence data using a long short-term memory (LSTM) network.

To train a deep neural network to classify each time step of sequence data, you can use a *sequence-to-sequence LSTM network*. A sequence-to-sequence LSTM network enables you to make different predictions for each individual time step of the sequence data.

This example uses sensor data obtained from a smartphone worn on the body. The example trains an LSTM network to recognize the activity of the wearer given time series data representing accelerometer readings in three different directions. The training data contains time series data for seven people. Each sequence has three features and varies in length. The data set contains six training observations and one test observation.

Load Sequence Data

Load the human activity recognition data. The data contains seven time series of sensor data obtained from a smartphone worn on the body. Each sequence has three features and varies in length. The three features correspond to the accelerometer readings in three different directions.

```
load HumanActivityTrain
XTrain
```

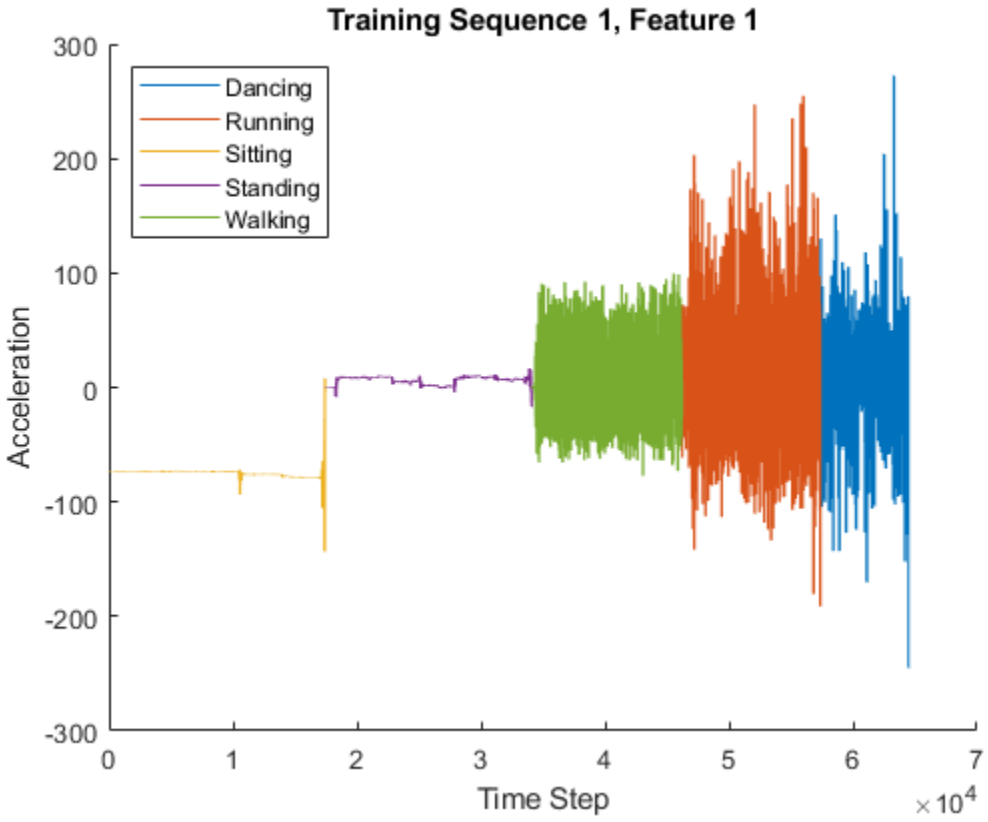
```
XTrain=6×1 cell array
    {3×64480 double}
    {3×53696 double}
    {3×56416 double}
    {3×50688 double}
    {3×51888 double}
    {3×54256 double}
```

Visualize one training sequence in a plot. Plot the first feature of the first training sequence and color the plot according to the corresponding activity.

```
X = XTrain{1}(1,:);
classes = categories(YTrain{1});

figure
for j = 1:numel(classes)
    label = classes(j);
    idx = find(YTrain{1} == label);
    hold on
    plot(idx,X(idx))
end
hold off

xlabel("Time Step")
ylabel("Acceleration")
title("Training Sequence 1, Feature 1")
legend(classes,'Location','northwest')
```



Define LSTM Network Architecture

Define the LSTM network architecture. Specify the input to be sequences of size 3 (the number of features of the input data). Specify an LSTM layer with 200 hidden units, and output the full sequence. Finally, specify five classes by including a fully connected layer of size 5, followed by a softmax layer and a classification layer.

```
numFeatures = 3;
numHiddenUnits = 200;
numClasses = 5;

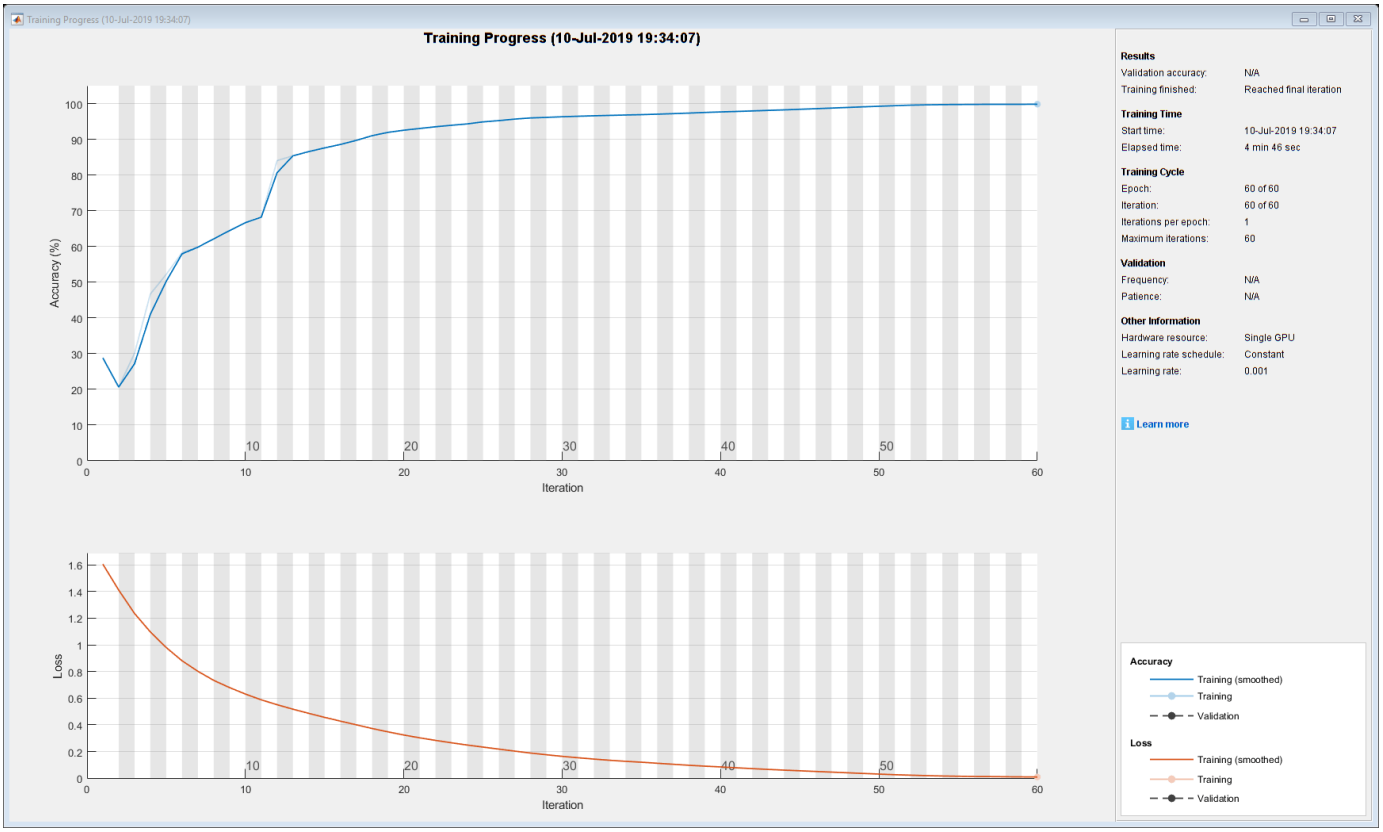
layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','sequence')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify the training options. Set the solver to `'adam'`. Train for 60 epochs. To prevent the gradients from exploding, set the gradient threshold to 2.

```
options = trainingOptions('adam', ...
    'MaxEpochs',60, ...
    'GradientThreshold',2, ...
    'Verbose',0, ...
    'Plots','training-progress');
```

Train the LSTM network with the specified training options using `trainNetwork`. Each mini-batch contains the whole training set, so the plot is updated once per epoch. The sequences are very long, so it might take some time to process each mini-batch and update the plot.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```

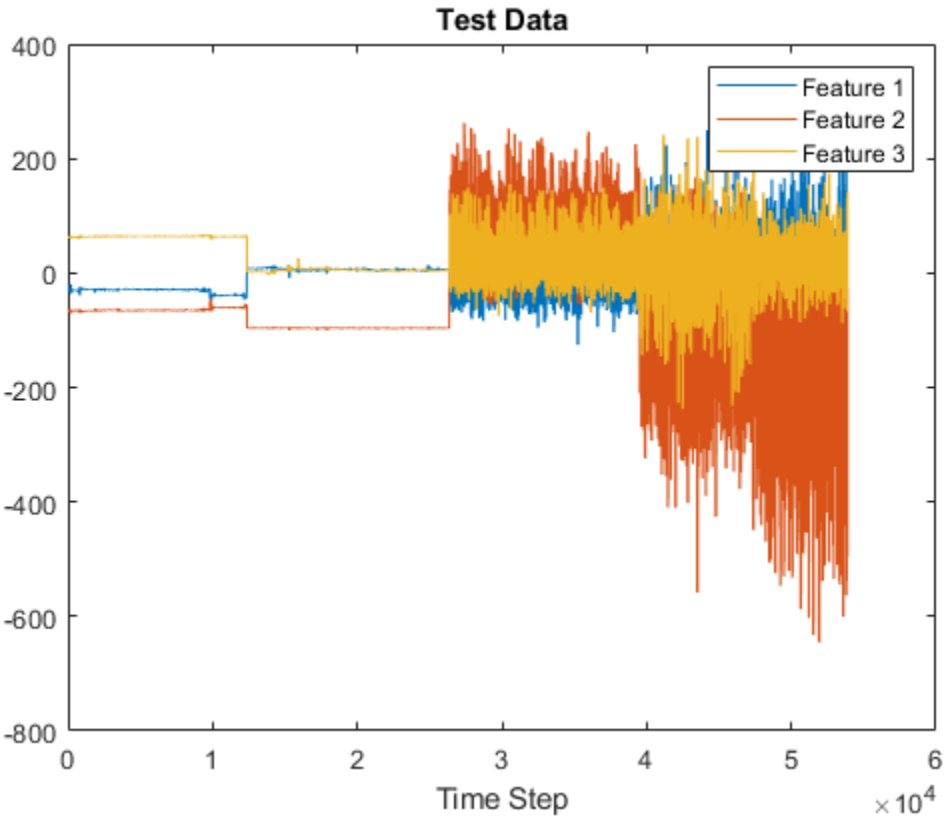


Test LSTM Network

Load the test data and classify the activity at each time step.

Load the human activity test data. `XTest` contains a single sequence of dimension 3. `YTest` is contains sequence of categorical labels corresponding to the activity at each time step.

```
load HumanActivityTest
figure
plot(XTest{1}')
xlabel("Time Step")
legend("Feature " + (1:numFeatures))
title("Test Data")
```



Classify the test data using `classify`.

```
YPred = classify(net,XTest{1});
```

Alternatively, you can make predictions one time step at a time by using `classifyAndUpdateState`. This is useful when you have the values of the time steps arriving in a stream. Usually, it is faster to make predictions on full sequences when compared to making predictions one time step at a time. For an example showing how to forecast future time steps by updating the network between single time step predictions, see “Time Series Forecasting Using Deep Learning” on page 4-15.

Calculate the accuracy of the predictions.

```
acc = sum(YPred == YTest{1})./numel(YTest{1})
```

```
acc = 0.9998
```

Compare the predictions with the test data by using a plot.

```
figure
plot(YPred,'.-')
hold on
plot(YTest{1})
hold off

xlabel("Time Step")
ylabel("Activity")
title("Predicted Activities")
legend(["Predicted" "Test Data"])
```

Sequence-to-Sequence Regression Using Deep Learning

This example shows how to predict the remaining useful life (RUL) of engines by using deep learning.

To train a deep neural network to predict numeric values from time series or sequence data, you can use a long short-term memory (LSTM) network.

This example uses the Turbofan Engine Degradation Simulation Data Set as described in [1]. The example trains an LSTM network to predict the remaining useful life of an engine (predictive maintenance), measured in cycles, given time series data representing various sensors in the engine. The training data contains simulated time series data for 100 engines. Each sequence varies in length and corresponds to a full run to failure (RTF) instance. The test data contains 100 partial sequences and corresponding values of the remaining useful life at the end of each sequence.

The data set contains 100 training observations and 100 test observations.

Download Data

Download and unzip the Turbofan Engine Degradation Simulation Data Set from https://ti.arc.nasa.gov/tech/dash/groups/pcoe/prognostic-data-repository/ [2].

Each time series of the Turbofan Engine Degradation Simulation data set represents a different engine. Each engine starts with unknown degrees of initial wear and manufacturing variation. The engine is operating normally at the start of each time series, and develops a fault at some point during the series. In the training set, the fault grows in magnitude until system failure.

The data contains a ZIP-compressed text files with 26 columns of numbers, separated by spaces. Each row is a snapshot of data taken during a single operational cycle, and each column is a different variable. The columns correspond to the following:

- Column 1 – Unit number
- Column 2 – Time in cycles
- Columns 3–5 – Operational settings
- Columns 6–26 – Sensor measurements 1–21

Create a directory to store the Turbofan Engine Degradation Simulation data set.

```
dataFolder = fullfile(tempdir,"turbofan");
if ~exist(dataFolder,'dir')
    mkdir(dataFolder);
end
```

Download and extract the Turbofan Engine Degradation Simulation Data Set from https://ti.arc.nasa.gov/tech/dash/groups/pcoe/prognostic-data-repository/.

Unzip the data from the file `CMAPSSData.zip`.

```
filename = "CMAPSSData.zip";
unzip(filename,dataFolder)
```

Prepare Training Data

Load the data using the function `processTurboFanDataTrain` attached to this example. The function `processTurboFanDataTrain` extracts the data from `filenamePredictors` and returns the cell arrays `XTrain` and `YTrain`, which contain the training predictor and response sequences.

```
filenamePredictors = fullfile(dataFolder,"train_FD001.txt");
[XTrain,YTrain] = processTurboFanDataTrain(filenamePredictors);
```

Remove Features with Constant Values

Features that remain constant for all time steps can negatively impact the training. Find the rows of data that have the same minimum and maximum values, and remove the rows.

```
m = min([XTrain{:}],[],2);
M = max([XTrain{:}],[],2);
idxConstant = M == m;

for i = 1:numel(XTrain)
    XTrain{i}(idxConstant,:) = [];
end
```

View the number of remaining features in the sequences.

```
numFeatures = size(XTrain{1},1)
```

```
numFeatures = 17
```

Normalize Training Predictors

Normalize the training predictors to have zero mean and unit variance. To calculate the mean and standard deviation over all observations, concatenate the sequence data horizontally.

```
mu = mean([XTrain{:}],2);
sig = std([XTrain{:}],0,2);

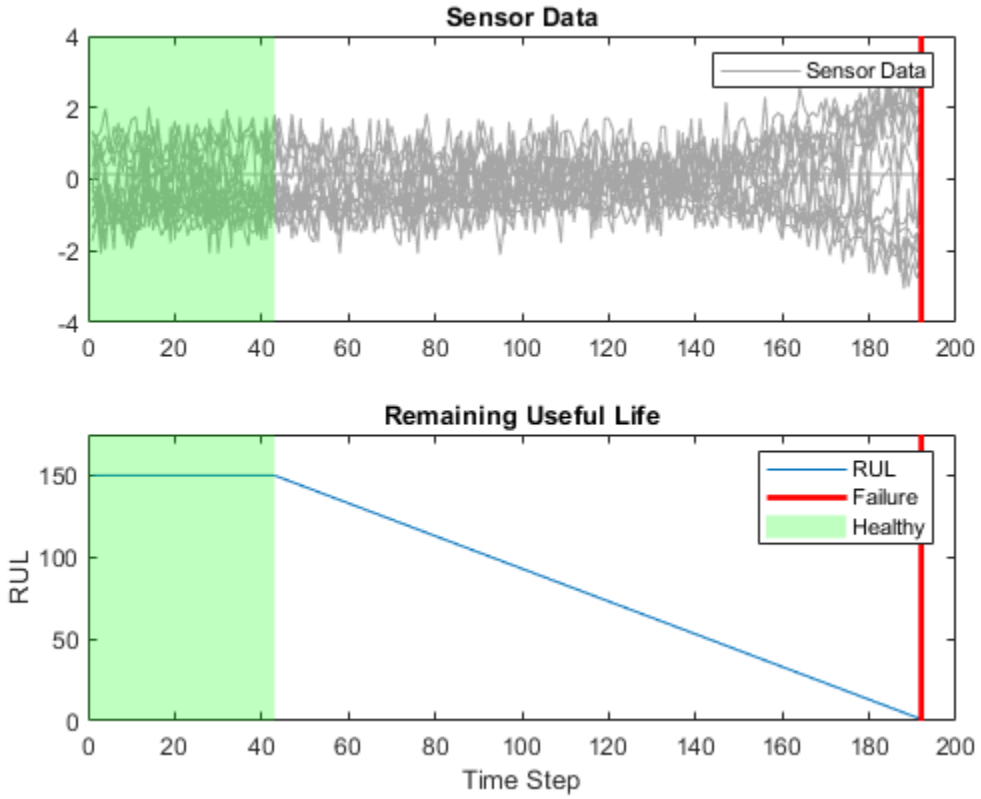
for i = 1:numel(XTrain)
    XTrain{i} = (XTrain{i} - mu) ./ sig;
end
```

Clip Responses

To learn more from the sequence data when the engines are close to failing, clip the responses at the threshold 150. This makes the network treat instances with higher RUL values as equal.

```
thr = 150;
for i = 1:numel(YTrain)
    YTrain{i}(YTrain{i} > thr) = thr;
end
```

This figure shows the first observation and the corresponding clipped response.



Prepare Data for Padding

To minimize the amount of padding added to the mini-batches, sort the training data by sequence length. Then, choose a mini-batch size which divides the training data evenly and reduces the amount of padding in the mini-batches.

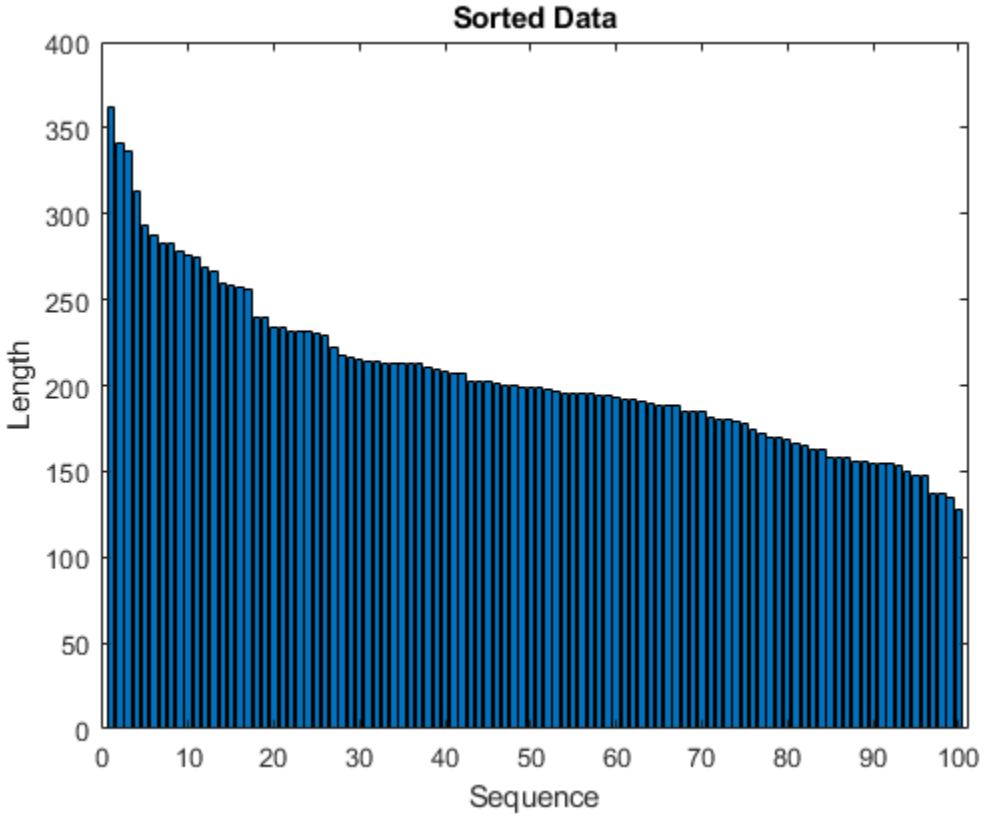
Sort the training data by sequence length.

```
for i=1:numel(XTrain)
    sequence = XTrain{i};
    sequenceLengths(i) = size(sequence,2);
end

[sequenceLengths,idx] = sort(sequenceLengths,'descend');
XTrain = XTrain(idx);
YTrain = YTrain(idx);
```

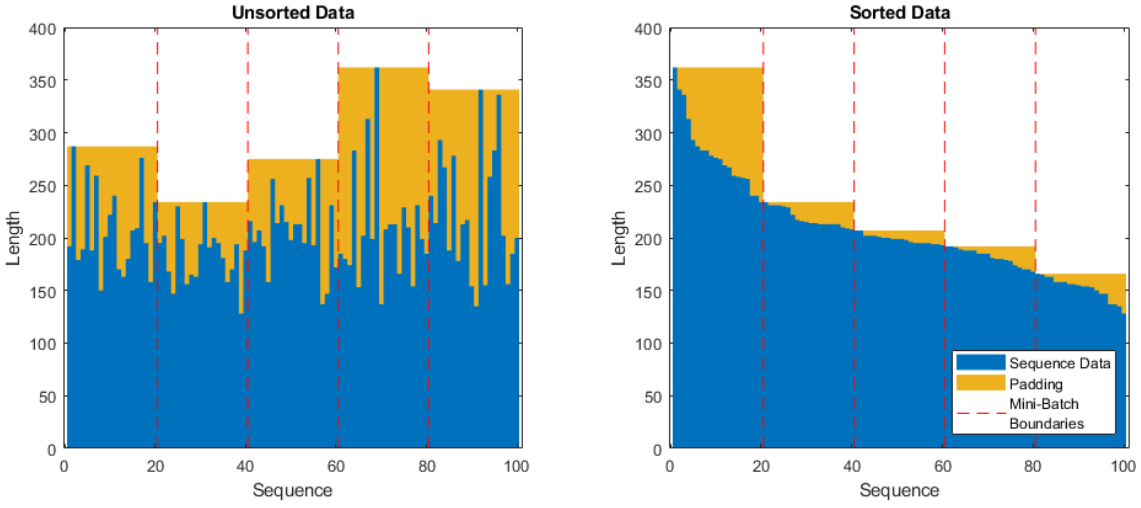
View the sorted sequence lengths in a bar chart.

```
figure
bar(sequenceLengths)
xlabel("Sequence")
ylabel("Length")
title("Sorted Data")
```



Choose a mini-batch size which divides the training data evenly and reduces the amount of padding in the mini-batches. Specify a mini-batch size of 20. This figure illustrates the padding added to the unsorted and sorted sequences.

```
miniBatchSize = 20;
```



Define Network Architecture

Define the network architecture. Create an LSTM network that consists of an LSTM layer with 200 hidden units, followed by a fully connected layer of size 50 and a dropout layer with dropout probability 0.5.

```
numResponses = size(YTrain{1},1);
numHiddenUnits = 200;

layers = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits,'OutputMode','sequence')
    fullyConnectedLayer(50)
    dropoutLayer(0.5)
    fullyConnectedLayer(numResponses)
    regressionLayer];
```

Specify the training options. Train for 60 epochs with mini-batches of size 20 using the solver `'adam'`. Specify the learning rate 0.01. To prevent the gradients from exploding, set the gradient threshold to 1. To keep the sequences sorted by length, set `'Shuffle'` to `'never'`.

```
maxEpochs = 60;
miniBatchSize = 20;

options = trainingOptions('adam', ...
    'MaxEpochs',maxEpochs, ...
    'MiniBatchSize',miniBatchSize, ...
    'InitialLearnRate',0.01, ...
    'GradientThreshold',1, ...
    'Shuffle','never', ...
    'Plots','training-progress',...
    'Verbose',0);
```

Train the Network

Train the network using `trainNetwork`.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```

Test the Network

Prepare the test data using the function `processTurboFanDataTest` attached to this example. The function `processTurboFanDataTest` extracts the data from `filenamePredictors` and `filenameResponses` and returns the cell arrays `XTest` and `YTest`, which contain the test predictor and response sequences, respectively.

```
filenamePredictors = fullfile(dataFolder,"test_FD001.txt");
filenameResponses = fullfile(dataFolder,"RUL_FD001.txt");
[XTest,YTest] = processTurboFanDataTest(filenamePredictors,filenameResponses);
```

Remove features with constant values using `idxConstant` calculated from the training data. Normalize the test predictors using the same parameters as in the training data. Clip the test responses at the same threshold used for the training data.

```
for i = 1:numel(XTest)
    XTest{i}(idxConstant,:) = [];
    XTest{i} = (XTest{i} - mu) ./ sig;
```

```
    YTest{i}(YTest{i} > thr) = thr;
end
```

Make predictions on the test data using `predict`. To prevent the function from adding padding to the data, specify the mini-batch size 1.

```
YPred = predict(net,XTest,'MiniBatchSize',1);
```

The LSTM network makes predictions on the partial sequence one time step at a time. At each time step, the network predicts using the value at this time step, and the network state calculated from the previous time steps only. The network updates its state between each prediction. The `predict` function returns a sequence of these predictions. The last element of the prediction corresponds to the predicted RUL for the partial sequence.

Alternatively, you can make predictions one time step at a time by using `predictAndUpdateState`. This is useful when you have the values of the time steps arriving in a stream. Usually, it is faster to make predictions on full sequences when compared to making predictions one time step at a time. For an example showing how to forecast future time steps by updating the network between single time step predictions, see “Time Series Forecasting Using Deep Learning” on page 4-15.

Visualize some of the predictions in a plot.

```
idx = randperm(numel(YPred),4);
figure
for i = 1:numel(idx)
    subplot(2,2,i)

    plot(YTest{idx(i)},'--')
    hold on
    plot(YPred{idx(i)},'.-')
    hold off

    ylim([0 thr + 25])
    title("Test Observation " + idx(i))
    xlabel("Time Step")
    ylabel("RUL")
end
legend(["Test Data" "Predicted"],'Location','southeast')
```

For a given partial sequence, the predicted current RUL is the last element of the predicted sequences. Calculate the root-mean-square error (RMSE) of the predictions, and visualize the prediction error in a histogram.

```
for i = 1:numel(YTest)
    YTestLast(i) = YTest{i}(end);
    YPredLast(i) = YPred{i}(end);
end
figure
rmse = sqrt(mean((YPredLast - YTestLast).^2))
histogram(YPredLast - YTestLast)
title("RMSE = " + rmse)
ylabel("Frequency")
xlabel("Error")
```

Classify Videos Using Deep Learning

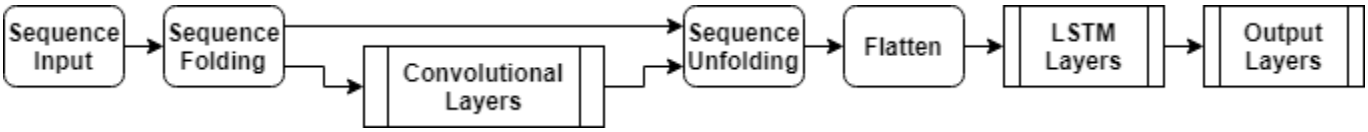
This example shows how to create a network for video classification by combining a pretrained image classification model and an LSTM network.

To create a deep learning network for video classification:

1. Convert videos to sequences of feature vectors using a pretrained convolutional neural network, such as GoogLeNet, to extract features from each frame.
2. Train an LSTM network on the sequences to predict the video labels.
3. Assemble a network that classifies videos directly by combining layers from both networks.

The following diagram illustrates the network architecture.

- To input image sequences to the network, use a sequence input layer.
- To use convolutional layers to extract features, that is, to apply the convolutional operations to each frame of the videos independently, use a sequence folding layer followed by the convolutional layers.
- To restore the sequence structure and reshape the output to vector sequences, use a sequence unfolding layer and a flatten layer.
- To classify the resulting vector sequences, include the LSTM layers followed by the output layers.



Load Pretrained Convolutional Network

To convert frames of videos to feature vectors, use the activations of a pretrained network.

Load a pretrained GoogLeNet model using the `googlenet` function. This function requires the Deep Learning Toolbox™ Model *for GoogLeNet Network* support package. If this support package is not installed, then the function provides a download link.

```
netCNN = googlenet;
```

Load Data

Download the HMBD51 data set from HMDB: a large human motion database and extract the RAR file into a folder named `"hmdb51_org"`. The data set contains about 2 GB of video data for 7000 clips over 51 classes, such as `"drink"`, `"run"`, and `"shake_hands"`.

After extracting the RAR files, use the supporting function `hmdb51Files` to get the file names and the labels of the videos.

```
dataFolder = "hmdb51_org";
[files,labels] = hmdb51Files(dataFolder);
```

Read the first video using the `readVideo` helper function, defined at the end of this example, and view the size of the video. The video is a *H*-by-*W*-by-*C*-by-*S* array, where *H*, *W*, *C*, and *S* are the height, width, number of channels, and number of frames of the video, respectively.

```
idx = 1;
filename = files(idx);
video = readVideo(filename);
size(video)
```

```
ans = 1×4

   240   320     3   409
```

View the corresponding label.

```
labels(idx)
```

```
ans = categorical
     brush_hair
```

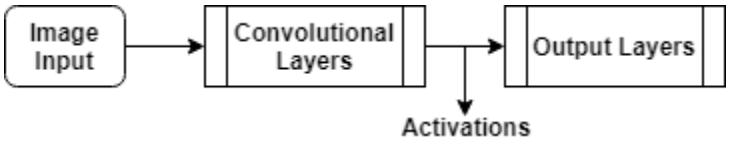
To view the video, use the `implay` function (requires Image Processing Toolbox™). This function expects data in the range [0,1], so you must first divide the data by 255. Alternatively, you can loop over the individual frames and use the `imshow` function.

```
numFrames = size(video,4);
figure
for i = 1:numFrames
    frame = video(:,:,:,i);
    imshow(frame/255);
    drawnow
end
```

Convert Frames to Feature Vectors

Use the convolutional network as a feature extractor by getting the activations when inputting the video frames to the network. Convert the videos to sequences of feature vectors, where the feature vectors are the output of the `activations` function on the last pooling layer of the GoogLeNet network (`"pool5-7x7_s1"`).

This diagram illustrates the data flow through the network.



To read the video data and resize it to match the input size of the GoogLeNet network, use the `readVideo` and `centerCrop` helper functions, defined at the end of this example. This step can take a long time to run. After converting the videos to sequences, save the sequences in a MAT-file in the `tempdir` folder. If the MAT file already exists, then load the sequences from the MAT-file without reconverting them.

```
inputSize = netCNN.Layers(1).InputSize(1:2);
layerName = "pool5-7x7_s1";

tempFile = fullfile(tempdir,"hmdb51_org.mat");

if exist(tempFile,'file')
    load(tempFile,"sequences")
```

```
else
    numFiles = numel(files);
    sequences = cell(numFiles,1);

    for i = 1:numFiles
        fprintf("Reading file %d of %d...\n", i, numFiles)

        video = readVideo(files(i));
        video = centerCrop(video,inputSize);

        sequences{i,1} = activations(netCNN,video,layerName,'OutputAs','columns');
    end

    save(tempFile,"sequences","-v7.3");
end
```

View the sizes of the first few sequences. Each sequence is a *D*-by-*S* array, where *D* is the number of features (the output size of the pooling layer) and *S* is the number of frames of the video.

```
sequences(1:10)
```

```
ans = 10×1 cell array
    {1024×409 single}
    {1024×395 single}
    {1024×323 single}
    {1024×246 single}
    {1024×159 single}
    {1024×137 single}
    {1024×359 single}
    {1024×191 single}
    {1024×439 single}
    {1024×528 single}
```

Prepare Training Data

Prepare the data for training by partitioning the data into training and validation partitions and removing any long sequences.

Create Training and Validation Partitions

Partition the data. Assign 90% of the data to the training partition and 10% to the validation partition.

```
numObservations = numel(sequences);
idx = randperm(numObservations);
N = floor(0.9 * numObservations);

idxTrain = idx(1:N);
sequencesTrain = sequences(idxTrain);
labelsTrain = labels(idxTrain);

idxValidation = idx(N+1:end);
sequencesValidation = sequences(idxValidation);
labelsValidation = labels(idxValidation);
```

Remove Long Sequences

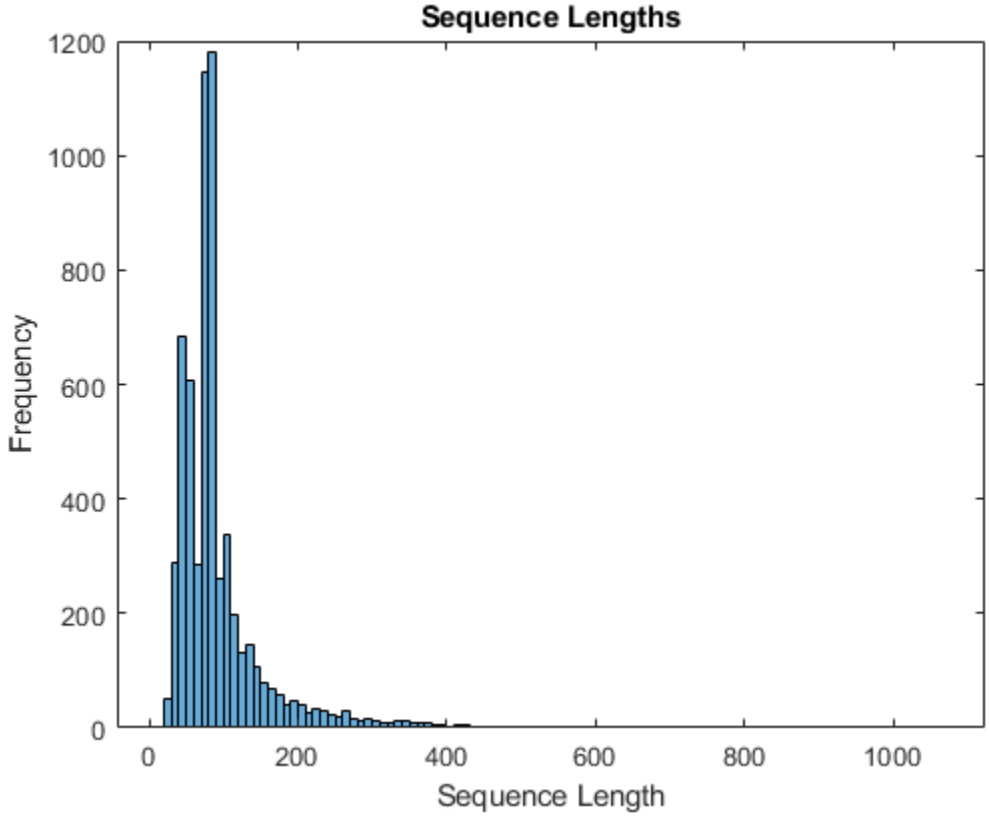
Sequences that are much longer than typical sequences in the networks can introduce lots of padding into the training process. Having too much padding can negatively impact the classification accuracy.

Get the sequence lengths of the training data and visualize them in a histogram of the training data.

```
numObservationsTrain = numel(sequencesTrain);
sequenceLengths = zeros(1,numObservationsTrain);

for i = 1:numObservationsTrain
    sequence = sequencesTrain{i};
    sequenceLengths(i) = size(sequence,2);
end

figure
histogram(sequenceLengths)
title("Sequence Lengths")
xlabel("Sequence Length")
ylabel("Frequency")
```



Only a few sequences have more than 400 time steps. To improve the classification accuracy, remove the training sequences that have more than 400 time steps along with their corresponding labels.

```
maxLength = 400;
idx = sequenceLengths > maxLength;
sequencesTrain(idx) = [];
labelsTrain(idx) = [];
```

Create LSTM Network

Next, create an LSTM network that can classify the sequences of feature vectors representing the videos.

Define the LSTM network architecture. Specify the following network layers.

- A sequence input layer with an input size corresponding to the feature dimension of the feature vectors
- A BiLSTM layer with 2000 hidden units with a dropout layer afterwards. To output only one label for each sequence by setting the `'OutputMode'` option of the BiLSTM layer to `'last'`
- A fully connected layer with an output size corresponding to the number of classes, a softmax layer, and a classification layer.

```
numFeatures = size(sequencesTrain{1},1);
numClasses = numel(categories(labelsTrain));

layers = [
    sequenceInputLayer(numFeatures,'Name','sequence')
    bilstmLayer(2000,'OutputMode','last','Name','bilstm')
    dropoutLayer(0.5,'Name','drop')
    fullyConnectedLayer(numClasses,'Name','fc')
    softmaxLayer('Name','softmax')
    classificationLayer('Name','classification')];
```

Specify Training Options

Specify the training options using the `trainingOptions` function.

- Set a mini-batch size 16, an initial learning rate of 0.0001, and a gradient threshold of 2 (to prevent the gradients from exploding).
- Shuffle the data every epoch.
- Validate the network once per epoch.
- Display the training progress in a plot and suppress verbose output.

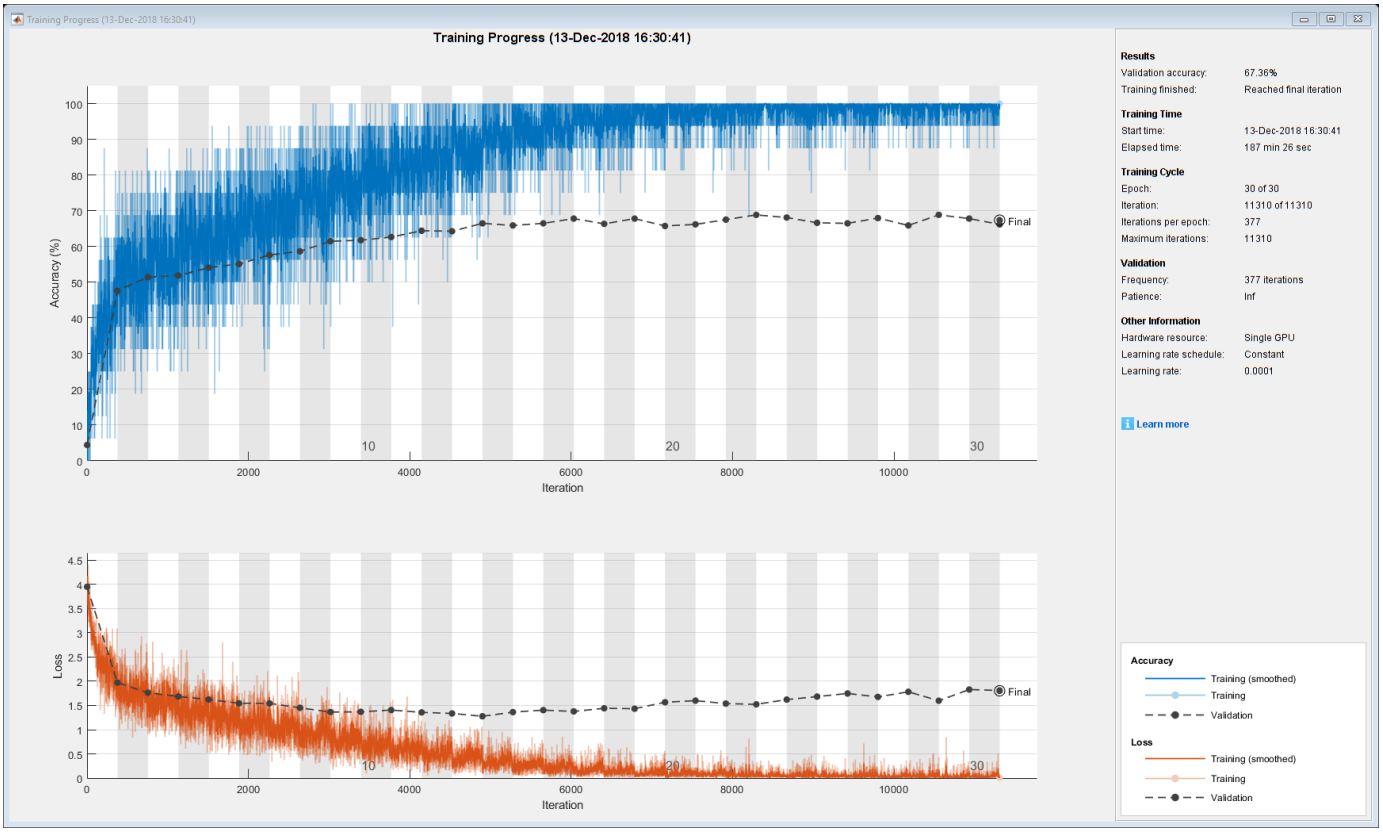
```
miniBatchSize = 16;
numObservations = numel(sequencesTrain);
numIterationsPerEpoch = floor(numObservations / miniBatchSize);

options = trainingOptions('adam', ...
    'MiniBatchSize',miniBatchSize, ...
    'InitialLearnRate',1e-4, ...
    'GradientThreshold',2, ...
    'Shuffle','every-epoch', ...
    'ValidationData',{sequencesValidation,labelsValidation}, ...
    'ValidationFrequency',numIterationsPerEpoch, ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train LSTM Network

Train the network using the `trainNetwork` function. This can take a long time to run.

```
[netLSTM,info] = trainNetwork(sequencesTrain,labelsTrain,layers,options);
```



Calculate the classification accuracy of the network on the validation set. Use the same mini-batch size as for the training options.

```
YPred = classify(netLSTM,sequencesValidation,'MiniBatchSize',miniBatchSize);
YValidation = labelsValidation;
accuracy = mean(YPred == YValidation)
```

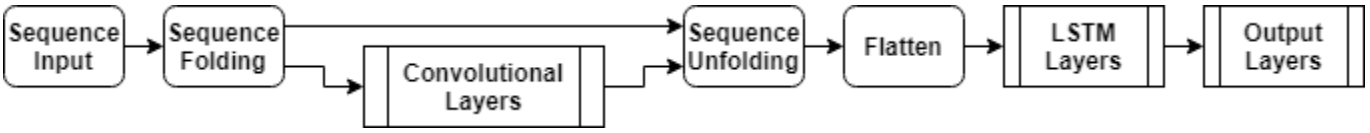
```
accuracy = 0.6647
```

Assemble Video Classification Network

To create a network that classifies videos directly, assemble a network using layers from both of the created networks. Use the layers from the convolutional network to transform the videos into vector sequences and the layers from the LSTM network to classify the vector sequences.

The following diagram illustrates the network architecture.

- To input image sequences to the network, use a sequence input layer.
- To use convolutional layers to extract features, that is, to apply the convolutional operations to each frame of the videos independently, use a sequence folding layer followed by the convolutional layers.
- To restore the sequence structure and reshape the output to vector sequences, use a sequence unfolding layer and a flatten layer.
- To classify the resulting vector sequences, include the LSTM layers followed by the output layers.



Add Convolutional Layers

First, create a layer graph of the GoogLeNet network.

```
cnnLayers = layerGraph(netCNN);
```

Remove the input layer (`"data"`) and the layers after the pooling layer used for the activations (`"pool5-drop_7x7_s1"`, `"loss3-classifier"`, `"prob"`, and `"output"`).

```
layerNames = ["data" "pool5-drop_7x7_s1" "loss3-classifier" "prob" "output"];
cnnLayers = removeLayers(cnnLayers,layerNames);
```

Add Sequence Input Layer

Create a sequence input layer that accepts image sequences containing images of the same input size as the GoogLeNet network. To normalize the images using the same average image as the GoogLeNet network, set the `'Normalization'` option of the sequence input layer to `'zerocenter'` and the `'Mean'` option to the average image of the input layer of GoogLeNet.

```
inputSize = netCNN.Layers(1).InputSize(1:2);
averageImage = netCNN.Layers(1).Mean;

inputLayer = sequenceInputLayer([inputSize 3], ...
    'Normalization','zerocenter', ...
    'Mean',averageImage, ...
    'Name','input');
```

Add the sequence input layer to the layer graph. To apply the convolutional layers to the images of the sequences independently, remove the sequence structure of the image sequences by including a sequence folding layer between the sequence input layer and the convolutional layers. Connect the output of the sequence folding layer to the input of the first convolutional layer (`"conv1-7x7_s2"`).

```
layers = [
    inputLayer
    sequenceFoldingLayer('Name','fold')];

lgraph = addLayers(cnnLayers,layers);
lgraph = connectLayers(lgraph,"fold/out","conv1-7x7_s2");
```

Add LSTM Layers

Add the LSTM layers to the layer graph by removing the sequence input layer of the LSTM network. To restore the sequence structure removed by the sequence folding layer, include a sequence unfolding layer after the convolution layers. The LSTM layers expect sequences of vectors. To reshape the output of the sequence unfolding layer to vector sequences, include a flatten layer after the sequence unfolding layer.

Take the layers from the LSTM network and remove the sequence input layer.

```
lstmLayers = netLSTM.Layers;
lstmLayers(1) = [];
```

Add the sequence unfolding layer, the flatten layer, and the LSTM layers to the layer graph. Connect the last convolutional layer (`"pool5-7x7_s1"`) to the input of the sequence unfolding layer (`"unfold/in"`).

```
layers = [
    sequenceUnfoldingLayer('Name','unfold')
    flattenLayer('Name','flatten')
    lstmLayers];

lgraph = addLayers(lgraph,layers);
lgraph = connectLayers(lgraph,"pool5-7x7_s1","unfold/in");
```

To enable the unfolding layer to restore the sequence structure, connect the `"miniBatchSize"` output of the sequence folding layer to the corresponding input of the sequence unfolding layer.

```
lgraph = connectLayers(lgraph,"fold/miniBatchSize","unfold/miniBatchSize");
```

Assemble Network

Check that the network is valid using the `analyzeNetwork` function.

```
analyzeNetwork(lgraph)
```

Assemble the network so that it is ready for prediction using the `assembleNetwork` function.

```
net = assembleNetwork(lgraph)
```

```
net =
  DAGNetwork with properties:

         Layers: [148×1 nnet.cnn.layer.Layer]
    Connections: [175×2 table]
```

Classify Using New Data

Read and center-crop the video `"pushup.mp4"` using the same steps as before.

```
filename = "pushup.mp4";
video = readVideo(filename);
```

To view the video, use the `implay` function (requires Image Processing Toolbox). This function expects data in the range [0,1], so you must first divide the data by 255. Alternatively, you can loop over the individual frames and use the `imshow` function.

```
numFrames = size(video,4);
figure
for i = 1:numFrames
    frame = video(:,:,:,i);
    imshow(frame/255);
    drawnow
end
```

Classify the video using the assembled network. The `classify` function expects a cell array containing the input videos, so you must input a 1-by-1 cell array containing the video.

```
video = centerCrop(video,inputSize);
YPred = classify(net,{video})
```

```
YPred = categorical
     pushup
```

Helper Functions

The `readVideo` function reads the video in `filename` and returns an `H`-by-`W`-by-`C`-by-`S` array, where `H`, `W`, `C`, and `S` are the height, width, number of channels, and number of frames of the video, respectively.

```
function video = readVideo(filename)

vr = VideoReader(filename);
H = vr.Height;
W = vr.Width;
C = 3;

% Preallocate video array
numFrames = floor(vr.Duration * vr.FrameRate);
video = zeros(H,W,C,numFrames);

% Read frames
i = 0;
while hasFrame(vr)
```

```
    i = i + 1;
    video(:,:,:,i) = readFrame(vr);
end

% Remove unallocated frames
if size(video,4) > i
    video(:,:,:,i+1:end) = [];
end

end
```

The `centerCrop` function crops the longest edges of a video and resizes it have size `inputSize`.

```
function videoResized = centerCrop(video,inputSize)

sz = size(video);

if sz(1) < sz(2)
    % Video is landscape
    idx = floor((sz(2) - sz(1))/2);
    video(:,1:(idx-1),:,:) = [];
    video(:,(sz(1)+1):end,:,:) = [];

elseif sz(2) < sz(1)
    % Video is portrait
    idx = floor((sz(1) - sz(2))/2);
    video(1:(idx-1),:,:,:) = [];
    video((sz(2)+1):end,:,:,:) = [];
end

videoResized = imresize(video,inputSize(1:2));

end
```

Classify Videos Using Deep Learning with Custom Training Loop

This example shows how to create a network for video classification by combining a pretrained image classification model and a sequence classification network.

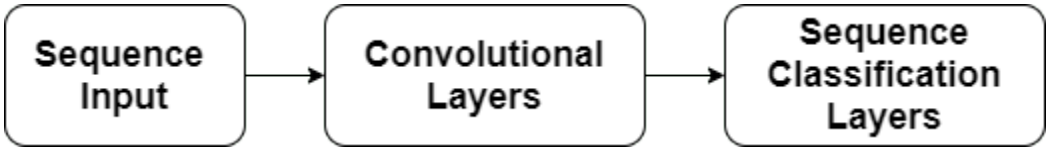
You can perform video classification without using a custom training loop by using the `trainNetwork` function. For an example, see “Classify Videos Using Deep Learning” on page 4-54. However, If `trainingOptions` does not provide the options you need (for example, a custom learning rate schedule), then you can define your own custom training loop as shown in this example.

To create a deep learning network for video classification:

1. Convert videos to sequences of feature vectors using a pretrained convolutional neural network, such as GoogLeNet, to extract features from each frame.
2. Train a sequence classification network on the sequences to predict the video labels.
3. Assemble a network that classifies videos directly by combining layers from both networks.

The following diagram illustrates the network architecture:

- To input image sequences to the network, use a sequence input layer.
- To extract features from the image sequences, use convolutional layers from the pretrained GoogLeNet network.
- To classify the resulting vector sequences, include the sequence classification layers.



When training this type of network with the `trainNetwork` function (not done in this example), you must use sequence folding and unfolding layers to process the video frames independently. When you train this type of network with a `dlnetwork` object and a custom training loop (as in this example), sequence folding and unfolding layers are not required because the network uses dimension information given by the `dlarray` dimension labels.

Load Pretrained Convolutional Network

To convert frames of videos to feature vectors, use the activations of a pretrained network.

Load a pretrained GoogLeNet model using the `googlenet` function. This function requires the Deep Learning Toolbox™ Model *for GoogLeNet Network* support package. If this support package is not installed, then the function provides a download link.

```
netCNN = googlenet;
```

Load Data

Download the HMBD51 data set from HMDB: a large human motion database and extract the RAR file into a folder named `"hmdb51_org"`. The data set contains about 2 GB of video data for 7000 clips over 51 classes, such as `"drink"`, `"run"`, and `"shake_hands"`.

After extracting the RAR file, make sure that the folder `hmdb51_org` contains subfolders named after the body motions. If it contains RAR files, you need to extract them as well. Use the supporting function `hmdb51Files` to get the file names and the labels of the videos. To speed up training at the cost of accuracy, specify a fraction in the range [0 1] to read only a random subset of files from the database. If the `fraction` input argument is not specified, the function `hmdb51Files` reads the full dataset without changing the order of the files.

```
dataFolder = "hmdb51_org";
fraction = 1;
[files,labels] = hmdb51Files(dataFolder,fraction);
```

Read the first video using the `readVideo` helper function, defined at the end of this example, and view the size of the video. The video is an *H*-by-*W*-by-*C*-by-*T* array, where *H*, *W*, *C*, and *T* are the height, width, number of channels, and number of frames of the video, respectively.

```
idx = 1;
filename = files(idx);
video = readVideo(filename);
size(video)
```

```
ans = 1×4

   240   352     3   115
```

View the corresponding label.

```
labels(idx)
```

```
ans = categorical
     shoot_ball
```

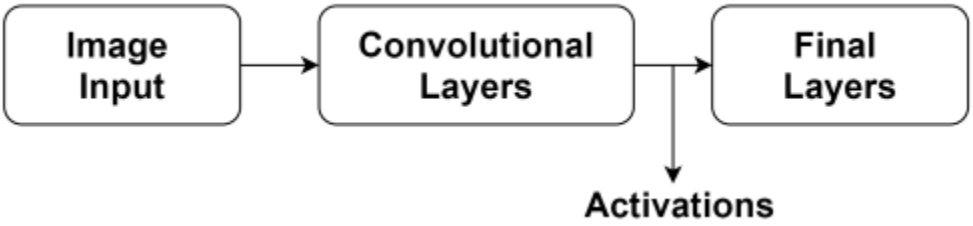
To view the video, loop over the individual frames and use the `image` function. Alternatively, you can use the `implay` function (requires Image Processing Toolbox).

```
numFrames = size(video,4);
figure
for i = 1:numFrames
    frame = video(:,:,:,i);
    image(frame);
    xticklabels([]);
    yticklabels([]);
    drawnow
end
```

Convert Frames to Feature Vectors

Use the convolutional network as a feature extractor: input video frames to the network and extract the activations. Convert the videos to sequences of feature vectors, where the feature vectors are the output of the `activations` function on the last pooling layer of the GoogLeNet network (`"pool5-7x7_s1"`).

This diagram illustrates the data flow through the network.



Read the video data using the `readVideo` function, defined at the end of this example, and resize it to match the input size of the GoogLeNet network. Note that this step can take a long time to run. After converting the videos to sequences, save the sequences and corresponding labels in a MAT file in the `tempdir` folder. If the MAT file already exists, then load the sequences and labels from the MAT file directly. In case a MAT file already exists but you want to overwrite it, set the variable `overwriteSequences` to `true`.

```
inputSize = netCNN.Layers(1).InputSize(1:2);
layerName = "pool5-7x7_s1";

tempFile = fullfile(tempdir,"hmdb51_org.mat");

overwriteSequences = false;

if exist(tempFile,'file') && ~overwriteSequences
    load(tempFile)
else
    numFiles = numel(files);
    sequences = cell(numFiles,1);

    for i = 1:numFiles
        fprintf("Reading file %d of %d...\n", i, numFiles)

        video = readVideo(files(i));
        video = imresize(video,inputSize);
        sequences{i,1} = activations(netCNN,video,layerName,'OutputAs','columns');

    end
    % Save the sequences and the labels associated with them.
    save(tempFile,"sequences","labels","-v7.3");
end
```

View the sizes of the first few sequences. Each sequence is a *D*-by-*T* array, where *D* is the number of features (the output size of the pooling layer) and *T* is the number of frames of the video.

```
sequences(1:10)
```

```
ans=10×1 cell array
    {1024×115 single}
    {1024×227 single}
    {1024×180 single}
    {1024×40  single}
    {1024×60  single}
    {1024×156 single}
    {1024×83  single}
    {1024×42  single}
    {1024×82  single}
```

```
    {1024×110 single}
```

Prepare Training Data

Prepare the data for training by partitioning the data into training and validation partitions and removing any long sequences.

Create Training and Validation Partitions

Partition the data. Assign 90% of the data to the training partition and 10% to the validation partition.

```
numObservations = numel(sequences);
idx = randperm(numObservations);
N = floor(0.9 * numObservations);

idxTrain = idx(1:N);
sequencesTrain = sequences(idxTrain);
labelsTrain = labels(idxTrain);

idxValidation = idx(N+1:end);
sequencesValidation = sequences(idxValidation);
labelsValidation = labels(idxValidation);
```

Remove Long Sequences

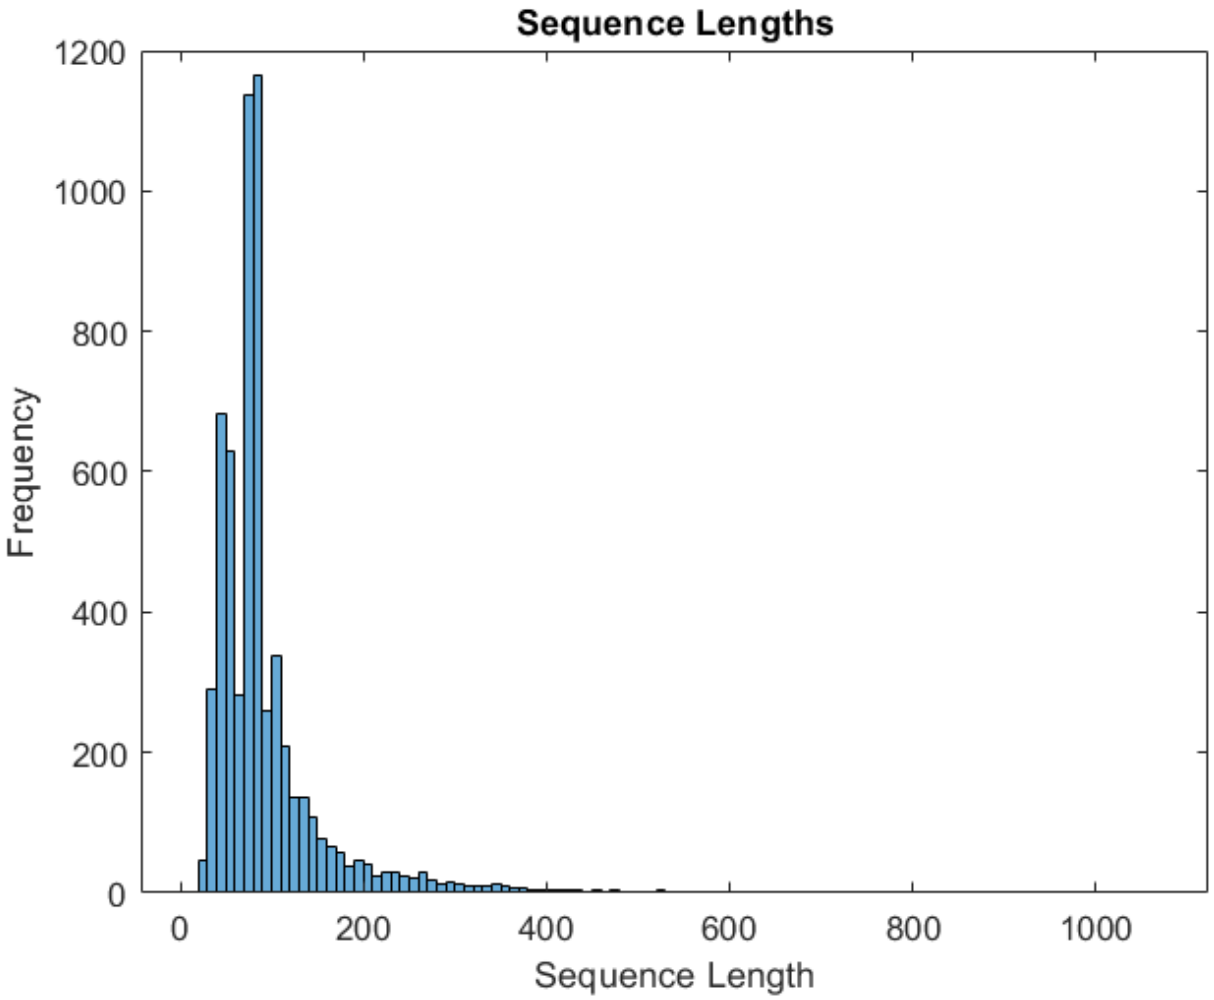
Sequences that are much longer than typical sequences in the networks can introduce lots of padding into the training process. Having too much padding can negatively impact the classification accuracy.

Get the sequence lengths of the training data and visualize them in a histogram of the training data.

```
numObservationsTrain = numel(sequencesTrain);
sequenceLengths = zeros(1,numObservationsTrain);

for i = 1:numObservationsTrain
    sequence = sequencesTrain{i};
    sequenceLengths(i) = size(sequence,2);
end

figure
histogram(sequenceLengths)
title("Sequence Lengths")
xlabel("Sequence Length")
ylabel("Frequency")
```



Only a few sequences have more than 400 time steps. To improve the classification accuracy, remove the training sequences that have more than 400 time steps along with their corresponding labels.

```
maxLength = 400;
idx = sequenceLengths > maxLength;
sequencesTrain(idx) = [];
labelsTrain(idx) = [];
```

Create Datastore for Data

Create an `arrayDatastore` object for the sequences and the labels, and then combine them into a single datastore.

```
dsXTrain = arrayDatastore(sequencesTrain,'OutputType','same');
dsYTrain = arrayDatastore(labelsTrain,'OutputType','cell');

dsTrain = combine(dsXTrain,dsYTrain);
```

Determine the classes in the training data.

```
classes = categories(labelsTrain);
```

Create Sequence Classification Network

Next, create a sequence classification network that can classify the sequences of feature vectors representing the videos.

Define the sequence classification network architecture. Specify the following network layers:

- A sequence input layer with an input size corresponding to the feature dimension of the feature vectors.
- A BiLSTM layer with 2000 hidden units with a dropout layer afterwards. To output only one label for each sequence, set the `'OutputMode'` option of the BiLSTM layer to `'last'`.
- A dropout layer with a probability of 0.5.
- A fully connected layer with an output size corresponding to the number of classes and a softmax layer.

```
numFeatures = size(sequencesTrain{1},1);
numClasses = numel(categories(labelsTrain));

layers = [
    sequenceInputLayer(numFeatures,'Name','sequence')
    bilstmLayer(2000,'OutputMode','last','Name','bilstm')
    dropoutLayer(0.5,'Name','drop')
    fullyConnectedLayer(numClasses,'Name','fc')
    softmaxLayer('Name','softmax')
    ];
```

Convert the layers to a `layerGraph` object.

```
lgraph = layerGraph(layers);
```

Create a `dlnetwork` object from the layer graph.

```
dlnet = dlnetwork(lgraph);
```

Specify Training Options

Train for 15 epochs and specify a mini-batch size of 16.

```
numEpochs = 15;
miniBatchSize = 16;
```

Specify the options for Adam optimization. Specify an initial learning rate of `1e-4` with a decay of 0.001, a gradient decay of 0.9, and a squared gradient decay of 0.999.

```
initialLearnRate = 1e-4;
decay = 0.001;
gradDecay = 0.9;
sqGradDecay = 0.999;
```

Visualize the training progress in a plot.

```
plots = "training-progress";
```

Train Sequence Classification Network

Create a `minibatchqueue` object that processes and manages mini-batches of sequences during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessLabeledSequences` (defined at the end of this example) to convert the labels to dummy variables.
- Format the vector sequence data with the dimension labels `'CTB'` (channel, time, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` object if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see "GPU Support by Release" (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @preprocessLabeledSequences,...
    'MiniBatchFormat',{'CTB',''});
```

Initialize the training progress plot.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Initialize the average gradient and average squared gradient parameters for the Adam solver.

```
averageGrad = [];
averageSqGrad = [];
```

Train the model using a custom training loop. For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients, state, and loss using `dlfeval` and the `modelGradients` function and update the network state.
- Determine the learning rate for the time-based decay learning rate schedule: for each iteration, the solver uses the learning rate given by $\rho_t = \frac{\rho_0}{1 + k\,t}$, where t is the iteration number, ρ_0 is the initial learning rate, and k is the decay.
- Update the network parameters using the `adamupdate` function.
- Display the training progress.

Note that training can take a long time to run.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs
    % Shuffle data.
    shuffle(mbq);

    % Loop over mini-batches.
    while hasdata(mbq)
```

```
        iteration = iteration + 1;

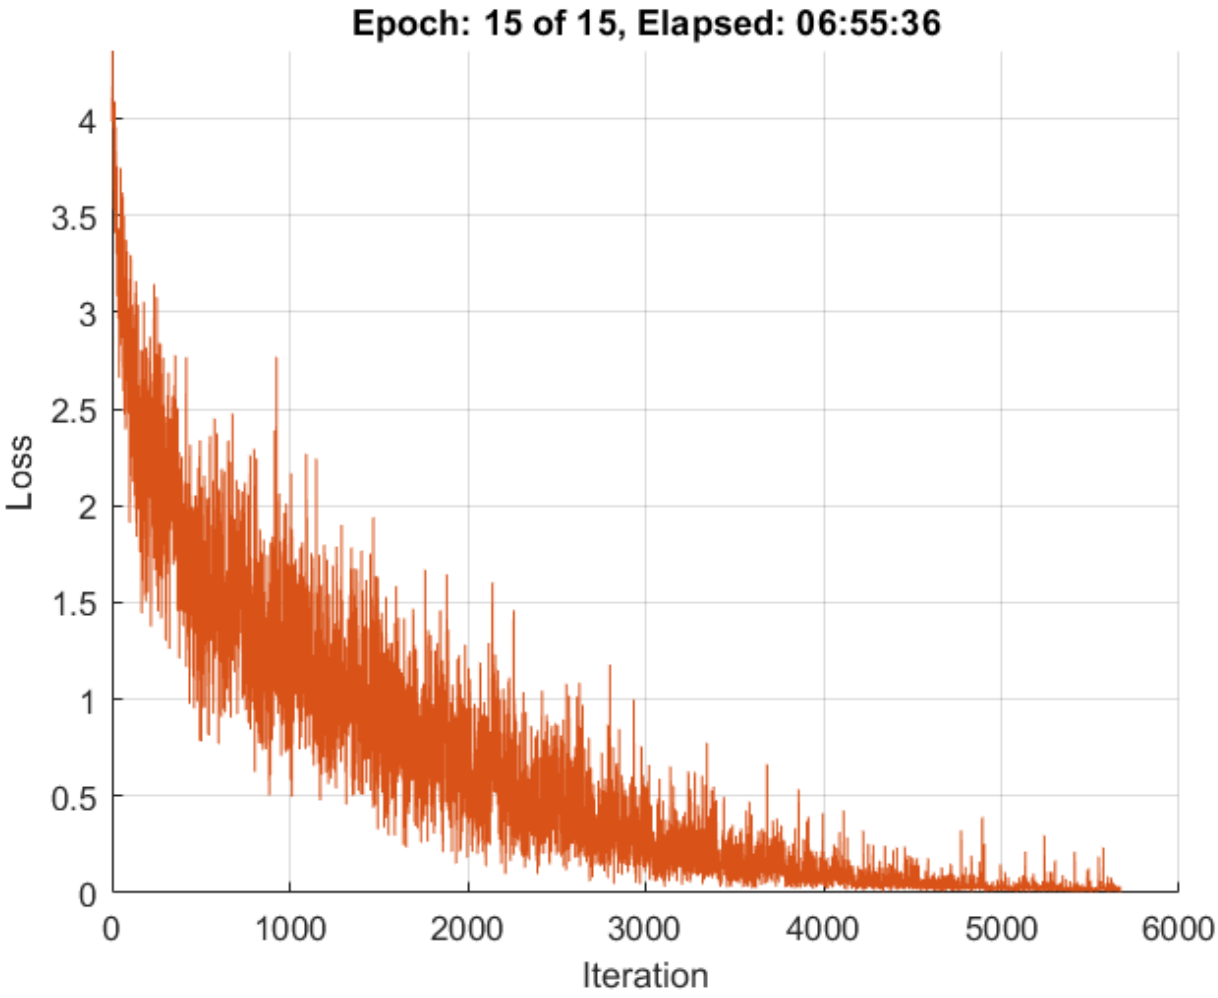
        % Read mini-batch of data.
        [dlX, dlY] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function.
        [gradients,state,loss] = dlfeval(@modelGradients,dlnet,dlX,dlY);

        % Determine learning rate for time-based decay learning rate schedule.
        learnRate = initialLearnRate/(1 + decay*iteration);

        % Update the network parameters using the Adam optimizer.
        [dlnet,averageGrad,averageSqGrad] = adamupdate(dlnet,gradients,averageGrad,averageSqGrad
            iteration,learnRate,gradDecay,sqGradDecay);

        % Display the training progress.
        if plots == "training-progress"
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
            title("Epoch: " + epoch + " of " + numEpochs + ", Elapsed: " + string(D))
            drawnow
        end
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on the validation set with the true labels.

After training is complete, making predictions on new data does not require the labels.

To create a `minibatchqueue` object for testing:

- Create an array datastore containing only the predictors of the test data.
- Specify the same mini-batch size used for training.
- Preprocess the predictors using the `preprocessUnlabeledSequences` helper function, listed at the end of the example.
- For the single output of the datastore, specify the mini-batch format `'CTB'` (channel, time, batch).

```
dsXValidation = arrayDatastore(sequencesValidation,'OutputType','same');
mbqTest = minibatchqueue(dsXValidation, ...
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFcn',@preprocessUnlabeledSequences, ...
    'MiniBatchFormat','CTB');
```

Loop over the mini-batches and classify the images using the `modelPredictions` helper function, listed at the end of the example.

```
predictions = modelPredictions(dlnet,mbqTest,classes);
```

Evaluate the classification accuracy by comparing the predicted labels to the true validation labels.

```
accuracy = mean(predictions == labelsValidation)
```

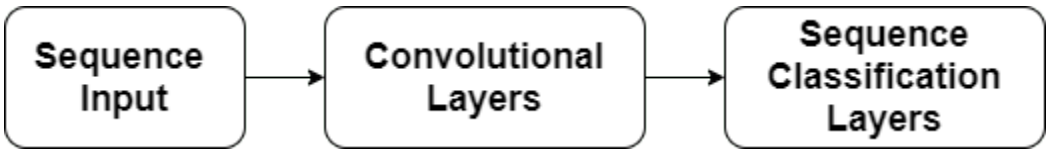
```
accuracy = 0.6721
```

Assemble Video Classification Network

To create a network that classifies videos directly, assemble a network using layers from both of the created networks. Use the layers from the convolutional network to transform the videos into vector sequences and the layers from the sequence classification network to classify the vector sequences.

The following diagram illustrates the network architecture:

- To input image sequences to the network, use a sequence input layer.
- To use convolutional layers to extract features, that is, to apply the convolutional operations to each frame of the videos independently, use the GoogLeNet convolutional layers.
- To classify the resulting vector sequences, include the sequence classification layers.



When training this type of network with the `trainNetwork` function (not done in this example), you have to use sequence folding and unfolding layers to process the video frames independently. When training this type of network with a `dlnetwork` object and a custom training loop (as in this example), sequence folding and unfolding layers are not required because the network uses dimension information given by the `dlarray` dimension labels.

Add Convolutional Layers

First, create a layer graph of the GoogLeNet network.

```
cnnLayers = layerGraph(netCNN);
```

Remove the input layer (`"data"`) and the layers after the pooling layer used for the activations (`"pool5-drop_7x7_s1"`, `"loss3-classifier"`, `"prob"`, and `"output"`).

```
layerNames = ["data" "pool5-drop_7x7_s1" "loss3-classifier" "prob" "output"];
cnnLayers = removeLayers(cnnLayers,layerNames);
```

Add Sequence Input Layer

Create a sequence input layer that accepts image sequences containing images of the same input size as the GoogLeNet network. To normalize the images using the same average image as the GoogLeNet network, set the `'Normalization'` option of the sequence input layer to `'zerocenter'` and the `'Mean'` option to the average image of the input layer of GoogLeNet.

```
inputSize = netCNN.Layers(1).InputSize(1:2);
averageImage = netCNN.Layers(1).Mean;
```

```
inputLayer = sequenceInputLayer([inputSize 3], ...
    'Normalization','zerocenter', ...
    'Mean',averageImage, ...
    'Name','input');
```

Add the sequence input layer to the layer graph. Connect the output of the input layer to the input of the first convolutional layer (`"conv1-7x7_s2"`).

```
lgraph = addLayers(cnnLayers,inputLayer);
lgraph = connectLayers(lgraph,"input","conv1-7x7_s2");
```

Add Sequence Classification Layers

Add the previously trained sequence classification network layers to the layer graph and connect them.

Take the layers from the sequence classification network and remove the sequence input layer.

```
lstmLayers = dlnet.Layers;
lstmLayers(1) = [];
```

Add the sequence classification layers to the layer graph. Connect the last convolutional layer `pool5-7x7_s1` to the `bilstm` layer.

```
lgraph = addLayers(lgraph,lstmLayers);
lgraph = connectLayers(lgraph,"pool5-7x7_s1","bilstm");
```

Convert to `dlnetwork`

To be able to do predictions, convert the layer graph to a `dlnetwork` object.

```
dlnetAssembled = dlnetwork(lgraph)
```

```
dlnetAssembled =
  dlnetwork with properties:

         Layers: [144×1 nnet.cnn.layer.Layer]
    Connections: [170×2 table]
     Learnables: [119×3 table]
          State: [2×3 table]
     InputNames: {'input'}
    OutputNames: {'softmax'}
    Initialized: 1
```

Classify Using New Data

Unzip the file `pushup_mathworker.zip`.

```
unzip("pushup_mathworker.zip")
```

The extracted `pushup_mathworker` folder contains a video of a push-up. Create a file datastore for this folder. Use a custom read function to read the videos.

```
ds = fileDatastore("pushup_mathworker", ...
    'ReadFcn',@readVideo);
```

Read the first video from the datastore. To be able to read the video again, reset the datastore.

```
video = read(ds);
reset(ds);
```

To view the video, loop over the individual frames and use the `image` function. Alternatively, you can use the `implay` function (requires Image Processing Toolbox).

```
numFrames = size(video,4);
figure
for i = 1:numFrames
    frame = video(:,:,:,i);
    image(frame);
    xticklabels([]);
    yticklabels([]);
    drawnow
end
```

To preprocess the videos to have the input size expected by the network, use the `transform` function and apply the `imresize` function to each image in the datastore.

```
dsXTest = transform(ds,@(x) imresize(x,inputSize));
```

To manage and process the unlabeled videos, create a `minibatchqueue`:

- Specify a mini-batch size of 1.
- Preprocess the videos using the `preprocessUnlabeledVideos` helper function, listed at the end of the example.
- For the single output of the datastore, specify the mini-batch format `'SSCTB'` (spatial, spatial, channel, time, batch).

```
mbqTest = minibatchqueue(dsXTest,...
    'MiniBatchSize',1,...
    'MiniBatchFcn', @preprocessUnlabeledVideos,...
    'MiniBatchFormat',{'SSCTB'});
```

Classify the videos using the `modelPredictions` helper function, defined at the end of this example. The function expects three inputs: a `dlnetwork` object, a `minibatchqueue` object, and a cell array containing the network classes.

```
[predictions] = modelPredictions(dlnetAssembled,mbqTest,classes)
```

```
predictions = categorical
     pushup
```

Helper Functions

Video Reading Function

The `readVideo` function reads the video in `filename` and returns an *H*-by-*W*-by-*C*-by-*T* array, where *H*, *W*, *C*, and *T* are the height, width, number of channels, and number of frames of the video, respectively.

```
function video = readVideo(filename)

vr = VideoReader(filename);
H = vr.Height;
W = vr.Width;
C = 3;

% Preallocate video array
numFrames = floor(vr.Duration * vr.FrameRate);
video = zeros(H,W,C,numFrames,'uint8');

% Read frames
i = 0;
while hasFrame(vr)
    i = i + 1;
    video(:,:,:,i) = readFrame(vr);
end

% Remove unallocated frames
if size(video,4) > i
    video(:,:,:,i+1:end) = [];
end

end
```

Model Gradients Function

The `modelGradients` function takes as input a `dlnetwork` object `dlnet` and a mini-batch of input data `dlX` with corresponding labels `Y`, and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, the network state, and the loss. To compute the gradients automatically, use the `dlgradient` function.

```
function [gradients,state,loss] = modelGradients(dlnet,dlX,Y)

    [dlYPred,state] = forward(dlnet,dlX);

    loss = crossentropy(dlYPred,Y);
    gradients = dlgradient(loss,dlnet.Learnables);

end
```

Model Predictions Function

The `modelPredictions` function takes as input a `dlnetwork` object `dlnet`, a `minibatchqueue` object of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in the mini-batch queue. The function uses the `onehotdecode` function to find the predicted class with the highest score. The function returns the predicted labels.

```
function [predictions] = modelPredictions(dlnet,mbq,classes)
    predictions = [];

    while hasdata(mbq)

        % Extract a mini-batch from the minibatchqueue and pass it to the
        % network for predictions
        [dlXTest] = next(mbq);
        dlYPred = predict(dlnet,dlXTest);

        % To obtain categorical labels, one-hot decode the predictions
        YPred = onehotdecode(dlYPred,classes,1)';
        predictions = [predictions; YPred];
    end
end
```

Labeled Sequence Data Preprocessing Function

The `preprocessLabeledSequences` function preprocesses the sequence data using the following steps:

1. Use the `padsequences` function to pad the sequences in the time dimension and concatenate them in the batch dimension.
2. Extract the label data from the incoming cell array and concatenate into a categorical array.
3. One-hot encode the categorical labels into numeric arrays.
4. Transpose the array of one-hot encoded labels to match the shape of the network output.

```
function [X, Y] = preprocessLabeledSequences(XCell,YCell)
    % Pad the sequences with zeros in the second dimension (time) and concatenate along the third
    % dimension (batch)
    X = padsequences(XCell,2);

    % Extract label data from cell and concatenate
```

```
    Y = cat(1,YCell{1:end});

    % One-hot encode labels
    Y = onehotencode(Y,2);

    % Transpose the encoded labels to match the network output
    Y = Y';
end
```

Unlabeled Sequence Data Preprocessing Function

The `preprocessUnlabeledSequences` function preprocesses the sequence data using the `padsequences` function. This function pads the sequences with zeros in the time dimension and concatenates the result in the batch dimension.

```
function [X] = preprocessUnlabeledSequences(XCell)
    % Pad the sequences with zeros in the second dimension (time) and concatenate along the third
    % dimension (batch)
    X = padsequences(XCell,2);
end
```

Unlabeled Video Data Preprocessing Function

The `preprocessUnlabeledVideos` function preprocesses unlabeled video data using the `padsequences` function. This function pads the videos with zero in the time dimension and concatenates the result in the batch dimension.

```
function [X] = preprocessUnlabeledVideos(XCell)
    % Pad the sequences with zeros in the fourth dimension (time) and
    % concatenate along the fifth dimension (batch)
    X = padsequences(XCell,4);
end
```

Sequence-to-Sequence Classification Using 1-D Convolutions

This example shows how to classify each time step of sequence data using a generic temporal convolutional network (TCN).

While sequence-to-sequence tasks are commonly solved with recurrent neural network architectures, Bai et al. [1] show that convolutional neural networks can match the performance of recurrent networks on typical sequence modeling tasks or even outperform them. Potential benefits of using convolutional networks are better parallelism, better control over the receptive field size, better control of the memory footprint of the network during training, and more stable gradients. Just like recurrent networks, convolutional networks can operate on variable length input sequences and can be used to model sequence-to-sequence or sequence-to-one tasks.

In this example, you train a TCN to recognize the activity of person wearing a smartphone on the body. You train the network using time series data representing accelerometer readings in three directions.

Load Training Data

Load the Human Activity Recognition data. The data contains seven time series of sensor data obtained from a smartphone worn on the body. Each sequence has three features and varies in length. The three features correspond to accelerometer readings in three directions.

```
s = load("HumanActivityTrain.mat");
XTrain = s.XTrain;
TTrain = s.YTrain;
```

View the number of observations in the training data.

```
numObservations = numel(XTrain)
```

```
numObservations = 6
```

View the number of classes in the training data.

```
classes = categories(TTrain{1});
numClasses = numel(classes)
```

```
numClasses = 5
```

View the number of features of the training data.

```
numFeatures = size(s.XTrain{1},1)
```

```
numFeatures = 3
```

Visualize one of the training sequences in a plot. Plot the features of the first training sequence and the corresponding activity.

```
figure
for i = 1:3
    X = s.XTrain{1}(i,:);

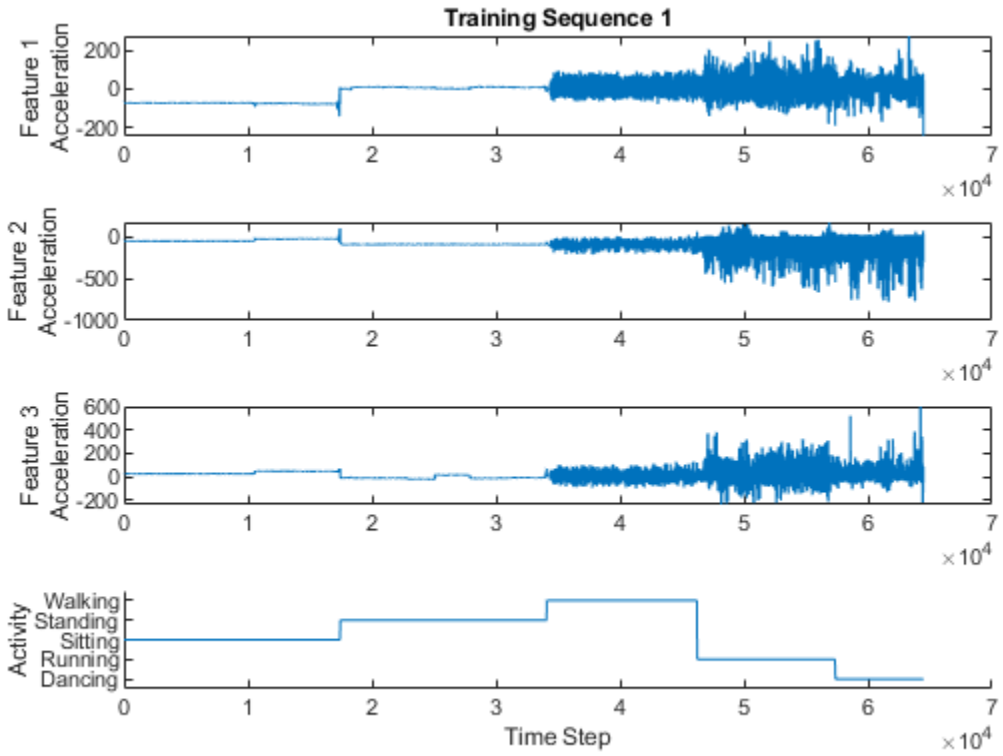
    subplot(4,1,i)
    plot(X)
    ylabel("Feature " + i + newline + "Acceleration")
end
```

```
subplot(4,1,4)

hold on
plot(s.YTrain{1})
hold off

xlabel("Time Step")
ylabel("Activity")

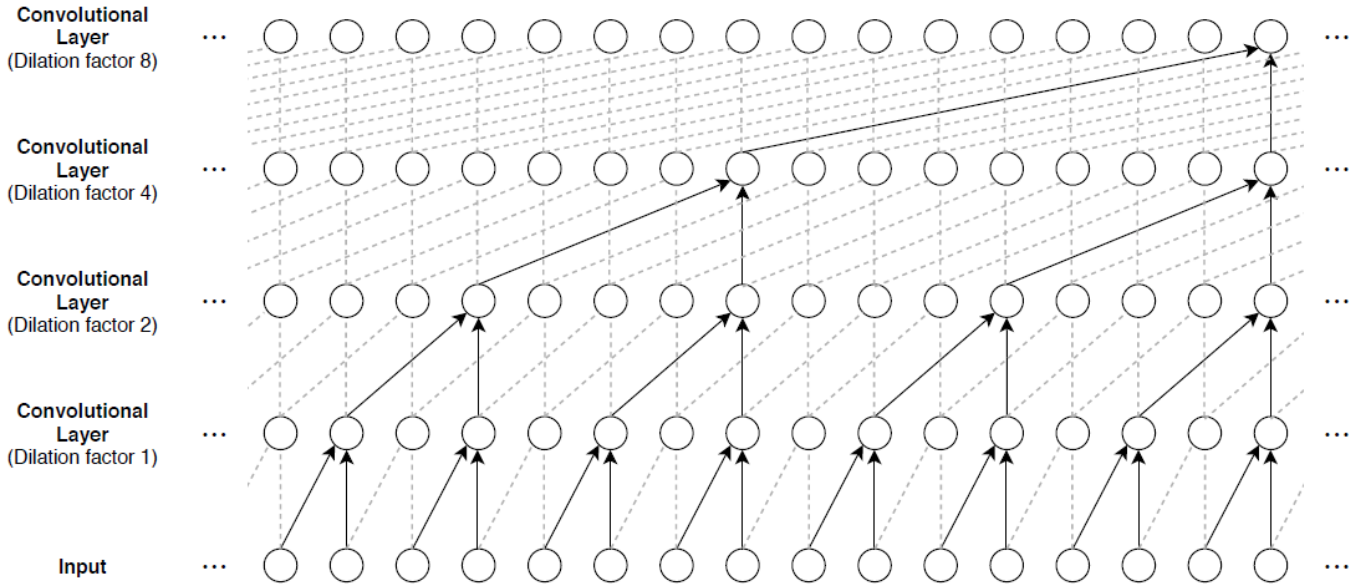
subplot(4,1,1)
title("Training Sequence 1")
```



Define Deep Learning Model

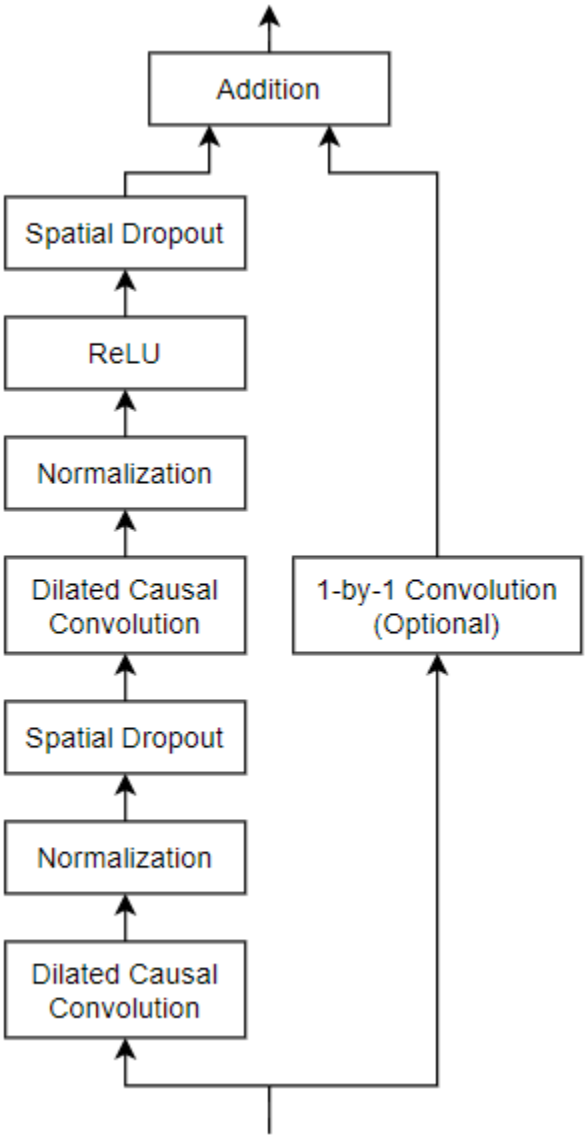
The main building block of a TCN is a dilated causal convolution layer, which operates over the time steps of each sequence. In this context, "causal" means that the activations computed for a particular time step cannot depend on activations from future time steps.

To build up context from previous time steps, multiple convolutional layers are typically stacked on top of each other. To achieve large receptive field sizes, the dilation factor of subsequent convolution layers is increased exponentially, as shown in the following image. Assuming that the dilation factor of the k-th convolutional layer is $2^{(k-1)}$ and the stride is 1, then the receptive field size of such a network can be computed as $R = (f-1)\left(2^K - 1\right) + 1$, where f is the filter size and K is the number of convolutional layers. Change the filter size and number of layers to easily adjust the receptive field size and the number of learnable parameters as necessary for the data and task at hand.



One of the disadvantages of TCNs compared to recurrent networks is that they have a larger memory footprint during inference. The entire raw sequence is required to compute the next time step. To reduce inference time and memory consumption, especially for step-ahead predictions, train with the smallest sensible receptive field size R and perform prediction only with the last R time steps of the input sequence.

The general TCN architecture (as described in [1]) consists of multiple residual blocks, each containing two sets of dilated causal convolution layers with the same dilation factor, followed by normalization, ReLU activation, and spatial dropout layers. The network adds the input of each block to the output of the block (including a 1-by-1 convolution on the input when the number of channels between the input and output do not match) and applies a final activation function.



Define a network containing four of these residual blocks in series, each with double the dilation factor of the previous layer, starting with a dilation factor of 1. For the residual blocks, specify 64 filters for the 1-D convolutional layers with a filter size of 5 and a dropout factor of 0.005 for the spatial dropout layers. For spatial dropout, use the custom layer `spatialDropoutLayer`, attached to this example as a supporting file. To access this layer, open this example as a live script.

```
numFilters = 64;
filterSize = 5;
dropoutFactor = 0.005;
numBlocks = 4;

layer = sequenceInputLayer(numFeatures,Normalization="rescale-symmetric",Name="input");
lgraph = layerGraph(layer);

outputName = layer.Name;
```

```
for i = 1:numBlocks
    dilationFactor = 2^(i-1);

    layers = [
        convolution1dLayer(filterSize,numFilters,DilationFactor=dilationFactor,Padding="causal",N
        layerNormalizationLayer
        spatialDropoutLayer(dropoutFactor)
        convolution1dLayer(filterSize,numFilters,DilationFactor=dilationFactor,Padding="causal")
        layerNormalizationLayer
        reluLayer
        spatialDropoutLayer(dropoutFactor)
        additionLayer(2,Name="add_"+i)];

    % Add and connect layers.
    lgraph = addLayers(lgraph,layers);
    lgraph = connectLayers(lgraph,outputName,"conv1_"+i);

    % Skip connection.
    if i == 1
        % Include convolution in first skip connection.
        layer = convolution1dLayer(1,numFilters,Name="convSkip");

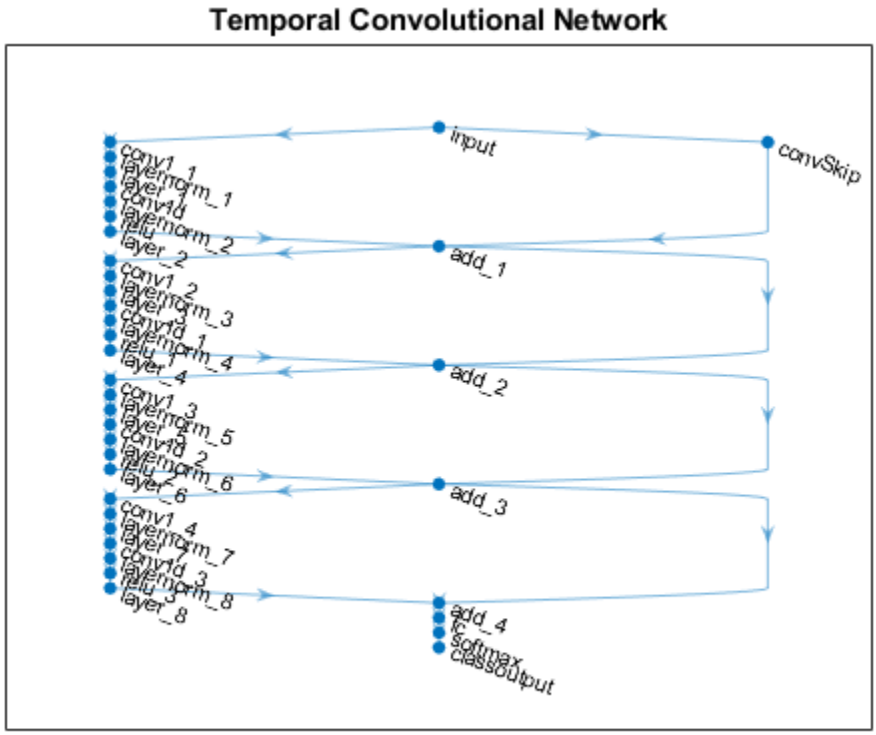
        lgraph = addLayers(lgraph,layer);
        lgraph = connectLayers(lgraph,outputName,"convSkip");
        lgraph = connectLayers(lgraph,"convSkip","add_" + i + "/in2");
    else
        lgraph = connectLayers(lgraph,outputName,"add_" + i + "/in2");
    end

    % Update layer output name.
    outputName = "add_" + i;
end

layers = [
    fullyConnectedLayer(numClasses,Name="fc")
    softmaxLayer
    classificationLayer];
lgraph = addLayers(lgraph,layers);
lgraph = connectLayers(lgraph,outputName,"fc");
```

View the network in a plot.

```
figure
plot(lgraph)
title("Temporal Convolutional Network")
```



Specify Training Options

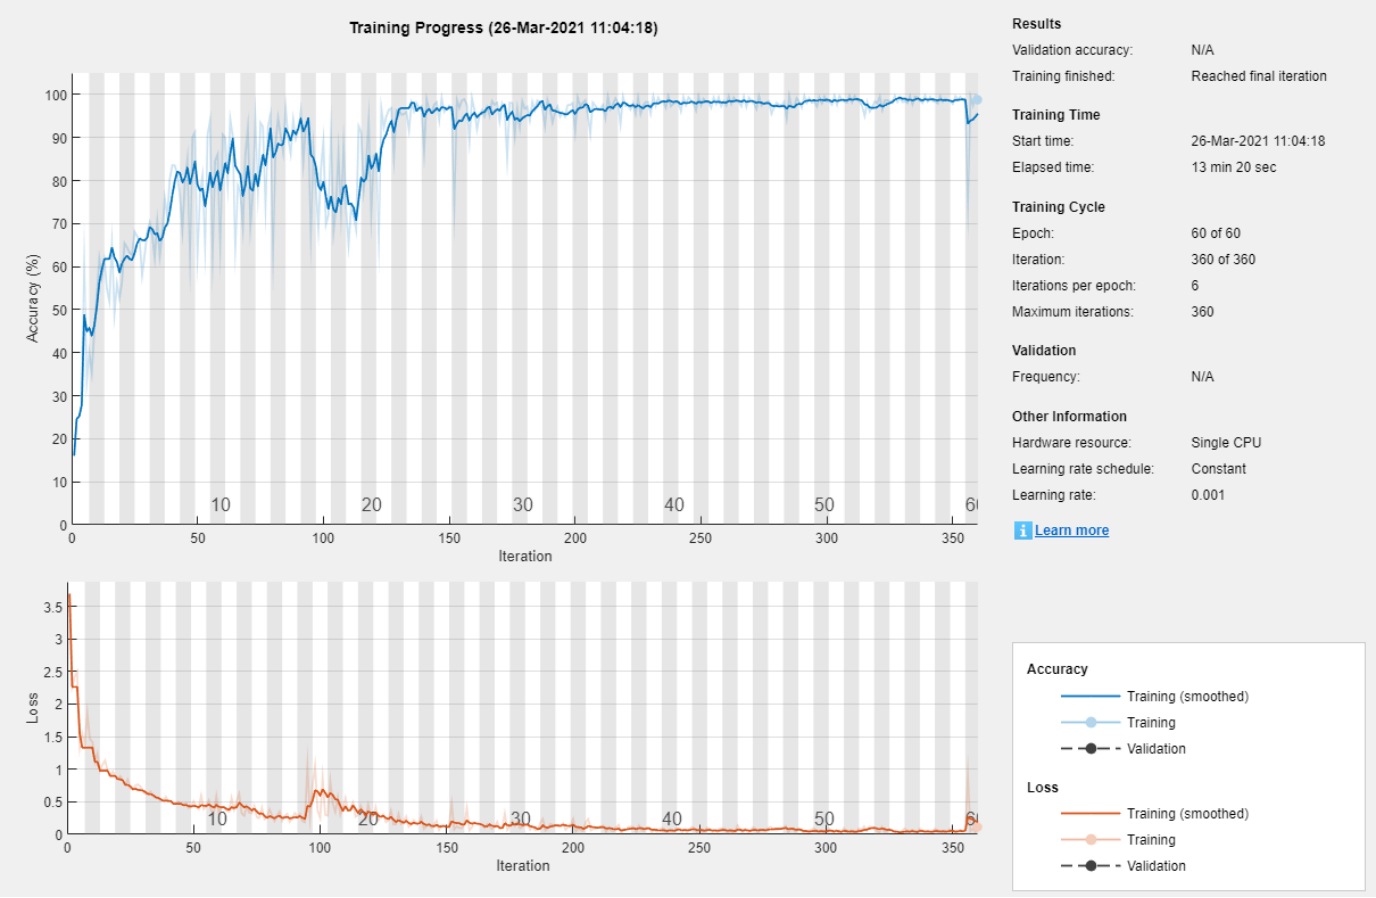
Specify a set of options used for training.

- Train for 60 epochs with a mini-batch size of 1.
- Train with a learning rate of 0.001.
- Display the training progress in a plot and suppress the verbose output.

```
options = trainingOptions("adam", ...
    MaxEpochs=60, ...
    miniBatchSize=1, ...
    Plots="training-progress", ...
    Verbose=0);
```

Train Model

```
net = trainNetwork(XTrain,TTrain,lgraph,options);
```



Test Model

Test the classification accuracy of the model by comparing the predictions on a held-out test set with the true labels for each time step.

Load the test data.

```
s = load("HumanActivityTest.mat");
XTest = s.XTest;
TTest = s.YTest;
```

Use the trained network to make predictions by using the `classify` function.

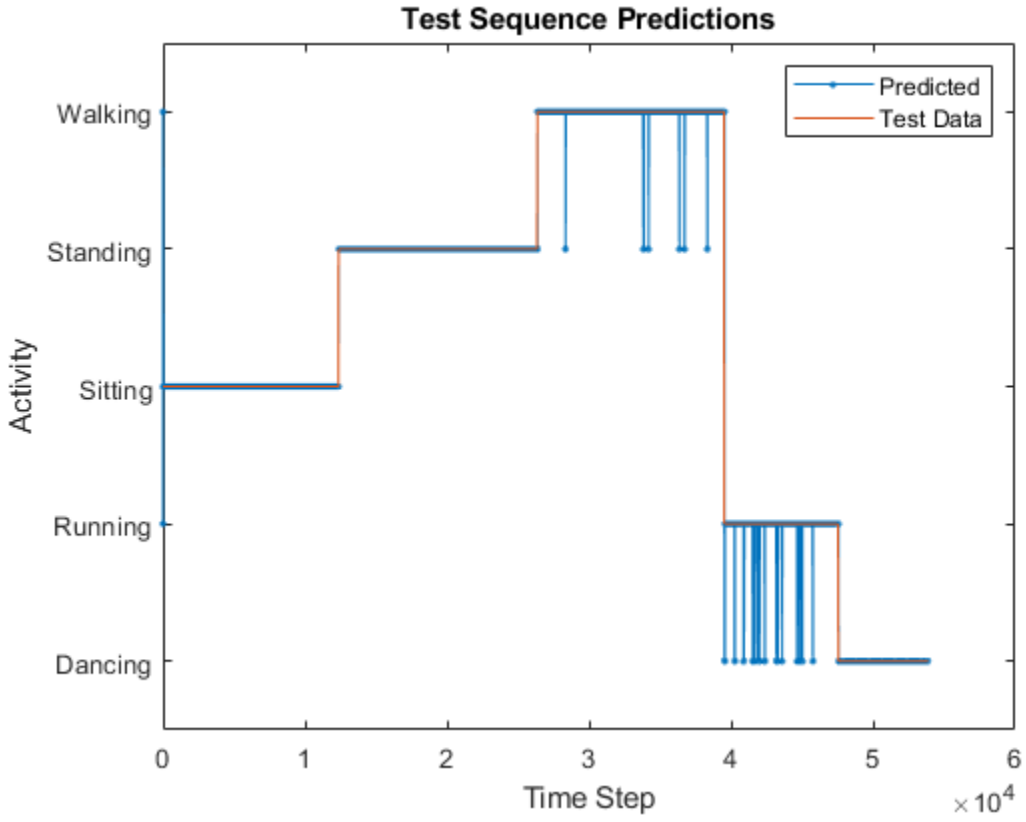
```
YPred = classify(net,XTest);
```

Compare the predictions with the corresponding test data in a plot.

```
figure
plot(YPred{1},".-")
hold on
plot(TTest{1})
hold off

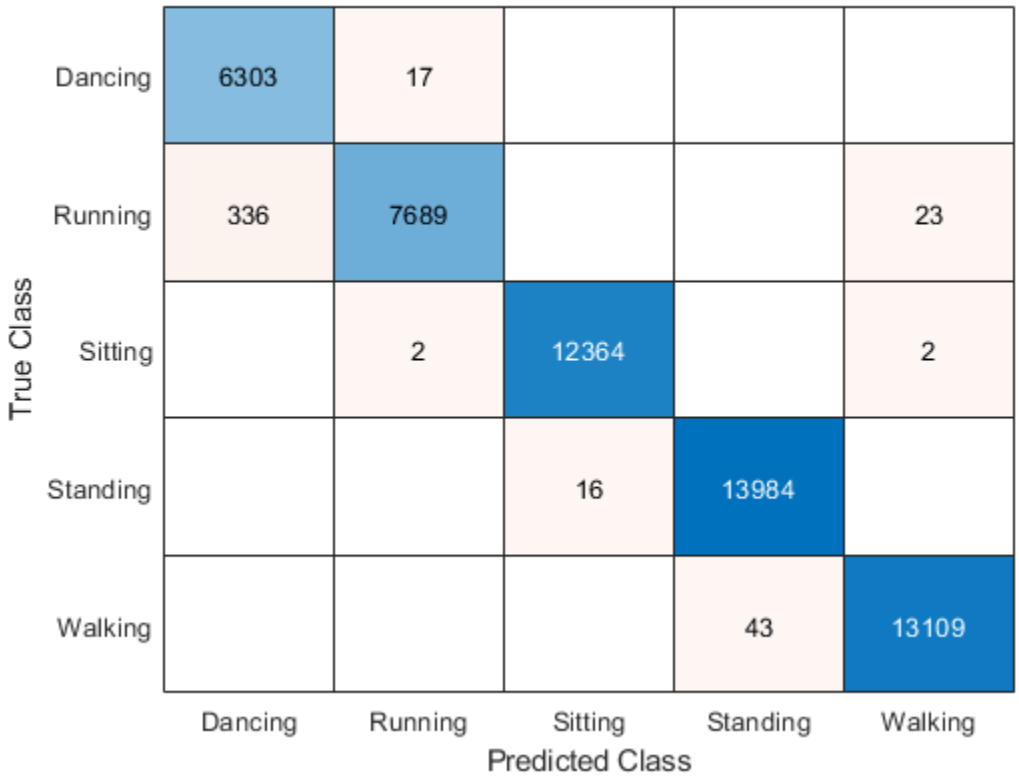
xlabel("Time Step")
ylabel("Activity")
```

```
legend(["Predicted" "Test Data"],Location="northeast")
title("Test Sequence Predictions")
```



Visualize the predictions in a confusion matrix.

```
figure
confusionchart(TTest{1},YPred{1})
```



Evaluate the classification accuracy by comparing the predictions to the test labels.

```
accuracy = mean(YPred{1} == TTest{1})
```

```
accuracy = 0.9919
```

Classify Text Data Using Deep Learning

This example shows how to classify text data using a deep learning long short-term memory (LSTM) network.

Text data is naturally sequential. A piece of text is a sequence of words, which might have dependencies between them. To learn and use long-term dependencies to classify sequence data, use an LSTM neural network. An LSTM network is a type of recurrent neural network (RNN) that can learn long-term dependencies between time steps of sequence data.

To input text to an LSTM network, first convert the text data into numeric sequences. You can achieve this using a word encoding which maps documents to sequences of numeric indices. For better results, also include a word embedding layer in the network. Word embeddings map words in a vocabulary to numeric vectors rather than scalar indices. These embeddings capture semantic details of the words, so that words with similar meanings have similar vectors. They also model relationships between words through vector arithmetic. For example, the relationship "*Rome is to Italy as* Paris *is to France*" is described by the equation Italy – *Rome* + *Paris* = *France*.

There are four steps in training and using the LSTM network in this example:

- Import and preprocess the data.
- Convert the words to numeric sequences using a word encoding.
- Create and train an LSTM network with a word embedding layer.
- Classify new text data using the trained LSTM network.

Import Data

Import the factory reports data. This data contains labeled textual descriptions of factory events. To import the text data as strings, specify the text type to be `'string'`.

```
filename = "factoryReports.csv";
data = readtable(filename,'TextType','string');
head(data)
```

```
ans=8×5 table
                                Description                                 Category
    ____________________________________________________________________    ____________

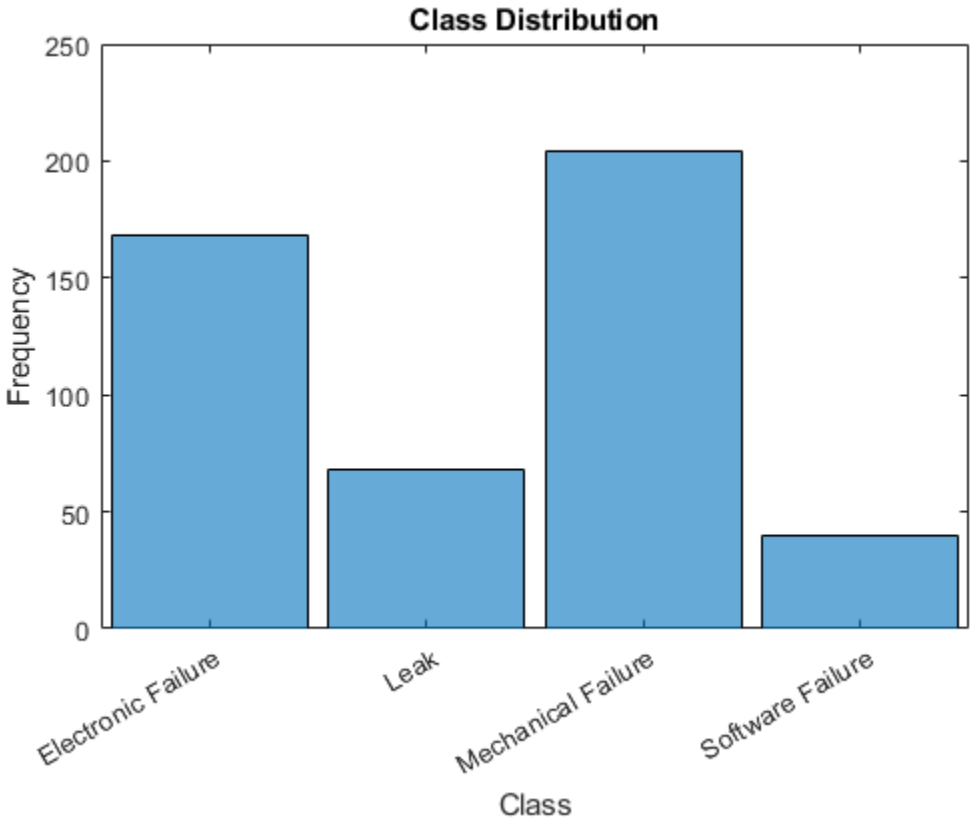
    "Items are occasionally getting stuck in the scanner spools."           "Mechanical Failure"
    "Loud rattling and banging sounds are coming from assembler pistons."   "Mechanical Failure"
    "There are cuts to the power when starting the plant."                  "Electronic Failure"
    "Fried capacitors in the assembler."                                    "Electronic Failure"
    "Mixer tripped the fuses."                                              "Electronic Failure"
    "Burst pipe in the constructing agent is spraying coolant."             "Leak"
    "A fuse is blown in the mixer."                                         "Electronic Failure"
    "Things continue to tumble off of the belt."                            "Mechanical Failure"
```

The goal of this example is to classify events by the label in the `Category` column. To divide the data into classes, convert these labels to categorical.

```
data.Category = categorical(data.Category);
```

View the distribution of the classes in the data using a histogram.

```
figure
histogram(data.Category);
xlabel("Class")
ylabel("Frequency")
title("Class Distribution")
```



The next step is to partition it into sets for training and validation. Partition the data into a training partition and a held-out partition for validation and testing. Specify the holdout percentage to be 20%.

```
cvp = cvpartition(data.Category,'Holdout',0.2);
dataTrain = data(training(cvp),:);
dataValidation = data(test(cvp),:);
```

Extract the text data and labels from the partitioned tables.

```
textDataTrain = dataTrain.Description;
textDataValidation = dataValidation.Description;
YTrain = dataTrain.Category;
YValidation = dataValidation.Category;
```

To check that you have imported the data correctly, visualize the training text data using a word cloud.

```
figure
wordcloud(textDataTrain);
title("Training Data")
```

Preprocess Text Data

Create a function that tokenizes and preprocesses the text data. The function `preprocessText`, listed at the end of the example, performs these steps:

1. Tokenize the text using `tokenizedDocument`.
2. Convert the text to lowercase using `lower`.
3. Erase the punctuation using `erasePunctuation`.

Preprocess the training data and the validation data using the `preprocessText` function.

```
documentsTrain = preprocessText(textDataTrain);
documentsValidation = preprocessText(textDataValidation);
```

View the first few preprocessed training documents.

```
documentsTrain(1:5)
```

```
ans =
  5×1 tokenizedDocument:

     9 tokens: items are occasionally getting stuck in the scanner spools
    10 tokens: loud rattling and banging sounds are coming from assembler pistons
    10 tokens: there are cuts to the power when starting the plant
     5 tokens: fried capacitors in the assembler
     4 tokens: mixer tripped the fuses
```

Convert Document to Sequences

To input the documents into an LSTM network, use a word encoding to convert the documents into sequences of numeric indices.

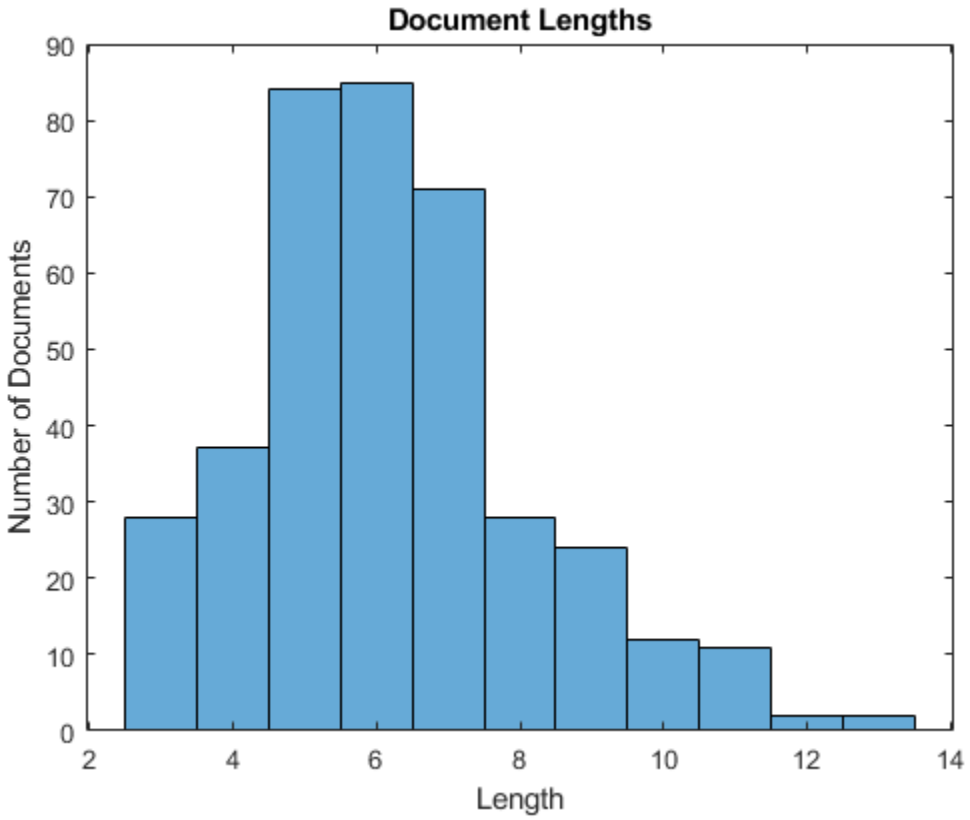
To create a word encoding, use the `wordEncoding` function.

```
enc = wordEncoding(documentsTrain);
```

The next conversion step is to pad and truncate documents so they are all the same length. The `trainingOptions` function provides options to pad and truncate input sequences automatically. However, these options are not well suited for sequences of word vectors. Instead, pad and truncate the sequences manually. If you *left-pad* and truncate the sequences of word vectors, then the training might improve.

To pad and truncate the documents, first choose a target length, and then truncate documents that are longer than it and left-pad documents that are shorter than it. For best results, the target length should be short without discarding large amounts of data. To find a suitable target length, view a histogram of the training document lengths.

```
documentLengths = doclength(documentsTrain);
figure
histogram(documentLengths)
title("Document Lengths")
xlabel("Length")
ylabel("Number of Documents")
```



Most of the training documents have fewer than 10 tokens. Use this as your target length for truncation and padding.

Convert the documents to sequences of numeric indices using `doc2sequence`. To truncate or left-pad the sequences to have length 10, set the `'Length'` option to 10.

```
sequenceLength = 10;
XTrain = doc2sequence(enc,documentsTrain,'Length',sequenceLength);
XTrain(1:5)
```

```
ans=5×1 cell array
    {1×10 double}
    {1×10 double}
    {1×10 double}
    {1×10 double}
    {1×10 double}
```

Convert the validation documents to sequences using the same options.

```
XValidation = doc2sequence(enc,documentsValidation,'Length',sequenceLength);
```

Create and Train LSTM Network

Define the LSTM network architecture. To input sequence data into the network, include a sequence input layer and set the input size to 1. Next, include a word embedding layer of dimension 50 and the same number of words as the word encoding. Next, include an LSTM layer and set the number of hidden units to 80. To use the LSTM layer for a sequence-to-label classification problem, set the output mode to `'last'`. Finally, add a fully connected layer with the same size as the number of classes, a softmax layer, and a classification layer.

```
inputSize = 1;
embeddingDimension = 50;
numHiddenUnits = 80;

numWords = enc.NumWords;
numClasses = numel(categories(YTrain));

layers = [ ...
    sequenceInputLayer(inputSize)
    wordEmbeddingLayer(embeddingDimension,numWords)
    lstmLayer(numHiddenUnits,'OutputMode','last')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer]
```

```
layers =
  6x1 Layer array with layers:

     1   ''   Sequence Input          Sequence input with 1 dimensions
     2   ''   Word Embedding Layer    Word embedding layer with 50 dimensions and 423 unique word
     3   ''   LSTM                   LSTM with 80 hidden units
     4   ''   Fully Connected         4 fully connected layer
     5   ''   Softmax                softmax
     6   ''   Classification Output   crossentropyex
```

Specify Training Options

Specify the training options:

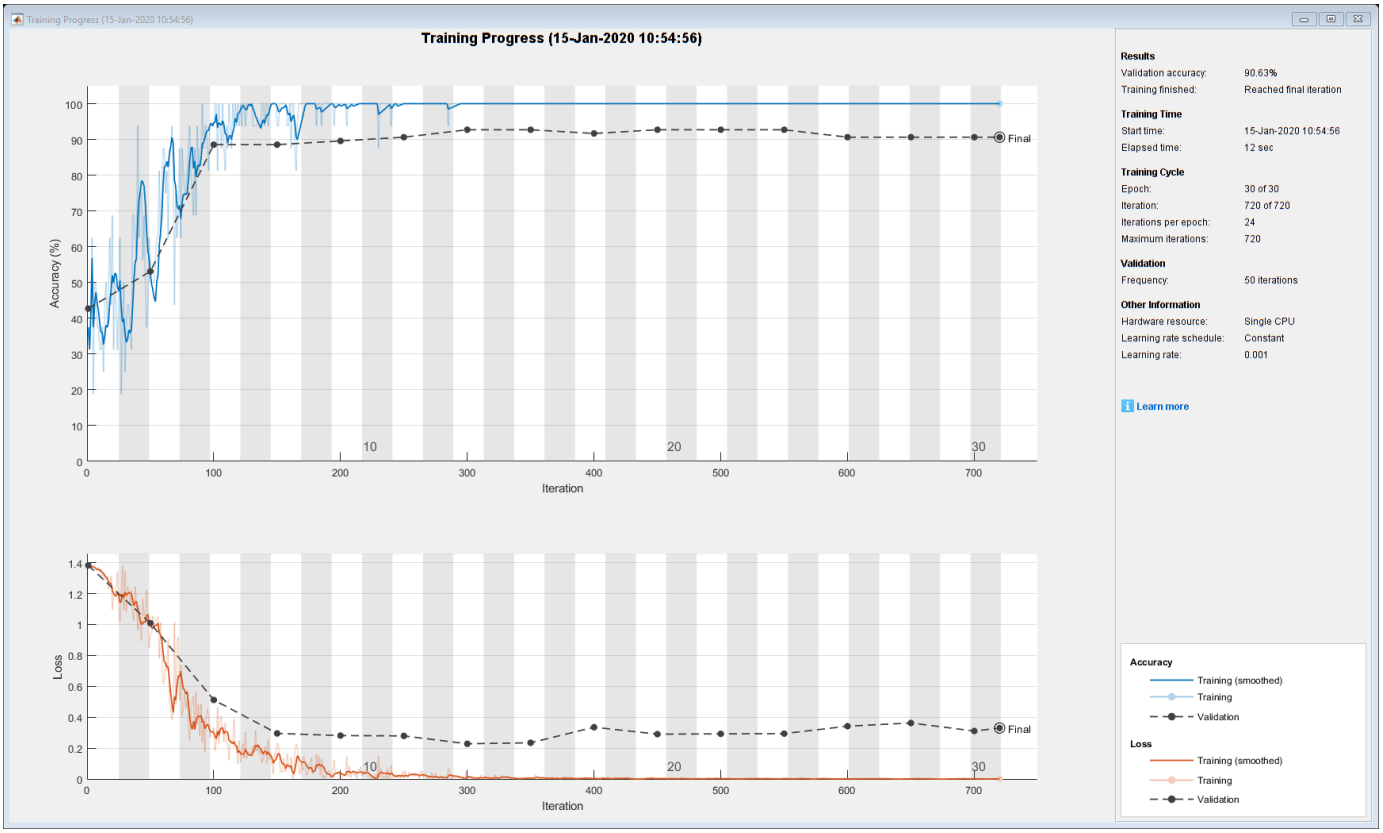
- Train using the Adam solver.
- Specify a mini-batch size of 16.
- Shuffle the data every epoch.
- Monitor the training progress by setting the `'Plots'` option to `'training-progress'`.
- Specify the validation data using the `'ValidationData'` option.
- Suppress verbose output by setting the `'Verbose'` option to `false`.

By default, `trainNetwork` uses a GPU if one is available. Otherwise, it uses the CPU. To specify the execution environment manually, use the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`. Training on a CPU can take significantly longer than training on a GPU. Training with a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
options = trainingOptions('adam', ...
    'MiniBatchSize',16, ...
    'GradientThreshold',2, ...
    'Shuffle','every-epoch', ...
    'ValidationData',{XValidation,YValidation}, ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the LSTM network using the `trainNetwork` function.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```



Predict Using New Data

Classify the event type of three new reports. Create a string array containing the new reports.

```
reportsNew = [ ...
    "Coolant is pooling underneath sorter."
    "Sorter blows fuses at start up."
    "There are some very loud rattling sounds coming from the assembler."];
```

Preprocess the text data using the preprocessing steps as the training documents.

```
documentsNew = preprocessText(reportsNew);
```

Convert the text data to sequences using `doc2sequence` with the same options as when creating the training sequences.

```
XNew = doc2sequence(enc,documentsNew,'Length',sequenceLength);
```

Classify the new sequences using the trained LSTM network.

```
labelsNew = classify(net,XNew)
```

```
labelsNew = 3×1 categorical
     Leak
     Electronic Failure
     Mechanical Failure
```

Preprocessing Function

The function `preprocessText` performs these steps:

1. Tokenize the text using `tokenizedDocument`.
2. Convert the text to lowercase using `lower`.
3. Erase the punctuation using `erasePunctuation`.

```
function documents = preprocessText(textData)

% Tokenize the text.
documents = tokenizedDocument(textData);

% Convert to lowercase.
documents = lower(documents);

% Erase punctuation.
documents = erasePunctuation(documents);

end
```

Classify Text Data Using Convolutional Neural Network

This example shows how to classify text data using a convolutional neural network.

To classify text data using convolutions, you must convert the text data into images. To do this, pad or truncate the observations to have constant length S and convert the documents into sequences of word vectors of length C using a word embedding. You can then represent a document as a 1-by-S-by-C image (an image with height 1, width S, and C channels).

To convert text data from a CSV file to images, create a `tabularTextDatastore` object. The convert the data read from the `tabularTextDatastore` object to images for deep learning by calling `transform` with a custom transformation function. The `transformTextData` function, listed at the end of the example, takes data read from the datastore and a pretrained word embedding, and converts each observation to an array of word vectors.

This example trains a network with 1-D convolutional filters of varying widths. The width of each filter corresponds the number of words the filter can see (the n-gram length). The network has multiple branches of convolutional layers, so it can use different n-gram lengths.

Load Pretrained Word Embedding

Load the pretrained fastText word embedding. This function requires the Text Analytics Toolbox™ Model *for fastText English 16 Billion Token Word Embedding* support package. If this support package is not installed, then the function provides a download link.

```
emb = fastTextWordEmbedding;
```

Load Data

Create a tabular text datastore from the data in `factoryReports.csv`. Read the data from the `"Description"` and `"Category"` columns only.

```
filenameTrain = "factoryReports.csv";
textName = "Description";
labelName = "Category";
ttdsTrain = tabularTextDatastore(filenameTrain,'SelectedVariableNames',[textName labelName]);
```

Preview the datastore.

```
ttdsTrain.ReadSize = 8;
preview(ttdsTrain)
```

```
ans=8×2 table
                                Description                                                Category
    ____________________________________________________________________________    ____________________

    {'Items are occasionally getting stuck in the scanner spools.'        }    {'Mechanical Failu
    {'Loud rattling and banging sounds are coming from assembler pistons.'}    {'Mechanical Failu
    {'There are cuts to the power when starting the plant.'               }    {'Electronic Failu
    {'Fried capacitors in the assembler.'                                 }    {'Electronic Failu
    {'Mixer tripped the fuses.'                                           }    {'Electronic Failu
    {'Burst pipe in the constructing agent is spraying coolant.'          }    {'Leak'
    {'A fuse is blown in the mixer.'                                      }    {'Electronic Failu
    {'Things continue to tumble off of the belt.'                         }    {'Mechanical Failu
```

Create a custom transform function that converts data read from the datastore to a table containing the predictors and the responses. The `transformTextData` function, listed at the end of the example, takes the data read from a `tabularTextDatastore` object and returns a table of predictors and responses. The predictors are 1-by-`sequenceLength`-by-*C* arrays of word vectors given by the word embedding `emb`, where *C* is the embedding dimension. The responses are categorical labels over the classes in `classNames`.

Read the labels from the training data using the `readLabels` function, listed at the end of the example, and find the unique class names.

```
labels = readLabels(ttdsTrain,labelName);
classNames = unique(labels);
numObservations = numel(labels);
```

Transform the datastore using `transformTextData` function and specify a sequence length of 14.

```
sequenceLength = 14;
tdsTrain = transform(ttdsTrain, @(data) transformTextData(data,sequenceLength,emb,classNames))
```

```
tdsTrain =
  TransformedDatastore with properties:

       UnderlyingDatastore: [1×1 matlab.io.datastore.TabularTextDatastore]
    SupportedOutputFormats: ["txt"    "csv"    "xlsx"    "xls"    "parquet"    "parq"    "png"
                Transforms: {@(data)transformTextData(data,sequenceLength,emb,classNames)}
              IncludeInfo: 0
```

Preview the transformed datastore. The predictors are 1-by-*S*-by-*C* arrays, where *S* is the sequence length and *C* is the number of features (the embedding dimension). The responses are the categorical labels.

```
preview(tdsTrain)
```

```
ans=8×2 table
       Predictors            Responses

Define Network Architecture

Define the network architecture for the classification task.

The following steps describe the network architecture.

- Specify an input size of 1-by-*S*-by-*C*, where *S* is the sequence length and *C* is the number of features (the embedding dimension).
- For the n-gram lengths 2, 3, 4, and 5, create blocks of layers containing a convolutional layer, a batch normalization layer, a ReLU layer, a dropout layer, and a max pooling layer.

- For each block, specify 200 convolutional filters of size 1-by-*N* and pooling regions of size 1-by-*S*, where *N* is the n-gram length.
- Connect the input layer to each block and concatenate the outputs of the blocks using a depth concatenation layer.
- To classify the outputs, include a fully connected layer with output size *K*, a softmax layer, and a classification layer, where *K* is the number of classes.

First, in a layer array, specify the input layer, the first block for unigrams, the depth concatenation layer, the fully connected layer, the softmax layer, and the classification layer.

```
numFeatures = emb.Dimension;
inputSize = [1 sequenceLength numFeatures];
numFilters = 200;

ngramLengths = [2 3 4 5];
numBlocks = numel(ngramLengths);

numClasses = numel(classNames);
```

Create a layer graph containing the input layer. Set the normalization option to `'none'` and the layer name to `'input'`.

```
layer = imageInputLayer(inputSize,'Normalization','none','Name','input');
lgraph = layerGraph(layer);
```

For each of the n-gram lengths, create a block of convolution, batch normalization, ReLU, dropout, and max pooling layers. Connect each block to the input layer.

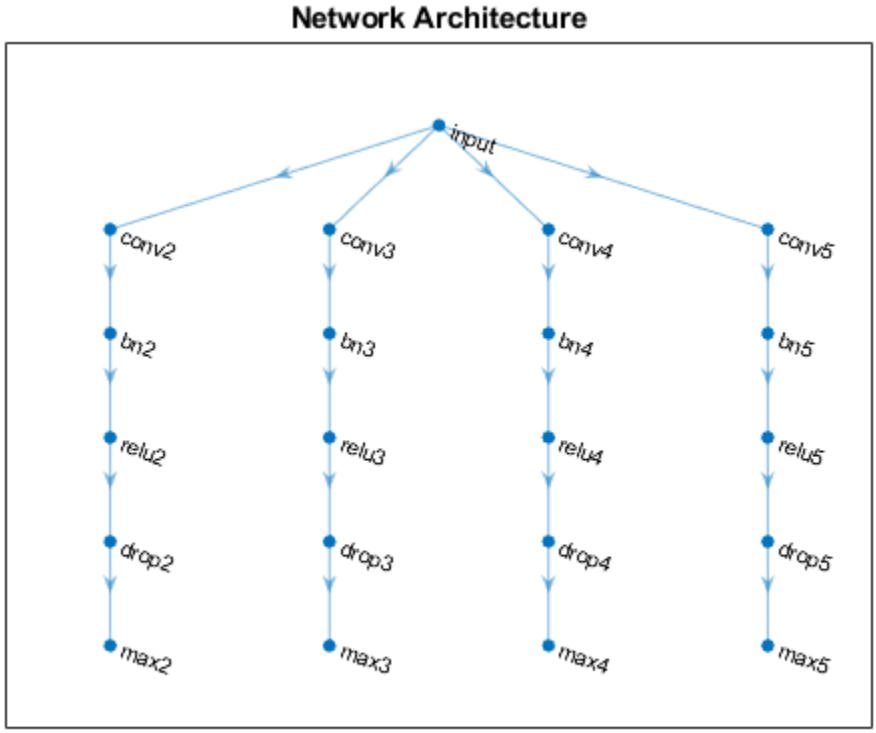
```
for j = 1:numBlocks
    N = ngramLengths(j);

    block = [
        convolution2dLayer([1 N],numFilters,'Name',"conv"+N,'Padding','same')
        batchNormalizationLayer('Name',"bn"+N)
        reluLayer('Name',"relu"+N)
        dropoutLayer(0.2,'Name',"drop"+N)
        maxPooling2dLayer([1 sequenceLength],'Name',"max"+N)];

    lgraph = addLayers(lgraph,block);
    lgraph = connectLayers(lgraph,'input',"conv"+N);
end
```

View the network architecture in a plot.

```
figure
plot(lgraph)
title("Network Architecture")
```

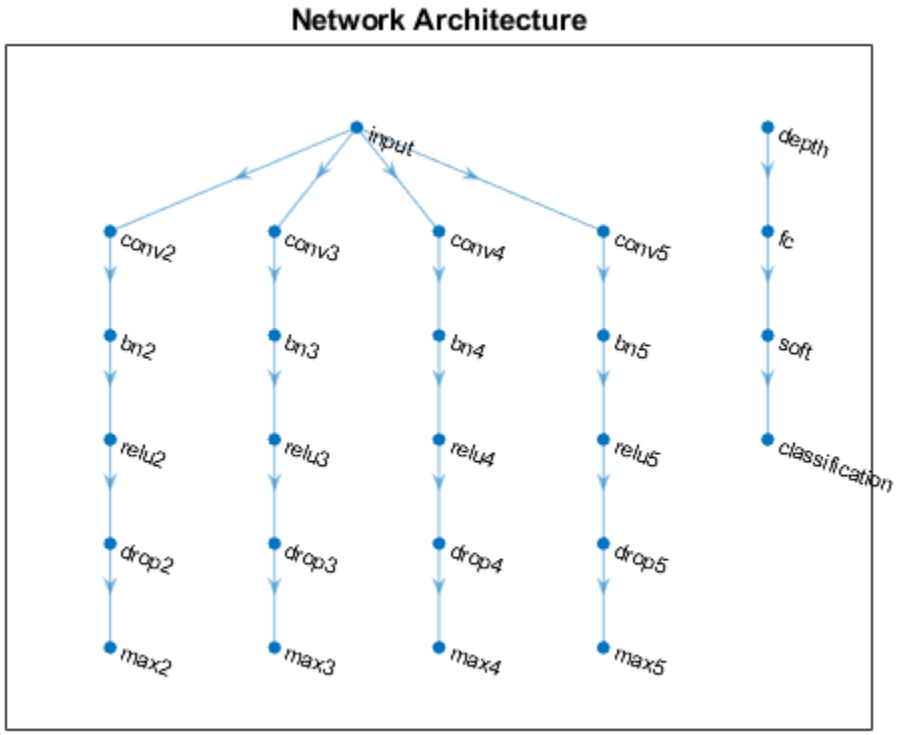


Add the depth concatenation layer, the fully connected layer, the softmax layer, and the classification layer.

```
layers = [
    depthConcatenationLayer(numBlocks,'Name','depth')
    fullyConnectedLayer(numClasses,'Name','fc')
    softmaxLayer('Name','soft')
    classificationLayer('Name','classification')];

lgraph = addLayers(lgraph,layers);

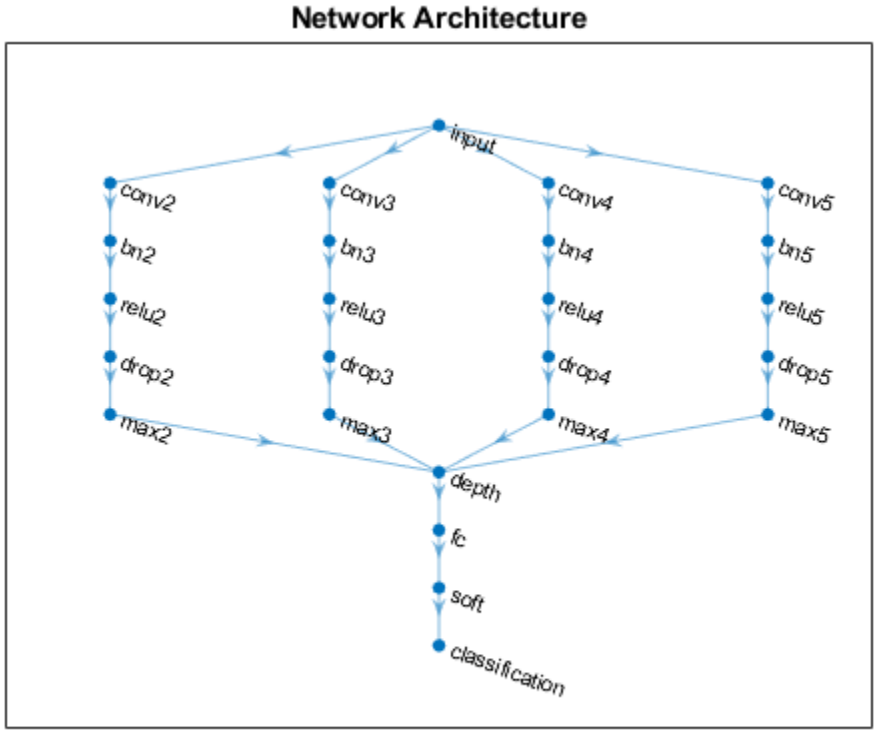
figure
plot(lgraph)
title("Network Architecture")
```



Connect the max pooling layers to the depth concatenation layer and view the final network architecture in a plot.

```
for j = 1:numBlocks
    N = ngramLengths(j);
    lgraph = connectLayers(lgraph,"max"+N,"depth/in"+j);
end

figure
plot(lgraph)
title("Network Architecture")
```



Train Network

Specify the training options:

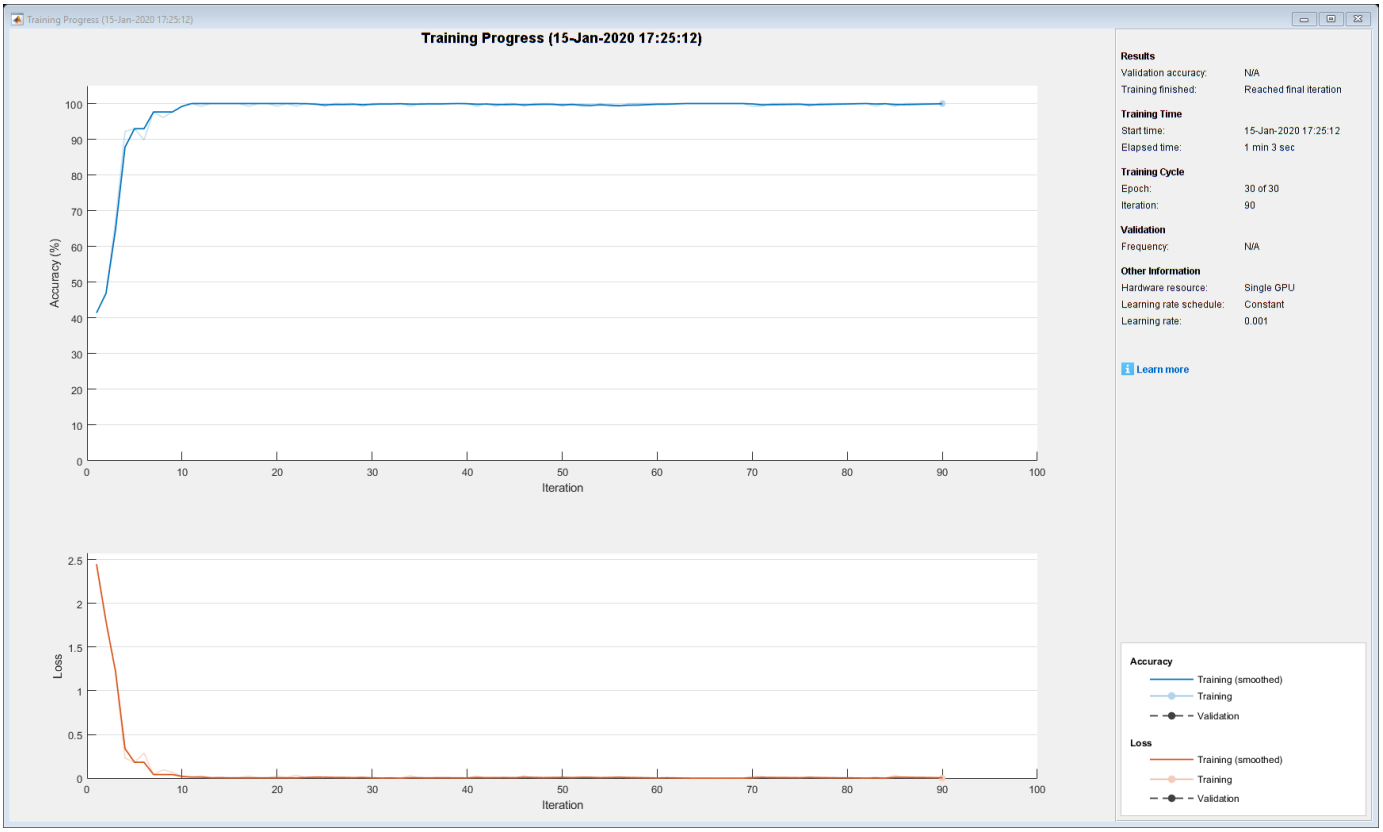
- Train with a mini-batch size of 128.
- Do not shuffle the data because the datastore is not shuffleable.
- Display the training progress plot and suppress the verbose output.

```
miniBatchSize = 128;
numIterationsPerEpoch = floor(numObservations/miniBatchSize);

options = trainingOptions('adam', ...
    'MiniBatchSize',miniBatchSize, ...
    'Shuffle','never', ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the network using the `trainNetwork` function.

```
net = trainNetwork(tdsTrain,lgraph,options);
```



Predict Using New Data

Classify the event type of three new reports. Create a string array containing the new reports.

```
reportsNew = [
    "Coolant is pooling underneath sorter."
    "Sorter blows fuses at start up."
    "There are some very loud rattling sounds coming from the assembler."];
```

Preprocess the text data using the preprocessing steps as the training documents.

```
XNew = preprocessText(reportsNew,sequenceLength,emb);
```

Classify the new sequences using the trained LSTM network.

```
labelsNew = classify(net,XNew)
```

```
labelsNew = 3×1 categorical
     Leak
     Electronic Failure
     Mechanical Failure
```

Read Labels Function

The `readLabels` function creates a copy of the `tabularTextDatastore` object `ttds` and reads the labels from the `labelName` column.

```
function labels = readLabels(ttds,labelName)
```

```
ttdsNew = copy(ttds);
ttdsNew.SelectedVariableNames = labelName;
tbl = readall(ttdsNew);
labels = tbl.(labelName);

end
```

Transform Text Data Function

The `transformTextData` function takes the data read from a `tabularTextDatastore` object and returns a table of predictors and responses. The predictors are 1-by-`sequenceLength`-by-*C* arrays of word vectors given by the word embedding `emb`, where *C* is the embedding dimension. The responses are categorical labels over the classes in `classNames`.

```
function dataTransformed = transformTextData(data,sequenceLength,emb,classNames)

% Preprocess documents.
textData = data{:,1};

% Prepocess text
dataTransformed = preprocessText(textData,sequenceLength,emb);

% Read labels.
labels = data{:,2};
responses = categorical(labels,classNames);

% Convert data to table.
dataTransformed.Responses = responses;

end
```

Preprocess Text Function

The `preprocessTextData` function takes text data, a sequence length, and a word embedding and performs these steps:

1. Tokenize the text.
2. Convert the text to lowercase.
3. Converts the documents to sequences of word vectors of the specified length using the embedding.
4. Reshapes the word vector sequences to input into the network.

```
function tbl = preprocessText(textData,sequenceLength,emb)

documents = tokenizedDocument(textData);
documents = lower(documents);

% Convert documents to embeddingDimension-by-sequenceLength-by-1 images.
predictors = doc2sequence(emb,documents,'Length',sequenceLength);

% Reshape images to be of size 1-by-sequenceLength-embeddingDimension.
predictors = cellfun(@(X) permute(X,[3 2 1]),predictors,'UniformOutput',false);

tbl = table;
tbl.Predictors = predictors;
```

```
end
```

Multilabel Text Classification Using Deep Learning

This example shows how to classify text data that has multiple independent labels.

For classification tasks where there can be multiple independent labels for each observation—for example, tags on an scientific article—you can train a deep learning model to predict probabilities for each independent class. To enable a network to learn multilabel classification targets, you can optimize the loss of each class independently using binary cross-entropy loss.

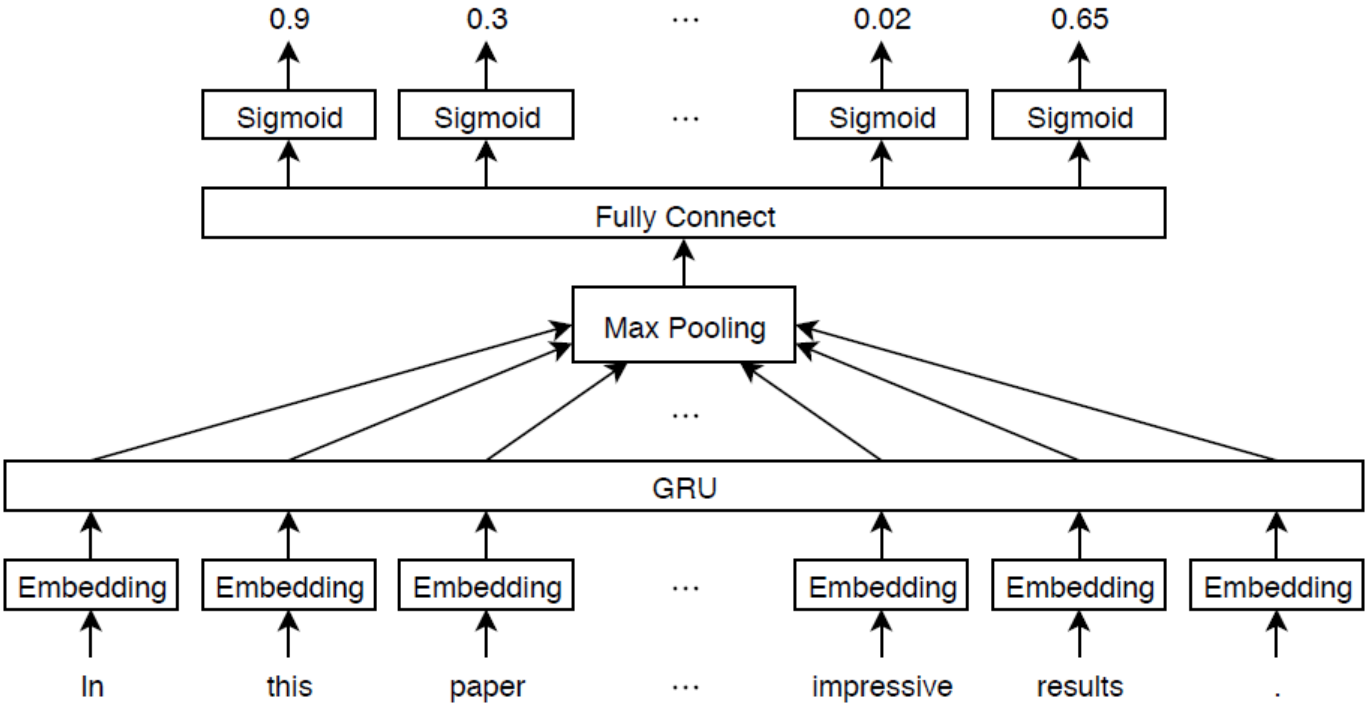
This example defines a deep learning model that classifies subject areas given the abstracts of mathematical papers collected using the arXiv API [1]. The model consists of a word embedding and GRU, max pooling operation, fully connected, and sigmoid operations.

To measure the performance of multilabel classification, you can use the labeling F-score [2]. The labeling F-score evaluates multilabel classification by focusing on per-text classification with partial matches. The measure is the normalized proportion of matching labels against the total number of true and predicted labels.

This example defines the following model:

- A word embedding that maps a sequence of words to a sequence of numeric vectors.
- A GRU operation that learns dependencies between the embedding vectors.
- A max pooling operation that reduces a sequence of feature vectors to a single feature vector.
- A fully connected layer that maps the features to the binary outputs.
- A sigmoid operation for learning the binary cross entropy loss between the outputs and the target labels.

This diagram shows a piece of text propagating through the model architecture and outputting a vector of probabilities. The probabilities are independent, so they need not sum to one.



Import Text Data

Import a set of abstracts and category labels from math papers using the arXiv API. Specify the number of records to import using the `importSize` variable.

```
importSize = 50000;
```

Create a URL that queries records with set `"math"` and metadata prefix `"arXiv"`.

```
url = "https://export.arxiv.org/oai2?verb=ListRecords" + ...
    "&set=math" + ...
    "&metadataPrefix=arXiv";
```

Extract the abstract text, category labels, and the resumption token returned by the query URL using the `parseArXivRecords` function which is attached to this example as a supporting file. To access this file, open this example as a live script. Note that the arXiv API is rate limited and requires waiting between multiple requests.

```
[textData,labelsAll,resumptionToken] = parseArXivRecords(url);
```

Iteratively import more chunks of records until the required amount is reached, or there are no more records. To continue importing records from where you left off, use the resumption token from the previous result in the query URL. To adhere to the rate limits imposed by the arXiv API, add a delay of 20 seconds before each query using the `pause` function.

```
while numel(textData) < importSize

    if resumptionToken == ""
        break
    end
```

```
    url = "https://export.arxiv.org/oai2?verb=ListRecords" + ...
        "&resumptionToken=" + resumptionToken;

    pause(20)
    [textDataNew,labelsNew,resumptionToken] = parseArXivRecords(url);

    textData = [textData; textDataNew];
    labelsAll = [labelsAll; labelsNew];
end
```

Preprocess Text Data

Tokenize and preprocess the text data using the `preprocessText` function, listed at the end of the example.

```
documentsAll = preprocessText(textData);
documentsAll(1:5)
```

```
ans =
  5×1 tokenizedDocument:

    72 tokens: describe new algorithm $(k,\ell)$ pebble game color obtain characterization family
    22 tokens: show determinant stirling cycle number count unlabeled acyclic singlesource automa
    18 tokens: paper show compute $\lambda_{\alpha}$ norm alpha dyadic grid result consequence de
    62 tokens: partial cube isometric subgraphs hypercubes structure graph define mean semicubes
    29 tokens: paper present algorithm compute hecke eigensystems hilbertsiegel cusp form real qu
```

Remove labels that do not belong to the `"math"` set.

```
for i = 1:numel(labelsAll)
    labelsAll{i} = labelsAll{i}(startsWith(labelsAll{i},"math."));
end
```

Visualize some of the classes in a word cloud. Find the documents corresponding to the following:

- Abstracts tagged with "Combinatorics" and not tagged with `"Statistics Theory"`
- Abstracts tagged with "Statistics Theory" and not tagged with `"Combinatorics"`
- Abstracts tagged with both `"Combinatorics"` and `"Statistics Theory"`

Find the document indices for each of the groups using the `ismember` function.

```
idxCO = cellfun(@(lbls) ismember("math.CO",lbls) && ~ismember("math.ST",lbls),labelsAll);
idxST = cellfun(@(lbls) ismember("math.ST",lbls) && ~ismember("math.CO",lbls),labelsAll);
idxCOST = cellfun(@(lbls) ismember("math.CO",lbls) && ismember("math.ST",lbls),labelsAll);
```

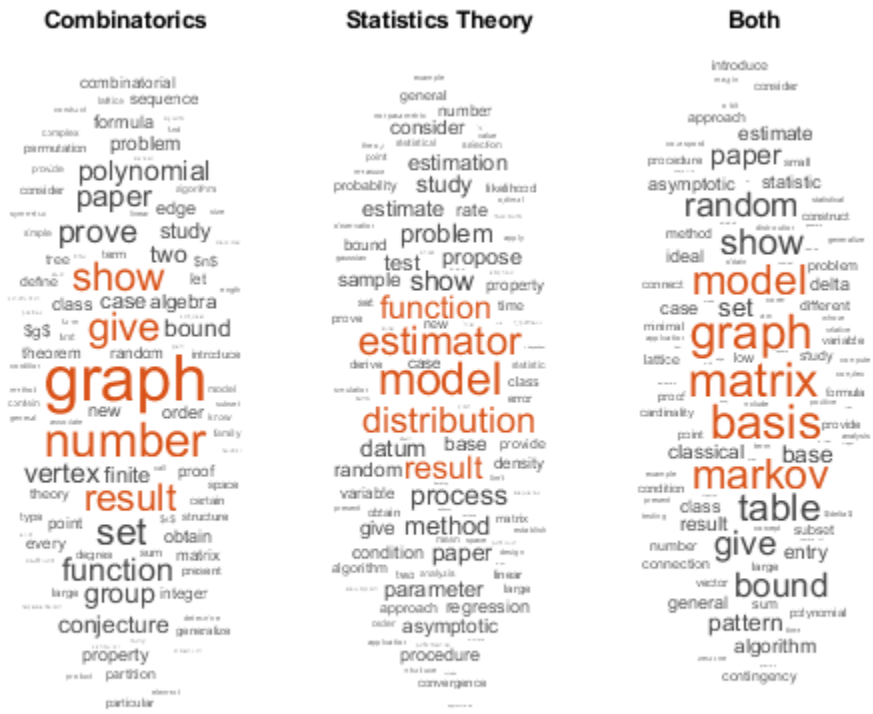
Visualize the documents for each group in a word cloud.

```
figure
subplot(1,3,1)
wordcloud(documentsAll(idxCO));
title("Combinatorics")

subplot(1,3,2)
wordcloud(documentsAll(idxST));
title("Statistics Theory")

subplot(1,3,3)
```

```
wordcloud(documentsAll(idxCOST));
title("Both")
```



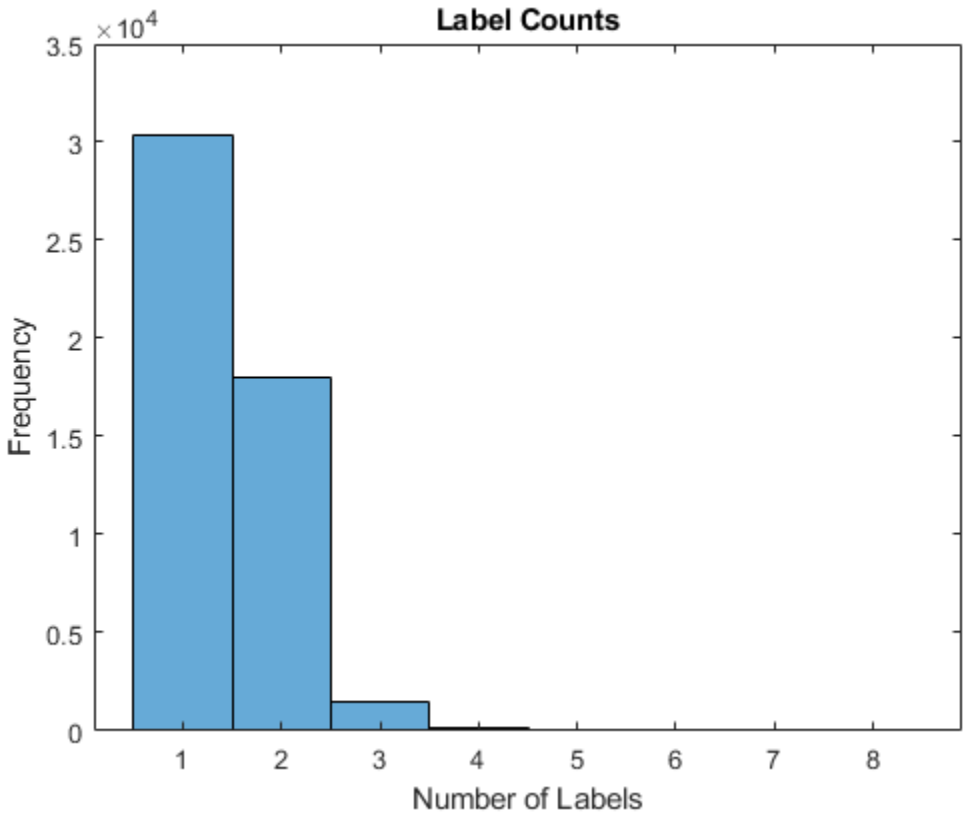
View the number of classes.

```
classNames = unique(cat(1,labelsAll{:}));
numClasses = numel(classNames)
```

```
numClasses = 32
```

Visualize the number of per-document labels using a histogram.

```
labelCounts = cellfun(@numel, labelsAll);
figure
histogram(labelCounts)
xlabel("Number of Labels")
ylabel("Frequency")
title("Label Counts")
```



Prepare Text Data for Deep Learning

Partition the data into training and validation partitions using the `cvpartition` function. Hold out 10% of the data for validation by setting the `'HoldOut'` option to 0.1.

```
cvp = cvpartition(numel(documentsAll),'HoldOut',0.1);
documentsTrain = documentsAll(training(cvp));
documentsValidation = documentsAll(test(cvp));

labelsTrain = labelsAll(training(cvp));
labelsValidation = labelsAll(test(cvp));
```

Create a word encoding object that encodes the training documents as sequences of word indices. Specify a vocabulary of the 5000 words by setting the `'Order'` option to `'frequency'`, and the `'MaxNumWords'` option to 5000.

```
enc = wordEncoding(documentsTrain,'Order','frequency','MaxNumWords',5000)
```

```
enc =
  wordEncoding with properties:

      NumWords: 5000
    Vocabulary: [1×5000 string]
```

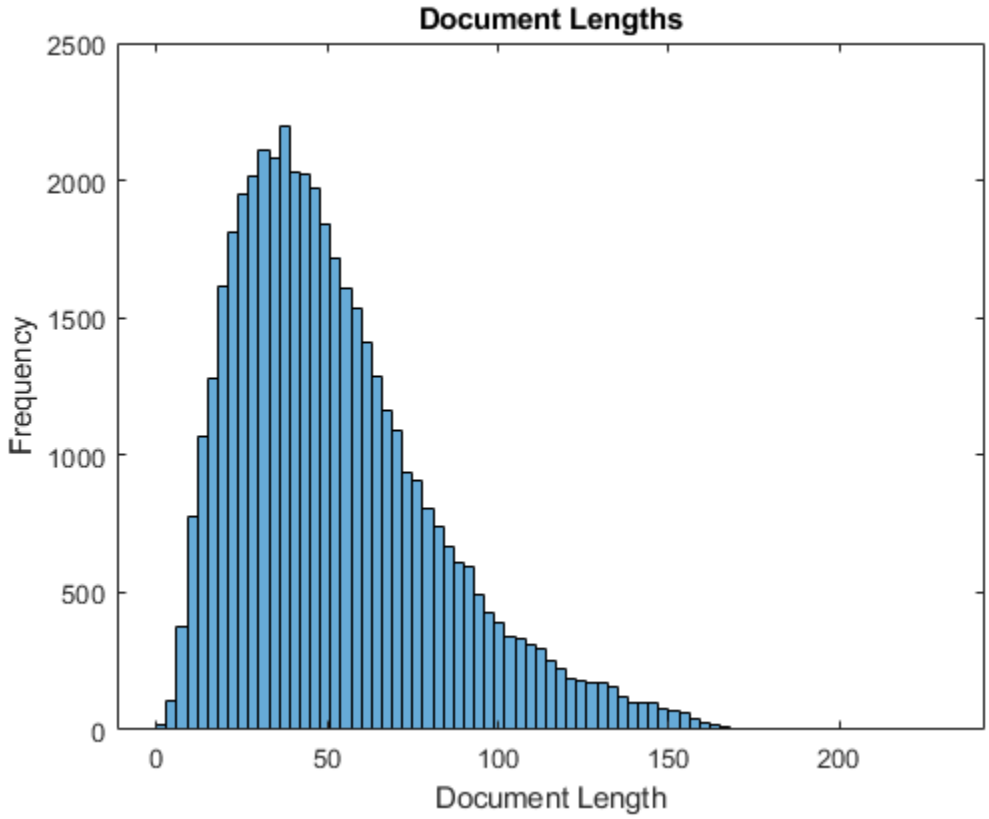
To improve training, use the following techniques:

1. When training, truncate the documents to a length that reduces the amount of padding used and does not does discard too much data.
2. Train for one epoch with the documents sorted by length in ascending order, then shuffle the data each epoch. This technique is known as *sortagrad*.

To choose a sequence length for truncation, visualize the document lengths in a histogram and choose a value that captures most of the data.

```
documentLengths = doclength(documentsTrain);

figure
histogram(documentLengths)
xlabel("Document Length")
ylabel("Frequency")
title("Document Lengths")
```



Most of the training documents have fewer than 175 tokens. Use 175 tokens as the target length for truncation and padding.

```
maxSequenceLength = 175;
```

To use the sortagrad technique, sort the documents by length in ascending order.

```
[~,idx] = sort(documentLengths);
documentsTrain = documentsTrain(idx);
labelsTrain = labelsTrain(idx);
```

Define and Initialize Model Parameters

Define the parameters for each of the operations and include them in a struct. Use the format `parameters.OperationName.ParameterName`, where `parameters` is the struct, `OperationName` is the name of the operation (for example `"fc"`), and `ParameterName` is the name of the parameter (for example, `"Weights"`).

Create a struct `parameters` containing the model parameters. Initialize the bias with zeros. Use the following weight initializers for the operations:

- For the embedding, initialize the weights with random normal values.
- For the GRU operation, initialize the weights using the `initializeGlorot` function, listed at the end of the example.
- For the fully connect operation, initialize the weights using the `initializeGaussian` function, listed at the end of the example.

```
embeddingDimension = 300;
numHiddenUnits = 250;
inputSize = enc.NumWords + 1;

parameters = struct;
parameters.emb.Weights = dlarray(randn([embeddingDimension inputSize]));

parameters.gru.InputWeights = dlarray(initializeGlorot(3*numHiddenUnits,embeddingDimension));
parameters.gru.RecurrentWeights = dlarray(initializeGlorot(3*numHiddenUnits,numHiddenUnits));
parameters.gru.Bias = dlarray(zeros(3*numHiddenUnits,1,'single'));

parameters.fc.Weights = dlarray(initializeGaussian([numClasses,numHiddenUnits]));
parameters.fc.Bias = dlarray(zeros(numClasses,1,'single'));
```

View the `parameters` struct.

```
parameters
```

```
parameters = struct with fields:
    emb: [1×1 struct]
    gru: [1×1 struct]
     fc: [1×1 struct]
```

View the parameters for the GRU operation.

```
parameters.gru
```

```
ans = struct with fields:
        InputWeights: [750×300 dlarray]
    RecurrentWeights: [750×250 dlarray]
                Bias: [750×1 dlarray]
```

Define Model Function

Create the function `model`, listed at the end of the example, which computes the outputs of the deep learning model described earlier. The function `model` takes as input the input data `dlX` and the model parameters `parameters`. The network outputs the predictions for the labels.

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, which takes as input a mini-batch of input data `dlX` and the corresponding targets `T` containing the labels, and returns the gradients of the loss with respect to the learnable parameters, the corresponding loss, and the network outputs.

Specify Training Options

Train for 5 epochs with a mini-batch size of 256.

```
numEpochs = 5;
miniBatchSize = 256;
```

Train using the Adam optimizer, with a learning rate of 0.01, and specify gradient decay and squared gradient decay factors of 0.5 and 0.999, respectively.

```
learnRate = 0.01;
gradientDecayFactor = 0.5;
squaredGradientDecayFactor = 0.999;
```

Clip the gradients with a threshold of 1 using L_2 norm gradient clipping.

```
gradientThreshold = 1;
```

Visualize the training progress in a plot.

```
plots = "training-progress";
```

To convert a vector of probabilities to labels, use the labels with probabilities higher than a specified threshold. Specify a label threshold of 0.5.

```
labelThreshold = 0.5;
```

Validate the network every epoch.

```
numObservationsTrain = numel(documentsTrain);
numIterationsPerEpoch = floor(numObservationsTrain/miniBatchSize);
validationFrequency = numIterationsPerEpoch;
```

Train on a GPU if one is available. This requires Parallel Computing Toolbox™. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
executionEnvironment = "auto";
```

Train Model

Train the model using a custom training loop.

For each epoch, loop over mini-batches of data. At the end of each epoch, shuffle the data. At the end of each iteration, update the training progress plot.

For each mini-batch:

- Convert the documents to sequences of word indices and convert the labels to dummy variables.
- Convert the sequences to `dlarray` objects with underlying type single and specify the dimension labels `'BTC'` (batch, time, channel).

- For GPU training, convert to `gpuArray` objects.
- Evaluate the model gradients and loss using `dlfeval` and the `modelGradients` function.
- Clip the gradients.
- Update the network parameters using the `adamupdate` function.
- If necessary, validate the network using the `modelPredictions` function, listed at the end of the example.
- Update the training plot.

Initialize the training progress plot.

```
if plots == "training-progress"
    figure

    % Labeling F-Score.
    subplot(2,1,1)
    lineFScoreTrain = animatedline('Color',[0 0.447 0.741]);
    lineFScoreValidation = animatedline( ...
        'LineStyle','--', ...
        'Marker','o', ...
        'MarkerFaceColor','black');
    ylim([0 1])
    xlabel("Iteration")
    ylabel("Labeling F-Score")
    grid on

    % Loss.
    subplot(2,1,2)
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    lineLossValidation = animatedline( ...
        'LineStyle','--', ...
        'Marker','o', ...
        'MarkerFaceColor','black');
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
    grid on
end
```

Initialize parameters for the Adam optimizer.

```
trailingAvg = [];
trailingAvgSq = [];
```

Prepare the validation data. Create a one-hot encoded matrix where non-zero entries correspond to the labels of each observation.

```
numObservationsValidation = numel(documentsValidation);
TValidation = zeros(numClasses, numObservationsValidation, 'single');
for i = 1:numObservationsValidation
    [~,idx] = ismember(labelsValidation{i},classNames);
    TValidation(idx,i) = 1;
end
```

Train the model.

```
iteration = 0;
start = tic;
```

```
% Loop over epochs.
for epoch = 1:numEpochs

    % Loop over mini-batches.
    for i = 1:numIterationsPerEpoch
        iteration = iteration + 1;
        idx = (i-1)*miniBatchSize+1:i*miniBatchSize;

        % Read mini-batch of data and convert the labels to dummy
        % variables.
        documents = documentsTrain(idx);
        labels = labelsTrain(idx);

        % Convert documents to sequences.
        len = min(maxSequenceLength,max(doclength(documents)));
        X = doc2sequence(enc,documents, ...
            'PaddingValue',inputSize, ...
            'Length',len);
        X = cat(1,X{:});

        % Dummify labels.
        T = zeros(numClasses, miniBatchSize, 'single');
        for j = 1:miniBatchSize
            [~,idx2] = ismember(labels{j},classNames);
            T(idx2,j) = 1;
        end

        % Convert mini-batch of data to dlarray.
        dlX = dlarray(X,'BTC');

        % If training on a GPU, then convert data to gpuArray.
        if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
            dlX = gpuArray(dlX);
        end

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function.
        [gradients,loss,dlYPred] = dlfeval(@modelGradients, dlX, T, parameters);

        % Gradient clipping.
        gradients = dlupdate(@(g) thresholdL2Norm(g, gradientThreshold),gradients);

        % Update the network parameters using the Adam optimizer.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
            trailingAvg,trailingAvgSq,iteration,learnRate,gradientDecayFactor,squaredGradientDeca

        % Display the training progress.
        if plots == "training-progress"
            subplot(2,1,1)
            D = duration(0,0,toc(start),'Format','hh:mm:ss');
            title("Epoch: " + epoch + ", Elapsed: " + string(D))

            % Loss.
            addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))

            % Labeling F-score.
            YPred = extractdata(dlYPred) > labelThreshold;
```

```
            score = labelingFScore(YPred,T);
            addpoints(lineFScoreTrain,iteration,double(gather(score)))

            drawnow

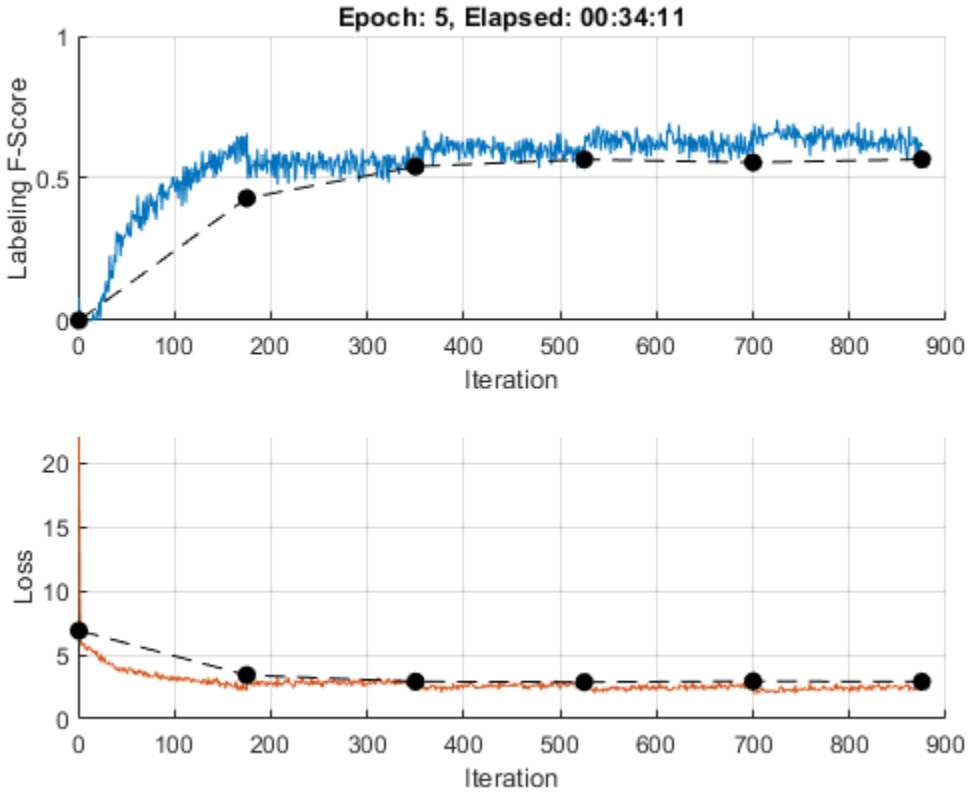
            % Display validation metrics.
            if iteration == 1 || mod(iteration,validationFrequency) == 0
                dlYPredValidation = modelPredictions(parameters,enc,documentsValidation,miniBatch

                % Loss.
                lossValidation = crossentropy(dlYPredValidation,TValidation, ...
                    'TargetCategories','independent', ...
                    'DataFormat','CB');
                addpoints(lineLossValidation,iteration,double(gather(extractdata(lossValidation)

                % Labeling F-score.
                YPredValidation = extractdata(dlYPredValidation) > labelThreshold;
                score = labelingFScore(YPredValidation,TValidation);
                addpoints(lineFScoreValidation,iteration,double(gather(score)))

                drawnow
            end
        end
    end

    % Shuffle data.
    idx = randperm(numObservationsTrain);
    documentsTrain = documentsTrain(idx);
    labelsTrain = labelsTrain(idx);
end
```



Test Model

To make predictions on a new set of data, use the `modelPredictions` function, listed at the end of the example. The `modelPredictions` function takes as input the model parameters, a word encoding, and an array of tokenized documents, and outputs the model predictions corresponding to the specified mini-batch size and the maximum sequence length.

```
dlYPredValidation = modelPredictions(parameters,enc,documentsValidation,miniBatchSize,maxSequence
```

To convert the network outputs to an array of labels, find the labels with scores higher than the specified label threshold.

```
YPredValidation = extractdata(dlYPredValidation) > labelThreshold;
```

To evaluate the performance, calculate the labeling F-score using the `labelingFScore` function, listed at the end of the example. The labeling F-score evaluates multilabel classification by focusing on per-text classification with partial matches.

```
score = labelingFScore(YPredValidation,TValidation)
```

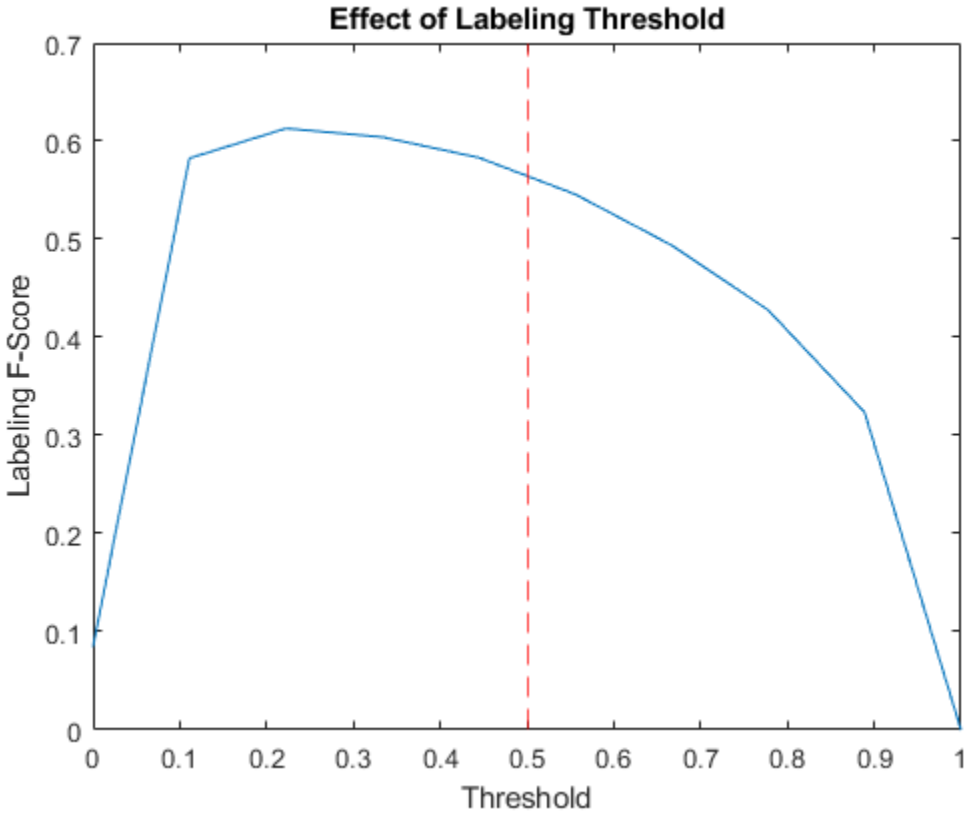
```
score = single
    0.5663
```

View the effect of the labeling threshold on the labeling F-score by trying a range of values for the threshold and comparing the results.

```
thr = linspace(0,1,10);
score = zeros(size(thr));
```

```
for i = 1:numel(thr)
    YPredValidationThr = extractdata(dlYPredValidation) >= thr(i);
    score(i) = labelingFScore(YPredValidationThr,TValidation);
end

figure
plot(thr,score)
xline(labelThreshold,'r--');
xlabel("Threshold")
ylabel("Labeling F-Score")
title("Effect of Labeling Threshold")
```



Visualize Predictions

To visualize the correct predictions of the classifier, calculate the numbers of true positives. A true positive is an instance of a classifier correctly predicting a particular class for an observation.

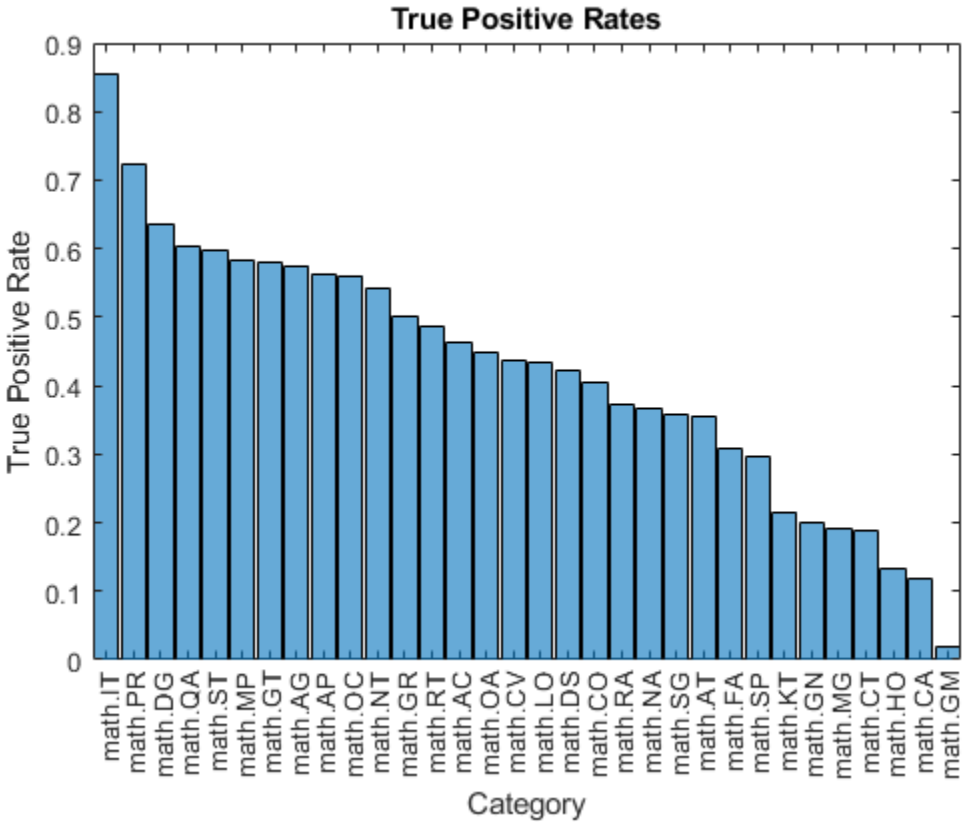
```
Y = YPredValidation;
T = TValidation;

numTruePositives = sum(T & Y,2);

numObservationsPerClass = sum(T,2);
truePositiveRates = numTruePositives ./ numObservationsPerClass;
```

Visualize the numbers of true positives for each class in a histogram.

```
figure
[~,idx] = sort(truePositiveRates,'descend');
histogram('Categories',classNames(idx),'BinCounts',truePositiveRates(idx))
xlabel("Category")
ylabel("True Positive Rate")
title("True Positive Rates")
```



Visualize the instances where the classifier predicts incorrectly by showing the distribution of true positives, false positives, and false negatives. A false positive is an instance of a classifier assigning a particular incorrect class to an observation. A false negative is an instance of a classifier failing to assign a particular correct class to an observation.

Create a confusion matrix showing the true positive, false positive, and false negative counts:

- For each class, display the true positive counts on the diagonal.
- For each pair of classes (i,j), display the number of instances of a false positive for j when the instance is also a false negative for i.

That is, the confusion matrix with elements given by:

$$\mathrm{TPFN}_{ij} = \begin{cases} \text{numTruePositives}(i), & \text{if } i = j \\ \text{numFalsePositives}(j \mid i \text{ is a false negative}), & \text{if } i \neq j \end{cases}$$

Calculate the false negatives and false positives.

```
falseNegatives = T & ~Y;
falsePositives = ~T & Y;
```

Calculate the off-diagonal elements.

```
falseNegatives = permute(falseNegatives,[3 2 1]);
numConditionalFalsePositives = sum(falseNegatives & falsePositives, 2);
numConditionalFalsePositives = squeeze(numConditionalFalsePositives);

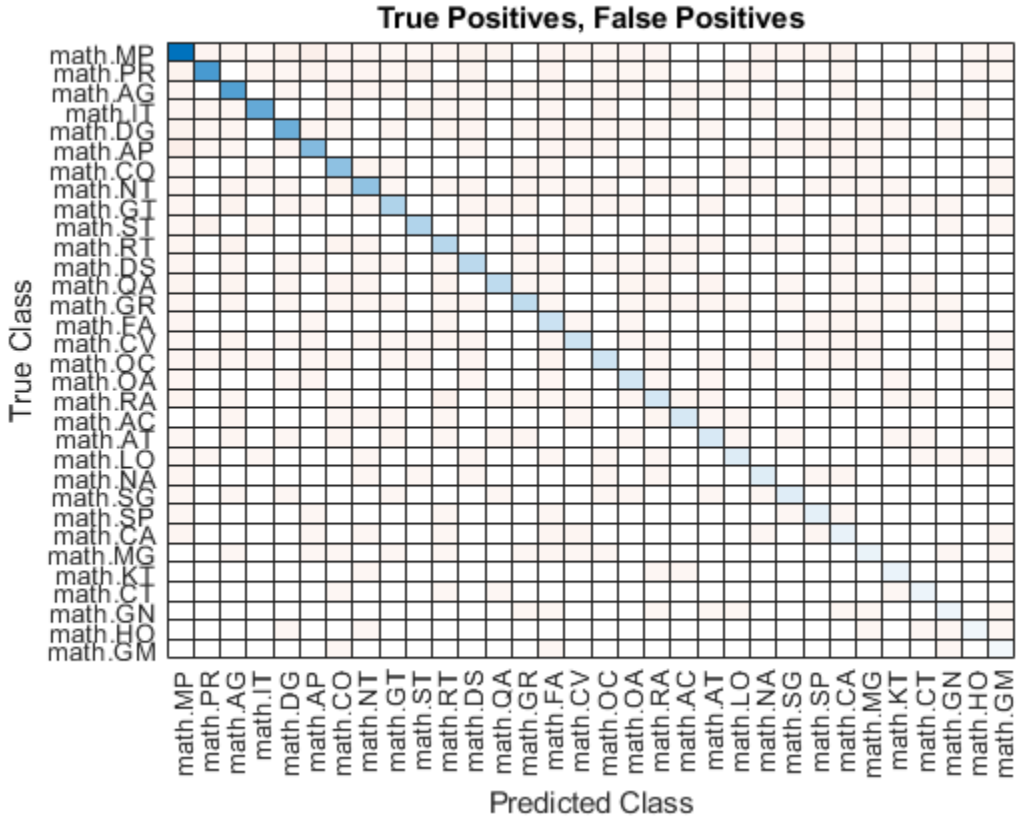
tpfnMatrix = numConditionalFalsePositives;
```

Set the diagonal elements to the true positive counts.

```
idxDiagonal = 1:numClasses+1:numClasses^2;
tpfnMatrix(idxDiagonal) = numTruePositives;
```

Visualize the true positive and false positive counts in a confusion matrix using the `confusionchart` function and sort the matrix such that the elements on the diagonal are in descending order.

```
figure
cm = confusionchart(tpfnMatrix,classNames);
sortClasses(cm,"descending-diagonal");
title("True Positives, False Positives")
```



To view the matrix in more detail, open this example as a live script and open the figure in a new window.

Preprocess Text Function

The `preprocessText` function tokenizes and preprocesses the input text data using the following steps:

1. Tokenize the text using the `tokenizedDocument` function. Extract mathematical equations as a single token using the `'RegularExpressions'` option by specifying the regular expression `"\$.*?\$"`, which captures text appearing between two "$" symbols.
2. Erase the punctuation using the `erasePunctuation` function.
3. Convert the text to lowercase using the `lower` function.
4. Remove the stop words using the `removeStopWords` function.
5. Lemmatize the text using the `normalizeWords` function with the `'Style'` option set to `'lemma'`.

```
function documents = preprocessText(textData)

% Tokenize the text.
regularExpressions = table;
regularExpressions.Pattern = "\$.*?\$";
regularExpressions.Type = "equation";

documents = tokenizedDocument(textData,'RegularExpressions',regularExpressions);

% Erase punctuation.
documents = erasePunctuation(documents);

% Convert to lowercase.
documents = lower(documents);

% Lemmatize.
documents = addPartOfSpeechDetails(documents);
documents = normalizeWords(documents,'Style','Lemma');

% Remove stop words.
documents = removeStopWords(documents);

% Remove short words.
documents = removeShortWords(documents,2);

end
```

Model Function

The function `model` takes as input the input data `dlX` and the model parameters `parameters`, and returns the predictions for the labels.

```
function dlY = model(dlX,parameters)

% Embedding
weights = parameters.emb.Weights;
dlX = embedding(dlX, weights);

% GRU
inputWeights = parameters.gru.InputWeights;
recurrentWeights = parameters.gru.RecurrentWeights;
bias = parameters.gru.Bias;

numHiddenUnits = size(inputWeights,1)/3;
hiddenState = dlarray(zeros([numHiddenUnits 1]));

dlY = gru(dlX, hiddenState, inputWeights, recurrentWeights, bias,'DataFormat','CBT');
```

```
% Max pooling along time dimension
dlY = max(dlY,[],3);

% Fully connect
weights = parameters.fc.Weights;
bias = parameters.fc.Bias;
dlY = fullyconnect(dlY,weights,bias,'DataFormat','CB');

% Sigmoid
dlY = sigmoid(dlY);

end
```

Model Gradients Function

The `modelGradients` function takes as input a mini-batch of input data `dlX` with corresponding targets `T` containing the labels and returns the gradients of the loss with respect to the learnable parameters, the corresponding loss, and the network outputs.

```
function [gradients,loss,dlYPred] = modelGradients(dlX,T,parameters)

dlYPred = model(dlX,parameters);

loss = crossentropy(dlYPred,T,'TargetCategories','independent','DataFormat','CB');

gradients = dlgradient(loss,parameters);

end
```

Model Predictions Function

The `modelPredictions` function takes as input the model parameters, a word encoding, an array of tokenized documents, a mini-batch size, and a maximum sequence length, and returns the model predictions by iterating over mini-batches of the specified size.

```
function dlYPred = modelPredictions(parameters,enc,documents,miniBatchSize,maxSequenceLength)

inputSize = enc.NumWords + 1;

numObservations = numel(documents);
numIterations = ceil(numObservations / miniBatchSize);

numFeatures = size(parameters.fc.Weights,1);
dlYPred = zeros(numFeatures,numObservations,'like',parameters.fc.Weights);

for i = 1:numIterations

    idx = (i-1)*miniBatchSize+1:min(i*miniBatchSize,numObservations);

    len = min(maxSequenceLength,max(doclength(documents(idx))));
    X = doc2sequence(enc,documents(idx), ...
        'PaddingValue',inputSize, ...
        'Length',len);
    X = cat(1,X{:});

    dlX = dlarray(X,'BTC');
```

```
    dlYPred(:,idx) = model(dlX,parameters);
end

end
```

Labeling F-Score Function

The labeling F-score function [2] evaluates multilabel classification by focusing on per-text classification with partial matches. The measure is the normalized proportion of matching labels against the total number of true and predicted labels given by

$$\frac{1}{N}\sum_{n=1}^{N}\left(\frac{2\sum_{c=1}^{C}Y_{nc}T_{nc}}{\sum_{c=1}^{C}(Y_{nc}+T_{nc})}\right),$$

where N and C correspond to the number of observations and classes, respectively, and Y and T correspond to the predictions and targets, respectively.

```
function score = labelingFScore(Y,T)

numObservations = size(T,2);

scores = (2 * sum(Y .* T)) ./ sum(Y + T);
score = sum(scores) / numObservations;

end
```

Glorot Weights Initialization Function

The `initializeGlorot` function generates an array of weights according to Glorot initialization.

```
function weights = initializeGlorot(numOut, numIn)

varWeights = sqrt( 6 / (numIn + numOut) );
weights = varWeights * (2 * rand([numOut, numIn], 'single') - 1);

end
```

Gaussian Weights Initialization Function

The `initializeGaussian` function samples weights from a Gaussian distribution with mean 0 and standard deviation 0.01.

```
function parameter = initializeGaussian(sz)

parameter = randn(sz,'single') .* 0.01;

end
```

Embedding Function

The `embedding` function maps numeric indices to the corresponding vector given by the input weights.

```
function Z = embedding(X, weights)
% Reshape inputs into a vector.
[N, T] = size(X, 2:3);
X = reshape(X, N*T, 1);
```

```
% Index into embedding matrix.
Z = weights(:, X);

% Reshape outputs by separating batch and sequence dimensions.
Z = reshape(Z, [], N, T);
end
```

L_2 Norm Gradient Clipping Function

The `thresholdL2Norm` function scales the input gradients so that their L_2 norm values equal the specified gradient threshold when the L_2 norm value of the gradient of a learnable parameter is larger than the specified threshold.

```
function gradients = thresholdL2Norm(gradients,gradientThreshold)

gradientNorm = sqrt(sum(gradients(:).^2));
if gradientNorm > gradientThreshold
    gradients = gradients * (gradientThreshold / gradientNorm);
end

end
```

Classify Text Data Using Custom Training Loop

This example shows how to classify text data using a deep learning bidirectional long short-term memory (BiLSTM) network with a custom training loop.

When training a deep learning network using the `trainNetwork` function, if `trainingOptions` does not provide the options you need (for example, a custom learning rate schedule), then you can define your own custom training loop using automatic differentiation. For an example showing how to classify text data using the `trainNetwork` function, see “Classify Text Data Using Deep Learning” on page 4-89.

This example trains a network to classify text data with the *time-based decay* learning rate schedule: for each iteration, the solver uses the learning rate given by $\rho_t = \frac{\rho_0}{1 + kt}$, where t is the iteration number, ρ_0 is the initial learning rate, and k is the decay.

Import Data

Import the factory reports data. This data contains labeled textual descriptions of factory events. To import the text data as strings, specify the text type to be `'string'`.

```
filename = "factoryReports.csv";
data = readtable(filename,'TextType','string');
head(data)
```

```
ans=8×5 table
                                Description                                 
    ____________________________________________________________________    

    "Items are occasionally getting stuck in the scanner spools."           
    "Loud rattling and banging sounds are coming from assembler pistons."   
    "There are cuts to the power when starting the plant."                  
    "Fried capacitors in the assembler."                                    
    "Mixer tripped the fuses."                                              
    "Burst pipe in the constructing agent is spraying coolant."             
    "A fuse is blown in the mixer."                                         
    "Things continue to tumble off of the belt."                            
```

```
                Category         
    _____________________________

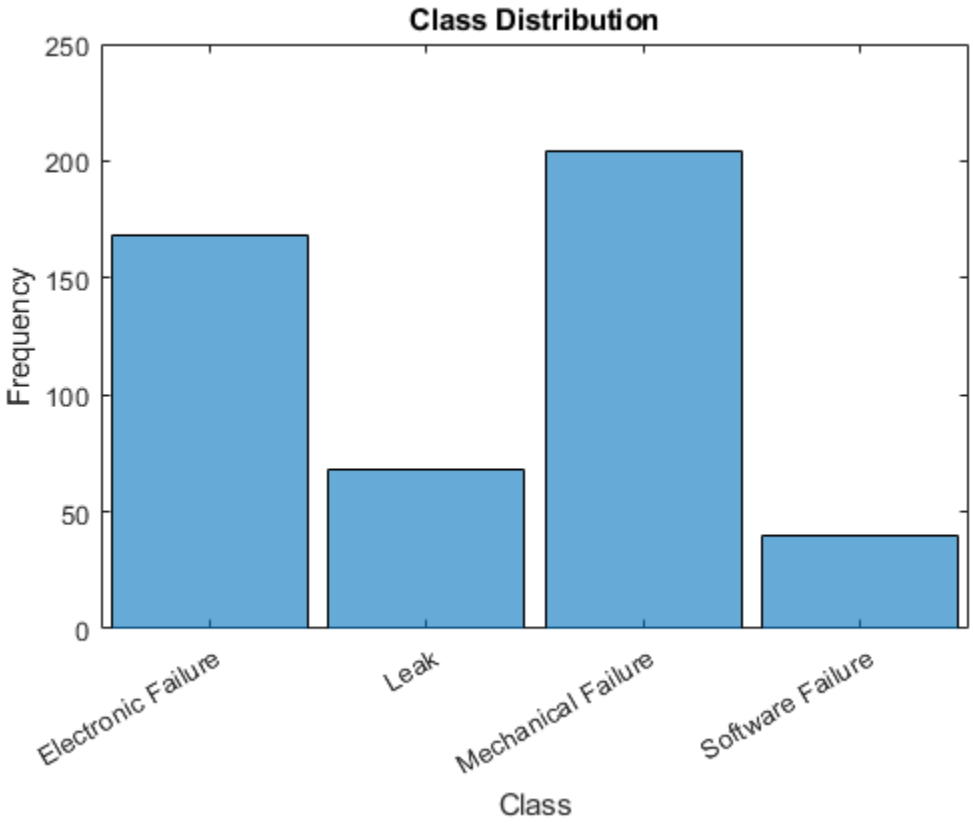
    "Mechanical Failure"
    "Mechanical Failure"
    "Electronic Failure"
    "Electronic Failure"
    "Electronic Failure"
    "Leak"
    "Electronic Failure"
    "Mechanical Failure"
```

The goal of this example is to classify events by the label in the `Category` column. To divide the data into classes, convert these labels to categorical.

```
data.Category = categorical(data.Category);
```

View the distribution of the classes in the data using a histogram.

```
figure
histogram(data.Category);
xlabel("Class")
ylabel("Frequency")
title("Class Distribution")
```



The next step is to partition it into sets for training and validation. Partition the data into a training partition and a held-out partition for validation and testing. Specify the holdout percentage to be 20%.

```
cvp = cvpartition(data.Category,'Holdout',0.2);
dataTrain = data(training(cvp),:);
dataValidation = data(test(cvp),:);
```

Extract the text data and labels from the partitioned tables.

```
textDataTrain = dataTrain.Description;
textDataValidation = dataValidation.Description;
YTrain = dataTrain.Category;
YValidation = dataValidation.Category;
```

To check that you have imported the data correctly, visualize the training text data using a word cloud.

```
figure
wordcloud(textDataTrain);
title("Training Data")
```

View the number of classes.

```
classes = categories(YTrain);
numClasses = numel(classes)
```

```
numClasses = 4
```

Preprocess Text Data

Create a function that tokenizes and preprocesses the text data. The function `preprocessText`, listed at the end of the example, performs these steps:

1. Tokenize the text using `tokenizedDocument`.
2. Convert the text to lowercase using `lower`.
3. Erase the punctuation using `erasePunctuation`.

Preprocess the training data and the validation data using the `preprocessText` function.

```
documentsTrain = preprocessText(textDataTrain);
documentsValidation = preprocessText(textDataValidation);
```

View the first few preprocessed training documents.

```
documentsTrain(1:5)
```

```
ans =
  5×1 tokenizedDocument:
```

```
     9 tokens: items are occasionally getting stuck in the scanner spools
    10 tokens: loud rattling and banging sounds are coming from assembler pistons
     5 tokens: fried capacitors in the assembler
     4 tokens: mixer tripped the fuses
     9 tokens: burst pipe in the constructing agent is spraying coolant
```

Create a single datastore that contains both the documents and the labels by creating `arrayDatastore` objects, then combining them using the `combine` function.

```
dsDocumentsTrain = arrayDatastore(documentsTrain,'OutputType','cell');
dsYTrain = arrayDatastore(YTrain,'OutputType','cell');
dsTrain = combine(dsDocumentsTrain,dsYTrain);
```

Create a datastore for the validation data using the same steps.

```
dsDocumentsValidation = arrayDatastore(documentsValidation,'OutputType','cell');
dsYValidation = arrayDatastore(YValidation,'OutputType','cell');
dsValidation = combine(dsDocumentsValidation,dsYValidation);
```

Create Word Encoding

To input the documents into a BiLSTM network, use a word encoding to convert the documents into sequences of numeric indices.

To create a word encoding, use the `wordEncoding` function.

```
enc = wordEncoding(documentsTrain)
```

```
enc =
  wordEncoding with properties:

      NumWords: 421
    Vocabulary: [1×421 string]
```

Define Network

Define the BiLSTM network architecture. To input sequence data into the network, include a sequence input layer and set the input size to 1. Next, include a word embedding layer of dimension 25 and the same number of words as the word encoding. Next, include a BiLSTM layer and set the number of hidden units to 40. To use the BiLSTM layer for a sequence-to-label classification problem, set the output mode to `'last'`. Finally, add a fully connected layer with the same size as the number of classes, and a softmax layer.

```
inputSize = 1;
embeddingDimension = 25;
numHiddenUnits = 40;

numWords = enc.NumWords;

layers = [
    sequenceInputLayer(inputSize,'Name','in')
    wordEmbeddingLayer(embeddingDimension,numWords,'Name','emb')
    bilstmLayer(numHiddenUnits,'OutputMode','last','Name','bilstm')
    fullyConnectedLayer(numClasses,'Name','fc')
    softmaxLayer('Name','sm')]
```

```
layers =
  5×1 Layer array with layers:

     1   'in'       Sequence Input         Sequence input with 1 dimensions
     2   'emb'      Word Embedding Layer   Word embedding layer with 25 dimensions and 421 unique
     3   'bilstm'   BiLSTM                 BiLSTM with 40 hidden units
     4   'fc'       Fully Connected        4 fully connected layer
     5   'sm'       Softmax                softmax
```

Convert the layer array to a layer graph and create a `dlnetwork` object.

```
lgraph = layerGraph(layers);
dlnet = dlnetwork(lgraph)
```

```
dlnet =
  dlnetwork with properties:

         Layers: [5×1 nnet.cnn.layer.Layer]
    Connections: [4×2 table]
     Learnables: [6×3 table]
          State: [2×3 table]
     InputNames: {'in'}
    OutputNames: {'sm'}
```

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, that takes a `dlnetwork` object, a mini-batch of input data with corresponding labels, and returns the gradients of the loss with respect to the learnable parameters in the network and the corresponding loss.

Specify Training Options

Train for 30 epochs with a mini-batch size of 16.

```
numEpochs = 30;
miniBatchSize = 16;
```

Specify the options for Adam optimization. Specify an initial learn rate of 0.001 with a decay of 0.01, gradient decay factor 0.9, and squared gradient decay factor 0.999.

```
initialLearnRate = 0.001;
decay = 0.01;
gradientDecayFactor = 0.9;
squaredGradientDecayFactor = 0.999;
```

Train Model

Train the model using a custom training loop.

Initialize the training progress plot.

```
figure
lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);

lineLossValidation = animatedline( ...
    'LineStyle','--', ...
    'Marker','o', ...
```

```
    'MarkerFaceColor','black');

ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Initialize the parameters for Adam.

```
trailingAvg = [];
trailingAvgSq = [];
```

Create a `minibatchqueue` object that processes and manages the mini-batches of data. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to convert documents to sequences and one-hot encode the labels. To pass the word encoding to the mini-batch, create an anonymous function that takes two inputs.
- Format the predictors with the dimension labels `'BTC'` (batch, time, channel). The `minibatchqueue` object, by default, converts the data to `dlarray` objects with underlying type `single`.
- Train on a GPU if one is available. The `minibatchqueue` object, by default, converts each output to `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain, ...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn', @(X,Y) preprocessMiniBatch(X,Y,enc), ...
    'MiniBatchFormat',{'BTC',''});
```

Create a `minibatchqueue` object for the validation data using the same options and also specify to return partial mini-batches.

```
mbqValidation = minibatchqueue(dsValidation, ...
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFcn', @(X,Y) preprocessMiniBatch(X,Y,enc), ...
    'MiniBatchFormat',{'BTC',''}, ...
    'PartialMiniBatch','return');
```

Train the network. For each epoch, shuffle the data and loop over mini-batches of data. At the end of each iteration, display the training progress. At the end of each epoch, validate the network using the validation data.

For each mini-batch:

- Convert the documents to sequences of integers and one-hot encode the labels.
- Convert the data to `dlarray` objects with underlying type single and specify the dimension labels `'BTC'` (batch, time, channel).
- For GPU training, convert to `gpuArray` objects.
- Evaluate the model gradients, state, and loss using `dlfeval` and the `modelGradients` function and update the network state.
- Determine the learning rate for the time-based decay learning rate schedule.

- Update the network parameters using the `adamupdate` function.
- Update the training plot.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    shuffle(mbq);

    % Loop over mini-batches.
    while hasdata(mbq)
        iteration = iteration + 1;

        % Read mini-batch of data.
        [dlX, dlY] = next(mbq);

        % Evaluate the model gradients, state, and loss using dlfeval and the
        % modelGradients function.
        [gradients,loss] = dlfeval(@modelGradients,dlnet,dlX,dlY);

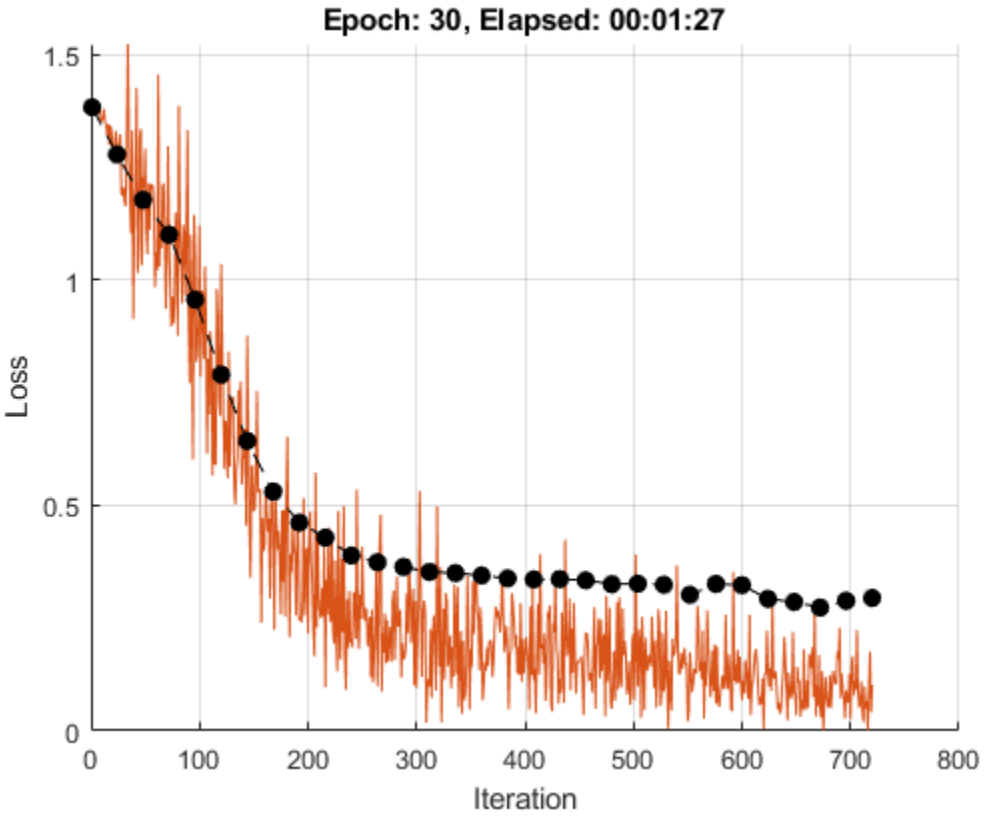
        % Determine learning rate for time-based decay learning rate schedule.
        learnRate = initialLearnRate/(1 + decay*iteration);

        % Update the network parameters using the Adam optimizer.
        [dlnet,trailingAvg,trailingAvgSq] = adamupdate(dlnet, gradients, ...
            trailingAvg, trailingAvgSq, iteration, learnRate, ...
            gradientDecayFactor, squaredGradientDecayFactor);

        % Display the training progress.
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        addpoints(lineLossTrain,iteration,loss)
        title("Epoch: " + epoch + ", Elapsed: " + string(D))
        drawnow

        % Validate network.
        if iteration == 1 || ~hasdata(mbq)
            % Validation predictions.
            [~,lossValidation] = modelPredictions(dlnet,mbqValidation,classes);

            % Update plot.
            addpoints(lineLossValidation,iteration,lossValidation)
            drawnow
        end
    end
end
```



Test Model

Test the classification accuracy of the model by comparing the predictions on the validation set with the true labels.

Classify the validation data using `modelPredictions` function, listed at the end of the example.

```
dlYPred = modelPredictions(dlnet,mbqValidation,classes);
YPred = onehotdecode(dlYPred,classes,1)';
```

Evaluate the classification accuracy.

```
accuracy = mean(YPred == YValidation)
```

```
accuracy = 0.9167
```

Predict Using New Data

Classify the event type of three new reports. Create a string array containing the new reports.

```
reportsNew = [
    "Coolant is pooling underneath sorter."
    "Sorter blows fuses at start up."
    "There are some very loud rattling sounds coming from the assembler."];
```

Preprocess the text data using the preprocessing steps as the training documents.

```
documentsNew = preprocessText(reportsNew);
dsNew = arrayDatastore(documentsNew,'OutputType','cell');
```

Create a `minibatchqueue` object that processes and manages the mini-batches of data. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatchPredictors` (defined at the end of this example) to convert documents to sequences. This preprocessing function does not require label data. To pass the word encoding to the mini-batch, create an anonymous function that takes one input only.
- Format the predictors with the dimension labels `'BTC'` (batch, time, channel). The `minibatchqueue` object, by default, converts the data to `dlarray` objects with underlying type `single`.
- To make predictions for all observations, return any partial mini-batches.

```
mbqNew = minibatchqueue(dsNew, ...
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFcn',@(X) preprocessMiniBatchPredictors(X,enc), ...
    'MiniBatchFormat','BTC', ...
    'PartialMiniBatch','return');
```

Classify the text data using `modelPredictions` function, listed at the end of the example and find the classes with the highest scores.

```
dlYPred = modelPredictions(dlnet,mbqNew,classes);
YPred = onehotdecode(dlYPred,classes,1)'
```

```
YPred = 3×1 categorical
     Leak
     Electronic Failure
     Mechanical Failure
```

Text Preprocessing Function

The function `preprocessText` performs these steps:

1. Tokenize the text using `tokenizedDocument`.
2. Convert the text to lowercase using `lower`.
3. Erase the punctuation using `erasePunctuation`.

```
function documents = preprocessText(textData)

% Tokenize the text.
documents = tokenizedDocument(textData);

% Convert to lowercase.
documents = lower(documents);

% Erase punctuation.
documents = erasePunctuation(documents);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function converts a mini-batch of documents to sequences of integers and one-hot encodes label data.

```
function [X, Y] = preprocessMiniBatch(documentsCell,labelsCell,enc)

% Preprocess predictors.
X = preprocessMiniBatchPredictors(documentsCell,enc);

% Extract labels from cell and concatenate.
Y = cat(1,labelsCell{1:end});

% One-hot encode labels.
Y = onehotencode(Y,2);

% Transpose the encoded labels to match the network output.
Y = Y';

end
```

Mini-Batch Predictors Preprocessing Function

The `preprocessMiniBatchPredictors` function converts a mini-batch of documents to sequences of integers.

```
function X = preprocessMiniBatchPredictors(documentsCell,enc)

% Extract documents from cell and concatenate.
documents = cat(4,documentsCell{1:end});

% Convert documents to sequences of integers.
X = doc2sequence(enc,documents);
X = cat(1,X{:});

end
```

Model Gradients Function

The `modelGradients` function takes a `dlnetwork` object `dlnet`, a mini-batch of input data `dlX` with corresponding target labels `T` and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, and the loss. To compute the gradients automatically, use the `dlgradient` function.

```
function [gradients,loss] = modelGradients(dlnet,dlX,T)

dlYPred = forward(dlnet,dlX);

loss = crossentropy(dlYPred,T);
gradients = dlgradient(loss,dlnet.Learnables);

loss = double(gather(extractdata(loss)));

end
```

Model Predictions Function

The `modelPredictions` function takes a `dlnetwork` object `dlnet`, a mini-batch queue, and outputs the model predictions by iterating over mini-batches in the queue. To evaluate validation data, this function optionally calcualtes the loss when given a mini-batch queue with two outputs.

```
function [dlYPred,loss] = modelPredictions(dlnet,mbq,classes)
```

```
% Initialize predictions.
numClasses = numel(classes);
outputCast = mbq.OutputCast{1};
dlYPred = dlarray(zeros(numClasses,0,outputCast),'CB');

% Reset mini-batch queue.
reset(mbq);

% For mini-batch queues with two ouputs, also compute the loss.
if mbq.NumOutputs == 1

    % Loop over mini-batches.
    while hasdata(mbq)

        % Make predictions.
        dlX = next(mbq);
        dlY = predict(dlnet,dlX);
        dlYPred = [dlYPred dlY];
    end

else
    % Initialize loss.
    numObservations = 0;
    loss = 0;

    % Loop over mini-batches.
    while hasdata(mbq)

        % Make predictions.
        [dlX,dlT] = next(mbq);
        dlY = predict(dlnet,dlX);
        dlYPred = [dlYPred dlY];

        % Calculate unnormalized loss.
        miniBatchSize = size(dlX,2);
        loss = loss + miniBatchSize * crossentropy(dlY, dlT);

        % Count observations.
        numObservations = numObservations + miniBatchSize;
    end

    % Normalize loss.
    loss = loss / numObservations;

    % Convert to double.
    loss = double(gather(extractdata(loss)));
end

end
```

Generate Text Using Autoencoders

This example shows how to generate text data using autoencoders.

An autoencoder is a type of deep learning network that is trained to replicate its input. An autoencoder consists of two smaller networks: and encoder and a decoder. The encoder maps the input data to a feature vector in some latent space. The decoder reconstructs data using vectors in this latent space.

The training process is unsupervised. In other words, the model does not require labeled data. To generate text, you can use the decoder to reconstruct text from arbitrary input.

This example trains an autoencoder to generate text. The encoder uses a word embedding and an LSTM operation to map the input text into latent vectors. The decoder uses an LSTM operation and the same embedding to reconstruct the text from the latent vectors.

Load Data

The file `sonnets.txt` contains all of Shakespeare's sonnets in a single text file.

Read the Shakespeare's Sonnets data from the file `"sonnets.txt"`.

```
filename = "sonnets.txt";
textData = fileread(filename);
```

The sonnets are indented by two whitespace characters. Remove the indentations using `replace` and split the text into separate lines using the `split` function. Remove the header from the first nine elements and the short sonnet titles.

```
textData = replace(textData,"  ","");
textData = split(textData,newline);
textData(1:9) = [];
textData(strlength(textData)<5) = [];
```

Prepare Data

Create a function that tokenizes and preprocesses the text data. The function `preprocessText`, listed at the end of the example, performs these steps:

1. Prepends and appends each input string with the specified start and stop tokens, respectively.
2. Tokenize the text using `tokenizedDocument`.

Preprocess the text data and specify the start and stop tokens `"<start>"` and `"<stop>"`, respectively.

```
startToken = "<start>";
stopToken = "<stop>";
documents = preprocessText(textData,startToken,stopToken);
```

Create a word encoding object from the tokenized documents.

```
enc = wordEncoding(documents);
```

When training a deep learning model, the input data must be a numeric array containing sequences of a fixed length. Because the documents have different lengths, you must pad the shorter sequences with a padding value.

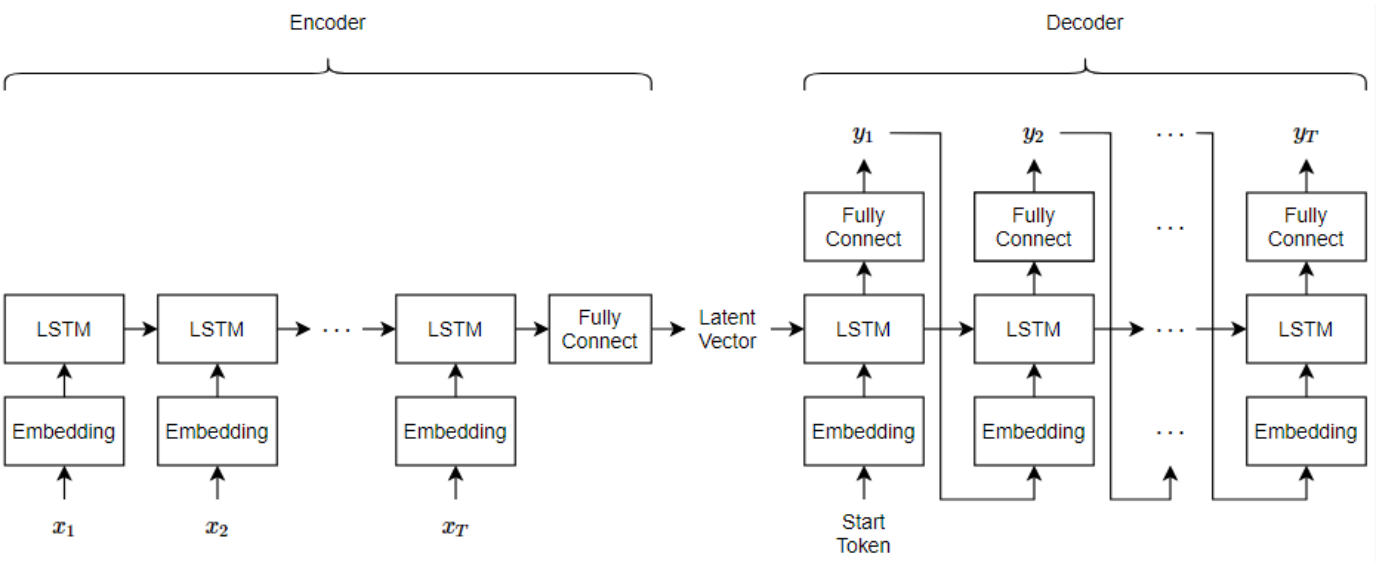
Recreate the word encoding to also include a padding token and determine the index of that token.

```
paddingToken = "<pad>";
newVocabulary = [enc.Vocabulary paddingToken];
enc = wordEncoding(newVocabulary);
paddingIdx = word2ind(enc,paddingToken)
```

```
paddingIdx = 3595
```

Initialize Model Parameters

Initialize the parameters for the following model.



Here, T is the sequence length, $x_1, \cdots, x_T$ is the input sequence of word indices, and $y_1, \cdots, y_T$ is the reconstructed sequence.

The encoder maps sequences of word indices to a latent vector by converting the input to sequences of word vectors using an embedding, inputting the word vector sequences into an LSTM operation, and applying a fully connected operation to the last time step of the LSTM output. The decoder reconstructs the input using an LSTM initialized the encoder output. For each time step, the decoder predicts the next time step and uses the output for the next time-step predictions. Both the encoder and the decoder use the same embedding.

Specify the dimensions of the parameters.

```
embeddingDimension = 100;
numHiddenUnits = 150;
latentDimension = 75;
vocabularySize = enc.NumWords;
```

Create a struct for the parameters.

```
parameters = struct;
```

Initialize the weights of the embedding using the Gaussian using the `initializeGaussian` function which is attached to this example as a supporting file. Specify a mean of 0 and a standard deviation of 0.01. To learn more, see “Gaussian Initialization” on page 18-299.

```
mu = 0;
sigma = 0.01;
parameters.emb.Weights = initializeGaussian([embeddingDimension vocabularySize],mu,sigma);
```

Initialize the learnable parameters for the encoder LSTM operation:

- Initialize the input weights with the Glorot initializer using the `initializeGlorot` function which is attached to this example as a supporting file. To learn more, see “Glorot Initialization” on page 18-296.
- Initialize the recurrent weights with the orthogonal initializer using the `initializeOrthogonal` function which is attached to this example as a supporting file. To learn more, see “Orthogonal Initialization” on page 18-300.
- Initialize the bias with the unit forget gate initializer using the `initializeUnitForgetGate` function which is attached to this example as a supporting file. To learn more, see “Unit Forget Gate Initialization” on page 18-301.

```
sz = [4*numHiddenUnits embeddingDimension];
numOut = 4*numHiddenUnits;
numIn = embeddingDimension;

parameters.lstmEncoder.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.lstmEncoder.RecurrentWeights = initializeOrthogonal([4*numHiddenUnits numHiddenUnits])
parameters.lstmEncoder.Bias = initializeUnitForgetGate(numHiddenUnits);
```

Initialize the learnable parameters for the encoder fully connected operation:

- Initialize the weights with the Glorot initializer.
- Initialize the bias with zeros using the `initializeZeros` function which is attached to this example as a supporting file. To learn more, see “Zeros Initialization” on page 18-302.

```
sz = [latentDimension numHiddenUnits];
numOut = latentDimension;
numIn = numHiddenUnits;

parameters.fcEncoder.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fcEncoder.Bias = initializeZeros([latentDimension 1]);
```

Initialize the learnable parameters for the decoder LSTM operation:

- Initialize the input weights with the Glorot initializer.
- Initialize the recurrent weights with the orthogonal initializer.
- Initialize the bias with the unit forget gate initializer.

```
sz = [4*latentDimension embeddingDimension];
numOut = 4*latentDimension;
numIn = embeddingDimension;

parameters.lstmDecoder.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.lstmDecoder.RecurrentWeights = initializeOrthogonal([4*latentDimension latentDimensio
parameters.lstmDecoder.Bias = initializeZeros([4*latentDimension 1]);
```

Initialize the learnable parameters for the decoder fully connected operation:

- Initialize the weights with the Glorot initializer.

- Initialize the bias with zeros.

```
sz = [vocabularySize latentDimension];
numOut = vocabularySize;
numIn = latentDimension;

parameters.fcDecoder.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fcDecoder.Bias = initializeZeros([vocabularySize 1]);
```

To learn more about weight initialization, see “Initialize Learnable Parameters for Model Function” on page 18-292.

Define Model Encoder Function

Create the function `modelEncoder`, listed in the Encoder Model Function on page 4-0 section of the example, that computes the output of the encoder model. The `modelEncoder` function, takes as input sequences of word indices, the model parameters, and the sequence lengths, and returns the corresponding latent feature vector. To learn more about defining a model encoder function, see “Define Text Encoder Model Function” on page 4-150.

Define Model Decoder Function

Create the function `modelDecoder`, listed in the Decoder Model Function on page 4-0 section of the example, that computes the output of the decoder model. The `modelDecoder` function, takes as input sequences of word indices, the model parameters, and the sequence lengths, and returns the corresponding latent feature vector. To learn more about defining a model decoder function, see “Define Text Decoder Model Function” on page 4-157.

Define Model Gradients Function

The `modelGradients` function, listed in the Model Gradients Function on page 4-0 section of the example, takes as input the model learnable parameters, the input data `dlX`, and a vector of sequence lengths for masking, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss. To learn more about defining a model gradients function, see “Define Model Gradients Function for Custom Training Loop” on page 18-231.

Specify Training Options

Specify the options for training.

Train for 100 epochs with a mini-batch size of 128.

```
miniBatchSize = 128;
numEpochs = 100;
```

Train with a learning rate of 0.01.

```
learnRate = 0.01;
```

Display the training progress in a plot.

```
plots = "training-progress";
```

Train on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
executionEnvironment = "auto";
```

Train Network

Train the network using a custom training loop.

Initialize the parameters for the Adam optimizer.

```
trailingAvg = [];
trailingAvgSq = [];
```

Initialize the training progress plot. Create an animated line that plots the loss against the corresponding iteration.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    xlabel("Iteration")
    ylabel("Loss")
    ylim([0 inf])
    grid on
end
```

Train the model. For the first epoch, shuffle the data and loop over mini-batches of data.

For each mini-batch:

- Convert the text data to sequences of word indices.
- Convert the data to `dlarray`.
- For GPU training, convert the data to `gpuArray` objects.
- Compute loss and gradients.
- Update the learnable parameters using the `adamupdate` function.
- Update the training progress plot.

Training can take some time to run.

```
numObservations = numel(documents);
numIterationsPerEpoch = floor(numObservations / miniBatchSize);

iteration = 0;
start = tic;

for epoch = 1:numEpochs

    % Shuffle.
    idx = randperm(numObservations);
    documents = documents(idx);

    for i = 1:numIterationsPerEpoch
        iteration = iteration + 1;

        % Read mini-batch.
        idx = (i-1)*miniBatchSize+1:i*miniBatchSize;
        documentsBatch = documents(idx);

        % Convert to sequences.
```

```
            X = doc2sequence(enc,documentsBatch, ...
                'PaddingDirection','right', ...
                'PaddingValue',paddingIdx);
            X = cat(1,X{:});

            % Convert to dlarray.
            dlX = dlarray(X,'BTC');

            % If training on a GPU, then convert data to gpuArray.
            if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
                dlX = gpuArray(dlX);
            end

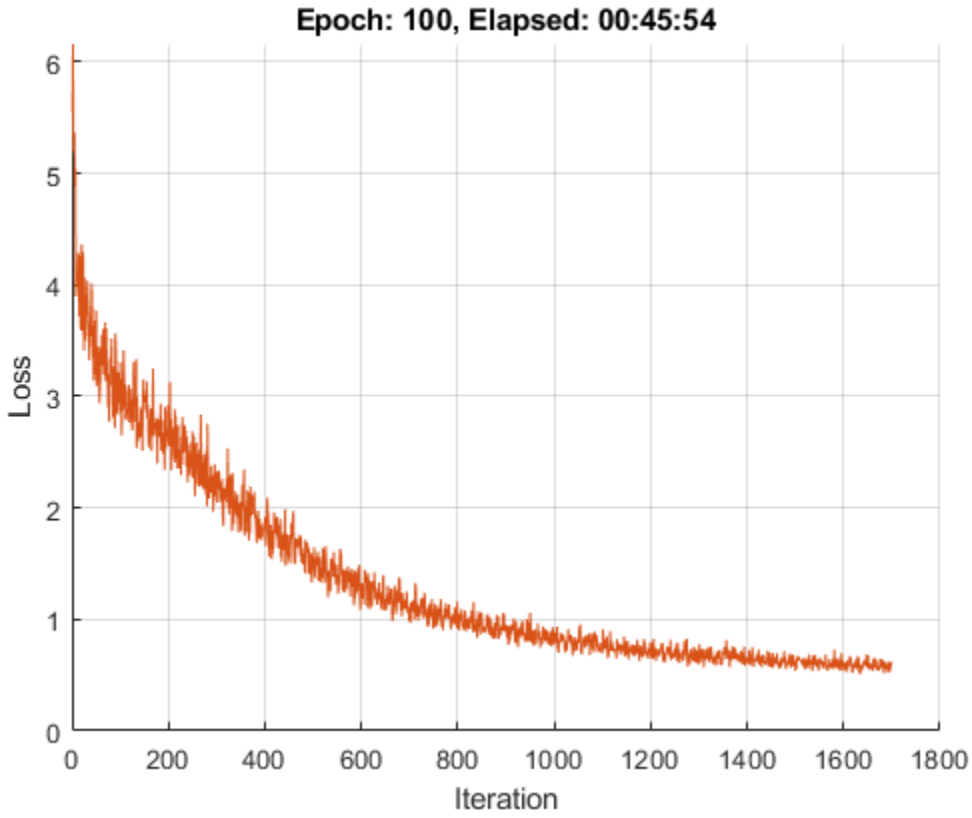
            % Calculate sequence lengths.
            sequenceLengths = doclength(documentsBatch);

            % Evaluate model gradients.
            [gradients,loss] = dlfeval(@modelGradients, parameters, dlX, sequenceLengths);

            % Update learnable parameters.
            [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
                trailingAvg,trailingAvgSq,iteration,learnRate);

            % Display the training progress.
            if plots == "training-progress"
                D = duration(0,0,toc(start),'Format','hh:mm:ss');
                addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
                title("Epoch: " + epoch + ", Elapsed: " + string(D))

                drawnow
            end
        end
    end
```



Generate Text

Generate text using closed loop generation by initializing the decoder with different random states. Closed loop generation is when the model generates data one time-step at a time and uses the previous prediction as input for the next prediction.

Specify to generate 3 sequences of length 16.

```
numGenerations = 3;
sequenceLength = 16;
```

Create an array of random values to initialize the decoder state.

```
dlZ = dlarray(randn(latentDimension,numGenerations),'CB');
```

If predicting on a GPU, then convert data to `gpuArray`.

```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZ = gpuArray(dlZ);
end
```

Make predictions using the `modelPredictions` function, listed at the end of the example. The `modelPredictions` function returns the output scores of the decoder given the model parameters, decoder initial state, maximum sequence length, word encoding, start token, and mini-batch size.

```
dlY = modelDecoderPredictions(parameters,dlZ,sequenceLength,enc,startToken,miniBatchSize);
```

Find the word indices with the highest scores.

```
[~,idx] = max(dlY,[],1);
idx = squeeze(idx);
```

Convert the numeric indices to words and join them using the `join` function.

```
strGenerated = join(enc.Vocabulary(idx));
```

Extract the text before the first stop token using the `extractBefore` function. To prevent the function from returning missing when there are no stop tokens, append a stop token to the end of each sequence.

```
strGenerated = extractBefore(strGenerated+stopToken,stopToken);
```

Remove padding tokens.

```
strGenerated = erase(strGenerated,paddingToken);
```

The generation process introduces whitespace characters between each prediction, which means that some punctuation characters appear with unnecessary spaces before and after. Reconstruct the generated text by removing the spaces before and after the appropriate punctuation characters.

Remove the spaces that appear before the specified punctuation characters.

```
punctuationCharacters = ["." "," "’" ")" ":" ";" "?" "!"];
strGenerated = replace(strGenerated," " + punctuationCharacters,punctuationCharacters);
```

Remove the spaces that appear after the specified punctuation characters.

```
punctuationCharacters = ["(" "‘"];
strGenerated = replace(strGenerated,punctuationCharacters + " ",punctuationCharacters);
```

Remove leading and trailing white space using the `strip` function and view the generated text.

```
strGenerated = strip(strGenerated)
```

```
strGenerated = 3×1 string
    "love's thou rest light best ill mistake show seeing farther cross enough by me"
    "as before his bending sickle's compass come look find."
    "summer's lays? truth once lead mayst take,"
```

Encoder Model Function

The `modelEncoder` function, takes as input the model parameters, sequences of word indices, and the sequence lengths, and returns the corresponding latent feature vector.

Because the input data contains padded sequences of different lengths, the padding can have adverse effects on loss calculations. For the LSTM operation, instead of returning the output of the last time step of the sequence (which likely corresponds to the LSTM state after processing lots of padding values), determine the actual last time step given by the `sequenceLengths` input.

```
function dlZ = modelEncoder(parameters,dlX,sequenceLengths)

% Embedding.
weights = parameters.emb.Weights;
dlZ = embedding(dlX,weights);

% LSTM.
```

```
inputWeights = parameters.lstmEncoder.InputWeights;
recurrentWeights = parameters.lstmEncoder.RecurrentWeights;
bias = parameters.lstmEncoder.Bias;

numHiddenUnits = size(recurrentWeights,2);
hiddenState = zeros(numHiddenUnits,1,'like',dlX);
cellState = zeros(numHiddenUnits,1,'like',dlX);

dlZ1 = lstm(dlZ,hiddenState,cellState,inputWeights,recurrentWeights,bias,'DataFormat','CBT');

% Output mode 'last' with masking.
miniBatchSize = size(dlZ1,2);
dlZ = zeros(numHiddenUnits,miniBatchSize,'like',dlZ1);

for n = 1:miniBatchSize
    t = sequenceLengths(n);
    dlZ(:,n) = dlZ1(:,n,t);
end

% Fully connect.
weights = parameters.fcEncoder.Weights;
bias = parameters.fcEncoder.Bias;
dlZ = fullyconnect(dlZ,weights,bias,'DataFormat','CB');

end
```

Decoder Model Function

The `modelDecoder` function, takes as input the model parameters, sequences of word indices, and the network state, and returns the decoded sequences.

Because the `lstm` function is *stateful* (when given a time series as input, the function propagates and updates the state between each time step) and that the `embedding` and `fullyconnect` functions are time-distributed by default (when given a time series as input, the functions operate on each time step independently), the `modelDecoder` function supports both sequence and single time-step inputs.

```
function [dlY,state] = modelDecoder(parameters,dlX,state)

% Embedding.
weights = parameters.emb.Weights;
dlX = embedding(dlX,weights);

% LSTM.
inputWeights = parameters.lstmDecoder.InputWeights;
recurrentWeights = parameters.lstmDecoder.RecurrentWeights;
bias = parameters.lstmDecoder.Bias;

hiddenState = state.HiddenState;
cellState = state.CellState;

[dlY,hiddenState,cellState] = lstm(dlX,hiddenState,cellState, ...
    inputWeights,recurrentWeights,bias,'DataFormat','CBT');

state.HiddenState = hiddenState;
state.CellState = cellState;

% Fully connect.
```

```
weights = parameters.fcDecoder.Weights;
bias = parameters.fcDecoder.Bias;
dlY = fullyconnect(dlY,weights,bias,'DataFormat','CBT');

% Softmax.
dlY = softmax(dlY,'DataFormat','CBT');

end
```

Model Gradients Function

The `modelGradients` function that takes as input the model learnable parameters, the input data `dlX`, and a vector of sequence lengths for masking, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss.

To calculate the masked loss, the model gradients function uses the `maskedCrossEntropy` loss function, listed at the end of the example. To train the decoder to predict the next time-step of the sequence, specify the targets to be the input sequences shifted by one time-step.

To learn more about defining a model gradients function, see “Define Model Gradients Function for Custom Training Loop” on page 18-231.

```
function [gradients, loss] = modelGradients(parameters,dlX,sequenceLengths)

% Model encoder.
dlZ = modelEncoder(parameters,dlX,sequenceLengths);

% Initialize LSTM state.
state = struct;
state.HiddenState = dlZ;
state.CellState = zeros(size(dlZ),'like',dlZ);

% Teacher forcing.
dlY = modelDecoder(parameters,dlX,state);

% Loss.
dlYPred = dlY(:,:,1:end-1);
dlT = dlX(:,:,2:end);
loss = mean(maskedCrossEntropy(dlYPred,dlT,sequenceLengths));

% Gradients.
gradients = dlgradient(loss,parameters);

% Normalize loss for plotting.
sequenceLength = size(dlX,3);
loss = loss / sequenceLength;

end
```

Model Predictions Function

The `modelPredictions` function returns the output scores of the decoder given the model parameters, decoder initial state, maximum sequence length, word encoding, start token, and mini-batch size.

```
function dlY = modelDecoderPredictions(parameters,dlZ,maxLength,enc,startToken,miniBatchSize)

numObservations = size(dlZ,2);
```

```
numIterations = ceil(numObservations / miniBatchSize);

startTokenIdx = word2ind(enc,startToken);
vocabularySize = enc.NumWords;

dlY = zeros(vocabularySize,numObservations,maxLength,'like',dlZ);

% Loop over mini-batches.
for i = 1:numIterations
    idxMiniBatch = (i-1)*miniBatchSize+1:min(i*miniBatchSize,numObservations);
    miniBatchSize = numel(idxMiniBatch);

    % Initialize state.
    state = struct;
    state.HiddenState = dlZ(:,idxMiniBatch);
    state.CellState = zeros(size(dlZ(:,idxMiniBatch)),'like',dlZ);

    % Initialize decoder input.
    decoderInput = dlarray(repmat(startTokenIdx,[1 miniBatchSize]),'CBT');

    % Loop over time steps.
    for t = 1:maxLength
        % Predict next time step.
        [dlY(:,idxMiniBatch,t), state] = modelDecoder(parameters,decoderInput,state);

        % Closed loop generation.
        [~,idx] = max(dlY(:,idxMiniBatch,t));
        decoderInput = idx;
    end
end

end
```

Masked Cross Entropy Loss Function

The `maskedCrossEntropy` function calculates the loss between the specified input sequences and target sequences ignoring any time steps containing padding using the specified vector of sequence lengths.

```
function maskedLoss = maskedCrossEntropy(dlY,T,sequenceLengths)

numClasses = size(dlY,1);
miniBatchSize = size(dlY,2);
sequenceLength = size(dlY,3);

maskedLoss = zeros(sequenceLength,miniBatchSize,'like',dlY);

for t = 1:sequenceLength
    T1 = single(oneHot(T(:,:,t),numClasses));

    mask = (t<=sequenceLengths)';

    maskedLoss(t,:) = mask .* crossentropy(dlY(:,:,t),T1,'DataFormat','CBT');
end

maskedLoss = sum(maskedLoss,1);

end
```

Text Preprocessing Function

The function `preprocessText` performs these steps:

1. Prepends and appends each input string with the specified start and stop tokens, respectively.
2. Tokenize the text using `tokenizedDocument`.

```
function documents = preprocessText(textData,startToken,stopToken)

% Add start and stop tokens.
textData = startToken + textData + stopToken;

% Tokenize the text.
documents = tokenizedDocument(textData,'CustomTokens',[startToken stopToken]);

end
```

Embedding Function

The `embedding` function maps sequences of indices to vectors using the given weights.

```
function Z = embedding(X, weights)

% Reshape inputs into a vector.
[N, T] = size(X, 2:3);
X = reshape(X, N*T, 1);

% Index into embedding matrix.
Z = weights(:, X);

% Reshape outputs by separating out batch and sequence dimensions.
Z = reshape(Z, [], N, T);

end
```

One-Hot Encoding Function

The `oneHot` function converts an array of numeric indices to one-hot encoded vectors.

```
function oh = oneHot(idx, outputSize)

miniBatchSize = numel(idx);
oh = zeros(outputSize,miniBatchSize);

for n = 1:miniBatchSize
    c = idx(n);
    oh(c,n) = 1;
end

end
```

More About

- “Define Custom Training Loops, Loss Functions, and Networks” on page 18-209
- “Define Text Encoder Model Function” on page 4-150
- “Define Text Decoder Model Function” on page 4-157

Define Text Encoder Model Function

This example shows how to define a text encoder model function.

In the context of deep learning, an encoder is the part of a deep learning network that maps the input to some latent space. You can use these vectors for various tasks. For example,

- Classification by applying a softmax operation to the encoded data and using cross entropy loss.
- Sequence-to-sequence translation by using the encoded vector as a context vector.

Load Data

The file `sonnets.txt` contains all of Shakespeare's sonnets in a single text file.

Read the Shakespeare's Sonnets data from the file `"sonnets.txt"`.

```
filename = "sonnets.txt";
textData = fileread(filename);
```

The sonnets are indented by two whitespace characters. Remove the indentations using `replace` and split the text into separate lines using the `split` function. Remove the header from the first nine elements and the short sonnet titles.

```
textData = replace(textData,"  ","");
textData = split(textData,newline);
textData(1:9) = [];
textData(strlength(textData)<5) = [];
```

Prepare Data

Create a function that tokenizes and preprocesses the text data. The function `preprocessText`, listed at the end of the example, performs these steps:

1. Prepends and appends each input string with the specified start and stop tokens, respectively.
2. Tokenize the text using `tokenizedDocument`.

Preprocess the text data and specify the start and stop tokens `"<start>"` and `"<stop>"`, respectively.

```
startToken = "<start>";
stopToken = "<stop>";
documents = preprocessText(textData,startToken,stopToken);
```

Create a word encoding object from the tokenized documents.

```
enc = wordEncoding(documents);
```

When training a deep learning model, the input data must be a numeric array containing sequences of a fixed length. Because the documents have different lengths, you must pad the shorter sequences with a padding value.

Recreate the word encoding to also include a padding token and determine the index of that token.

```
paddingToken = "<pad>";
newVocabulary = [enc.Vocabulary paddingToken];
enc = wordEncoding(newVocabulary);
paddingIdx = word2ind(enc,paddingToken)
```

```
paddingIdx = 3595
```

Initialize Model Parameters

The goal of the encoder is to map sequences of word indices to vectors in some latent space.

Initialize the parameters for the following model.

This model uses three operations:

- The embedding maps word indices in the range 1 though `vocabularySize` to vectors of dimension `embeddingDimension`, where `vocabularySize` is the number of words in the encoding vocabulary and `embeddingDimension` is the number of components learned by the embedding.
- The LSTM operation takes as input sequences of word vectors and outputs 1-by-`numHiddenUnits` vectors, where `numHiddenUnits` is the number of hidden units in the LSTM operation.
- The fully connected operation multiplies the input by a weight matrix adding bias and outputs vectors of size `latentDimension`, where `latentDimension` is the dimension of the latent space.

Specify the dimensions of the parameters.

```
embeddingDimension = 100;
numHiddenUnits = 150;
latentDimension = 50;
vocabularySize = enc.NumWords;
```

Create a struct for the parameters.

```
parameters = struct;
```

Initialize the weights of the embedding using the Gaussian using the `initializeGaussian` function which is attached to this example as a supporting file. Specify a mean of 0 and a standard deviation of 0.01. To learn more, see “Gaussian Initialization” on page 18-299.

```
mu = 0;
sigma = 0.01;
parameters.emb.Weights = initializeGaussian([embeddingDimension vocabularySize],mu,sigma);
```

Initialize the learnable parameters for the encoder LSTM operation:

- Initialize the input weights with the Glorot initializer using the `initializeGlorot` function which is attached to this example as a supporting file. To learn more, see “Glorot Initialization” on page 18-296.
- Initialize the recurrent weights with the orthogonal initializer using the `initializeOrthogonal` function which is attached to this example as a supporting file. To learn more, see “Orthogonal Initialization” on page 18-300.

- Initialize the bias with the unit forget gate initializer using the `initializeUnitForgetGate` function which is attached to this example as a supporting file. To learn more, see “Unit Forget Gate Initialization” on page 18-301.

The sizes of the learnable parameters depend on the size of the input. Because the inputs to the LSTM operation are sequences of word vectors from the embedding operation, the number of input channels is `embeddingDimension`.

- The input weight matrix has size `4*numHiddenUnits`-by-`inputSize`, where `inputSize` is the dimension of the input data.
- The recurrent weight matrix has size `4*numHiddenUnits`-by-`numHiddenUnits`.
- The bias vector has size `4*numHiddenUnits`-by-1.

```
sz = [4*numHiddenUnits embeddingDimension];
numOut = 4*numHiddenUnits;
numIn = embeddingDimension;

parameters.lstmEncoder.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.lstmEncoder.RecurrentWeights = initializeOrthogonal([4*numHiddenUnits numHiddenUnits])
parameters.lstmEncoder.Bias = initializeUnitForgetGate(numHiddenUnits);
```

Initialize the learnable parameters for the encoder fully connected operation:

- Initialize the weights with the Glorot initializer.
- Initialize the bias with zeros using the `initializeZeros` function which is attached to this example as a supporting file. To learn more, see “Zeros Initialization” on page 18-302.

The sizes of the learnable parameters depend on the size of the input. Because the inputs to the fully connected operation are the outputs of the LSTM operation, the number of input channels is `numHiddenUnits`. To make the fully connected operation output vectors with size `latentDimension`, specify an output size of `latentDimension`.

- The weights matrix has size `outputSize`-by-`inputSize`, where `outputSize` and `inputSize` correspond to the output and input dimensions, respectively.
- The bias vector has size `outputSize`-by-1.

```
sz = [latentDimension numHiddenUnits];
numOut = latentDimension;
numIn = numHiddenUnits;

parameters.fcEncoder.Weights = initializeGlorot(sz,numOut,numIn);
parameters.fcEncoder.Bias = initializeZeros([latentDimension 1]);
```

Define Model Encoder Function

Create the function `modelEncoder`, listed in the Encoder Model Function on page 4-0 section of the example, that computes the output of the encoder model. The `modelEncoder` function, takes as input sequences of word indices, the model parameters, and the sequence lengths, and returns the corresponding latent feature vector.

Prepare Mini-Batch of Data

To train the model using a custom training loop, you must iterate over mini-batches of data and convert it into the format required for the encoder model and the model gradients functions. This

section of the example illustrates the steps needed for preparing a mini-batch of data inside the custom training loop.

Prepare an example mini-batch of data. Select a mini-batch of 32 documents from `documents`. This represents the mini-batch of data used in an iteration of a custom training loop.

```
miniBatchSize = 32;
idx = 1:miniBatchSize;
documentsBatch = documents(idx);
```

Convert the documents to sequences using the `doc2sequence` function and specify to right-pad the sequences with the word index corresponding to the padding token.

```
X = doc2sequence(enc,documentsBatch, ...
    'PaddingDirection','right', ...
    'PaddingValue',paddingIdx);
```

The output of the `doc2sequence` function is a cell array, where each element is a row vector of word indices. Because the encoder model function requires numeric input, concatenate the rows of the data using the `cat` function and specify to concatenate along the first dimension. The output has size `miniBatchSize`-by-`sequenceLength`, where `sequenceLength` is the length of the longest sequence in the mini-batch.

```
X = cat(1,X{:});
size(X)
```

```
ans = 1×2

    32    14
```

Convert the data to a `dlarray` with format `'BTC'` (batch, time, channel). The software automatically rearranges the output to have format `'CTB'` so the output has size `1`-by-`miniBatchSize`-by-`sequenceLength`.

```
dlX = dlarray(X,'BTC');
size(dlX)
```

```
ans = 1×3

     1    32    14
```

For masking, calculate the unpadded sequence lengths of the input data using the `doclength` function with the mini-batch of documents as input.

```
sequenceLengths = doclength(documentsBatch);
```

This code snippet shows an example of preparing a mini-batch in a custom training loop.

```
iteration = 0;

% Loop over epochs.
for epoch = 1:numEpochs

    % Loop over mini-batches.
    for i = 1:numIterationsPerEpoch
```

```
        iteration = iteration + 1;

        % Read mini-batch.
        idx = (i-1)*miniBatchSize+1:i*miniBatchSize;
        documentsBatch = documents(idx);

        % Convert to sequences.
        X = doc2sequence(enc,documentsBatch, ...
            'PaddingDirection','right', ...
            'PaddingValue',paddingIdx);
        X = cat(1,X{:});

        % Convert to dlarray.
        dlX = dlarray(X,'BTC');

        % Calculate sequence lengths.
        sequenceLengths = doclength(documentsBatch);

        % Evaluate model gradients.
        % ...

        % Update learnable parameters.
        % ...
    end
end
```

Use Model Function in Model Gradients Function

When training a deep learning model with a custom training loop, you must calculate the gradients of the loss with respect to the learnable parameters. This calculation depends on the output of a forward pass of the model function.

To perform a forward pass of the encoder, use the `modelEncoder` function directly with the parameters, data, and sequence lengths as input. The output is a `latentDimension`-by-`miniBatchSize` matrix.

```
dlZ = modelEncoder(parameters,dlX,sequenceLengths);
size(dlZ)
```

```
ans = 1×2

    50    32
```

This code snippet shows an example of using a model encoder function inside the model gradients function.

```
function gradients = modelGradients(parameters,dlX,sequenceLengths)

    dlZ = modelEncoder(parameters,dlX,sequenceLengths);

    % Calculate loss.
    % ...

    % Calculate gradients.
    % ...

end
```

This code snippet shows an example of evaluating the model gradients in a custom training loop.

```
iteration = 0;

% Loop over epochs.
for epoch = 1:numEpochs

    % Loop over mini-batches.
    for i = 1:numIterationsPerEpoch
        iteration = iteration + 1;

        % Prepare mini-batch.
        % ...

        % Evaluate model gradients.
        gradients = dlfeval(@modelGradients, parameters, dlX, sequenceLengths);

        % Update learnable parameters.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients, ...
            trailingAvg,trailingAvgSq,iteration);
    end
end
```

Encoder Model Function

The `modelEncoder` function, takes as input the model parameters, sequences of word indices, and the sequence lengths, and returns the corresponding latent feature vector.

Because the input data contains padded sequences of different lengths, the padding can have adverse effects on loss calculations. For the LSTM operation, instead of returning the output of the last time step of the sequence (which likely corresponds to the LSTM state after processing lots of padding values), determine the actual last time step given by the `sequenceLengths` input.

```
function dlZ = modelEncoder(parameters,dlX,sequenceLengths)

% Embedding.
weights = parameters.emb.Weights;
dlZ = embed(dlX,weights);

% LSTM.
inputWeights = parameters.lstmEncoder.InputWeights;
recurrentWeights = parameters.lstmEncoder.RecurrentWeights;
bias = parameters.lstmEncoder.Bias;

numHiddenUnits = size(recurrentWeights,2);
hiddenState = zeros(numHiddenUnits,1,'like',dlX);
cellState = zeros(numHiddenUnits,1,'like',dlX);

dlZ1 = lstm(dlZ,hiddenState,cellState,inputWeights,recurrentWeights,bias);

% Output mode 'last' with masking.
miniBatchSize = size(dlZ1,2);
dlZ = zeros(numHiddenUnits,miniBatchSize,'like',dlZ1);
dlZ = dlarray(dlZ,'CB');

for n = 1:miniBatchSize
    t = sequenceLengths(n);
    dlZ(:,n) = dlZ1(:,n,t);
```

```
end

% Fully connect.
weights = parameters.fcEncoder.Weights;
bias = parameters.fcEncoder.Bias;
dlZ = fullyconnect(dlZ,weights,bias);

end
```

Preprocessing Function

The function `preprocessText` performs these steps:

1. Prepends and appends each input string with the specified start and stop tokens, respectively.
2. Tokenize the text using `tokenizedDocument`.

```
function documents = preprocessText(textData,startToken,stopToken)

% Add start and stop tokens.
textData = startToken + textData + stopToken;

% Tokenize the text.
documents = tokenizedDocument(textData,'CustomTokens',[startToken stopToken]);

end
```

- “Define Text Decoder Model Function” on page 4-157

Define Text Decoder Model Function

This example shows how to define a text decoder model function.

In the context of deep learning, a decoder is the part of a deep learning network that maps a latent vector to some sample space. You can use decode the vectors for various tasks. For example,

- Text generation by initializing a recurrent network with the encoded vector.
- Sequence-to-sequence translation by using the encoded vector as a context vector.
- Image captioning by using the encoded vector as a context vector.

Load Data

Load the encoded data from `sonnetsEncoded.mat`. This MAT file contains the word encoding, a mini-batch of sequences `dlX`, and the corresponding encoded data `dlZ` output by the encoder used in the example “Define Text Encoder Model Function” on page 4-150.

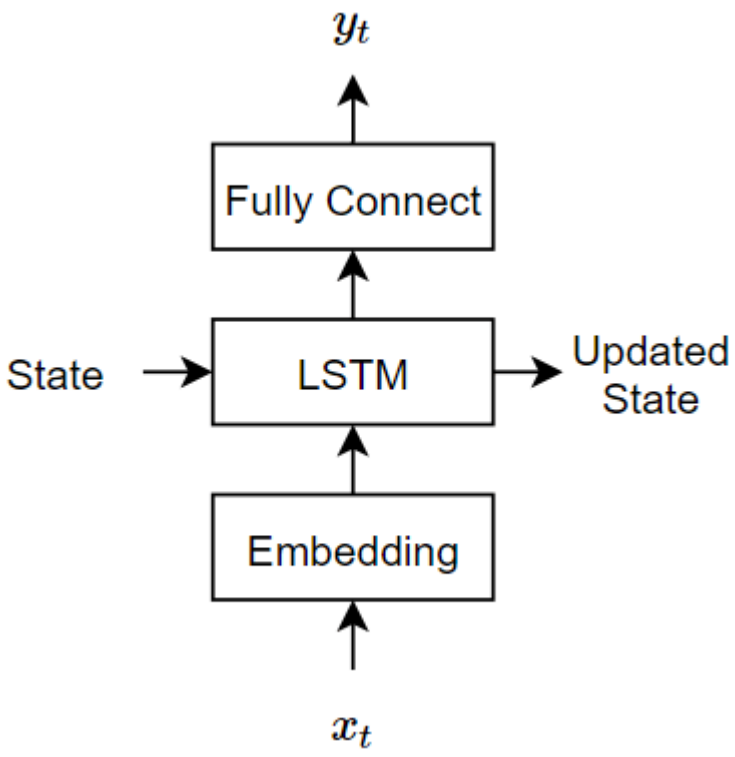
```
s = load("sonnetsEncoded.mat");
enc = s.enc;
dlX = s.dlX;
dlZ = s.dlZ;

[latentDimension,miniBatchSize] = size(dlZ,1:2);
```

Initialize Model Parameters

The goal of the decoder is to generate sequences given some initial input data and network state.

Initialize the parameters for the following model.



The decoder reconstructs the input using an LSTM initialized the encoder output. For each time step, the decoder predicts the next time step and uses the output for the next time-step predictions. Both the encoder and the decoder use the same embedding.

This model uses three operations:

- The embedding maps word indices in the range 1 though `vocabularySize` to vectors of dimension `embeddingDimension`, where `vocabularySize` is the number of words in the encoding vocabulary and `embeddingDimension` is the number of components learned by the embedding.
- The LSTM operation takes as input a single word vector and outputs 1-by-`numHiddenUnits` vector, where `numHiddenUnits` is the number of hidden units in the LSTM operation. The initial state of the LSTM network (the state at the first time-step) is the encoded vector, so the number of hidden units must match the latent dimension of the encoder.
- The fully connected operation multiplies the input by a weight matrix adding bias and outputs vectors of size `vocabularySize`.

Specify the dimensions of the parameters. The embedding sizes must match the encoder.

```
embeddingDimension = 100;
vocabularySize = enc.NumWords;
numHiddenUnits = latentDimension;
```

Create a struct for the parameters.

```
parameters = struct;
```

Initialize the weights of the embedding using the Gaussian using the `initializeGaussian` function which is attached to this example as a supporting file. Specify a mean of 0 and a standard deviation of 0.01. To learn more, see “Gaussian Initialization” on page 18-299.

```
mu = 0;
sigma = 0.01;
parameters.emb.Weights = initializeGaussian([embeddingDimension vocabularySize],mu,sigma);
```

Initialize the learnable parameters for the decoder LSTM operation:

- Initialize the input weights with the Glorot initializer using the `initializeGlorot` function which is attached to this example as a supporting file. To learn more, see “Glorot Initialization” on page 18-296.
- Initialize the recurrent weights with the orthogonal initializer using the `initializeOrthogonal` function which is attached to this example as a supporting file. To learn more, see “Orthogonal Initialization” on page 18-300.
- Initialize the bias with the unit forget gate initializer using the `initializeUnitForgetGate` function which is attached to this example as a supporting file. To learn more, see “Unit Forget Gate Initialization” on page 18-301.

The sizes of the learnable parameters depend on the size of the input. Because the inputs to the LSTM operation are sequences of word vectors from the embedding operation, the number of input channels is `embeddingDimension`.

- The input weight matrix has size `4*numHiddenUnits`-by-`inputSize`, where `inputSize` is the dimension of the input data.

- The recurrent weight matrix has size `4*numHiddenUnits`-by-`numHiddenUnits`.
- The bias vector has size `4*numHiddenUnits`-by-1.

```
sz = [4*numHiddenUnits embeddingDimension];
numOut = 4*numHiddenUnits;
numIn = embeddingDimension;

parameters.lstmDecoder.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.lstmDecoder.RecurrentWeights = initializeOrthogonal([4*numHiddenUnits numHiddenUnits]);
parameters.lstmDecoder.Bias = initializeUnitForgetGate(numHiddenUnits);
```

Initialize the learnable parameters for the encoder fully connected operation:

- Initialize the weights with the Glorot initializer.
- Initialize the bias with zeros using the `initializeZeros` function which is attached to this example as a supporting file. To learn more, see “Zeros Initialization” on page 18-302.

The sizes of the learnable parameters depend on the size of the input. Because the inputs to the fully connected operation are the outputs of the LSTM operation, the number of input channels is `numHiddenUnits`. To make the fully connected operation output vectors with size `latentDimension`, specify an output size of `latentDimension`.

- The weights matrix has size `outputSize`-by-`inputSize`, where `outputSize` and `inputSize` correspond to the output and input dimensions, respectively.
- The bias vector has size `outputSize`-by-1.

To make the fully connected operation output vectors with size `vocabularySize`, specify an output size of `vocabularySize`.

```
inputSize = numHiddenUnits;
outputSize = vocabularySize;
parameters.fcDecoder.Weights = dlarray(randn(outputSize,inputSize,'single'));
parameters.fcDecoder.Bias = dlarray(zeros(outputSize,1,'single'));
```

Define Model Decoder Function

Create the function `modelDecoder`, listed in the Decoder Model Function on page 4-0 section of the example, that computes the output of the decoder model. The `modelDecoder` function, takes as input sequences of word indices, the model parameters, and the sequence lengths, and returns the corresponding latent feature vector.

Use Model Function in Model Gradients Function

When training a deep learning model with a custom training loop, you must calculate the gradients of the loss with respect to the learnable parameters. This calculation depends on the output of a forward pass of the model function.

There are two common approaches to generating text data with a decoder:

1. Closed loop — For each time step, make predictions using the previous prediction as input.
2. Open loop — For each time step, make predictions using inputs from an external source (for example, training targets).

Closed Loop Generation

Closed loop generation is when the model generates data one time-step at a time and uses the previous prediction as input for the next prediction. Unlike open loop generation, this process does

not require any input between predictions and is best suited for scenarios without supervision. For example, a language translation model that generates output text in one go.

To use closed loop

Initialize the hidden state of the LSTM network with the encoder output `dlZ`.

```
state = struct;
state.HiddenState = dlZ;
state.CellState = zeros(size(dlZ),'like',dlZ);
```

For the first time step, use an array of start tokens as input for the decoder. For simplicity, extract an array of start tokens from the first time-step of the training data.

```
decoderInput = dlX(:,:,1);
```

Preallocate the decoder output to have size `numClasses`-by-`miniBatchSize`-by-`sequenceLength` with the same datatype as `dlX`, where `sequenceLength` is the desired length of the generation, for example, the length of the training targets. For this example, specify a sequence length of 16.

```
sequenceLength = 16;
dlY = zeros(vocabularySize,miniBatchSize,sequenceLength,'like',dlX);
dlY = dlarray(dlY,'CBT');
```

For each time step, predict the next time step of the sequence using the `modelDecoder` function. After each prediction, find the indices corresponding to the maximum values of the decoder output and use these indices as the decoder input for the next time step.

```
for t = 1:sequenceLength
    [dlY(:,:,t), state] = modelDecoder(parameters,decoderInput,state);

    [~,idx] = max(dlY(:,:,t));
    decoderInput = idx;
end
```

The output is a `vocabularySize`-by-`miniBatchSize`-by-`sequenceLength` array.

```
size(dlY)
```

```
ans = 1×3

        3595          32          16
```

This code snippet shows an example of performing closed loop generation in a model gradients function.

```
function gradients = modelGradients(parameters,dlX,sequenceLengths)

    % Encode input.
    dlZ = modelEncoder(parameters,dlX,sequenceLengths);

    % Initialize LSTM state.
    state = struct;
    state.HiddenState = dlZ;
    state.CellState = zeros(size(dlZ),'like',dlZ);

    % Initialize decoder input.
```

```
    decoderInput = dlX(:,:,1);

    % Closed loop prediction.
    sequenceLength = size(dlX,3);
    dlY = zeros(numClasses,miniBatchSize,sequenceLength,'like',dlX);
    for t = 1:sequenceLength
        [dlY(:,:,t), state] = modelDecoder(parameters,decoderInput,state);

        [~,idx] = max(dlY(:,:,t));
        decoderInput = idx;
    end

    % Calculate loss.
    % ...

    % Calculate gradients.
    % ...

end
```

Open Loop Generation: Teacher Forcing

When training with closed loop generation, predicting the most likely word for each step in the sequence can lead to suboptimal results. For example, in an image captioning workflow, if the decoder predicts the first word of a caption is "a" when given an image of an elephant, then the probability of predicting "elephant" for the next word becomes much more unlikely because of the extremely low probability of the phrase "a elephant" appearing in English text.

To help the network converge faster, you can use *teacher forcing:* use the target values as input to the decoder instead of the previous predictions. Using teacher forcing helps the network to learn characteristics from the later time steps of the sequences without having to wait for the network to correctly generate the earlier time steps of the sequences.

To perform teacher forcing, use the `modelEncoder` function directly with the target sequence as input.

Initialize the hidden state of the LSTM network with the encoder output `dlZ`.

```
state = struct;
state.HiddenState = dlZ;
state.CellState = zeros(size(dlZ),'like',dlZ);
```

Make predictions using the target sequence as input.

```
dlY = modelDecoder(parameters,dlX,state);
```

The output is a `vocabularySize`-by-`miniBatchSize`-by-`sequenceLength` array, where `sequenceLength` is the length of the input sequences.

```
size(dlY)
```

```
ans = 1×3

        3595          32          14
```

This code snippet shows an example of performing teacher forcing in a model gradients function.

```
function gradients = modelGradients(parameters,dlX,sequenceLengths)

    % Encode input.
    dlZ = modelEncoder(parameters,dlX,dlZ);

    % Initialize LSTM state.
    state = struct;
    state.HiddenState = dlZ;
    state.CellState = zeros(size(dlZ),'like',dlZ);

    % Teacher forcing.
    dlY = modelDecoder(parameters,dlX,state);

    % Calculate loss.
    % ...

    % Calculate gradients.
    % ...

end
```

Decoder Model Function

The `modelDecoder` function, takes as input the model parameters, sequences of word indices, and the network state, and returns the decoded sequences.

Because the `lstm` function is *stateful* (when given a time series as input, the function propagates and updates the state between each time step) and that the `embed` and `fullyconnect` functions are time-distributed by default (when given a time series as input, the functions operate on each time step independently), the `modelDecoder` function supports both sequence and single time-step inputs.

```
function [dlY,state] = modelDecoder(parameters,dlX,state)

% Embedding.
weights = parameters.emb.Weights;
dlX = embed(dlX,weights);

% LSTM.
inputWeights = parameters.lstmDecoder.InputWeights;
recurrentWeights = parameters.lstmDecoder.RecurrentWeights;
bias = parameters.lstmDecoder.Bias;

hiddenState = state.HiddenState;
cellState = state.CellState;

[dlY,hiddenState,cellState] = lstm(dlX,hiddenState,cellState, ...
    inputWeights,recurrentWeights,bias);

state.HiddenState = hiddenState;
state.CellState = cellState;

% Fully connect.
weights = parameters.fcDecoder.Weights;
bias = parameters.fcDecoder.Bias;
dlY = fullyconnect(dlY,weights,bias);
```

```
end
```

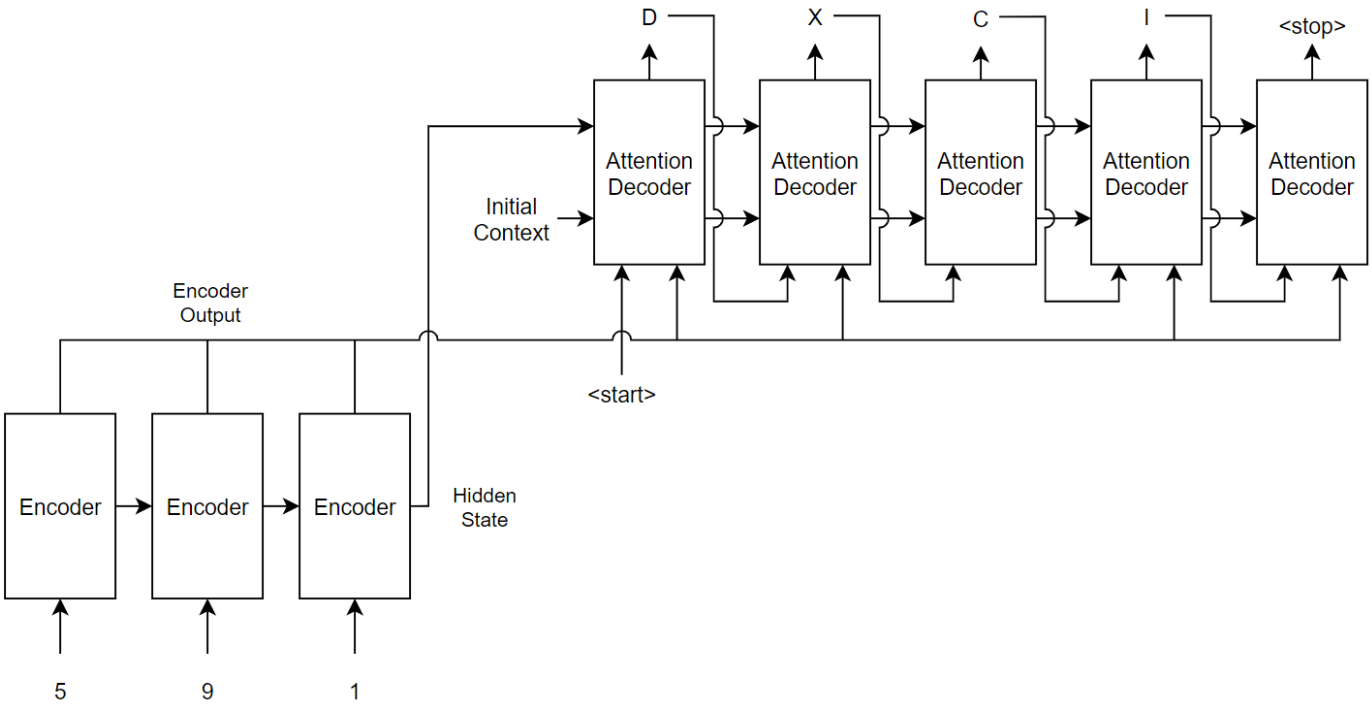
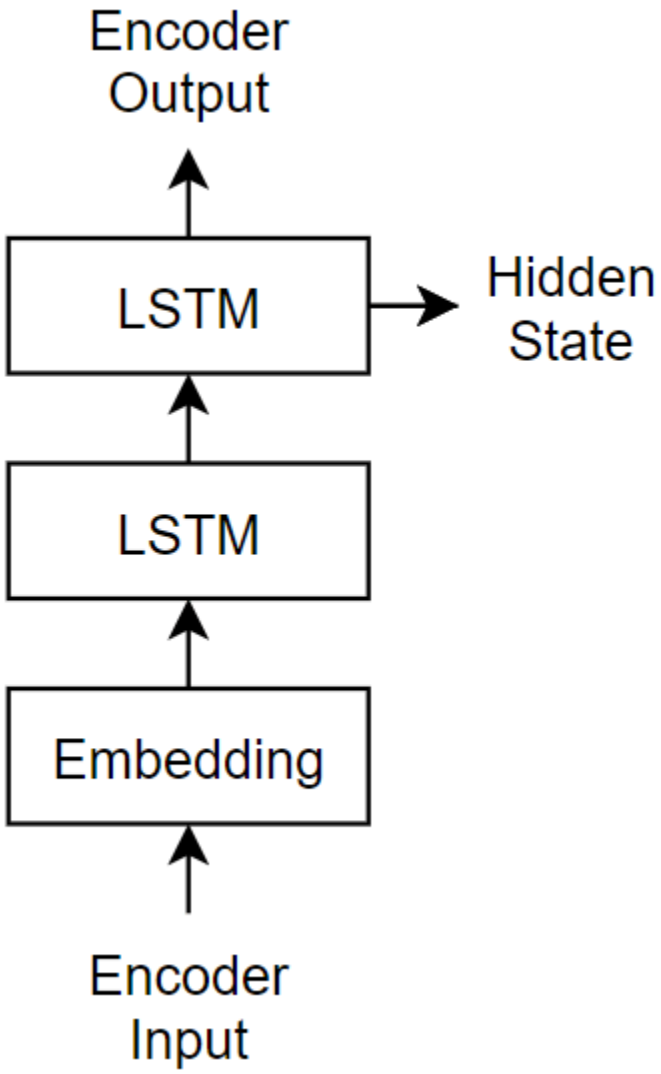
Sequence-to-Sequence Translation Using Attention

This example shows how to convert decimal strings to Roman numerals using a recurrent sequence-to-sequence encoder-decoder model with attention.

Recurrent encoder-decoder models have proven successful at tasks like abstractive text summarization and neural machine translation. The model consists of an *encoder* which typically processes input data with a recurrent layer such as LSTM, and a *decoder* which maps the encoded input into the desired output, typically with a second recurrent layer. Models that incorporate *attention mechanisms* into the models allows the decoder to focus on parts of the encoded input while generating the translation.



For the encoder model, this example uses a simple network consisting of an embedding followed by two LSTM operations. Embedding is a method of converting categorical tokens into numeric vectors.



For the decoder model, this example uses a network very similar to the encoder that contains two LSTMs. However, an important difference is that the decoder contains an attention mechanism. The attention mechanism allows the decoder to *attend* to specific parts of the encoder output.

Load Training Data

Download the decimal-Roman numeral pairs from "romanNumerals.csv"

```
filename = fullfile("romanNumerals.csv");

options = detectImportOptions(filename, ...
    'TextType','string', ...
    'ReadVariableNames',false);
options.VariableNames = ["Source" "Target"];
options.VariableTypes = ["string" "string"];

data = readtable(filename,options);
```

Split the data into training and test partitions containing 50% of the data each.

```
idx = randperm(size(data,1),500);
dataTrain = data(idx,:);
dataTest = data;
dataTest(idx,:) = [];
```

View some of the decimal-Roman numeral pairs.

```
head(dataTrain)
```

```
ans=8×2 table
    Source     Target
    ______    ________

    "492"     "CDXCII"
    "911"     "CMXI"
    "965"     "CMLXV"
    "951"     "CMLI"
    "160"     "CLX"
    "662"     "DCLXII"
    "102"     "CII"
    "440"     "CDXL"
```

Preprocess Data

Preprocess the text data using the `transformText` function, listed at the end of the example. The `transformText` function preprocesses and tokenizes the input text for translation by splitting the text into characters and adding start and stop tokens. To translate text by splitting the text into words instead of characters, skip the first step.

```
startToken = "<start>";
stopToken = "<stop>";

strSource = dataTrain.Source;
documentsSource = transformText(strSource,startToken,stopToken);
```

Create a `wordEncoding` object that maps tokens to a numeric index and vice-versa using a vocabulary.

```
encSource = wordEncoding(documentsSource);
```

Using the word encoding, convert the source text data to numeric sequences.

```
sequencesSource = doc2sequence(encSource, documentsSource,'PaddingDirection','none');
```

Convert the target data to sequences using the same steps.

```
strTarget = dataTrain.Target;
documentsTarget = transformText(strTarget,startToken,stopToken);
encTarget = wordEncoding(documentsTarget);
sequencesTarget = doc2sequence(encTarget, documentsTarget,'PaddingDirection','none');
```

Sort the sequences by length. Training with the sequences sorted by increasing sequence length results in batches with sequences of approximately the same sequence length and ensures smaller sequence batches are used to update the model before longer sequence batches.

```
sequenceLengths = cellfun(@(sequence) size(sequence,2),sequencesSource);
[~,idx] = sort(sequenceLengths);
sequencesSource = sequencesSource(idx);
sequencesTarget = sequencesTarget(idx);
```

Create `arrayDatastore` objects containing the source and target data and combine them using the `combine` function.

```
sequencesSourceDs = arrayDatastore(sequencesSource,'OutputType','same');
sequencesTargetDs = arrayDatastore(sequencesTarget,'OutputType','same');

sequencesDs = combine(sequencesSourceDs,sequencesTargetDs);
```

Initialize Model Parameters

Initialize the model parameters. for both the encoder and decoder, specify an embedding dimension of 128, two LSTM layers with 200 hidden units, and dropout layers with random dropout with probability 0.05.

```
embeddingDimension = 128;
numHiddenUnits = 200;
dropout = 0.05;
```

Initialize Encoder Model Parameters

Initialize the weights of the encoding embedding using the Gaussian using the `initializeGaussian` function which is attached to this example as a supporting file. Specify a mean of 0 and a standard deviation of 0.01. To learn more, see “Gaussian Initialization” on page 18-299.

```
inputSize = encSource.NumWords + 1;
sz = [embeddingDimension inputSize];
mu = 0;
sigma = 0.01;
parameters.encoder.emb.Weights = initializeGaussian(sz,mu,sigma);
```

Initialize the learnable parameters for the encoder LSTM operations:

- Initialize the input weights with the Glorot initializer using the `initializeGlorot` function which is attached to this example as a supporting file. To learn more, see “Glorot Initialization” on page 18-296.
- Initialize the recurrent weights with the orthogonal initializer using the `initializeOrthogonal` function which is attached to this example as a supporting file. To learn more, see “Orthogonal Initialization” on page 18-300.

- Initialize the bias with the unit forget gate initializer using the `initializeUnitForgetGate` function which is attached to this example as a supporting file. To learn more, see “Unit Forget Gate Initialization” on page 18-301.

Initialize the learnable parameters for the first encoder LSTM operation.

```
sz = [4*numHiddenUnits embeddingDimension];
numOut = 4*numHiddenUnits;
numIn = embeddingDimension;

parameters.encoder.lstm1.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.encoder.lstm1.RecurrentWeights = initializeOrthogonal([4*numHiddenUnits numHiddenUnits
parameters.encoder.lstm1.Bias = initializeUnitForgetGate(numHiddenUnits);
```

Initialize the learnable parameters for the second encoder LSTM operation.

```
sz = [4*numHiddenUnits numHiddenUnits];
numOut = 4*numHiddenUnits;
numIn = numHiddenUnits;

parameters.encoder.lstm2.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.encoder.lstm2.RecurrentWeights = initializeOrthogonal([4*numHiddenUnits numHiddenUnits
parameters.encoder.lstm2.Bias = initializeUnitForgetGate(numHiddenUnits);
```

Initialize Decoder Model Parameters

Initialize the weights of the encoding embedding using the Gaussian using the `initializeGaussian` function. Specify a mean of 0 and a standard deviation of 0.01.

```
outputSize = encTarget.NumWords + 1;
sz = [embeddingDimension outputSize];
mu = 0;
sigma = 0.01;
parameters.decoder.emb.Weights = initializeGaussian(sz,mu,sigma);
```

Initialize the weights of the attention mechanism using the Glorot initializer using the `initializeGlorot` function.

```
sz = [numHiddenUnits numHiddenUnits];
numOut = numHiddenUnits;
numIn = numHiddenUnits;
parameters.decoder.attn.Weights = initializeGlorot(sz,numOut,numIn);
```

Initialize the learnable parameters for the decoder LSTM operations:

- Initialize the input weights with the Glorot initializer using the `initializeGlorot` function.
- Initialize the recurrent weights with the orthogonal initializer using the `initializeOrthogonal` function.
- Initialize the bias with the unit forget gate initializer using the `initializeUnitForgetGate` function.

Initialize the learnable parameters for the first decoder LSTM operation.

```
sz = [4*numHiddenUnits embeddingDimension+numHiddenUnits];
numOut = 4*numHiddenUnits;
numIn = embeddingDimension + numHiddenUnits;
```

```
parameters.decoder.lstm1.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.decoder.lstm1.RecurrentWeights = initializeOrthogonal([4*numHiddenUnits numHiddenUnits
parameters.decoder.lstm1.Bias = initializeUnitForgetGate(numHiddenUnits);
```

Initialize the learnable parameters for the second decoder LSTM operation.

```
sz = [4*numHiddenUnits numHiddenUnits];
numOut = 4*numHiddenUnits;
numIn = numHiddenUnits;

parameters.decoder.lstm2.InputWeights = initializeGlorot(sz,numOut,numIn);
parameters.decoder.lstm2.RecurrentWeights = initializeOrthogonal([4*numHiddenUnits numHiddenUnits
parameters.decoder.lstm2.Bias = initializeUnitForgetGate(numHiddenUnits);
```

Initialize the learnable parameters for the decoder fully connected operation:

- Initialize the weights with the Glorot initializer.
- Initialize the bias with zeros using the `initializeZeros` function which is attached to this example as a supporting file. To learn more, see “Zeros Initialization” on page 18-302.

```
sz = [outputSize 2*numHiddenUnits];
numOut = outputSize;
numIn = 2*numHiddenUnits;

parameters.decoder.fc.Weights = initializeGlorot(sz,numOut,numIn);
parameters.decoder.fc.Bias = initializeZeros([outputSize 1]);
```

Define Model Functions

Create the functions `modelEncoder` and `modelDecoder`, listed at the end of the example, that compute the outputs of the encoder and decoder models, respectively.

The `modelEncoder` function, listed in the Encoder Model Function on page 4-0 section of the example, takes the input data, the model parameters, the optional mask that is used to determine the correct outputs for training and returns the model outputs and the LSTM hidden state.

The `modelDecoder` function, listed in the Decoder Model Function on page 4-0 section of the example, takes the input data, the model parameters, the context vector, the LSTM initial hidden state, the outputs of the encoder, and the dropout probability and outputs the decoder output, the updated context vector, the updated LSTM state, and the attention scores.

Define Model Gradients Function

Create the function `modelGradients`, listed in the Model Gradients Function on page 4-0 section of the example, that takes the encoder and decoder model parameters, a mini-batch of input data and the padding masks corresponding to the input data, and the dropout probability and returns the gradients of the loss with respect to the learnable parameters in the models and the corresponding loss.

Specify Training Options

Train with a mini-batch size of 32 for 75 epochs with a learning rate of 0.002.

```
miniBatchSize = 32;
numEpochs = 75;
learnRate = 0.002;
```

Initialize the options from Adam.

```
gradientDecayFactor = 0.9;
squaredGradientDecayFactor = 0.999;
```

Train Model

Train the model using a custom training loop. Use `minibatchqueue` to process and manage mini-batches of images during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to find the lengths of all sequence in the mini-batch and pad the sequences to the same length as the longest sequence, for the source and target sequences, respectively.
- Permute the second and third dimensions of the padded sequences.
- Return the mini-batch variables unformatted `dlarray` objects with underlying data type `single`. All other outputs are arrays of data type `single`.
- Train on a GPU if one is available. Return all mini-batch variables on the GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see GPU Support by Release.

The `minibatchqueue` object returns four output arguments for each mini-batch: the source sequences, the target sequences, the lengths of all source sequences in the mini-batch, and the sequence mask of the target sequences.

```
numMiniBatchOutputs = 4;

mbq = minibatchqueue(sequencesDs,numMiniBatchOutputs,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn',@(x,t) preprocessMiniBatch(x,t,inputSize,outputSize));
```

Initialize the training progress plot.

```
figure
lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
ylim([0 inf])

xlabel("Iteration")
ylabel("Loss")
grid on
```

Initialize the values for the `adamupdate` function.

```
trailingAvg = [];
trailingAvgSq = [];
```

Train the model. For each mini-batch:

- Read a mini-batch of padded sequences.
- Compute loss and gradients.
- Update the encoder and decoder model parameters using the `adamupdate` function.
- Update the training progress plot.

```
iteration = 0;
start = tic;
```

```
% Loop over epochs.
for epoch = 1:numEpochs

    reset(mbq);

    % Loop over mini-batches.
    while hasdata(mbq)

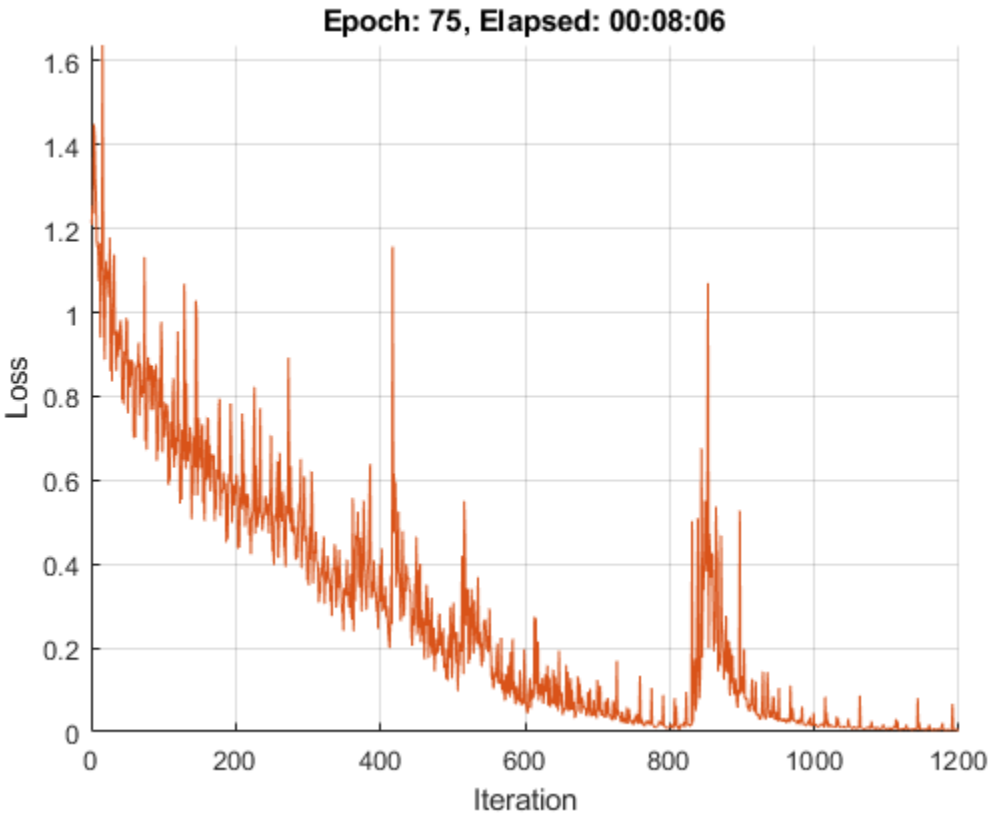
        iteration = iteration + 1;

        [dlX,T,sequenceLengthsSource,maskSequenceTarget] = next(mbq);

        % Compute loss and gradients.
        [gradients,loss] = dlfeval(@modelGradients,parameters,dlX,T,sequenceLengthsSource,...
            maskSequenceTarget,dropout);

        % Update parameters using adamupdate.
        [parameters,trailingAvg,trailingAvgSq] = adamupdate(parameters,gradients,trailingAvg,tra
            iteration,learnRate,gradientDecayFactor,squaredGradientDecayFactor);

        % Display the training progress.
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        addpoints(lineLossTrain,iteration,double(gather(loss)))
        title("Epoch: " + epoch + ", Elapsed: " + string(D))
        drawnow
    end
end
```



Generate Translations

To generate translations for new data using the trained model, convert the text data to numeric sequences using the same steps as when training and input the sequences into the encoder-decoder model and convert the resulting sequences back into text using the token indices.

Preprocess the text data using the same steps as when training. Use the `transformText` function, listed at the end of the example, to split the text into characters and add the start and stop tokens.

```
strSource = dataTest.Source;
strTarget = dataTest.Target;
```

Translate the text using the `modelPredictions` function.

```
maxSequenceLength = 10;
delimiter = "";

strTranslated = translateText(parameters,strSource,maxSequenceLength,miniBatchSize, ...
    encSource,encTarget,startToken,stopToken,delimiter);
```

Create a table containing the test source text, target text, and translations.

```
tbl = table;
tbl.Source = strSource;
tbl.Target = strTarget;
tbl.Translated = strTranslated;
```

View a random selection of the translations.

```
idx = randperm(size(dataTest,1),miniBatchSize);
tbl(idx,:)
```

```
ans=32×3 table
    Source      Target       Translated
    ______    ___________    __________

    "108"     "CVIII"        "CVIIII"
    "651"     "DCLI"         "DCI"
    "147"     "CXLVII"       "CCLXVII"
    "850"     "DCCCL"        "DCCCDCC"
    "468"     "CDLXVIII"     "CCLXVIII"
    "168"     "CLXVIII"      "CDLXVIII"
    "220"     "CCXX"         "CCC"
    "832"     "DCCCXXXII"    "DCCCXXII"
    "162"     "CLXII"        "CDXLII"
    "659"     "DCLIX"        "DCXIX"

    "647"     "DCXLVII"      "DCXLVII"
    "596"     "DXCVI"        "DCXVI"
      ⋮
```

Text Transformation Function

The `transformText` function preprocesses and tokenizes the input text for translation by splitting the text into characters and adding start and stop tokens. To translate text by splitting the text into words instead of characters, skip the first step.

```
function documents = transformText(str,startToken,stopToken)

str = strip(replace(str,"","" ""));
str = startToken + str + stopToken;
documents = tokenizedDocument(str,'CustomTokens',[startToken stopToken]);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function, described in the Train Model section of the example, preprocesses the data for training. The function preprocesses the data using the following steps:

1. Determine the lengths of all source and target sequences in the mini-batch
2. Pad the sequences to the same length as the longest sequence in the mini-batch using the `padsequences` function.
3. Permute the last two dimensions of the sequences

```
function [X,T,sequenceLengthsSource,maskTarget] = preprocessMiniBatch(sequencesSource,sequencesTa

sequenceLengthsSource = cellfun(@(x) size(x,2),sequencesSource);

X = padsequences(sequencesSource,2,"PaddingValue",inputSize);
X = permute(X,[1 3 2]);

[T,maskTarget] = padsequences(sequencesTarget,2,"PaddingValue",outputSize);
T = permute(T,[1 3 2]);
maskTarget = permute(maskTarget,[1 3 2]);

end
```

Model Gradients Function

The `modelGradients` function takes the encoder and decoder model parameters, a mini-batch of input data and the padding masks corresponding to the input data, and the dropout probability and returns the gradients of the loss with respect to the learnable parameters in the models and the corresponding loss.

```
function [gradients,loss] = modelGradients(parameters,dlX,T,...
    sequenceLengthsSource,maskTarget,dropout)

% Forward through encoder.
[dlZ,hiddenState] = modelEncoder(parameters.encoder,dlX,sequenceLengthsSource);

% Decoder Output.
doTeacherForcing = rand < 0.5;
sequenceLength = size(T,3);
dlY = decoderPredictions(parameters.decoder,dlZ,T,hiddenState,dropout,...
     doTeacherForcing,sequenceLength);

% Masked loss.
```

```
dlY = dlY(:,:,1:end-1);
T = extractdata(gather(T(:,:,2:end)));
T = onehotencode(T,1,'ClassNames',1:size(dlY,1));

maskTarget = maskTarget(:,:,2:end);
maskTarget = repmat(maskTarget,[size(dlY,1),1,1]);

loss = crossentropy(dlY,T,'Mask',maskTarget,'Dataformat','CBT');

% Update gradients.
gradients = dlgradient(loss,parameters);

% For plotting, return loss normalized by sequence length.
loss = extractdata(loss) ./ sequenceLength;

end
```

Encoder Model Function

The function `modelEncoder` takes the input data, the model parameters, the optional mask that is used to determine the correct outputs for training and returns the model output and the LSTM hidden state.

If `sequenceLengths` is empty, then the function does not mask the output. Specify and empty value for `sequenceLengths` when using the `modelEncoder` function for prediction.

```
function [dlZ, hiddenState] = modelEncoder(parametersEncoder, dlX, sequenceLengths)

% Embedding.
weights = parametersEncoder.emb.Weights;
dlZ = embed(dlX,weights,'DataFormat','CBT');

% LSTM 1.
inputWeights = parametersEncoder.lstm1.InputWeights;
recurrentWeights = parametersEncoder.lstm1.RecurrentWeights;
bias = parametersEncoder.lstm1.Bias;

numHiddenUnits = size(recurrentWeights, 2);
initialHiddenState = dlarray(zeros([numHiddenUnits 1]));
initialCellState = dlarray(zeros([numHiddenUnits 1]));

dlZ = lstm(dlZ, initialHiddenState, initialCellState, inputWeights, ...
    recurrentWeights, bias, 'DataFormat', 'CBT');

% LSTM 2.
inputWeights = parametersEncoder.lstm2.InputWeights;
recurrentWeights = parametersEncoder.lstm2.RecurrentWeights;
bias = parametersEncoder.lstm2.Bias;

[dlZ, hiddenState] = lstm(dlZ,initialHiddenState, initialCellState, ...
    inputWeights, recurrentWeights, bias, 'DataFormat', 'CBT');

% Masking for training.
if ~isempty(sequenceLengths)
    miniBatchSize = size(dlZ,2);
    for n = 1:miniBatchSize
        hiddenState(:,n) = dlZ(:,n,sequenceLengths(n));
    end
```

```
end

end
```

Decoder Model Function

The function `modelDecoder` takes the input data, the model parameters, the context vector, the LSTM initial hidden state, the outputs of the encoder, and the dropout probability and outputs the decoder output, the updated context vector, the updated LSTM state, and the attention scores.

```
function [dlY, context, hiddenState, attentionScores] = modelDecoder(parametersDecoder, dlX, con
    hiddenState, dlZ, dropout)

% Embedding.
weights = parametersDecoder.emb.Weights;
dlX = embed(dlX, weights,'DataFormat','CBT');

% RNN input.
sequenceLength = size(dlX,3);
dlY = cat(1, dlX, repmat(context, [1 1 sequenceLength]));

% LSTM 1.
inputWeights = parametersDecoder.lstm1.InputWeights;
recurrentWeights = parametersDecoder.lstm1.RecurrentWeights;
bias = parametersDecoder.lstm1.Bias;

initialCellState = dlarray(zeros(size(hiddenState)));

dlY = lstm(dlY, hiddenState, initialCellState, inputWeights, recurrentWeights, bias, 'DataFormat

% Dropout.
mask = ( rand(size(dlY), 'like', dlY) > dropout );
dlY = dlY.*mask;

% LSTM 2.
inputWeights = parametersDecoder.lstm2.InputWeights;
recurrentWeights = parametersDecoder.lstm2.RecurrentWeights;
bias = parametersDecoder.lstm2.Bias;

[dlY, hiddenState] = lstm(dlY, hiddenState, initialCellState,inputWeights, recurrentWeights, bias

% Attention.
weights = parametersDecoder.attn.Weights;
[attentionScores, context] = attention(hiddenState, dlZ, weights);

% Concatenate.
dlY = cat(1, dlY, repmat(context, [1 1 sequenceLength]));

% Fully connect.
weights = parametersDecoder.fc.Weights;
bias = parametersDecoder.fc.Bias;
dlY = fullyconnect(dlY,weights,bias,'DataFormat','CBT');

% Softmax.
dlY = softmax(dlY,'DataFormat','CBT');

end
```

Attention Function

The `attention` function returns the attention scores according to Luong "general" scoring and the updated context vector. The energy at each time step is the dot product of the hidden state and the learnable attention weights times the encoder output.

```
function [attentionScores, context] = attention(hiddenState, encoderOutputs, weights)

% Initialize attention energies.
[miniBatchSize, sequenceLength] = size(encoderOutputs, 2:3);
attentionEnergies = zeros([sequenceLength miniBatchSize],'like',hiddenState);

% Attention energies.
hWX = hiddenState .* pagemtimes(weights,encoderOutputs);
for tt = 1:sequenceLength
    attentionEnergies(tt, :) = sum(hWX(:, :, tt), 1);
end

% Attention scores.
attentionScores = softmax(attentionEnergies, 'DataFormat', 'CB');

% Context.
encoderOutputs = permute(encoderOutputs, [1 3 2]);
attentionScores = permute(attentionScores,[1 3 2]);
context = pagemtimes(encoderOutputs,attentionScores);
context = squeeze(context);

end
```

Decoder Model Predictions Function

The `decoderModelPredictions` function returns the predicted sequence `dlY` given the input sequence, target sequence, hidden state, dropout probability, flag to enable teacher forcing, and the sequence length.

```
function dlY = decoderPredictions(parametersDecoder,dlZ,T,hiddenState,dropout, ...
    doTeacherForcing,sequenceLength)

% Convert to dlarray.
dlT = dlarray(T);

% Initialize context.
miniBatchSize = size(dlT,2);
numHiddenUnits = size(dlZ,1);
context = zeros([numHiddenUnits miniBatchSize],'like',dlZ);

if doTeacherForcing
    % Forward through decoder.
    dlY = modelDecoder(parametersDecoder, dlT, context, hiddenState, dlZ, dropout);
else
    % Get first time step for decoder.
    decoderInput = dlT(:,:,1);

    % Initialize output.
    numClasses = numel(parametersDecoder.fc.Bias);
    dlY = zeros([numClasses miniBatchSize sequenceLength],'like',decoderInput);

    % Loop over time steps.
```

```
    for t = 1:sequenceLength
        % Forward through decoder.
        [dlY(:,:,t), context, hiddenState] = modelDecoder(parametersDecoder, decoderInput, contex
            hiddenState, dlZ, dropout);

        % Update decoder input.
        [~, decoderInput] = max(dlY(:,:,t),[],1);
    end
end

end
```

Text Translation Function

The `translateText` function translates an array of text by iterating over mini-batches. The function takes as input the model parameters, the input string array, a maximum sequence length, the mini-batch size, the source and target word encoding objects, the start and stop tokens, and the delimiter for assembling the output.

```
function strTranslated = translateText(parameters,strSource,maxSequenceLength,miniBatchSize, ...
    encSource,encTarget,startToken,stopToken,delimiter)

% Transform text.
documentsSource = transformText(strSource,startToken,stopToken);
sequencesSource = doc2sequence(encSource,documentsSource, ...
    'PaddingDirection','right', ...
    'PaddingValue',encSource.NumWords + 1);

% Convert to dlarray.
X = cat(3,sequencesSource{:});
X = permute(X,[1 3 2]);
dlX = dlarray(X);

% Initialize output.
numObservations = numel(strSource);
strTranslated = strings(numObservations,1);

% Loop over mini-batches.
numIterations = ceil(numObservations / miniBatchSize);
for i = 1:numIterations
    idxMiniBatch = (i-1)*miniBatchSize+1:min(i*miniBatchSize,numObservations);
    miniBatchSize = numel(idxMiniBatch);

    % Encode using model encoder.
    sequenceLengths = [];
    [dlZ, hiddenState] = modelEncoder(parameters.encoder, dlX(:,idxMiniBatch,:), sequenceLengths

    % Decoder predictions.
    doTeacherForcing = false;
    dropout = 0;
    decoderInput = repmat(word2ind(encTarget,startToken),[1 miniBatchSize]);
    decoderInput = dlarray(decoderInput);
    dlY = decoderPredictions(parameters.decoder,dlZ,decoderInput,hiddenState,dropout, ...
        doTeacherForcing,maxSequenceLength);
    [~, idxPred] = max(extractdata(dlY), [], 1);

    % Keep translating flag.
    idxStop = word2ind(encTarget,stopToken);
```

```
    keepTranslating = idxPred ~= idxStop;

    % Loop over time steps.
    t = 1;
    while t <= maxSequenceLength && any(keepTranslating(:,:,t))

        % Update output.
        newWords = ind2word(encTarget, idxPred(:,:,t))';
        idxUpdate = idxMiniBatch(keepTranslating(:,:,t));
        strTranslated(idxUpdate) = strTranslated(idxUpdate) + delimiter + newWords(keepTranslati

        t = t + 1;
    end
end

end
```

Generate Text Using Deep Learning

This example shows how to train a deep learning long short-term memory (LSTM) network to generate text.

To train a deep learning network for text generation, train a sequence-to-sequence LSTM network to predict the next character in a sequence of characters. To train the network to predict the next character, specify the input sequences shifted by one time step as the responses.

To input a sequence of characters into an LSTM network, convert each training observation to a sequence of characters represented by the vectors $x \in \mathbb{R}^D$, where D is the number of unique characters in the vocabulary. For each vector, $x_i = 1$ if x corresponds to the character with index i in a given vocabulary, and $x_j = 0$ for $j \neq i$.

Load Training Data

Extract the text data from the text file `sonnets.txt`.

```
filename = "sonnets.txt";
textData = fileread(filename);
```

The sonnets are indented by two whitespace characters and are separated by two newline characters. Remove the indentations using `replace` and split the text into separate sonnets using `split`. Remove the main title from the first three elements and the sonnet titles which appear before each sonnet.

```
textData = replace(textData,"  ","");
textData = split(textData,[newline newline]);
textData = textData(5:2:end);
```

View the first few observations.

```
textData(1:10)
```

```
ans = 10×1 cell array
    {'From fairest creatures we desire increase,↵That thereby beauty's rose might never die,↵But
    {'When forty winters shall besiege thy brow,↵And dig deep trenches in thy beauty's field,↵Thy
    {'Look in thy glass and tell the face thou viewest↵Now is the time that face should form anot

```

Convert Text Data to Sequences

Convert the text data to sequences of vectors for the predictors and categorical sequences for the responses.

Create special characters to denote "start of text", "whitespace", "end of text" and "newline". Use the special characters `"\x0002"` (start of text), `"\x00B7"` ("·", middle dot), `"\x2403"` ("ETX", end of text), and `"\x00B6"` ("¶", pilcrow) respectively. To prevent ambiguity, you must choose special characters

that do not appear in the text. Because these characters do not appear in the training data, they can be used for this purpose.

```
startOfTextCharacter = compose("\x0002");
whitespaceCharacter = compose("\x00B7");
endOfTextCharacter = compose("\x2403");
newlineCharacter = compose("\x00B6");
```

For each observation, insert the start of text character at the beginning and replace the whitespace and newlines with the corresponding characters.

```
textData = startOfTextCharacter + textData;
textData = replace(textData,[" " newline],[whitespaceCharacter newlineCharacter]);
```

Create a vocabulary of the unique characters in the text.

```
uniqueCharacters = unique([textData{:}]);
numUniqueCharacters = numel(uniqueCharacters);
```

Loop over the text data and create a sequence of vectors representing the characters of each observation and a categorical sequence of characters for the responses. To denote the end of each observation, include the end of text character.

```
numDocuments = numel(textData);
XTrain = cell(1,numDocuments);
YTrain = cell(1,numDocuments);
for i = 1:numel(textData)
    characters = textData{i};
    sequenceLength = numel(characters);

    % Get indices of characters.
    [~,idx] = ismember(characters,uniqueCharacters);

    % Convert characters to vectors.
    X = zeros(numUniqueCharacters,sequenceLength);
    for j = 1:sequenceLength
        X(idx(j),j) = 1;
    end

    % Create vector of categorical responses with end of text character.
    charactersShifted = [cellstr(characters(2:end)')' endOfTextCharacter];
    Y = categorical(charactersShifted);

    XTrain{i} = X;
    YTrain{i} = Y;
end
```

View the first observation and the size of the corresponding sequence. The sequence is a *D*-by-*S* matrix, where *D* is the number of features (the number of unique characters) and *S* is the sequence length (the number of characters in the text).

```
textData{1}
```

```
ans =
'From·fairest·creatures·we·desire·increase,¶That·thereby·beauty's·rose·might·never·die,¶But·as·t
```

```
size(XTrain{1})
```

```
ans = 1×2

    62   611
```

View the corresponding response sequence. The sequence is a 1-by-*S* categorical vector of responses.

```
YTrain{1}
```

```
ans = 1×611 categorical array
     F      r      o      m      ·      f      a      i      r      e      s      t      ·      c
```

Create and Train LSTM Network

Define the LSTM architecture. Specify a sequence-to-sequence LSTM classification network with 200 hidden units. Set the feature dimension of the training data (the number of unique characters) as the input size, and the number of categories in the responses as the output size of the fully connected layer.

```
inputSize = size(XTrain{1},1);
numHiddenUnits = 200;
numClasses = numel(categories([YTrain{:}]));

layers = [
    sequenceInputLayer(inputSize)
    lstmLayer(numHiddenUnits,'OutputMode','sequence')
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

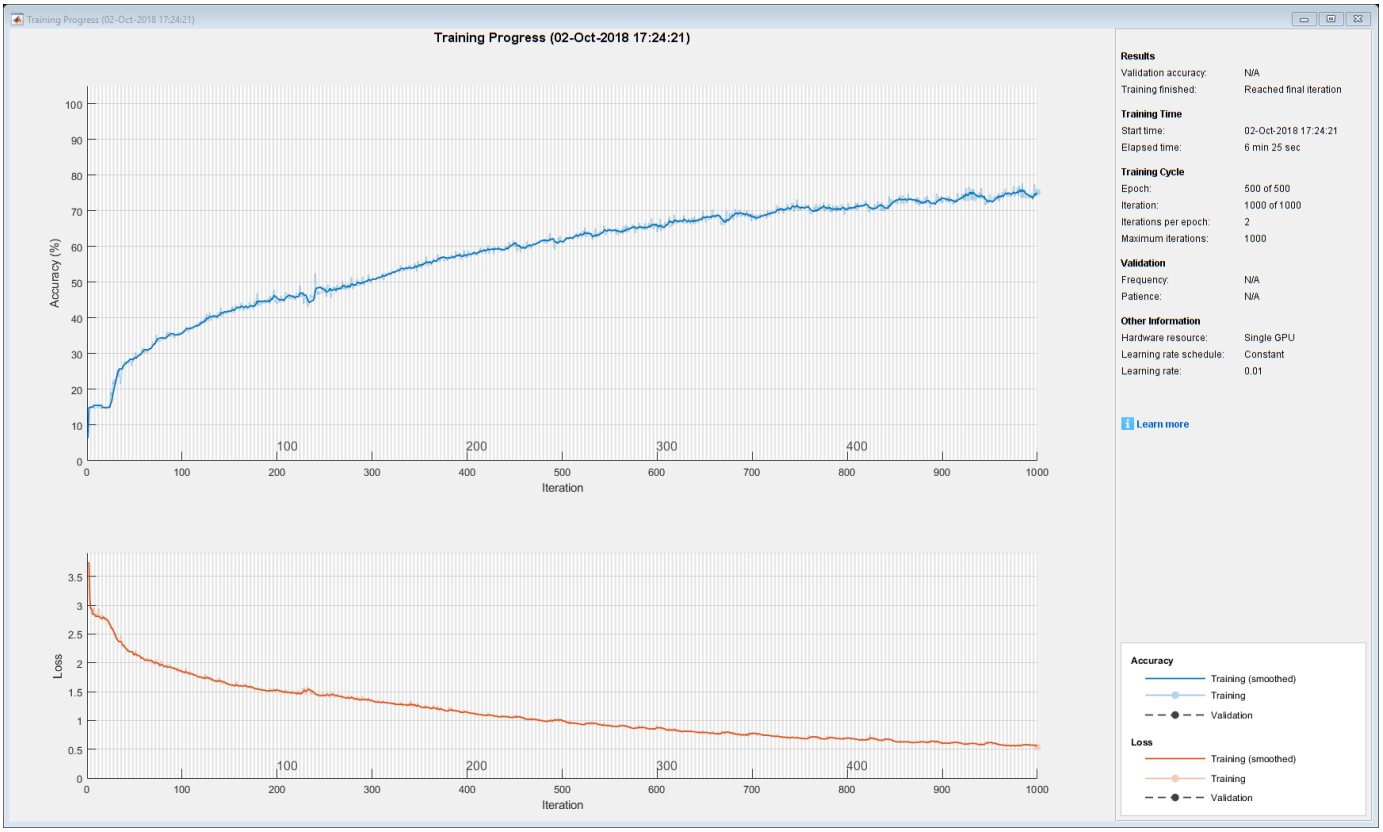
Specify the training options using the `trainingOptions` function. Specify the number of training epochs as 500 and the initial learn rate as 0.01. To prevent the gradients from exploding, set the gradient threshold to 2. Specify to shuffle the data every epoch by setting the `'Shuffle'` option to `'every-epoch'`. To monitor the training progress, set the `'Plots'` option to `'training-progress'`. To suppress verbose output, set `'Verbose'` to `false`.

The mini-batch size option specifies the number of observations to process in a single iteration. Specify a mini-batch size that evenly divides the data to ensure that the function uses all observations for training. Otherwise, the function ignores observations that do not complete a mini-batch. Set the mini-batch size to 77.

```
options = trainingOptions('adam', ...
    'MaxEpochs',500, ...
    'InitialLearnRate',0.01, ...
    'GradientThreshold',2, ...
    'MiniBatchSize',77,...
    'Shuffle','every-epoch', ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the network.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```



Generate New Text

Use the `generateText` function, listed at the end of the example, to generate text using the trained network.

The `generateText` function generates text character by character, starting with the start of text character and reconstructs the text using the special characters. The function samples each character using the output prediction scores. The function stops predicting when the network predicts the end-of-text character or when the generated text is 500 characters long.

Generate text using the trained network.

```
generatedText = generateText(net,uniqueCharacters,startOfTextCharacter,newlineCharacter,whitespac
```

```
generatedText =
    "Look, that your lepperites of such soous toor men,
     Where than proud on your sweetest but lever ill lie.
     One of Death a deal doth teal hearts come,
     And that which gives did mistress one learn
     Made mens of tongue that hands hear,
     And all they with me, do I fortune to brief;
     And every peinted could with this right ampontion sorend
     By genilir'd lime thau hours, and wonder sposing,
     And night by day you waster'd then new;
     For ailling thuse borrowest vein fulse were of here spent,
     Since my heart morey "
```

Text Generation Function

The `generateText` function generates text character by character, starting with the start of text character and reconstructs the text using the special characters. The function samples each character using the output prediction scores. The function stops predicting when the network predicts the end-of-text character or when the generated text is 500 characters long.

```
function generatedText = generateText(net,uniqueCharacters,startOfTextCharacter,newlineCharacter
```

Create the vector of the start of text character by finding its index.

```
numUniqueCharacters = numel(uniqueCharacters);
X = zeros(numUniqueCharacters,1);
idx = strfind(uniqueCharacters,startOfTextCharacter);
X(idx) = 1;
```

Generate the text character by character using the trained LSTM network using `predictAndUpdateState` and `datasample`. Stop predicting when the network predicts the end-of-text character or when the generated text is 500 characters long. The `datasample` function requires Statistics and Machine Learning Toolbox™.

For large collections of data, long sequences, or large networks, predictions on the GPU are usually faster to compute than predictions on the CPU. Otherwise, predictions on the CPU are usually faster to compute. For single time step predictions, use the CPU. To use the CPU for prediction, set the `'ExecutionEnvironment'` option of `predictAndUpdateState` to `'cpu'`.

```
generatedText = "";
vocabulary = string(net.Layers(end).Classes);

maxLength = 500;
while strlength(generatedText) < maxLength
    % Predict the next character scores.
    [net,characterScores] = predictAndUpdateState(net,X,'ExecutionEnvironment','cpu');

    % Sample the next character.
    newCharacter = datasample(vocabulary,1,'Weights',characterScores);

    % Stop predicting at the end of text.
    if newCharacter == endOfTextCharacter
        break
    end

    % Add the character to the generated text.
    generatedText = generatedText + newCharacter;

    % Create a new vector for the next input.
    X(:) = 0;
    idx = strfind(uniqueCharacters,newCharacter);
    X(idx) = 1;
end
```

Reconstruct the generated text by replacing the special characters with their corresponding whitespace and newline characters.

```
generatedText = replace(generatedText,[newlineCharacter whitespaceCharacter],[newline " "]);

end
```

Pride and Prejudice and MATLAB

This example shows how to train a deep learning LSTM network to generate text using character embeddings.

To train a deep learning network for text generation, train a sequence-to-sequence LSTM network to predict the next character in a sequence of characters. To train the network to predict the next character, specify the responses to be the input sequences shifted by one time step.

To use character embeddings, convert each training observation to a sequence of integers, where the integers index into a vocabulary of characters. Include a word embedding layer in the network which learns an embedding of the characters and maps the integers to vectors.

Load Training Data

Read the HTML code from The Project Gutenberg EBook of Pride and Prejudice, by Jane Austen and parse it using `webread` and `htmlTree`.

```
url = "https://www.gutenberg.org/files/1342/1342-h/1342-h.htm";
code = webread(url);
tree = htmlTree(code);
```

Extract the paragraphs by finding the `p` elements. Specify to ignore paragraph elements with class `"toc"` using the CSS selector `':not(.toc)'`.

```
paragraphs = findElement(tree,'p:not(.toc)');
```

Extract the text data from the paragraphs using `extractHTMLText`. and remove the empty strings.

```
textData = extractHTMLText(paragraphs);
textData(textData == "") = [];
```

Remove strings shorter than 20 characters.

```
idx = strlength(textData) < 20;
textData(idx) = [];
```

Visualize the text data in a word cloud.

```
figure
wordcloud(textData);
title("Pride and Prejudice")
```

Convert Text Data to Sequences

Convert the text data to sequences of character indices for the predictors and categorical sequences for the responses.

The categorical function treats newline and whitespace entries as undefined. To create categorical elements for these characters, replace them with the special characters "¶" (pilcrow, `"\x00B6"`) and "·" (middle dot, `"\x00B7"`) respectively. To prevent ambiguity, you must choose special characters that do not appear in the text. These characters do not appear in the training data so can be used for this purpose.

```
newlineCharacter = compose("\x00B6");
whitespaceCharacter = compose("\x00B7");
textData = replace(textData,[newline " "],[newlineCharacter whitespaceCharacter]);
```

Loop over the text data and create a sequence of character indices representing the characters of each observation and a categorical sequence of characters for the responses. To denote the end of each observation, include the special character "ETX" (end of text, `"\x2403"`).

```
endOfTextCharacter = compose("\x2403");
numDocuments = numel(textData);
for i = 1:numDocuments
    characters = textData{i};
    X = double(characters);

    % Create vector of categorical responses with end of text character.
    charactersShifted = [cellstr(characters(2:end)')' endOfTextCharacter];
```

```
    Y = categorical(charactersShifted);

    XTrain{i} = X;
    YTrain{i} = Y;
end
```

During training, by default, the software splits the training data into mini-batches and pads the sequences so that they have the same length. Too much padding can have a negative impact on the network performance.

To prevent the training process from adding too much padding, you can sort the training data by sequence length, and choose a mini-batch size so that sequences in a mini-batch have a similar length.

Get the sequence lengths for each observation.

```
numObservations = numel(XTrain);
for i=1:numObservations
    sequence = XTrain{i};
    sequenceLengths(i) = size(sequence,2);
end
```

Sort the data by sequence length.

```
[~,idx] = sort(sequenceLengths);
XTrain = XTrain(idx);
YTrain = YTrain(idx);
```

Create and Train LSTM Network

Define the LSTM architecture. Specify a sequence-to-sequence LSTM classification network with 400 hidden units. Set the input size to be the feature dimension of the training data. For sequences of character indices, the feature dimension is 1. Specify a word embedding layer with dimension 200 and specify the number of words (which correspond to characters) to be the highest character value in the input data. Set the output size of the fully connected layer to be the number of categories in the responses. To help prevent overfitting, include a dropout layer after the LSTM layer.

The word embedding layer learns an embedding of characters and maps each character to a 200-dimension vector.

```
inputSize = size(XTrain{1},1);
numClasses = numel(categories([YTrain{:}]));
numCharacters = max([textData{:}]);

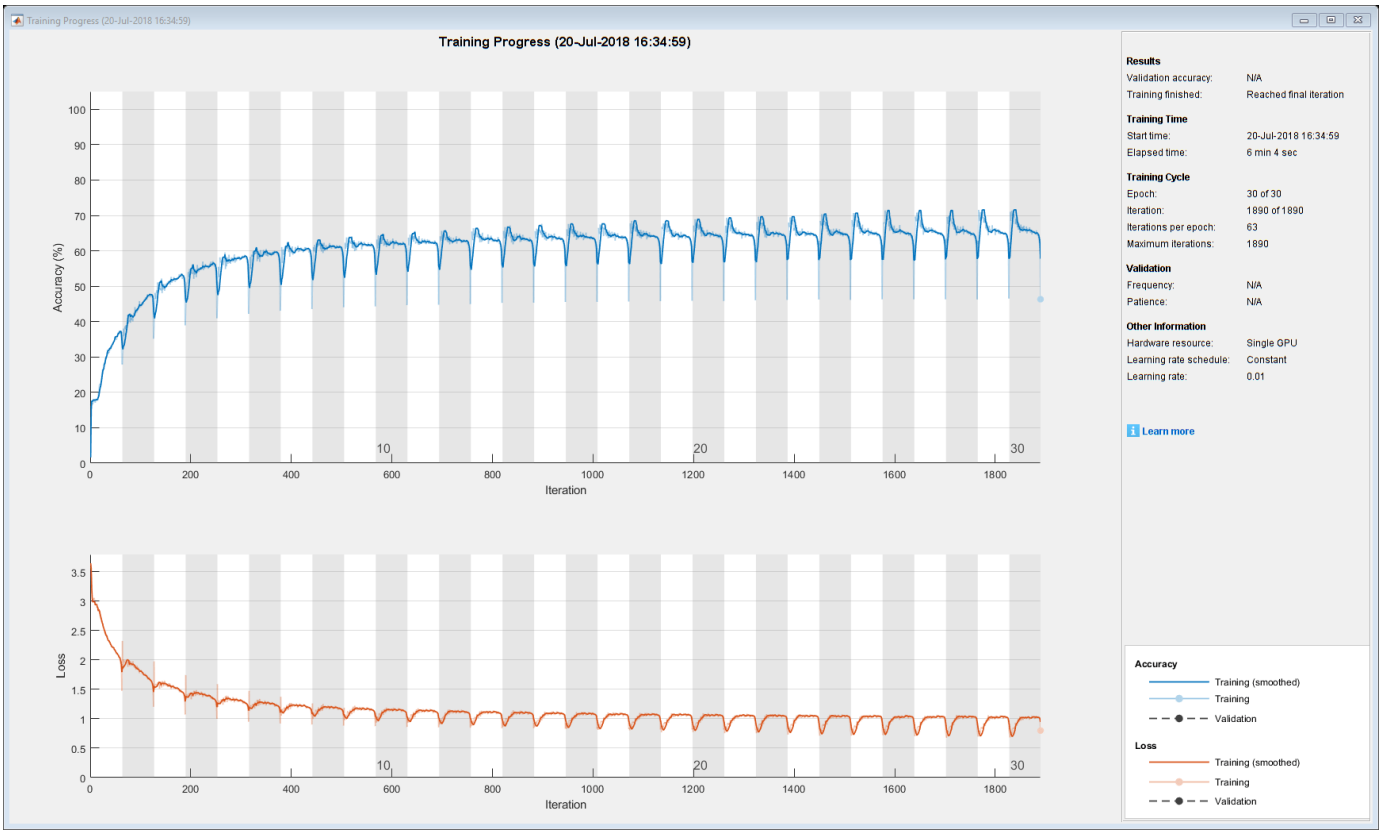
layers = [
    sequenceInputLayer(inputSize)
    wordEmbeddingLayer(200,numCharacters)
    lstmLayer(400,'OutputMode','sequence')
    dropoutLayer(0.2);
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify the training options. Specify to train with a mini-batch size of 32 and initial learn rate 0.01. To prevent the gradients from exploding, set the gradient threshold to 1. To ensure the data remains sorted, set `'Shuffle'` to `'never'`. To monitor the training progress, set the `'Plots'` option to `'training-progress'`. To suppress verbose output, set `'Verbose'` to `false`.

```
options = trainingOptions('adam', ...
    'MiniBatchSize',32,...
    'InitialLearnRate',0.01, ...
    'GradientThreshold',1, ...
    'Shuffle','never', ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the network.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```



Generate New Text

Generate the first character of the text by sampling a character from a probability distribution according to the first characters of the text in the training data. Generate the remaining characters by using the trained LSTM network to predict the next sequence using the current sequence of generated text. Keep generating characters one-by-one until the network predicts the "end of text" character.

Sample the first character according to the distribution of the first characters in the training data.

```
initialCharacters = extractBefore(textData,2);
firstCharacter = datasample(initialCharacters,1);
generatedText = firstCharacter;
```

Convert the first character to a numeric index.

```
X = double(char(firstCharacter));
```

For the remaining predictions, sample the next character according to the prediction scores of the network. The prediction scores represent the probability distribution of the next character. Sample the characters from the vocabulary of characters given by the class names of the output layer of the network. Get the vocabulary from the classification layer of the network.

```
vocabulary = string(net.Layers(end).ClassNames);
```

Make predictions character by character using `predictAndUpdateState`. For each prediction, input the index of the previous character. Stop predicting when the network predicts the end of text character or when the generated text is 500 characters long. For large collections of data, long sequences, or large networks, predictions on the GPU are usually faster to compute than predictions on the CPU. Otherwise, predictions on the CPU are usually faster to compute. For single time step predictions, use the CPU. To use the CPU for prediction, set the `'ExecutionEnvironment'` option of `predictAndUpdateState` to `'cpu'`.

```
maxLength = 500;
while strlength(generatedText) < maxLength
    % Predict the next character scores.
    [net,characterScores] = predictAndUpdateState(net,X,'ExecutionEnvironment','cpu');

    % Sample the next character.
    newCharacter = datasample(vocabulary,1,'Weights',characterScores);

    % Stop predicting at the end of text.
    if newCharacter == endOfTextCharacter
        break
    end

    % Add the character to the generated text.
    generatedText = generatedText + newCharacter;

    % Get the numeric index of the character.
    X = double(char(newCharacter));
end
```

Reconstruct the generated text by replacing the special characters with their corresponding whitespace and new line characters.

```
generatedText = replace(generatedText,[newlineCharacter whitespaceCharacter],[newline " "])
```

```
generatedText =
""“I wish Mr. Darcy, upon latter of my sort sincerely fixed in the regard to relanth. We were to
```

To generate multiple pieces of text, reset the network state between generations using `resetState`.

```
net = resetState(net);
```

Word-By-Word Text Generation Using Deep Learning

This example shows how to train a deep learning LSTM network to generate text word-by-word.

To train a deep learning network for word-by-word text generation, train a sequence-to-sequence LSTM network to predict the next word in a sequence of words. To train the network to predict the next word, specify the responses to be the input sequences shifted by one time step.

This example reads text from a website. It reads and parses the HTML code to extract the relevant text, then uses a custom mini-batch datastore `documentGenerationDatastore` to input the documents to the network as mini-batches of sequence data. The datastore converts documents to sequences of numeric word indices. The deep learning network is an LSTM network that contains a word embedding layer.

A mini-batch datastore is an implementation of a datastore with support for reading data in batches. You can use a mini-batch datastore as a source of training, validation, test, and prediction data sets for deep learning applications. Use mini-batch datastores to read out-of-memory data or to perform specific preprocessing operations when reading batches of data.

You can adapt the custom mini-batch datastore specified by `documentGenerationDatastore.m` to your data by customizing the functions. This file is eattached to this example as a supporting file. To access this file, open the example as a live script. For an example showing how to create your own custom mini-batch datastore, see “Develop Custom Mini-Batch Datastore” on page 19-36.

Load Training Data

Load the training data. Read the HTML code from Alice's Adventures in Wonderland by Lewis Carroll from Project Gutenberg.

```
url = "https://www.gutenberg.org/files/11/11-h/11-h.htm";
code = webread(url);
```

Parse HTML Code

The HTML code contains the relevant text inside <p> (paragraph) elements. Extract the relevant text by parsing the HTML code using `htmlTree` and then finding all the elements with element name `"p"`.

```
tree = htmlTree(code);
selector = "p";
subtrees = findElement(tree,selector);
```

Extract the text data from the HTML subtrees using `extractHTMLText` and view the first 10 paragraphs.

```
textData = extractHTMLText(subtrees);
textData(1:10)
```

```
ans = 10×1 string
    "Alice was beginning to get very tired of sitting by her sister on the bank, and of having no
    "So she was considering in her own mind (as well as she could, for the hot day made her feel
    "There was nothing so very remarkable in that; nor did Alice think it so very much out of the
    "In another moment down went Alice after it, never once considering how in the world she was
    "The rabbit-hole went straight on like a tunnel for some way, and then dipped suddenly down,
    "Either the well was very deep, or she fell very slowly, for she had plenty of time as she we
    "“Well!” thought Alice to herself, “after such a fall as this, I shall think nothing of tumbl
```

```
    "Down, down, down. Would the fall never come to an end? “I wonder how many miles I’ve fallen
    "Presently she began again. “I wonder if I shall fall right through the earth! How funny it’l
    "Down, down, down. There was nothing else to do, so Alice soon began talking again. “Dinah’l
```

Remove the empty paragraphs and view the first 10 remaining paragraphs.

```
textData(textData == "") = [];
textData(1:10)
```

```
ans = 10×1 string
    "Alice was beginning to get very tired of sitting by her sister on the bank, and of having no
    "So she was considering in her own mind (as well as she could, for the hot day made her feel
    "There was nothing so very remarkable in that; nor did Alice think it so very much out of the
    "In another moment down went Alice after it, never once considering how in the world she was

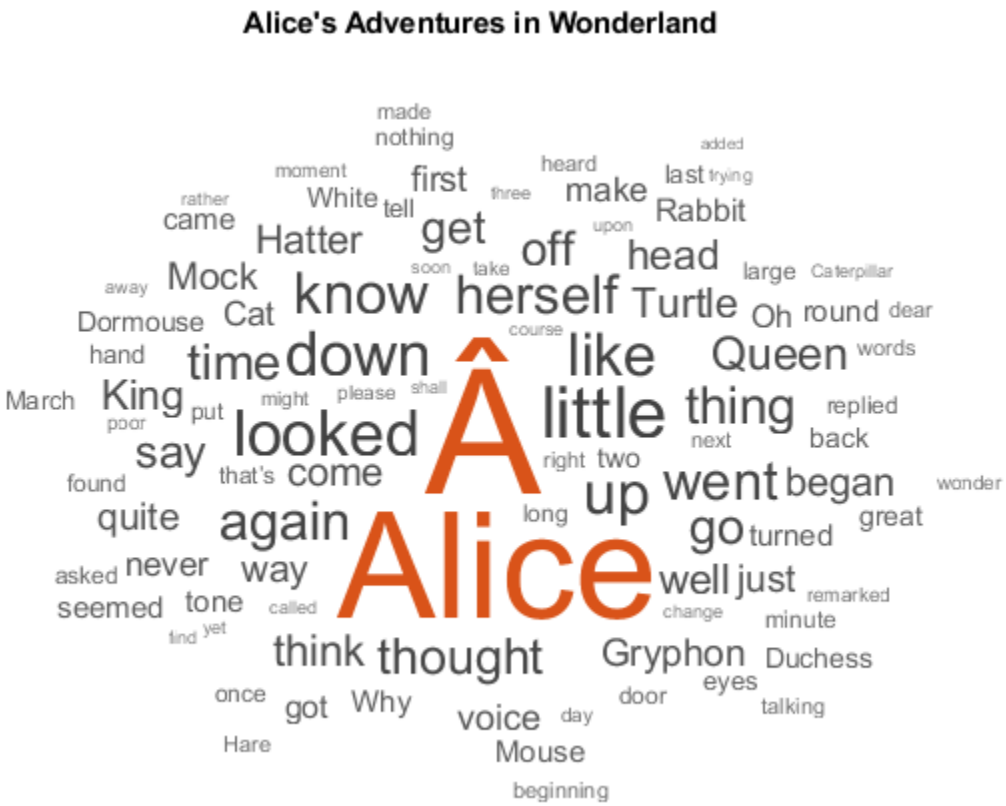
    "Either the well was very deep, or she fell very slowly, for she had plenty of time as she we
    "“Well!” thought Alice to herself, “after such a fall as this, I shall think nothing of tumbl
    "Down, down, down. Would the fall never come to an end? “I wonder how many miles I’ve fallen
    "Presently she began again. “I wonder if I shall fall right through the earth! How funny it’l
    "Down, down, down. There was nothing else to do, so Alice soon began talking again. “Dinah’l
```

Visualize the text data in a word cloud.

```
figure
wordcloud(textData);
title("Alice's Adventures in Wonderland")
```



Prepare Data for Training

Create a datastore that contains the data for training using `documentGenerationDatastore`. For the predictors, this datastore converts the documents into sequences of word indices using a word encoding. The first word index for each document corresponds to a "start of text" token. The "start of text" token is given by the string `"startOfText"`. For the responses, the datastore returns categorical sequences of the words shifted by one.

Tokenize the text data using `tokenizedDocument`.

```
documents = tokenizedDocument(textData);
```

Create a document generation datastore using the tokenized documents.

```
ds = documentGenerationDatastore(documents);
```

To reduce the amount of padding added to the sequences, sort the documents in the datastore by sequence length.

```
ds = sort(ds);
```

Create and Train LSTM Network

Define the LSTM network architecture. To input sequence data into the network, include a sequence input layer and set the input size to 1. Next, include a word embedding layer of dimension 100 and the same number of words as the word encoding. Next, include an LSTM layer and specify the hidden size to be 100. Finally, add a fully connected layer with the same size as the number of classes, a softmax layer, and a classification layer. The number of classes is the number of words in the vocabulary plus an extra class for the "end of text" class.

```
inputSize = 1;
embeddingDimension = 100;
numWords = numel(ds.Encoding.Vocabulary);
numClasses = numWords + 1;

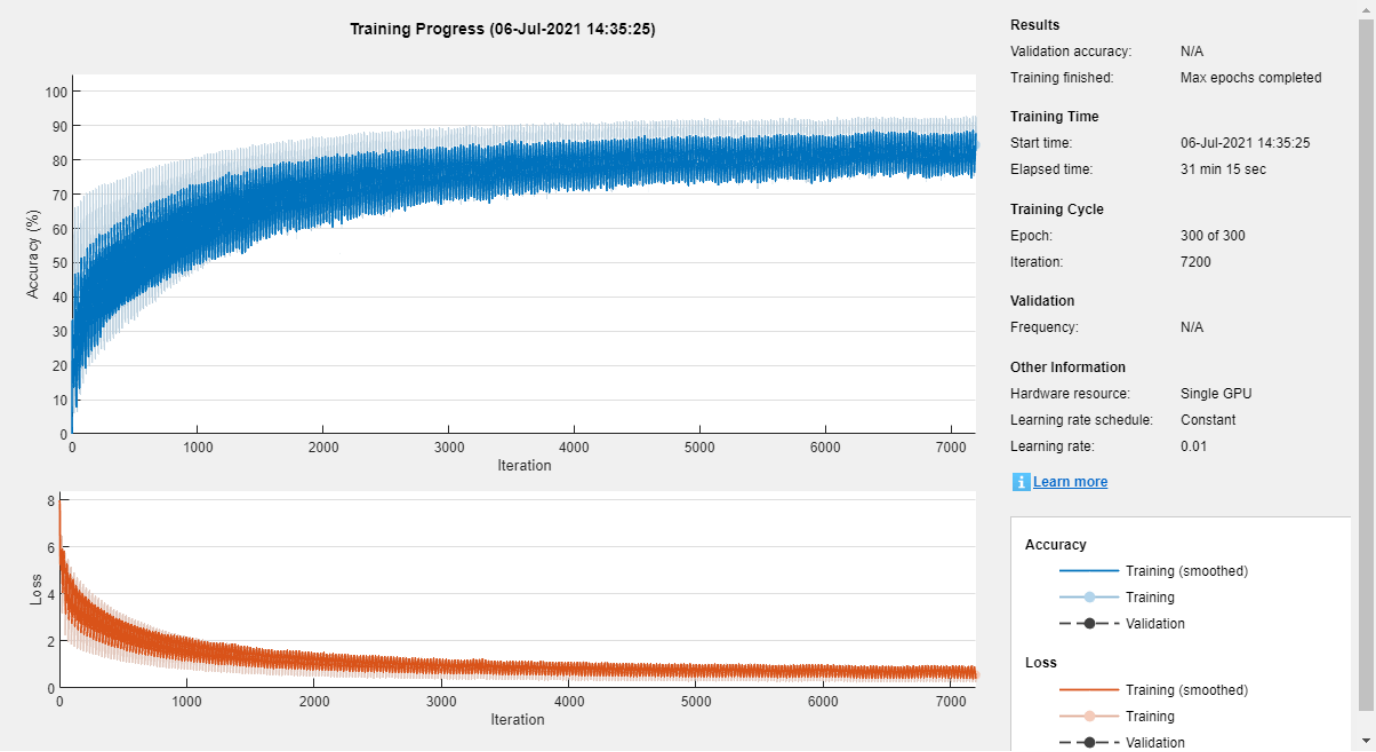
layers = [
    sequenceInputLayer(inputSize)
    wordEmbeddingLayer(embeddingDimension,numWords)
    lstmLayer(100)
    dropoutLayer(0.2)
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Specify the training options. Specify the solver to be `'adam'`. Train for 300 epochs with learn rate 0.01. Set the mini-batch size to 32. To keep the data sorted by sequence length, set the `'Shuffle'` option to `'never'`. To monitor the training progress, set the `'Plots'` option to `'training-progress'`. To suppress verbose output, set `'Verbose'` to `false`.

```
options = trainingOptions('adam', ...
    'MaxEpochs',300, ...
    'InitialLearnRate',0.01, ...
    'MiniBatchSize',32, ...
    'Shuffle','never', ...
    'Plots','training-progress', ...
    'Verbose',false);
```

Train the network using `trainNetwork`.

```
net = trainNetwork(ds,layers,options);
```



Generate New Text

Generate the first word of the text by sampling a word from a probability distribution according to the first words of the text in the training data. Generate the remaining words by using the trained LSTM network to predict the next time step using the current sequence of generated text. Keep generating words one-by-one until the network predicts the "end of text" word.

To make the first prediction using the network, input the index that represents the "start of text" token. Find the index by using the `word2ind` function with the word encoding used by the document datastore.

```
enc = ds.Encoding;
wordIndex = word2ind(enc,"startOfText")
```

```
wordIndex = 1
```

For the remaining predictions, sample the next word according to the prediction scores of the network. The prediction scores represent the probability distribution of the next word. Sample the words from the vocabulary given by the class names of the output layer of the network.

```
vocabulary = string(net.Layers(end).Classes);
```

Make predictions word by word using `predictAndUpdateState`. For each prediction, input the index of the previous word. Stop predicting when the network predicts the end of text word or when the generated text is 500 characters long. For large collections of data, long sequences, or large networks, predictions on the GPU are usually faster to compute than predictions on the CPU. Otherwise, predictions on the CPU are usually faster to compute. For single time step predictions, use

the CPU. To use the CPU for prediction, set the `'ExecutionEnvironment'` option of `predictAndUpdateState` to `'cpu'`.

```
generatedText = "";
maxLength = 500;
while strlength(generatedText) < maxLength
    % Predict the next word scores.
    [net,wordScores] = predictAndUpdateState(net,wordIndex,'ExecutionEnvironment','cpu');

    % Sample the next word.
    newWord = datasample(vocabulary,1,'Weights',wordScores);

    % Stop predicting at the end of text.
    if newWord == "EndOfText"
        break
    end

    % Add the word to the generated text.
    generatedText = generatedText + " " + newWord;

    % Find the word index for the next input.
    wordIndex = word2ind(enc,newWord);
end
```

The generation process introduces whitespace characters between each prediction, which means that some punctuation characters appear with unnecessary spaces before and after. Reconstruct the generated text by removing the spaces before and after the appropriate punctuation characters.

Remove the spaces that appear before the specified punctuation characters.

```
punctuationCharacters = ["." "," "’" ")" ":" "?" "!"];
generatedText = replace(generatedText," " + punctuationCharacters,punctuationCharacters);
```

Remove the spaces that appear after the specified punctuation characters.

```
punctuationCharacters = ["(" "‘"];
generatedText = replace(generatedText,punctuationCharacters + " ",punctuationCharacters)
```

```
generatedText =
" “ Just about as much right, ” said the Duchess, “ and that’s all the least, ” said the Hatter.
```

To generate multiple pieces of text, reset the network state between generations using `resetState`.

```
net = resetState(net);
```

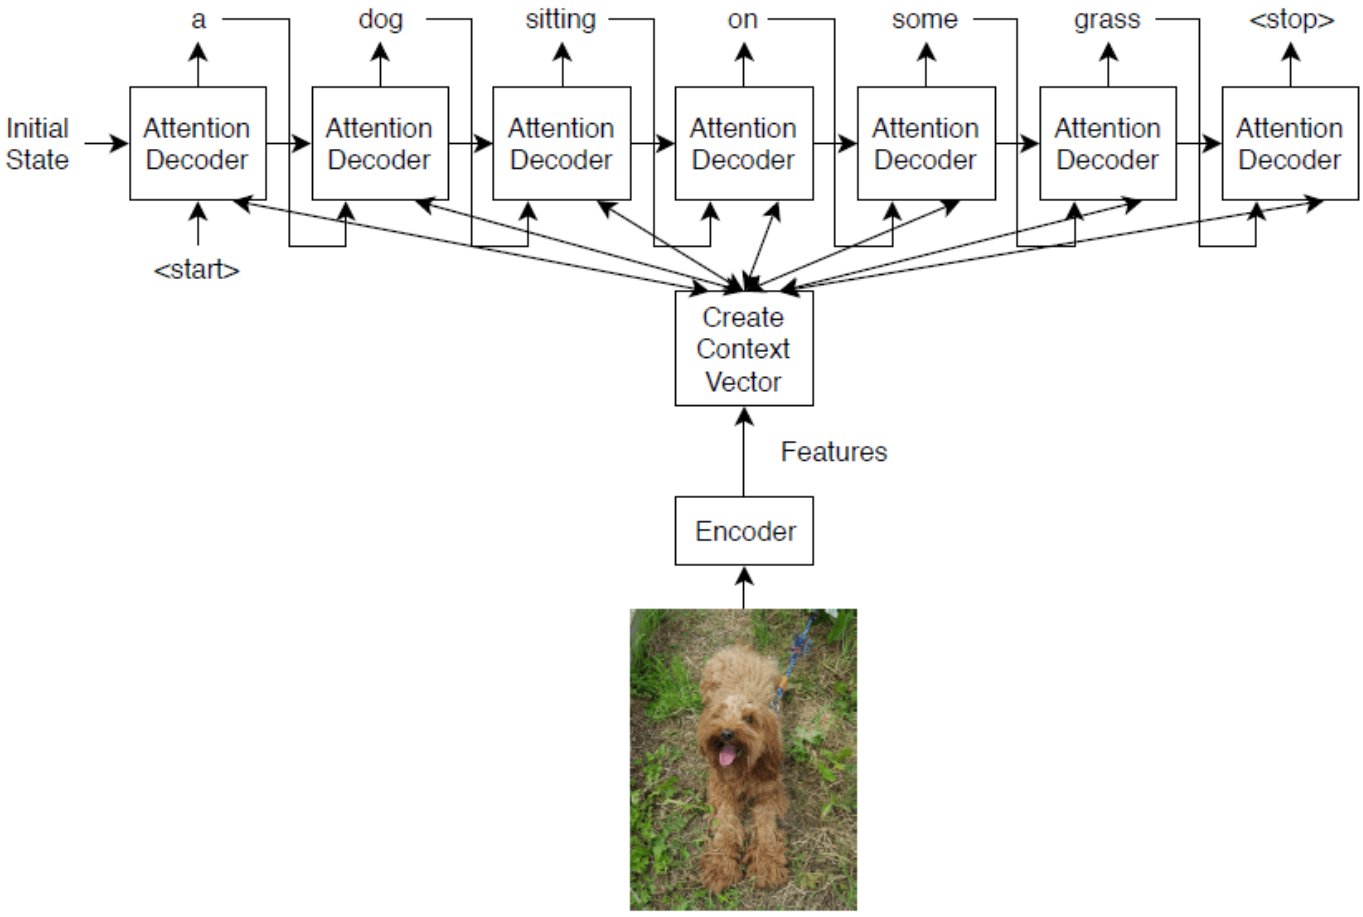
Image Captioning Using Attention

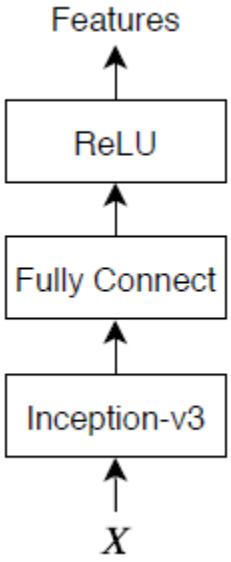
This example shows how to train a deep learning model for image captioning using attention.

Most pretrained deep learning networks are configured for single-label classification. For example, given an image of a typical office desk, the network might predict the single class "keyboard" or "mouse". In contrast, an image captioning model combines convolutional and recurrent operations to produce a textual description of what is in the image, rather than a single label.

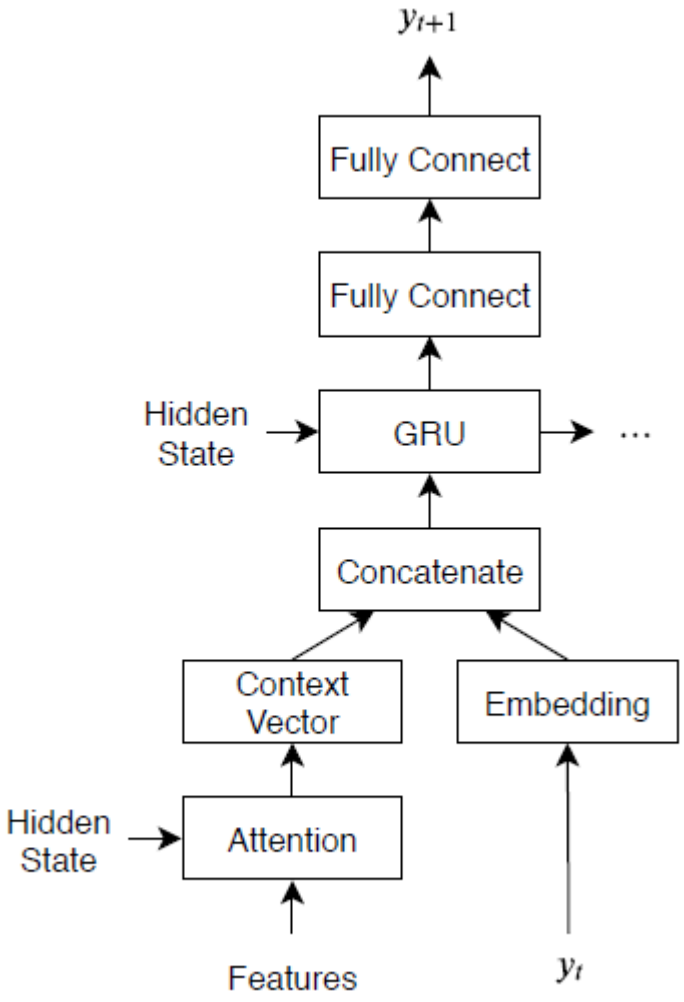
This model trained in this example uses an encoder-decoder architecture. The encoder is a pretrained Inception-v3 network used as a feature extractor. The decoder is a recurrent neural network (RNN) that takes the extracted features as input and generates a caption. The decoder incorporates an *attention mechanism* that allows the decoder to focus on parts of the encoded input while generating the caption.



The encoder model is a pretrained Inception-v3 model that extracts features from the `"mixed10"` layer, followed by fully connected and ReLU operations.



The decoder model consists of a word embedding, an attention mechanism, a gated recurrent unit (GRU), and two fully connected operations.



Load Pretrained Network

Load a pretrained Inception-v3 network. This step requires the Deep Learning Toolbox™ Model *for Inception-v3 Network* support package. If you do not have the required support package installed, then the software provides a download link.

```
net = inceptionv3;
inputSizeNet = net.Layers(1).InputSize;
```

Convert the network to a `dlnetwork` object for feature extraction and remove the last four layers, leaving the `"mixed10"` layer as the last layer.

```
lgraph = layerGraph(net);
lgraph = removeLayers(lgraph,["avg_pool" "predictions" "predictions_softmax" "ClassificationLaye
```

View the input layer of the network. The Inception-v3 network uses symmetric-rescale normalization with a minimum value of 0 and a maximum value of 255.

```
lgraph.Layers(1)
```

```
ans =
  ImageInputLayer with properties:

                     Name: 'input_1'
                InputSize: [299 299 3]

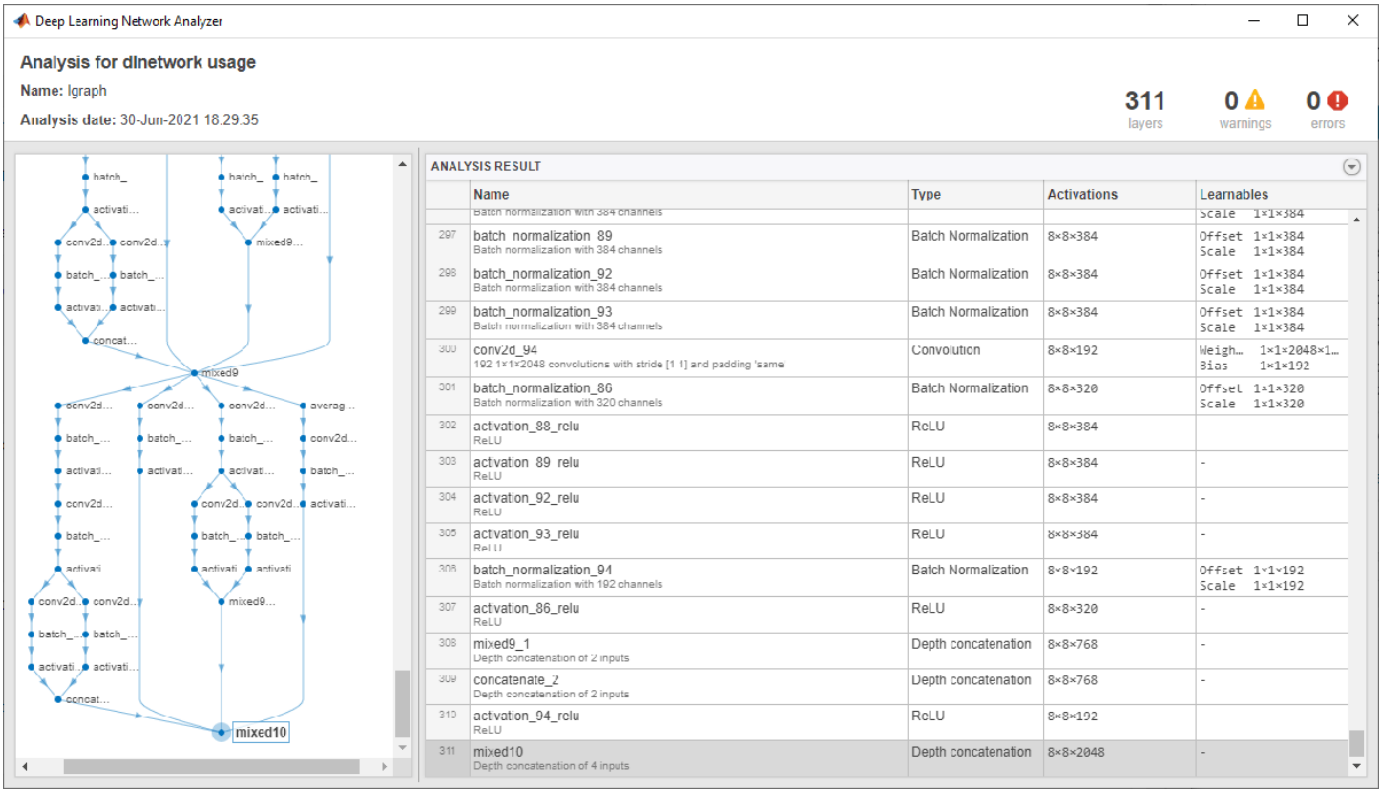
   Hyperparameters
          DataAugmentation: 'none'
             Normalization: 'rescale-symmetric'
    NormalizationDimension: 'auto'
                      Max: 255
                      Min: 0
```

Custom training does not support this normalization, so you must disable normalization in the network and perform the normalization in the custom training loop instead. Save the minimum and maximum values as doubles in variables named `inputMin` and `inputMax`, respectively, and replace the input layer with an image input layer without normalization.

```
inputMin = double(lgraph.Layers(1).Min);
inputMax = double(lgraph.Layers(1).Max);
layer = imageInputLayer(inputSizeNet,'Normalization','none','Name','input');
lgraph = replaceLayer(lgraph,'input_1',layer);
```

Determine the output size of the network. Use the `analyzeNetwork` function to see the activation sizes of the last layer. To analyze the network for custom training loop workflows, set the `TargetUsage` option to `'dlnetwork'`.

```
analyzeNetwork(lgraph,'TargetUsage','dlnetwork')
```



Create a variable named `outputSizeNet` containing the network output size.

```
outputSizeNet = [8 8 2048];
```

Convert the layer graph to a `dlnetwork` object and view the output layer. The output layer is the `"mixed10"` layer of the Inception-v3 network.

```
dlnet = dlnetwork(lgraph)
```

```
dlnet =
  dlnetwork with properties:

         Layers: [311×1 nnet.cnn.layer.Layer]
    Connections: [345×2 table]
     Learnables: [376×3 table]
          State: [188×3 table]
     InputNames: {'input'}
    OutputNames: {'mixed10'}
```

Import COCO Data Set

Download images and annotations from the data sets "2014 Train images" and "2014 Train/val annotations," respectively, from https://cocodataset.org/#download. Extract the images and annotations into a folder named `"coco"`. The COCO 2014 data set was collected by Coco Consortium.

Extract the captions from the file `"captions_train2014.json"` using the `jsondecode` function.

```
dataFolder = fullfile(tempdir,"coco");
filename = fullfile(dataFolder,"annotations_trainval2014","annotations","captions_train2014.json
str = fileread(filename);
data = jsondecode(str)
```

```
data = struct with fields:
           info: [1×1 struct]
         images: [82783×1 struct]
       licenses: [8×1 struct]
    annotations: [414113×1 struct]
```

The `annotations` field of the struct contains the data required for image captioning.

```
data.annotations
```

```
ans=414113×1 struct array with fields:
    image_id
    id
    caption
```

The data set contains multiple captions for each image. To ensure the same images do not appear in both training and validation sets, identify the unique images in the data set using the `unique` function by using the IDs in the `image_id` field of the annotations field of the data, then view the number of unique images.

```
numObservationsAll = numel(data.annotations)
```

```
numObservationsAll = 414113
```

```
imageIDs = [data.annotations.image_id];
imageIDsUnique = unique(imageIDs);
numUniqueImages = numel(imageIDsUnique)
```

```
numUniqueImages = 82783
```

Each image has at least five captions. Create a struct `annotationsAll` with these fields:

- `ImageID` — Image ID
- `Filename` — File name of the image
- `Captions` — String array of raw captions
- `CaptionIDs` — Vector of indices of the corresponding captions in `data.annotations`

To make merging easier, sort the annotations by the image IDs.

```
[~,idx] = sort([data.annotations.image_id]);
data.annotations = data.annotations(idx);
```

Loop over the annotations and merge multiple annotations when necessary.

```
i = 0;
j = 0;
imageIDPrev = 0;
while i < numel(data.annotations)
    i = i + 1;

    imageID = data.annotations(i).image_id;
    caption = string(data.annotations(i).caption);

    if imageID ~= imageIDPrev
        % Create new entry
        j = j + 1;
        annotationsAll(j).ImageID = imageID;
        annotationsAll(j).Filename = fullfile(dataFolder,"train2014","COCO_train2014_" + pad(str
        annotationsAll(j).Captions = caption;
        annotationsAll(j).CaptionIDs = i;
    else
        % Append captions
        annotationsAll(j).Captions = [annotationsAll(j).Captions; caption];
        annotationsAll(j).CaptionIDs = [annotationsAll(j).CaptionIDs; i];
    end

    imageIDPrev = imageID;
end
```

Partition the data into training and validation sets. Hold out 5% of the observations for testing.

```
cvp = cvpartition(numel(annotationsAll),'HoldOut',0.05);
idxTrain = training(cvp);
idxTest = test(cvp);
annotationsTrain = annotationsAll(idxTrain);
annotationsTest = annotationsAll(idxTest);
```

The struct contains three fields:

- `id` — Unique identifier for the caption

- `caption` — Image caption, specified as a character vector
- `image_id` — Unique identifier of the image corresponding to the caption

To view the image and the corresponding caption, locate the image file with file name `"train2014\COCO_train2014_XXXXXXXXXXX.jpg"`, where `"XXXXXXXXXXX"` corresponds to the image ID left-padded with zeros to have length 12.

```
imageID = annotationsTrain(1).ImageID;
captions = annotationsTrain(1).Captions;
filename = annotationsTrain(1).Filename;
```

To view the image, use the `imread` and `imshow` functions.

```
img = imread(filename);
figure
imshow(img)
title(captions)
```

Prepare Data for Training

Prepare the captions for training and testing. Extract the text from the `Captions` field of the struct containing both the training and test data (`annotationsAll`), erase the punctuation, and convert the text to lowercase.

```
captionsAll = cat(1,annotationsAll.Captions);
captionsAll = erasePunctuation(captionsAll);
captionsAll = lower(captionsAll);
```

In order to generate captions, the RNN decoder requires special start and stop tokens to indicate when to start and stop generating text, respectively. Add the custom tokens `"<start>"` and `"<stop>"` to the beginnings and ends of the captions, respectively.

```
captionsAll = "<start>" + captionsAll + "<stop>";
```

Tokenize the captions using the `tokenizedDocument` function and specify the start and stop tokens using the `'CustomTokens'` option.

```
documentsAll = tokenizedDocument(captionsAll,'CustomTokens',["<start>" "<stop>"]);
```

Create a `wordEncoding` object that maps words to numeric indices and back. Reduce the memory requirements by specifying a vocabulary size of 5000 corresponding to the most frequently observed words in the training data. To avoid bias, use only the documents corresponding to the training set.

```
enc = wordEncoding(documentsAll(idxTrain),'MaxNumWords',5000,'Order','frequency');
```

Create an augmented image datastore containing the images corresponding to the captions. Set the output size to match the input size of the convolutional network. To keep the images synchronized with the captions, specify a table of file names for the datastore by reconstructing the file names using the image ID. To return grayscale images as 3-channel RGB images, set the `'ColorPreprocessing'` option to `'gray2rgb'`.

```
tblFilenames = table(cat(1,annotationsTrain.Filename));
augimdsTrain = augmentedImageDatastore(inputSizeNet,tblFilenames,'ColorPreprocessing','gray2rgb'
```

```
augimdsTrain =
  augmentedImageDatastore with properties:
```

```
         NumObservations: 78644
           MiniBatchSize: 1
       DataAugmentation: 'none'
     ColorPreprocessing: 'gray2rgb'
             OutputSize: [299 299]
         OutputSizeMode: 'resize'
    DispatchInBackground: 0
```

Initialize Model Parameters

Initialize the model parameters. Specify 512 hidden units with a word embedding dimension of 256.

```
embeddingDimension = 256;
numHiddenUnits = 512;
```

Initialize a struct containing the parameters for the encoder model.

- Initialize the weights of the fully connected operations using the Glorot initializer, specified by the `initializeGlorot` function, listed at the end of the example. Specify the output size to match the embedding dimension of the decoder (256) and an input size to match the number of output channels of the pretrained network. The `'mixed10'` layer of the Inception-v3 network outputs data with 2048 channels.

```
numFeatures = outputSizeNet(1) * outputSizeNet(2);
inputSizeEncoder = outputSizeNet(3);
parametersEncoder = struct;

% Fully connect
parametersEncoder.fc.Weights = dlarray(initializeGlorot(embeddingDimension,inputSizeEncoder));
parametersEncoder.fc.Bias = dlarray(zeros([embeddingDimension 1],'single'));
```

Initialize a struct containing parameters for the decoder model.

- Initialize the word embedding weights with the size given by the embedding dimension and the vocabulary size plus one, where the extra entry corresponds to the padding value.
- Initialize the weights and biases for the Bahdanau attention mechanism with sizes corresponding to the number of hidden units of the GRU operation.
- Initialize the weights and bias of the GRU operation.
- Initialize the weights and biases of two fully connected operations.

For the model decoder parameters, initialize each of the weighs and biases with the Glorot initializer and zeros, respectively.

```
inputSizeDecoder = enc.NumWords + 1;
parametersDecoder = struct;

% Word embedding
parametersDecoder.emb.Weights = dlarray(initializeGlorot(embeddingDimension,inputSizeDecoder));

% Attention
parametersDecoder.attention.Weights1 = dlarray(initializeGlorot(numHiddenUnits,embeddingDimensio
parametersDecoder.attention.Bias1 = dlarray(zeros([numHiddenUnits 1],'single'));
parametersDecoder.attention.Weights2 = dlarray(initializeGlorot(numHiddenUnits,numHiddenUnits));
parametersDecoder.attention.Bias2 = dlarray(zeros([numHiddenUnits 1],'single'));
parametersDecoder.attention.WeightsV = dlarray(initializeGlorot(1,numHiddenUnits));
```

```
parametersDecoder.attention.BiasV = dlarray(zeros(1,1,'single'));

% GRU
parametersDecoder.gru.InputWeights = dlarray(initializeGlorot(3*numHiddenUnits,2*embeddingDimens
parametersDecoder.gru.RecurrentWeights = dlarray(initializeGlorot(3*numHiddenUnits,numHiddenUnit
parametersDecoder.gru.Bias = dlarray(zeros(3*numHiddenUnits,1,'single'));

% Fully connect
parametersDecoder.fc1.Weights = dlarray(initializeGlorot(numHiddenUnits,numHiddenUnits));
parametersDecoder.fc1.Bias = dlarray(zeros([numHiddenUnits 1],'single'));

% Fully connect
parametersDecoder.fc2.Weights = dlarray(initializeGlorot(enc.NumWords+1,numHiddenUnits));
parametersDecoder.fc2.Bias = dlarray(zeros([enc.NumWords+1 1],'single'));
```

Define Model Functions

Create the functions `modelEncoder` and `modelDecoder`, listed at the end of the example, which compute the outputs of the encoder and decoder models, respectively.

The `modelEncoder` function, listed in the Encoder Model Function on page 4-0 section of the example, takes as input an array of activations `dlX` from the output of the pretrained network and passes it through a fully connected operation and a ReLU operation. Because the pretrained network does not need to be traced for automatic differentiation, extracting the features outside the encoder model function is more computationally efficient.

The `modelDecoder` function, listed in the Decoder Model Function on page 4-0 section of the example, takes as input a single input time-step corresponding to an input word, the decoder model parameters, the features from the encoder, and the network state, and returns the predictions for the next time step, the updated network state, and the attention weights.

Specify Training Options

Specify the options for training. Train for 30 epochs with a mini-batch size of 128 and display the training progress in a plot.

```
miniBatchSize = 128;
numEpochs = 30;
plots = "training-progress";
```

Train on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
executionEnvironment = "auto";
```

Train Network

Train the network using a custom training loop.

At the beginning of each epoch, shuffle the input data. To keep the images in the augmented image datastore and the captions synchronized, create an array of shuffled indices that indexes into both data sets.

For each mini-batch:

- Rescale the images to the size that the pretrained network expects.
- For each image, select a random caption.
- Convert the captions to sequences of word indices. Specify right-padding of the sequences with the padding value corresponding to the index of the padding token.
- Convert the data to `dlarray` objects. For the images, specify dimension labels `'SSCB'` (spatial, spatial, channel, batch).
- For GPU training, convert the data to `gpuArray` objects.
- Extract the image features using the pretrained network and reshape them to the size the encoder expects.
- Evaluate the model gradients and loss using the `dlfeval` and `modelGradients` functions.
- Update the encoder and decoder model parameters using the `adamupdate` function.
- Display the training progress in a plot.

Initialize the parameters for the Adam optimizer.

```
trailingAvgEncoder = [];
trailingAvgSqEncoder = [];

trailingAvgDecoder = [];
trailingAvgSqDecoder = [];
```

Initialize the training progress plot. Create an animated line that plots the loss against the corresponding iteration.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    xlabel("Iteration")
    ylabel("Loss")
    ylim([0 inf])
    grid on
end
```

Train the model.

```
iteration = 0;
numObservationsTrain = numel(annotationsTrain);
numIterationsPerEpoch = floor(numObservationsTrain / miniBatchSize);
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs

    % Shuffle data.
    idxShuffle = randperm(numObservationsTrain);

    % Loop over mini-batches.
    for i = 1:numIterationsPerEpoch
        iteration = iteration + 1;

        % Determine mini-batch indices.
        idx = (i-1)*miniBatchSize+1:i*miniBatchSize;
        idxMiniBatch = idxShuffle(idx);
```

```
            % Read mini-batch of data.
            tbl = readByIndex(augimdsTrain,idxMiniBatch);
            X = cat(4,tbl.input{:});
            annotations = annotationsTrain(idxMiniBatch);

            % For each image, select random caption.
            idx = cellfun(@(captionIDs) randsample(captionIDs,1),{annotations.CaptionIDs});
            documents = documentsAll(idx);

            % Create batch of data.
            [dlX, dlT] = createBatch(X,documents,dlnet,inputMin,inputMax,enc,executionEnvironment);

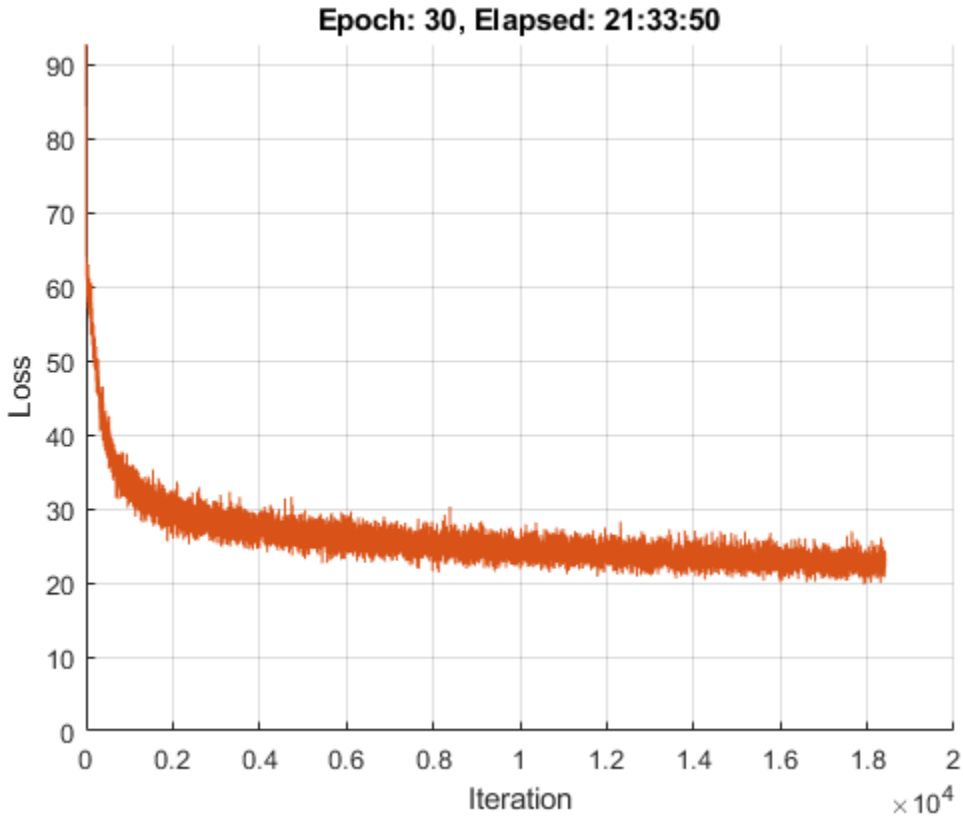
            % Evaluate the model gradients and loss using dlfeval and the
            % modelGradients function.
            [gradientsEncoder, gradientsDecoder, loss] = dlfeval(@modelGradients, parametersEncoder,
                parametersDecoder, dlX, dlT);

            % Update encoder using adamupdate.
            [parametersEncoder, trailingAvgEncoder, trailingAvgSqEncoder] = adamupdate(parametersEnco
                gradientsEncoder, trailingAvgEncoder, trailingAvgSqEncoder, iteration);

            % Update decoder using adamupdate.
            [parametersDecoder, trailingAvgDecoder, trailingAvgSqDecoder] = adamupdate(parametersDeco
                gradientsDecoder, trailingAvgDecoder, trailingAvgSqDecoder, iteration);

            % Display the training progress.
            if plots == "training-progress"
                D = duration(0,0,toc(start),'Format','hh:mm:ss');
                addpoints(lineLossTrain,iteration,double(gather(extractdata(loss))))
                title("Epoch: " + epoch + ", Elapsed: " + string(D))

                drawnow
            end
        end
    end
```



Predict New Captions

The caption generation process is different from the process for training. During training, at each time step, the decoder uses the true value of the previous time step as input. This is known as "teacher forcing". When making predictions on new data, the decoder uses the previous predicted values instead of the true values.

Predicting the most likely word for each step in the sequence can lead to suboptimal results. For example, if the decoder predicts the first word of a caption is "a" when given an image of an elephant, then the probability of predicting "elephant" for the next word becomes much more unlikely because of the extremely low probability of the phrase "a elephant" appearing in English text.

To address this issue, you can use the beam search algorithm: instead of taking the most likely prediction for each step in the sequence, take the top k predictions (the beam index) and for each following step, keep the top k predicted sequences so far according to the overall score.

Generate a caption of a new image by extracting the image features, inputting them into the encoder, and then using the `beamSearch` function, listed in the Beam Search Function on page 4-0 section of the example.

```
img = imread("laika_sitting.jpg");
dlX = extractImageFeatures(dlnet,img,inputMin,inputMax,executionEnvironment);

beamIndex = 3;
maxNumWords = 20;
[words,attentionScores] = beamSearch(dlX,beamIndex,parametersEncoder,parametersDecoder,enc,maxNu
caption = join(words)
```

```
caption =
"a dog is standing on a tile floor"
```

Display the image with the caption.

```
figure
imshow(img)
title(caption)
```

a dog is standing on a tile floor

Predict Captions for Data Set

To predict captions for a collection of images, loop over mini-batches of data in the datastore and extract the features from the images using the `extractImageFeatures` function. Then, loop over the images in the mini-batch and generate captions using the `beamSearch` function.

Create an augmented image datastore and set the output size to match the input size of the convolutional network. To output grayscale images as 3-channel RGB images, set the `'ColorPreprocessing'` option to `'gray2rgb'`.

```
tblFilenamesTest = table(cat(1,annotationsTest.Filename));
augimdsTest = augmentedImageDatastore(inputSizeNet,tblFilenamesTest,'ColorPreprocessing','gray2rg
```

```
augimdsTest =
  augmentedImageDatastore with properties:

         NumObservations: 4139
           MiniBatchSize: 1
        DataAugmentation: 'none'
      ColorPreprocessing: 'gray2rgb'
              OutputSize: [299 299]
          OutputSizeMode: 'resize'
    DispatchInBackground: 0
```

Generate captions for the test data. Predicting captions on a large data set can take some time. If you have Parallel Computing Toolbox™, then you can make predictions in parallel by generating captions inside a `parfor` look. If you do not have Parallel Computing Toolbox. then the `parfor` loop runs in serial.

```
beamIndex = 2;
maxNumWords = 20;

numObservationsTest = numel(annotationsTest);
numIterationsTest = ceil(numObservationsTest/miniBatchSize);

captionsTestPred = strings(1,numObservationsTest);
documentsTestPred = tokenizedDocument(strings(1,numObservationsTest));

for i = 1:numIterationsTest
    % Mini-batch indices.
    idxStart = (i-1)*miniBatchSize+1;
    idxEnd = min(i*miniBatchSize,numObservationsTest);
    idx = idxStart:idxEnd;

    sz = numel(idx);

    % Read images.
    tbl = readByIndex(augimdsTest,idx);

    % Extract image features.
    X = cat(4,tbl.input{:});
    dlX = extractImageFeatures(dlnet,X,inputMin,inputMax,executionEnvironment);

    % Generate captions.
    captionsPredMiniBatch = strings(1,sz);
    documentsPredMiniBatch = tokenizedDocument(strings(1,sz));
```

```
    parfor j = 1:sz
        words = beamSearch(dlX(:,:,j),beamIndex,parametersEncoder,parametersDecoder,enc,maxNumWo
        captionsPredMiniBatch(j) = join(words);
        documentsPredMiniBatch(j) = tokenizedDocument(words,'TokenizeMethod','none');
    end

    captionsTestPred(idx) = captionsPredMiniBatch;
    documentsTestPred(idx) = documentsPredMiniBatch;
end
```

```
Analyzing and transferring files to the workers ...done.
```

To view a test image with the corresponding caption, use the `imshow` function and set the title to the predicted caption.

```
idx = 1;
tbl = readByIndex(augimdsTest,idx);
img = tbl.input{1};
figure
imshow(img)
title(captionsTestPred(idx))
```

Evaluate Model Accuracy

To evaluate the accuracy of the captions using the BLEU score, calculate the BLEU score for each caption (the candidate) against the corresponding captions in the test set (the references) using the `bleuEvaluationScore` function. Using the `bleuEvaluationScore` function, you can compare a single candidate document to multiple reference documents.

The `bleuEvaluationScore` function, by default, scores similarity using n-grams of length one through four. As the captions are short, this behavior can lead to uninformative results as most scores are close to zero. Set the n-gram length to one through two by setting the `'NgramWeights'` option to a two-element vector with equal weights.

```
ngramWeights = [0.5 0.5];

for i = 1:numObservationsTest
    annotation = annotationsTest(i);

    captionIDs = annotation.CaptionIDs;
    candidate = documentsTestPred(i);
    references = documentsAll(captionIDs);

    score = bleuEvaluationScore(candidate,references,'NgramWeights',ngramWeights);

    scores(i) = score;
end
```

View the mean BLEU score.

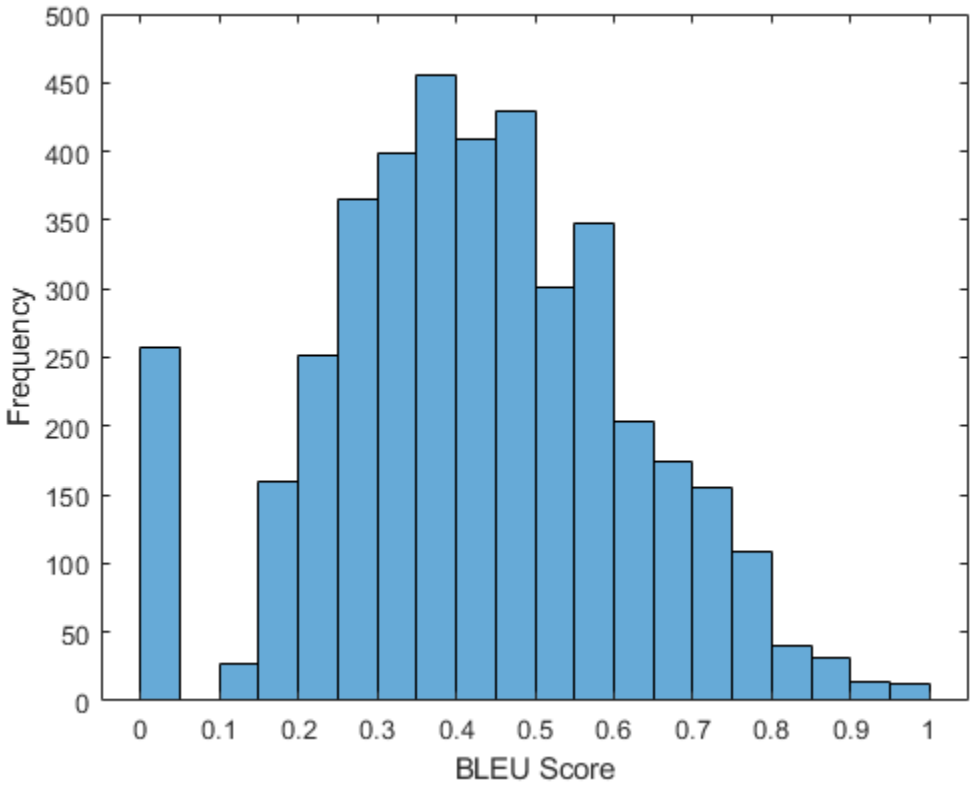
```
scoreMean = mean(scores)
```

```
scoreMean = 0.4224
```

Visualize the scores in a histogram.

```
figure
histogram(scores)
```

```
xlabel("BLEU Score")
ylabel("Frequency")
```



Attention Function

The `attention` function calculates the context vector and the attention weights using Bahdanau attention.

```
function [contextVector, attentionWeights] = attention(hidden,features,weights1, ...
    bias1,weights2,bias2,weightsV,biasV)

% Model dimensions.
[embeddingDimension,numFeatures,miniBatchSize] = size(features);
numHiddenUnits = size(weights1,1);

% Fully connect.
dlY1 = reshape(features,embeddingDimension, numFeatures*miniBatchSize);
dlY1 = fullyconnect(dlY1,weights1,bias1,'DataFormat','CB');
dlY1 = reshape(dlY1,numHiddenUnits,numFeatures,miniBatchSize);

% Fully connect.
dlY2 = fullyconnect(hidden,weights2,bias2,'DataFormat','CB');
dlY2 = reshape(dlY2,numHiddenUnits,1,miniBatchSize);

% Addition, tanh.
scores = tanh(dlY1 + dlY2);
scores = reshape(scores, numHiddenUnits, numFeatures*miniBatchSize);
```

```
% Fully connect, softmax.
attentionWeights = fullyconnect(scores,weightsV,biasV,'DataFormat','CB');
attentionWeights = reshape(attentionWeights,1,numFeatures,miniBatchSize);
attentionWeights = softmax(attentionWeights,'DataFormat','SCB');

% Context.
contextVector = attentionWeights .* features;
contextVector = squeeze(sum(contextVector,2));

end
```

Embedding Function

The `embedding` function maps an array of indices to a sequence of embedding vectors.

```
function Z = embedding(X, weights)

% Reshape inputs into a vector
[N, T] = size(X, 1:2);
X = reshape(X, N*T, 1);

% Index into embedding matrix
Z = weights(:, X);

% Reshape outputs by separating out batch and sequence dimensions
Z = reshape(Z, [], N, T);

end
```

Feature Extraction Function

The `extractImageFeatures` function takes as input a trained `dlnetwork` object, an input image, statistics for image rescaling, and the execution environment, and returns a `dlarray` containing the features extracted from the pretrained network.

```
function dlX = extractImageFeatures(dlnet,X,inputMin,inputMax,executionEnvironment)

% Resize and rescale.
inputSize = dlnet.Layers(1).InputSize(1:2);
X = imresize(X,inputSize);
X = rescale(X,-1,1,'InputMin',inputMin,'InputMax',inputMax);

% Convert to dlarray.
dlX = dlarray(X,'SSCB');

% Convert to gpuArray.
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlX = gpuArray(dlX);
end

% Extract features and reshape.
dlX = predict(dlnet,dlX);
sz = size(dlX);
numFeatures = sz(1) * sz(2);
inputSizeEncoder = sz(3);
miniBatchSize = sz(4);
dlX = reshape(dlX,[numFeatures inputSizeEncoder miniBatchSize]);

end
```

Batch Creation Function

The `createBatch` function takes as input a mini-batch of data, tokenized captions, a pretrained network, statistics for image rescaling, a word encoding, and the execution environment, and returns a mini-batch of data corresponding to the extracted image features and captions for training.

```
function [dlX, dlT] = createBatch(X,documents,dlnet,inputMin,inputMax,enc,executionEnvironment)

dlX = extractImageFeatures(dlnet,X,inputMin,inputMax,executionEnvironment);

% Convert documents to sequences of word indices.
T = doc2sequence(enc,documents,'PaddingDirection','right','PaddingValue',enc.NumWords+1);
T = cat(1,T{:});

% Convert mini-batch of data to dlarray.
dlT = dlarray(T);

% If training on a GPU, then convert data to gpuArray.
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlT = gpuArray(dlT);
end

end
```

Encoder Model Function

The `modelEncoder` function takes as input an array of activations `dlX` and passes it through a fully connected operation and a ReLU operation. For the fully connected operation, operate on the channel dimension only. To apply the fully connected operation across the channel dimension only, flatten the other channels into a single dimension and specify this dimension as the batch dimension using the `'DataFormat'` option of the `fullyconnect` function.

```
function dlY = modelEncoder(dlX,parametersEncoder)

[numFeatures,inputSizeEncoder,miniBatchSize] = size(dlX);

% Fully connect
weights = parametersEncoder.fc.Weights;
bias = parametersEncoder.fc.Bias;
embeddingDimension = size(weights,1);

dlX = permute(dlX,[2 1 3]);
dlX = reshape(dlX,inputSizeEncoder,numFeatures*miniBatchSize);
dlY = fullyconnect(dlX,weights,bias,'DataFormat','CB');
dlY = reshape(dlY,embeddingDimension,numFeatures,miniBatchSize);

% ReLU
dlY = relu(dlY);

end
```

Decoder Model Function

The `modelDecoder` function takes as input a single time-step `dlX`, the decoder model parameters, the features from the encoder, and the network state, and returns the predictions for the next time step, the updated network state, and the attention weights.

```
function [dlY,state,attentionWeights] = modelDecoder(dlX,parametersDecoder,features,state)

hiddenState = state.gru.HiddenState;

% Attention
weights1 = parametersDecoder.attention.Weights1;
bias1 = parametersDecoder.attention.Bias1;
weights2 = parametersDecoder.attention.Weights2;
bias2 = parametersDecoder.attention.Bias2;
weightsV = parametersDecoder.attention.WeightsV;
biasV = parametersDecoder.attention.BiasV;
[contextVector, attentionWeights] = attention(hiddenState,features,weights1,bias1,weights2,bias2

% Embedding
weights = parametersDecoder.emb.Weights;
dlX = embedding(dlX,weights);

% Concatenate
dlY = cat(1,contextVector,dlX);

% GRU
inputWeights = parametersDecoder.gru.InputWeights;
recurrentWeights = parametersDecoder.gru.RecurrentWeights;
bias = parametersDecoder.gru.Bias;
[dlY, hiddenState] = gru(dlY, hiddenState, inputWeights, recurrentWeights, bias, 'DataFormat','CB

% Update state
state.gru.HiddenState = hiddenState;

% Fully connect
weights = parametersDecoder.fc1.Weights;
bias = parametersDecoder.fc1.Bias;
dlY = fullyconnect(dlY,weights,bias,'DataFormat','CB');

% Fully connect
weights = parametersDecoder.fc2.Weights;
bias = parametersDecoder.fc2.Bias;
dlY = fullyconnect(dlY,weights,bias,'DataFormat','CB');

end
```

Model Gradients

The `modelGradients` function takes as input the encoder and decoder parameters, the encoder features `dlX`, and the target caption `dlT`, and returns the gradients of the encoder and decoder parameters with respect to the loss, the loss, and the predictions.

```
function [gradientsEncoder,gradientsDecoder,loss,dlYPred] = ...
    modelGradients(parametersEncoder,parametersDecoder,dlX,dlT)

miniBatchSize = size(dlX,3);
sequenceLength = size(dlT,2) - 1;
vocabSize = size(parametersDecoder.emb.Weights,2);

% Model encoder
features = modelEncoder(dlX,parametersEncoder);

% Initialize state
```

```
numHiddenUnits = size(parametersDecoder.attention.Weights1,1);
state = struct;
state.gru.HiddenState = dlarray(zeros([numHiddenUnits miniBatchSize],'single'));

dlYPred = dlarray(zeros([vocabSize miniBatchSize sequenceLength],'like',dlX));
loss = dlarray(single(0));

padToken = vocabSize;

for t = 1:sequenceLength
    decoderInput = dlT(:,t);

    dlYReal = dlT(:,t+1);

    [dlYPred(:,:,t),state] = modelDecoder(decoderInput,parametersDecoder,features,state);

    mask = dlYReal ~= padToken;

    loss = loss + sparseCrossEntropyAndSoftmax(dlYPred(:,:,t),dlYReal,mask);
end

% Calculate gradients
[gradientsEncoder,gradientsDecoder] = dlgradient(loss, parametersEncoder,parametersDecoder);

end
```

Sparse Cross Entropy and Softmax Loss Function

The `sparseCrossEntropyAndSoftmax` takes as input the predictions `dlY`, corresponding targets `dlT`, and sequence padding mask, and applies the `softmax` functions and returns the cross-entropy loss.

```
function loss = sparseCrossEntropyAndSoftmax(dlY, dlT, mask)

miniBatchSize = size(dlY, 2);

% Softmax.
dlY = softmax(dlY,'DataFormat','CB');

% Find rows corresponding to the target words.
idx = sub2ind(size(dlY), dlT', 1:miniBatchSize);
dlY = dlY(idx);

% Bound away from zero.
dlY = max(dlY, single(1e-8));

% Masked loss.
loss = log(dlY) .* mask';
loss = -sum(loss,'all') ./ miniBatchSize;

end
```

Beam Search Function

The `beamSearch` function takes as input the image features `dlX`, a beam index, the parameters for the encoder and decoder networks, a word encoding, and a maximum sequence length, and returns the caption words for the image using the beam search algorithm.

```
function [words,attentionScores] = beamSearch(dlX,beamIndex,parametersEncoder,parametersDecoder,
    enc,maxNumWords)

% Model dimensions
numFeatures = size(dlX,1);
numHiddenUnits = size(parametersDecoder.attention.Weights1,1);

% Extract features
features = modelEncoder(dlX,parametersEncoder);

% Initialize state
state = struct;
state.gru.HiddenState = dlarray(zeros([numHiddenUnits 1],'like',dlX));

% Initialize candidates
candidates = struct;
candidates.State = state;
candidates.Words = "<start>";
candidates.Score = 0;
candidates.AttentionScores = dlarray(zeros([numFeatures maxNumWords],'like',dlX));
candidates.StopFlag = false;

t = 0;

% Loop over words
while t < maxNumWords
    t = t + 1;

    candidatesNew = [];

    % Loop over candidates
    for i = 1:numel(candidates)

        % Stop generating when stop token is predicted
        if candidates(i).StopFlag
            continue
        end

        % Candidate details
        state = candidates(i).State;
        words = candidates(i).Words;
        score = candidates(i).Score;
        attentionScores = candidates(i).AttentionScores;

        % Predict next token
        decoderInput = word2ind(enc,words(end));
        [dlYPred,state,attentionScores(:,t)] = modelDecoder(decoderInput,parametersDecoder,featu

        dlYPred = softmax(dlYPred,'DataFormat','CB');
        [scoresTop,idxTop] = maxk(extractdata(dlYPred),beamIndex);
        idxTop = gather(idxTop);

        % Loop over top predictions
        for j = 1:beamIndex
            candidate = struct;

            candidateWord = ind2word(enc,idxTop(j));
            candidateScore = scoresTop(j);
```

```
            if candidateWord == "<stop>"
                candidate.StopFlag = true;
                attentionScores(:,t+1:end) = [];
            else
                candidate.StopFlag = false;
            end

            candidate.State = state;
            candidate.Words = [words candidateWord];
            candidate.Score = score + log(candidateScore);
            candidate.AttentionScores = attentionScores;

            candidatesNew = [candidatesNew candidate];
        end
    end

    % Get top candidates
    [~,idx] = maxk([candidatesNew.Score],beamIndex);
    candidates = candidatesNew(idx);

    % Stop predicting when all candidates have stop token
    if all([candidates.StopFlag])
        break
    end
end

% Get top candidate
words = candidates(1).Words(2:end-1);
attentionScores = candidates(1).AttentionScores;

end
```

Glorot Weight Initialization Function

The `initializeGlorot` function generates an array of weights according to Glorot initialization.

```
function weights = initializeGlorot(numOut, numIn)

varWeights = sqrt( 6 / (numIn + numOut) );
weights = varWeights * (2 * rand([numOut, numIn], 'single') - 1);

end
```

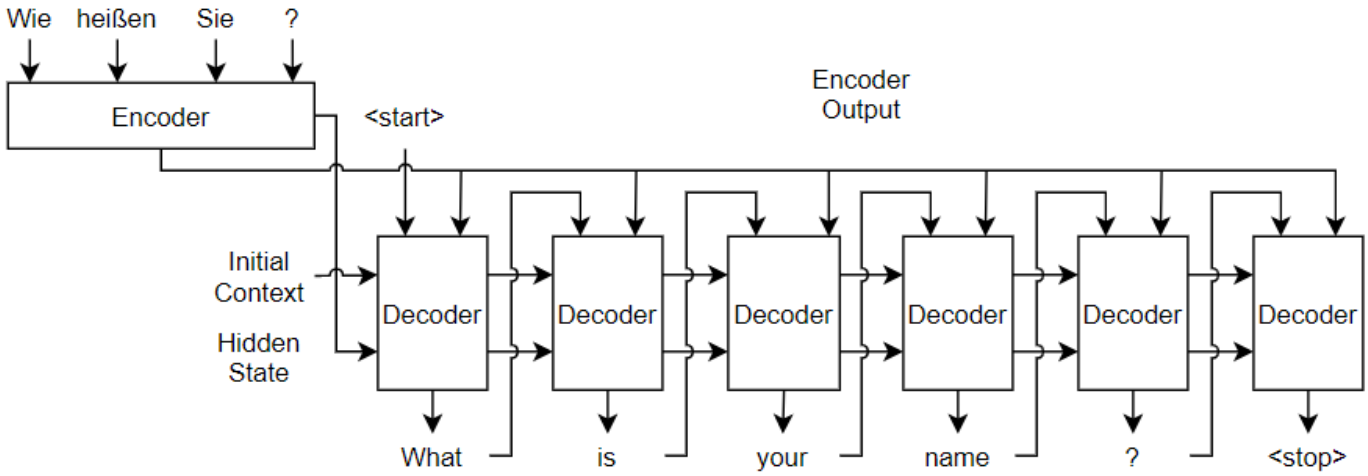
Language Translation Using Deep Learning

This example shows how to train a German to English language translator using a recurrent sequence-to-sequence encoder-decoder model with attention.

Recurrent encoder-decoder models have proven successful at tasks such as abstractive text summarization and neural machine translation. These models consist of an *encoder*, which typically processes input data with a recurrent layer such as an LSTM layer, and a *decoder* which maps the encoded input into the desired output, typically also with a recurrent layer. Models that incorporate *attention mechanisms* into the models allow the decoder to focus on parts of the encoded input while generating the translation one time step at a time. This example implements *Bahdanau attention* [1] on page 4-0 using the custom layer `attentionLayer`, attached to this example as a supporting file. To access this layer, open this example as a live script.

This diagram shows the structure of a language translation model. The input text, specified as a sequence of words, is passed through the encoder, which outputs an encoded version of the input sequence and a hidden state used to initialize the decoder state. The decoder makes predictions one word at a time using previous prediction as input and also outputs update state and context values.



For more information and the details about the encoder and decoder networks used in this example, see the Define Encoder and Decoder Networks on page 4-0 section of the example.

Predicting the most likely word for each step in the sequence can lead to suboptimal results. Any incorrect predictions can cause even more incorrect predictions in later time steps. For example, for the target text `"An eagle flew by."`, if the decoder predicts the first word of a translation as `"A"`, then the probability of predicting "eagle" for the next word becomes much more unlikely because of the low probability of the phrase "a eagle" appearing in English text. The translation generation process differs for training and prediction. This example uses different approaches to stabilize training and the predictions:

- To stabilize training, you can randomly use the target values as inputs to the decoder. In particular, you can adjust the probability used to inject the target values as training progresses. For example, you can train using the target values at a much higher rate at the start of training, then decay the probability such that towards the end of training the model uses only the previous predictions. This technique is known as *scheduled sampling* [2] on page 4-0 . For more information, see the Decoder Predictions Function on page 4-0 section of the example.

- To improve the predictions at translation time, for each time step, you can consider the top K predictions for some positive integer K and explore different sequences of predictions to identify the best combination. This technique is known as *beam search*. For more information, see the Beam Search Function on page 4-0 section of the example.

This example shows how to load and preprocess text data to train a German to English language translator, define the encoder and decoder networks, train the model using a custom training loop, and generate translations using beam search.

Note: Language translation is a computationally intensive task. Training on the full data set used in this example can take many hours to run. To make the example run quicker, you can reduce training time at the cost of accuracy of predictions with previously unseen data by discarding a portion of the training data. Removing observations can speed up training because it reduces the amount of data to process in an epoch and reduces the vocabulary size of the training data.

To shorten the time it takes to run the example, discard 70% of the data. Note that discarding large amounts of data negatively affects the accuracy of the learned model. For more accurate results, reduce the amount of discarded data. To speed up the example, increase the amount of discarded data.

```
discardProp = 0.70;
```

Load Training Data

Download and extract the English-German Tab-delimited Bilingual Sentence Pairs data set. The data comes from http://www.manythings.org/anki and https://tatoeba.org, and is provided under the Tatoeba Terms of Use and the CC-BY license.

```
downloadFolder = tempdir;
url = "http://www.manythings.org/anki/deu-eng.zip";
filename = fullfile(downloadFolder,"deu-eng.zip");
dataFolder = fullfile(downloadFolder,"deu-eng");

if ~exist(dataFolder,"dir")
    fprintf("Downloading English-German Tab-delimited Bilingual Sentence Pairs data set (7.6 MB)
    websave(filename,url);
    unzip(filename,dataFolder);
    fprintf("Done.\n")
end
```

Create a table that contains the sentence pairs specified as strings. Read the tab-delimited sentences pairs using `readtable`. Specify the German text as the source and the English text as the target.

```
filename = fullfile(dataFolder,"deu.txt");

opts = delimitedTextImportOptions(...
    Delimiter="\t", ...
    VariableNames=["Target" "Source" "License"], ...
    SelectedVariableNames=["Source" "Target"], ...
    VariableTypes=["string" "string" "string"], ...
    Encoding="UTF-8");
```

View the first few sentence pairs in the data.

```
data = readtable(filename, opts);
head(data)
```

```
ans=8×2 table
        Source          Target
    ________________    _______

    "Geh."              "Go."
    "Hallo!"            "Hi."
    "Grüß Gott!"        "Hi."
    "Lauf!"             "Run!"
    "Lauf!"             "Run."
    "Potzdonner!"       "Wow!"
    "Donnerwetter!"     "Wow!"
    "Feuer!"            "Fire!"
```

Training on the full dataset can take a long time to run. To reduce training time at the cost of accuracy, you can discard a portion of the training data. Removing observations can speed up training because it reduces the amount of data to process in an epoch as well as reducing the vocabulary size of the training data.

Discard a portion of the data according to the `discardProp` variable defined at the start of the example. Note that discarding large amounts of data negatively affects the accuracy of the learned model. For more accurate results, reduce the amount of discarded data by setting `discardProp` to a lower value.

```
idx = size(data,1) - floor(discardProp*size(data,1)) + 1;
data(idx:end,:) = [];
```

View the number of remaining observations.

```
size(data,1)
```

```
ans = 68124
```

Split the data into training and test partitions containing 90% and 10% of the data, respectively.

```
trainingProp = 0.9;
idx = randperm(size(data,1),floor(trainingProp*size(data,1)));
dataTrain = data(idx,:);
dataTest = data;
dataTest(idx,:) = [];
```

View the first few rows of the training data.

```
head(dataTrain)
```

```
ans=8×2 table
                  Source                          Target
    ____________________________________    ____________________________

    "Tom erschoss Mary."                    "Tom shot Mary."
    "Ruf mich bitte an."                    "Call me, please."
    "Kann das einer nachprüfen?"            "Can someone check this?"
    "Das lasse ich mir nicht gefallen!"     "I won't stand for it."
    "Ich mag Englisch nicht."               "I don't like English."
    "Er ist auf dem Laufenden."             "He is up to date."
    "Sie sieht glücklich aus."              "She seems happy."
    "Wo wurden sie geboren?"                "Where were they born?"
```

View the number of training observations.

```
numObservationsTrain = size(dataTrain,1)
```

```
numObservationsTrain = 61311
```

Preprocess Data

Preprocess the text data using the `preprocessText` function, listed at the end of the example. The `preprocessText` function preprocesses and tokenizes the input text for translation by splitting the text into words and adding start and stop tokens.

```
documentsGerman = preprocessText(dataTrain.Source);
```

Create a `wordEncoding` object that maps tokens to a numeric index and vice versa using a vocabulary.

```
encGerman = wordEncoding(documentsGerman);
```

Convert the target data to sequences using the same steps.

```
documentsEnglish = preprocessText(dataTrain.Target);
encEnglish = wordEncoding(documentsEnglish);
```

View the vocabulary sizes of the source and target encodings.

```
numWordsGerman = encGerman.NumWords
```

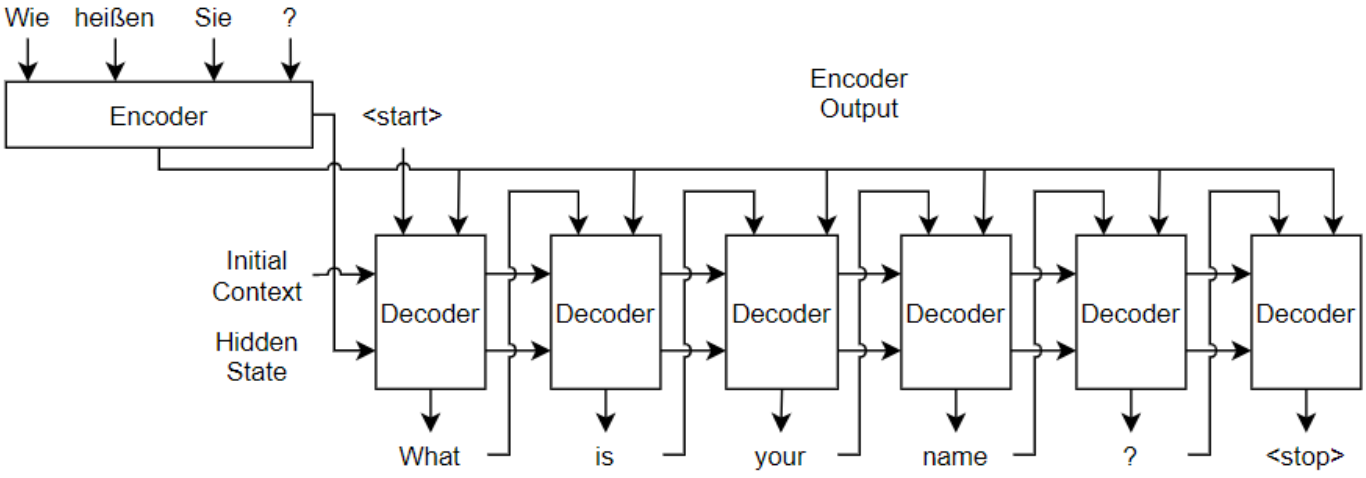
```
numWordsGerman = 12117
```

```
numWordsEnglish = encEnglish.NumWords
```

```
numWordsEnglish = 7226
```

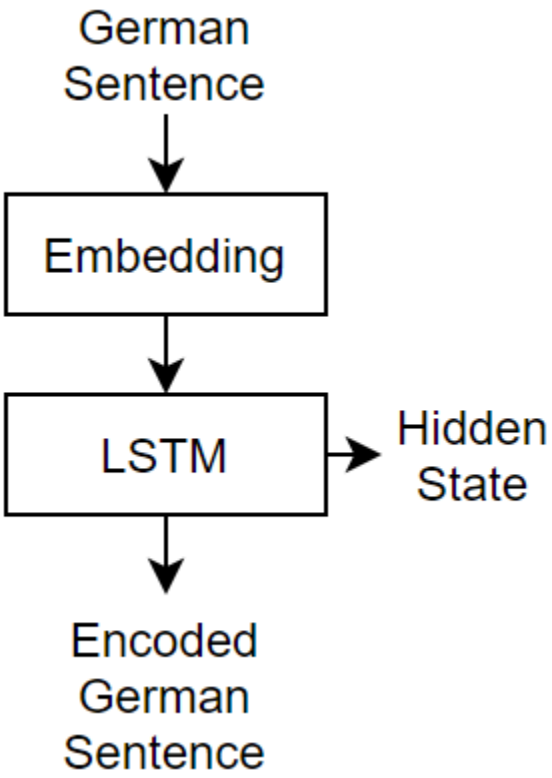
Define Encoder and Decoder Networks

This diagram shows the structure of a language translation model. The input text, specified as a sequence of words, is passed through the encoder, which outputs an encoded version of the input sequence and a hidden state used to initialize the decoder state. The decoder makes predictions one word at a time using previous the prediction as input and also outputs updated state and context values.



Create the encoder and decoder networks using the `languageTranslationLayers` function, attached to this example as a supporting file. To access this function, open the example as a live script.

For the encoder network, the `languageTranslationLayers` function defines a simple network consisting of an embedding layer followed by an LSTM layer. An embedding operation converts categorical tokens into numeric vectors, where the numeric vectors are learned by the network.



For the decoder network, the `languageTranslationLayers` function defines a network that passes the input data concatenated with the input context through an LSTM layer, and takes the updated hidden state and the encoder output and passes it through an attention mechanism to determine the context vector. The LSTM output and the context vector are then concatenated and passed through a fully connected and a softmax layer for classification.

Create the encoder and decoder networks using the `languageTranslationLayers` function, attached to this example as a supporting file. To access this function, open the example as a live script. Specify an embedding dimension of 128, and 128 hidden units in the LSTM layers.

```
embeddingDimension = 128;
numHiddenUnits = 128;

[lgraphEncoder,lgraphDecoder] = languageTranslationLayers(embeddingDimension,numHiddenUnits,numWo
```

To train the network in a custom training loop, convert the encoder and decoder networks to `dlnetwork` objects.

```
dlnetEncoder = dlnetwork(lgraphEncoder);
dlnetDecoder = dlnetwork(lgraphDecoder);
```

The decoder has multiple outputs including the context output of the attention layer, which is also passed to another layer. Specify the network outputs using the `OutputNames` property of the decoder `dlnetwork` object.

```
dlnetDecoder.OutputNames = ["softmax" "context" "lstm2/hidden" "lstm2/cell"];
```

Define Model Gradients Function

Create the function `modelGradients`, listed in the Model Gradients Function on page 4-0 section of the example, which takes as input the encoder and decoder model parameters, a mini-batch of input data and the padding masks corresponding to the input data, and the dropout probability and returns the gradients of the loss with respect to the learnable parameters in the models and the corresponding loss.

Specify Training Options

Train with a mini-batch size of 64 for 15 epochs and a learning rate of 0.005.

```
miniBatchSize = 64;
numEpochs = 15;
learnRate = 0.005;
```

Initialize the options for Adam optimization.

```
gradientDecayFactor = 0.9;
squaredGradientDecayFactor = 0.999;
```

Train using gradually decaying values of ϵ for scheduled sampling. Start with a value of $\epsilon = 0.5$ and linearly decay to end with a value of $\epsilon = 0$. For more information about scheduled sampling, see the Decoder Predictions Function on page 4-0 section of the example.

```
epsilonStart = 0.5;
epsilonEnd = 0;
```

Train using SortaGrad [3] on page 4-0 , which is a strategy to improve training of ragged sequences by training for one epoch with the sequences sorted by sequence then shuffling once per epoch thereafter.

Sort the training sequences by sequence length.

```
sequenceLengths = doclength(documentsGerman);
[~,idx] = sort(sequenceLengths);
```

```
documentsGerman = documentsGerman(idx);
documentsEnglish = documentsEnglish(idx);
```

Train Model

Train the model using a custom training loop.

Create array datastores for the source and target data using the `arrayDatastore` function. Combine the datastores using the `combine` function.

```
adsSource = arrayDatastore(documentsGerman);
adsTarget = arrayDatastore(documentsEnglish);
cds = combine(adsSource,adsTarget);
```

Create a mini-batch queue to automatically prepare mini-batches for training.

- Preprocess the training data using the `preprocessMiniBatch` function, which returns a mini-batch of source sequences, target sequences, the corresponding mask, and the initial start token.
- Output `dlarray` objects with the format `"CTB"` (channel, time, batch).
- Discard any partial mini-batches.

```
mbq = minibatchqueue(cds,4, ...
    MiniBatchSize=miniBatchSize, ...
    MiniBatchFcn=@(X,Y) preprocessMiniBatch(X,Y,encGerman,encEnglish), ...
    MiniBatchFormat=["CTB" "CTB" "CTB" "CTB"], ...
    PartialMiniBatch="discard");
```

Initialize the training progress plot.

```
figure
C = colororder;
lineLossTrain = animatedline(Color=C(2,:));

xlabel("Iteration")
ylabel("Loss")
ylim([0 inf])
grid on
```

For the encoder and decoder networks, initialize the values for Adam optimization.

```
trailingAvgEncoder = [];
trailingAvgSqEncoder = [];
trailingAvgDecder = [];
trailingAvgSqDecoder = [];
```

Create an array of ϵ values for scheduled sampling.

```
numIterationsPerEpoch = floor(numObservationsTrain/miniBatchSize);
numIterations = numIterationsPerEpoch * numEpochs;
epsilon = linspace(epsilonStart,epsilonEnd,numIterations);
```

Train the model. For each iteration:

- Read a mini-batch of data from the mini-batch queue.
- Compute the model gradients and loss.
- Update the encoder and decoder networks using the `adamupdate` function.

- Update the training progress plot and display an example translation using the `ind2str` function, attached to this example as a supporting file. To access this function, open this example as a live script.
- If the iteration yields the lowest training loss, then save the network.

At the end of each epoch, shuffle the mini-batch queue.

For large data sets, training can take many hours to run.

```
iteration = 0;
start = tic;
lossMin = inf;
reset(mbq)

% Loop over epochs.
for epoch = 1:numEpochs

    % Loop over mini-batches.
    while hasdata(mbq)
        iteration = iteration + 1;

        % Read mini-batch of data.
        [dlX,dlT,maskT,decoderInput] = next(mbq);

        % Compute loss and gradients.
        [gradientsEncoder,gradientsDecoder,loss,dlYPred] = dlfeval(@modelGradients,dlnetEncoder,d

        % Update network learnable parameters using adamupdate.
        [dlnetEncoder, trailingAvgEncoder, trailingAvgSqEncoder] = adamupdate(dlnetEncoder,gradie
            iteration,learnRate,gradientDecayFactor,squaredGradientDecayFactor);

        [dlnetDecoder, trailingAvgDecder, trailingAvgSqDecoder] = adamupdate(dlnetDecoder,gradien
            iteration,learnRate,gradientDecayFactor,squaredGradientDecayFactor);

        % Generate translation for plot.
        if iteration == 1 || mod(iteration,10) == 0
            strGerman = ind2str(dlX(:,1,:),encGerman);
            strEnglish = ind2str(dlT(:,1,:),encEnglish,Mask=maskT);
            strTranslated = ind2str(dlYPred(:,1,:),encEnglish);
        end

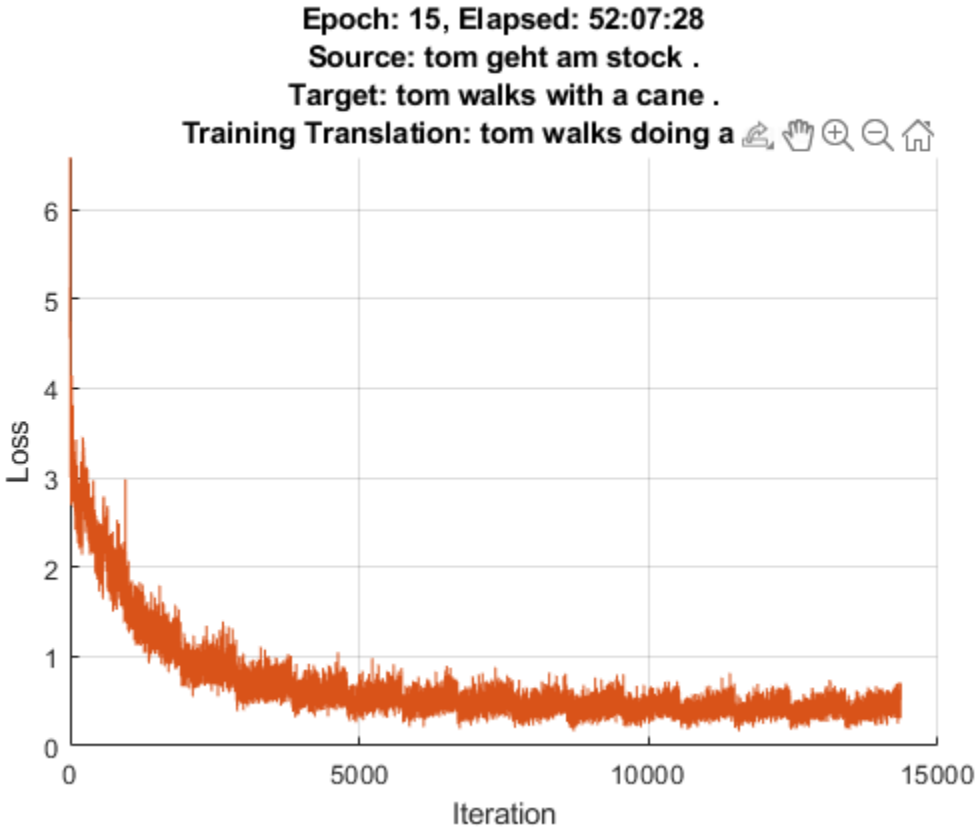
        % Display training progress.
        D = duration(0,0,toc(start),Format="hh:mm:ss");
        loss = double(gather(extractdata(loss)));
        addpoints(lineLossTrain,iteration,loss)
        title( ...
            "Epoch: " + epoch + ", Elapsed: " + string(D) + newline + ...
            "Source: " + strGerman + newline + ...
            "Target: " + strEnglish + newline + ...
            "Training Translation: " + strTranslated)

        drawnow

        % Save best network.
        if loss < lossMin
            lossMin = loss;
            netBest.dlnetEncoder = dlnetEncoder;
```

```
            netBest.dlnetDecoder = dlnetDecoder;
            netBest.loss = loss;
            netBest.iteration = iteration;
            netBest.D = D;
        end
    end

    % Shuffle.
    shuffle(mbq);
end
```



The plot shows two translations of the source text. The target is the target translation provided by the training data that the network attempts to reproduce. The training translation is the predicted translation, which uses information from the target text via the scheduled sampling mechanism.

Add the word encodings to the `netBest` structure and save the structure in a MAT file.

```
netBest.encGerman = encGerman;
netBest.encEnglish = encEnglish;

D = datestr(now,'yyyy_mm_dd__HH_MM_SS');
filename = "dlnet_best__" + D + ".mat";
save(filename,"netBest");
```

Extract the best network from `netBest`.

```
dlnetEncoder = netBest.dlnetEncoder;
dlnetDecoder = netBest.dlnetDecoder;
```

Test Model

To evaluate the quality of the translations, use the BiLingual Evaluation Understudy (BLEU) scoring algorithm [4] on page 4-0 .

Translate the test data using the `translateText` function listed at the end of the example.

```
strTranslatedTest = translateText(dlnetEncoder,dlnetDecoder,encGerman,encEnglish,dataTest.Source)
```

View a random selection of the test source text, target text, and predicted translations in a table.

```
numObservationsTest = size(dataTest,1);
idx = randperm(numObservationsTest,8);
tbl = table;
tbl.Source = dataTest.Source(idx);
tbl.Target = dataTest.Target(idx);
tbl.Translated = strTranslatedTest(idx)
```

```
tbl=8×3 table
                    Source                                Target                          Translated
    ____________________________________    ____________________________    ____________________

    "Er sieht krank aus."                   "He seems ill."                 "he looks sick ."
    "Ich werde das Buch holen."             "I'll get the book."            "i'll get the book .
    "Ruhst du dich jemals aus?"             "Do you ever rest?"             "do you look out of ?
    "Was willst du?"                        "What are you after?"           "what do you want wan
    "Du hast keinen Beweis."                "You have no proof."            "you have no proof .
    "Macht es, wann immer ihr wollt."       "Do it whenever you want."      "do it you like it .
    "Tom ist gerade nach Hause gekommen."   "Tom has just come home."       "tom just came home ho
    "Er lügt nie."                          "He never tells a lie."         "he never lie lies .
```

To evaluate the quality of the translations using the BLEU similarity score, first preprocess the text data using the same steps as for training. Specify empty start and stop tokens, as these are not used in the translation.

```
candidates = preprocessText(strTranslatedTest,StartToken="",StopToken="");
references = preprocessText(dataTest.Target,StartToken="",StopToken="");
```

The `bleuEvaluationScore` function, by default, evaluates the similarity scores by comparing n-grams of length one through four (multiword phrases with four or fewer words or single words). If the candidate or reference documents have fewer than four tokens, then the resulting BLEU evaluation score is zero. To ensure that `bleuEvaluationScore` returns nonzero scores for these short candidate documents, set the n-gram weights to a vector with fewer elements than the number of words in `candidate`.

Determine the length of the shortest candidate document.

```
minLength = min([doclength(candidates); doclength(references)])
```

```
minLength = 2
```

If the shortest document has fewer than four tokens, then set the n-gram weights to a vector with a length matching the shortest document with equal weights that sum to one. Otherwise, specify n-gram weights of `[0.25 0.25 0.25 0.25]`. Note that if `minLength` is `1` (and consequently the n-gram weights is also `1`), then the `bleuEvaluationScore` function can return less meaningful results as it only compares individual words (unigrams) and does not compare any n-grams (multiword phrases).

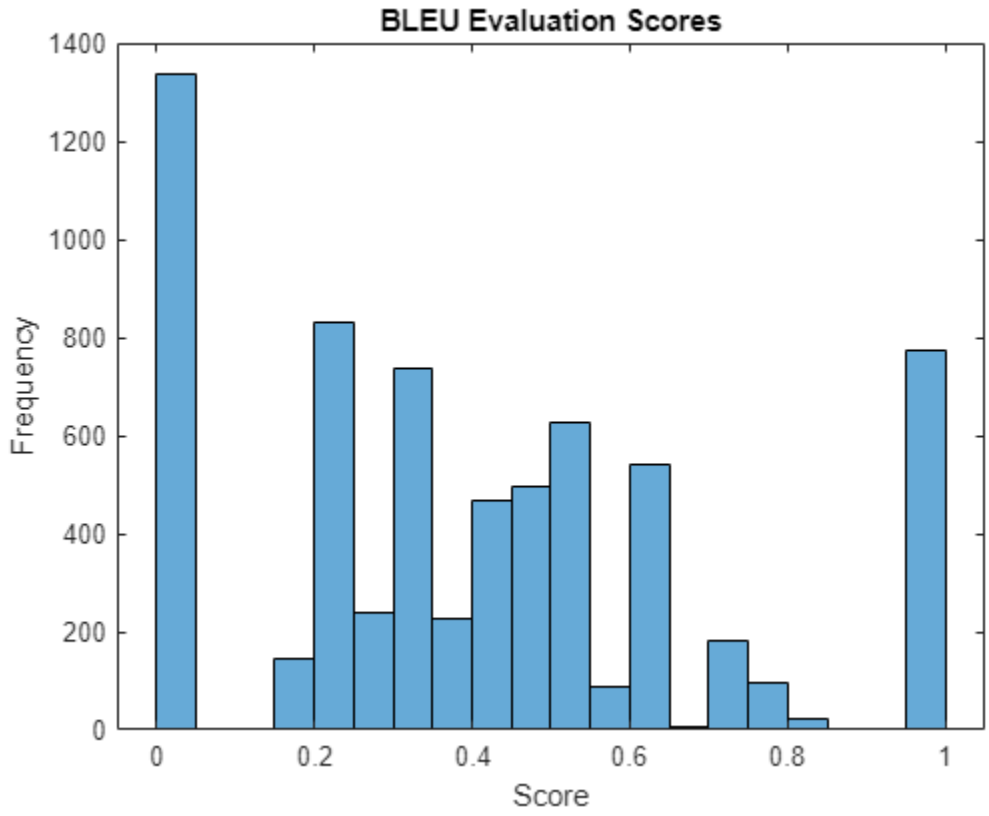
```
if minLength < 4
    ngramWeights = ones(1,minLength) / minLength;
else
    ngramWeights = [0.25 0.25 0.25 0.25];
end
```

Calculate the BLEU evaluation scores by iterating over the translations and using the `bleuEvaluationScore` function.

```
for i = 1:numObservationsTest
    score(i) = bleuEvaluationScore(candidates(i),references(i),NgramWeights=ngramWeights);
end
```

Visualize the BLEU evaluation scores in a histogram.

```
figure
histogram(score);
title("BLEU Evaluation Scores")
xlabel("Score")
ylabel("Frequency")
```



View a table of some of the best translations.

```
[~,idxSorted] = sort(score,"descend");
idx = idxSorted(1:8);
tbl = table;
tbl.Source = dataTest.Source(idx);
```

```
tbl.Target = dataTest.Target(idx);
tbl.Translated = strTranslatedTest(idx)
```

```
tbl=8×3 table
             Source                Target        Translated

    ______________________________________________________________________    ____________________________

    "Diese Schnecken kann man essen."                                         "These snails are edible."
    "Sie stehen noch zu Verfügung."                                           "They're still available."
    "Diese Schraube passt zu dieser Mutter."                                  "This bolt fits this nut."
    "Diese Puppe gehört mir."                                                 "This doll belongs to me."
    "Das ist eine japanische Puppe."                                          "This is a Japanese doll."
    "Das ist eine Kreuzung, an der alle Fahrzeuge anhalten müssen."           "This is a four-way stop."
    "Diese Sendung ist eine Wiederholung."                                    "This program is a rerun."
    "Die heutige Folge ist eine Wiederholung."                                "Today's show is a rerun."
```

Generate Translations

Generate translations for new data using the `translateText` function.

```
strGermanNew = [
    "Wie geht es Dir heute?"
    "Wie heißen Sie?"
    "Das Wetter ist heute gut."];
```

Translate the text using the `translateText`, function listed at the end of the example.

```
strTranslatedNew = translateText(dlnetEncoder,dlnetDecoder,encGerman,encEnglish,strGermanNew)
```

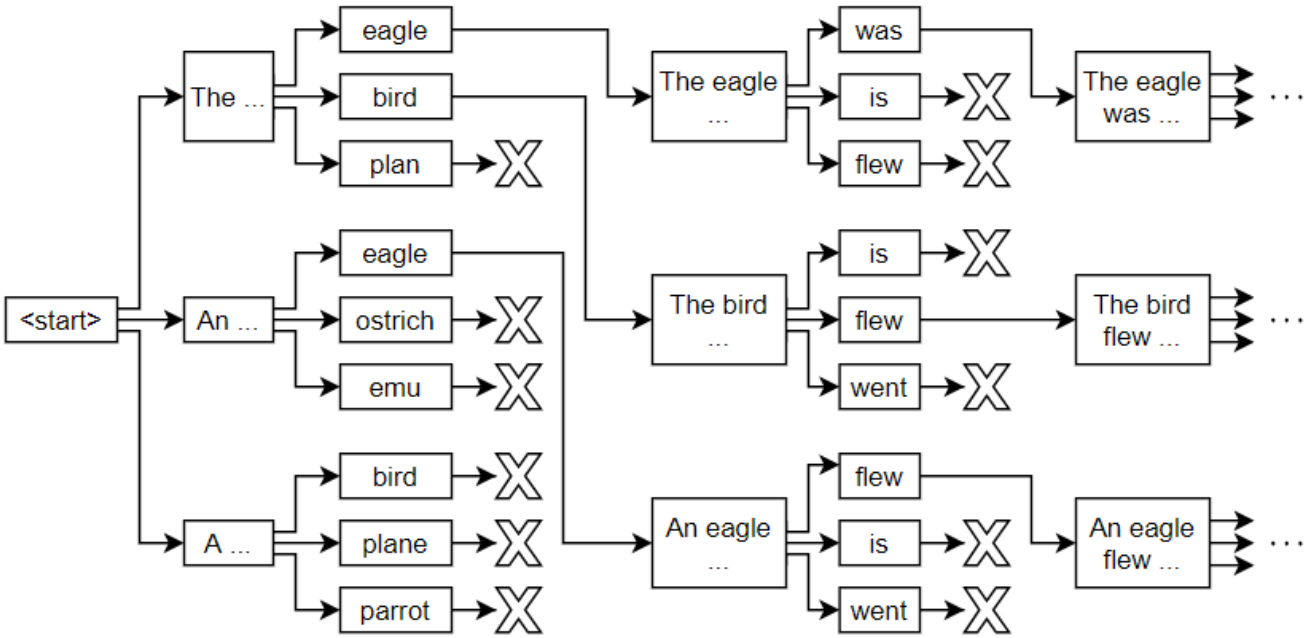
```
strTranslatedNew = 3×1 string
    "how do you feel today ?"
    "what's your your name ? ? ? ? ?"
    "the is is today . . today . ."
```

Prediction Functions

Beam Search Function

Beam search is technique for exploring different combinations of time-step predictions to help find the best prediction sequence. The premise of beam search is for each time-step prediction, identify the top K predictions for some positive integer K (also known as the *beam index* or the *beam width*), and maintain the top K predicted sequences so far at each time step.

This diagram shows the structure of an example beam search with beam index $K = 3$. For each prediction, the top three sequences are maintained.



The `beamSearch` function takes as input the input data `dlX`, the encoder and decoder networks, and the target word encoding, and returns the predicted translated words using the beam search algorithm with a beam index of 3 and a maximum sequence length of 10. You can also specify optional arguments using name-value arguments:

- `BeamIndex` — Beam index. The default is 3.
- `MaxNumWords` — Maximum sequence length. The default is 10.

```
function str = beamSearch(dlX,dlnetEncoder,dlnetDecoder,encEnglish,args)

% Parse input arguments.
arguments
    dlX
    dlnetEncoder
    dlnetDecoder
    encEnglish

    args.BeamIndex = 3;
    args.MaxNumWords = 10;
end
```

```
beamIndex = args.BeamIndex;
maxNumWords = args.MaxNumWords;
startToken = "<start>";
stopToken = "<stop>";

% Encoder predictions.
[dlZ, hiddenState, cellState] = predict(dlnetEncoder,dlX);

% Initialize context.
miniBatchSize = size(dlX,2);
numHiddenUnits = size(dlZ,1);
context = zeros([numHiddenUnits miniBatchSize],"like",dlZ);
context = dlarray(context,"CB");

% Initialize candidates.
candidates = struct;
candidates.Words = startToken;
candidates.Score = 0;
candidates.StopFlag = false;
candidates.HiddenState = hiddenState;
candidates.CellState = cellState;

% Loop over words.
t = 0;
while t < maxNumWords
    t = t + 1;

    candidatesNew = [];

    % Loop over candidates.
    for i = 1:numel(candidates)

        % Stop generating when stop token is predicted.
        if candidates(i).StopFlag
            continue
        end

        % Candidate details.
        words = candidates(i).Words;
        score = candidates(i).Score;
        hiddenState = candidates(i).HiddenState;
        cellState = candidates(i).CellState;

        % Predict next token.
        decoderInput = word2ind(encEnglish,words(end));
        decoderInput = dlarray(decoderInput,"CBT");

        [dlYPred,context,hiddenState,cellState] = predict(dlnetDecoder,decoderInput,hiddenState,
            Outputs=["softmax" "context" "lstm2/hidden" "lstm2/cell"]);

        % Find top predictions.
        [scoresTop,idxTop] = maxk(extractdata(dlYPred),beamIndex);
        idxTop = gather(idxTop);

        % Loop over top predictions.
        for j = 1:beamIndex
            candidate = struct;
```

```
            % Determine candidate word and score.
            candidateWord = ind2word(encEnglish,idxTop(j));
            candidateScore = scoresTop(j);

            % Set stop translating flag.
            if candidateWord == stopToken
                candidate.StopFlag = true;
            else
                candidate.StopFlag = false;
            end

            % Update candidate details.
            candidate.Words = [words candidateWord];
            candidate.Score = score + log(candidateScore);
            candidate.HiddenState = hiddenState;
            candidate.CellState = cellState;

            % Add to new candidates.
            candidatesNew = [candidatesNew candidate];
        end
    end

    % Get top candidates.
    [~,idx] = maxk([candidatesNew.Score],beamIndex);
    candidates = candidatesNew(idx);

    % Stop predicting when all candidates have stop token.
    if all([candidates.StopFlag])
        break
    end
end

% Get top candidate.
words = candidates(1).Words;

% Convert to string scalar.
words(ismember(words,[startToken stopToken])) = [];
str = join(words);

end
```

Translate Text Function

The `translateText` function takes as input the encoder and decoder networks, an input string, and source and target word encodings and returns the translated text.

```
function strTranslated = translateText(dlnetEncoder,dlnetDecoder,encGerman,encEnglish,strGerman,a

% Parse input arguments.
arguments
    dlnetEncoder
    dlnetDecoder
    encGerman
    encEnglish
    strGerman

    args.BeamIndex = 3;
```

```
end

beamIndex = args.BeamIndex;

% Preprocess text.
documentsGerman = preprocessText(strGerman);
dlX = preprocessPredictors(documentsGerman,encGerman);
dlX = dlarray(dlX,"CTB");

% Loop over observations.
numObservations = numel(strGerman);
strTranslated = strings(numObservations,1);
for n = 1:numObservations

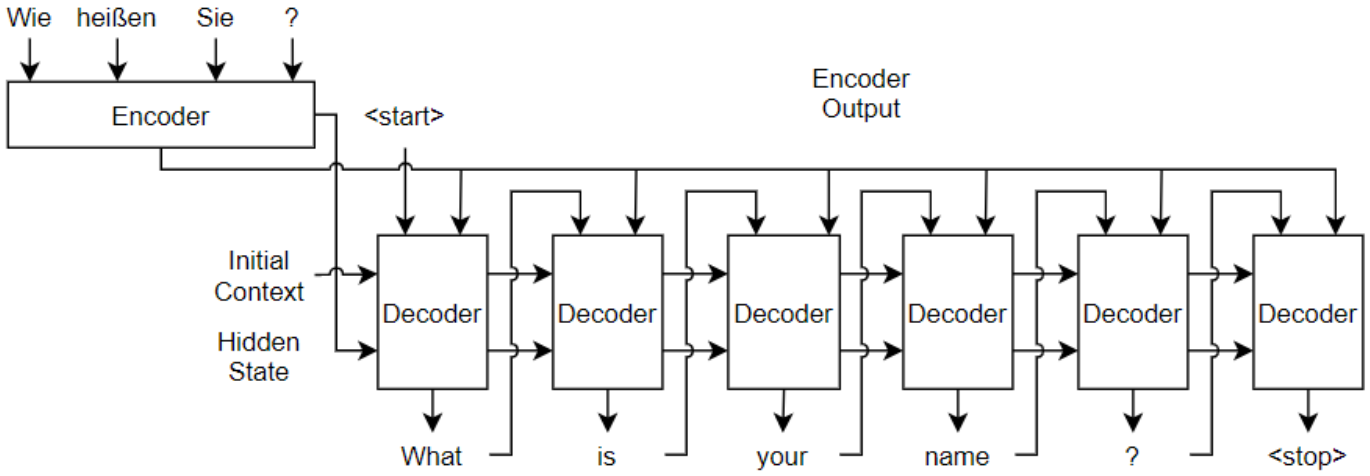
    % Translate text.
    strTranslated(n) = beamSearch(dlX(:,n,:),dlnetEncoder,dlnetDecoder,encEnglish,BeamIndex=beam
end

end
```

Model Functions

Model Gradients Function

The `modelGradients` function takes as input the encoder network, decoder network, mini-batches of predictors `dlX`, targets `dlT`, padding mask corresponding to the targets `maskT`, and ϵ value for scheduled sampling. The function returns the gradients of the loss with respect to the learnable parameters in the networks `gradientsE` and `gradientsD`, the corresponding loss, and the decoder predictions `dlYPred` encoded as sequences of one-hot vectors.



```
function [gradientsE,gradientsD,loss,dlYPred] = modelGradients(dlnetEncoder,dlnetDecoder,dlX,dlT

% Forward through encoder.
[dlZ, hiddenState, cellState] = forward(dlnetEncoder,dlX);

% Decoder output.
dlY = decoderPredictions(dlnetDecoder,dlZ,dlT,hiddenState,cellState,decoderInput,epsilon);

% Sparse cross-entropy loss.
loss = sparseCrossEntropy(dlY,dlT,maskT);
```

```
% Update gradients.
[gradientsE,gradientsD] = dlgradient(loss,dlnetEncoder.Learnables,dlnetDecoder.Learnables);

% For plotting, return loss normalized by sequence length.
sequenceLength = size(dlT,3);
loss = loss ./ sequenceLength;

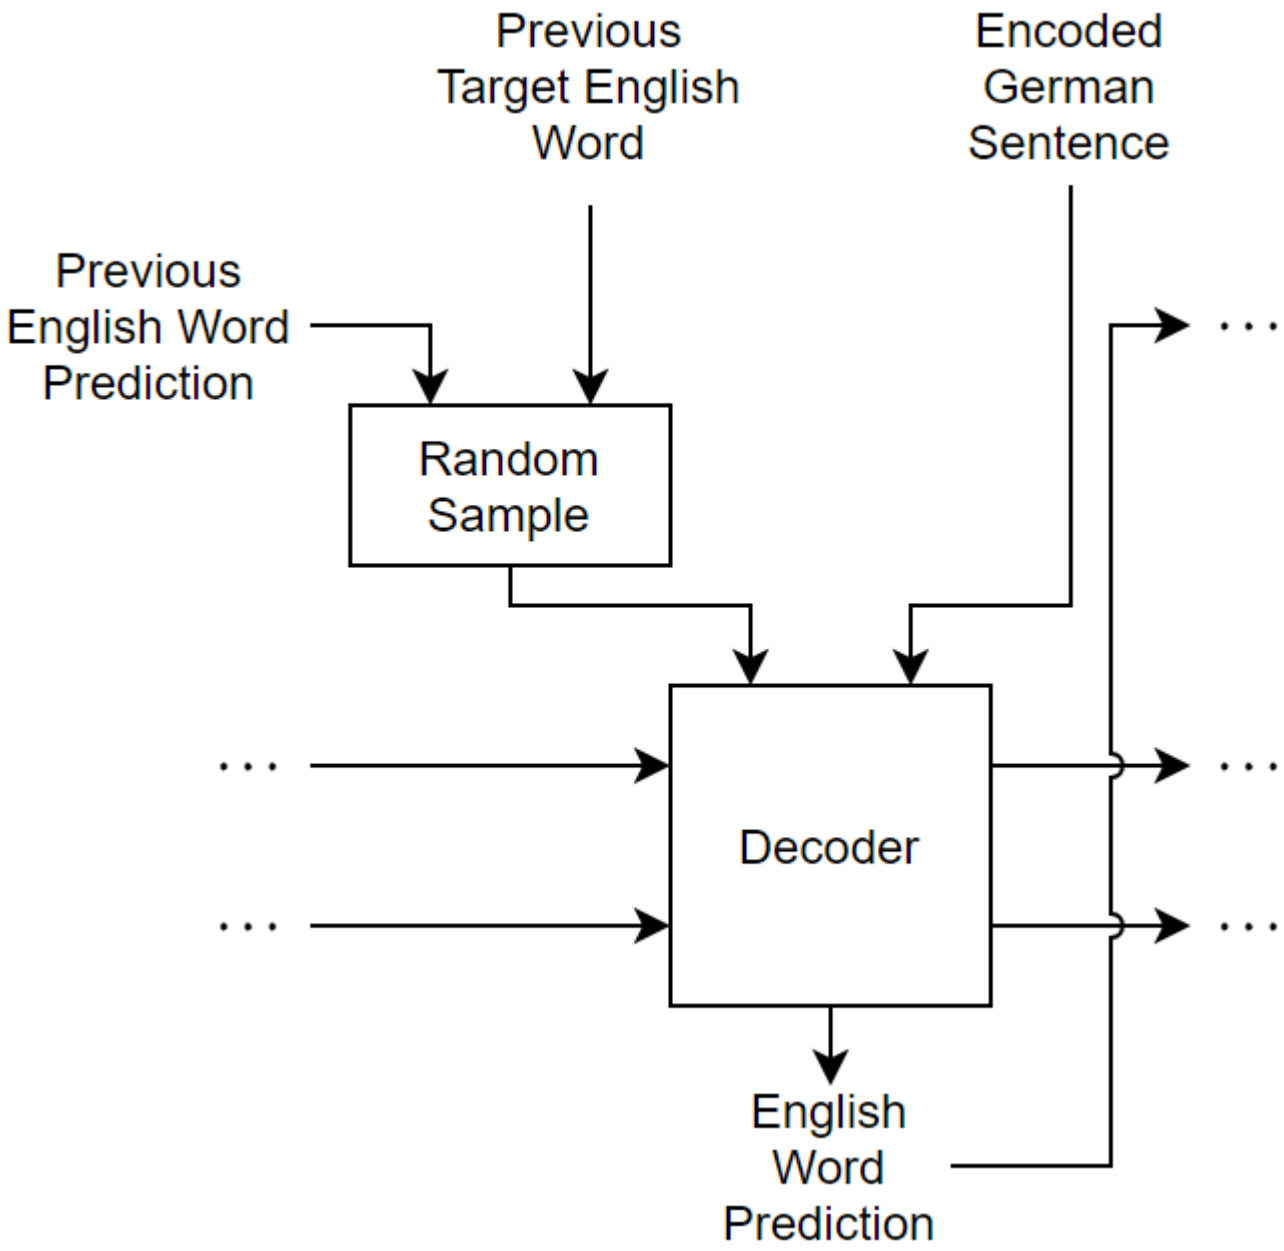
% For plotting example translations, return the decoder output.
dlYPred = onehotdecode(dlY,1:size(dlY,1),1,"single");

end
```

Decoder Predictions Function

The `decoderPredictions` function takes as input, the decoder network, the encoder output `dlZ`, the targets `dlT`, the decoder input hidden and cell state values, and the ϵ value for scheduled sampling.

To stabilize training, you can randomly use the target values as inputs to the decoder. In particular, you can adjust the probability used to inject the target values as training progresses. For example, you can train using the target values at a much higher rate at the start of training, then decay the probability such that towards the end of training the model uses only the previous predictions. This technique is known as *scheduled sampling* [2] on page 4-0 . This diagram shows the sampling mechanism incorporated into one time step of a decoder prediction.



The decoder makes predictions one time step at a time. At each time step, the input is randomly selected according to the ϵ value for scheduled sampling. In particular, the function uses the target value as input with probability ϵ and uses the previous prediction otherwise.

```
function dlY = decoderPredictions(dlnetDecoder,dlZ,dlT,hiddenState,cellState,decoderInput,epsilo

% Initialize context.
numHiddenUnits = size(dlZ,1);
miniBatchSize = size(dlZ,2);
context = zeros([numHiddenUnits miniBatchSize],"like",dlZ);
context = dlarray(context,"CB");
```

```
% Initialize output.
idx = (dlnetDecoder.Learnables.Layer == "fc" & dlnetDecoder.Learnables.Parameter=="Bias");
numClasses = numel(dlnetDecoder.Learnables.Value{idx});
sequenceLength = size(dlT,3);
dlY = zeros([numClasses miniBatchSize sequenceLength],"like",dlZ);
dlY = dlarray(dlY,"CBT");

% Forward start token through decoder.
[dlY(:,:,1),context,hiddenState,cellState] = forward(dlnetDecoder,decoderInput,hiddenState,cellS

% Loop over remaining time steps.
for t = 2:sequenceLength

    % Scheduled sampling. Randomly select previous target or previous
    % prediction.
    if rand < epsilon
        % Use target value.
        decoderInput = dlT(:,:,t-1);
    else
        % Use previous prediction.
        [~,dlYhat] = max(dlY(:,:,t-1),[],1);
        decoderInput = dlYhat;
    end

    % Forward through decoder.
    [dlY(:,:,t),context,hiddenState,cellState] = forward(dlnetDecoder,decoderInput,hiddenState,ce
end

end
```

Sparse Cross-Entropy Loss

The `sparseCrossEntropy` function calculates the cross-entropy loss between the predictions `dlY` and targets `dlT` with the target mask `maskT`, where `dlY` is an array of probabilities and `dlT` is encoded as a sequence of integer values.

```
function loss = sparseCrossEntropy(dlY,dlT,maskT)

% Initialize loss.
[~,miniBatchSize,sequenceLength] = size(dlY);
loss = zeros([miniBatchSize sequenceLength],"like",dlY);

% To prevent calculating log of 0, bound away from zero.
precision = underlyingType(dlY);
dlY(dlY < eps(precision)) = eps(precision);

% Loop over time steps.
for n = 1:miniBatchSize
    for t = 1:sequenceLength
        idx = dlT(1,n,t);
        loss(n,t) = -log(dlY(idx,n,t));
    end
end

% Apply masking.
maskT = squeeze(maskT);
loss = loss .* maskT;
```

```
% Calculate sum and normalize.
loss = sum(loss,"all");
loss = loss / miniBatchSize;

end
```

Preprocessing Functions

Text Preprocessing Function

The `preprocessText` function preprocesses the input text for translation by converting the text to lowercase, adding start and stop tokens, and tokenizing.

```
function documents = preprocessText(str,args)

arguments
    str
    args.StartToken = "<start>";
    args.StopToken = "<stop>";
end

startToken = args.StartToken;
stopToken = args.StopToken;

str = lower(str);
str = startToken + str + stopToken;
documents = tokenizedDocument(str,CustomTokens=[startToken stopToken]);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses tokenized documents for training. The function encodes mini-batches of documents as sequences of numeric indices and pads the sequences to have the same length.

```
function [XSource,XTarget,mask,decoderInput] = preprocessMiniBatch(dataSource,dataTarget,encGerma

documentsGerman = cat(1,dataSource{:});
XSource = preprocessPredictors(documentsGerman,encGerman);

documentsEnglish = cat(1,dataTarget{:});
sequencesTarget = doc2sequence(encEnglish,documentsEnglish,PaddingDirection="none");

[XTarget,mask] = padsequences(sequencesTarget,2,PaddingValue=1);

decoderInput = XTarget(:,1,:);
XTarget(:,1,:) = [];
mask(:,1,:) = [];

end
```

Predictors Preprocessing Function

The `preprocessPredictors` function preprocesses source documents for training or prediction. The function encodes an array of tokenized documents as sequences of numeric indices.

```
function XSource = preprocessPredictors(documentsGerman,encGerman)
```

```
sequencesSource = doc2sequence(encGerman,documentsGerman,PaddingDirection="none");
XSource = padsequences(sequencesSource,2);

end
```

Predict and Update Network State in Simulink

This example shows how to predict responses for a trained recurrent neural network in Simulink® by using the `Stateful Predict` block. This example uses a pretrained long short-term memory (LSTM) network.

Load Pretrained Network

Load `JapaneseVowelsNet`, a pretrained long short-term memory (LSTM) network trained on the Japanese Vowels data set as described in [1] and [2]. This network was trained on the sequences sorted by sequence length with a mini-batch size of 27.

```
load JapaneseVowelsNet
```

View the network architecture.

```
net.Layers
```

```
ans =

  5x1 Layer array with layers:

     1   'sequenceinput'   Sequence Input          Sequence input with 12 dimensions
     2   'lstm'            LSTM                    LSTM with 100 hidden units
     3   'fc'              Fully Connected         9 fully connected layer
     4   'softmax'         Softmax                 softmax
     5   'classoutput'     Classification Output   crossentropyex with '1' and 8 other classes
```

Load Test Data

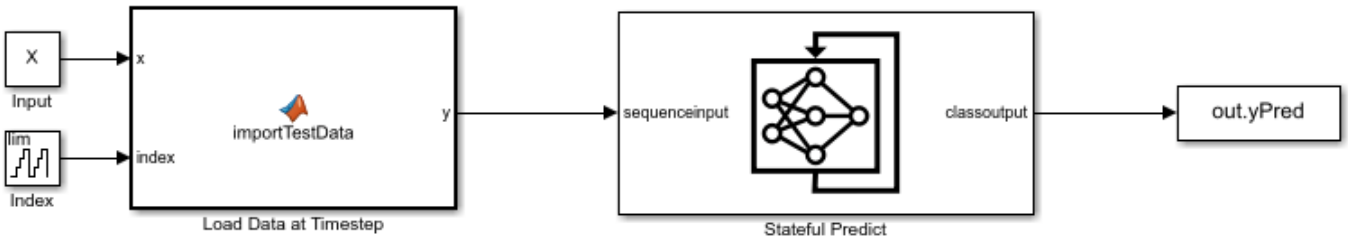
Load the Japanese Vowels test data. `XTest` is a cell array containing 370 sequences of dimension 12 of varying length. `YTest` is a categorical vector of labels "1","2",..."9", which correspond to the nine speakers.

```
[XTest,YTest] = japaneseVowelsTestData;
X = XTest{94};
numTimeSteps = size(X,2);
```

Simulink Model for Predicting Responses

The Simulink model for predicting responses contains a `Stateful Predict` block to predict the scores and `MATLAB Function` blocks to load the input data sequence over the time steps.

```
open_system('StatefulPredictExample');
```



Configure Model for Simulation

Set the model configuration parameters for the input blocks and the `Stateful Predict` block.

```
set_param('StatefulPredictExample/Input','Value','X');
set_param('StatefulPredictExample/Index','uplimit','numTimeSteps-1');
set_param('StatefulPredictExample/Stateful Predict','NetworkFilePath','JapaneseVowelsNet.mat');
set_param('StatefulPredictExample', 'SimulationMode', 'Normal');
```

Run the Simulation

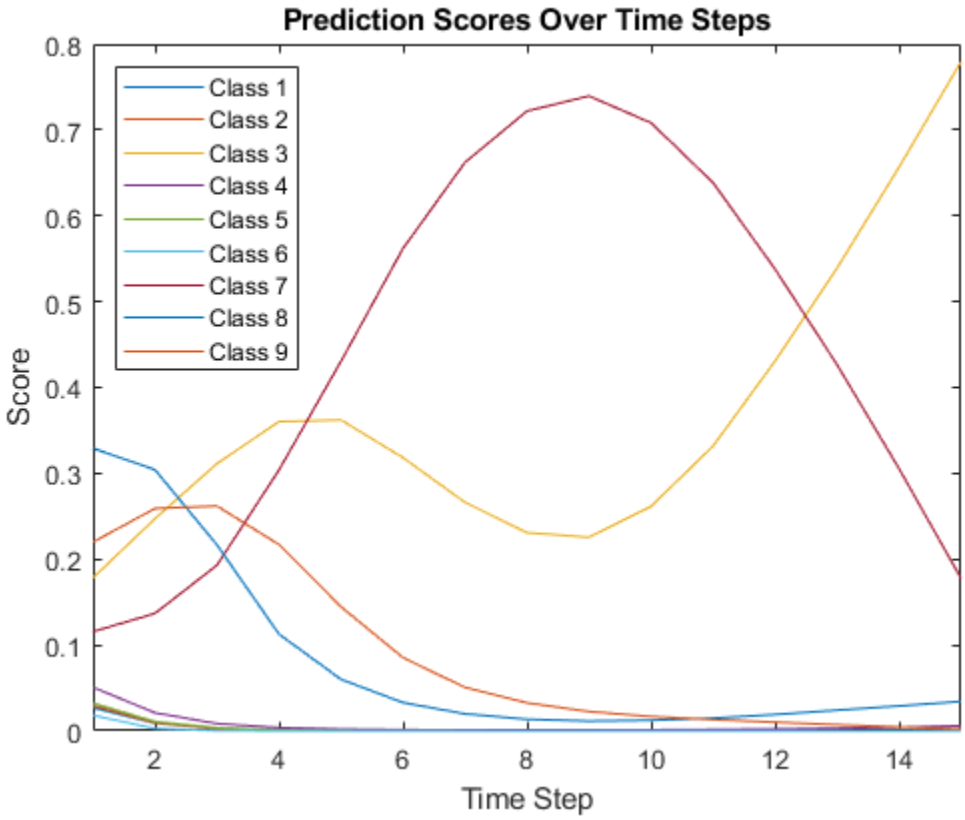
To compute responses for the `JapaneseVowelsNet` network, run the simulation. The prediction scores are saved in the MATLAB® workspace.

```
out = sim('StatefulPredictExample');
```

Plot the prediction scores. The plot shows how the prediction scores change between time steps.

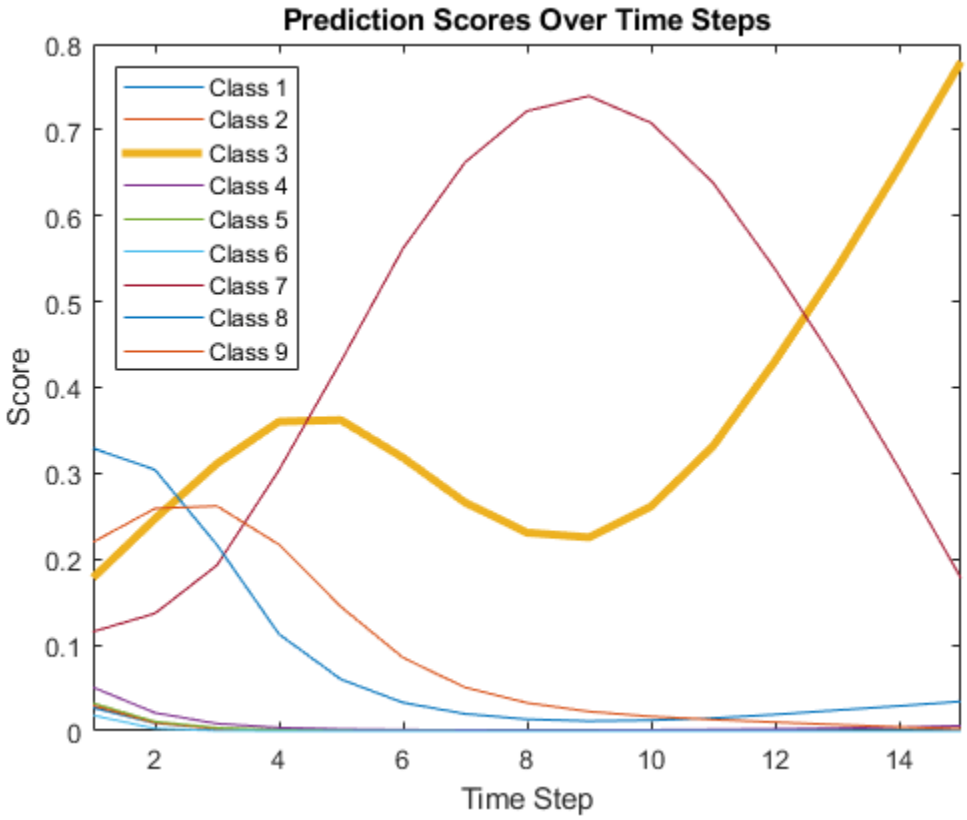
```
scores = squeeze(out.yPred.Data(:,:,1:numTimeSteps));

classNames = string(net.Layers(end).Classes);
figure
lines = plot(scores');
xlim([1 numTimeSteps])
legend("Class " + classNames,'Location','northwest')
xlabel("Time Step")
ylabel("Score")
title("Prediction Scores Over Time Steps")
```



Highlight the prediction scores over time steps for the correct class.

```
trueLabel = YTest(94);
lines(trueLabel).LineWidth = 3;
```



Display the final time step prediction in a bar chart.

```
figure
bar(scores(:,end))
title("Final Prediction Scores")
xlabel("Class")
ylabel("Score")
```

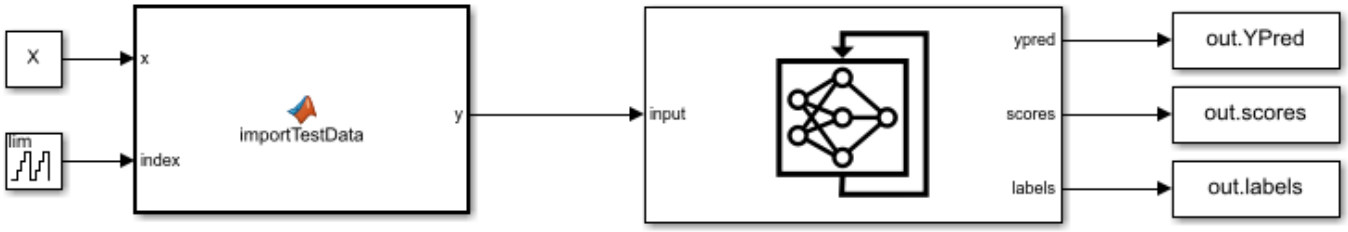
X = XTest{94};
numTimeSteps = size(X,2);
```

Simulink Model for Classifying Data

The Simulink model for classifying data contains a `Stateful Classify` block to predict the labels and `MATLAB Function` blocks to load the input data sequence over the time steps.

```
open_system('StatefulClassifyExample');
```



Configure Model for Simulation

Set the model configuration parameters for the input blocks and the `Stateful Classify` block.

```
set_param('StatefulClassifyExample/Input','Value','X');
set_param('StatefulClassifyExample/Index','uplimit','numTimeSteps-1');
set_param('StatefulClassifyExample/Stateful Classify','NetworkFilePath','JapaneseVowelsNet.mat')
set_param('StatefulClassifyExample','SimulationMode','Normal');
```

Run the Simulation

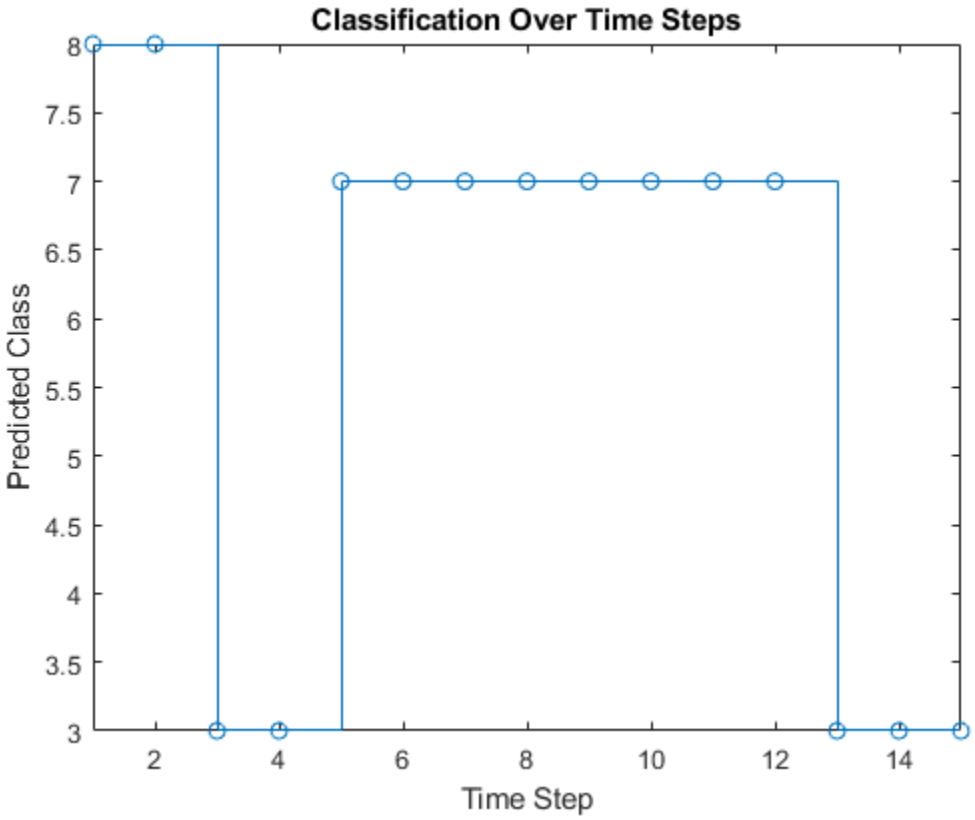
To compute responses for the `JapaneseVowelsNet` network, run the simulation. The prediction labels are saved in the MATLAB® workspace.

```
out = sim('StatefulClassifyExample');
```

Plot the predicted labels in a stair plot. The plot shows how the predictions change between time steps.

```
labels = squeeze(out.YPred.Data(1:numTimeSteps,1));

figure
stairs(labels, '-o')
xlim([1 numTimeSteps])
xlabel("Time Step")
ylabel("Predicted Class")
title("Classification Over Time Steps")
```



Compare the predictions with the true label. Plot a horizontal line showing the true label of the observation.

```
trueLabel = double(YTest(94));
hold on
line([1 numTimeSteps],[trueLabel trueLabel], ...
    'Color','red', ...
    'LineStyle','--')
legend(["Prediction" "True Label"])
axis([1 numTimeSteps+1 0 9]);
```

Time Series Prediction in Simulink Using Deep Learning Network

This example shows how to use an LSTM deep learning network inside a Simulink® model to predict the remaining useful life (RUL) of an engine. You include the network inside the Simulink model by using a `Stateful Predict` block, which predicts the RUL at every simulation step.

This example uses data from the *Turbofan Engine Degradation Simulation Data Set* as described in [1]. The example uses a trained LSTM network to predict the RUL of an engine (predictive maintenance), measured in cycles, given time series data representing various sensors in the engine. The data used to train the network contains simulated time series data for 100 engines. Each sequence has 17 features of varying length and corresponds to a full run to failure (RTF) instance. For more information on how to train the network, see “Sequence-to-Sequence Regression Using Deep Learning” on page 4-47.

Download Data

Download and unzip the *Turbofan Engine Degradation Simulation Data Set* from the Prognostics Data Repository (NASA) [2].

Each time series represents a different engine. Each engine starts with unknown degrees of initial wear and manufacturing variation. The engine is operating normally at the start of each time series, and develops a fault at some point during the series. In the training set, the fault grows in magnitude until system failure.

The data contains zip-compressed text files with 26 columns of numbers, separated by spaces. Each row is a snapshot of data taken during a single operational cycle, and each column is a different variable. The columns correspond to the following:

- Column 1: Unit number
- Column 2: Time in cycles
- Columns 3–5: Operational settings
- Columns 6–26: Sensor measurements 1–21

```
filename = "CMAPSSData.zip";
dataFolder = "data";
unzip(filename,dataFolder)
```

Prepare Data

Load the data using the `processTurboFanDataTrain` helper function. The `processTurboFanDataTrain` function extracts the data from `filenamePredictors` and returns the cell array `XTrain`, which contains the training predictor data.

```
filenamePredictors = fullfile(dataFolder,"train_FD001.txt");
[XTrain] = processTurboFanDataTrain(filenamePredictors);
```

Remove Features with Constant Values

Since the network was trained with features that do not remain constant for all time steps, features with constant values for all time steps need to be removed for prediction. Find the rows of data that have the same minimum and maximum values, and remove the rows.

```
m = min([XTrain{:}],[],2);
M = max([XTrain{:}],[],2);
idxConstant = M == m;

for i = 1:numel(XTrain)
    XTrain{i}(idxConstant,:) = [];
end
```

Normalize Training Predictors

Normalize the training predictors to have zero mean and unit variance. To calculate the mean and standard deviation over all observations, concatenate the sequence data horizontally.

```
mu = mean([XTrain{:}],2);
sig = std([XTrain{:}],0,2);

for i = 1:numel(XTrain)
    XTrain{i} = (XTrain{i} - mu) ./ sig;
end
```

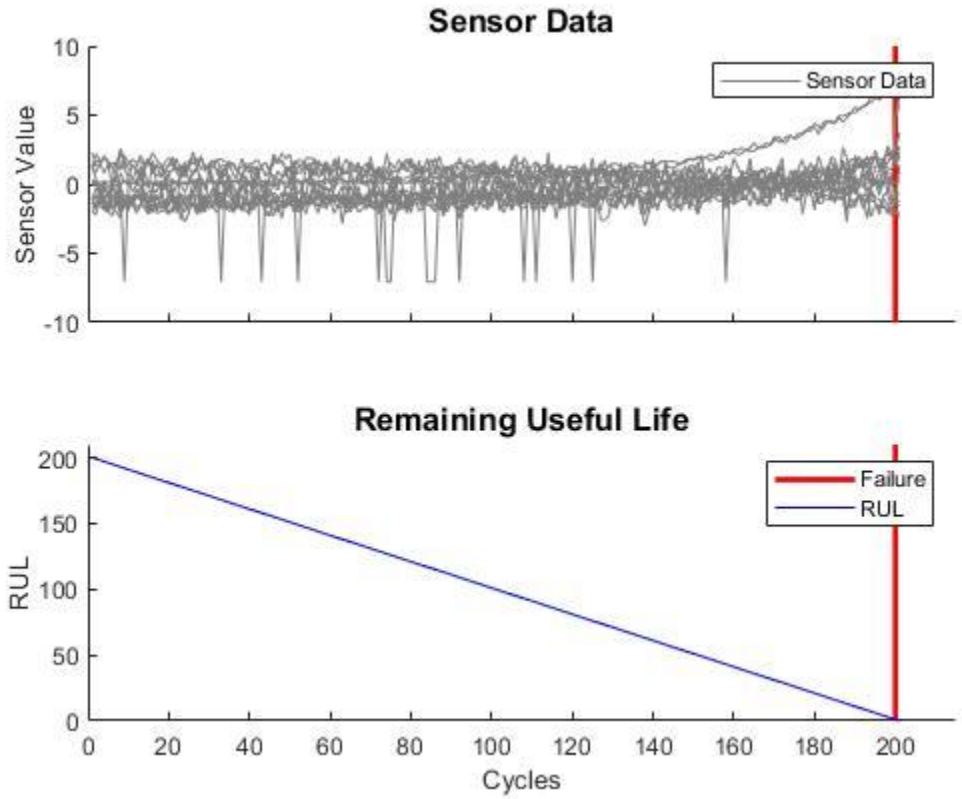
Extract data for one engine

In the Simulink model, we calculate the RUL for one engine only. In this example, we extract the 9th element of `XTrain` and store it in a variable named `SensorData`. You can choose any other engine from the `XTrain` cell array. `SensorData` is a double array of size 17-by-201. Every row corresponds to one feature and every column corresponds to the sensor readings at a given cycle.

```
SensorData = XTrain{9};
```

Simulink models have an associated simulation time, which in this example needs to be related to the engine cycles. For this reason, we define a timeseries named `EngineData`, which stores the sensor data as a timeseries object that can be loaded in the Simulink model. As the default simulation time in Simulink is `10.0` and the engine runs through 201 cycles, the `Time` field of `EngineData` needs to be an array of size 201-by-1 with values linearly increasing from 0 to 10.

```
Time = linspace(0,10,201)';
EngineData = timeseries(SensorData',Time);
```

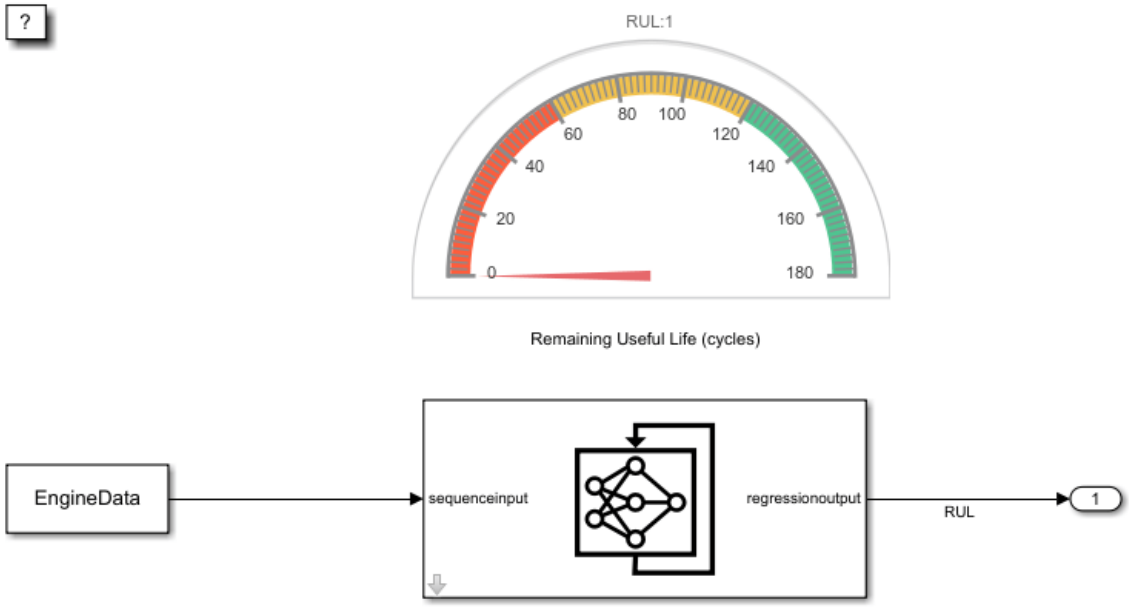


The top panel of this figure shows the sensor readings from each sensor at each cycle and the bottom panel shows the RUL of the engine in units of cycles. After 201 cycles, the engine stops operating. Note, if you select another engine from the `XTrain` data, then you need to adapt the `Time` field of `EngineData` accordingly, as each engine operates for a different number of cycles.

Simulink Model to Predict RUL

Load the Simulink model `RULPredictionLSTM.slx`.

```
modelName = 'RULPredictionLSTM';
open_system(modelName);
```



`EngineData` is loaded from the base workspace using a `From Workspace` block. In this example, the time step in `EngineData` is `0.05`. So, we set the sample time of the `From Workspace` block to 0.05. Hence, at the first step the block outputs the first row of `EngineData`, at the second step it outputs the second row - corresponding to the second engine cycle - and so on. If another engine is chosen from `XData`, then the sample time of the block needs to be updated accordingly.

```
set_param([modelName,'/From Workspace'],'SampleTime','0.05');
```

The `Stateful Predict` block loads the pretrained LSTM network in the `turbofanNet` MAT-file and returns the RUL at its output port. The `Stateful Predict` block updates the state of the network with every prediction, improving the prediction of the current RUL.The `Half Gauge` block shows the value of the calculated RUL (in units of engine cycles) during the simulation.

```
RUL_sigSpec = Simulink.HMI.SignalSpecification;
RUL_sigSpec.BlockPath = Simulink.BlockPath('RULPredictionLSTM/Stateful Predict');
set_param('RULPredictionLSTM/Half Gauge','Binding',RUL_sigSpec)
```

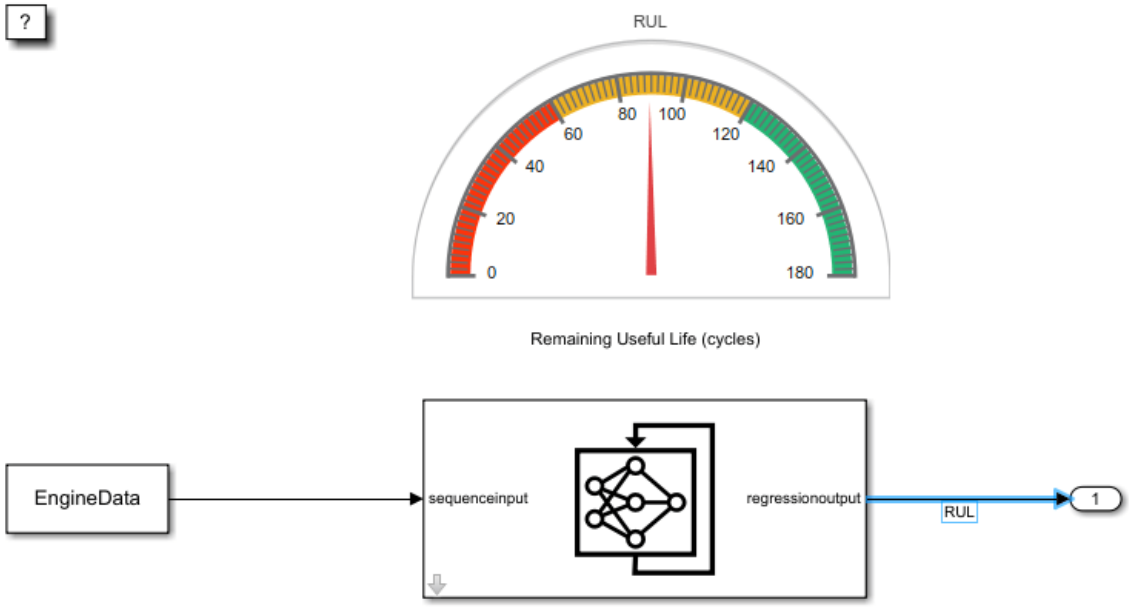
Run the Simulation

Because the simulation reads data from a MAT-file, it runs very quickly and can be difficult to follow. To slow down the simulation, set the Simulation Pacing option to 0.5.

```
set_param(modelName,'EnablePacing','on');
set_param(modelName,'PacingRate',0.5);
```

To compute the RUL, run the simulation.

```
sim(modelName);
```



The figure shows the model while it is running. The gauge shows the estimated RUL, corresponding in this case to 90 cycles. At the end of the simulation, the RUL is returned to the Base Workspace in the form of a single array, containing the values calculated at each simulation iteration.

You could integrate this system within a bigger framework, for example in a system that continuously monitors the status of an engine, and which adopts precautionary measures if the RUL falls below a given user-defined value.

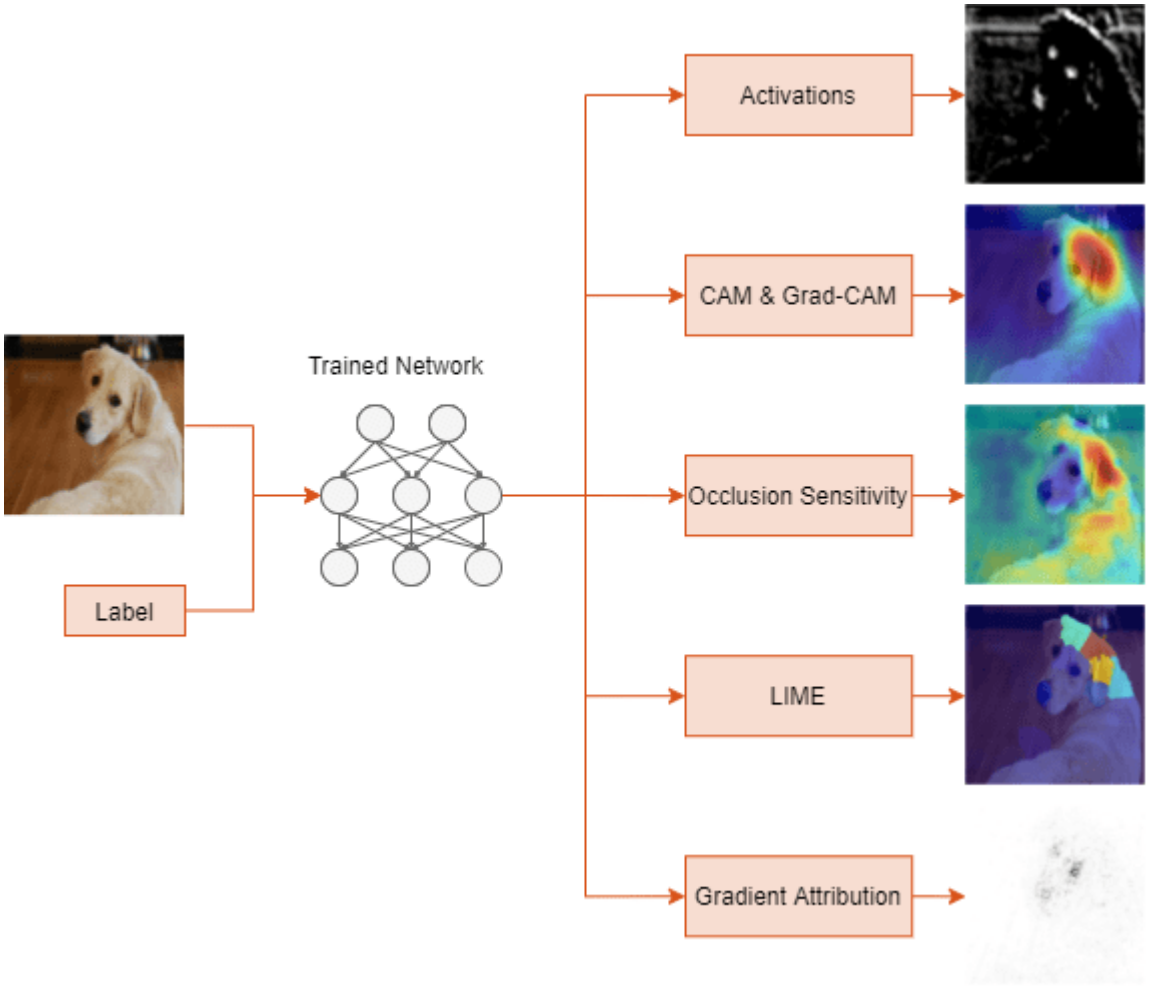
Deep Learning Tuning and Visualization

Explore Network Predictions Using Deep Learning Visualization Techniques

This example shows how to investigate network predictions using deep learning visualization techniques.

Deep learning networks are often described as "black boxes" because why a network makes a certain decision is not always obvious. You can use an interpretability technique to translate network behavior into output that a person can interpret. This interpretable output can then answer questions about the predictions of a network. This example focuses on visualization methods, which are interpretability techniques that explain network predictions using visual representations of what a network is “looking” at.



Load Pretrained Network

Load a pretrained image classification network. For this example, use GoogLeNet, a pretrained network that can classify images into 1000 object categories, such as keyboard, mouse, pencil, and many animals.

```
net = googlenet;
```

Find the input size of the network and the class labels.

```
inputSize = net.Layers(1).InputSize(1:2);
classes = net.Layers(end).Classes;
```

Classify Image

Load a test image containing a picture of a golden retriever.

```
img = imread("sherlock.jpg");
img = imresize(img,inputSize);

figure
imshow(img)
```

Classify the image using the pretrained network.

```
[YPred,scores] = classify(net,img);
YPred
```

```
YPred = categorical
     golden retriever
```

The network correctly classifies the image as a golden retriever. Find the three classes with the highest scores.

```
[~,topIdx] = maxk(scores,3);
topScores = scores(topIdx)';
topClasses = classes(topIdx);
table(topClasses,topScores)
```

```
ans=3×2 table
        topClasses        topScores
    __________________    _________

    golden retriever       0.55419
```

```
Labrador retriever     0.39633
kuvasz                 0.02544
```

The classes with the top three scores are all dog breeds. The network outputs higher scores for the classes that share similar features with the true golden retriever class.

You can use visualization techniques to understand why the network classifies this image as a golden retriever.

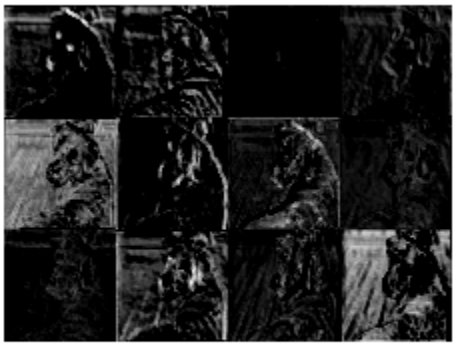
Activation Visualization

One of the simplest ways of understanding network behavior is to visualize the activations of each layer. Most convolutional neural networks learn to detect features such as color and edges in their first convolutional layer. In deeper convolutional layers, the network learns to detect more complicated features, such as eyes. Pass the image through the network and examine the output activations of the `conv2-relu_3x3_reduce` layer.

```
act = activations(net,img,"conv2-relu_3x3_reduce");
sz = size(act);
act = reshape(act,[sz(1) sz(2) 1 sz(3)]);
```

Display the activations for the first 12 channels of the layer.

```
I = imtile(mat2gray(act(:,:,:,1:12)));
figure
imshow(I)
```



White pixels represent strong positive activations and black pixels represent strong negative activations. You can see that the network is learning low-level features, such as edges and texture. The first channel highlights the eyes and nose of the dog, possibly due to their distinctive edge and color.

Investigate a deeper layer.

```
actDeep = activations(net,img,"inception_5b-output");
sz = size(actDeep)
```

```
sz = 1×3

           7           7        1024
```

```
actDeep = reshape(actDeep,[sz(1) sz(2) 1 sz(3)]);
```

This layer has 1024 channels. Each channel has an image. Investigating every image in detail is impractical. Instead, you can gain insight into the network behavior by considering the channel with the strongest activation.

```
[maxValue,maxValueIndex] = max(max(max(actDeep)));
actDeepMax = actDeep(:,:,:,maxValueIndex);

tiledlayout("flow")
nexttile
imshow(img)
nexttile
imshow(imresize(mat2gray(actDeepMax),inputSize))
```

The strongest activating channel focuses on the head of the dog, indicating that this layer is picking out more complex features.

To further explore network behavior, you can use more complex visualization methods.

Grad-CAM

Explore the network predictions using gradient-weighted class activation mapping (Grad-CAM). To understand which parts of the image are most important for classification, Grad-CAM uses the gradient of the classification score with respect to the convolutional features determined by the network. The places where this gradient is large are exactly the places where the final score depends most on the data. Compute the Grad-CAM map using the `gradCAM` function and the predicted class.

```
gradcamMap = gradCAM(net,img,YPred);
```

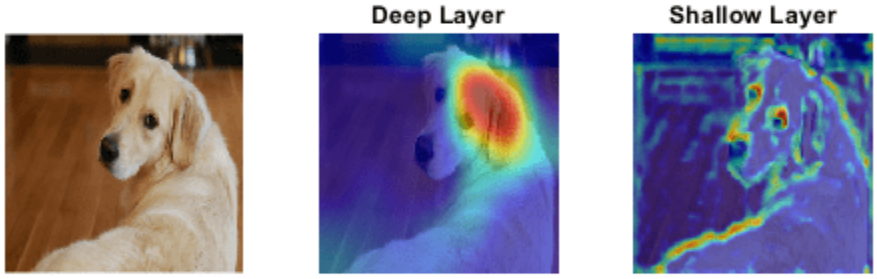
By default, the `gradCAM` function extracts the feature maps from the last ReLU layer with nonsingleton spatial dimensions or the last layer that gathers the outputs of ReLU layers (such as depth concatenation or addition layers). You can compute the Grad-CAM map for earlier layers in the

network by specifying the feature layer. Compute the Grad-CAM map for the early convolutional layer `conv2-relu_3x3`.

```
gradcamMapShallow = gradCAM(net,img,YPred,'FeatureLayer',"conv2-relu_3x3");
```

Use the `plotMaps` on page 5-0 supporting function, listed at the end of this example, to compare the Grad-CAM maps.

```
figure
alpha = 0.5;
cmap = "jet";
plotMaps(img,gradcamMap,gradcamMapShallow,"Deep Layer","Shallow Layer",alpha,cmap)
```



The Grad-CAM map for the layer at the end of the network highlights the head and ear of the dog, suggesting that the shape of the ear and the eye are important for classifying this dog as a golden retriever. The Grad-CAM map produced by the earlier layer highlights the edges of the dog. This is because earlier layers in a network learn simple features such as color and edges, while deep layers learn more complex features such as ears or eyes.

Occlusion Sensitivity

Compute the occlusion sensitivity of the image. Occlusion sensitivity is a simple technique for measuring network sensitivity to small perturbations in the input data. This method perturbs small areas of the input by replacing it with an occluding mask, typically a gray square. The mask moves across the image and the change in probability score for a given class is measured. You can use this method to highlight which parts of the image are most important to the classification. You can perform occlusion sensitivity using `occlusionSensitivity`.

Compute the occlusion sensitivity map for the golden retriever class.

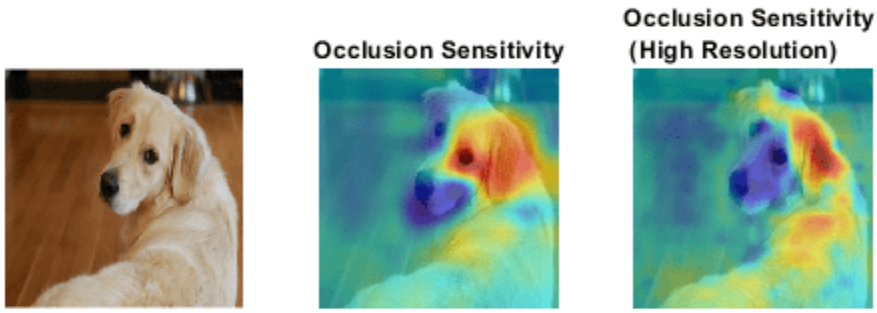
```
occlusionMap = occlusionSensitivity(net,img,YPred);
```

To examine the results of occlusion with higher resolution, reduce the mask size and stride using the `MaskSize` and `Stride` options. A smaller `Stride` value yields a higher resolution map but can take longer to compute and use more memory. A smaller `MaskSize` value yields more detail but can lead to noisier results. To get the best results from occlusion sensitivity, you must carefully choose the right values for the `MaskSize` and `Stride` options.

```
occlusionMapDetail = occlusionSensitivity(net,img,YPred,'Stride',10,'MaskSize',15);
```

Use the `plotMaps` function to compare the different occlusion sensitivity results.

```
plotMaps(img,occlusionMap,occlusionMapDetail, ...
    "Occlusion Sensitivity","Occlusion Sensitivity \newline (High Resolution)",alpha,cmap)
```



The lower resolution map shows similar results to Grad-CAM, highlighting the ear and eye of the dog. The higher resolution map shows that the ear is most important to the classification. The higher resolution map also indicates that the fur on the back of the dog is contributing to the classification decision.

LIME

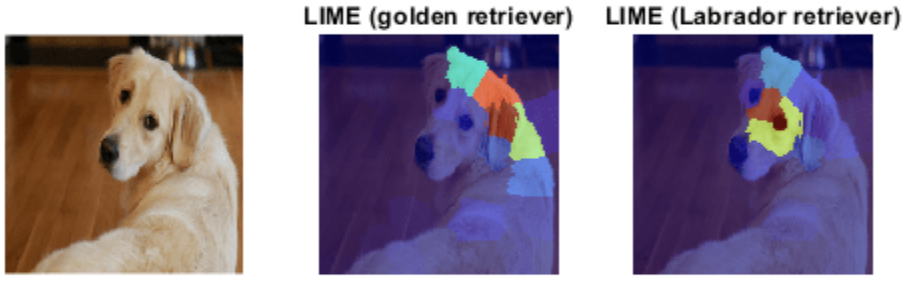
Next, consider the locally interpretable model-agnostic explanations (LIME) technique. LIME approximates the classification behavior of a deep neural network using a simpler, more interpretable model, such as a regression tree. Interpreting the decisions of this simpler model provides insight

into the decisions of the neural network. The simple model is used to determine the importance of features of the input data, as a proxy for the importance of the features to the deep neural network. The LIME technique uses a very different underlying mechanism to occlusion sensitivity or Grad-CAM.

Use the `imageLIME` function to view the most important features in the classification decision of a deep network. Compute the LIME map for the top two classes: golden retriever and Labrador retriever.

```
limeMapClass1 = imageLIME(net,img,topClasses(1));
limeMapClass2 = imageLIME(net,img,topClasses(2));

titleClass1 = "LIME (" + string(topClasses(1)) + ")";
titleClass2 = "LIME (" + string(topClasses(2)) + ")";
plotMaps(img,limeMapClass1,limeMapClass2,titleClass1,titleClass2,alpha,cmap)
```



The maps show which areas of the image are important to the classification. Red areas of the map have a higher importance—an image lacking these areas would have a lower score for the specified class. For the golden retriever class, the network focuses on the dog's head and ear to make its prediction. For the Labrador retriever class, the network is more focused on the dog's nose and eyes, rather than the ear. While both maps highlight the dog's forehead, for the network, the dog's ear and neck indicate the golden retriever class, while the dog's eyes indicate the Labrador retriever class.

The LIME maps are consistent with the occlusion sensitivity and Grad-CAM maps. Comparing the results of different interpretability techniques is important for verifying the conclusions you make.

Gradient Attribution

Gradient attribution methods produce pixel-resolution maps showing which pixels are most important to the network classification decision. These methods compute the gradient of the class score with respect to the input pixels. Intuitively, the map shows which pixels most affect the class score when changed. The gradient attribution methods produce maps with a higher resolution than those from Grad-CAM or occlusion sensitivity, but that tend to be much noisier, as a well-trained deep network is not strongly dependent on the exact value of specific pixels.

Use the `gradientAttribution` on page 5-0 supporting function, listed at the end of this example, to compute the gradient attribution map for the golden retriever class.

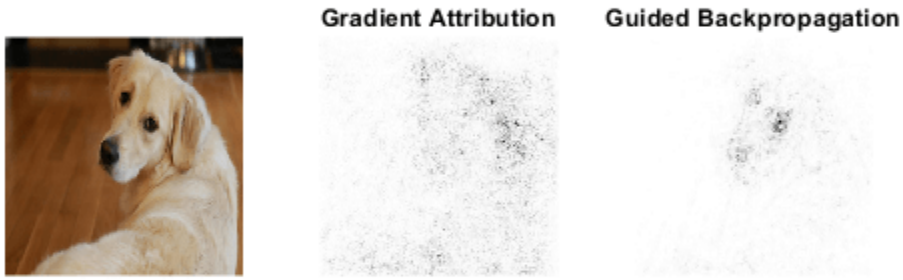
```
softmaxName = 'prob';
pixelMap = gradientAttribution(net,img,YPred,softmaxName,"autodiff");
```

You can obtain a sharper gradient attribution map by modifying the backwards pass through ReLU layers so that elements of the gradient that are less than zero and elements of the input to the ReLU layer that are less than zero are both set to zero. This method is known as guided backpropagation. Compute the gradient attribution map for the network using guided backpropagation.

```
pixelGuidedBackpropMap = gradientAttribution(net,img,YPred,softmaxName,"guided-backprop");
```

Display the gradient attribution maps using a custom colormap with 255 colors that maps values of `0` to white and `1` to black. The darker pixels are those most important for classification.

```
alpha = 1;
cmap = [linspace(1,0,255)' linspace(1,0,255)' linspace(1,0,255)'];
plotMaps(img,pixelMap,pixelGuidedBackpropMap, ...
    "Gradient Attribution","Guided Backpropagation",alpha,cmap)
```



The darkest parts of the map are those centered around the dog. The map is very noisy, but it does suggest that the network is using the expected information in the image to perform classification. The pixels in the dog have much more impact on the classification score than the pixels of the background. In the guided backpropagation map, the pixels are focused on the face of the dog, specifically the eyes and nose. Interestingly, this method highlights different regions than the lower resolution visualization techniques. The result suggests that, at a pixel level, the nose and eyes of the dog are important for classifying the image as a golden retriever.

Deep Dream Image

Deep dream is a feature visualization technique that creates images that strongly activate network layers. By visualizing these images, you can highlight the image features learned by a network. These images are useful for understanding and diagnosing network behavior. You can generate images by visualizing the features of the layers toward the end of the network. Unlike the previous methods, this technique is global and shows you the overall behavior of the network, not just for a specific input image.

To produce images that resemble a given class most closely, use the final fully connected layer `loss3-classifier`. Generate deep dream images for the top three classes the network predicts for the test image. Set `'Verbose'` to `false` to suppress detailed information on the optimization process.

```
channels = topIdx;
learnableLayer =  "loss3-classifier";
dreamImage = deepDreamImage(net,learnableLayer,channels,'Verbose',false);
```

Increasing the number of pyramid levels and iterations per pyramid level can produce more detailed images at the expense of additional computation. Generate detailed deep dream images.

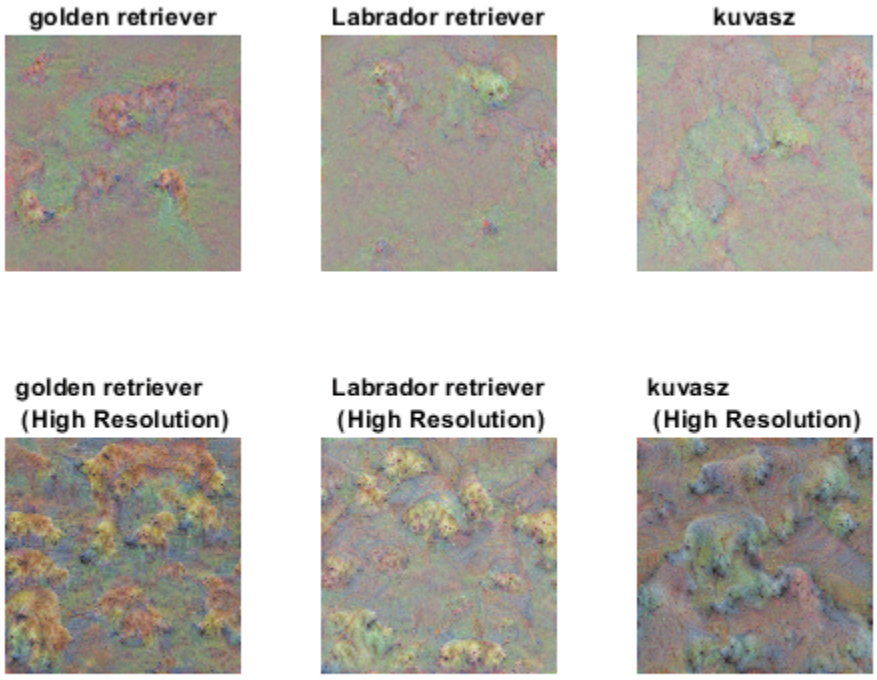
```
dreamImageDetailed = deepDreamImage(net,learnableLayer,channels, ...
    'Verbose',false,'NumIterations',100,'PyramidLevels',4);
```

Compare the deep dream images of the top three classes.

```
tiledlayout(2,3)

for i = 1:3
nexttile
imshow(dreamImage(:,:,:,i));
title(string(topClasses(i)));
end

for i = 1:3
nexttile
imshow(dreamImageDetailed(:,:,:,i));
title(string(topClasses(i)) + "\newline (High Resolution)");
end
```



The deep dream images show how the network envisions each of the three classes. Although these images are quite abstract, you can see key features for each of the top classes. It also shows how the network distinguishes the golden and Labrador retriever classes.

Supporting Functions

Replace Layers Function

The `replaceLayersOfType` function replaces all layers of the specified class with instances of a new layer. The new layers have the same names as the original layers.

```
function lgraph = replaceLayersOfType(lgraph,layerType,newLayer)

% Replace layers in the layerGraph lgraph of the type specified by
% layerType with copies of the layer newLayer.

for i=1:length(lgraph.Layers)
    if isa(lgraph.Layers(i),layerType)
        % Match names between the old and new layers.
        layerName = lgraph.Layers(i).Name;
        newLayer.Name = layerName;

        lgraph = replaceLayer(lgraph,layerName,newLayer);
    end
end
end
```

Plot Maps

Plot two maps, `map1` and `map2`, for the input image `img`. Use `alpha` to set the transparency of the map. Specify which colormap to use using `cmap`.

```
function plotMaps(img,map1,map2,title1,title2,alpha,cmap)

figure
subplot(1,3,1)
imshow(img)

subplot(1,3,2)
imshow(img)
hold on
imagesc(map1,'AlphaData',alpha)
colormap(cmap)
title(title1)
hold off

subplot(1,3,3)
imshow(img)
hold on
imagesc(map2,'AlphaData',alpha)
colormap(cmap)
title(title2)
hold off
end
```

Gradient Attribution Map

Compute the gradient attribution map. You must specify the softmax layer. You can compute the basic map, or a higher resolution map using guided backpropagation.

```
function map = gradientAttribution(net,img,YPred,softmaxName,method)
```

```
lgraph = layerGraph(net);
lgraph = removeLayers(lgraph,lgraph.Layers(end).Name);
dlnet = dlnetwork(lgraph);

% To use automatic differentiation, convert the image to a dlarray.
dlImg = dlarray(single(img),"SSC");

if method == "autodiff"
% Use dlfeval and the gradientMap function to compute the derivative. The gradientMap
% function passes the image forward through the network to obtain the class scores
% and contains a call to dlgradient to evaluate the gradients of the scores with respect
% to the image.
dydI = dlfeval(@gradientMap,dlnet,dlImg,softmaxName,YPred);
end

if method == "guided-backprop"

% Use the custom layer CustomBackpropReluLayer (attached as a supporting file)
% with a nonstandard backward pass, and use it with automatic differentiation.
customRelu = CustomBackpropReluLayer();

% Set the BackpropMode property of each CustomBackpropReluLayer to "guided-backprop".
customRelu.BackpropMode = "guided-backprop";

% Use the supporting function replaceLayersofType to replace all instances of reluLayer in the ne
% instances of CustomBackpropReluLayer.
lgraphGB = replaceLayersOfType(lgraph, ...
    'nnet.cnn.layer.ReLULayer',customRelu);

% Convert the layer graph containing the CustomBackpropReluLayers into a dlnetwork.
dlnetGB = dlnetwork(lgraphGB);
dydI = dlfeval(@gradientMap,dlnetGB,dlImg,softmaxName,YPred);
end

% Sum the absolute values of each pixel along the channel dimension, then rescale
% between 0 and 1.
map = sum(abs(extractdata(dydI)),3);
map = rescale(map);
end
```

Gradient Map

Compute the gradient of a class score with respect to one or more input images.

```
function dydI = gradientMap(dlnet,dlImgs,softmaxName,classIdx)

dydI = dlarray(zeros(size(dlImgs)));

for i=1:size(dlImgs,4)
    I = dlImgs(:,:,:,i);
    scores = predict(dlnet,I,'Outputs',{softmaxName});
    classScore = scores(classIdx);
    dydI(:,:,:,i) = dlgradient(classScore,I);
```

```
end
end
```

Deep Dream Images Using GoogLeNet

This example shows how to generate images using `deepDreamImage` with the pretrained convolutional neural network GoogLeNet.

Deep Dream is a feature visualization technique in deep learning that synthesizes images that strongly activate network layers. By visualizing these images, you can highlight the image features learned by a network. These images are useful for understanding and diagnosing network behavior.

You can generate interesting images by visualizing the features of the layers towards the end of the network.

The example uses Deep Learning Toolbox™ and Deep Learning Toolbox Model *for GoogLeNet Network* to generate the images.

Load Pretrained Network

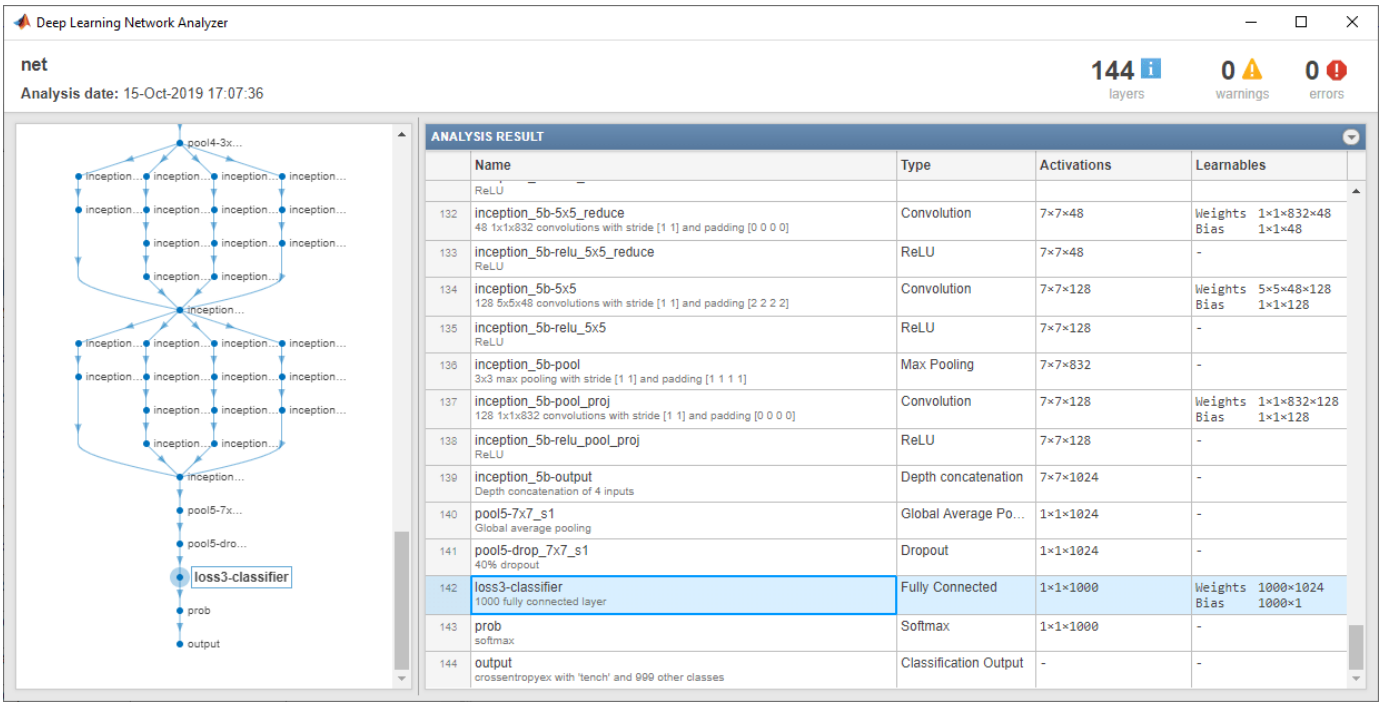
Load a pretrained GoogLeNet Network. If the Deep Learning Toolbox Model *for GoogLeNet Network* support package is not installed, then the software provides a download link.

```
net = googlenet;
```

Generate Image

To produce images that resemble a given class the most closely, select the fully connected layer. First, locate the layer index of this layer by viewing the network architecture using `analyzeNetwork`.

```
analyzeNetwork(net)
```



Then select the fully connected layer, in this example, 142.

```
layer = 142;
layerName = net.Layers(layer).Name
```

```
layerName =
'loss3-classifier'
```

You can generate multiple images at once by selecting multiple classes. Select the classes you want to visualize by setting `channels` to be the indices of those class names.

```
channels = [114 293 341 484 563 950];
```

The classes are stored in the `Classes` property of the output layer (the last layer). You can view the names of the selected classes by selecting the entries in `channels`.

```
net.Layers(end).Classes(channels)
```

```
ans = 6×1 categorical
     snail
     tiger
     zebra
     castle
     fountain
     strawberry
```

Generate the images using `deepDreamImage`. This command uses a compatible GPU, if available. Otherwise it uses the CPU. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
I = deepDreamImage(net,layerName,channels);
```

```

```

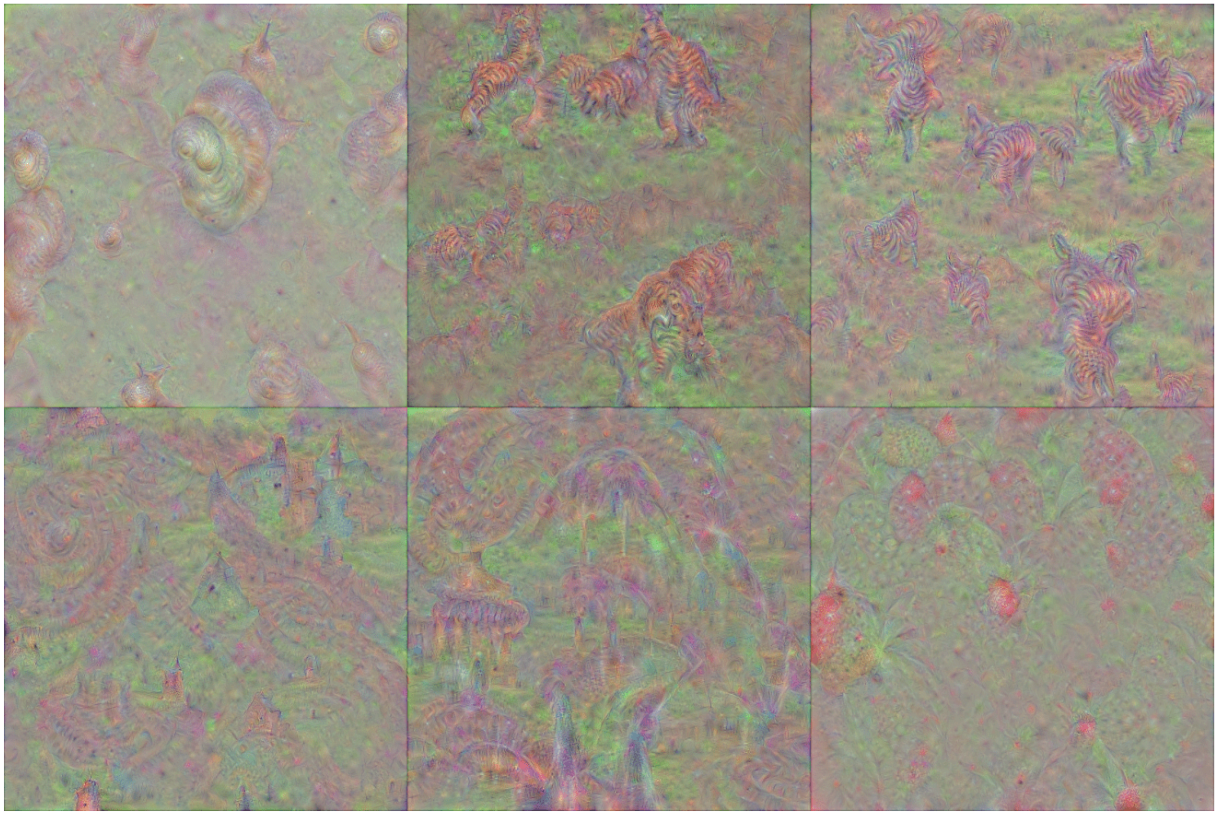
Display all the images together using `imtile`.

```
figure
I = imtile(I);
imshow(I)
```



Generate More Detailed Images

Increasing the number of pyramid levels and iterations per pyramid level can produce more detailed images at the expense of additional computation.

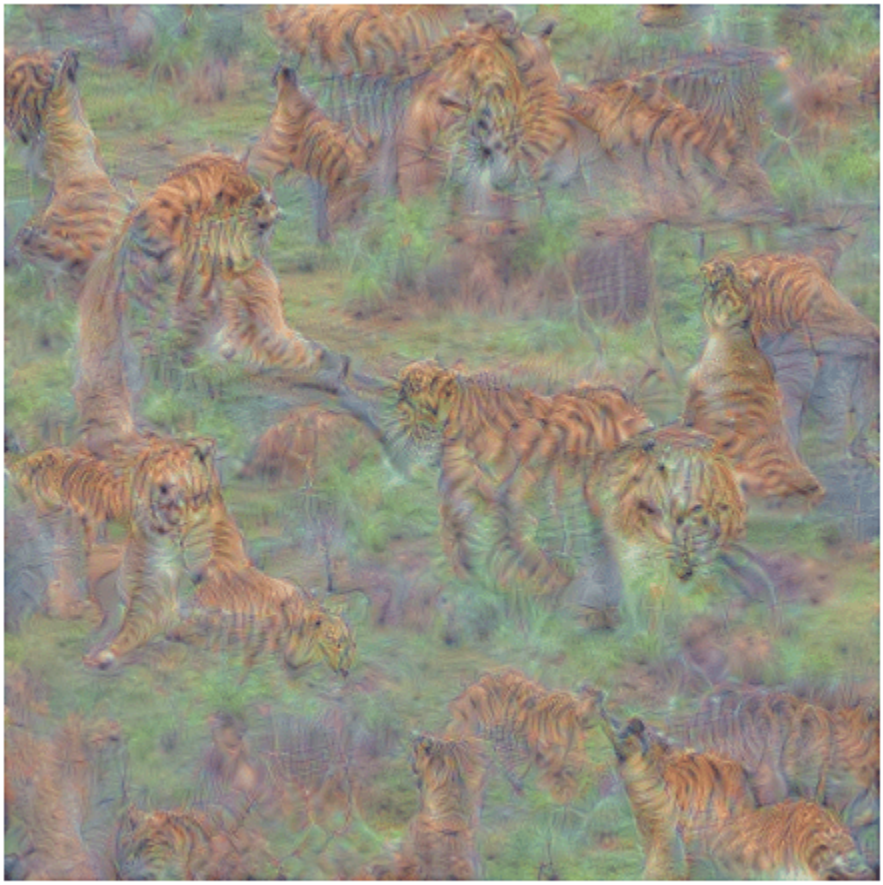
You can increase the number of iterations using the `'NumIterations'` option. Set the number of iterations to 100.

```
iterations = 100;
```

Generate a detailed image that strongly activates the 'tiger' class (channel 293). Set `'Verbose'` to false to suppress detailed information on the optimization process.

```
channels = 293;
I = deepDreamImage(net,layerName,channels, ...
    'Verbose',false, ...
    'NumIterations',iterations);

figure
imshow(I)
```



To produce larger and more detailed output images, you can increase both the number of pyramid levels and iterations per pyramid level.

Set the number of pyramid levels to 4.

```
levels = 4;
```

Generate a detailed image that strongly activates the 'castle' class (channel 484).

```
channels = 484;

I = deepDreamImage(net,layerName,channels, ...
    'Verbose',false, ...
    'NumIterations',iterations, ...
    'PyramidLevels',levels);

figure
imshow(I)
```

Grad-CAM Reveals the Why Behind Deep Learning Decisions

This example shows how to use the gradient-weighted class activation mapping (Grad-CAM) technique to understand why a deep learning network makes its classification decisions. Grad-CAM, invented by Selvaraju and coauthors [1] on page 5-0 , uses the gradient of the classification score with respect to the convolutional features determined by the network in order to understand which parts of the image are most important for classification. This example uses the GoogLeNet pretrained network for images.

Grad-CAM is a generalization of the class activation mapping (CAM) technique. For activation mapping techniques on live webcam data, see "Investigate Network Predictions Using Class Activation Mapping" on page 5-123. Grad-CAM can also be applied to nonclassification examples such as regression or semantic segmentation. For an example showing how to use Grad-CAM to investigate the predictions of a semantic segmentation network, see "Explore Semantic Segmentation Network Using Grad-CAM" on page 5-66.

Load Pretrained Network

Load the GoogLeNet network.

```
net = googlenet;
```

Classify Image

Read the GoogLeNet image size.

```
inputSize = net.Layers(1).InputSize(1:2);
```

Load `sherlock.jpg`., an image of a golden retriever included with this example.

```
img = imread("sherlock.jpg");
```

Resize the image to the network input dimensions.

```
img = imresize(img,inputSize);
```

Classify the image and display it, along with its classification and classification score.

```
[classfn,score] = classify(net,img);
imshow(img);
title(sprintf("%s (%.2f)", classfn, score(classfn)));
```

GoogLeNet correctly classifies the image as a golden retriever. But why? What characteristics of the image cause the network to make this classification?

Grad-CAM Explains Why

The Grad-CAM technique utilizes the gradients of the classification score with respect to the final convolutional feature map, to identify the parts of an input image that most impact the classification score. The places where this gradient is large are exactly the places where the final score depends most on the data.

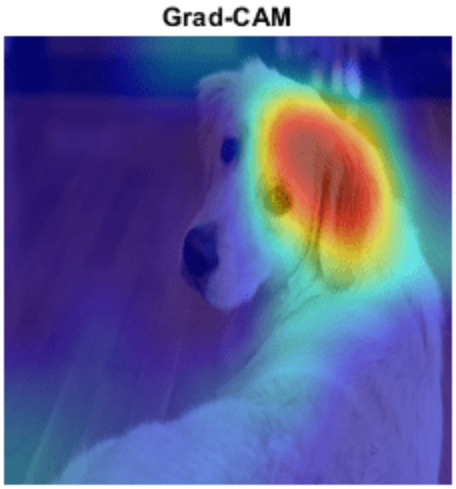
The `gradCAM` function computes the importance map by taking the derivative of the reduction layer output for a given class with respect to a convolutional feature map. For classification tasks, the `gradCAM` function automatically selects suitable layers to compute the importance map for. You can also specify the layers with the `'ReductionLayer'` and `'FeatureLayer'` name-value arguments.

Compute the Grad-CAM map.

```
map = gradCAM(net,img,classfn);
```

Show the Grad-CAM map on top of the image by using an `'AlphaData'` value of 0.5. The `'jet'` colormap has deep blue as the lowest value and deep red as the highest.

```
imshow(img);
hold on;
imagesc(map,'AlphaData',0.5);
colormap jet
hold off;
title("Grad-CAM");
```



Clearly, the upper face and ear of the dog have the greatest impact on the classification.

For a different approach to investigating the reasons for deep network classifications, see `occlusionSensitivity` and `imageLIME`.

Understand Network Predictions Using Occlusion

This example shows how to use occlusion sensitivity maps to understand why a deep neural network makes a classification decision. Occlusion sensitivity is a simple technique for understanding which parts of an image are most important for a deep network's classification. You can measure a network's sensitivity to occlusion in different regions of the data using small perturbations of the data. Use occlusion sensitivity to gain a high-level understanding of what image features a network uses to make a particular classification, and to provide insight into the reasons why a network can misclassify an image.

Deep Learning Toolbox provides the `occlusionSensitivity` function to compute occlusion sensitivity maps for deep neural networks that accept image inputs. The `occlusionSensitivity` function perturbs small areas of the input by replacing it with an occluding mask, typically a gray square. The mask moves across the image, and the change in probability score for a given class is measured as a function of mask position. You can use this method to highlight which parts of the image are most important to the classification: when that part of the image is occluded, the probability score for the predicted class will fall sharply.

Load Pretrained Network and Image

Load the pretrained network GoogLeNet, which will be used for image classification.

```
net = googlenet;
```

Extract the image input size and the output classes of the network.

```
inputSize = net.Layers(1).InputSize(1:2);
classes = net.Layers(end).Classes;
```

Load the image. The image is of a dog named Laika. Resize the image to the network input size.

```
imgLaikaGrass = imread("laika_grass.jpg");
imgLaikaGrass = imresize(imgLaikaGrass,inputSize);
```

Classify the image, and display the three classes with the highest classification score in the image title.

```
[YPred,scores] = classify(net,imgLaikaGrass);
[~,topIdx] = maxk(scores, 3);
topScores = scores(topIdx);
topClasses = classes(topIdx);

imshow(imgLaikaGrass)
titleString = compose("%s (%.2f)",topClasses,topScores');
title(sprintf(join(titleString, "; ")));
```

Laika is a poodle-cocker spaniel cross. This breed is not a class in GoogLeNet, so the network has some difficulty classifying the image. The network is not very confident in its predictions — the predicted class `miniature poodle` only has a score of 23%. The class with the next highest score is also a type of poodle, which is a reasonable classification. The network also assigns a moderate probability to the `Tibetan terrier` class. We can use occlusion to understand which parts of the image cause the network to suggest these three classes.

Identify Areas of an Image the Network Uses for Classification

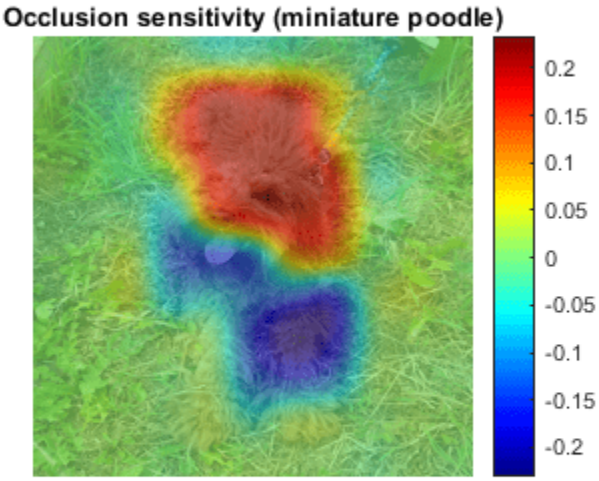
You can use occlusion to find out which parts of the image are important for the classification. First, look at the predicted class of `miniature poodle`. What parts of the image suggest this class? Use the occlusion sensitivity function to map the change in the classification score when parts of the image are occluded.

```
map = occlusionSensitivity(net,imgLaikaGrass,YPred);
```

Display the image of Laika with the occlusion sensitivity map overlaid.

```
imshow(imgLaikaGrass,'InitialMagnification', 150)
hold on
imagesc(map,'AlphaData',0.5)
colormap jet
colorbar

title(sprintf("Occlusion sensitivity (%s)", ...
    YPred))
```



The occlusion map shows which parts of the image have a positive contribution to the score for the `miniature poodle` class, and which parts have a negative contribution. Red areas of the map have a higher value and are evidence for the `miniature poodle` class — when the red areas are obscured, the score for `miniature poodle` goes down. In this image, Laika's head, back, and ears provide the strongest evidence for the `miniature poodle` class.

Blue areas of the map with lower values are parts of the image that lead to an increase in the score for `miniature poodle` when occluded. Often, these areas are evidence of another class, and can confuse the network. In this case, Laika's mouth and legs have a negative contribution to the overall score for `miniature poodle`.

The occlusion map is strongly focused on the dog in the image, which shows that GoogLeNet is classifying the correct object in the image. If your network is not producing the results you expect, an occlusion map can help you understand why. For example, if the network is strongly focused on other parts of the image, this suggests that the network learned the wrong features.

You can get similar results using the gradient class activation mapping (Grad-CAM) technique. Grad-CAM uses the gradient of the classification score with respect to the last convolutional layer in a network in order to understand which parts of the image are most important for classification. For an example, see “Grad-CAM Reveals the Why Behind Deep Learning Decisions” on page 5-21.

Occlusion sensitivity and Grad-CAM usually return qualitatively similar results, although they work in different ways. Typically, you can compute the Grad-CAM map faster that the occlusion map, without tuning any parameters. However, the Grad-CAM map can usually has a lower spatial resolution than an occlusion map and can miss fine details. The underlying resolution of Grad-CAM is the spatial

resolution of the last convolutional feature map; in the case of GoogleNet this is 7-by-7 pixels. To get the best results from occlusion sensitivity, you must choose the right values for the `MaskSize` and `Stride` options. This tuning provides more flexibility to examine the input features at different length scales.

Compare Evidence for Different Classes

You can use occlusion to compare which parts of the image the network identifies as evidence for different classes. This can be useful in cases where the network is not confident in the classification and gives similar scores to several classes.

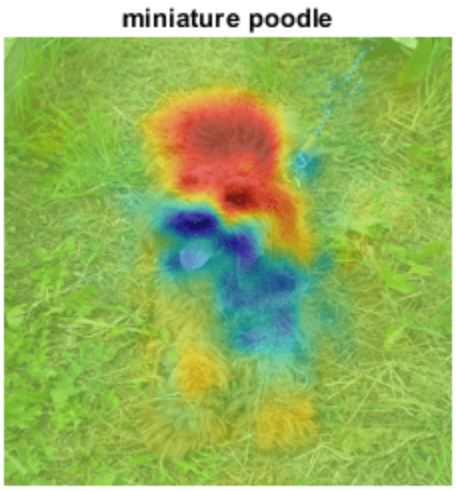
Compute an occlusion map for each of the top three classes. To examine the results of occlusion with higher resolution, reduce the mask size and stride using the `MaskSize` and `Stride` options. A smaller `Stride` leads to a higher-resolution map, but can take longer to compute and use more memory. A smaller `MaskSize` illustrates smaller details, but can lead to noisier results.

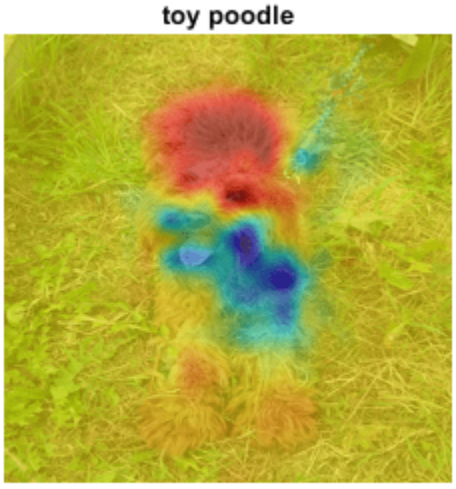
```
topClasses = classes(topIdx);
topClassesMap = occlusionSensitivity(net, imgLaikaGrass, topClasses, ...
    "Stride", 10, ...
    "MaskSize", 15);
```

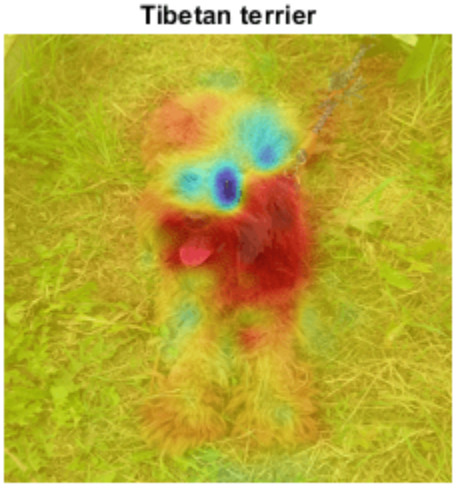
Plot the results for each of the top three classes.

```
for i=1:length(topIdx)
    figure
    imshow(imgLaikaGrass);
    hold on
    imagesc(topClassesMap(:,:,i), 'AlphaData', 0.5);
    colormap jet;

    classLabel = string(classes(topIdx(i)));
    title(sprintf("%s", classLabel));
end
```







Different parts of the image have a very different impact on the class scores for different dog breeds. The dog's back has a strong influence in favor of the `miniature poodle` and `toy poodle` classes, while the mouth and ears contribute to the `Tibetan terrier` class.

Investigate Misclassification Issues

If your network is consistently misclassifying certain types of input data, you can use occlusion sensitivity to determine if particular features of your input data are confusing the network. From the occlusion map of Laika sitting on the grass, you could expect that images of Laika which are more focused on her face are likely to be misclassified as `Tibetan terrier`. You can verify that this is the case using another image of Laika.

```
imgLaikaSit = imresize(imread("laika_sitting.jpg"),inputSize);

[YPred,scores] = classify(net,imgLaikaSit);
[score,idx] = max(scores);
YPred, score
```

```
YPred = categorical
     Tibetan terrier

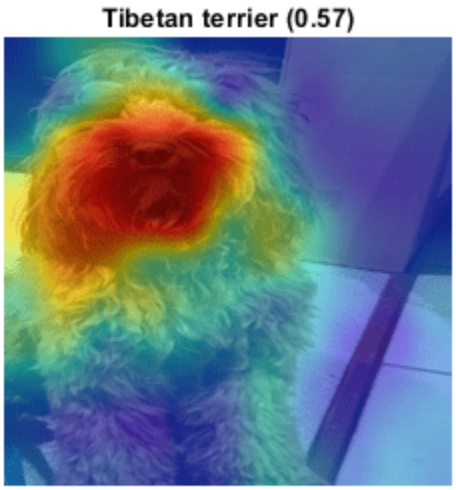
score = single
    0.5668
```

Compute the occlusion map of the new image.

```
map = occlusionSensitivity(net,imgLaikaSit,YPred);

imshow(imgLaikaSit);
hold on;
imagesc(map, 'AlphaData', 0.5);
colormap jet;

title(sprintf("%s (%.2f)",...
    string(classes(idx)),score));
```



Again, the network strongly associates the dog's nose and mouth with the `Tibetan terrier` class. This highlights a possible failure mode of the network, since it suggests that images of Laika's face will consistently be misclassified as `Tibetan terrier`.

You can use the insights gained from the `occlusionSensitivity` function to make sure your network is focusing on the correct features of the input data. The cause of the classification problem in this example is that the available classes of GoogleNet do not include cross-breed dogs like Laika. The occlusion map demonstrates why the network is confused by these images of Laika. It is important to be sure that the network you are using is suitable for the task at hand.

In this example, the network is mistakenly identifying different parts of the object in the image as different classes. One solution to this issue is to retrain the network with more labeled data that covers a wider range of observations of the misclassified class. For example, the network here could be retrained using a large number of images of Laika taken at different angles, so that it learns to associate both the back and the front of the dog with the correct class.

Investigate Classification Decisions Using Gradient Attribution Techniques

This example shows how to use gradient attribution maps to investigate which parts of an image are most important for classification decisions made by a deep neural network.

Deep neural networks can look like black box decision makers — they give excellent results on complex problems, but it can be hard to understand why a network gives a particular output. Explainability is increasingly important as deep networks are used in more applications. To consider a network explainable, it must be clear what parts of the input data the network is using to make a decision and how much this data contributes to the network output.

A range of visualization techniques are available to determine if a network is using sensible parts of the input data to make a classification decision. As well as the gradient attribution methods shown in this example, you can use techniques such as gradient-weighted class-activation mapping (Grad-CAM) and occlusion sensitivity. For examples, see

- “Understand Network Predictions Using Occlusion” on page 5-24
- “Grad-CAM Reveals the Why Behind Deep Learning Decisions” on page 5-21

The gradient attribution methods explored in this example provide pixel-resolution maps that show which pixels are most important to the network's classification. They compute the gradient of the class score with respect to the input pixels. Intuitively, the map shows which pixels most affect the class score when changed. The gradient attribution methods produce maps with higher resolution than those from Grad-CAM or occlusion sensitivity, but that tend to be much noisier, as a well-trained deep network is not strongly dependent on the exact value of specific pixels. Use the gradient attribution techniques to find the broad areas of an image that are important to the classification.

The simplest gradient attribution map is the gradient of the class score for the predicted class with respect to each pixel in the input image [1]. This shows which pixels have the largest impact on the class score, and therefore which pixels are most important to the classification. This example shows how to use gradient attribution and two extended methods: guided backpropagation [2] and integrated gradients [3]. The use of these techniques is under debate as it is not clear how much insight these extensions can provide into the model [4].

Load Pretrained Network and Image

Load the pretrained GoogLeNet network.

```
net = googlenet;
```

Extract the image input size and the output classes of the network.

```
inputSize = net.Layers(1).InputSize(1:2);
classes = net.Layers(end).Classes;
```

Load the image. The image is of a dog named Laika. Resize the image to the network input size.

```
img = imread("laika_grass.jpg");
img = imresize(img,inputSize);
```

Classify the image and display the predicted class and classification score.

```
[YPred, scores] = classify(net, img);
[score, classIdx] = max(scores);
```

```
predClass = classes(classIdx);

imshow(img);
title(sprintf("%s (%.2f)",string(predClass),score));
```

The network classifies Laika as a miniature poodle, which is a reasonable guess. She is a poodle/cocker spaniel cross.

Compute Gradient Attribution Map Using Automatic Differentiation

The gradient attribution techniques rely on finding the gradient of the prediction score with respect to the input image. The gradient attribution map is calculated using the following formula:

$$W_{\mathrm{xy}}^{c} = \frac{\partial S^{c}}{\partial I_{\mathrm{xy}}}$$

where W_{xy}^{c} represents the importance of the pixel at location (x, y) to the prediction of class c, S^{c} is the softmax score for that class, and I_{xy} is the image at pixel location (x, y) [1].

Convert the network to a `dlnetwork` so that you can use automatic differentiation to compute the gradients.

```
lgraph = layerGraph(net);
lgraph = removeLayers(lgraph,lgraph.Layers(end).Name);

dlnet = dlnetwork(lgraph);
```

Specify the name of the softmax layer, `'prob'`.

```
softmaxName = 'prob';
```

To use automatic differentiation, convert the image of Laika to a `dlarray`.

```
dlImg = dlarray(single(img),'SSC');
```

Use `dlfeval` and the `gradientMap` function (defined in the Supporting Functions on page 5-0 section of this example) to compute the derivative $\frac{\partial S^C}{\partial I_{xy}}$. The `gradientMap` function passes the image forward through the network to obtain the class scores and contains a call to `dlgradient` to evaluate the gradients of the scores with respect to the image.

```
dydI = dlfeval(@gradientMap,dlnet,dlImg,softmaxName,classIdx);
```

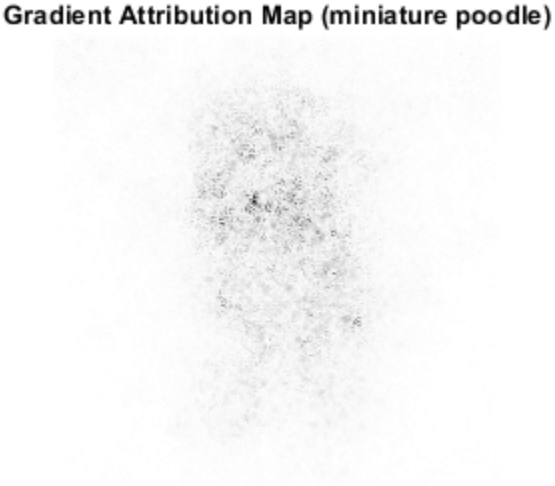
The attribution map `dydI` is a 227-by-227-by-3 array. Each element in each channel corresponds to the gradient of the class score with respect to the input image for that channel of the original RGB image.

There are a number of ways to visualize this map. Directly plotting the gradient attribution map as an RGB image can be unclear as the map is typically quite noisy. Instead, sum the absolute values of each pixel along the channel dimension, then rescale between `0` and `1`. Display the gradient attribution map using a custom colormap with 255 colors that maps values of `0` to white and `1` to black.

```
map = sum(abs(extractdata(dydI)),3);
map = rescale(map);

cmap = [linspace(1,0,255)' linspace(1,0,255)' linspace(1,0,255)'];

imshow(map, "Colormap", cmap);
title("Gradient Attribution Map (" + string(predClass) + ")");
```



The darkest parts of the map are those centered around the dog. The map is extremely noisy, but it does suggest that the network is using the expected information in the image to perform classification. The pixels in the dog have much more impact on the classification score than the pixels of the grassy background.

Sharpen the Gradient Attribution Map Using Guided Backpropagation

You can obtain a sharper gradient attribution map by modifying the network's backwards pass through ReLU layers so that elements of the gradient that are less than zero and elements of the input to the ReLU layer that are less than zero are both set to zero. This is known as guided backpropagation [2].

The guided backpropagation backward function is:

$$\frac{dL}{dZ} = (X > 0) * \left(\frac{dL}{dZ} > 0\right) * \frac{dL}{dZ}$$

where L is the loss, X is the input to the ReLU layer, and Z is the output.

You can write a custom layer with a non-standard backward pass, and use it with automatic differentiation. A custom layer class `CustomBackpropReluLayer` that implements this modification is included as a supporting file in this example. When automatic differentiation backpropagates through `CustomBackpropReluLayer` objects, it uses the modified guided backpropagation function defined in the custom layer.

Use the supporting function `replaceLayersofType` (defined in the Supporting Functions on page 5-0 section of this example) to replace all instances of `reluLayer` in the network with instances of `CustomBackpropReluLayer`. Set the `BackpropMode` property of each `CustomBackpropReluLayer` to `"guided-backprop"`.

```
customRelu = CustomBackpropReluLayer();
customRelu.BackpropMode = "guided-backprop";

lgraphGB = replaceLayersOfType(lgraph, ...
    "nnet.cnn.layer.ReLULayer",customRelu);
```

Convert the layer graph containing the `CustomBackpropReluLayers` into a `dlnetwork`.

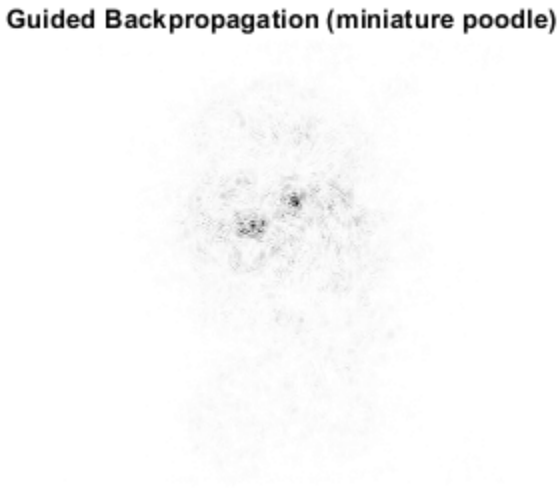
```
dlnetGB = dlnetwork(lgraphGB);
```

Compute and plot the gradient attribution map for the network using guided backpropagation.

```
dydIGB = dlfeval(@gradientMap,dlnetGB,dlImg,softmaxName,classIdx);

mapGB = sum(abs(extractdata(dydIGB)),3);
mapGB = rescale(mapGB);

imshow(mapGB, "Colormap", cmap);
title("Guided Backpropagation (" + string(predClass) + ")");
```



You can see that guided backpropagation technique more clearly highlights different parts of the dog, such as the eyes and nose.

You can also use the Zeiler-Fergus technique for backpropagation through ReLU layers [5]. For the Zeiler-Fergus technique, the backward function is given as:

$$\frac{dL}{dZ} = \left(\frac{dL}{dZ} > 0\right) * \frac{dL}{dZ}$$

Set the `BackpropMode` property of the `CustomBackpropReluLayer` instances to `"zeiler-fergus"`.

```
customReluZF = CustomBackpropReluLayer();
customReluZF.BackpropMode = "zeiler-fergus";

lgraphZF = replaceLayersOfType(lgraph, ...
    "nnet.cnn.layer.ReLULayer",customReluZF);

dlnetZF = dlnetwork(lgraphZF);

dydIZF = dlfeval(@gradientMap,dlnetZF,dlImg,softmaxName,classIdx);

mapZF = sum(abs(extractdata(dydIZF)),3);
mapZF = rescale(mapZF);

imshow(mapZF,"Colormap", cmap);
title("Zeiler-Fergus (" + string(predClass) + ")");
```

The gradient attribution maps computed using the Zeiler-Fergus backpropagation technique are much less clear than those computed using guided backpropagation.

Evaluate Sensitivity to Image Changes Using Integrated Gradients

The integrated gradients approach computes integrates the gradients of class score with respect to image pixels across a set of images that are linearly interpolated between a baseline image and the original image of interest [3]. The integrated gradients technique is designed to be sensitive to the changes in the pixel value over the integration, such that if a change in a pixel value affects the class score, that pixel has a non-zero value in the map. Non-linearities in the network, such as ReLU layers, can prevent this sensitivity in simpler gradient attribution techniques.

The integrated gradients attribution map is calculated as

$$W_{\mathrm{xy}}^{c} = \left(I_{\mathrm{xy}} - I_{\mathrm{xy}}^{0}\right)\int_{\alpha=0}^{1} d\alpha \frac{\partial S^{c}\left(I_{\mathrm{xy}}(\alpha)\right)}{\partial I_{\mathrm{xy}}(\alpha)},$$

where W_{xy}^{c} is the map's value for class c at pixel location (x, y), I_{xy}^{0} is a baseline image, and $I_{\mathrm{xy}}(\alpha)$ is the image at a distance α along the path between the baseline image and the input image:

$$I_{\mathrm{xy}}(\alpha) = I_{\mathrm{xy}}^{0} + \alpha\left(I_{\mathrm{xy}} - I_{\mathrm{xy}}^{0}\right).$$

In this example, the integrated gradients formula is simplified by summing over a discrete index,n, instead of integrating over α :

$$W_{\mathrm{xy}}^{c} = \left(I_{\mathrm{xy}} - I_{\mathrm{xy}}^{0}\right)\sum_{n=0}^{N} \frac{\partial S^{c}\left(I_{\mathrm{xy}}^{n}\right)}{\partial I_{\mathrm{xy}}^{n}},$$

with

$$I_{\mathrm{xy}}^{n} = I_{\mathrm{xy}}^{0} + \frac{n}{N}\left(I_{\mathrm{xy}} - I_{\mathrm{xy}}^{0}\right).$$

For image data, choose the baseline image to be a black image of zeros. Find the image that is the difference between the original image and the baseline image. In this case, `differenceImg` is the same as the original image as the baseline image is zero.

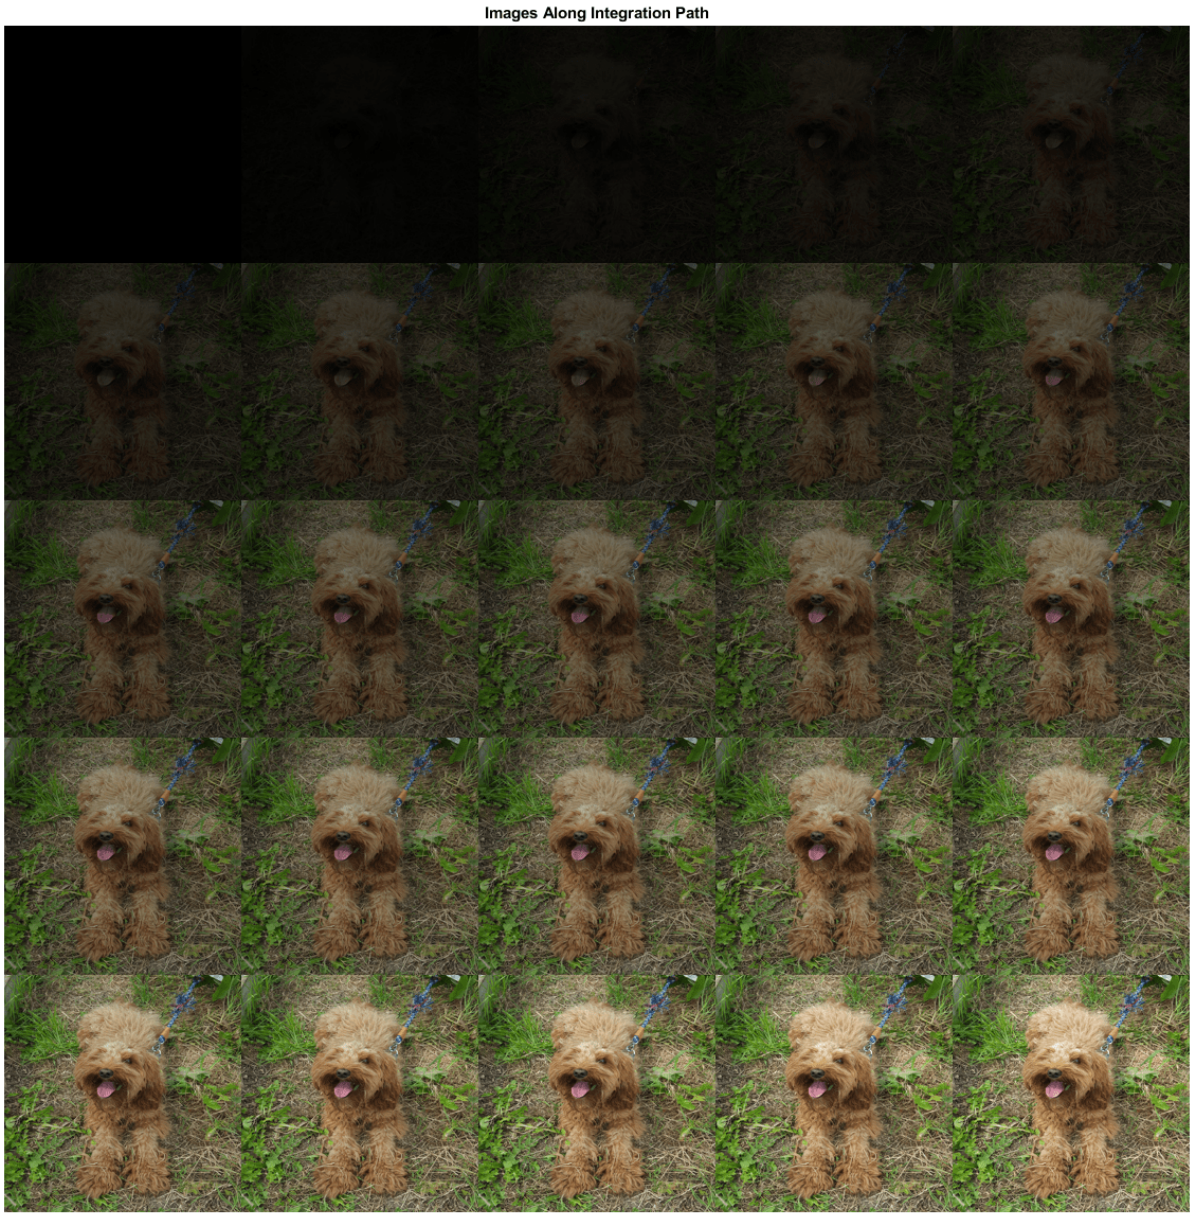
```
baselineImg = zeros([inputSize, 3]);
differenceImg = single(img) - baselineImg;
```

Create an array of images corresponding to discrete steps along the linear path from the baseline image to the original input image. A larger number of images will give smoother results but take longer to compute.

```
numPathImages = 25 ;
```

```
pathImgs = zeros([inputSize 3 numPathImages-1]);
for n=0:numPathImages-1
    pathImgs(:,:,:,n+1) = baselineImg + (n)/(numPathImages-1) * differenceImg;
end

figure;
imshow(imtile(rescale(pathImgs)));
title("Images Along Integration Path");
```



Convert the mini-batch of path images to a `dlarray`. Format the data with the format `'SSCB'` for the two spatial, one channel and one batch dimensions. Each path image is a single observation in the mini-batch. Compute the gradient map for the resulting batch of images along the path.

```
dlPathImgs = dlarray(pathImgs, 'SSCB');
dydIIG = dlfeval(@gradientMap, dlnet, dlPathImgs, softmaxName, classIdx);
```

For each channel, sum the gradients of all observations in the mini-batch.

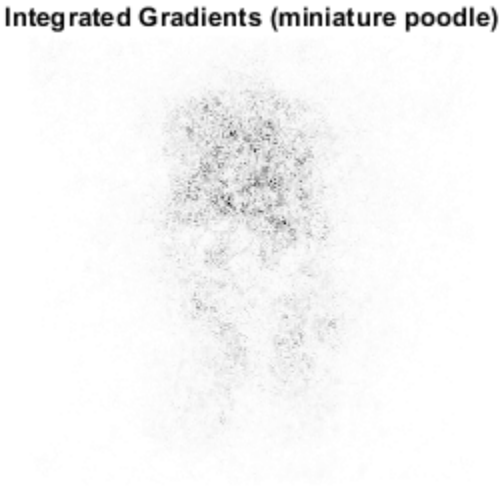
```
dydIIGSum = sum(dydIIG,4);
```

Multiply each element of the summed gradient attribution maps with the corresponding element of `differenceImg`. To compute the integrated gradient attribution map, sum over each channel and rescale.

```
dydIIGSum = differenceImg .* dydIIGSum;

mapIG = sum(extractdata(abs(dydIIGSum)),3);
mapIG = rescale(mapIG);

imshow(mapIG, "Colormap", cmap);
title("Integrated Gradients (" + string(predClass) + ")");
```



The computed map shows the network is more strongly focused on the dog's face as a means of deciding on its class.

The gradient attribution techniques demonstrated here can be used to check whether your network is focusing on the expected parts of the image when making a classification. To get good insights into the way your model is working and explain classification decisions, you can perform these techniques on a range of images and find the specific features that strongly contribute to a particular class. The unmodified gradient attributions technique is likely to be the more reliable method for explaining network decisions. While the guided backpropagation and integrated gradient techniques can produce the clearest gradient maps, it is not clear how much insight these techniques can provide into how the model works [4].

Supporting Functions

Gradient Map Function

The function `gradientMap` computes the gradients of the score with respect to an image, for a specified class. The function accepts a single image or a mini-batch of images. Within this example, the function `gradientMap` is introduced in the section Compute Gradient Attribution Map Using Automatic Differentiation on page 5-0 .

```
function dydI = gradientMap(dlnet, dlImgs, softmaxName, classIdx)
% Compute the gradient of a class score with respect to one or more input
% images.

dydI = dlarray(zeros(size(dlImgs)));

for i=1:size(dlImgs,4)
    I = dlImgs(:,:,:,i);
    scores = predict(dlnet,I,'Outputs',{softmaxName});
    classScore = scores(classIdx);
    dydI(:,:,:,i) = dlgradient(classScore,I);
end
end
```

Replace Layers Function

The `replaceLayersOfType` function replaces all layers of the specified class with instances of a new layer. The new layers are named with the same names as the original layers. Within this example, the function `replaceLayersOfType` is introduced in the section Sharpen the Gradient Attribution Map using Guided Backpropagation on page 5-0 .

```
function lgraph = replaceLayersOfType(lgraph, layerType, newLayer)
% Replace layers in the layerGraph lgraph of the type specified by
% layerType with copies of the layer newLayer.

for i=1:length(lgraph.Layers)
    if isa(lgraph.Layers(i), layerType)
        % Match names between old and new layer.
        layerName = lgraph.Layers(i).Name;
        newLayer.Name = layerName;

        lgraph = replaceLayer(lgraph, layerName, newLayer);
    end
end
end
```

Understand Network Predictions Using LIME

This example shows how to use locally interpretable model-agnostic explanations (LIME) to understand why a deep neural network makes a classification decision.

Deep neural networks are very complex and their decisions can be hard to interpret. The LIME technique approximates the classification behavior of a deep neural network using a simpler, more interpretable model, such as a regression tree. Interpreting the decisions of this simpler model provides insight into the decisions of the neural network [1]. The simple model is used to determine the importance of features of the input data, as a proxy for the importance of the features to the deep neural network.

When a particular feature is very important to a deep network's classification decision, removing that feature significantly affects the classification score. That feature is therefore important to the simple model too.

Deep Learning Toolbox provides the `imageLIME` function to compute maps of the feature importance determined by the LIME technique. The LIME algorithm for images works by:

- Segmenting an image into features.
- Generating many synthetic images by randomly including or excluding features. Excluded features have every pixel replaced with the value of the image average, so they no longer contain information useful for the network.
- Classifying the synthetic images with the deep network.
- Fitting a simpler regression model using the presence or absence of image features for each synthetic image as binary regression predictors for the scores of the target class.The model approximates the behavior of the complex deep neural network in the region of the observation.
- Computing the importance of features using the simple model, and converting this feature importance into a map that indicates the parts of the image that are most important to the model.

You can compare results from the LIME technique to other explainability techniques, such as occlusion sensitivity or Grad-CAM. For examples of how to use these related techniques, see the following examples.

- “Understand Network Predictions Using Occlusion” on page 5-24
- “Grad-CAM Reveals the Why Behind Deep Learning Decisions” on page 5-21

Load Pretrained Network and Image

Load the pretrained network GoogLeNet.

```
net = googlenet;
```

Extract the image input size and the output classes of the network.

```
inputSize = net.Layers(1).InputSize(1:2);
classes = net.Layers(end).Classes;
```

Load the image. The image is of a retriever called Sherlock. Resize the image to the network input size.

```
img = imread("sherlock.jpg");
img = imresize(img,inputSize);
```

Classify the image, and display the three classes with the highest classification score in the image title.

```
[YPred,scores] = classify(net,img);
[~,topIdx] = maxk(scores, 3);
topScores = scores(topIdx);
topClasses = classes(topIdx);

imshow(img)
titleString = compose("%s (%.2f)",topClasses,topScores');
title(sprintf(join(titleString, "; ")));
```

GoogLeNet classifies Sherlock as a `golden retriever`. Understandably, the network also assigns a high probability to the `Labrador retriever` class. You can use `imageLIME` to understand which parts of the image the network is using to make these classification decisions.

Identify Areas of an Image the Network Uses for Classification

You can use LIME to find out which parts of the image are important for a class. First, look at the predicted class of `golden retriever`. What parts of the image suggest this class?

By default, `imageLIME` identifies features in the input image by segmenting the image into superpixels. This method of segmentation requires Image Processing Toolbox; however, if you do not have Image Processing Toolbox, you can use the option `"Segmentation","grid"` to segment the image into square features.

Use the `imageLIME` function to map the importance of different superpixel features. By default, the simple model is a regression tree.

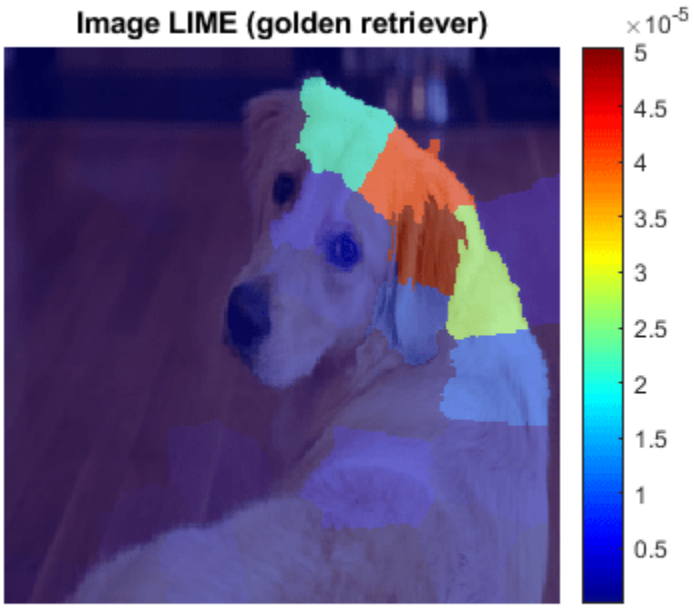
```
map = imageLIME(net,img,YPred);
```

Display the image of Sherlock with the LIME map overlaid.

```
figure
imshow(img,'InitialMagnification',150)
```

```
hold on
imagesc(map,'AlphaData',0.5)
colormap jet
colorbar

title(sprintf("Image LIME (%s)", ...
    YPred))
hold off
```



The maps shows which areas of the image are important to the classification of `golden retriever`. Red areas of the map have a higher importance — when these areas are removed, the score for the `golden retriever` class goes down. The network focuses on the dog's face and ear to make its prediction of golden retriever. This is consistent with other explainability techniques like occlusion sensitivity or Grad-CAM.

Compare to Results of a Different Class

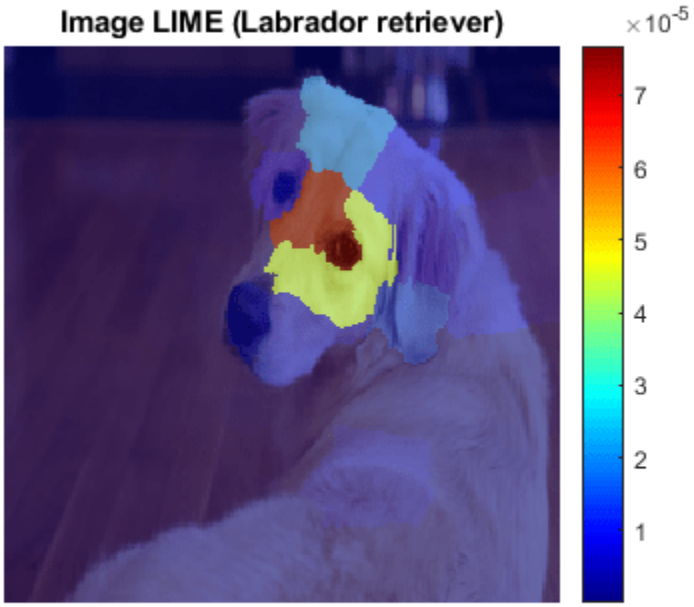
GoogLeNet predicts a score of 55% for the `golden retriever` class, and 40% for the `Labrador retriever` class. These classes are very similar. You can determine which parts of the dog are more important for both classes by comparing the LIME maps computed for each class.

Using the same settings, compute the LIME map for the `Labrador retriever` class.

```
secondClass = topClasses(2);
map = imageLIME(net,img,secondClass);
figure;
```

```
imshow(img,'InitialMagnification',150)
hold on
imagesc(map,'AlphaData',0.5)
colormap jet
colorbar

title(sprintf("Image LIME (%s)",secondClass))
hold off
```



For the `Labrador retriever` class, the network is more focused on the dog's nose and eyes, rather than the ear. While both maps highlight the dog's forehead, the network has decided that the dog's ear and neck indicate the `golden retriever` class, while the dog's eye and nose indicate the `Labrador retriever` class.

Compare LIME with Grad-CAM

Other image interpretability techniques such as Grad-CAM upsample the resulting map to produce a smooth heatmap of the important areas of the image. You can produce similar-looking maps with `imageLIME`, by calculating the importance of square or rectangular features and upsampling the resulting map.

To segment the image into a grid of square features instead of irregular superpixels, use the `"Segmentation","grid"` name-value pair. Upsample the computed map to match the image resolution using bicubic interpolation, by setting `"OutputUpsampling","bicubic"`.

To increase the resolution of the initially computed map, increase the number of features to 100 by specifying the `"NumFeatures",100` name-value pair. As the image is square, this produces a 10-by-10 grid of features.

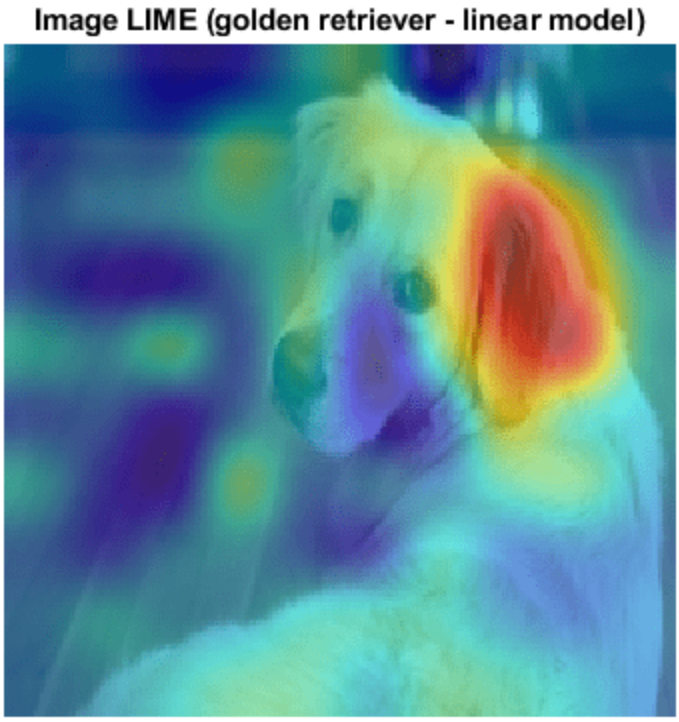
The LIME technique generates synthetic images based on the original observation by randomly choosing some features and replacing all the pixels in those features with the average image pixel, effectively removing that feature. Increase the number of random samples to 6000 by setting `"NumSamples",6000`. When you increase the number of features, increasing the number of samples usually gives better results.

By default the `imageLIME` function uses a regression tree as its simple model. Instead, fit a linear regression model with lasso regression by setting `"Model","linear"`.

```
map = imageLIME(net,img,"golden retriever", ...
    "Segmentation","grid",...
    "OutputUpsampling","bicubic",...
    "NumFeatures",100,...
    "NumSamples",6000,...
    "Model","linear");

imshow(img,'InitialMagnification', 150)
hold on
imagesc(map,'AlphaData',0.5)
colormap jet

title(sprintf("Image LIME (%s - linear model)", ...
    YPred))
hold off
```



Similar to the gradient map computed by Grad-CAM, the LIME technique also strongly identifies the dog's ear as significant to the prediction of `golden retriever`.

Display Only the Most Important Features

LIME results are often plotted by showing only the most important few features. When you use the `imageLIME` function, you can also obtain a map of the features used in the computation and the calculated importance of each feature. Use these results to determine the four most important superpixel features and display only the four most important features in an image.

Compute the LIME map and obtain the feature map and the calculated importance of each feature.

```
[map,featureMap,featureImportance] = imageLIME(net,img,YPred);
```

Find the indices of the top four features.

```
numTopFeatures = 4;
[~,idx] = maxk(featureImportance,numTopFeatures);
```

Next, mask out the image using the LIME map so only pixels in the most important four superpixels are visible. Display the masked image.

```
mask = ismember(featureMap,idx);
maskedImg = uint8(mask).*img;

figure
imshow(maskedImg);
```

```
title(sprintf("Image LIME (%s - top %i features)", ...
    YPred, numTopFeatures))
```

Investigate Spectrogram Classifications Using LIME

This example shows how to use locally interpretable model-agnostic explanations (LIME) to investigate the robustness of a deep convolutional neural network trained to classify spectrograms. LIME is a technique for visualizing which parts of an observation contribute to the classification decision of a network. This example uses the `imageLIME` function to understand which features in the spectrogram data are most important for classification.

In this example, you create and train a neural network to classify four kinds of simulated time series data:

- Sine waves of a single frequency
- Superposition of three sine waves
- Broad Gaussian peaks in the time series
- Gaussian pulses in the time series

To make this problem more realistic, the time series include added confounding signals: a constant low-frequency background sinusoid and a large amount of high-frequency noise. Noisy time series data is a challenging sequence classification problem. You can approach the problem by first converting the time series data into a time-frequency spectrogram to reveal the underlying features in the time series data. You can then input the spectrograms to an image classification network.

Generate Waveforms and Spectrograms

Generate time series data for the four classes. This example uses the helper function `generateSpectrogramData` to generate the time series and the corresponding spectrogram data. The helper functions used in this example are attached as supporting files.

```
numObsPerClass = 500;

classes = categorical(["SingleFrequency","ThreeFrequency","Gaussian","Pulse"]);
numClasses = length(classes);

[noisyTimeSeries,spectrograms,labels] = generateSpectrogramData(numObsPerClass,classes);
```

Compute the size of the spectrogram images and the number of observations.

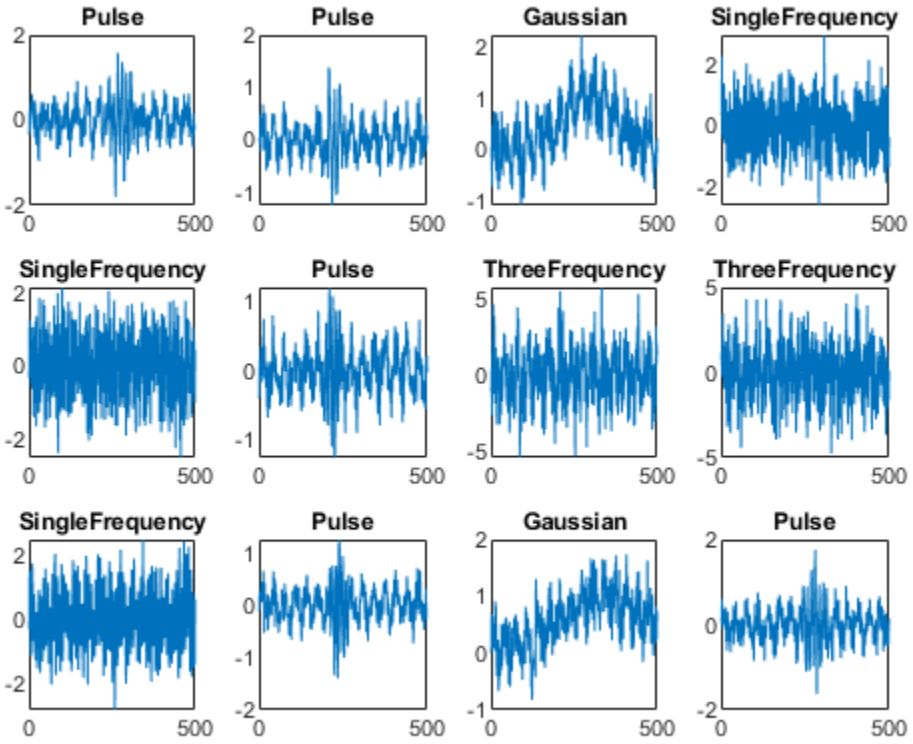
```
inputSize = size(spectrograms, [1 2]);
numObs = size(spectrograms,4);
```

Plot Generated Data

Plot a subset of the time series data with noise added. Because the noise has a comparable amplitude to the signal, the data appears noisy in the time domain. This feature makes classification a challenging problem.

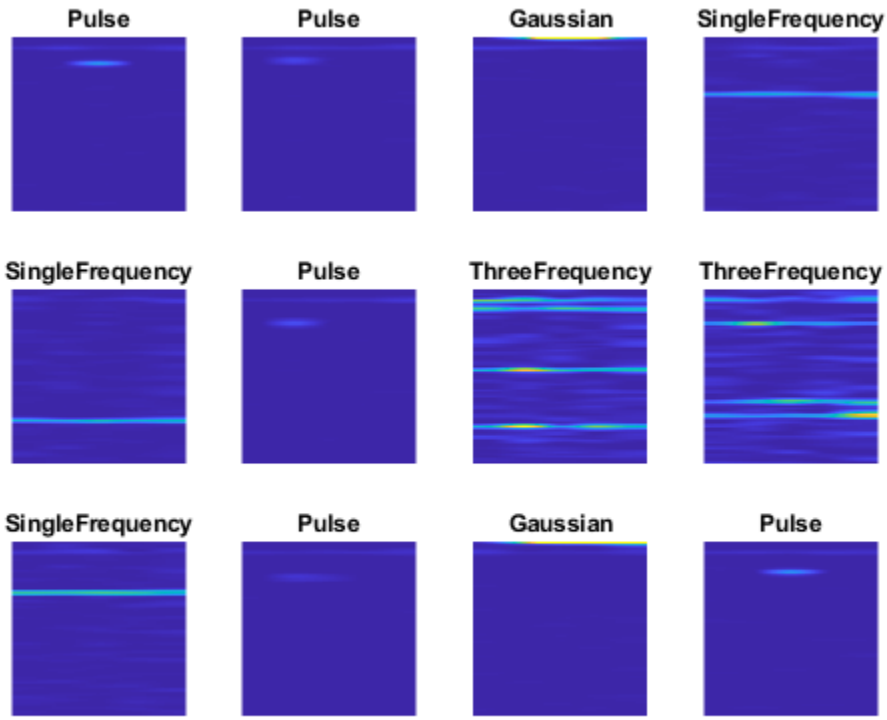
```
figure
numPlots = 12;

for i=1:numPlots
    subplot(3,4,i)
    plot(noisyTimeSeries(i,:))
    title(labels(i))
end
```



Plot the time-frequency spectrograms of the noisy data, in the same order as the time series plots. The horizontal axis is time and the vertical axis is frequency.

```
figure
for i=1:12
    subplot(3,4,i)
    imshow(spectrograms(:,:,1,i))
    hold on
    colormap parula
    title(labels(i))
    hold off
end
```



Features from each class are clearly visible, demonstrating why converting from the time domain to spectrogram images can be beneficial for this type of problem. For example, the `SingleFrequency` class has a single peak at the fundamental frequency, visible as a horizontal bar in the spectrogram. For the `ThreeFrequency` class, the three frequencies are visible.

All classes display a faint band at low frequency (near the top of the image), corresponding to the background sinusoid.

Split Data

Use the `splitlabels` function to divide the data into training and validation data. Use 80% of the data for training and 20% for validation.

```
splitIndices = splitlabels(labels,0.8);

trainLabels = labels(splitIndices{1});
trainSpectrograms = spectrograms(:,:,:,splitIndices{1});

valLabels = labels(splitIndices{2});
valSpectrograms = spectrograms(:,:,:,splitIndices{2});
```

Define Neural Network Architecture

Create a convolutional neural network with blocks of convolution, batch normalization, and ReLU layers.

```
dropoutProb = 0.2;
numFilters = 8;
```

```
layers = [
    imageInputLayer(inputSize)

    convolution2dLayer(3,numFilters,'Padding','same')
    batchNormalizationLayer
    reluLayer
    maxPooling2dLayer(3,'Stride',2,'Padding','same')

    convolution2dLayer(3,2*numFilters,'Padding','same')
    batchNormalizationLayer

    convolution2dLayer(3,4*numFilters,'Padding','same')
    batchNormalizationLayer
    reluLayer
    globalMaxPooling2dLayer

    dropoutLayer(dropoutProb)
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Define Training Options

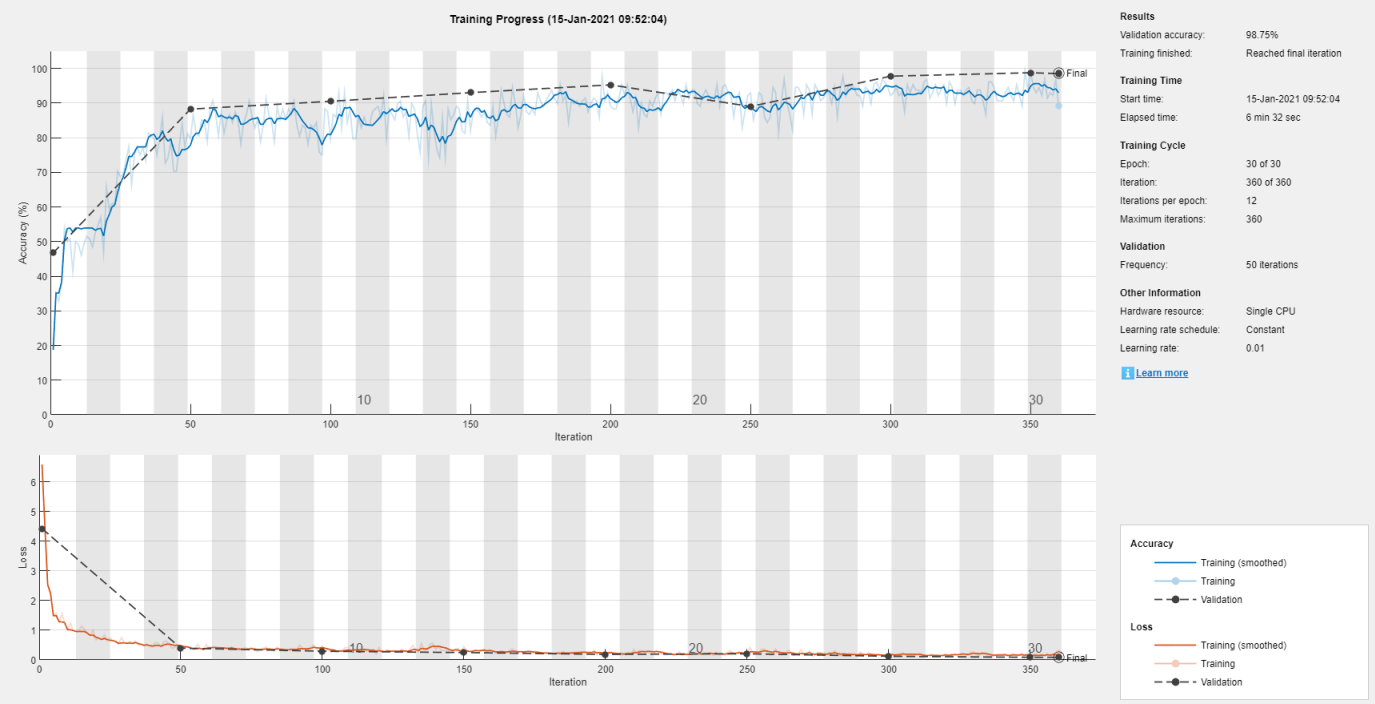
Define options for training using the SGDM optimizer. Shuffle the data every epoch by setting the `'Shuffle'` option to `'every-epoch'`. Monitor the training progress by setting the `'Plots'` option to `'training-progress'`. To suppress verbose output, set `'Verbose'` to `false`.

```
options = trainingOptions('sgdm', ...
    'Shuffle','every-epoch', ...
    'Plots','training-progress', ...
    'Verbose',false, ...
    'ValidationData',{valSpectrograms,valLabels});
```

Train Network

Train the network to classify the spectrogram images.

```
net = trainNetwork(trainSpectrograms,trainLabels,layers,options);
```



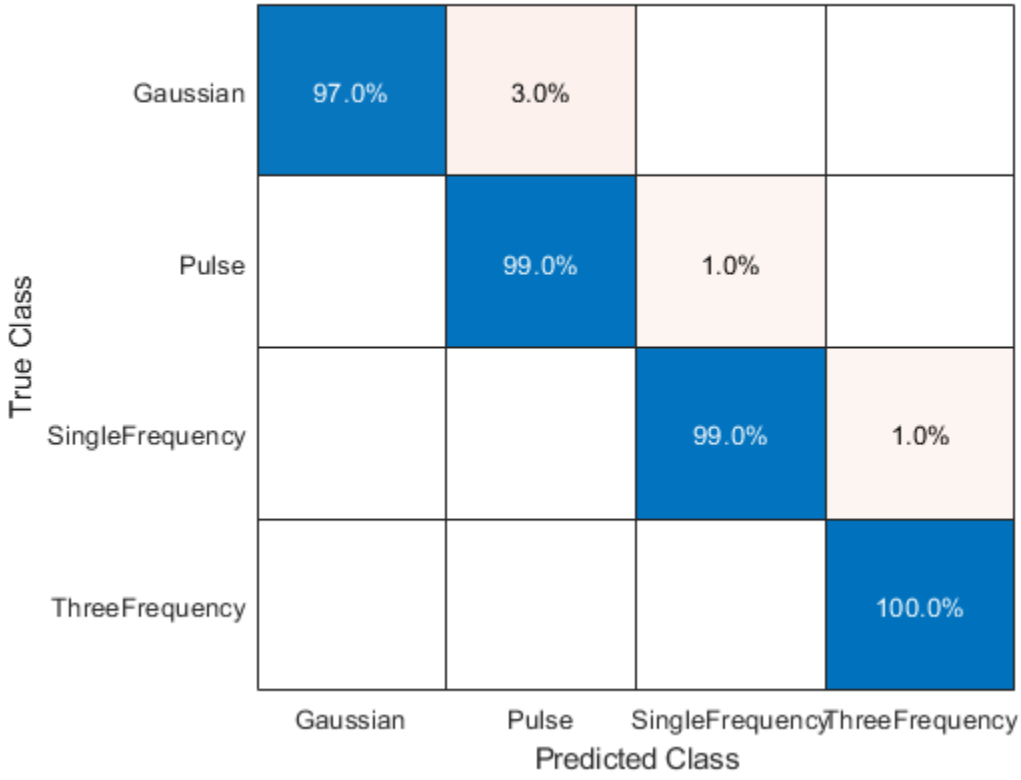
Accuracy

Classify the validation observations using the trained network.

```
predLabels = classify(net,valSpectrograms);
```

Investigate the network performance by plotting a confusion matrix with `confusionchart`.

```
figure
confusionchart(valLabels,predLabels,'Normalization','row-normalized')
```



The network accurately classifies the validation spectrograms, with close to 100% accuracy for most of the classes.

Investigate Network Predictions

Use the `imageLIME` function to understand which features in the image data are most important for classification.

The LIME technique segments an image into several features and generates synthetic observations by randomly including or excluding features. Each pixel in an excluded feature is replaced with the value of the average image pixel. The network classifies these synthetic observations, and uses the resulting scores for the predicted class, along with the presence or absence of a feature, as responses and predictors to train a regression problem with a simpler model—in this example, a regression tree. The regression tree tries to approximate the behavior of the network on a single observation. It learns which features are important and significantly impact the class score.

Define Custom Segmentation Map

By default, `imageLIME` uses superpixel segmentation to divide the image into features. This option works well for natural images, but is less effective for spectrogram data. You can specify a custom segmentation map by setting the `'Segmentation'` name-value argument to a numeric array the same size as the image, where each element is an integer corresponding to the index of the feature that pixel is in.

For the spectrogram data, the spectrogram images have much finer features in the y-dimension (frequency) than the x-dimension (time). Generate a segmentation map with 240 segments, in a 40-

by-6 grid, to provide higher frequency resolution. Upsample the grid to the size of the image by using the `imresize` function, specifying the upsampling method as `'nearest'`.

```
featureIdx = 1:240;
segmentationMap = reshape(featureIdx,6,40)';
segmentationMap = imresize(segmentationMap,inputSize,'nearest');
```

Compute LIME Map

Plot the spectrogram and compute the LIME map for two observations from each class.

```
obsToShowPerClass = 2;

for j=1:obsToShowPerClass
    figure

    for i=1:length(classes)

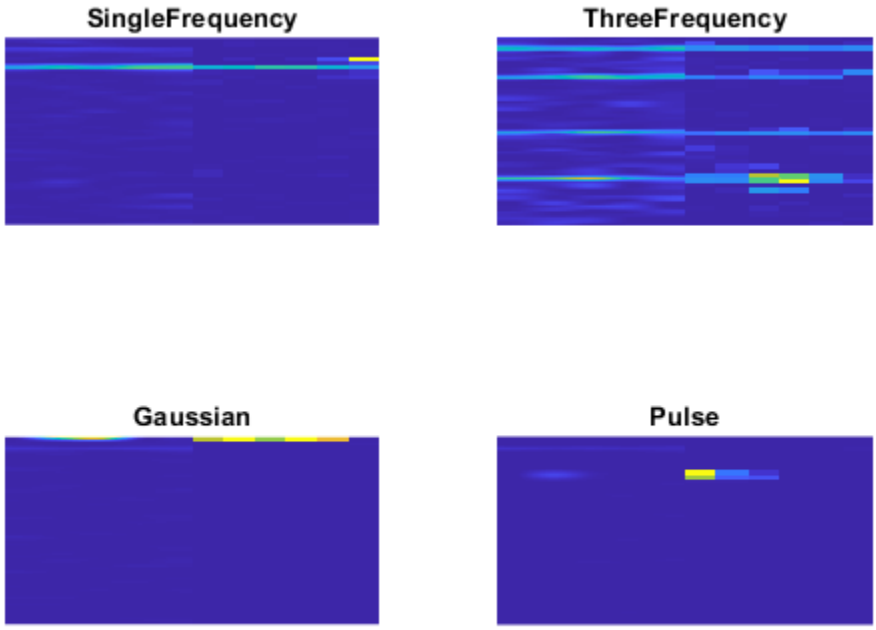
        idx = find(valLabels == classes(i),obsToShowPerClass);

        % Read the test image and label.
        testSpectrogram = valSpectrograms(:,:,:,idx(j));
        testLabel = valLabels(idx(j));

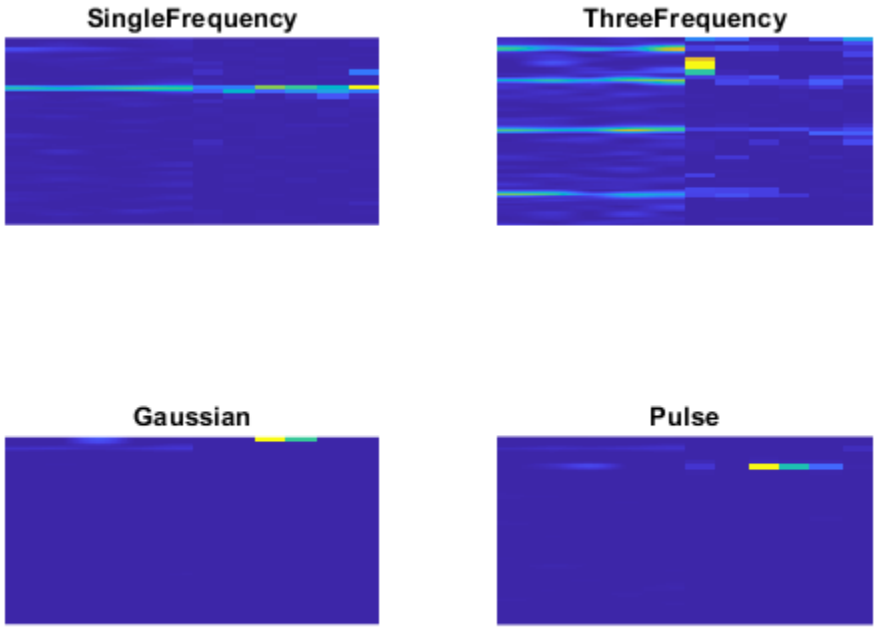
        % Compute the LIME importance map.
        map = imageLIME(net,testSpectrogram,testLabel, ...
            'NumSamples',4096, ...
            'Segmentation',segmentationMap);

        % Rescale the map to the size of the image.
        mapRescale = uint8(255*rescale(map));

        % Plot the spectrogram image next to the LIME map.
        subplot(2,2,i)
        imshow(imtile({testSpectrogram,mapRescale}))
        title(string(testLabel))
        colormap parula
    end
end
```



SingleFrequency
ThreeFrequency
Gaussian
Pulse



The LIME maps demonstrate that for most classes, the network is focused on the relevant features for classification. For example, for the `SingleFrequency` class, the network focuses on the frequency corresponding to the power spectrum of the sine wave and not on spurious background details or noise.

For the `SingleFrequency` class, the network uses the frequency to classify. For the `Pulse` and `Gaussian` classes, the network additionally focuses on the correct frequency part of the spectrogram. For these three classes, the network is not confused by the background frequency visible near the top of all of the spectrograms. This information is not helpful for distinguishing between these classes (as it is present in all classes), so the network ignores it. In contrast, for the `ThreeFrequency` class, the constant background frequency is relevant to the classification decision of the network. For this class, the network does not ignore this frequency, but treats it with similar importance to the three actual frequencies.

The `imageLIME` results demonstrate that the network is correctly using peaks in the time-frequency spectrograms and is not confused by the spurious background sinusoid for all classes except for the `ThreeFrequency` class, where the network does not distinguish between the three frequencies in the signal and the low-frequency background.

Interpret Deep Network Predictions on Tabular Data Using LIME

This example shows how to use the locally interpretable model-agnostic explanations (LIME) technique to understand the predictions of a deep neural network classifying tabular data. You can use the LIME technique to understand which predictors are most important to the classification decision of a network.

In this example, you interpret a feature data classification network using LIME. For a specified query observation, LIME generates a synthetic data set whose statistics for each feature match the real data set. This synthetic data set is passed through the deep neural network to obtain a classification, and a simple, interpretable model is fitted. This simple model can be used to understand the importance of the top few features to the classification decision of the network. In training this interpretable model, synthetic observations are weighted by their distance from the query observation, so the explanation is "local" to that observation.

This example uses `lime` (Statistics and Machine Learning Toolbox) and `fit` (Statistics and Machine Learning Toolbox) to generate a synthetic data set and fit a simple interpretable model to the synthetic data set. To understand the predictions of a trained image classification neural network, use `imageLIME`. For more information, see “Understand Network Predictions Using LIME” on page 5-42.

Load Data

Load the Fisher iris data set. This data contains 150 observations with four input features representing the parameters of the plant and one categorical response representing the plant species. Each observation is classified as one of the three species: setosa, versicolor, or virginica. Each observation has four measurements: sepal width, sepal length, petal width, and petal length.

```
filename = fullfile(toolboxdir('stats'),'statsdemos','fisheriris.mat');
load(filename)
```

Convert the numeric data to a table.

```
features = ["Sepal length","Sepal width","Petal length","Petal width"];

predictors = array2table(meas,"VariableNames",features);
trueLabels = array2table(categorical(species),"VariableNames","Response");
```

Create a table of training data whose final column is the response.

```
data = [predictors trueLabels];
```

Calculate the number of observations, features, and classes.

```
numObservations = size(predictors,1);
numFeatures = size(predictors,2);
numClasses = length(categories(data{:,5}));
```

Split Data into Training, Validation, and Test Sets

Partition the data set into training, validation, and test sets. Set aside 15% of the data for validation and 15% for testing.

Determine the number of observations for each partition. Set the random seed to make the data splitting and CPU training reproducible.

```
rng('default');
numObservationsTrain = floor(0.7*numObservations);
numObservationsValidation = floor(0.15*numObservations);
```

Create an array of random indices corresponding to the observations and partition it using the partition sizes.

```
idx = randperm(numObservations);
idxTrain = idx(1:numObservationsTrain);
idxValidation = idx(numObservationsTrain + 1:numObservationsTrain + numObservationsValidation);
idxTest = idx(numObservationsTrain + numObservationsValidation + 1:end);
```

Partition the table of data into training, validation, and testing partitions using the indices.

```
dataTrain = data(idxTrain,:);
dataVal = data(idxValidation,:);
dataTest = data(idxTest,:);
```

Define Network Architecture

Create a simple multi-layer perceptron, with a single hidden layer with five neurons and ReLU activations. The feature input layer accepts data containing numeric scalars representing features, such as the Fisher iris data set.

```
numHiddenUnits = 5;
layers = [
    featureInputLayer(numFeatures)
    fullyConnectedLayer(numHiddenUnits)
    reluLayer
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

Define Training Options and Train Network

Train the network using stochastic gradient descent with momentum (SGDM). Set the maximum number of epochs to 30 and use a mini-batch size of 15, as the training data does not contain many observations.

```
opts = trainingOptions("sgdm", ...
    "MaxEpochs",30, ...
    "MiniBatchSize",15, ...
    "Shuffle","every-epoch", ...
    "ValidationData",dataVal, ...
    "ExecutionEnvironment","cpu");
```

Train the network.

```
net = trainNetwork(dataTrain,layers,opts);
```

```
|=========================================================================================================

|=========================================================================================================
```

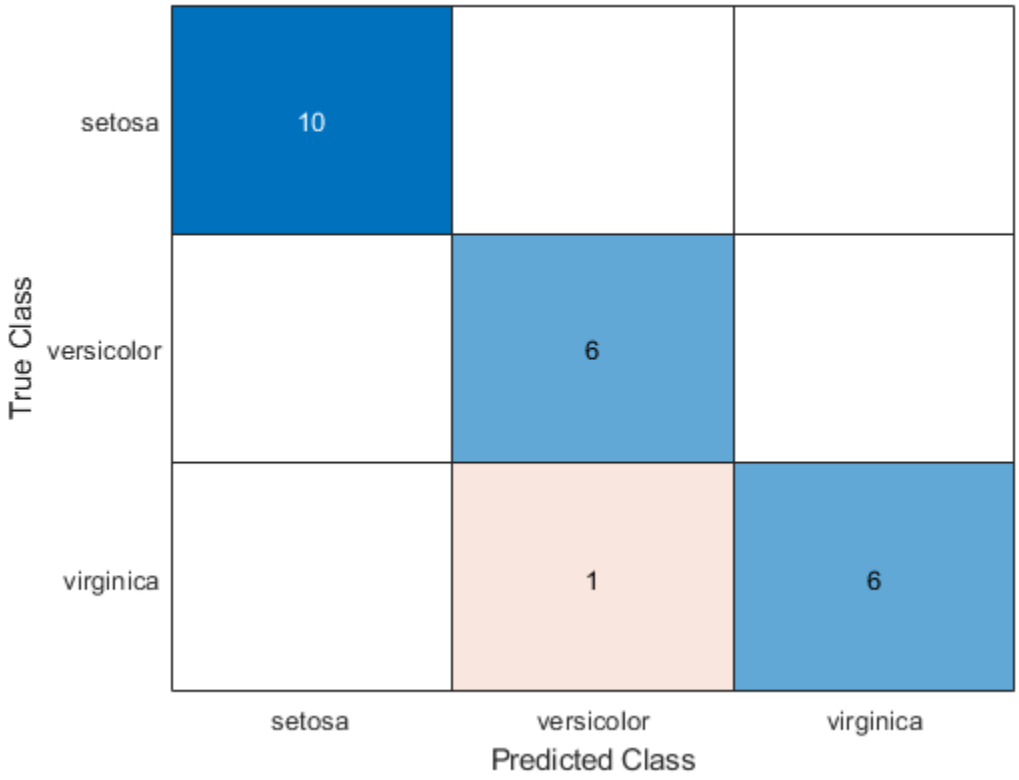
Assess Network Performance

Classify observations from the test set using the trained network.

```
predictedLabels = net.classify(dataTest);
trueLabels = dataTest{:,end};
```

Visualize the results using a confusion matrix.

```
figure
confusionchart(trueLabels,predictedLabels)
```



The network successfully uses the four plant features to predict the species of the test observations.

Understand How Different Predictors Are Important to Different Classes

Use LIME to understand the importance of each predictor to the classification decisions of the network.

Investigate the two most important predictors for each observation.

```
numImportantPredictors = 2;
```

Use `lime` to create a synthetic data set whose statistics for each feature match the real data set. Create a `lime` object using a deep learning model `blackbox` and the predictor data contained in

`predictors`. Use a low `'KernelWidth'` value so `lime` uses weights that are focused on the samples near the query point.

```
blackbox = @(x)classify(net,x);
explainer = lime(blackbox,predictors,'Type','classification','KernelWidth',0.1);
```

You can use the LIME explainer to understand the most important features to the deep neural network. The function estimates the importance of a feature by using a simple linear model that approximates the neural network in the vicinity of a query observation.

Find the indices of the first two observations in the test data corresponding to the setosa class.

```
trueLabelsTest = dataTest{:,end};

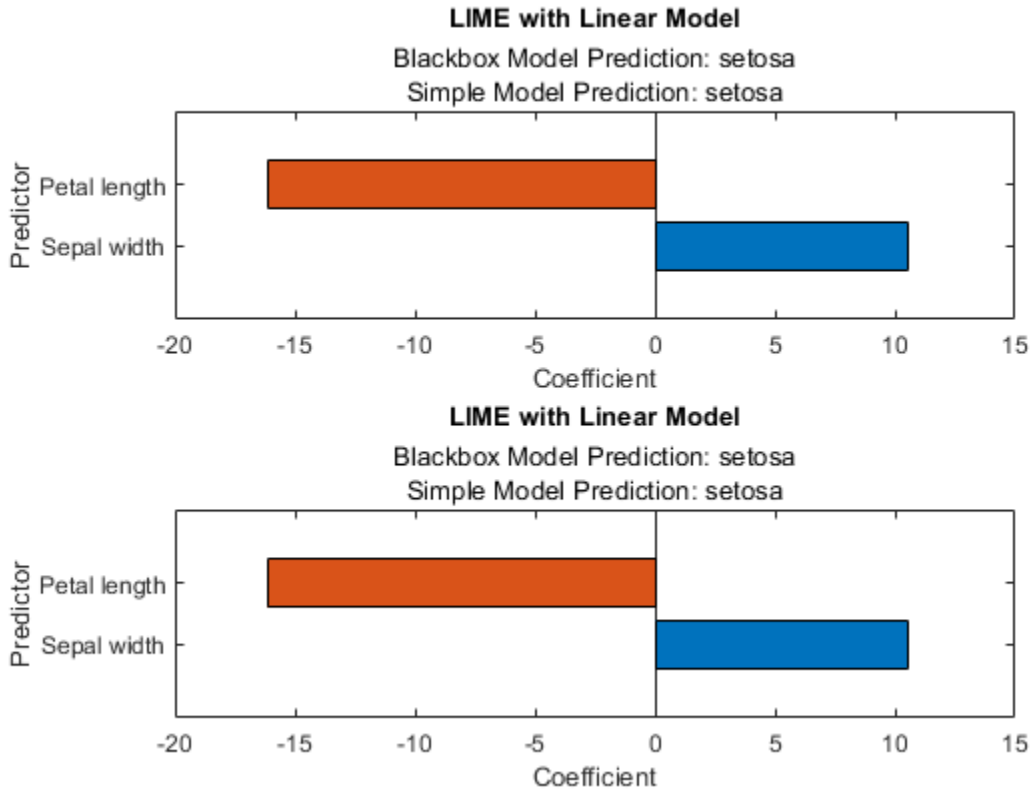
label = "setosa";
idxSetosa = find(trueLabelsTest == label,2);
```

Use the `fit` function to fit a simple linear model to the first two observations from the specified class.

```
explainerObs1 = fit(explainer,dataTest(idxSetosa(1),1:4),numImportantPredictors);
explainerObs2 = fit(explainer,dataTest(idxSetosa(2),1:4),numImportantPredictors);
```

Plot the results.

```
figure
subplot(2,1,1)
plot(explainerObs1);
subplot(2,1,2)
plot(explainerObs2);
```



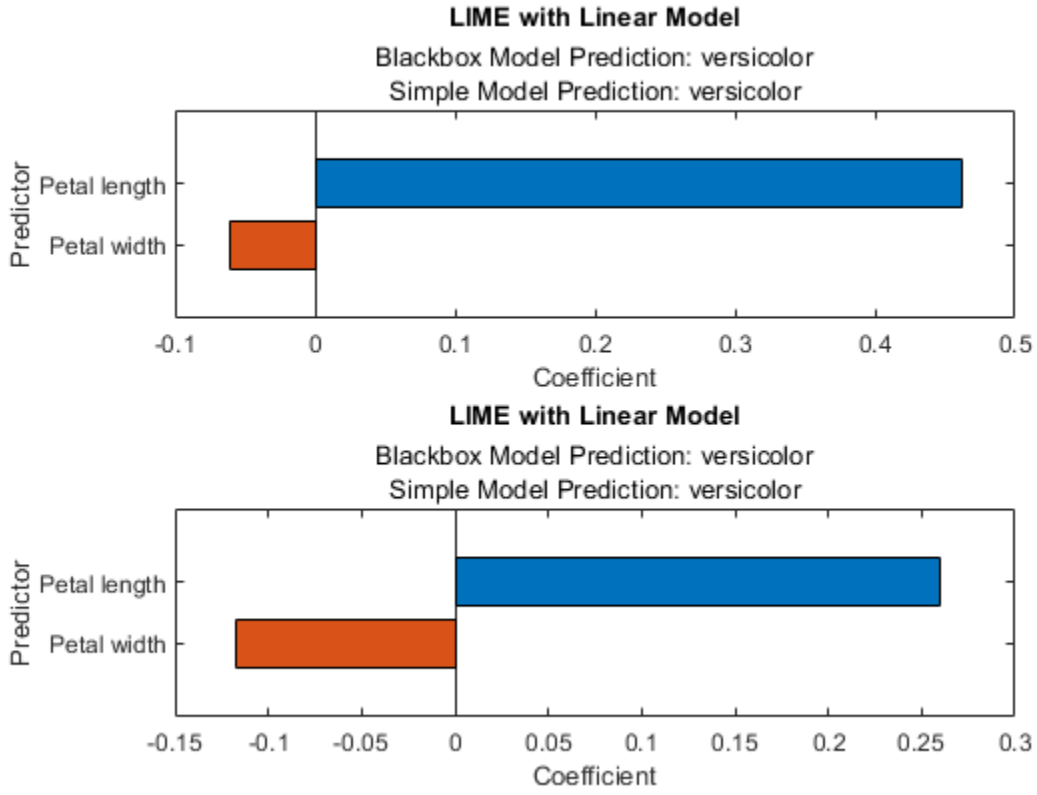
For the setosa class, the most important predictors are a low petal length value and a high sepal width value.

Perform the same analysis for class versicolor.

```
label = "versicolor";
idxVersicolor = find(trueLabelsTest == label,2);

explainerObs1 = fit(explainer,dataTest(idxVersicolor(1),1:4),numImportantPredictors);
explainerObs2 = fit(explainer,dataTest(idxVersicolor(2),1:4),numImportantPredictors);

figure
subplot(2,1,1)
plot(explainerObs1);
subplot(2,1,2)
plot(explainerObs2);
```



For the versicolor class, a high petal length value is important.

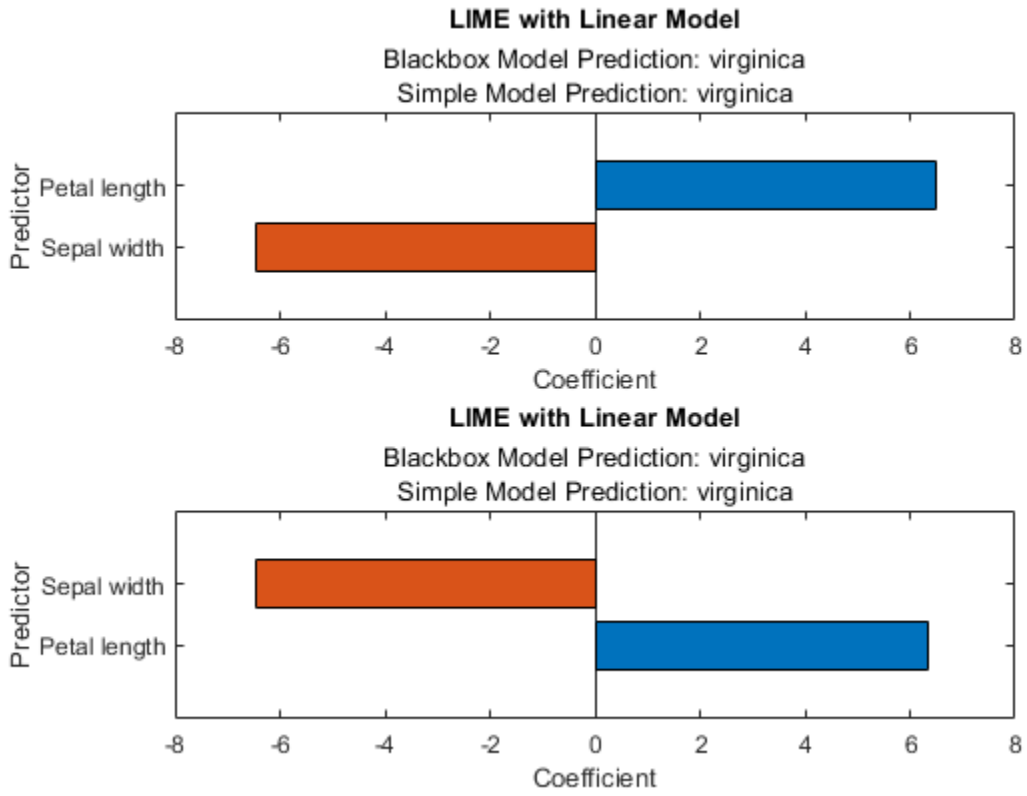
Finally, consider the virginica class.

```
label = "virginica";
idxVirginica = find(trueLabelsTest == label,2);

explainerObs1 = fit(explainer,dataTest(idxVirginica(1),1:4),numImportantPredictors);
explainerObs2 = fit(explainer,dataTest(idxVirginica(2),1:4),numImportantPredictors);

figure
```

```
subplot(2,1,1)
plot(explainerObs1);
subplot(2,1,2)
plot(explainerObs2);
```



For the virginica class, a high petal length value and a low sepal width value is important.

Validate LIME Hypothesis

The LIME plots suggest that a high petal length value is associated with the versicolor and virginica classes and a low petal length value is associated with the setosa class. You can investigate the results further by exploring the data.

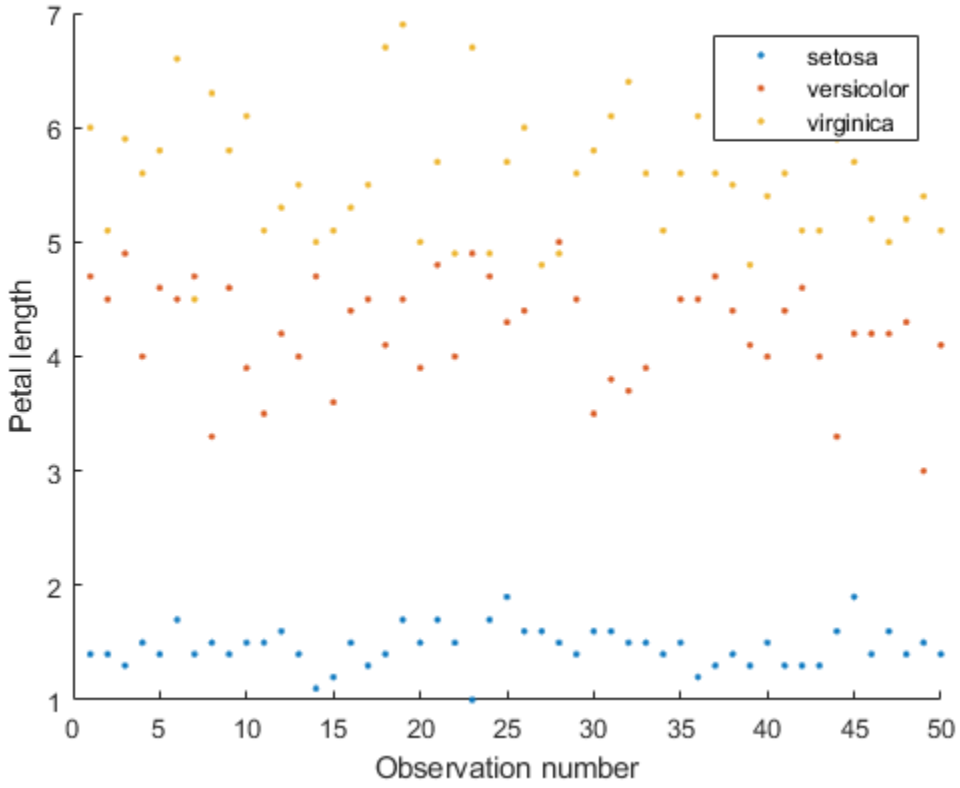
Plot the petal length of each image in the data set.

```
setosaIdx = ismember(data{:,end},"setosa");
versicolorIdx = ismember(data{:,end},"versicolor");
virginicaIdx = ismember(data{:,end},"virginica");

figure
hold on
plot(data{setosaIdx,"Petal length"},'.')
plot(data{versicolorIdx,"Petal length"},'.')
plot(data{virginicaIdx,"Petal length"},'.')
hold off

xlabel("Observation number")
```

```
ylabel("Petal length")
legend(["setosa","versicolor","virginica"])
```



The setosa class has much lower petal length values than the other classes, matching the results produced from the `lime` model.

Explore Semantic Segmentation Network Using Grad-CAM

This example shows how to explore the predictions of a semantic segmentation network using Grad-CAM.

A semantic segmentation network classifies every pixel in an image, resulting in an image that is segmented by class. You can use Grad-CAM, a deep learning visualization technique, to see which regions of the image are important for the pixel classification decision.

Load Data Set

This example uses the CamVid data set [1] from the University of Cambridge for training. This data set is a collection of images containing street-level views obtained while driving. The data set provides pixel-level labels for 32 semantic classes, including car, pedestrian, and road.

Download CamVid Data Set

Download the CamVid data set.

```
rng('default')

imageURL = 'http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData/files/701_StillsRaw_full.zi
labelURL = 'http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData/data/LabeledApproved_full.z

outputFolder = fullfile(tempdir,'CamVid');
labelsZip = fullfile(outputFolder,'labels.zip');
imagesZip = fullfile(outputFolder,'images.zip');

if ~exist(labelsZip, 'file') || ~exist(imagesZip,'file')
    mkdir(outputFolder)

    disp('Downloading 16 MB CamVid data set labels...');
    websave(labelsZip, labelURL);
    unzip(labelsZip, fullfile(outputFolder,'labels'));

    disp('Downloading 557 MB CamVid data set images...');
    websave(imagesZip, imageURL);
    unzip(imagesZip, fullfile(outputFolder,'images'));
end
```

```
Downloading 16 MB CamVid data set labels...

Downloading 557 MB CamVid data set images...
```

Load CamVid Images

Use an `imageDatastore` to load the CamVid images. The `imageDatastore` enables you to efficiently load a large collection of images on disk.

```
imgDir = fullfile(outputFolder,'images','701_StillsRaw_full');
imds = imageDatastore(imgDir);
```

The data set contains 32 classes. To make training easier, reduce the number of classes to 11 by grouping multiple classes from the original data set together. For example, create a "`Car`" class that combines the "`Car`", "`SUVPickupTruck`", "`Truck_Bus`", "`Train`", and "`OtherMoving`" classes from the original data set. Return the grouped label IDs by using the supporting function `camvidPixelLabelIDs`, which is listed at the end of this example.

```
classes = [
    "Sky"
    "Building"
    "Pole"
    "Road"
    "Pavement"
    "Tree"
    "SignSymbol"
    "Fence"
    "Car"
    "Pedestrian"
    "Bicyclist"
    ];

labelIDs = camvidPixelLabelIDs;
```

Use the classes and label IDs to create a `pixelLabelDatastore`.

```
labelDir = fullfile(outputFolder,'labels');
pxds = pixelLabelDatastore(labelDir,classes,labelIDs);
```

Load Pretrained Semantic Segmentation Network

Load a pretrained semantic segmentation network. The pretrained model allows you to run the entire example without having to wait for training to complete. This example loads a trained Deeplab v3+ network with weights initialized from a pretrained ResNet-18 network. To get a pretrained ResNet-18, install `resnet18`. For more information on building and training a semantic segmentation network, see Semantic Segmentation Using Deep Learning.

```
pretrainedURL = 'https://www.mathworks.com/supportfiles/vision/data/deeplabv3plusResnet18CamVid.m
pretrainedFolder = fullfile(tempdir,'pretrainedNetwork');
pretrainedNetwork = fullfile(pretrainedFolder,'deeplabv3plusResnet18CamVid.mat');

if ~exist(pretrainedNetwork,'file')
    mkdir(pretrainedFolder);
    disp('Downloading pretrained network (58 MB)...');
    websave(pretrainedNetwork,pretrainedURL);
end
```

```
Downloading pretrained network (58 MB)...
```

```
pretrainedNet = load(pretrainedNetwork);
net = pretrainedNet.net;
```

Test Network

The trained semantic segmentation network predicts the label of each pixel within an image. You can test the network by predicting the pixel labels of an image.

Load a test image.

```
figure
img = readimage(imds,615);
imshow(img,'InitialMagnification',35)
```

Use the `semanticseg` function to predict the pixel labels of the image by using the trained semantic segmentation network.

```
predLabels = semanticseg(img,net);
```

Display the results.

```
cmap = camvidColorMap;
segImg = labeloverlay(img,predLabels,'Colormap',cmap,'Transparency',0.4);
figure
imshow(segImg,'InitialMagnification',40)

pixelLabelColorbar(cmap,classes)
```

You can see that the network labels the parts of the image fairly accurately. The network does misclassify some areas, for example, the road to the left of the intersection, which is partially misclassified as pavement.

Explore Network Predictions

Deep networks are complex, so understanding how a network determines a particular prediction is difficult. You can use Grad-CAM to see which areas of the test image the semantic segmentation network is using to make its pixel classifications.

Grad-CAM computes the gradient of a differentiable output, such as class score, with respect to the convolutional features in a chosen layer. Grad-CAM is typically used for image classification tasks [2]; however, it can also be extended to semantic segmentation problems [3].

In semantic segmentation tasks, the softmax layer of the network outputs a score for each class for every pixel in the original image. This contrasts with standard image classification problems, where the softmax layer outputs a score for each class for the entire image. The Grad-CAM map for class c is

$$M^c = ReLU(\sum_k \alpha_c^k A^k) \text{ where } \alpha_c^k = 1/N \sum_{i,j} \frac{dy^c}{dA_{i,j}^k}$$

N is the number of pixels, A^k is the feature map of interest, and y^c corresponds to a scalar class score. For a simple image classification problem, y^c is the softmax score for the class of interest. For semantic segmentation, you can obtainy^c by reducing the pixel-wise class scores for the class of interest to a scalar. For example, sum over the spatial dimensions of the softmax layer:

$y^C = \sum_{(i,j) \in P} y^C_{i,j}$, where P is the pixels in the output layer of a semantic segmentation network [3]. In this example, the output layer is the softmax layer before the pixel classification layer. The map M^C highlights areas that influence the decision for class c. Higher values indicate regions of the image that are important for the pixel classification decision.

To use Grad-CAM, you must select a feature layer to extract the feature map from and a reduction layer to extract the output activations from. Use `analyzeNetwork` to find the layers to use with Grad-CAM.

```
analyzeNetwork(net)
```

Specify a feature layer. Typically this is a ReLU layer which takes the output of a convolutional layer at the end of the network.

```
featureLayer = 'dec_relu4';
```

Specify a reduction layer. The `gradCAM` function sums the spatial dimensions of the reduction layer, for the specified classes, to produce a scalar value. This scalar value is then differentiated with respect to each feature in the feature layer. For semantic segmentation problems, the reduction layer is usually the softmax layer.

```
reductionLayer = 'softmax-out';
```

Compute the Grad-CAM map for the road and pavement classes.

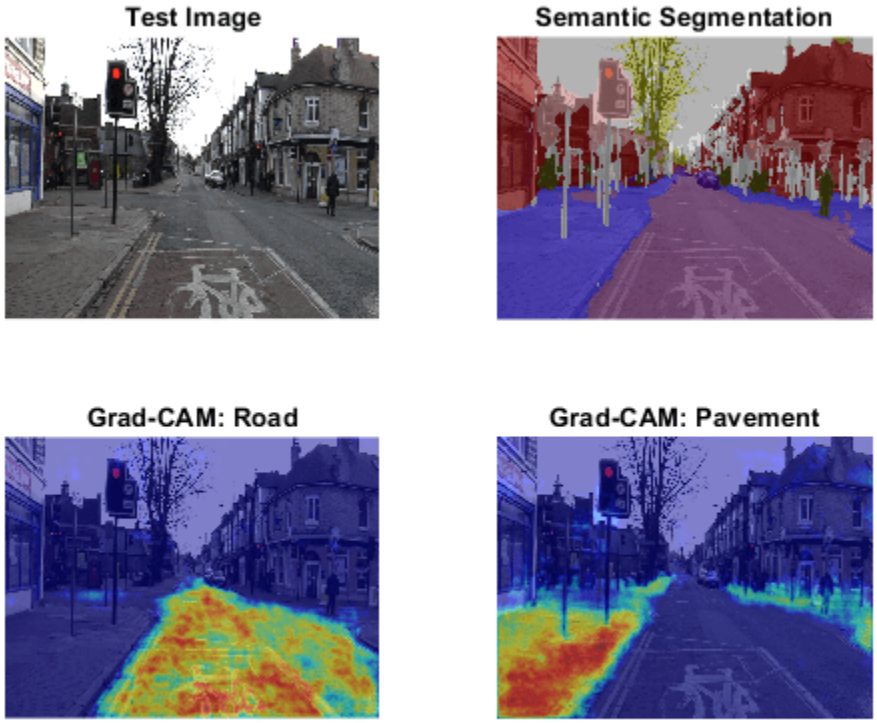
```
classes = ["Road" "Pavement"];

gradCAMMap = gradCAM(net,img,classes, ...
    'ReductionLayer',reductionLayer, ...
    'FeatureLayer',featureLayer);
```

Compare the Grad-CAM map for the two classes to the semantic segmentation map.

```
predLabels = semanticseg(img,net);
segMap = labeloverlay(img,predLabels,'Colormap',cmap,'Transparency',0.4);

figure;
subplot(2,2,1)
imshow(img)
title('Test Image')
subplot(2,2,2)
imshow(segMap)
title('Semantic Segmentation')
subplot(2,2,3)
imshow(img)
hold on
imagesc(gradCAMMap(:,:,1),'AlphaData',0.5)
title('Grad-CAM: ' + classes(1))
colormap jet
subplot(2,2,4)
imshow(img)
hold on
imagesc(gradCAMMap(:,:,2),'AlphaData',0.5)
title('Grad-CAM: ' + classes(2))
colormap jet
```



The Grad-CAM maps and semantic segmentation map show similar highlighting. None of the maps distinguish the road to the left of the intersection, which the semantic segmentation map labels as pavement. The Grad-CAM map for the pavement class shows that the edge of the pavement is more important than the center for the classification decision of the network. The network possibly misclassifies the road to the left of the intersection due to the poor visibility of the pavement edge.

Explore Intermediate Layers

The Grad-CAM map resembles the semantic segmentation map when you use a layer near the end of the network for the computation. You can also use Grad-CAM to investigate intermediate layers in the trained network. Earlier layers have a small receptive field size and learn small, low-level features compared to the layers at the end of the network.

Compute the Grad-CAM map for layers that are successively deeper in the network.

```
layers = ["res5b_relu","catAspp","dec_relu1"];
numLayers = length(layers);
```

The `res5b_relu` layer is near the middle of the network, whereas `dec_relu1` is near the end of the network.

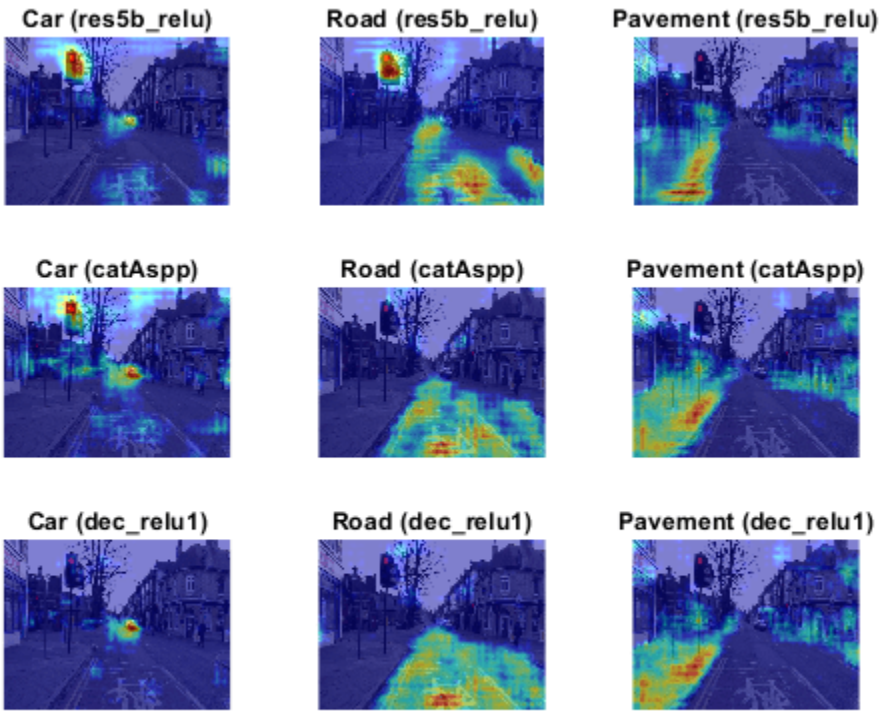
Investigate the network classification decisions for the car, road, and pavement classes. For each layer and class, compute the Grad-CAM map.

```
classes = ["Car" "Road" "Pavement"];
numClasses = length(classes);
```

```
gradCAMMaps = [];
for i = 1:numLayers
    gradCAMMaps(:,:,:,i) = gradCAM(net,img,classes, ...
        'ReductionLayer',reductionLayer, ...
        'FeatureLayer',layers(i));
end
```

Display the Grad-CAM maps for each layer and each class. The rows represent the map for each layer, with the layers ordered from those early in the network to those at the end of the network.

```
figure;
idx = 1;
for i=1:numLayers
    for j=1:numClasses
        subplot(numLayers,numClasses,idx)
        imshow(img)
        hold on
        imagesc(gradCAMMaps(:,:,j,i),'AlphaData',0.5)
        title(sprintf("%s (%s)",classes(j),layers(i)), ...
            "Interpreter","none")
        colormap jet
        idx = idx + 1;
    end
end
```



The later layers produce maps very similar to the segmentation map. However, the layers earlier in the network produce more abstract results and are typically more concerned with lower level

features like edges, with less awareness of semantic classes. For example, in the maps for earlier layers, you can see that for both car and road classes, the traffic light is highlighted. This suggests that the earlier layers focus on areas of the image that are related to the class but do not necessarily belong to it. For example, a traffic light is likely to appear near to a road, so the network might be using this information to predict which pixels are roads. You can also see that for the pavement class, the earlier layers are highly focused on the edge, suggesting this feature is important to the network when detecting which pixels are in the pavement class.

Generate Untargeted and Targeted Adversarial Examples for Image Classification

This example shows how to use the fast gradient sign method (FGSM) and the basic iterative method (BIM) to generate adversarial examples for a pretrained neural network.

Neural networks can be susceptible to a phenomenon known as *adversarial examples* [1], where very small changes to an input can cause the input to be misclassified. These changes are often imperceptible to humans.

In this example, you create two types of adversarial examples:

- Untargeted — Modify an image so that it is misclassified as any incorrect class.
- Targeted — Modify an image so that it is misclassified as a specific class.

Load Network and Image

Load a network that has been trained on the ImageNet [2] data set and convert it to a `dlnetwork`.

```
net = squeezenet;
```

```
lgraph = layerGraph(net);
lgraph = removeLayers(lgraph,lgraph.Layers(end).Name);
dlnet = dlnetwork(lgraph);
```

Extract the class labels.

```
classes = categories(net.Layers(end).Classes);
```

Load an image to use to generate an adversarial example. The image is a picture of a golden retriever.

```
img = imread('sherlock.jpg');
T = "golden retriever";
```

Resize the image to match the input size of the network.

```
inputSize = dlnet.Layers(1).InputSize;
img = imresize(img,inputSize(1:2));

figure
imshow(img)
title("Ground Truth: " + T)
```

Prepare the image by converting it to a `dlarray`.

```
X = dlarray(single(img),"SSCB");
```

Prepare the label by one-hot encoding it.

```
T = onehotencode(T,1,'ClassNames',classes);
T = dlarray(single(T),"CB");
```

Untargeted Fast Gradient Sign Method

Create an adversarial example using the untargeted FGSM [3]. This method calculates the gradient $\nabla_X L(X, T)$ of the loss function L, with respect to the image X you want to find an adversarial example for, and the class label T. This gradient describes the direction to "push" the image in to increase the chance it is misclassified. You can then add or subtract a small error from each pixel to increase the likelihood the image is misclassified.

The adversarial example is calculated as follows:

$X_{\text{adv}} = X + \epsilon \cdot \text{sign}(\nabla_X L(X, T))$.

Parameter ϵ controls the size of the push. A larger ϵ value increases the chance of generating a misclassified image, but makes the change in the image more visible. This method is untargeted, as the aim is to get the image misclassified, regardless of which class.

Calculate the gradient of the image with respect to the golden retriever class.

```
gradient = dlfeval(@untargetedGradients,dlnet,X,T);
```

Set `epsilon` to 1 and generate the adversarial example.

```
epsilon = 1;
XAdv = X + epsilon*sign(gradient);
```

Predict the class of the original image and the adversarial image.

```
YPred = predict(dlnet,X);
YPred = onehotdecode(squeeze(YPred),classes,1)
```

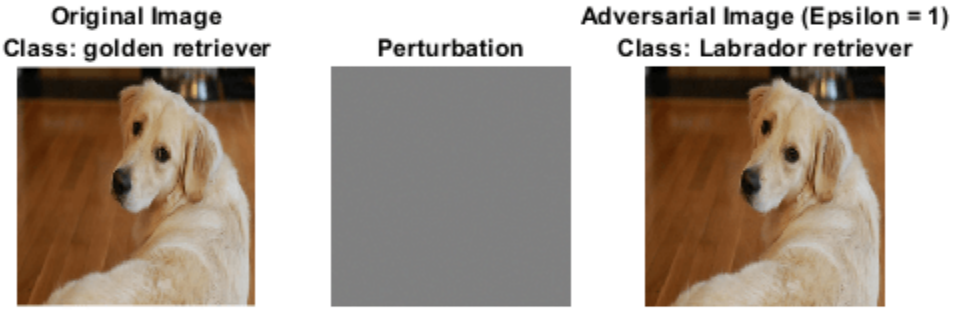
```
YPred = categorical
     golden retriever
```

```
YPredAdv = predict(dlnet,XAdv);
YPredAdv = onehotdecode(squeeze(YPredAdv),classes,1)
```

```
YPredAdv = categorical
     Labrador retriever
```

Display the original image, the perturbation added to the image, and the adversarial image. If the `epsilon` value is large enough, the adversarial image has a different class label from the original image.

```
showAdversarialImage(X,YPred,XAdv,YPredAdv,epsilon);
```



The network correctly classifies the unaltered image as a golden retriever. However, because of perturbation, the network misclassifies the adversarial image as a labrador retriever. Once added to the image, the perturbation is imperceptible, demonstrating how adversarial examples can exploit robustness issues within a network.

Targeted Adversarial Examples

A simple improvement to FGSM is to perform multiple iterations. This approach is known as the basic iterative method (BIM) [4] or projected gradient descent [5]. For the BIM, the size of the perturbation is controlled by parameter α representing the step size in each iteration. This is as the BIM usually takes many, smaller, FGSM steps in the direction of the gradient. After each iteration, clip the perturbation to ensure the magnitude does not exceed ϵ. This method can yield adversarial examples with less distortion than FGSM.

When you use untargeted FGSM, the predicted label of the adversarial example can be very similar to the label of the original image. For example, a dog might be misclassified as a different kind of dog. However, you can easily modify these methods to misclassify an image as a specific class. Instead of maximizing the cross-entropy loss, you can minimize the mean squared error between the output of the network and the desired target output.

Generate a targeted adversarial example using the BIM and the great white shark target class.

```
targetClass = "great white shark";
targetClass = onehotencode(targetClass,1,'ClassNames',classes);
```

Increase the `epsilon` value to 5, set the step size `alpha` to 0.2, and perform 25 iterations. Note that you may have to adjust these settings for other networks.

```
epsilon = 5;
alpha = 0.2;
numIterations = 25;
```

Keep track of the perturbation and clip any values that exceed `epsilon`.

```
delta = zeros(size(X),'like',X);
for i = 1:numIterations
    gradient = dlfeval(@targetedGradients,dlnet,X+delta,targetClass);

    delta = delta - alpha*sign(gradient);
    delta(delta > epsilon) = epsilon;
    delta(delta < -epsilon) = -epsilon;
end

XAdvTarget = X + delta;
```

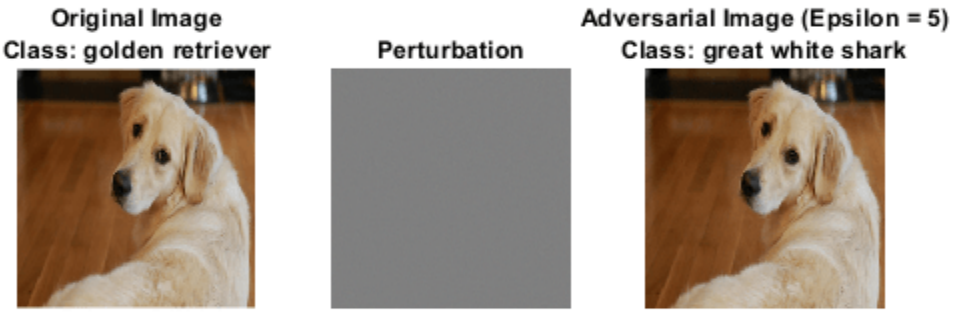
Predict the class of the targeted adversarial example.

```
YPredAdvTarget = predict(dlnet,XAdvTarget);
YPredAdvTarget = onehotdecode(squeeze(YPredAdvTarget),classes,1)
```

```
YPredAdvTarget = categorical
     great white shark
```

Display the original image, the perturbation added to the image, and the targeted adversarial image.

```
showAdversarialImage(X,YPred,XAdvTarget,YPredAdvTarget,epsilon);
```



Because of imperceptible perturbation, the network classifies the adversarial image as a great white shark.

To make the network more robust against adversarial examples, you can use adversarial training. For an example showing how to train a network robust to adversarial examples, see “Train Image Classification Network Robust to Adversarial Examples” on page 5-83.

Supporting Functions

Untargeted Input Gradient Function

Calculate the gradient used to create an untargeted adversarial example. This gradient is the gradient of the cross-entropy loss.

```
function gradient = untargetedGradients(dlnet,X,target)

Y = predict(dlnet,X);
Y = stripdims(squeeze(Y));
loss = crossentropy(Y,target,'DataFormat','CB');
gradient = dlgradient(loss,X);

end
```

Targeted Input Gradient Function

Calculate the gradient used to create a targeted adversarial example. This gradient is the gradient of the mean squared error.

```
function gradient = targetedGradients(dlnet,X,target)

Y = predict(dlnet,X);
Y = stripdims(squeeze(Y));
loss = mse(Y,target,'DataFormat','CB');
gradient = dlgradient(loss,X);

end
```

Show Adversarial Image

Show an image, the corresponding adversarial image, and the difference between the two (perturbation).

```
function showAdversarialImage(image,label,imageAdv,labelAdv,epsilon)

figure
subplot(1,3,1)
imgTrue = uint8(extractdata(image));
imshow(imgTrue)
title("Original Image" + newline + "Class: " + string(label))

subplot(1,3,2)
perturbation = uint8(extractdata(imageAdv-image+127.5));
imshow(perturbation)
title("Perturbation")

subplot(1,3,3)
advImg = uint8(extractdata(imageAdv));
imshow(advImg)
title("Adversarial Image (Epsilon = " + string(epsilon) + ")" + newline + ...
    "Class: " + string(labelAdv))
end
```

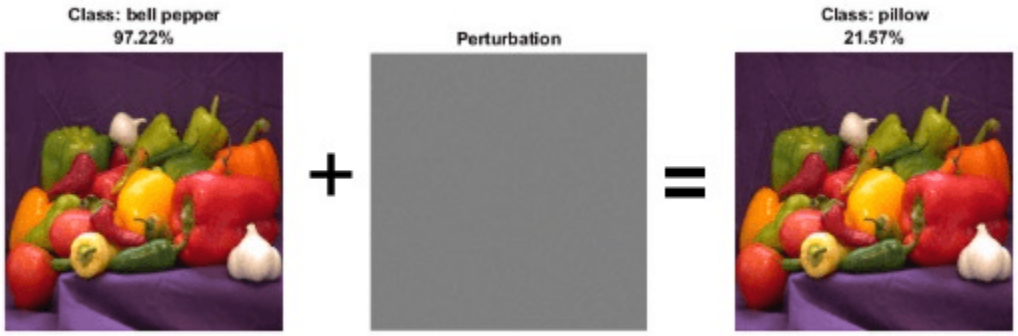
Train Image Classification Network Robust to Adversarial Examples

This example shows how to train a neural network that is robust to adversarial examples using fast gradient sign method (FGSM) adversarial training.

Neural networks can be susceptible to a phenomenon known as *adversarial examples* [1], where very small changes to an input can cause it to be misclassified. These changes are often imperceptible to humans.



Techniques for creating adversarial examples include the FGSM [2] and the basic iterative method (BIM) [3], also known as projected gradient descent [4]. These techniques can significantly degrade the accuracy of a network.

You can use *adversarial training* [5] to train networks that are robust to adversarial examples. This example shows how to:

1. Train an image classification network.
2. Investigate network robustness by generating adversarial examples.
3. Train an image classification network that is robust to adversarial examples.

Load Training Data

The `digitTrain4DArrayData` function loads images of handwritten digits and their digit labels. Create an `arrayDatastore` object for the images and the labels, and then use the `combine` function to make a single datastore containing all the training data.

```
rng default
[XTrain,TTrain] = digitTrain4DArrayData;

dsXTrain = arrayDatastore(XTrain,'IterationDimension',4);
dsTTrain = arrayDatastore(TTrain);

dsTrain = combine(dsXTrain,dsTTrain);
```

Extract the class names.

```
classes = categories(TTrain);
```

Construct Network Architecture

Define an image classification network.

```
layers = [
    imageInputLayer([28 28 1],'Normalization','none','Name','input')
    convolution2dLayer(3,32,'Padding',1,'Name','conv1')
    reluLayer('Name','relu1')
    convolution2dLayer(3,64,'Padding',1,'Name','conv3')
    reluLayer('Name','relu3')
    maxPooling2dLayer(2,'Stride',2,'Name','pool')
    fullyConnectedLayer(10,'Name','fc2')
    softmaxLayer('Name','softmax')];
lgraph = layerGraph(layers);
```

Create a `dlnetwork` object from the layer graph.

```
dlnet = dlnetwork(lgraph);
```

Define Model Gradients Function

Create the function `modelGradients`, listed at the end of the example, that takes as input a `dlnetwork` object and a mini-batch of input data with corresponding labels and returns the gradients of the loss with respect to the learnable parameters in the network and the corresponding loss.

Train Network

Train the network using a custom training loop.

Specify the training options. Train for 30 epochs with a mini-batch size of 100 and a learning rate of 0.01.

```
numEpochs = 30;
miniBatchSize = 100;
learnRate = 0.01;
executionEnvironment = "auto";
```

Create a `minibatchqueue` object that processes and manages mini-batches of images during training. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to convert the labels to one-hot encoded variables.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch).
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
mbq = minibatchqueue(dsTrain, ...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn',@preprocessMiniBatch,...
    'MiniBatchFormat',{'SSCB',''});
```

Initialize the training progress plot.

```
figure
lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Initialize the velocity parameter for the SGDM solver.

```
velocity = [];
```

Train the network using a custom training loop. For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients, state, and loss using the `dlfeval` and `modelGradients` functions and update the network state.
- Update the network parameters using the `sgdmupdate` function.
- Display the training progress.

```
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs
    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches.
    while hasdata(mbq)
        iteration = iteration +1;

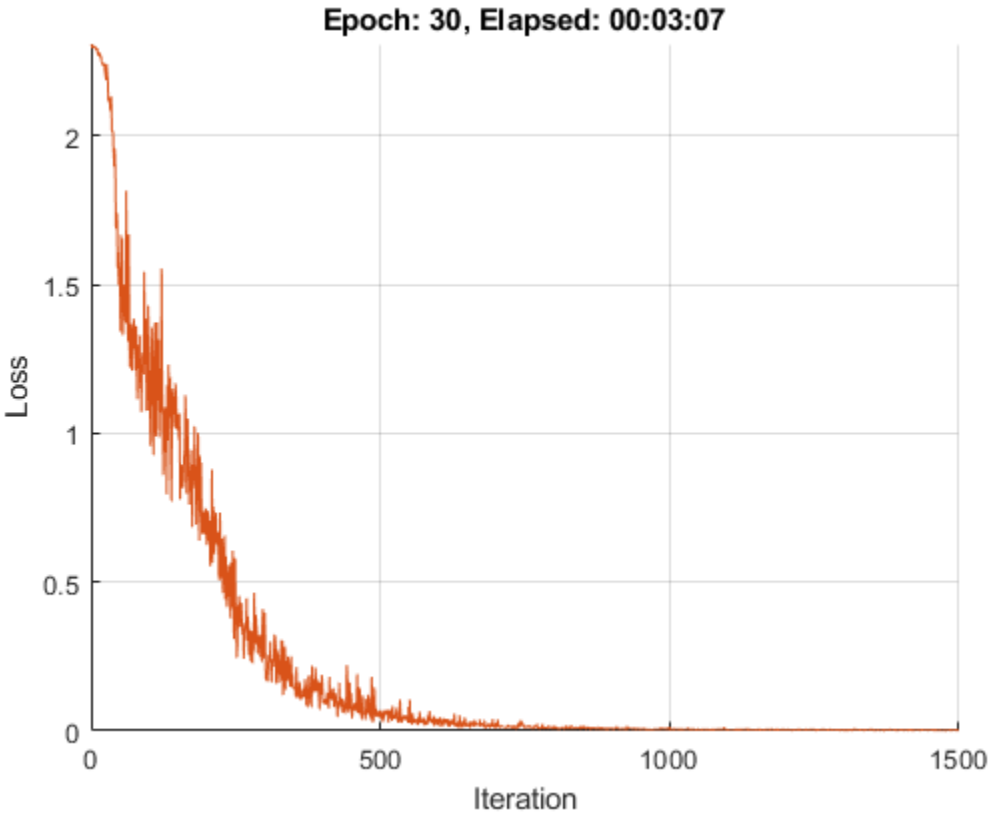
        % Read mini-batch of data.
        [dlX,dlT] = next(mbq);

        % If training on a GPU, then convert data to gpuArray.
        if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
            dlX = gpuArray(dlX);
            dlT = gpuArray(dlT);
        end

        % Evaluate the model gradients, state, and loss.
        [gradients,state,loss] = dlfeval(@modelGradients,dlnet,dlX,dlT);
        dlnet.State = state;

        % Update the network parameters using the SGDM optimizer.
        [dlnet,velocity] = sgdmupdate(dlnet,gradients,velocity,learnRate);

        % Display the training progress.
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        addpoints(lineLossTrain,iteration,loss)
        title("Epoch: " + epoch + ", Elapsed: " + string(D))
        drawnow
    end
end
```



Test Network

Test the classification accuracy of the network by evaluating network predictions on a test data set.

Create a `minibatchqueue` object containing the test data.

```
[XTest,TTest] = digitTest4DArrayData;

dsXTest = arrayDatastore(XTest,'IterationDimension',4);
dsTTest = arrayDatastore(TTest);

dsTest = combine(dsXTest,dsTTest);

mbqTest = minibatchqueue(dsTest, ...
    'MiniBatchSize',miniBatchSize, ...
    'MiniBatchFcn',@preprocessMiniBatch, ...
    'MiniBatchFormat','SSCB');
```

Predict the classes of the test data using the trained network and the `modelPredictions` function defined at the end of this example.

```
YPred = modelPredictions(dlnet,mbqTest,classes);
acc = mean(YPred == TTest)
```

```
acc = 0.9866
```

The network accuracy is very high.

Test Network with Adversarial Inputs

Apply adversarial perturbations to the input images and see how doing so affects the network accuracy.

You can generate adversarial examples using techniques such as FGSM and BIM. FGSM is a simple technique that takes a single step in the direction of the gradient $\nabla_X L(X, T)$ of the loss function L, with respect to the image X you want to find an adversarial example for, and the class label T. The adversarial example is calculated as

$X_{\text{adv}} = X + \epsilon \,.\, \text{sign}(\nabla_X L(X, T))$.

Parameter ϵ controls how different the adversarial examples look from the original images. In this example, the values of the pixels are between 0 and 1, so an ϵ value of 0.1 alters each individual pixel value by up to 10% of the range. The value of ϵ depends on the image scale. For example, if your image is instead between 0 and 255, you need to multiply this value by 255.

BIM is a simple improvement to FGSM which applies FGSM over multiple iterations and applies a threshold. After each iteration, the BIM clips the perturbation to ensure the magnitude does not exceed ϵ. This method can yield adversarial examples with less distortion than FGSM. For more information about generating adversarial examples, see “Generate Untargeted and Targeted Adversarial Examples for Image Classification” on page 5-76.

Create adversarial examples using the BIM. Set `epsilon` to 0.1.

```
epsilon = 0.1;
```

For the BIM, the size of the perturbation is controlled by parameter α representing the step size in each iteration. This is as the BIM usually takes many, smaller, FGSM steps in the direction of the gradient.

Define the step size `alpha` and the number of iterations.

```
alpha = 0.01;
numAdvIter = 20;
```

Use the `adversarialExamples` function (defined at the end of this example) to compute adversarial examples using the BIM on the test data set. This function also returns the new predictions for the adversarial images.

```
reset(mbqTest)
[XAdv,YPredAdv] = adversarialExamples(dlnet,mbqTest,epsilon,alpha,numAdvIter,classes);
```

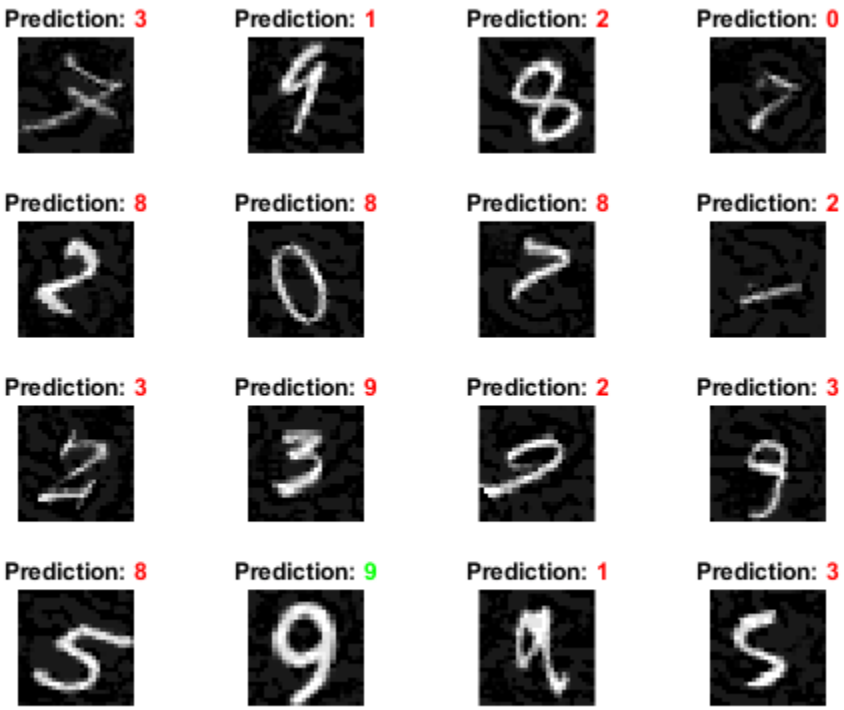
Compute the accuracy of the network on the adversarial example data.

```
accAdversarial = mean(YPredAdv == TTest)
```

```
accAdversarial = 0.0114
```

Plot the results.

```
visualizePredictions(XAdv,YPredAdv,TTest);
```



You can see that the accuracy is severely degraded by the BIM, even though the image perturbation is hardly visible.

Train Robust Network

You can train a network to be robust against adversarial examples. One popular method is adversarial training. Adversarial training involves applying adversarial perturbations to the training data during the training process [4] [5].

FGSM adversarial training is a fast and effective technique for training a network to be robust to adversarial examples. The FGSM is similar to the BIM, but it takes a single larger step in the direction of the gradient to generate an adversarial image.

Adversarial training involves applying the FGSM technique to each mini-batch of training data. However, for the training to be effective, these criteria must apply:

- The FGSM training method must use a randomly initialized perturbation instead of a perturbation that is initialized to zero.
- For the network to be robust to perturbations of size ϵ, perform FGSM training with a value slightly larger than ϵ. For this example, during adversarial training, you perturb the images using step size $\alpha = 1.25\epsilon$.

Train a new network with FGSM adversarial training. Start by using the same untrained network architecture as in the original network.

```
dlnetRobust = dlnetwork(lgraph);
```

Define the adversarial training parameters. Set the number of iterations to 1, as the FGSM is equivalent to the BIM with a single iteration. Randomly initialize the perturbation and perturb the images using `alpha`.

```
numIter = 1;
initialization = "random";
alpha = 1.25*epsilon;
```

Initialize the training progress plot.

```
figure
lineLossRobustTrain = animatedline('Color',[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

Train the robust network using a custom training loop and the same training options as previously defined. This loop is the same as in the previous custom training, but with added adversarial perturbation.

```
velocity = [];
iteration = 0;
start = tic;

% Loop over epochs.
for epoch = 1:numEpochs
    % Shuffle data.
    shuffle(mbq)

    % Loop over mini-batches.
    while hasdata(mbq)
        iteration = iteration + 1;

        % Read mini-batch of data.
        [dlX,dlT] = next(mbq);

        %  If training on a GPU, then convert data to gpuArray.
        if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
            dlX = gpuArray(dlX);
            dlT = gpuArray(dlT);
        end

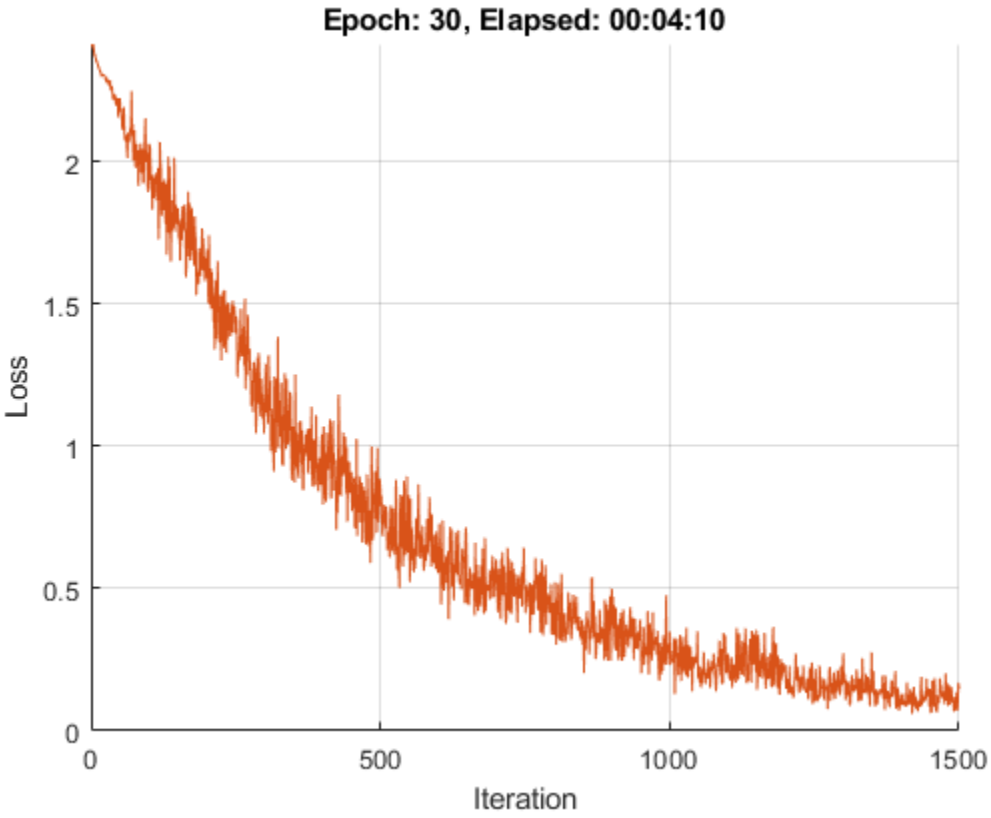
        % Apply adversarial perturbations to the data.
        dlX = basicIterativeMethod(dlnetRobust,dlX,dlT,alpha,epsilon, ...
            numIter,initialization);

        % Evaluate the model gradients, state, and loss.
        [gradients,state,loss] = dlfeval(@modelGradients,dlnetRobust,dlX,dlT);
        dlnet.State = state;

        % Update the network parameters using the SGDM optimizer.
        [dlnetRobust,velocity] = sgdmupdate(dlnetRobust,gradients,velocity,learnRate);

        % Display the training progress.
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        addpoints(lineLossRobustTrain,iteration,loss)
        title("Epoch: " + epoch + ", Elapsed: " + string(D))
```

```
        drawnow
    end
end
```



Test Robust Network

Calculate the accuracy of the robust network on the digits test data. The accuracy of the robust network can be slightly lower than the nonrobust network on the standard data.

```
reset(mbqTest)
YPred = modelPredictions(dlnetRobust,mbqTest,classes);
accRobust = mean(YPred == TTest)
```

```
accRobust = 0.9972
```

Compute the adversarial accuracy.

```
reset(mbqTest)
[XAdv,YPredAdv] = adversarialExamples(dlnetRobust,mbqTest,epsilon,alpha,numAdvIter,classes);
accRobustAdv = mean(YPredAdv == TTest)
```

```
accRobustAdv = 0.7558
```

The adversarial accuracy of the robust network is much better than that of the original network.

Supporting Functions

Model Gradients Function

The `modelGradients` function takes as input a `dlnetwork` object `dlnet` and a mini-batch of input data `dlX` with corresponding labels T and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, the network state, and the loss. To compute the gradients automatically, use the `dlgradient` function.

```
function [gradients,state,loss] = modelGradients(dlnet,dlX,T)

[dlYPred,state] = forward(dlnet,dlX);

loss = crossentropy(dlYPred,T);
gradients = dlgradient(loss,dlnet.Learnables);

loss = double(gather(extractdata(loss)));

end
```

Input Gradients Function

The `modelGradientsInput` function takes as input a `dlnetwork` object `dlnet` and a mini-batch of input data `dlX` with corresponding labels T and returns the gradients of the loss with respect to the input data `dlX`.

```
function gradient = modelGradientsInput(dlnet,dlX,T)

T = squeeze(T);
T = dlarray(T,'CB');

[dlYPred] = forward(dlnet,dlX);

loss = crossentropy(dlYPred,T);
gradient = dlgradient(loss,dlX);

end
```

Mini-Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses a mini-batch of predictors and labels using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a four-dimensional array.
2. Extract the label data from the incoming cell array and concatenate into a categorical array along the second dimension.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,T] = preprocessMiniBatch(XCell,TCell)

% Concatenate.
X = cat(4,XCell{1:end});

X = single(X);
```

```
% Extract label data from the cell and concatenate.
T = cat(2,TCell{1:end});

% One-hot encode labels.
T = onehotencode(T,1);

end
```

Model Predictions Function

The `modelPredictions` function takes as input a `dlnetwork` object `dlnet`, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in the `minibatchqueue` object. The function uses the `onehotdecode` function to find the predicted class with the highest score.

```
function predictions = modelPredictions(dlnet,mbq,classes)

predictions = [];

while hasdata(mbq)

    dlXTest = next(mbq);
    dlYPred = predict(dlnet,dlXTest);

    YPred = onehotdecode(dlYPred,classes,1)';

    predictions = [predictions; YPred];
end

end
```

Adversarial Examples Function

Generate adversarial examples for a `minibatchqueue` object using the basic iterative method (BIM) and predict the class of the adversarial examples using the trained network `dlnet`.

```
function [XAdv,predictions] = adversarialExamples(dlnet,mbq,epsilon,alpha,numIter,classes)

XAdv = {};
predictions = [];
iteration = 0;

% Generate adversarial images for each mini-batch.
while hasdata(mbq)

    iteration = iteration +1;
    [dlX,dlT] = next(mbq);

    initialization = "zero";

    % Generate adversarial images.
    XAdvMBQ = basicIterativeMethod(dlnet,dlX,dlT,alpha,epsilon, ...
        numIter,initialization);

    % Predict the class of the adversarial images.
    dlYPred = predict(dlnet,XAdvMBQ);
    YPred = onehotdecode(dlYPred,classes,1)';
```

```
    XAdv{iteration} = XAdvMBQ;
    predictions = [predictions; YPred];
end

% Concatenate.
XAdv = cat(4,XAdv{:});

end
```

Basic Iterative Method Function

Generate adversarial examples using the basic iterative method (BIM). This method runs for multiple iterations with a threshold at the end of each iteration to ensure that the entries do not exceed `epsilon`. When `numIter` is set to 1, this is equivalent to using the fast gradient sign method (FGSM).

```
function XAdv = basicIterativeMethod(dlnet,dlX,dlT,alpha,epsilon,numIter,initialization)

% Initialize the perturbation.
if initialization == "zero"
    delta = zeros(size(dlX),'like',dlX);
else
    delta = epsilon*(2*rand(size(dlX),'like',dlX) - 1);
end

for i = 1:numIter

    % Apply adversarial perturbations to the data.
    gradient = dlfeval(@modelGradientsInput,dlnet,dlX+delta,dlT);
    delta = delta + alpha*sign(gradient);
    delta(delta > epsilon) = epsilon;
    delta(delta < -epsilon) = -epsilon;
end

XAdv = dlX + delta;

end
```

Visualize Prediction Results Function

Visualize images along with their predicted classes. Correct predictions use green text. Incorrect predictions use red text.

```
function visualizePredictions(XTest,YPred,TTest)

figure
height = 4;
width = 4;
numImages = height*width;

% Select random images from the data.
indices = randperm(size(XTest,4),numImages);

XTest = extractdata(XTest);
XTest = XTest(:,:,:,indices);
YPred = YPred(indices);
TTest = TTest(indices);
```

```
% Plot images with the predicted label.
for i = 1:(numImages)
    subplot(height,width,i)
    imshow(XTest(:,:,:,i))

    % If the prediction is correct, use green. If the prediction is false,
    % use red.
    if YPred(i) == TTest(i)
        color = "\color{green}";
    else
        color = "\color{red}";
    end
    title("Prediction: " + color + string(YPred(i)))
end

end
```

Resume Training from Checkpoint Network

This example shows how to save checkpoint networks while training a deep learning network and resume training from a previously saved network.

Load Sample Data

Load the sample data as a 4-D array. `digitTrain4DArrayData` loads the digit training set as 4-D array data. `XTrain` is a 28-by-28-by-1-by-5000 array, where 28 is the height and 28 is the width of the images. 1 is the number of channels and 5000 is the number of synthetic images of handwritten digits. `YTrain` is a categorical vector containing the labels for each observation.

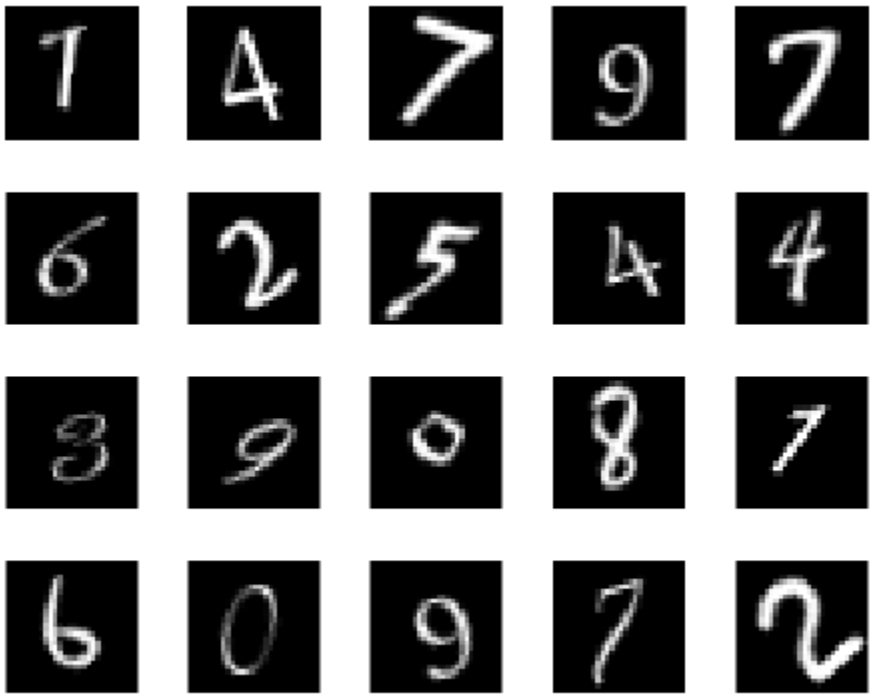
```
[XTrain,YTrain] = digitTrain4DArrayData;
size(XTrain)
```

```
ans = 1×4

          28          28           1        5000
```

Display some of the images in `XTrain`.

```
figure;
perm = randperm(size(XTrain,4),20);
for i = 1:20
    subplot(4,5,i);
    imshow(XTrain(:,:,:,perm(i)));
end
```



Define Network Architecture

Define the neural network architecture.

```
layers = [
    imageInputLayer([28 28 1])

    convolution2dLayer(3,8,'Padding','same')
    batchNormalizationLayer
    reluLayer
    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,16,'Padding','same')
    batchNormalizationLayer
    reluLayer
    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,32,'Padding','same')
    batchNormalizationLayer
    reluLayer
    averagePooling2dLayer(7)

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer];
```

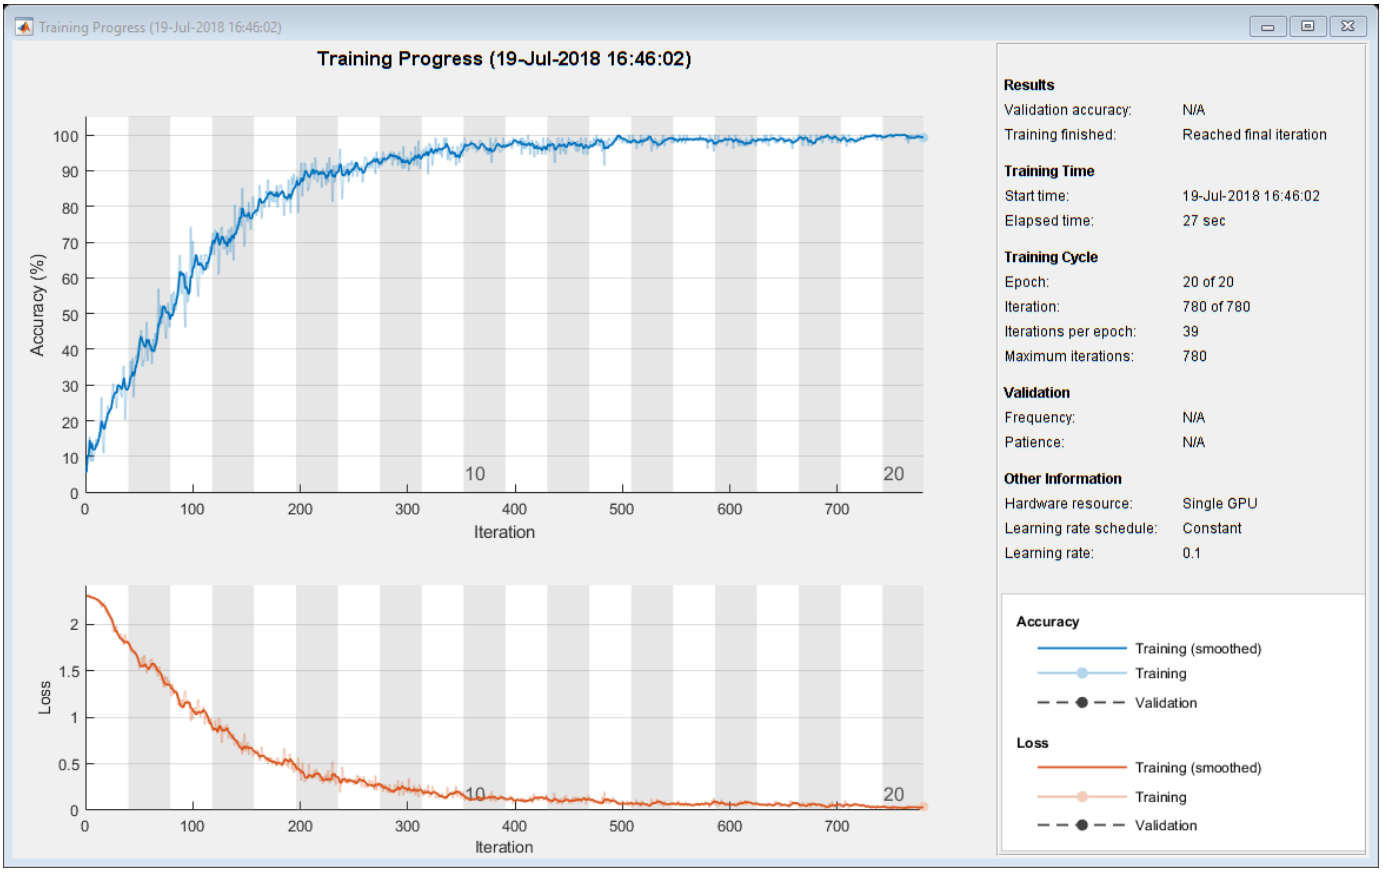
Specify Training Options and Train Network

Specify training options for stochastic gradient descent with momentum (SGDM) and specify the path for saving the checkpoint networks.

```
checkpointPath = pwd;
options = trainingOptions('sgdm', ...
    'InitialLearnRate',0.1, ...
    'MaxEpochs',20, ...
    'Verbose',false, ...
    'Plots','training-progress', ...
    'Shuffle','every-epoch', ...
    'CheckpointPath',checkpointPath);
```

Train the network. `trainNetwork` uses a GPU if there is one available. If there is no available GPU, then it uses CPU. `trainNetwork` saves one checkpoint network each epoch and automatically assigns unique names to the checkpoint files.

```
net1 = trainNetwork(XTrain,YTrain,layers,options);
```



Load Checkpoint Network and Resume Training

Suppose that training was interrupted and did not complete. Rather than restarting the training from the beginning, you can load the last checkpoint network and resume training from that point. `trainNetwork` saves the checkpoint files with file names on the form `net_checkpoint__195__2018_07_13__11_59_10.mat`, where 195 is the iteration number, `2018_07_13` is the date, and `11_59_10` is the time `trainNetwork` saved the network. The checkpoint network has the variable name `net`.

Load the checkpoint network into the workspace.

```
load('net_checkpoint__195__2018_07_13__11_59_10.mat','net')
```

Specify the training options and reduce the maximum number of epochs. You can also adjust other training options, such as the initial learning rate.

```
options = trainingOptions('sgdm', ...
    'InitialLearnRate',0.1, ...
    'MaxEpochs',15, ...
    'Verbose',false, ...
    'Plots','training-progress', ...
    'Shuffle','every-epoch', ...
    'CheckpointPath',checkpointPath);
```

Resume training using the layers of the checkpoint network you loaded with the new training options. If the checkpoint network is a DAG network, then use `layerGraph(net)` as the argument instead of `net.Layers`.

```
net2 = trainNetwork(XTrain,YTrain,net.Layers,options);
```

Deep Learning Using Bayesian Optimization

This example shows how to apply Bayesian optimization to deep learning and find optimal network hyperparameters and training options for convolutional neural networks.

To train a deep neural network, you must specify the neural network architecture, as well as options of the training algorithm. Selecting and tuning these hyperparameters can be difficult and take time. Bayesian optimization is an algorithm well suited to optimizing hyperparameters of classification and regression models. You can use Bayesian optimization to optimize functions that are nondifferentiable, discontinuous, and time-consuming to evaluate. The algorithm internally maintains a Gaussian process model of the objective function, and uses objective function evaluations to train this model.

This example shows how to:

- Download and prepare the CIFAR-10 data set for network training. This data set is one of the most widely used data sets for testing image classification models.
- Specify variables to optimize using Bayesian optimization. These variables are options of the training algorithm, as well as parameters of the network architecture itself.
- Define the objective function, which takes the values of the optimization variables as inputs, specifies the network architecture and training options, trains and validates the network, and saves the trained network to disk. The objective function is defined at the end of this script.
- Perform Bayesian optimization by minimizing the classification error on the validation set.
- Load the best network from disk and evaluate it on the test set.

As an alternative, you can use Bayesian optimization to find optimal training options in Experiment Manager. For more information, see “Tune Experiment Hyperparameters by Using Bayesian Optimization” on page 6-26.

Prepare Data

Download the CIFAR-10 data set [1]. This data set contains 60,000 images, and each image has the size 32-by-32 and three color channels (RGB). The size of the whole data set is 175 MB. Depending on your internet connection, the download process can take some time.

```
datadir = tempdir;
downloadCIFARData(datadir);
```

Load the CIFAR-10 data set as training images and labels, and test images and labels. To enable network validation, use 5000 of the test images for validation.

```
[XTrain,YTrain,XTest,YTest] = loadCIFARData(datadir);

idx = randperm(numel(YTest),5000);
XValidation = XTest(:,:,:,idx);
XTest(:,:,:,idx) = [];
YValidation = YTest(idx);
YTest(idx) = [];
```

You can display a sample of the training images using the following code.

```
figure;
idx = randperm(numel(YTrain),20);
for i = 1:numel(idx)
```

```
    subplot(4,5,i);
    imshow(XTrain(:,:,:,idx(i)));
end
```

Choose Variables to Optimize

Choose which variables to optimize using Bayesian optimization, and specify the ranges to search in. Also, specify whether the variables are integers and whether to search the interval in logarithmic space. Optimize the following variables:

- Network section depth. This parameter controls the depth of the network. The network has three sections, each with `SectionDepth` identical convolutional layers. So the total number of convolutional layers is `3*SectionDepth`. The objective function later in the script takes the number of convolutional filters in each layer proportional to `1/sqrt(SectionDepth)`. As a result, the number of parameters and the required amount of computation for each iteration are roughly the same for different section depths.
- Initial learning rate. The best learning rate can depend on your data as well as the network you are training.
- Stochastic gradient descent momentum. Momentum adds inertia to the parameter updates by having the current update contain a contribution proportional to the update in the previous iteration. This results in more smooth parameter updates and a reduction of the noise inherent to stochastic gradient descent.
- L2 regularization strength. Use regularization to prevent overfitting. Search the space of regularization strength to find a good value. Data augmentation and batch normalization also help regularize the network.

```
optimVars = [
    optimizableVariable('SectionDepth',[1 3],'Type','integer')
    optimizableVariable('InitialLearnRate',[1e-2 1],'Transform','log')
    optimizableVariable('Momentum',[0.8 0.98])
    optimizableVariable('L2Regularization',[1e-10 1e-2],'Transform','log')];
```

Perform Bayesian Optimization

Create the objective function for the Bayesian optimizer, using the training and validation data as inputs. The objective function trains a convolutional neural network and returns the classification error on the validation set. This function is defined at the end of this script. Because `bayesopt` uses the error rate on the validation set to choose the best model, it is possible that the final network overfits on the validation set. The final chosen model is then tested on the independent test set to estimate the generalization error.

```
ObjFcn = makeObjFcn(XTrain,YTrain,XValidation,YValidation);
```

Perform Bayesian optimization by minimizing the classification error on the validation set. Specify the total optimization time in seconds. To best utilize the power of Bayesian optimization, you should perform at least 30 objective function evaluations. To train networks in parallel on multiple GPUs, set the `'UseParallel'` value to `true`. If you have a single GPU and set the `'UseParallel'` value to `true`, then all workers share that GPU, and you obtain no training speed-up and increase the chances of the GPU running out of memory.

After each network finishes training, `bayesopt` prints the results to the command window. The `bayesopt` function then returns the file names in `BayesObject.UserDataTrace`. The objective function saves the trained networks to disk and returns the file names to `bayesopt`.

```
BayesObject = bayesopt(ObjFcn,optimVars, ...
    'MaxTime',14*60*60, ...
    'IsObjectiveDeterministic',false, ...
    'UseParallel',false);
```

Estimated objective function value = 0.17601
Estimated function evaluation time = 1898.2641
```

Evaluate Final Network

Load the best network found in the optimization and its validation accuracy.

```
bestIdx = BayesObject.IndexOfMinimumTrace(end);
fileName = BayesObject.UserDataTrace{bestIdx};
savedStruct = load(fileName);
valError = savedStruct.valError
```

```
valError = 0.1760
```

Predict the labels of the test set and calculate the test error. Treat the classification of each image in the test set as independent events with a certain probability of success, which means that the number of incorrectly classified images follows a binomial distribution. Use this to calculate the standard error (`testErrorSE`) and an approximate 95% confidence interval (`testError95CI`) of the generalization error rate. This method is often called the *Wald method*. `bayesopt` determines the best network using the validation set without exposing the network to the test set. It is then possible that the test error is higher than the validation error.

```
[YPredicted,probs] = classify(savedStruct.trainedNet,XTest);
testError = 1 - mean(YPredicted == YTest)
```

```
testError = 0.1910
```

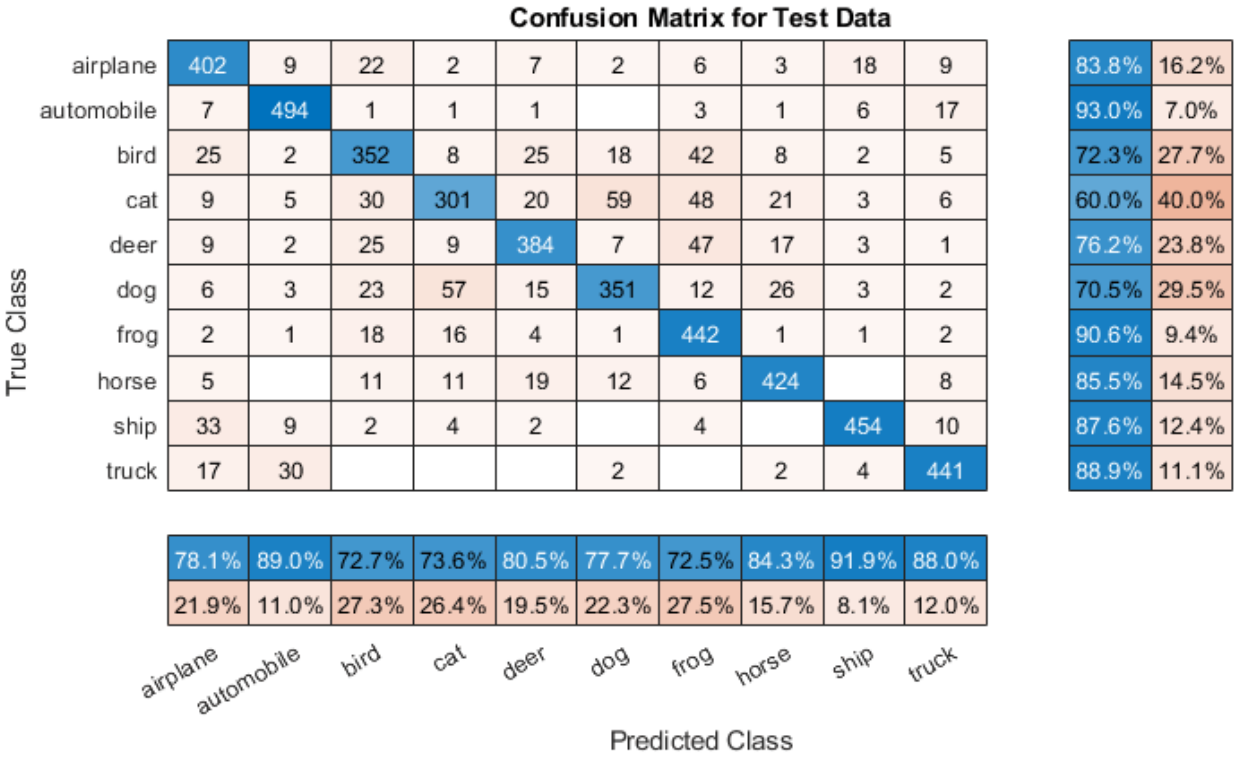
```
NTest = numel(YTest);
testErrorSE = sqrt(testError*(1-testError)/NTest);
testError95CI = [testError - 1.96*testErrorSE, testError + 1.96*testErrorSE]
```

```
testError95CI = 1×2

    0.1801    0.2019
```

Plot the confusion matrix for the test data. Display the precision and recall for each class by using column and row summaries.

```
figure('Units','normalized','Position',[0.2 0.2 0.4 0.4]);
cm = confusionchart(YTest,YPredicted);
cm.Title = 'Confusion Matrix for Test Data';
cm.ColumnSummary = 'column-normalized';
cm.RowSummary = 'row-normalized';
```



You can display some test images together with their predicted classes and the probabilities of those classes using the following code.

```
figure
idx = randperm(numel(YTest),9);
for i = 1:numel(idx)
    subplot(3,3,i)
    imshow(XTest(:,:,:,idx(i)));
    prob = num2str(100*max(probs(idx(i),:)),3);
    predClass = char(YPredicted(idx(i)));
    label = [predClass,', ',prob,'%'];
    title(label)
end
```

Objective Function for Optimization

Define the objective function for optimization. This function performs the following steps:

1. Takes the values of the optimization variables as inputs. `bayesopt` calls the objective function with the current values of the optimization variables in a table with each column name equal to the variable name. For example, the current value of the network section depth is `optVars.SectionDepth`.
2. Defines the network architecture and training options.
3. Trains and validates the network.
4. Saves the trained network, the validation error, and the training options to disk.
5. Returns the validation error and the file name of the saved network.

```
function ObjFcn = makeObjFcn(XTrain,YTrain,XValidation,YValidation)
ObjFcn = @valErrorFun;
    function [valError,cons,fileName] = valErrorFun(optVars)
```

Define the convolutional neural network architecture.

- Add padding to the convolutional layers so that the spatial output size is always the same as the input size.
- Each time you down-sample the spatial dimensions by a factor of two using max pooling layers, increase the number of filters by a factor of two. Doing so ensures that the amount of computation required in each convolutional layer is roughly the same.
- Choose the number of filters proportional to `1/sqrt(SectionDepth)`, so that networks of different depths have roughly the same number of parameters and require about the same amount of computation per iteration. To increase the number of network parameters and the overall network flexibility, increase `numF`. To train even deeper networks, change the range of the `SectionDepth` variable.
- Use `convBlock(filterSize,numFilters,numConvLayers)` to create a block of `numConvLayers` convolutional layers, each with a specified `filterSize` and `numFilters` filters, and each followed by a batch normalization layer and a ReLU layer. The `convBlock` function is defined at the end of this example.

```
    imageSize = [32 32 3];
    numClasses = numel(unique(YTrain));
    numF = round(16/sqrt(optVars.SectionDepth));
    layers = [
        imageInputLayer(imageSize)

        % The spatial input and output sizes of these convolutional
        % layers are 32-by-32, and the following max pooling layer
        % reduces this to 16-by-16.
        convBlock(3,numF,optVars.SectionDepth)
        maxPooling2dLayer(3,'Stride',2,'Padding','same')

        % The spatial input and output sizes of these convolutional
        % layers are 16-by-16, and the following max pooling layer
        % reduces this to 8-by-8.
        convBlock(3,2*numF,optVars.SectionDepth)
        maxPooling2dLayer(3,'Stride',2,'Padding','same')

        % The spatial input and output sizes of these convolutional
        % layers are 8-by-8. The global average pooling layer averages
        % over the 8-by-8 inputs, giving an output of size
        % 1-by-1-by-4*initialNumFilters. With a global average
        % pooling layer, the final classification output is only
        % sensitive to the total amount of each feature present in the
        % input image, but insensitive to the spatial positions of the
        % features.
        convBlock(3,4*numF,optVars.SectionDepth)
        averagePooling2dLayer(8)

        % Add the fully connected layer and the final softmax and
        % classification layers.
        fullyConnectedLayer(numClasses)
        softmaxLayer
        classificationLayer];
```

Specify options for network training. Optimize the initial learning rate, SGD momentum, and L2 regularization strength.

Specify validation data and choose the `'ValidationFrequency'` value such that `trainNetwork` validates the network once per epoch. Train for a fixed number of epochs and lower the learning rate by a factor of 10 during the last epochs. This reduces the noise of the parameter updates and lets the network parameters settle down closer to a minimum of the loss function.

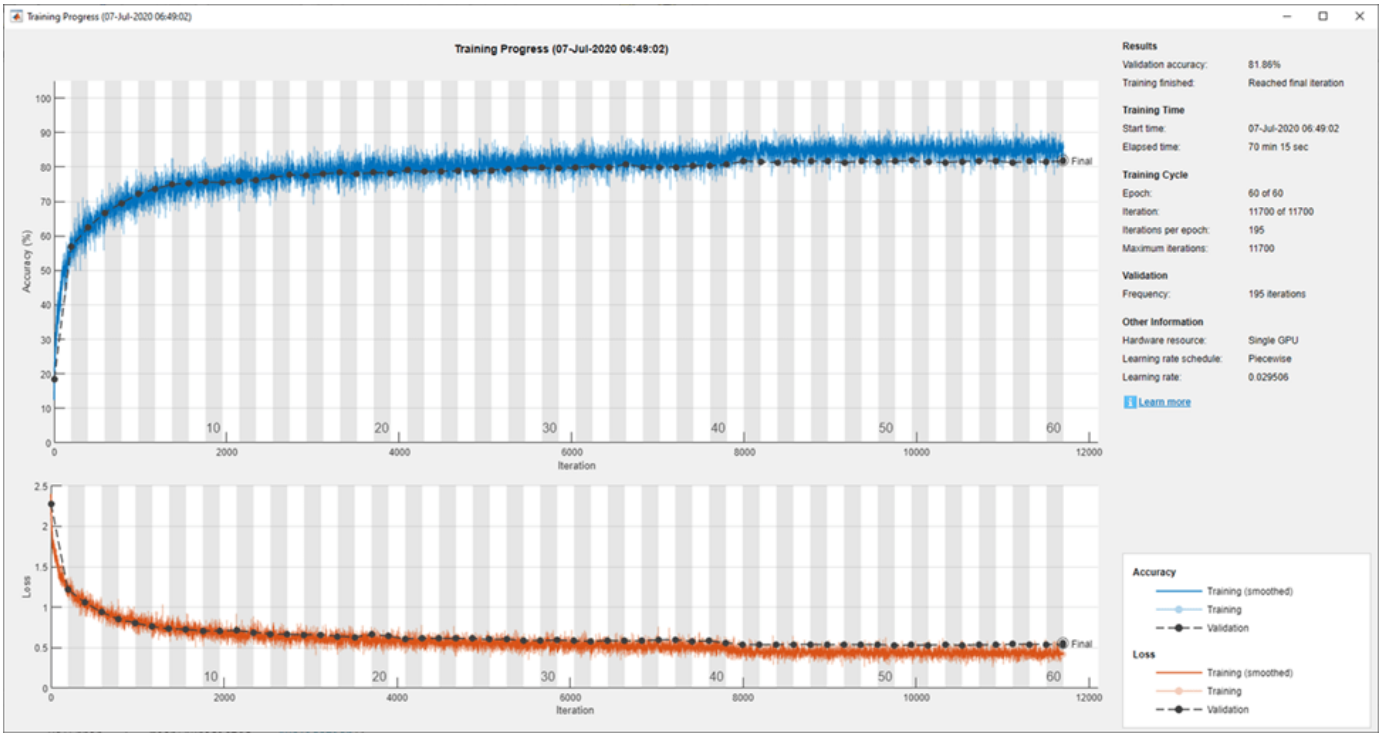
```
miniBatchSize = 256;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
options = trainingOptions('sgdm', ...
    'InitialLearnRate',optVars.InitialLearnRate, ...
    'Momentum',optVars.Momentum, ...
    'MaxEpochs',60, ...
    'LearnRateSchedule','piecewise', ...
    'LearnRateDropPeriod',40, ...
    'LearnRateDropFactor',0.1, ...
    'MiniBatchSize',miniBatchSize, ...
    'L2Regularization',optVars.L2Regularization, ...
    'Shuffle','every-epoch', ...
    'Verbose',false, ...
    'Plots','training-progress', ...
    'ValidationData',{XValidation,YValidation}, ...
    'ValidationFrequency',validationFrequency);
```

Use data augmentation to randomly flip the training images along the vertical axis, and randomly translate them up to four pixels horizontally and vertically. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
datasource = augmentedImageDatastore(imageSize,XTrain,YTrain,'DataAugmentation',imageAugr
```

Train the network and plot the training progress during training. Close all training plots after training finishes.

```
trainedNet = trainNetwork(datasource,layers,options);
close(findall(groot,'Tag','NNET_CNN_TRAININGPLOT_UIFIGURE'))
```



Evaluate the trained network on the validation set, calculate the predicted image labels, and calculate the error rate on the validation data.

```
        YPredicted = classify(trainedNet,XValidation);
        valError = 1 - mean(YPredicted == YValidation);
```

Create a file name containing the validation error, and save the network, validation error, and training options to disk. The objective function returns `fileName` as an output argument, and `bayesopt` returns all the file names in `BayesObject.UserDataTrace`. The additional required output argument `cons` specifies constraints among the variables. There are no variable constraints.

```
        fileName = num2str(valError) + ".mat";
        save(fileName,'trainedNet','valError','options')
        cons = [];

    end
end
```

The `convBlock` function creates a block of `numConvLayers` convolutional layers, each with a specified `filterSize` and `numFilters` filters, and each followed by a batch normalization layer and a ReLU layer.

```
function layers = convBlock(filterSize,numFilters,numConvLayers)
layers = [
    convolution2dLayer(filterSize,numFilters,'Padding','same')
    batchNormalizationLayer
    reluLayer];
```

```
layers = repmat(layers,numConvLayers,1);
end
```

Train Deep Learning Networks in Parallel

This example shows how to run multiple deep learning experiments on your local machine. Using this example as a template, you can modify the network layers and training options to suit your specific application needs. You can use this approach with a single or multiple GPUs. If you have a single GPU, the networks train one after the other in the background. The approach in this example enables you to continue using MATLAB® while deep learning experiments are in progress.

As an alternative, you can use Experiment Manager to interactively train multiple deep networks in parallel. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16.

Prepare Data Set

Before you can run the example, you must have access to a local copy of a deep learning data set. This example uses a data set with synthetic images of digits from 0 to 9. In the following code, change the location to point to your data set.

```
datasetLocation = fullfile(matlabroot,'toolbox','nnet', ...
    'nndemos','nndatasets','DigitDataset');
```

If you want to run the experiments with more resources, you can run this example in a cluster in the cloud.

- Upload the data set to an Amazon S3 bucket. For an example, see “Upload Deep Learning Data to the Cloud” on page 7-53.
- Create a cloud cluster. In MATLAB, you can create clusters in the cloud directly from the MATLAB Desktop. For more information, see “Create Cloud Cluster” (Parallel Computing Toolbox).
- Select your cloud cluster as the default, on the **Home** tab, in the **Environment** section, select **Parallel > Select a Default Cluster**.

Load Data Set

Load the data set by using an `imageDatastore` object. Split the data set into training, validation, and test sets.

```
imds = imageDatastore(datasetLocation, ...
 'IncludeSubfolders',true, ...
 'LabelSource','foldernames');

[imdsTrain,imdsValidation,imdsTest] = splitEachLabel(imds,0.8,0.1);
```

To train the network with augmented image data, create an `augmentedImageDatastore`. Use random translations and horizontal reflections. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
imageSize = [28 28 1];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augmentedImdsTrain = augmentedImageDatastore(imageSize,imdsTrain, ...
    'DataAugmentation',imageAugmenter);
```

Train Networks in Parallel

Start a parallel pool with as many workers as GPUs. You can check the number of available GPUs by using the `gpuDeviceCount` (Parallel Computing Toolbox) function. MATLAB assigns a different GPU to each worker. By default, `parpool` uses your default cluster profile. If you have not changed the default, it is `local`. This example was run using a machine with 2 GPUs.

```
numGPUs = gpuDeviceCount("available");
parpool(numGPUs);
```

```
Starting parallel pool (parpool) using the 'local' profile ...
Connected to the parallel pool (number of workers: 2).
```

To send training progress information from the workers during training, use a `parallel.pool.DataQueue` (Parallel Computing Toolbox) object. To learn more about how to use data queues to obtain feedback during training, see the example “Use parfeval to Train Multiple Deep Learning Networks” on page 7-32.

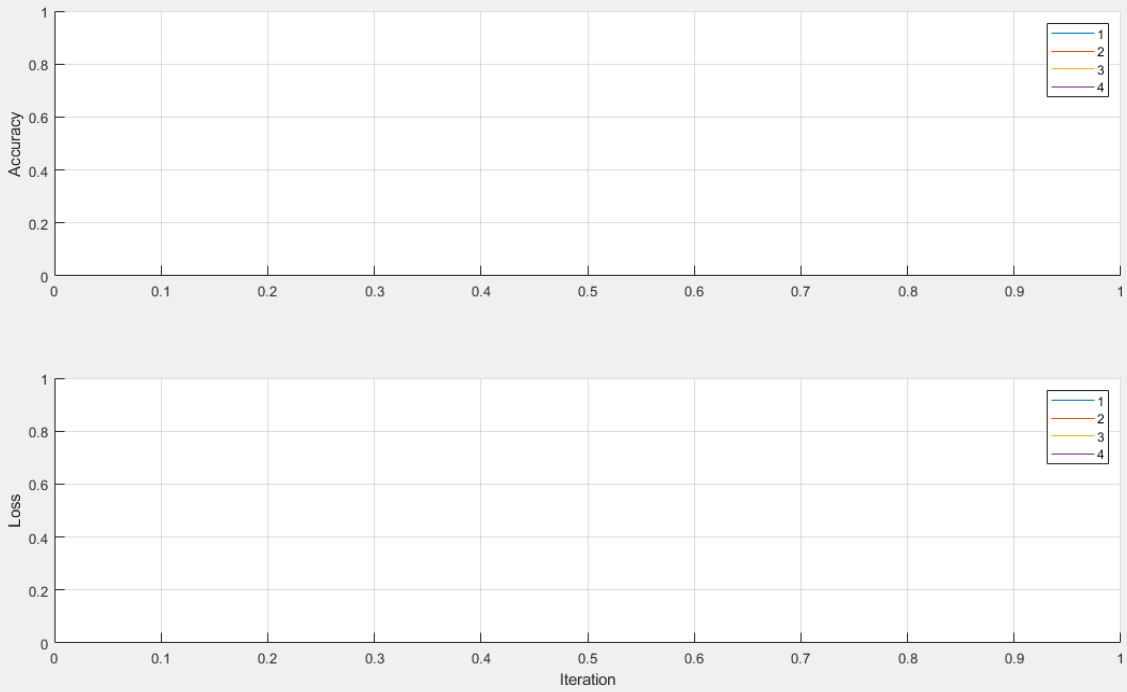
```
dataqueue = parallel.pool.DataQueue;
```

Define the network layers and training options. For code readability, you can define them in a separate function that returns several network architectures and training options. In this case, `networkLayersAndOptions` returns a cell array of network layers and an array of training options of the same length. Open this example in MATLAB and then click `networkLayersAndOptions` to open the supporting function `networkLayersAndOptions`. Paste in your own network layers and options. The file contains sample training options that show how to send information to the data queue using an output function.

```
[layersCell,options] = networkLayersAndOptions(augmentedImdsTrain,imdsValidation,dataqueue);
```

Prepare the training progress plots, and set a callback function to update these plots after each worker sends data to the queue. `preparePlots` and `updatePlots` are supporting functions for this example.

```
handles = preparePlots(numel(layersCell));
```



```
afterEach(dataqueue,@(data) updatePlots(handles,data));
```

To hold the computation results in parallel workers, use future objects. Preallocate an array of future objects for the result of each training.

```
trainingFuture(1:numel(layersCell)) = parallel.FevalFuture;
```

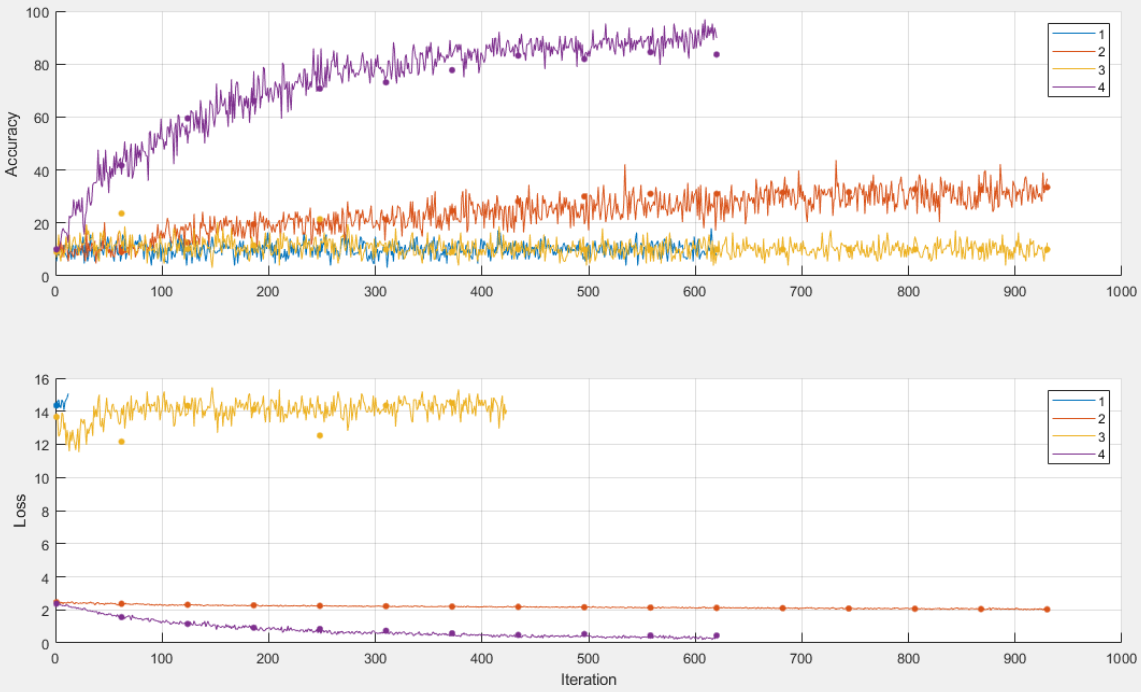
Loop through the network layers and options by using a `for` loop, and use `parfeval` (Parallel Computing Toolbox) to train the networks on a parallel worker. To request two output arguments from `trainNetwork`, specify 2 as the second input argument to `parfeval`.

```
for i=1:numel(layersCell)
    trainingFuture(i) = parfeval(@trainNetwork,2,augmentedImdsTrain,layersCell{i},options(i));
end
```

`parfeval` does not block MATLAB, so you can continue working while the computations take place.

To fetch results from future objects, use the `fetchOutputs` function. For this example, fetch the trained networks and their training information. `fetchOutputs` blocks MATLAB until the results are available. This step can take a few minutes.

```
[network,trainingInfo] = fetchOutputs(trainingFuture);
```



Save the results to disk using the `save` function. To load the results again later, use the `load` function. Use `sprintf` and `datetime` to name the file using the current date and time.

```
filename = sprintf('experiment-%s',datetime('now','Format','yyyyMMdd''T''HHmmss'));
save(filename,'network','trainingInfo');
```

Plot Results

After the networks complete training, plot their training progress by using the information in `trainingInfo`.

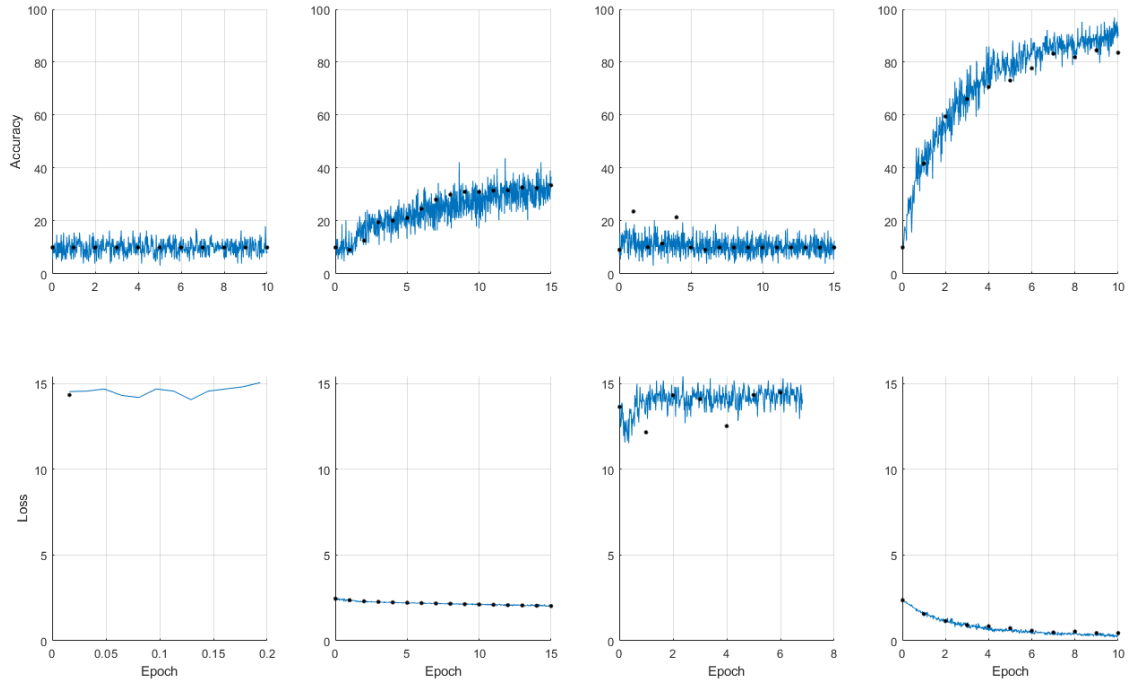
Use subplots to distribute the different plots for each network. For this example, use the first row of subplots to plot the training accuracy against the number of epoch along with the validation accuracy.

```
figure('Units','normalized','Position',[0.1 0.1 0.6 0.6]);
title('Training Progress Plots');

for i=1:numel(layersCell)
    subplot(2,numel(layersCell),i);
    hold on; grid on;
    ylim([0 100]);
    iterationsPerEpoch = floor(augmentedImdsTrain.NumObservations/options(i).MiniBatchSize);
    epoch = (1:numel(trainingInfo(i).TrainingAccuracy))/iterationsPerEpoch;
    plot(epoch,trainingInfo(i).TrainingAccuracy);
    plot(epoch,trainingInfo(i).ValidationAccuracy,'.k','MarkerSize',10);
end
subplot(2,numel(layersCell),1), ylabel('Accuracy');
```

Then, use the second row of subplots to plot the training loss against the number of epoch along with the validation loss.

```
for i=1:numel(layersCell)
    subplot(2,numel(layersCell),numel(layersCell) + i);
    hold on; grid on;
    ylim([0 max([trainingInfo.TrainingLoss])]);
    iterationsPerEpoch = floor(augmentedImdsTrain.NumObservations/options(i).MiniBatchSize);
    epoch = (1:numel(trainingInfo(i).TrainingAccuracy))/iterationsPerEpoch;
    plot(epoch,trainingInfo(i).TrainingLoss);
    plot(epoch,trainingInfo(i).ValidationLoss,'.k','MarkerSize',10);
    xlabel('Epoch');
end
subplot(2,numel(layersCell),numel(layersCell)+1), ylabel('Loss');
```



After you choose a network, you can use `classify` and obtain its accuracy on the test data `imdsTest`.

Monitor Deep Learning Training Progress

When you train networks for deep learning, it is often useful to monitor the training progress. By plotting various metrics during training, you can learn how the training is progressing. For example, you can determine if and how quickly the network accuracy is improving, and whether the network is starting to overfit the training data.

When you specify `'training-progress'` as the `'Plots'` value in `trainingOptions` and start network training, `trainNetwork` creates a figure and displays training metrics at every iteration. Each iteration is an estimation of the gradient and an update of the network parameters. If you specify validation data in `trainingOptions`, then the figure shows validation metrics each time `trainNetwork` validates the network. The figure plots the following:

- **Training accuracy** — Classification accuracy on each individual mini-batch.
- **Smoothed training accuracy** — Smoothed training accuracy, obtained by applying a smoothing algorithm to the training accuracy. It is less noisy than the unsmoothed accuracy, making it easier to spot trends.
- **Validation accuracy** — Classification accuracy on the entire validation set (specified using `trainingOptions`).
- **Training loss**, **smoothed training loss**, and **validation loss** — The loss on each mini-batch, its smoothed version, and the loss on the validation set, respectively. If the final layer of your network is a `classificationLayer`, then the loss function is the cross entropy loss. For more information about loss functions for classification and regression problems, see “Output Layers” on page 1-39.

For regression networks, the figure plots the root mean square error (RMSE) instead of the accuracy.

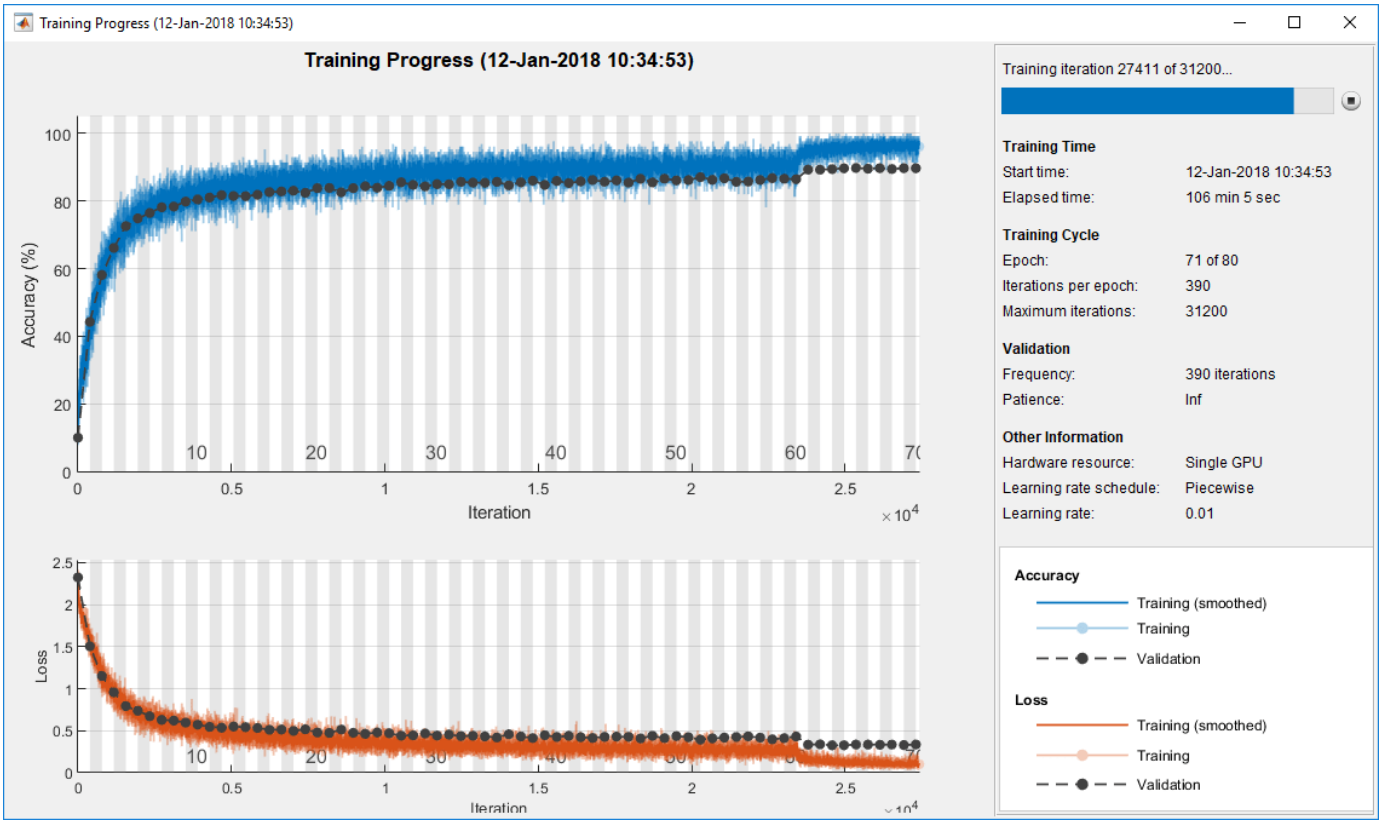
The figure marks each training **Epoch** using a shaded background. An epoch is a full pass through the entire data set.

During training, you can stop training and return the current state of the network by clicking the stop button in the top-right corner. For example, you might want to stop training when the accuracy of the network reaches a plateau and it is clear that the accuracy is no longer improving. After you click the stop button, it can take a while for the training to complete. Once training is complete, `trainNetwork` returns the trained network.

When training finishes, view the **Results** showing the finalized validation accuracy and the reason that training finished. If the `'OutputNetwork'` training option is set to `'last-iteration'` (default), the finalized metrics correspond to the last training iteration. If the `'OutputNetwork'` training option is set to `'best-validation-loss'`, the finalized metrics correspond to the iteration with the lowest validation loss. The iteration from which the final validation metrics are calculated is labeled **Final** in the plots.

If your network contains batch normalization layers, then the final validation metrics can be different to the validation metrics evaluated during training. This is because the mean and variance statistics used for batch normalization can be different after training completes. For example, if the `'BatchNormalizationStatisics'` training option is `'population'`, then after training, the software finalizes the batch normalization statistics by passing through the training data once more and uses the resulting mean and variance. If the `'BatchNormalizationStatisics'` training option is `'moving'`, then the software approximates the statistics during training using a running estimate and uses the latest values of the statistics.

On the right, view information about the training time and settings. To learn more about training options, see “Set Up Parameters and Train Convolutional Neural Network” on page 1-42.



Plot Training Progress During Training

Train a network and plot the training progress during training.

Load the training data, which contains 5000 images of digits. Set aside 1000 of the images for network validation.

```
[XTrain,YTrain] = digitTrain4DArrayData;

idx = randperm(size(XTrain,4),1000);
XValidation = XTrain(:,:,:,idx);
XTrain(:,:,:,idx) = [];
YValidation = YTrain(idx);
YTrain(idx) = [];
```

Construct a network to classify the digit image data.

```
layers = [
    imageInputLayer([28 28 1])

    convolution2dLayer(3,8,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(2,'Stride',2)
```

```
    convolution2dLayer(3,16,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,32,'Padding','same')
    batchNormalizationLayer
    reluLayer

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer];
```

Specify options for network training. To validate the network at regular intervals during training, specify validation data. Choose the `'ValidationFrequency'` value so that the network is validated about once per epoch. To plot training progress during training, specify `'training-progress'` as the `'Plots'` value.

```
options = trainingOptions('sgdm', ...
    'MaxEpochs',8, ...
    'ValidationData',{XValidation,YValidation}, ...
    'ValidationFrequency',30, ...
    'Verbose',false, ...
    'Plots','training-progress');
```

Train the network.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```

Customize Output During Deep Learning Network Training

This example shows how to define an output function that runs at each iteration during training of deep learning neural networks. If you specify output functions by using the `'OutputFcn'` name-value pair argument of `trainingOptions`, then `trainNetwork` calls these functions once before the start of training, after each training iteration, and once after training has finished. Each time the output functions are called, `trainNetwork` passes a structure containing information such as the current iteration number, loss, and accuracy. You can use output functions to display or plot progress information, or to stop training. To stop training early, make your output function return `true`. If any output function returns `true`, then training finishes and `trainNetwork` returns the latest network.

To stop training when the loss on the validation set stops decreasing, simply specify validation data and a validation patience using the `'ValidationData'` and the `'ValidationPatience'` name-value pair arguments of `trainingOptions`, respectively. The validation patience is the number of times that the loss on the validation set can be larger than or equal to the previously smallest loss before network training stops. You can add additional stopping criteria using output functions. This example shows how to create an output function that stops training when the classification accuracy on the validation data stops improving. The output function is defined at the end of the script.

Load the training data, which contains 5000 images of digits. Set aside 1000 of the images for network validation.

```
[XTrain,YTrain] = digitTrain4DArrayData;

idx = randperm(size(XTrain,4),1000);
XValidation = XTrain(:,:,:,idx);
XTrain(:,:,:,idx) = [];
YValidation = YTrain(idx);
YTrain(idx) = [];
```

Construct a network to classify the digit image data.

```
layers = [
    imageInputLayer([28 28 1])

    convolution2dLayer(3,8,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,16,'Padding','same')
    batchNormalizationLayer
    reluLayer

    maxPooling2dLayer(2,'Stride',2)

    convolution2dLayer(3,32,'Padding','same')
    batchNormalizationLayer
    reluLayer

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer];
```

Specify options for network training. To validate the network at regular intervals during training, specify validation data. Choose the `'ValidationFrequency'` value so that the network is validated once per epoch.

To stop training when the classification accuracy on the validation set stops improving, specify `stopIfAccuracyNotImproving` as an output function. The second input argument of `stopIfAccuracyNotImproving` is the number of times that the accuracy on the validation set can be smaller than or equal to the previously highest accuracy before network training stops. Choose any large value for the maximum number of epochs to train. Training should not reach the final epoch because training stops automatically.

```
miniBatchSize = 128;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
options = trainingOptions('sgdm', ...
    'InitialLearnRate',0.01, ...
    'MaxEpochs',100, ...
    'MiniBatchSize',miniBatchSize, ...
    'VerboseFrequency',validationFrequency, ...
    'ValidationData',{XValidation,YValidation}, ...
    'ValidationFrequency',validationFrequency, ...
    'Plots','training-progress', ...
    'OutputFcn',@(info)stopIfAccuracyNotImproving(info,3));
```

Train the network. Training stops when the validation accuracy stops increasing.

```
net = trainNetwork(XTrain,YTrain,layers,options);
```

```
Training on single CPU.
Initializing input data normalization.

|=========================================================================================================
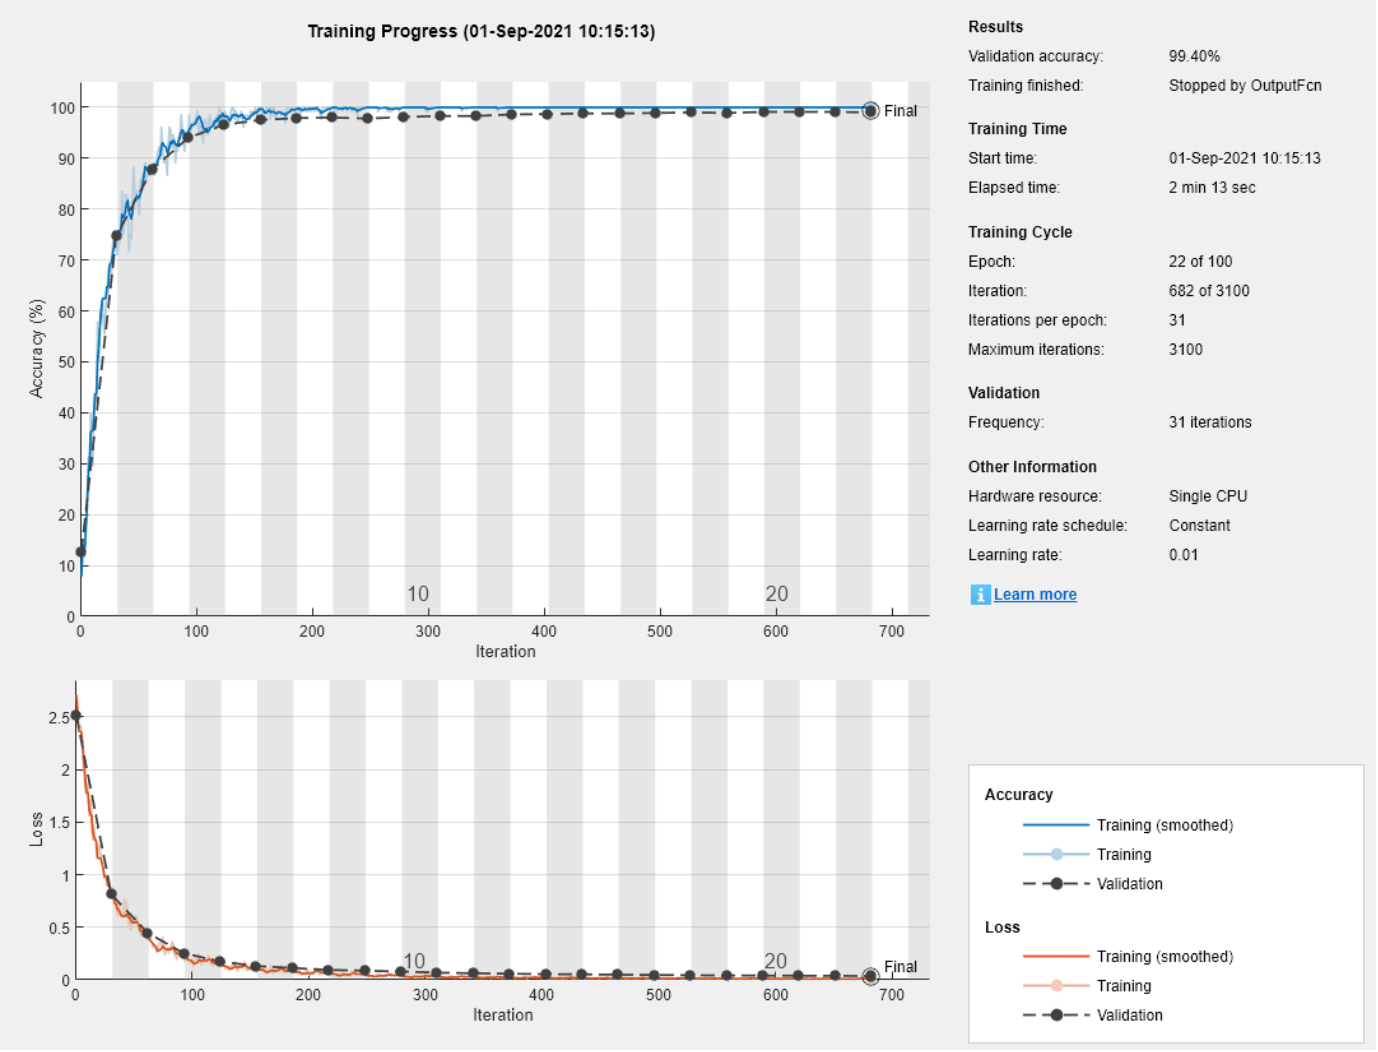
Training finished: Stopped by OutputFcn.
```



Define Output Function

Define the output function `stopIfAccuracyNotImproving(info,N)`, which stops network training if the best classification accuracy on the validation data does not improve for `N` network validations in a row. This criterion is similar to the built-in stopping criterion using the validation loss, except that it applies to the classification accuracy instead of the loss.

```
function stop = stopIfAccuracyNotImproving(info,N)

stop = false;

% Keep track of the best validation accuracy and the number of validations for which
% there has not been an improvement of the accuracy.
persistent bestValAccuracy
persistent valLag

% Clear the variables when training starts.
if info.State == "start"
    bestValAccuracy = 0;
    valLag = 0;
```

```
elseif ~isempty(info.ValidationLoss)

    % Compare the current validation accuracy to the best accuracy so far,
    % and either set the best accuracy to the current accuracy, or increase
    % the number of validations for which there has not been an improvement.
    if info.ValidationAccuracy > bestValAccuracy
        valLag = 0;
        bestValAccuracy = info.ValidationAccuracy;
    else
        valLag = valLag + 1;
    end

    % If the validation lag is at least N, that is, the validation accuracy
    % has not improved for at least N validations, then return true and
    % stop training.
    if valLag >= N
        stop = true;
    end

end

end
```

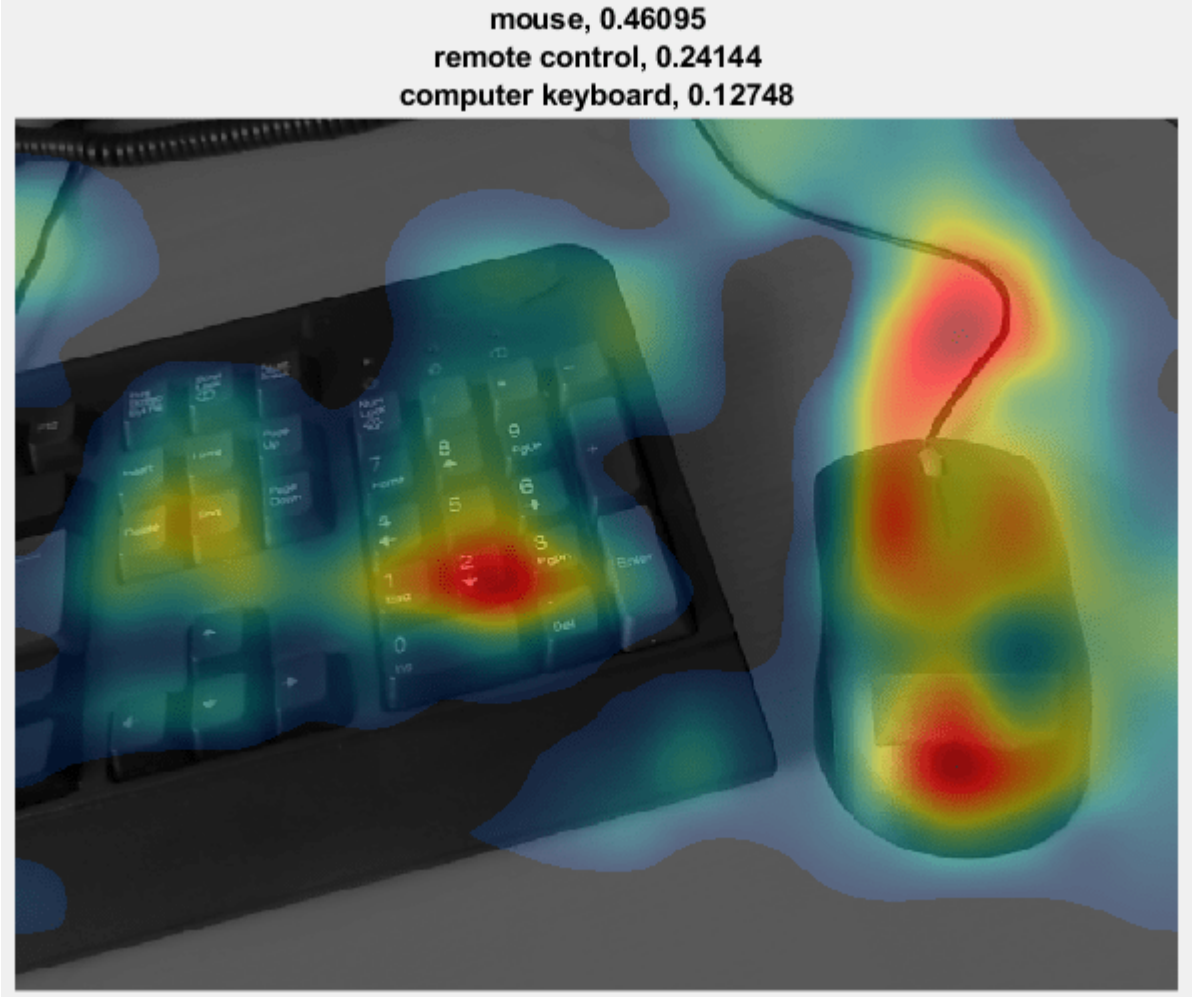
Investigate Network Predictions Using Class Activation Mapping

This example shows how to use class activation mapping (CAM) to investigate and explain the predictions of a deep convolutional neural network for image classification.

Deep learning networks are often considered to be "black boxes" that offer no way of figuring out what a network has learned or which part of an input to the network was responsible for the prediction of the network. When these models fail and give incorrect predictions, they often fail spectacularly without any warning or explanation. Class activation mapping [1] is one technique that you can use to get visual explanations of the predictions of convolutional neural networks. Incorrect, seemingly unreasonable predictions can often have reasonable explanations. Using class activation mapping, you can check if a specific part of an input image "confused" the network and led it to make an incorrect prediction.

You can use class activation mapping to identify bias in the training set and increase model accuracy. If you discover that the network bases predictions on the wrong features, then you can make the network more robust by collecting better data. For example, suppose that you train a network to distinguish images of cats and dogs. The network has high accuracy on the training set, but performs poorly on real-world examples. By using class activation mapping on the training examples, you discover that the network is basing predictions not on the cats and dogs in the images, but on the backgrounds. You then realize that all your cat pictures have red backgrounds, all your dog pictures have green backgrounds, and that it is the color of the background that the network learned during training. You can then collect new data that does not have this bias.

This example class activation map shows which regions of the input image contribute the most to the predicted class `mouse`. Red regions contribute the most.



Load Pretrained Network and Webcam

Load a pretrained convolutional neural network for image classification. SqueezeNet, GoogLeNet, ResNet-18, and MobileNet-v2 are relatively fast networks. SqueezeNet is the fastest network and its class activation map has four times higher resolution than the maps of the other networks. You cannot use class activation mapping with networks that have multiple fully connected layers at the end of the network, such as AlexNet, VGG-16, and VGG-19.

```
netName = "squeezenet";
net = eval(netName);
```

Create a `webcam` object and connect to your webcam.

```
camera = webcam;
```

Extract the image input size and the output classes of the network. The `activationLayerName` helper function, defined at the end of this example, returns the name of the layer to extract the activations from. This layer is the ReLU layer that follows the last convolutional layer of the network.

```
inputSize = net.Layers(1).InputSize(1:2);
classes = net.Layers(end).Classes;
layerName = activationLayerName(netName);
```

Display Class Activation Maps

Create a figure and perform class activation mapping in a loop. To terminate execution of the loop, close the figure.

```
h = figure('Units','normalized','Position',[0.05 0.05 0.9 0.8],'Visible','on');

while ishandle(h)
```

Take a snapshot using the webcam. Resize the image so that the length of its shortest side (in this case, the image height) equals the image input size of the network. As you resize, preserve the aspect ratio of the image. You can also resize the image to a larger or smaller size. Making the image larger increases the resolution of the final class activation map, but can lead to less accurate overall predictions.

Compute the activations of the resized image in the ReLU layer that follows the last convolutional layer of the network.

```
    im = snapshot(camera);
    imResized = imresize(im,[inputSize(1), NaN]);
    imageActivations = activations(net,imResized,layerName);
```

The class activation map for a specific class is the activation map of the ReLU layer that follows the final convolutional layer, weighted by how much each activation contributes to the final score of that class. Those weights equal the weights of the final fully connected layer of the network for that class. SqueezeNet does not have a final fully connected layer. Instead, the output of the ReLU layer that follows the last convolutional layer is already the class activation map.

You can generate a class activation map for any output class. For example, if the network makes an incorrect classification, you can compare the class activation maps for the true and predicted classes. For this example, generate the class activation map for the predicted class with the highest score.

```
    scores = squeeze(mean(imageActivations,[1 2]));

    if netName ~= "squeezenet"
        fcWeights = net.Layers(end-2).Weights;
        fcBias = net.Layers(end-2).Bias;
        scores =  fcWeights*scores + fcBias;

        [~,classIds] = maxk(scores,3);

        weightVector = shiftdim(fcWeights(classIds(1),:),-1);
        classActivationMap = sum(imageActivations.*weightVector,3);
    else
        [~,classIds] = maxk(scores,3);
        classActivationMap = imageActivations(:,:,classIds(1));
    end
```

Calculate the top class labels and the final normalized class scores.

```
    scores = exp(scores)/sum(exp(scores));
    maxScores = scores(classIds);
    labels = classes(classIds);
```

Plot the class activation map. Display the original image in the first subplot. In the second subplot, use the `CAMshow` helper function, defined at the end of this example, to display the class activation map on top of a darkened grayscale version of the original image. Display the top three predicted labels with their predicted scores.

```
    subplot(1,2,1)
    imshow(im)

    subplot(1,2,2)
    CAMshow(im,classActivationMap)
    title(string(labels) + ", " + string(maxScores));

    drawnow

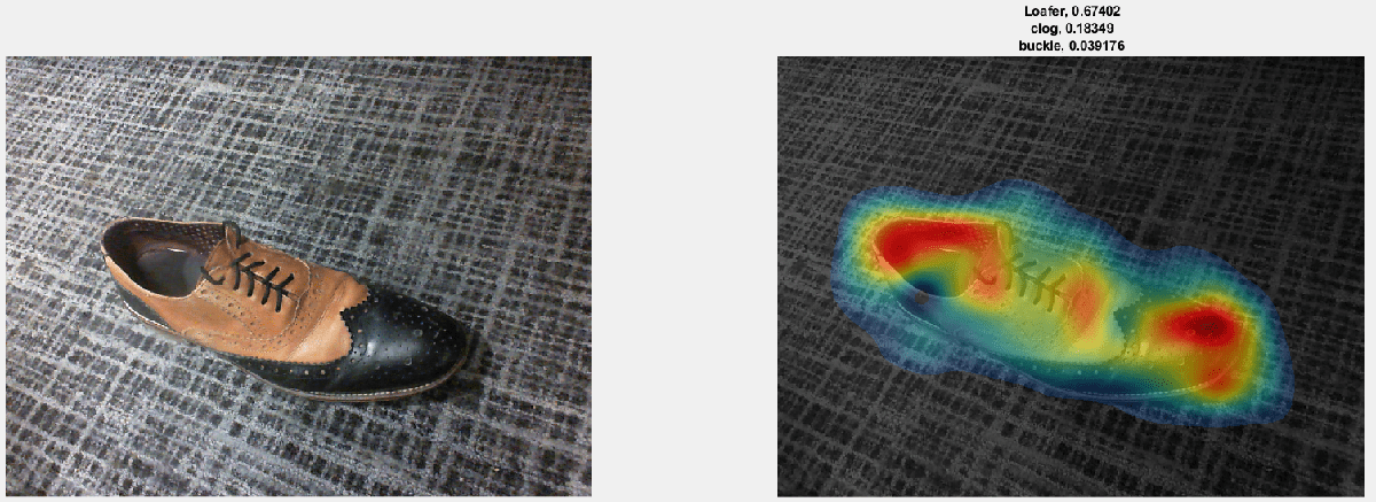
end
```

Clear the webcam object.

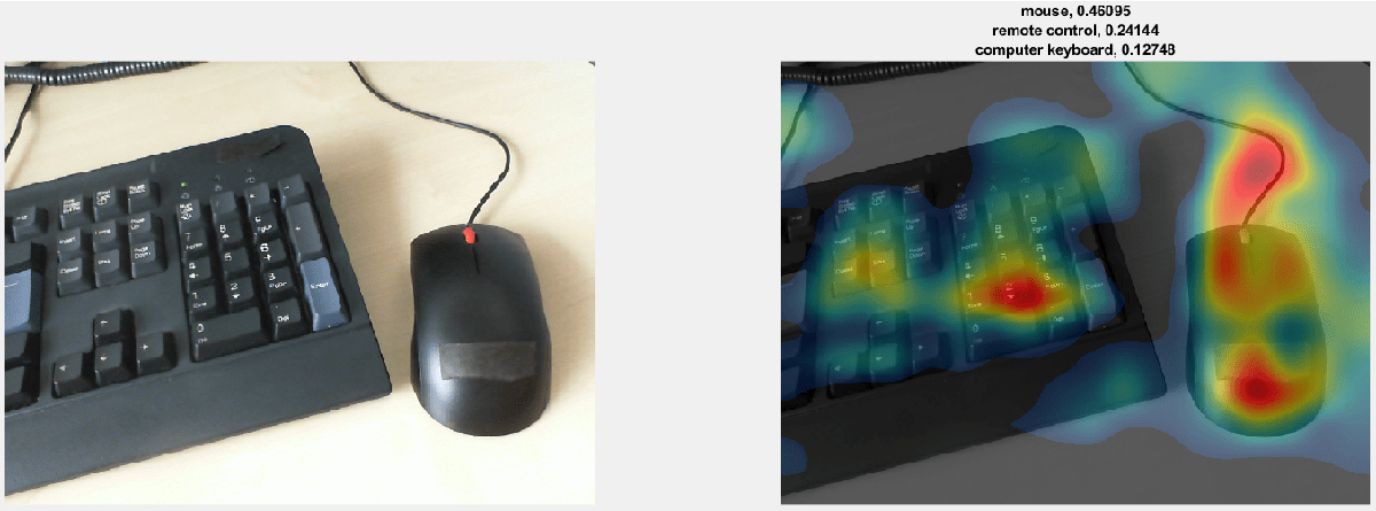
```
clear camera
```

Example Maps

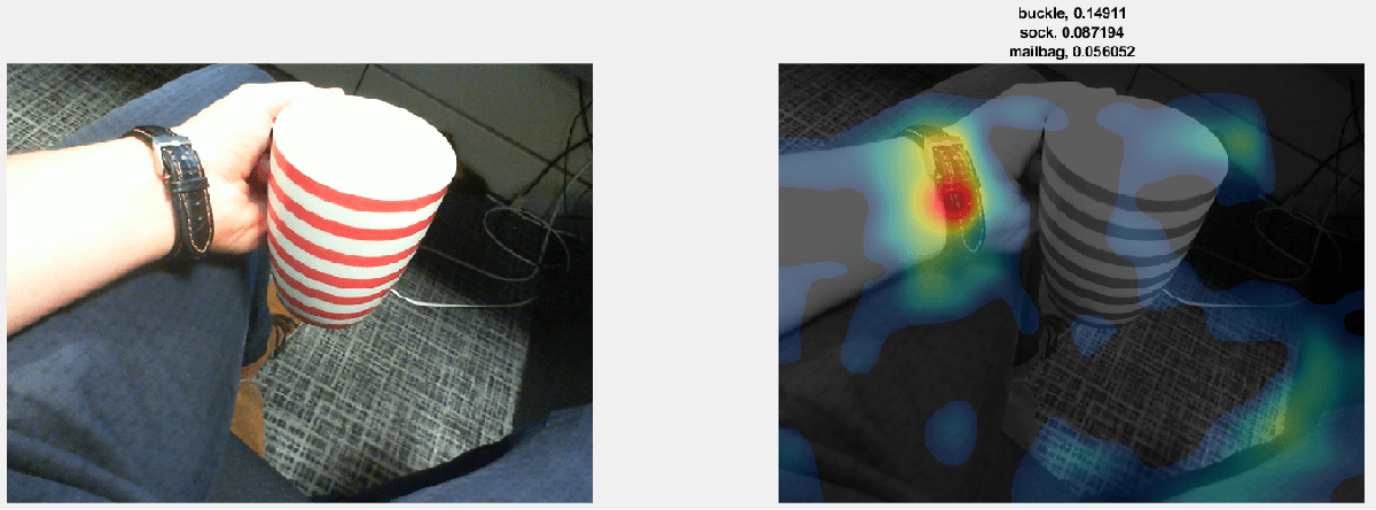
The network correctly identifies the object in this image as a loafer (a type of shoe). The class activation map in the image to the right shows the contribution of each region of the input image to the predicted class `Loafer`. Red regions contribute the most. The network bases its classification on the entire shoe, but the strongest input comes from the red areas – that is, the tip and the opening of the shoe.



The network classifies this image as a mouse. As the class activation map shows, the prediction is based not only on the mouse in the image, but also the keyboard. Because the training set likely has many images of mice next to keyboards, the network predicts that images containing keyboards are more likely to contain mice.



The network classifies this image of a coffee cup as a buckle. As the class activation map shows, the network misclassifies the image because the image contains too many confounding objects. The network detects and focuses on the watch wristband, not the coffee cup.



Helper Functions

`CAMshow(im,CAM)` overlays the class activation map `CAM` on a darkened, grayscale version of the image `im`. The function resizes the class activation map to the size of `im`, normalizes it, thresholds it from below, and visualizes it using a `jet` colormap.

```
function CAMshow(im,CAM)
imSize = size(im);
CAM = imresize(CAM,imSize(1:2));
CAM = normalizeImage(CAM);
CAM(CAM<0.2) = 0;
cmap = jet(255).*linspace(0,1,255)';
CAM = ind2rgb(uint8(CAM*255),cmap)*255;

combinedImage = double(rgb2gray(im))/2 + CAM;
combinedImage = normalizeImage(combinedImage)*255;
```

```
imshow(uint8(combinedImage));
end

function N = normalizeImage(I)
minimum = min(I(:));
maximum = max(I(:));
N = (I-minimum)/(maximum-minimum);
end

function layerName = activationLayerName(netName)

if netName == "squeezenet"
    layerName = 'relu_conv10';
elseif netName == "googlenet"
    layerName = 'inception_5b-output';
elseif netName == "resnet18"
    layerName = 'res5b_relu';
elseif netName == "mobilenetv2"
    layerName = 'out_relu';
end

end
```

View Network Behavior Using tsne

This example shows how to use the `tsne` function to view activations in a trained network. This view can help you understand how a network works.

The `tsne` (Statistics and Machine Learning Toolbox) function in Statistics and Machine Learning Toolbox™ implements t-distributed stochastic neighbor embedding (t-SNE) [1]. This technique maps high-dimensional data (such as network activations in a layer) to two dimensions. The technique uses a nonlinear map that attempts to preserve distances. By using t-SNE to visualize the network activations, you can gain an understanding of how the network responds.

You can use t-SNE to visualize how deep learning networks change the representation of input data as it passes through the network layers. You can also use t-SNE to find issues with the input data and to understand which observations the network classifies incorrectly.

For example, t-SNE can reduce the multidimensional activations of a softmax layer to a 2-D representation with a similar structure. Tight clusters in the resulting t-SNE plot correspond to classes that the network usually classifies correctly. The visualization allows you to find points that appear in the wrong cluster, indicating an observation that the network classifies incorrectly. The observation might be labeled incorrectly, or the network might predict that an observation is an instance of a different class because it appears similar to other observations from that class. Note that the t-SNE reduction of the softmax activations uses only those activations, not the underlying observations.

Download Data Set

This example uses the Example Food Images data set, which contains 978 photographs of food in nine classes and is approximately 77 MB in size. Download the data set into your temporary directory by calling the `downloadExampleFoodImagesData` helper function; the code for this helper function appears at the end of this example on page 5-0 .

```
dataDir = fullfile(tempdir, "ExampleFoodImageDataset");
url = "https://www.mathworks.com/supportfiles/nnet/data/ExampleFoodImageDataset.zip";

if ~exist(dataDir, "dir")
    mkdir(dataDir);
end

downloadExampleFoodImagesData(url,dataDir);
```

```
Downloading MathWorks Example Food Image dataset...
This can take several minutes to download...
Download finished...
Unzipping file...
Unzipping finished...
Done.
```

Train Network to Classify Food Images

Modify the SqueezeNet pretrained network to classify images of food from the data set. Replace the final convolutional layer, which has 1000 filters for the 1000 classes of ImageNet, with a new convolutional layer that has only nine filters. Each filter corresponds to a single type of food.

```
lgraph = layerGraph(squeezenet());
lgraph = lgraph.replaceLayer("ClassificationLayer_predictions",...
    classificationLayer("Name", "ClassificationLayer_predictions"));
```

```
newConv =  convolution2dLayer([14 14], 9, "Name", "conv", "Padding", "same");
lgraph = lgraph.replaceLayer("conv10", newConv);
```

Create an `imageDatastore` containing paths to the image data. Split the datastore into training and validation sets, using 65% of the data for training and the rest for validation. Because the data set is fairly small, overfitting is a significant issue. To minimize overfitting, augment the training set with random flips and scaling.

```
imds = imageDatastore(dataDir, ...
    "IncludeSubfolders", true, "LabelSource", "foldernames");

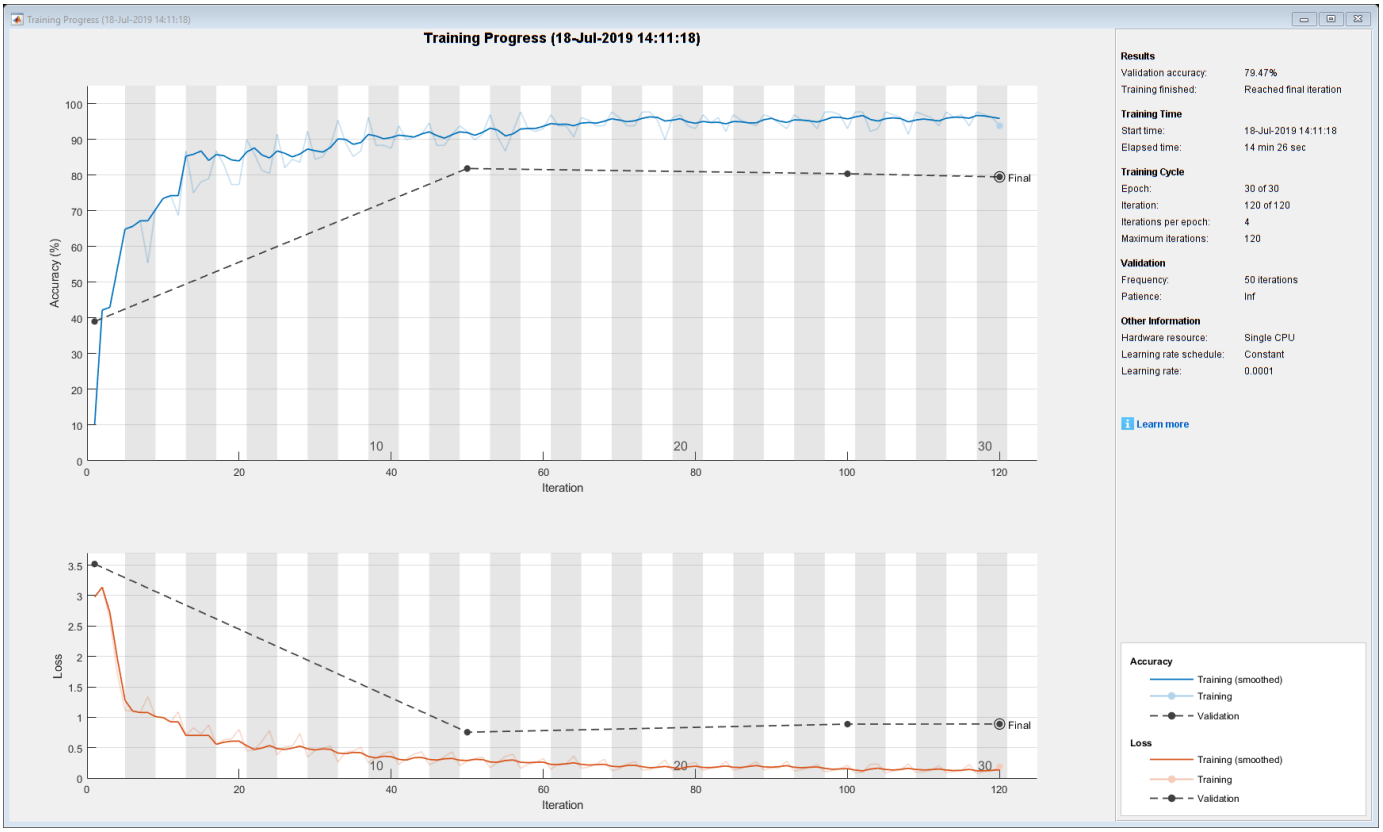
aug = imageDataAugmenter("RandXReflection", true, ...
    "RandYReflection", true, ...
    "RandXScale", [0.8 1.2], ...
    "RandYScale", [0.8 1.2]);

trainingFraction = 0.65;
[trainImds,valImds] = splitEachLabel(imds, trainingFraction);

augImdsTrain = augmentedImageDatastore([227 227], trainImds, ...
    'DataAugmentation', aug);
augImdsVal = augmentedImageDatastore([227 227], valImds);
```

Create training options and train the network. SqueezeNet is a small network that is quick to train. You can train on a GPU or a CPU; this example trains on a CPU.

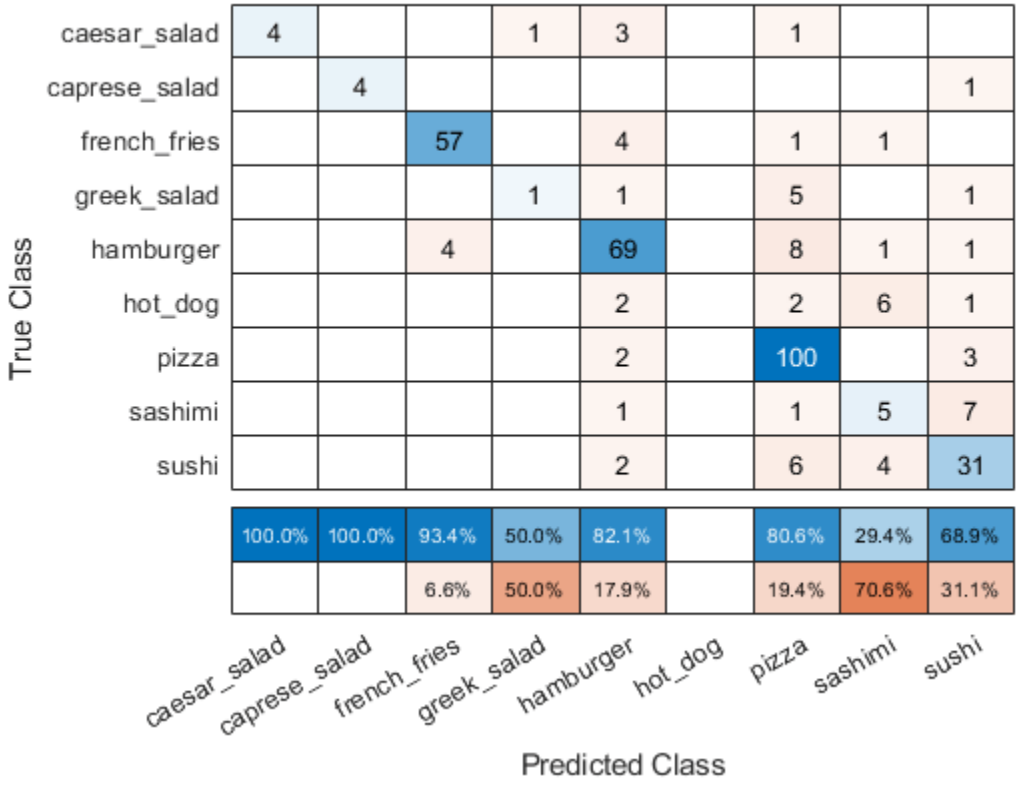
```
opts = trainingOptions("adam", ...
    "InitialLearnRate", 1e-4, ...
    "MaxEpochs", 30, ...
    "ValidationData", augImdsVal, ...
    "Verbose", false,...
    "Plots", "training-progress", ...
    "ExecutionEnvironment","cpu",...
    "MiniBatchSize",128);
rng default
net = trainNetwork(augImdsTrain, lgraph, opts);
```



Classify Validation Data

Use the network to classify images in the validation set. To verify that the network is reasonably accurate at classifying new data, plot a confusion matrix of the true and predicted labels.

```
figure();
YPred = classify(net,augImdsVal);
confusionchart(valImds.Labels,YPred,'ColumnSummary',"column-normalized")
```



The network classifies several images well. The network appears to have trouble with sushi images, classifying many as sushi but some as pizza or hamburger. The network does not classify any images into the hot dog class.

Compute Activations for Several Layers

To continue to analyze the network performance, compute activations for every observation in the data set at an early max pooling layer, the final convolutional layer, and the final softmax layer. Output the activations as an NxM matrix, where N is the number of observations and M is the number of dimensions of the activation. M is the product of spatial and channel dimensions. Each row is an observation, and each column is a dimension. At the softmax layer M = 9, because the food data set has nine classes. Each row in the matrix contains nine elements, corresponding to the probabilities that an observation belongs to each of the nine classes of food.

```
earlyLayerName = "pool1";
finalConvLayerName = "conv";
softmaxLayerName = "prob";
pool1Activations = activations(net,...
    augImdsVal,earlyLayerName,"OutputAs","rows");
finalConvActivations = activations(net,...
    augImdsVal,finalConvLayerName,"OutputAs","rows");
softmaxActivations = activations(net,...
    augImdsVal,softmaxLayerName,"OutputAs","rows");
```

Ambiguity of Classifications

You can use the softmax activations to calculate the image classifications that are most likely to be incorrect. Define the *ambiguity* of a classification as the ratio of the second-largest probability to the largest probability. The ambiguity of a classification is between zero (nearly certain classification) and 1 (nearly as likely to be classified to the most likely class as the second class). An ambiguity of near 1 means the network is unsure of the class in which a particular image belongs. This uncertainty might be caused by two classes whose observations appear so similar to the network that it cannot learn the differences between them. Or, a high ambiguity can occur because a particular observation contains elements of more than one class, so the network cannot decide which classification is correct. Note that low ambiguity does not necessarily imply correct classification; even if the network has a high probability for a class, the classification can still be incorrect.

```
[R,RI] = maxk(softmaxActivations,2,2);
ambiguity = R(:,2)./R(:,1);
```

Find the most ambiguous images.

```
[ambiguity,ambiguityIdx] = sort(ambiguity,"descend");
```

View the most probable classes of the ambiguous images and the true classes.

```
classList = unique(valImds.Labels);
top10Idx = ambiguityIdx(1:10);
top10Ambiguity = ambiguity(1:10);
mostLikely = classList(RI(ambiguityIdx,1));
secondLikely = classList(RI(ambiguityIdx,2));
table(top10Idx,top10Ambiguity,mostLikely(1:10),secondLikely(1:10),valImds.Labels(ambiguityIdx(1:1
    'VariableNames',["Image #","Ambiguity","Likeliest","Second","True Class"])
```

```
ans=10×5 table
    Image #    Ambiguity    Likeliest       Second        True Class
    _______    _________    _________    ____________    ____________

       94        0.9879     hamburger    pizza           hamburger
      175       0.96311     hamburger    french_fries    hot_dog
      179       0.94939     pizza        hamburger       hot_dog
      337       0.93426     sushi        sashimi         sushi
      256       0.92972     sushi        pizza           pizza
      297       0.91776     sushi        sashimi         sashimi
      283       0.80407     pizza        sushi           pizza
       27       0.80278     hamburger    pizza           french_fries
      302       0.79283     sashimi      sushi           sushi
      201       0.76034     pizza        greek_salad     pizza
```

The network predicts that image 27 is most likely hamburger or pizza. However, this image is actually French fries. View the image to see why this misclassification might occur.

```
v = 27;
figure();
imshow(valImds.Files{v});
title(sprintf("Observation: %i\n" + ...
    "Actual: %s. Predicted: %s", v, ...
    string(valImds.Labels(v)), string(YPred(v))), ...
    'Interpreter', 'none');
```

The image contains several distinct regions, some of which might confuse the network.

Compute 2-D Representations of Data Using t-SNE

Calculate a low-dimensional representation of the network data for an early max pooling layer, the final convolutional layer, and the final softmax layer. Use the `tsne` function to reduce the dimensionality of the activation data from M to 2. The larger the dimensionality of the activations, the longer the t-SNE computation takes. Therefore, computation for the early max pooling layer, where activations have 200,704 dimensions, takes longer than for the final softmax layer. Set the random seed for reproducibility of the t-SNE result.

```
rng default
pool1tsne = tsne(pool1Activations);
finalConvtsne = tsne(finalConvActivations);
softmaxtsne = tsne(softmaxActivations);
```

Compare Network Behavior for Early and Later Layers

The t-SNE technique tries to preserve distances so that points near each other in the high-dimensional representation are also near each other in the low-dimensional representation. As shown in the confusion matrix, the network is effective at classifying into different classes. Therefore, images that are semantically similar (or of the same type), such as caesar salad and caprese salad,

are near each other in the softmax activations space. t-SNE captures this proximity in a 2-D representation that is easier to understand and plot than the nine-dimensional softmax scores.

Early layers tend to operate on low-level features such as edges and colors. Deeper layers have learned high-level features with more semantic meaning, such as the difference between a pizza and a hot dog. Therefore, activations from early layers do not show any clustering by class. Two images that are similar pixelwise (for example, they both contain a lot of green pixels) are near each other in the high-dimensional space of the activations, regardless of their semantic contents. Activations from later layers tend to cluster points from the same class together. This behavior is most pronounced at the softmax layer and is preserved in the two-dimensional t-SNE representation.

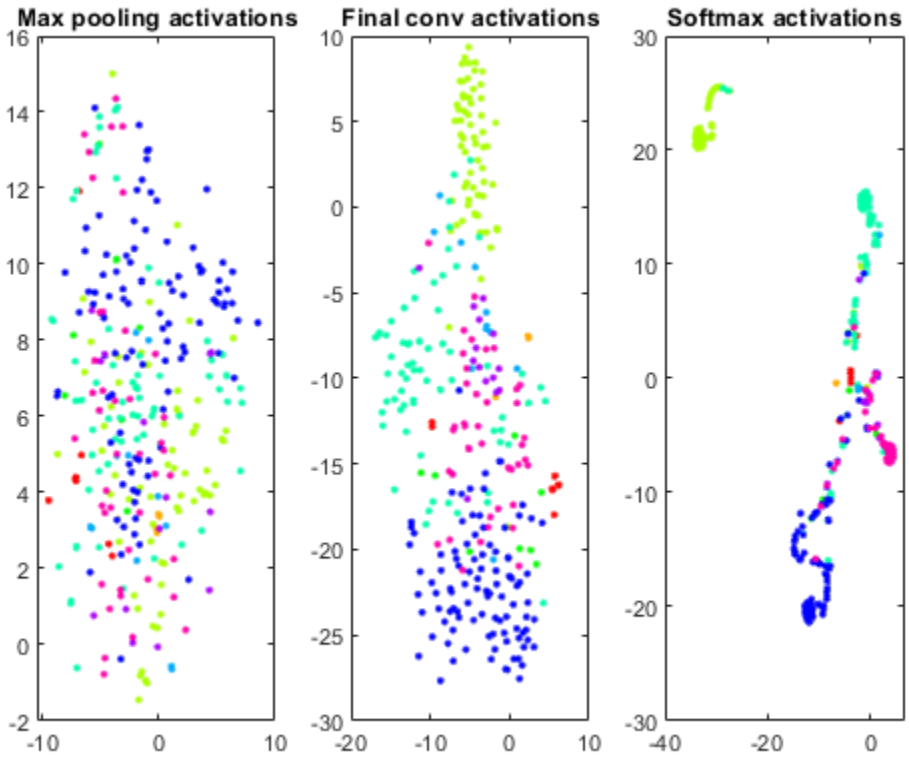
Plot the t-SNE data for the early max pooling layer, the final convolutional layer, and the final softmax layer using the `gscatter` function. Observe that the early max pooling activations do not exhibit any clustering between images of the same class. Activations of the final convolutional layer are clustered by class to some extent, but less so than the softmax activations. Different colors correspond to observations of different classes.

```
doLegend = 'off';
markerSize = 7;
figure;

subplot(1,3,1);
gscatter(pool1tsne(:,1),pool1tsne(:,2),valImds.Labels, ...
    [],'.',markerSize,doLegend);
title("Max pooling activations");

subplot(1,3,2);
gscatter(finalConvtsne(:,1),finalConvtsne(:,2),valImds.Labels, ...
    [],'.',markerSize,doLegend);
title("Final conv activations");

subplot(1,3,3);
gscatter(softmaxtsne(:,1),softmaxtsne(:,2),valImds.Labels, ...
    [],'.',markerSize,doLegend);
title("Softmax activations");
```



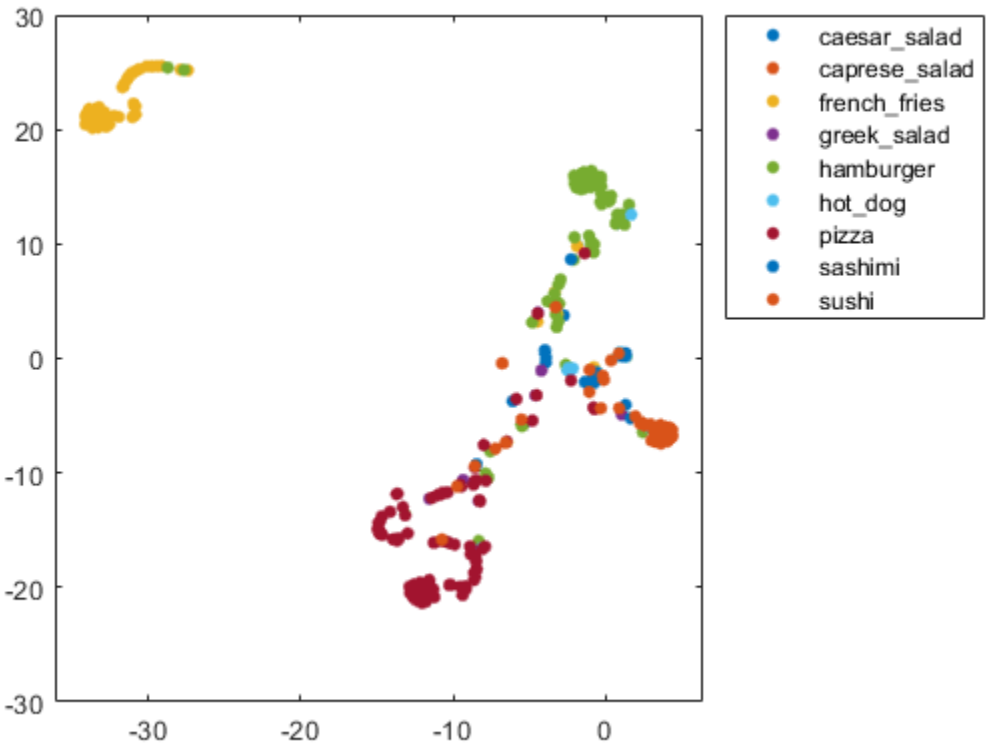
Explore Observations in t-SNE Plot

Create a larger plot of the softmax activations, including a legend labeling each class. From the t-SNE plot, you can understand more about the structure of the posterior probability distribution.

For example, the plot shows a distinct, separate cluster of French fries observations, whereas the sashimi and sushi clusters are not resolved very well. Similar to the confusion matrix, the plot suggests that the network is more accurate at predicting into the French fries class.

```
numClasses = length(classList);
colors = lines(numClasses);
h = figure;
gscatter(softmaxtsne(:,1),softmaxtsne(:,2),valImds.Labels,colors);

l = legend;
l.Interpreter = "none";
l.Location = "bestoutside";
```



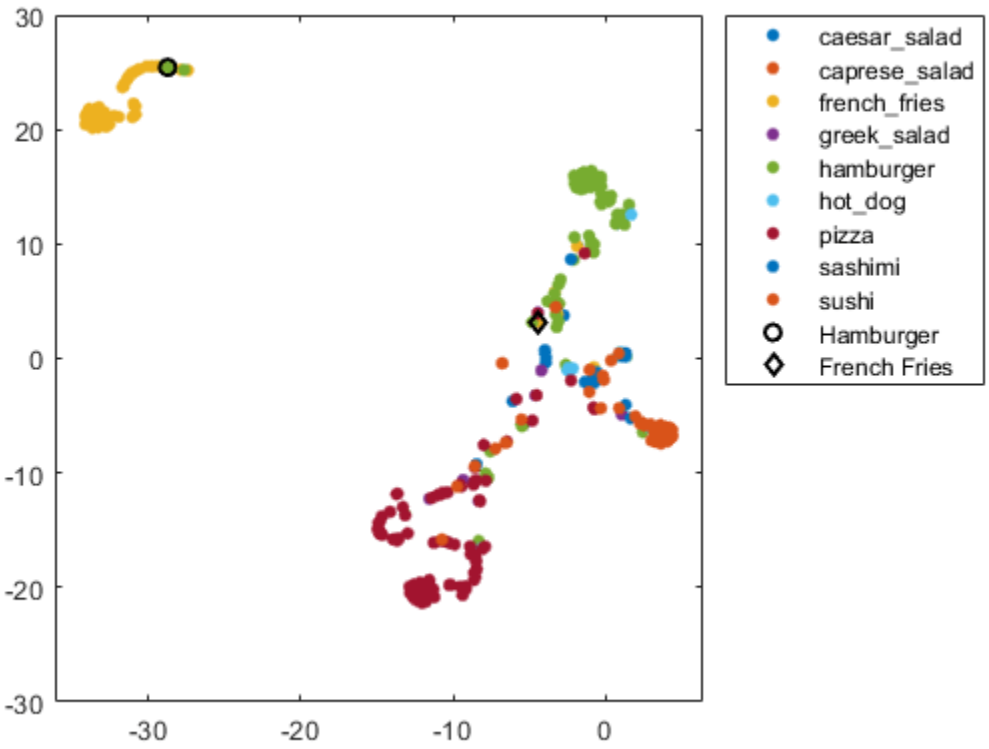
You can also use t-SNE to determine which images are misclassified by the network and why. Incorrect observations are often isolated points of the wrong color for their surrounding cluster. For example, a misclassified image of hamburger is very near the French fries region (the green dot nearest the center of the orange cluster). This dot is observation 99. Circle this observation on the t-SNE plot, and display the image with `imshow`.

```
obs =  99                ;
figure(h)
hold on;
hs = scatter(softmaxtsne(obs, 1), softmaxtsne(obs, 2), ...
    'black','LineWidth',1.5);
l.String{end} = 'Hamburger';
hold off;
figure();
imshow(valImds.Files{obs});
title(sprintf("Observation: %i\n" + ...
    "Actual: %s. Predicted: %s", obs, ...
    string(valImds.Labels(obs)), string(YPred(obs))), ...
    'Interpreter', 'none');
```

If an image contains multiple types of food, the network can get confused. In this case, the network classifies the image as French fries even though the food in the foreground is hamburger. The French fries visible at the edge of the image cause the confusion.

Similarly, the ambiguous image 27 (shown earlier in the example) has multiple regions. Examine the t-SNE plot highlighting the ambiguous aspect of this French fries image.

```
obs = 27                                ;
figure(h)
hold on;
h = scatter(softmaxtsne(obs, 1), softmaxtsne(obs, 2), ...
    'k','d','LineWidth',1.5);
l.String{end} = 'French Fries';
hold off;
```



The image is not in a well-defined cluster in the plot, which indicates that the classification is likely incorrect. The image is far from the French fries cluster, and close to the hamburger cluster.

The *why* of a misclassification must be provided by other information, typically a hypothesis based on the contents of the image. You can then test the hypothesis using other data, or using tools that indicate which spatial regions of an image are important to network classification. For examples, see `occlusionSensitivity` and “Grad-CAM Reveals the Why Behind Deep Learning Decisions” on page 5-21.

Visualize Activations of a Convolutional Neural Network

This example shows how to feed an image to a convolutional neural network and display the activations of different layers of the network. Examine the activations and discover which features the network learns by comparing areas of activation with the original image. Find out that channels in earlier layers learn simple features like color and edges, while channels in the deeper layers learn complex features like eyes. Identifying features in this way can help you understand what the network has learned.

The example requires Deep Learning Toolbox™ and the Image Processing Toolbox™.

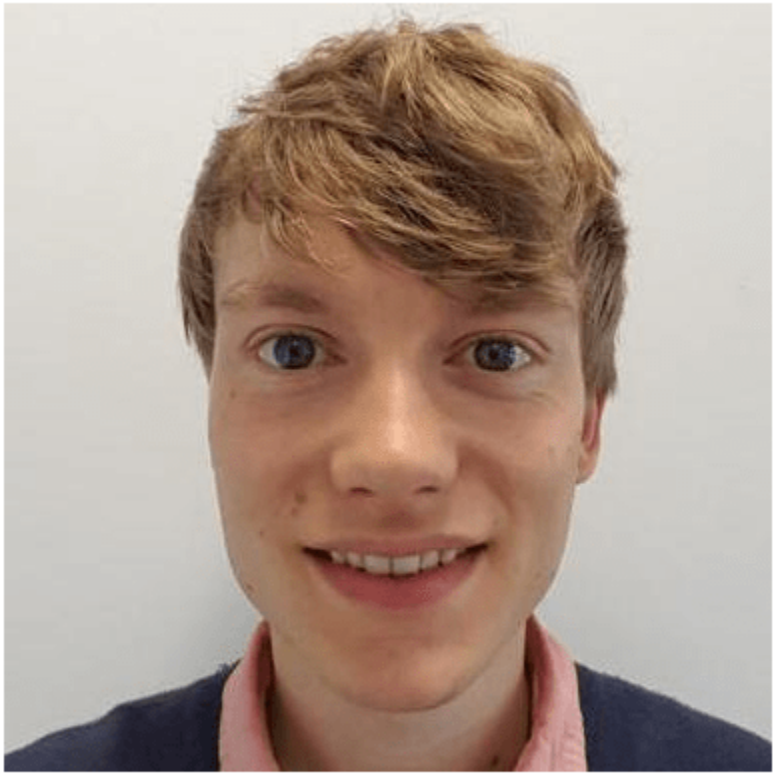
Load Pretrained Network and Data

Load a pretrained SqueezeNet network.

```
net = squeezenet;
```

Read and show an image. Save its size for future use.

```
im = imread('face.jpg');
imshow(im)
```

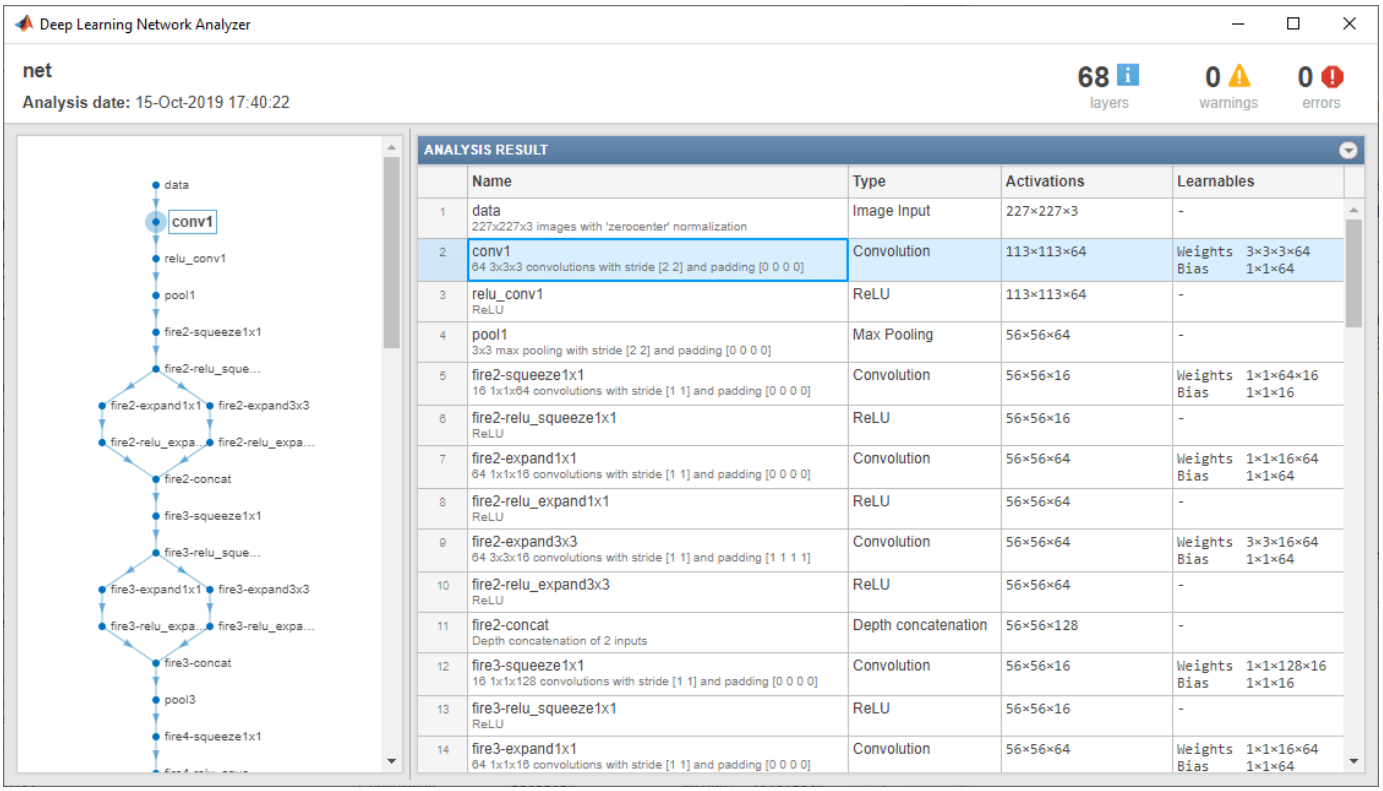


```
imgSize = size(im);
imgSize = imgSize(1:2);
```

View Network Architecture

Analyze the network to see which layers you can look at. The convolutional layers perform convolutions with learnable parameters. The network learns to identify useful features, often with one feature per channel. Observe that the first convolutional layer has 64 channels.

```
analyzeNetwork(net)
```



The Image Input layer specifies the input size. You can resize the image before passing it through the network, but the network also can process larger images. If you feed the network larger images, the activations also become larger. However, since the network is trained on images of size 227-by-227, it is not trained to recognize objects or features larger than that size.

Show Activations of First Convolutional Layer

Investigate features by observing which areas in the convolutional layers activate on an image and comparing with the corresponding areas in the original images. Each layer of a convolutional neural network consists of many 2-D arrays called *channels*. Pass the image through the network and examine the output activations of the `conv1` layer.

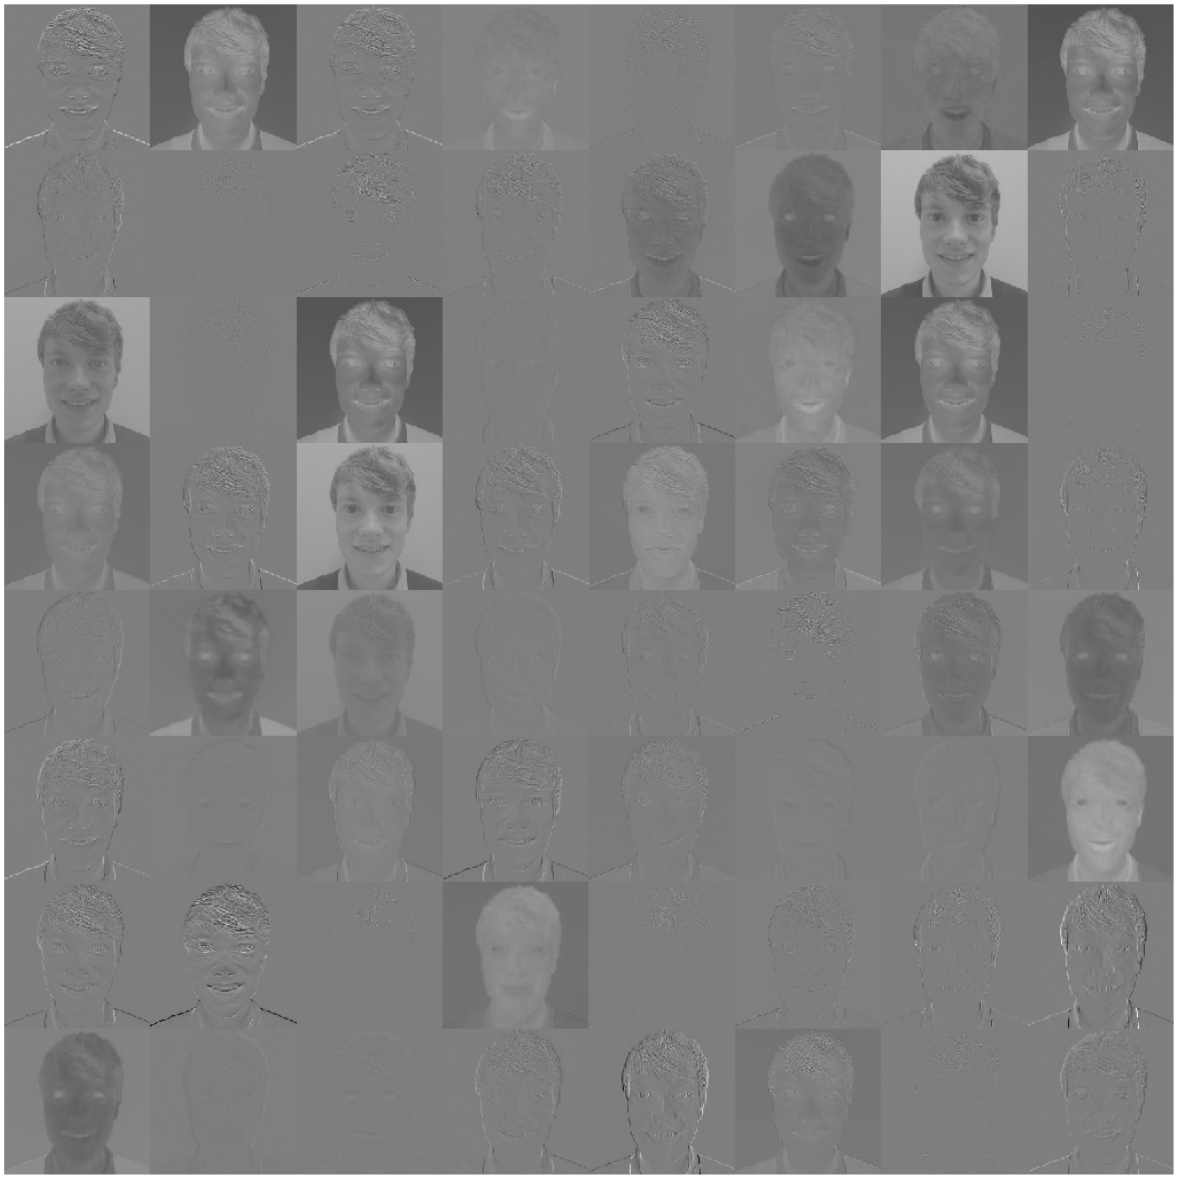
```
act1 = activations(net,im,'conv1');
```

The activations are returned as a 3-D array, with the third dimension indexing the channel on the `conv1` layer. To show these activations using the `imtile` function, reshape the array to 4-D. The third dimension in the input to `imtile` represents the image color. Set the third dimension to have size 1 because the activations do not have color. The fourth dimension indexes the channel.

```
sz = size(act1);
act1 = reshape(act1,[sz(1) sz(2) 1 sz(3)]);
```

Now you can show the activations. Each activation can take any value, so normalize the output using `mat2gray`. All activations are scaled so that the minimum activation is 0 and the maximum is 1. Display the 64 images on an 8-by-8 grid, one for each channel in the layer.

```
I = imtile(mat2gray(act1),'GridSize',[8 8]);
imshow(I)
```



Investigate the Activations in Specific Channels

Each tile in the grid of activations is the output of a channel in the `conv1` layer. White pixels represent strong positive activations and black pixels represent strong negative activations. A channel that is mostly gray does not activate as strongly on the input image. The position of a pixel in the activation of a channel corresponds to the same position in the original image. A white pixel at some location in a channel indicates that the channel is strongly activated at that position.

Resize the activations in channel 22 to have the same size as the original image and display the activations.

```
act1ch22 = act1(:,:,:,22);
act1ch22 = mat2gray(act1ch22);
act1ch22 = imresize(act1ch22,imgSize);

I = imtile({im,act1ch22});
imshow(I)
```

You can see that this channel activates on red pixels, because the whiter pixels in the channel correspond to red areas in the original image.

Find the Strongest Activation Channel

You also can try to find interesting channels by programmatically investigating channels with large activations. Find the channel with the largest activation using the `max` function, resize, and show the activations.

```
[maxValue,maxValueIndex] = max(max(max(act1)));
act1chMax = act1(:,:,:,maxValueIndex);
act1chMax = mat2gray(act1chMax);
act1chMax = imresize(act1chMax,imgSize);
```

```
I = imtile({im,act1chMax});
imshow(I)
```

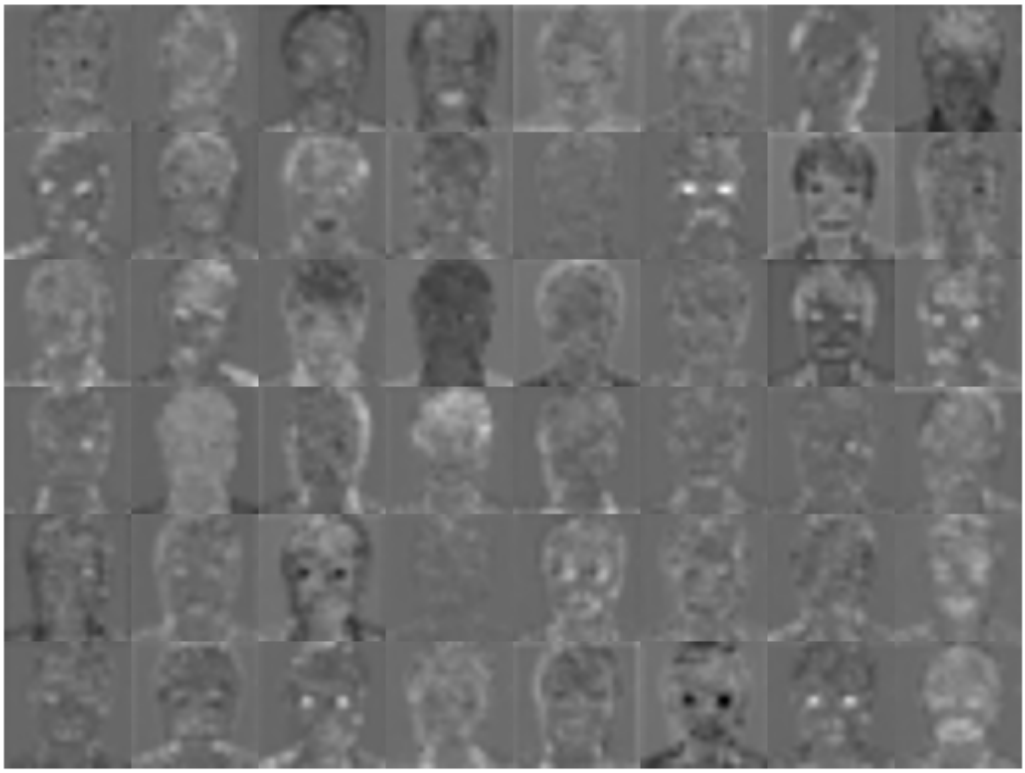
Compare to the original image and notice that this channel activates on edges. It activates positively on light left/dark right edges, and negatively on dark left/light right edges.

Investigate a Deeper Layer

Most convolutional neural networks learn to detect features like color and edges in their first convolutional layer. In deeper convolutional layers, the network learns to detect more complicated features. Later layers build up their features by combining features of earlier layers. Investigate the `fire6-squeeze1x1` layer in the same way as the `conv1` layer. Calculate, reshape, and show the activations in a grid.

```
act6 = activations(net,im,'fire6-squeeze1x1');
sz = size(act6);
act6 = reshape(act6,[sz(1) sz(2) 1 sz(3)]);

I = imtile(imresize(mat2gray(act6),[64 64]),'GridSize',[6 8]);
imshow(I)
```



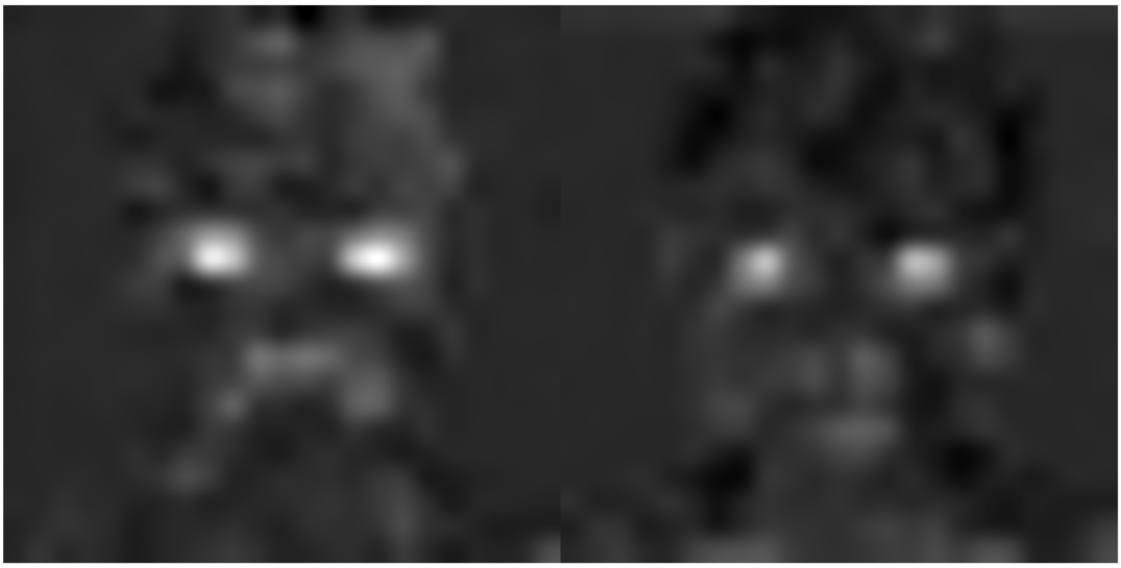
There are too many images to investigate in detail, so focus on some of the more interesting ones. Display the strongest activation in the `fire6-squeeze1x1` layer.

```
[maxValue6,maxValueIndex6] = max(max(max(act6)));
act6chMax = act6(:,:,:,maxValueIndex6);
imshow(imresize(mat2gray(act6chMax),imgSize))
```

In this case, the maximum activation channel is not as interesting for detailed features as some others, and shows strong negative (dark) as well as positive (light) activation. This channel is possibly focusing on faces.

In the grid of all channels, there are channels that might be activating on eyes. Investigate channels 14 and 47 further.

```
I = imtile(imresize(mat2gray(act6(:,:,:,[14 47])),imgSize));
imshow(I)
```



Many of the channels contain areas of activation that are both light and dark. These are positive and negative activations, respectively. However, only the positive activations are used because of the rectified linear unit (ReLU) that follows the `fire6-squeeze1x1` layer. To investigate only positive activations, repeat the analysis to visualize the activations of the `fire6-relu_squeeze1x1` layer.

```
act6relu = activations(net,im,'fire6-relu_squeeze1x1');
sz = size(act6relu);
act6relu = reshape(act6relu,[sz(1) sz(2) 1 sz(3)]);

I = imtile(imresize(mat2gray(act6relu(:,:,:,[14 47])),imgSize));
imshow(I)
```

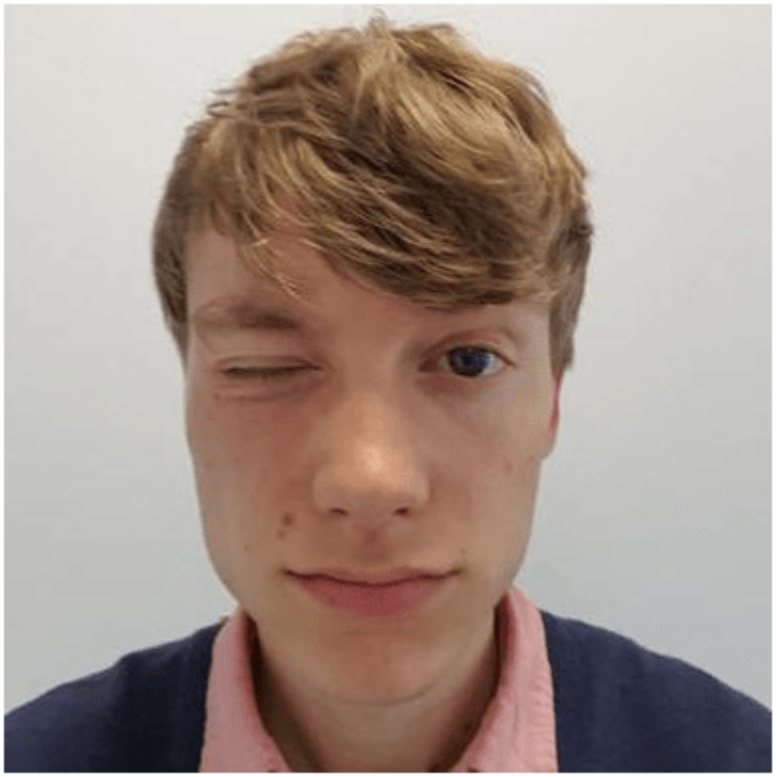
Compared to the activations of the `fire6-squeeze1x1` layer, the activations of the `fire6-relu_squeeze1x1` layer clearly pinpoint areas of the image that have strong facial features.

Test Whether a Channel Recognizes Eyes

Check whether channels 14 and 47 of the `fire6-relu_squeeze1x1` layer activate on eyes. Input a new image with one closed eye to the network and compare the resulting activations with the activations of the original image.

Read and show the image with one closed eye and compute the activations of the `fire6-relu_squeeze1x1` layer.

```
imClosed = imread('face-eye-closed.jpg');
imshow(imClosed)
```



```
act6Closed = activations(net,imClosed,'fire6-relu_squeeze1x1');
sz = size(act6Closed);
act6Closed = reshape(act6Closed,[sz(1),sz(2),1,sz(3)]);
```

Plot the images and activations in one figure.

```
channelsClosed = repmat(imresize(mat2gray(act6Closed(:,:,:,[14 47])),imgSize),[1 1 3]);
channelsOpen = repmat(imresize(mat2gray(act6relu(:,:,:,[14 47])),imgSize),[1 1 3]);
I = imtile(cat(4,im,channelsOpen*255,imClosed,channelsClosed*255));
imshow(I)
title('Input Image, Channel 14, Channel 47');
```

You can see from the activations that both channels 14 and 47 activate on individual eyes, and to some degree also on the area around the mouth.

The network has never been told to learn about eyes, but it has learned that eyes are a useful feature to distinguish between classes of images. Previous machine learning approaches often manually designed features specific to the problem, but these deep convolutional networks can learn useful features for themselves. For example, learning to identify eyes could help the network distinguish between a leopard and a leopard print rug.

Visualize Activations of LSTM Network

This example shows how to investigate and visualize the features learned by LSTM networks by extracting the activations.

Load pretrained network. `JapaneseVowelsNet` is a pretrained LSTM network trained on the Japanese Vowels dataset as described in [1] and [2]. It was trained on the sequences sorted by sequence length with a mini-batch size of 27.

```
load JapaneseVowelsNet
```

View the network architecture.

```
net.Layers
```

```
ans =
  5x1 Layer array with layers:

     1   'sequenceinput'   Sequence Input          Sequence input with 12 dimensions
     2   'lstm'            LSTM                    LSTM with 100 hidden units
     3   'fc'              Fully Connected         9 fully connected layer
     4   'softmax'         Softmax                 softmax
     5   'classoutput'     Classification Output   crossentropyex with '1' and 8 other classes
```

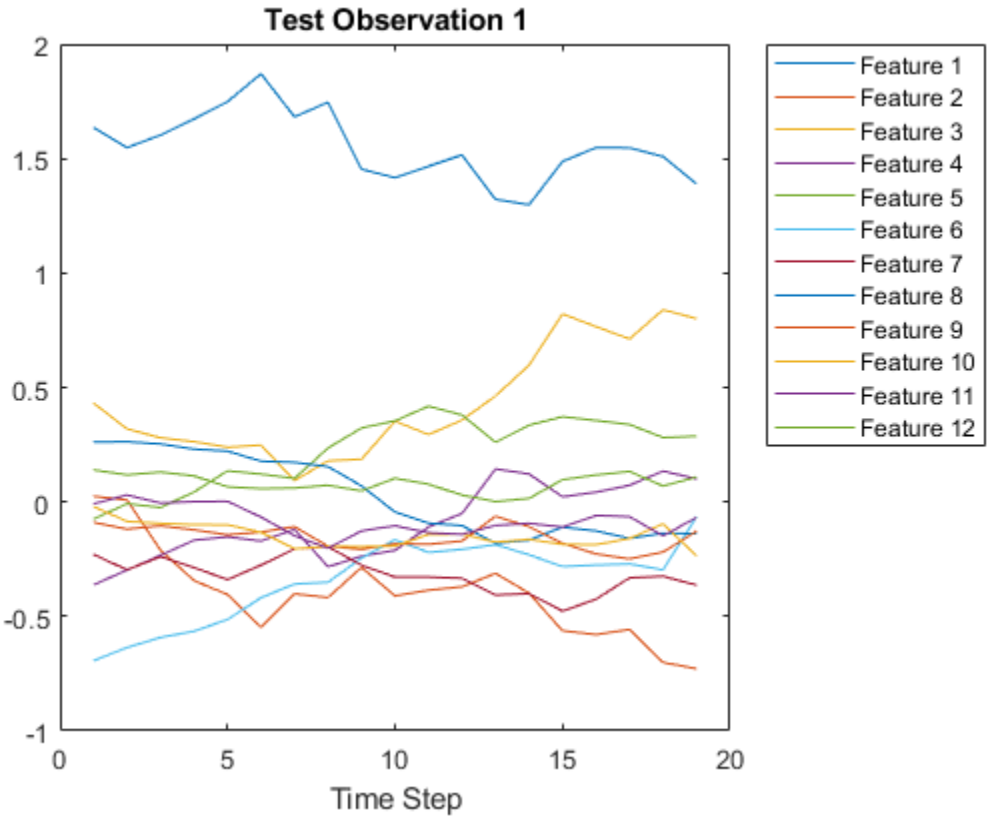
Load the test data.

```
[XTest,YTest] = japaneseVowelsTestData;
```

Visualize the first time series in a plot. Each line corresponds to a feature.

```
X = XTest{1};

figure
plot(XTest{1}')
xlabel("Time Step")
title("Test Observation 1")
numFeatures = size(XTest{1},1);
legend("Feature " + string(1:numFeatures),'Location','northeastoutside')
```



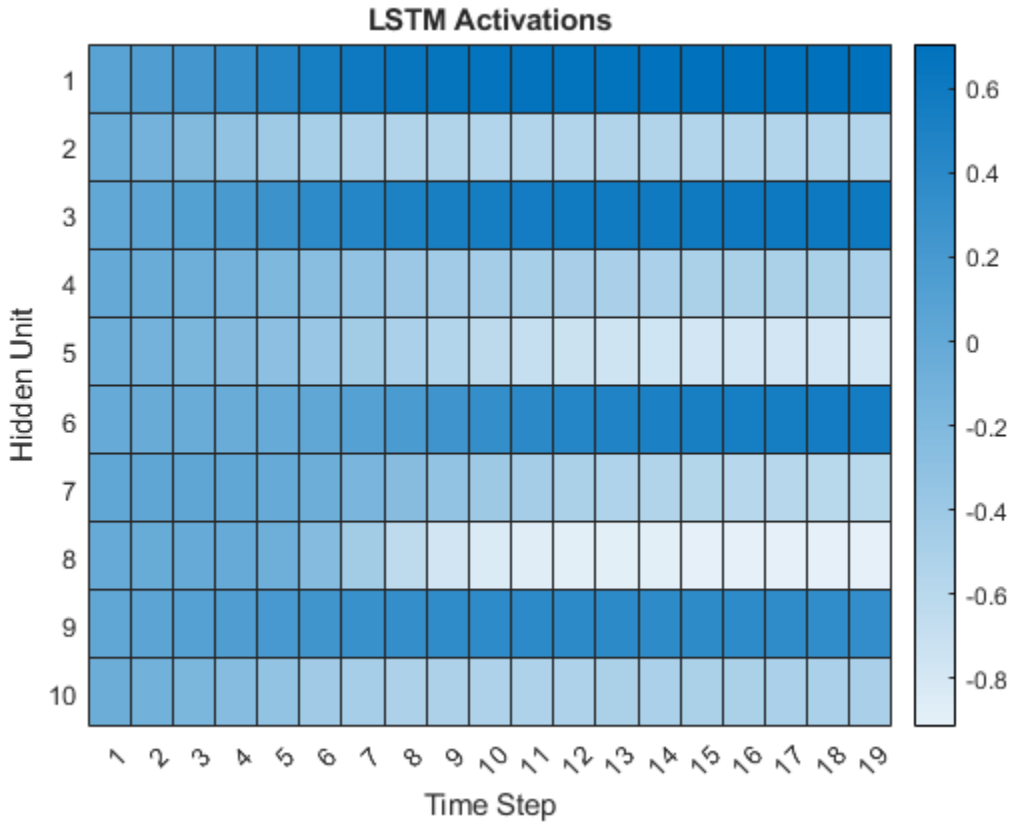
For each time step of the sequences, get the activations output by the LSTM layer (layer 2) for that time step and update the network state.

```
sequenceLength = size(X,2);
idxLayer = 2;
outputSize = net.Layers(idxLayer).NumHiddenUnits;

for i = 1:sequenceLength
    features(:,i) = activations(net,X(:,i),idxLayer);
    [net, YPred(i)] = classifyAndUpdateState(net,X(:,i));
end
```

Visualize the first 10 hidden units using a heatmap.

```
figure
heatmap(features(1:10,:));
xlabel("Time Step")
ylabel("Hidden Unit")
title("LSTM Activations")
```



The heatmap shows how strongly each hidden unit activates and highlights how the activations change over time.

Visualize Features of a Convolutional Neural Network

This example shows how to visualize the features learned by convolutional neural networks.

Convolutional neural networks use *features* to classify images. The network learns these features itself during the training process. What the network learns during training is sometimes unclear. However, you can use the `deepDreamImage` function to visualize the features learned.

The *convolutional* layers output a 3D activation volume, where slices along the third dimension correspond to a single filter applied to the layer input. The channels output by *fully connected* layers at the end of the network correspond to high-level combinations of the features learned by earlier layers.

You can visualize what the learned features look like by using `deepDreamImage` to generate images that strongly activate a particular channel of the network layers.

The example requires Deep Learning Toolbox™ and Deep Learning Toolbox Model *for GoogLeNet Network* support package.

Load Pretrained Network

Load a pretrained GoogLeNet network.

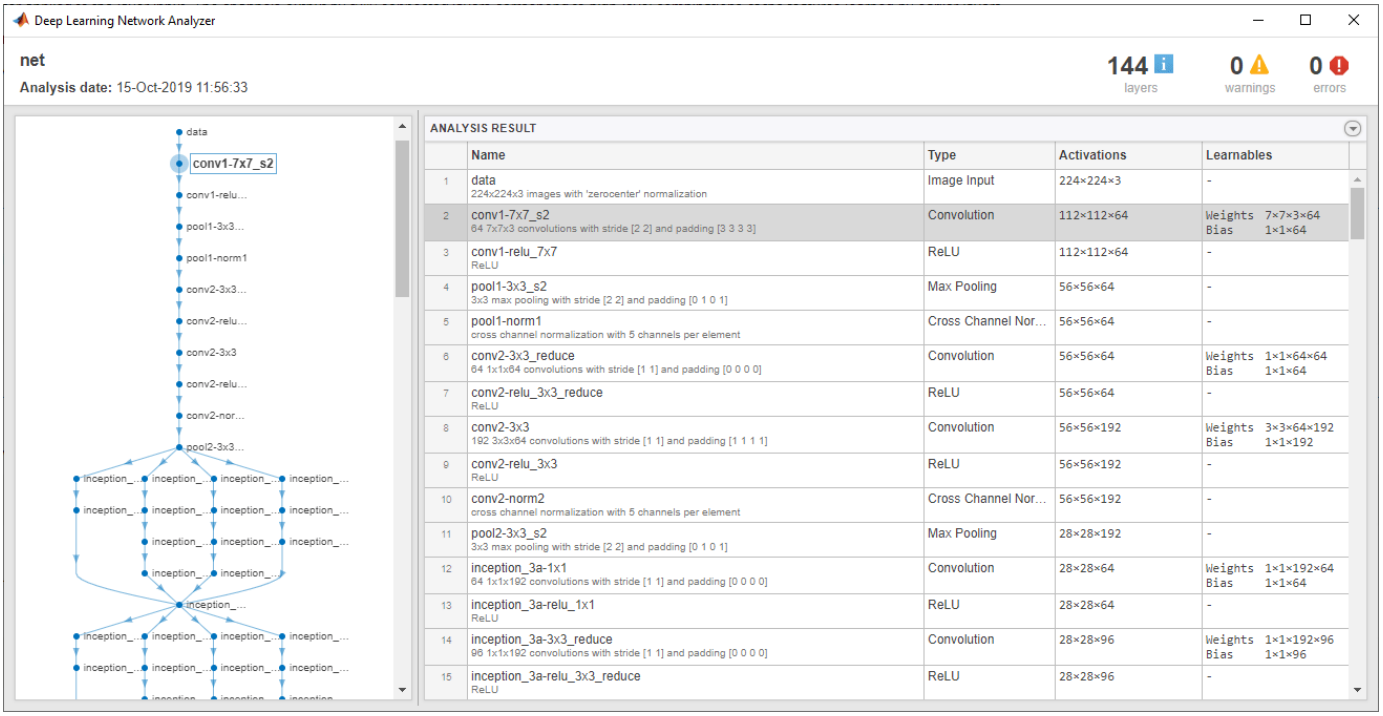
```
net = googlenet;
```

Visualize Early Convolutional Layers

There are multiple convolutional layers in the GoogLeNet network. The convolutional layers towards the beginning of the network have a small receptive field size and learn small, low-level features. The layers towards the end of the network have larger receptive field sizes and learn larger features.

Using `analyzeNetwork`, view the network architecture and locate the convolutional layers.

```
analyzeNetwork(net)
```



Features on Convolutional Layer 1

Set `layer` to be the first convolutional layer. This layer is the second layer in the network and is named `'conv1-7x7_s2'`.

```
layer = 2;
name = net.Layers(layer).Name
```

```
name =
'conv1-7x7_s2'
```

Visualize the first 36 features learned by this layer using `deepDreamImage` by setting `channels` to be the vector of indices `1:36`. Set `'PyramidLevels'` to 1 so that the images are not scaled. To display the images together, you can use `imtile`.

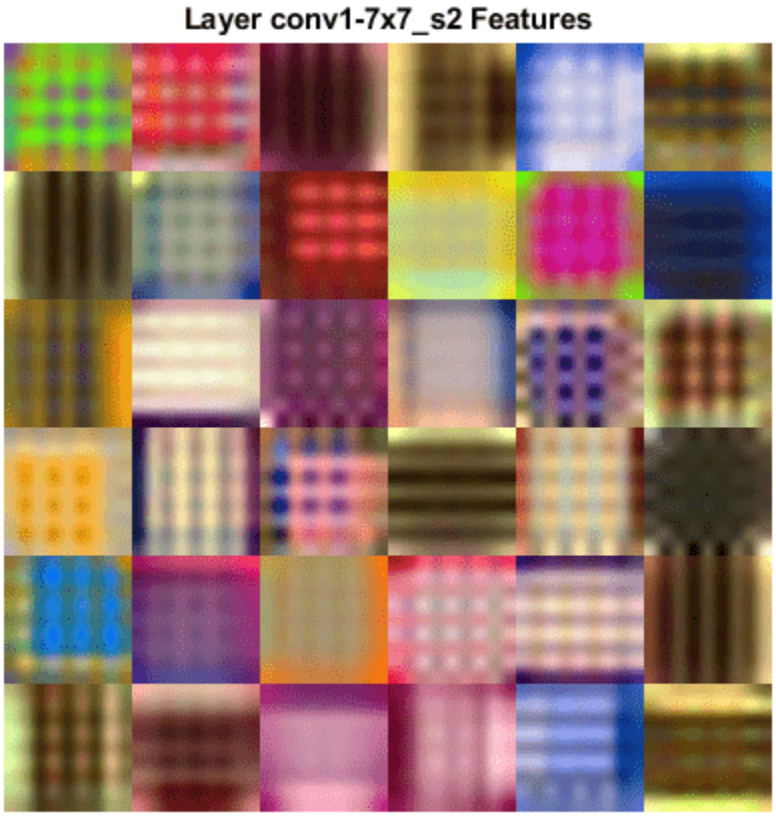
`deepDreamImage` uses a compatible GPU, by default, if available. Otherwise it uses the CPU. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox).

```
channels = 1:36;
I = deepDreamImage(net,name,channels, ...
    'PyramidLevels',1);
```

```
|=============================================|
|  Iteration  |  Activation  |  Pyramid Level  |
|             |   Strength   |                 |
|=============================================|
|           1 |         0.26 |               1 |
|           2 |         6.99 |               1 |
|           3 |        14.24 |               1 |
|           4 |        21.49 |               1 |
|           5 |        28.74 |               1 |
```

```
|           6 |        35.99 |               1 |
|           7 |        43.24 |               1 |
|           8 |        50.50 |               1 |
|           9 |        57.75 |               1 |
|          10 |        65.00 |               1 |
|=============================================|
```

```
figure
I = imtile(I,'ThumbnailSize',[64 64]);
imshow(I)
title(['Layer ',name,' Features'],'Interpreter','none')
```



These images mostly contain edges and colors, which indicates that the filters at layer `'conv1-7x7_s2'` are edge detectors and color filters.

Features on Convolutional Layer 2

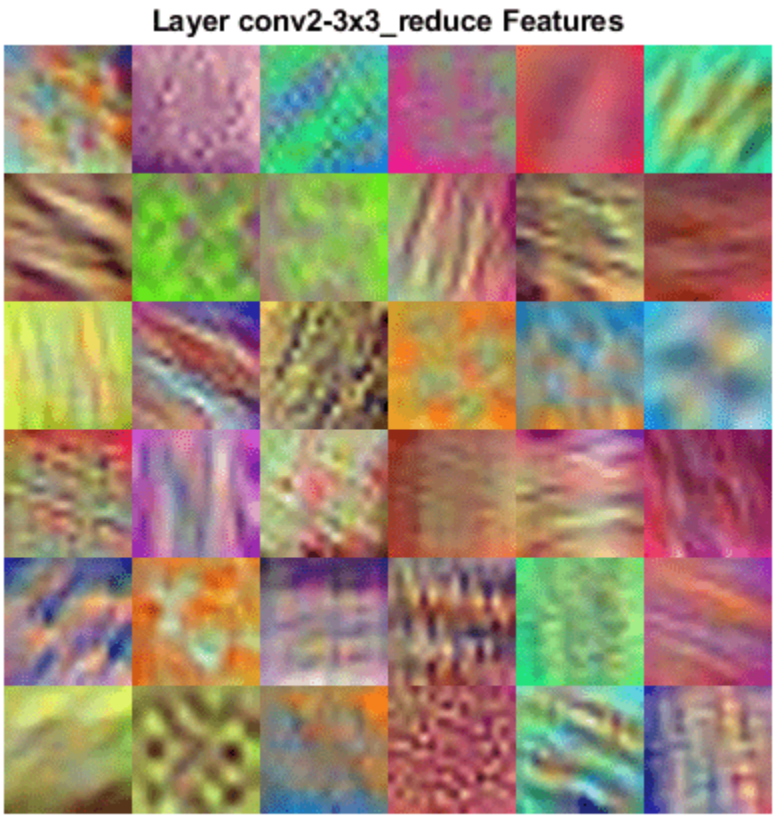
The second convolutional layer is named `'conv2-3x3_reduce'`, which corresponds to layer 6. Visualize the first 36 features learned by this layer by setting `channels` to be the vector of indices `1:36`.

To suppress detailed output on the optimization process, set `'Verbose'` to `'false'` in the call to `deepDreamImage`.

```
layer = 6;
name = net.Layers(layer).Name
```

```
name =
'conv2-3x3_reduce'
```

```
channels = 1:36;
I = deepDreamImage(net,name,channels, ...
    'Verbose',false, ...
    'PyramidLevels',1);
figure
I = imtile(I,'ThumbnailSize',[64 64]);
imshow(I)
name = net.Layers(layer).Name;
title(['Layer ',name,' Features'],'Interpreter','none')
```



Filters for this layer detect more complex patterns than the first convolutional layer.

Visualize Deeper Convolutional Layers

The deeper layers learn high-level combinations of features learned by the earlier layers.

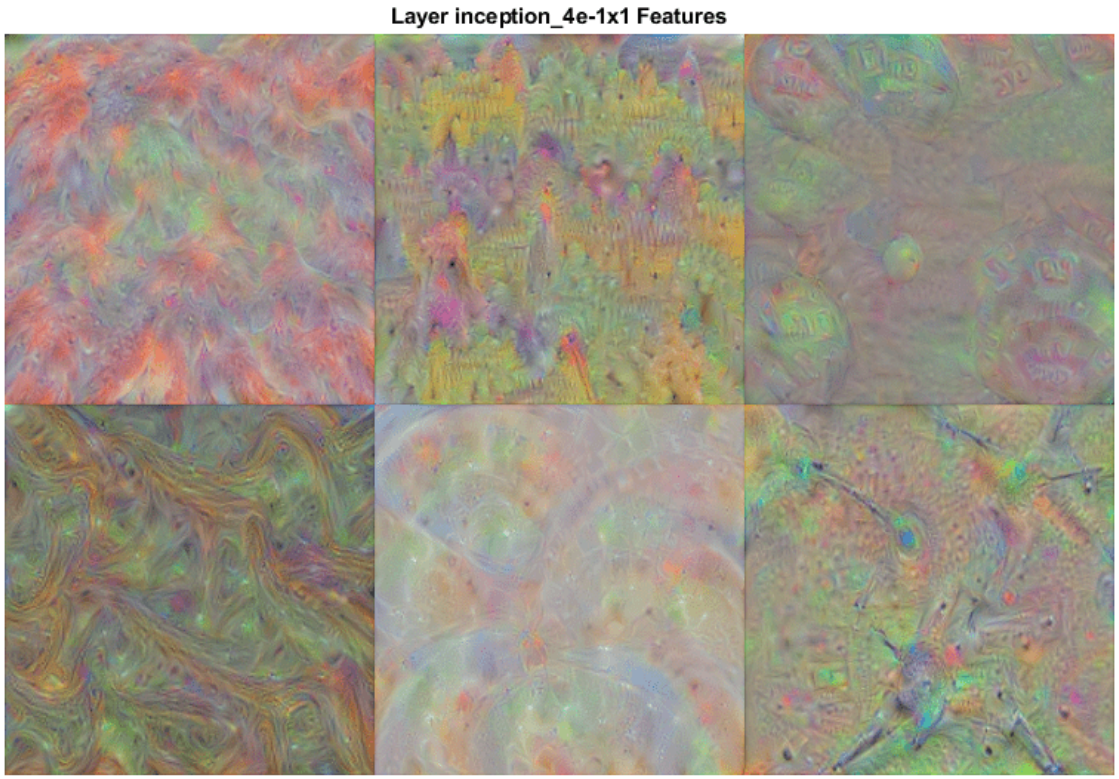
Increasing the number of pyramid levels and iterations per pyramid level can produce more detailed images at the expense of additional computation. You can increase the number of iterations using the

`'NumIterations'` option and increase the number of pyramid levels using the `'PyramidLevels'` option.

```
layer = 97;
name = net.Layers(layer).Name
```

```
name =
'inception_4e-1x1'
```

```
channels = 1:6;
I = deepDreamImage(net,name,channels, ...
    'Verbose',false, ...
    "NumIterations",20, ...
    'PyramidLevels',2);
figure
I = imtile(I,'ThumbnailSize',[250 250]);
imshow(I)
name = net.Layers(layer).Name;
title(['Layer ',name,' Features'],'Interpreter','none')
```



Notice that the layers which are deeper into the network yield more detailed filters which have learned complex patterns and textures.

Visualize Fully Connected Layer

To produce images that resemble each class the most closely, select the fully connected layer, and set `channels` to be the indices of the classes.

Select the fully connected layer (layer 142).

```
layer = 142;
name = net.Layers(layer).Name
```

```
name =
'loss3-classifier'
```

Select the classes you want to visualize by setting `channels` to be the indices of those class names.

```
channels = [114 293 341 484 563 950];
```

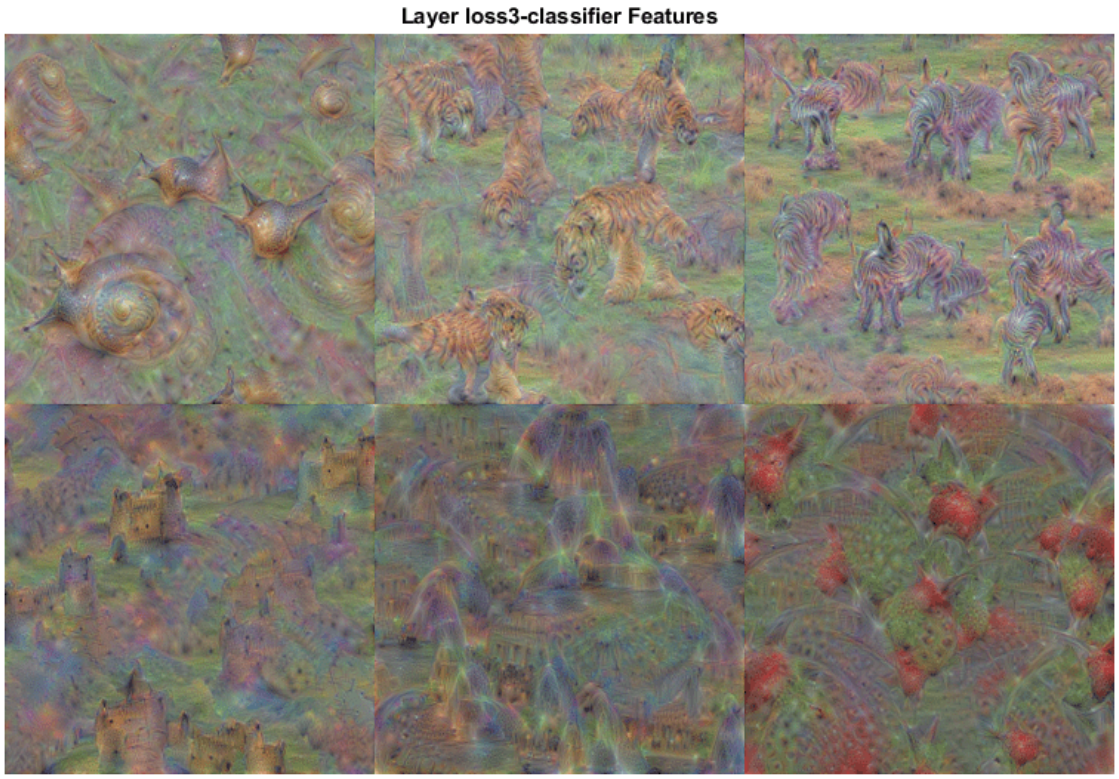
The classes are stored in the `Classes` property of the output layer (the last layer). You can view the names of the selected classes by selecting the entries in `channels`.

```
net.Layers(end).Classes(channels)
```

```
ans = 6×1 categorical
     snail
     tiger
     zebra
     castle
     fountain
     strawberry
```

Generate detailed images that strongly activate these classes. Set `'NumIterations'` to 100 in the call to `deepDreamImage` to produce more detailed images. The images generated from the fully connected layer correspond to the image classes.

```
I = deepDreamImage(net,name,channels, ...
    'Verbose',false, ...
    'NumIterations',100, ...
    'PyramidLevels',2);
figure
I = imtile(I,'ThumbnailSize',[250 250]);
imshow(I)
name = net.Layers(layer).Name;
title(['Layer ',name,' Features'])
```



The images generated strongly activate the selected classes. The image generated for the ‘zebra’ class contain distinct zebra stripes, whilst the image generated for the ‘castle’ class contains turrets and windows.

Visualize Image Classifications Using Maximal and Minimal Activating Images

This example shows how to use a data set to find out what activates the channels of a deep neural network. This allows you to understand how a neural network works and diagnose potential issues with a training data set.

This example covers a number of simple visualization techniques, using a GoogLeNet transfer-learned on a food data set. By looking at images that maximally or minimally activate the classifier, you can discover why a neural network gets classifications wrong.

Load and Preprocess the Data

Load the images as an image datastore. This small data set contains a total of 978 observations with 9 classes of food.

Split this data into a training, validation, and test sets to prepare for transfer learning using GoogLeNet. Display a selection of images from the data set.

```
rng default
dataDir = fullfile(tempdir,"Food Dataset");
url = "https://www.mathworks.com/supportfiles/nnet/data/ExampleFoodImageDataset.zip";

if ~exist(dataDir,"dir")
    mkdir(dataDir);
end

downloadExampleFoodImagesData(url,dataDir);
```

```
Downloading MathWorks Example Food Image dataset...
This can take several minutes to download...
Download finished...
Unzipping file...
Unzipping finished...
Done.
```

```
imds = imageDatastore(dataDir, ...
    "IncludeSubfolders",true,"LabelSource","foldernames");
[imdsTrain,imdsValidation,imdsTest] = splitEachLabel(imds,0.6,0.2);

rnd = randperm(numel(imds.Files),9);
for i = 1:numel(rnd)
subplot(3,3,i)
imshow(imread(imds.Files{rnd(i)}))
label = imds.Labels(rnd(i));
title(label,"Interpreter","none")
end
```

Train Network to Classify Food Images

Use the pretrained GoogLeNet network and train it again to classify the 9 types of food. If you don't have the Deep Learning Toolbox™ Model *for GoogLeNet Network* support package installed, then the software provides a download link.

To try a different pretrained network, open this example in MATLAB® and select a different network, such as `squeezenet`, a network that is even faster than `googlenet`. For a list of all available networks, see “Pretrained Deep Neural Networks” on page 1-8.

```
net = googlenet;
```

The first element of the `Layers` property of the network is the image input layer. This layer requires input images of size 224-by-224-by-3, where 3 is the number of color channels.

```
inputSize = net.Layers(1).InputSize;
```

Network Architecture

The convolutional layers of the network extract image features that the last learnable layer and the final classification layer use to classify the input image. These two layers, `'loss3-classifier'` and `'output'` in GoogLeNet, contain information on how to combine the features that the network extracts into class probabilities, a loss value, and predicted labels. To train a pretrained network to classify new images, replace these two layers with new layers adapted to the new data set.

Extract the layer graph from the trained network.

```
lgraph = layerGraph(net);
```

In most networks, the last layer with learnable weights is a fully connected layer. Replace this fully connected layer with a new fully connected layer with the number of outputs equal to the number of classes in the new data set (9, in this example).

```
numClasses = numel(categories(imdsTrain.Labels));

newfclayer = fullyConnectedLayer(numClasses,...
    'Name','new_fc',...
    'WeightLearnRateFactor',10,...
    'BiasLearnRateFactor',10);
lgraph = replaceLayer(lgraph,net.Layers(end-2).Name,newfclayer);
```

The classification layer specifies the output classes of the network. Replace the classification layer with a new one without class labels. `trainNetwork` automatically sets the output classes of the layer at training time.

```
newclasslayer = classificationLayer('Name','new_classoutput');
lgraph = replaceLayer(lgraph,net.Layers(end).Name,newclasslayer);
```

Train Network

The network requires input images of size 224-by-224-by-3, but the images in the image datastore have different sizes. Use an augmented image datastore to automatically resize the training images. Specify additional augmentation operations to perform on the training images: randomly flip the training images along the vertical axis, randomly translate them up to 30 pixels, and scale them up to 10% horizontally and vertically. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
pixelRange = [-30 30];
scaleRange = [0.9 1.1];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange, ...
    'RandXScale',scaleRange, ...
    'RandYScale',scaleRange);
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain, ...
    'DataAugmentation',imageAugmenter);
```

To automatically resize the validation images without performing further data augmentation, use an augmented image datastore without specifying any additional preprocessing operations.

```
augimdsValidation = augmentedImageDatastore(inputSize(1:2),imdsValidation);
```

Specify the training options. Set `InitialLearnRate` to a small value to slow down learning in the transferred layers that are not already frozen. In the previous step, you increased the learning rate factors for the last learnable layer to speed up learning in the new final layers. This combination of learning rate settings results in fast learning in the new layers, slower learning in the middle layers, and no learning in the earlier, frozen layers.

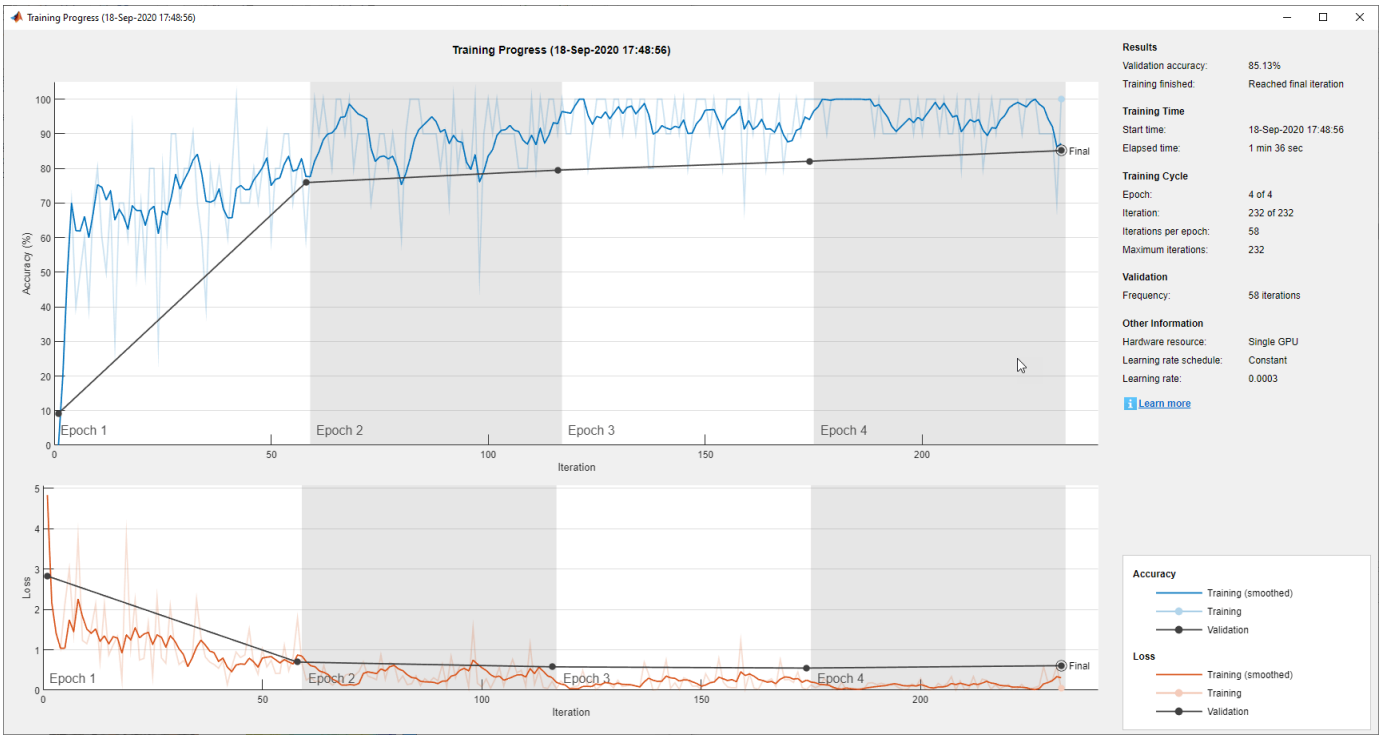
Specify the number of epochs to train for. When performing transfer learning, you do not need to train for as many epochs. An epoch is a full training cycle on the entire training data set. Specify the mini-batch size and validation data. Compute the validation accuracy once per epoch.

```
miniBatchSize = 10;
valFrequency = floor(numel(augimdsTrain.Files)/miniBatchSize);
```

```
options = trainingOptions('sgdm', ...
    'MiniBatchSize',miniBatchSize, ...
    'MaxEpochs',4, ...
    'InitialLearnRate',3e-4, ...
    'Shuffle','every-epoch', ...
    'ValidationData',augimdsValidation, ...
    'ValidationFrequency',valFrequency, ...
    'Verbose',false, ...
    'Plots','training-progress');
```

Train the network using the training data. By default, `trainNetwork` uses a GPU if one is available. This requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see "GPU Support by Release" (Parallel Computing Toolbox). Otherwise, `trainNetwork` uses a CPU. You can also specify the execution environment by using the `'ExecutionEnvironment'` name-value pair argument of `trainingOptions`. Because this data set is small, the training is fast. If you run this example and train the network yourself, you will get different results and misclassifications caused by the randomness involved in the training process.

```
net = trainNetwork(augimdsTrain,lgraph,options);
```



Classify Test Images

Classify the test images using the fine-tuned network and calculate the classification accuracy.

```
augimdsTest = augmentedImageDatastore(inputSize(1:2),imdsTest);
[predictedClasses,predictedScores] = classify(net,augimdsTest);

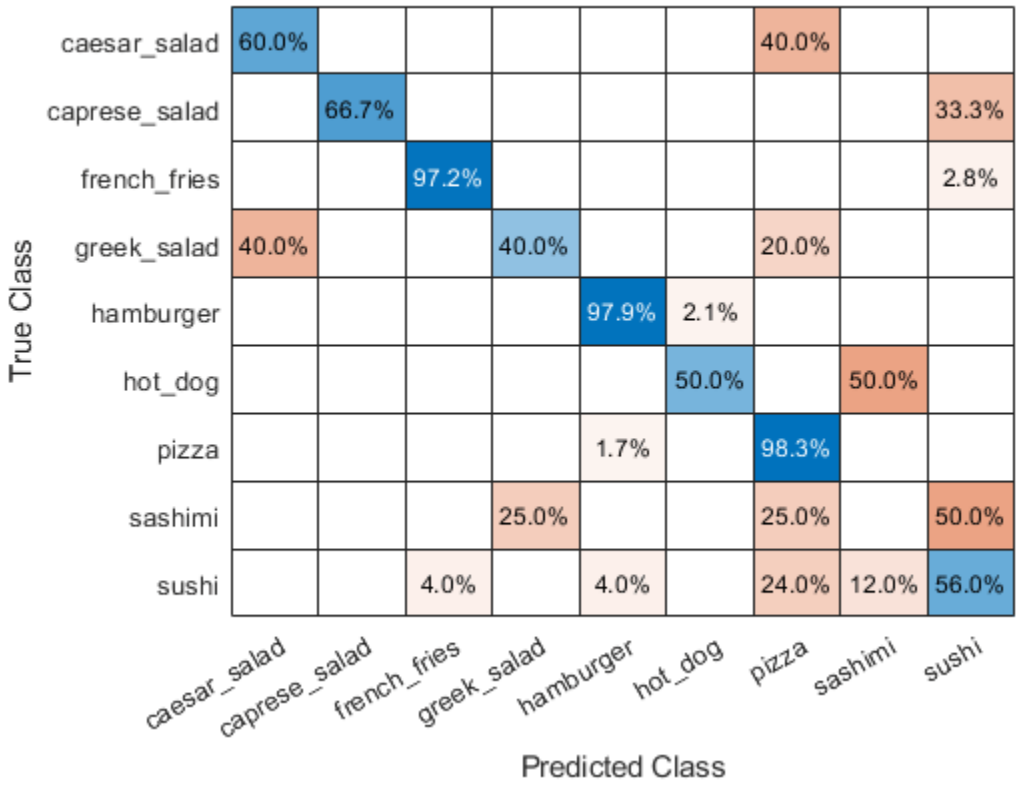
accuracy = mean(predictedClasses == imdsTest.Labels)

accuracy = 0.8418
```

Confusion Matrix for the Test Set

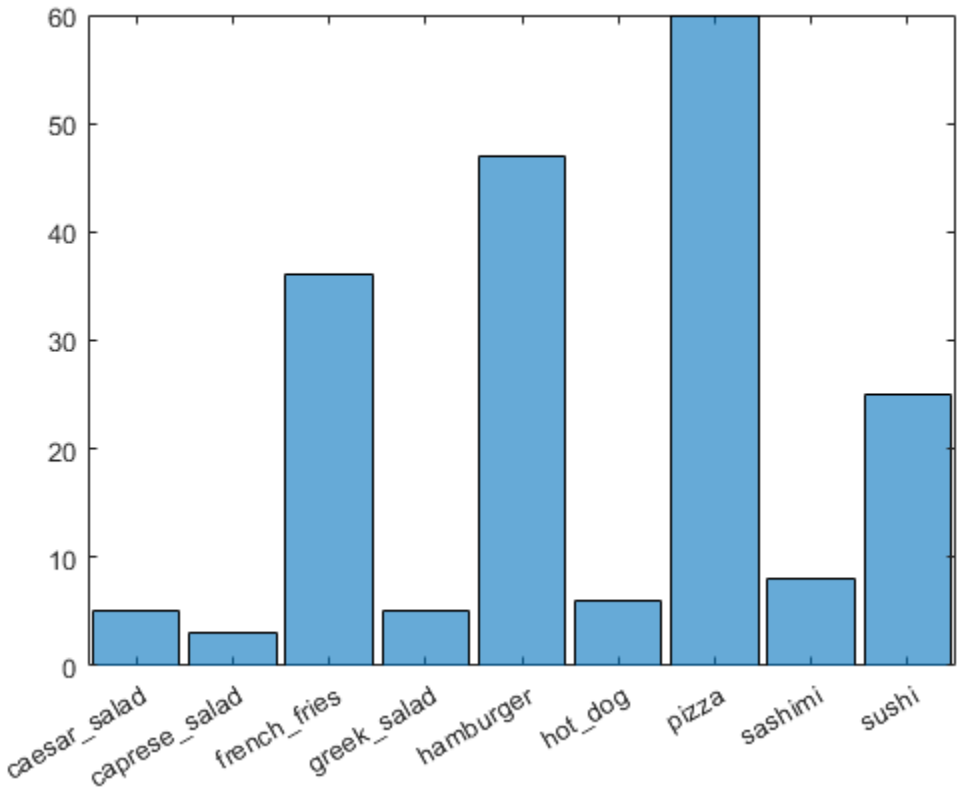
Plot a confusion matrix of the test set predictions. This highlights which particular classes cause most problems for the network.

```
figure;
confusionchart(imdsTest.Labels,predictedClasses,'Normalization',"row-normalized");
```



The confusion matrix shows that the network has poor performance for some classes, such as Greek salad, sashimi, hot dog, and sushi. These classes are underrepresented in the data set which may be impacting network performance. Investigate one of these classes to better understand why the network is struggling.

```
figure();
histogram(imdsValidation.Labels);
ax = gca();
ax.XAxis.TickLabelInterpreter = "none";
```



Investigate Classifications

Investigate network classification for the sushi class.

Sushi Most Like Sushi

First, find which images of sushi most strongly activate the network for the sushi class. This answers the question "Which images does the network think are most sushi-like?".

Plot the maximally-activating images, these are the input images that strongly activate the fully-connected layer's "sushi" neuron. This figure shows the top 4 images, in a descending class score.

```
chosenClass = "sushi";
classIdx = find(net.Layers(end).Classes == chosenClass);

numImgsToShow = 4;

[sortedScores,imgIdx] = findMaxActivatingImages(imdsTest,chosenClass,predictedScores,numImgsToSho

figure
plotImages(imdsTest,imgIdx,sortedScores,predictedClasses,numImgsToShow)
```

Visualize Cues for the Sushi Class

Is the network looking at the right thing for sushi? The maximally-activating images of the sushi class for the network all look similar to each other - a lot of round shapes clustered closely together.

The network is doing well at classifying those kinds of sushi. However, to verify that this is true and to better understand why the network makes its decisions, use a visualization technique like Grad-CAM. For more information on using Grad-CAM, see “Grad-CAM Reveals the Why Behind Deep Learning Decisions” on page 5-21.

Read the first resized image from the augmented image datastore, then plot the Grad-CAM visualization using `gradCAM`.

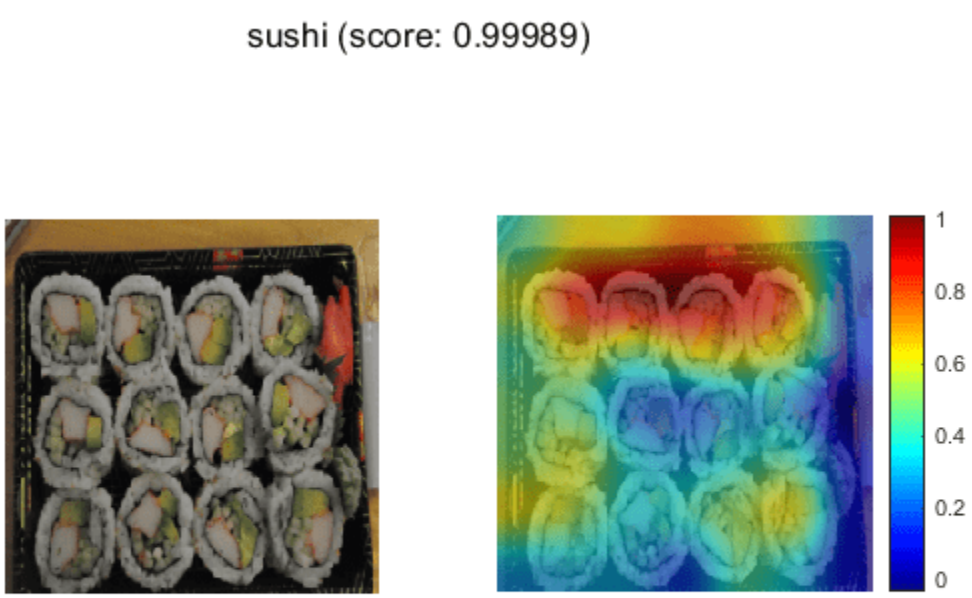
```
imageNumber = 1;

observation = augimdsTest.readByIndex(imgIdx(imageNumber));
img = observation.input{1};

label = predictedClasses(imgIdx(imageNumber));
score = sortedScores(imageNumber);

gradcamMap = gradCAM(net,img,label);

figure
alpha = 0.5;
plotGradCAM(img,gradcamMap,alpha);
sgtitle(string(label)+" (score: "+ max(score)+")")
```



The Grad-CAM map confirms that the network is focussing on the sushi in the image. However you can also see that the network is looking at parts of the plate and the table.

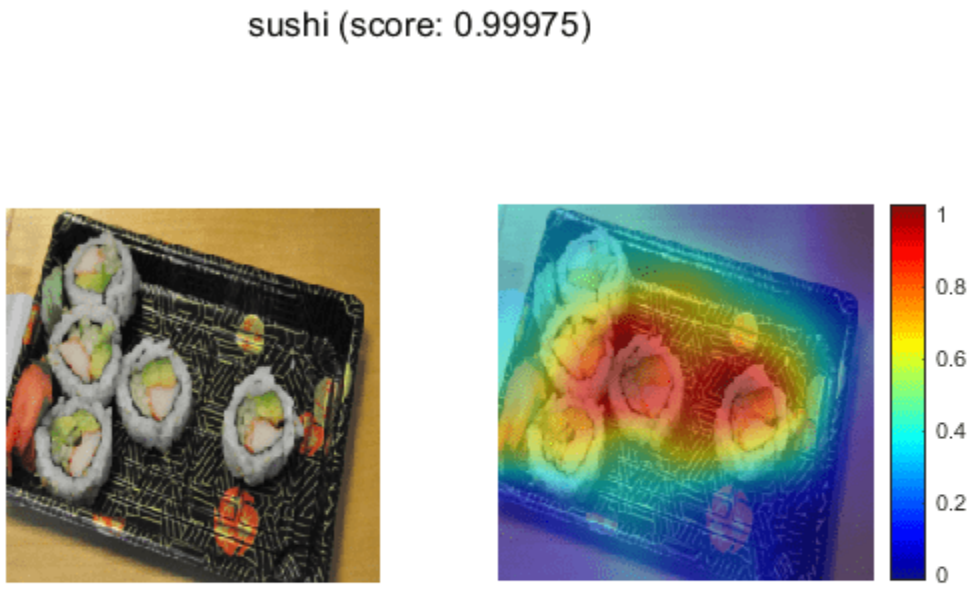
The second image has a cluster of sushi on the left and a lone sushi on the right. To see what the network focuses on, read the second image and plot the Grad-CAM.

```
imageNumber = 2;
observation = augimdsTest.readByIndex(imgIdx(imageNumber));
img = observation.input{1};

label = predictedClasses(imgIdx(imageNumber));
score = sortedScores(imageNumber);

gradcamMap = gradCAM(net,img,label);

figure
plotGradCAM(img,gradcamMap,alpha);
sgtitle(string(label)+" (score: "+ max(score)+")")
```



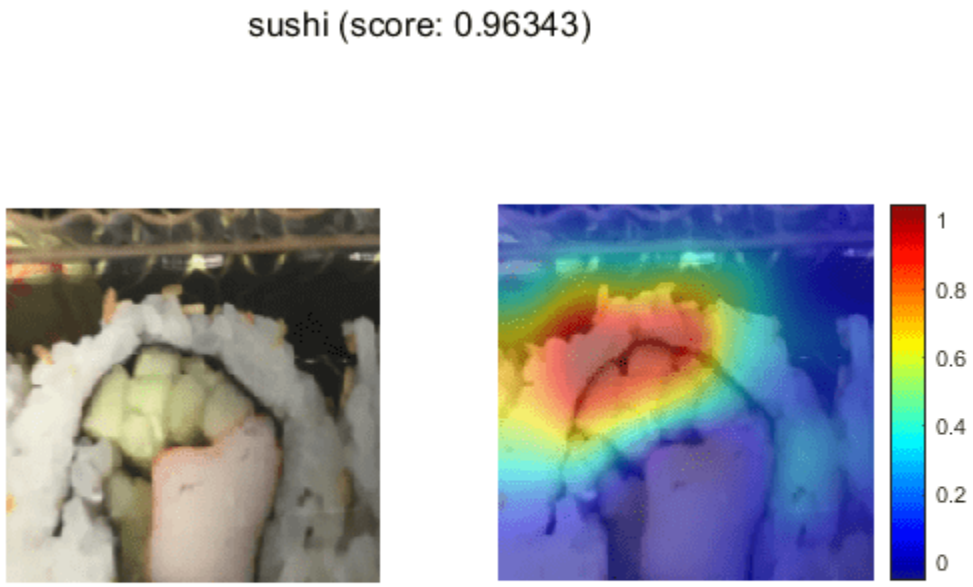
The network classifies this image as sushi because it sees a group of sushi. However, is it able to classify one sushi on its own? Test this by looking at a picture of just one sushi.

```
img = imread(strcat(tempdir,"Food Dataset/sushi/sushi_18.jpg"));
img = imresize(img,net.Layers(1).InputSize(1:2),"Method","bilinear","AntiAliasing",true);

[label,score] = classify(net,img);

gradcamMap = gradCAM(net,img,label);

figure
alpha = 0.5;
plotGradCAM(img,gradcamMap,alpha);
sgtitle(string(label)+" (score: "+ max(score)+")")
```



The network is able to classify this lone sushi correctly. However, the GradCAM shows that the network is focussing on the top of the sushi and the cluster of cucumber, rather than the whole piece together.

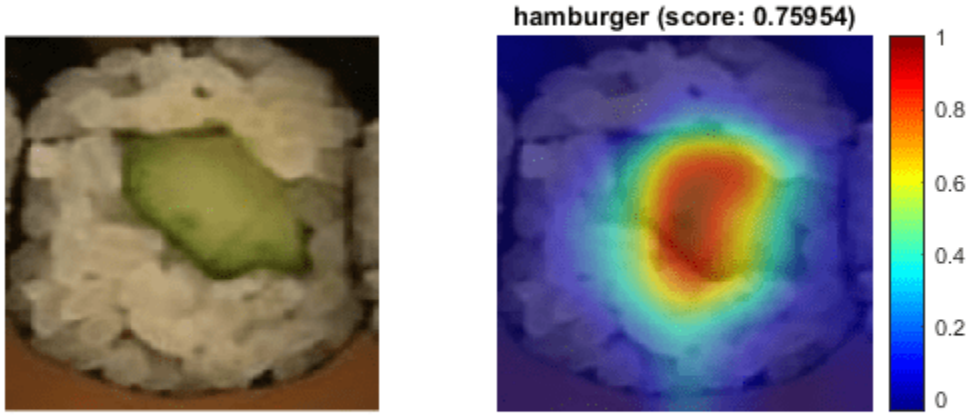
Run the Grad-CAM visualization technique on a lone sushi that does not contain any stacked small pieces of ingredients.

```
img = imread("crop__sushi34-copy.jpg");
img = imresize(img,net.Layers(1).InputSize(1:2),"Method","bilinear","AntiAliasing",true);

[label,score] = classify(net,img);

gradcamMap = gradCAM(net,img,label);

figure
alpha = 0.5;
plotGradCAM(img,gradcamMap,alpha);
title(string(label)+" (score: "+ max(score)+")")
```



In this case, the visualization technique highlights why the network performs poorly. It incorrectly classifies the image of the sushi as a hamburger.

To solve this issue, you must feed the network with more images of lone sushi during the training process.

Sushi Least Like Sushi

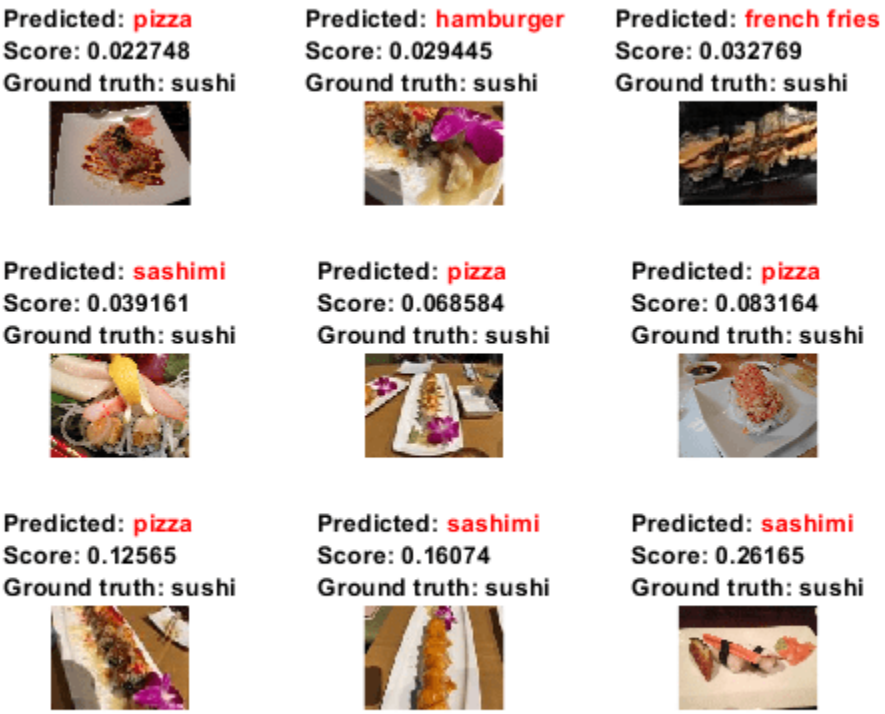
Now find which images of sushi activate the network for the sushi class the least. This answers the question "Which images does the network think are less sushi-like?".

This is useful because it finds the images on which the network performs badly, and it provides some insight into its decision.

```
chosenClass = "sushi";
numImgsToShow = 9;

[sortedScores,imgIdx] = findMinActivatingImages(imdsTest,chosenClass,predictedScores,numImgsToSho

figure
plotImages(imdsTest,imgIdx,sortedScores,predictedClasses,numImgsToShow)
```



Investigate Sushi Misclassified as Sashimi

Why is the network classifying sushi as sashimi? The network classifies 3 out of the 9 images as sashimi. Some of these images, for example images 4 and 9, actually contain sashimi, which means the network isn't actually misclassifying them. These images are mislabeled.

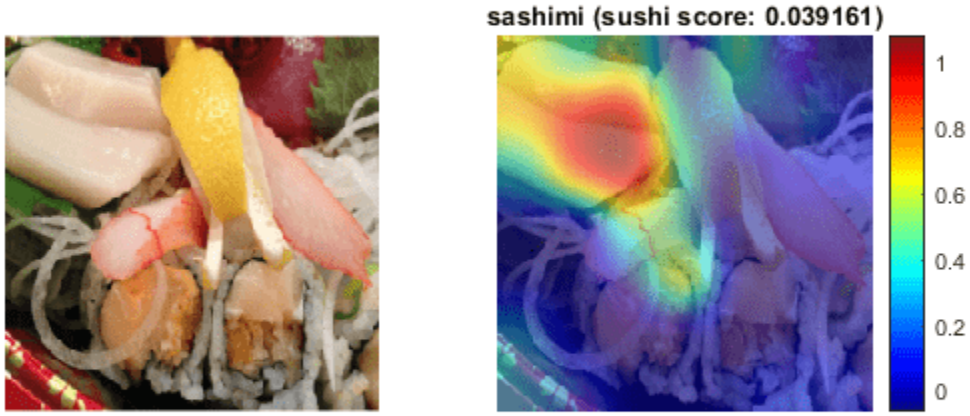
To see what the network is focusing on, run the Grad-CAM technique on one of these images.

```
imageNumber = 4;
observation = augimdsTest.readByIndex(imgIdx(imageNumber));
img = observation.input{1};

label = predictedClasses(imgIdx(imageNumber));
score = sortedScores(imageNumber);

gradcamMap = gradCAM(net,img,label);

figure
alpha = 0.5;
plotGradCAM(img,gradcamMap,alpha);
title(string(label)+" (sushi score: "+ max(score)+")")
```



As expected, the network focuses on the sashimi instead of the sushi.

Investigate Sushi Misclassified as Pizza

Why is the network classifying sushi as pizza? The network classifies four of the images as pizza instead of sushi. Consider image 1, this image has a colourful topping which may be confusing the network.

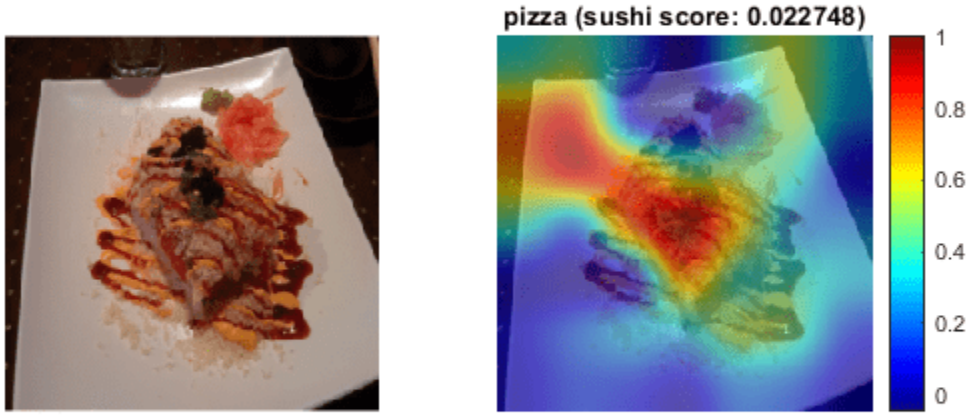
To see which part of the image the network is looking at, run the Grad-CAM technique on one of these images.

```
imageNumber = 1;
observation = augimdsTest.readByIndex(imgIdx(imageNumber));
img = observation.input{1};

label = predictedClasses(imgIdx(imageNumber));
score = sortedScores(imageNumber);

gradcamMap = gradCAM(net,img,label);

figure
alpha = 0.5;
plotGradCAM(img,gradcamMap,alpha);
title(string(label)+" (sushi score: "+ max(score)+")")
```



The network strongly focuses on the toppings. To help the network distinguish pizza from sushi with toppings, add more training images of sushi with toppings. The network also focuses on the plate. This may be as the network has learned to associate certain foods with certain types of plates, as also highlighted when looking at the sushi images. To improve the network's performance, train using more examples of food on different types of plates.

Investigate Sushi Misclassified as a Hamburger

Why is the network classifying sushi as a hamburger? To see what the network is focusing on, run the Grad-CAM technique on the misclassified image.

```
imageNumber = 2;
observation = augimdsTest.readByIndex(imgIdx(imageNumber));
img = observation.input{1};

label = predictedClasses(imgIdx(imageNumber));
score = sortedScores(imageNumber);

gradcamMap = gradCAM(net,img,label);

figure
alpha = 0.5;
plotGradCAM(img,gradcamMap,alpha);
title(string(label)+" (sushi score: "+ max(score)+")")
```

The network is focussing on the flower in the image. The colourful purple flower and brown stalk has confused the network into identifying this image as a hamburger.

Investigate Sushi Misclassified as French Fries

Why is the network classifying sushi as French fries? The network classifies the 3rd image as French fries instead of sushi. This specific sushi has a yellow topping and the network might associate this color with French fries.

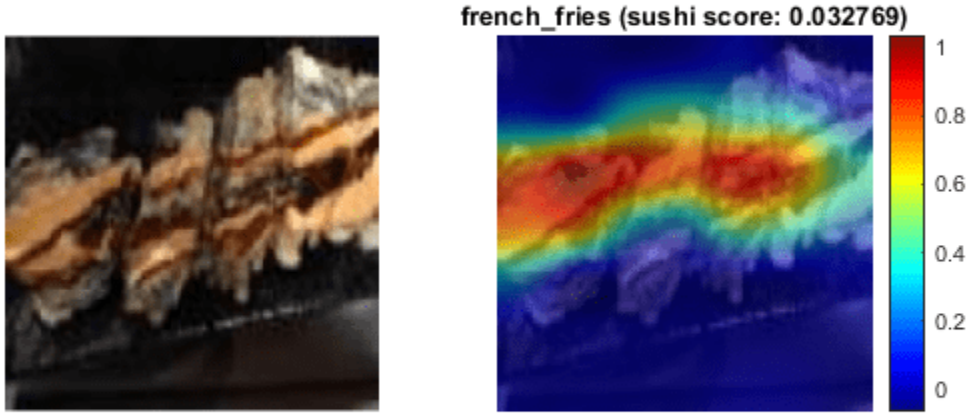
Run Grad-CAM on this image.

```
imageNumber = 3;
observation = augimdsTest.readByIndex(imgIdx(imageNumber));
img = observation.input{1};

label = predictedClasses(imgIdx(imageNumber));
score = sortedScores(imageNumber);

gradcamMap = gradCAM(net,img,label);

figure
alpha = 0.5;
plotGradCAM(img,gradcamMap,alpha);
title(string(label)+" (sushi score: "+ max(score)+")","Interpreter","none")
```



The networks focuses on the yellow sushi classifying it as French fries. As with the hamburger, the unusual colour has caused the network to misclassify the sushi.

To help the network in this specific case, train it with more images of yellow foods that are not French fries.

Conclusions

Investigating the datapoints that give rise to large or small class scores, and datapoints that the network classifies confidently but incorrectly, is a simple technique which can provide useful insight into how a trained network is functioning. In the case of the food data set, this example highlighted that:

- The test data contains several images with incorrect true labels, such as the "sashimi" which is actually "sushi". The data also contains incomplete labels, such as images which contain both sushi and sashimi.
- The network considers a "sushi" to be "multiple, clustered, round-shaped things". However, it must be able to distinguish a lone sushi as well.
- Any sushi or sashimi with toppings or unusual colors confuses the network. To resolve this problem, the data must have a wider variety of sushi and sashimi.
- To improve performance the network needs to see more images from the underrepresented classes.

Helper Functions

```
function downloadExampleFoodImagesData(url,dataDir)

Monitor GAN Training Progress and Identify Common Failure Modes

Training GANs can be a challenging task. This is because the generator and the discriminator networks compete against each other during the training. In fact, if one network learns too quickly, then the other network may fail to learn. This can often result in the network not being able to converge. To diagnose issues and monitor on a scale from 0 to 1 how well the generator and discriminator achieve their respective goals you can plot their scores. For an example showing how to train a GAN and plot the generator and discriminator scores, see “Train Generative Adversarial Network (GAN)” on page 3-76.

The discriminator learns to classify input images as "real" or "generated". The output of the discriminator corresponds to a probability $\widehat{Y}$ that the input images belong to the class "real".

The generator score is the mean of the probabilities corresponding to the discriminator output for the generated images:

$$\text{scoreGenerator} = \text{mean}(\widehat{Y}_{\text{Generated}}),$$

where $\widehat{Y}_{\text{Generated}}$ contains the probabilities for the generated images.

Given that $1 - \widehat{Y}$ is the probability of an image belonging to the class "generated", the discriminator score is the mean of the probabilities of the input images belonging to the correct class:

$$\text{scoreDiscriminator} = \frac{1}{2}\text{mean}(\widehat{Y}_{\text{Real}}) + \frac{1}{2}\text{mean}(1 - \widehat{Y}_{\text{Generated}}),$$

where $\widehat{Y}_{\text{Real}}$ contains the discriminator output probabilities for the real images and the numbers of real and generated images passed to the discriminator are equal.

In the ideal case, both scores would be 0.5. This is because the discriminator cannot tell the difference between real and fake images. However, in practice this scenario is not the only case in which you can achieve a successful GAN.

To monitor the training progress you can visually inspect the images over time and check if they are improving. If the images are not improving, then you can use the score plot to help you diagnose some problems. In some cases, the score plot can tell you there is no point continuing training, and you should stop, because a failure mode has occurred that training cannot recover from. The following sections tell you what to look for in the score plot and in the generated images to diagnose some common failure modes (convergence failure and mode collapse), and suggests possible actions you can take to improve the training.

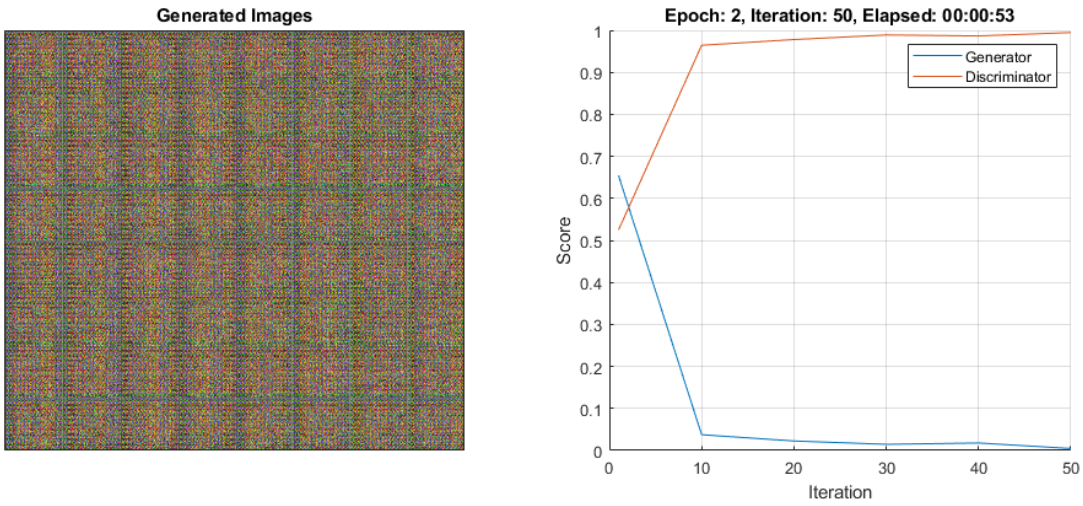
Convergence Failure

Convergence failure happens when the generator and discriminator do not reach a balance during training.

Discriminator Dominates

This scenario happens when the generator score reaches zero or near zero and the discriminator score reaches one or near one.

This plot shows an example of the discriminator overpowering the generator. Notice that the generator score approaches zero and does not recover. In this case, the discriminator classifies most of the images correctly. In turn, the generator cannot produce any images that fool the discriminator and thus fails to learn.



If the score does not recover from these values for many iterations, then it is better to stop the training. If this happens, then try balancing the performance of generator and the discriminator by:

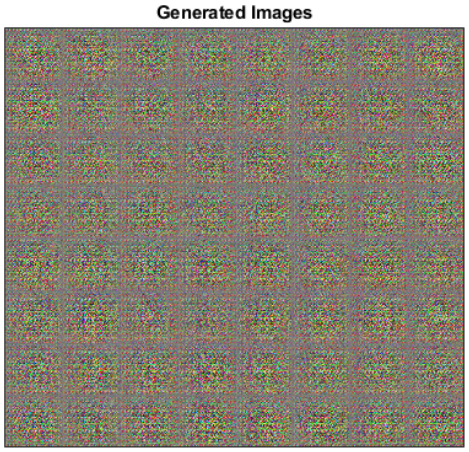
- Impairing the discriminator by randomly giving false labels to real images (one-sided label flipping)
- Impairing the discriminator by adding dropout layers
- Improving the generator's ability to create more features by increasing the number of filters in its convolution layers
- Impairing the discriminator by reducing its number of filters

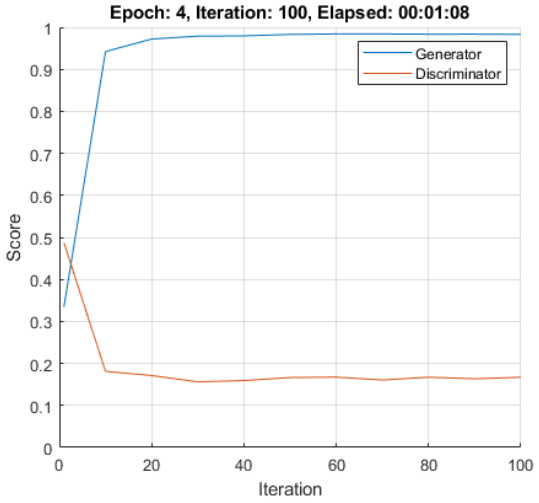
For an example showing how to flip the labels of the real images, see “Train Generative Adversarial Network (GAN)” on page 3-76.

Generator Dominates

This scenario happens when the generator score reaches one or near one.

This plot shows an example of the generator overpowering the discriminator. Notice that the generator score goes to one for a many iterations. In this case, the generator learns how to fool the discriminator almost always. When this happens very early in the training process, the generator is likely to learn a very simple feature representation which fools the discriminator easily. This means that the generated images can be very poor, despite having high scores. Note that in this example, the score of the discriminator does not go very close to zero because it is still able to classify correctly some real images.





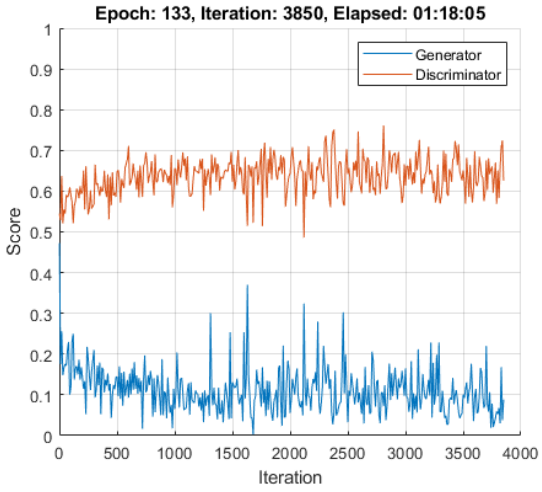
If the score does not recover from these values for many iterations, then it is better to stop the training. If this happens, then try balancing the performance of generator and the discriminator by:

- Improving the discriminator's ability to learn more features by increasing the number of filters
- Impairing the generator by adding dropout layers
- Impairing the generator by reducing its number of filters

Mode Collapse

Mode collapse is when the GAN produces a small variety of images with many duplicates (modes). This happens when the generator is unable to learn a rich feature representation because it learns to associate similar outputs to multiple different inputs. To check for mode collapse, inspect the generated images. If there is little diversity in the output and some of them are almost identical, then there is likely mode collapse.

This plot shows an example of mode collapse. Notice that the generated images plot contains a lot of almost identical images, even though the inputs to the generator were different and random.



If you observe this happening, then try to increase the ability of the generator to create more diverse outputs by:

- Increasing the dimensions of the input data to the generator
- Increasing the number of filters of the generator to allow it to generate a wider variety of features
- Impairing the discriminator by randomly giving false labels to real images (one-sided label flipping)

For an example showing how to flip the labels of the real images, see “Train Generative Adversarial Network (GAN)” on page 3-76.

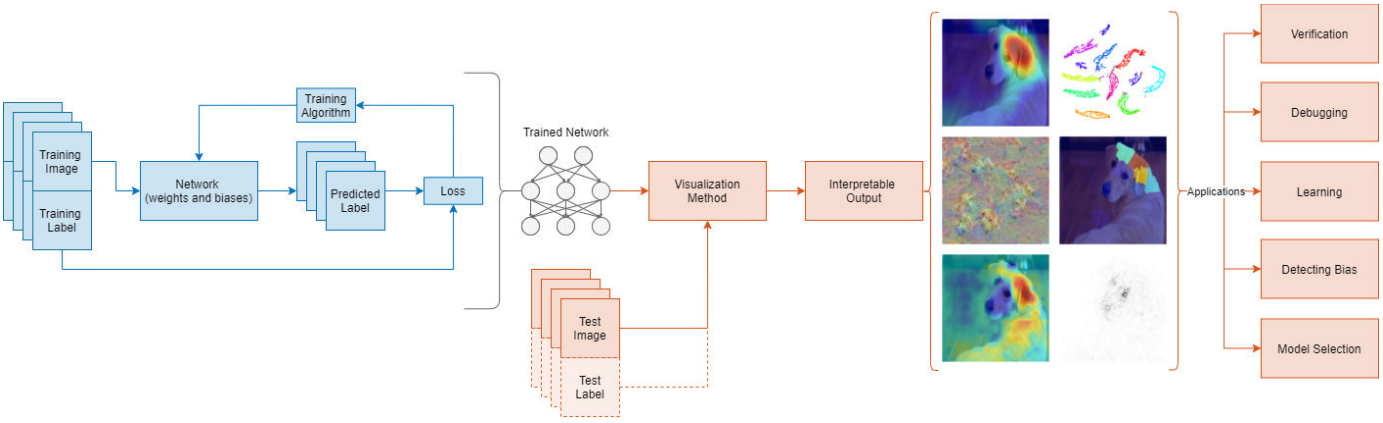
Deep Learning Visualization Methods

Deep learning networks are often described as "black boxes" because the reason that a network makes a certain decision is not always obvious. Increasingly, deep learning networks are being used in domains from medical treatment to loan applications, so understanding why a network makes a particular decision is crucial.

You can use interpretability techniques to translate network behavior into output that a person can interpret. This interpretable output can then answer questions about the predictions of a network. Interpretability techniques have many applications, for example, verification, debugging, learning, assessing bias, and model selection.

You can apply interpretability techniques after network training, or build them into the network. The advantage of post-training methods is that you do not have to spend time constructing an interpretable deep learning network. This topic focuses on post-training methods that use test images to explain the predictions of a network trained on image data.

Visualization methods are a type of interpretability technique that explain network predictions using visual representations of what a network is looking at. There are many techniques for visualizing network behavior, such as heat maps, saliency maps, feature importance maps, and low-dimensional projections.



Visualization Methods

Interpretability techniques have varying characteristics; which method you use will depend on the interpretation you want and the network you have trained. Methods can be *local* and only investigate network behaviour for a specific input or *global* and investigate network behaviour across an entire data set.

Each visualization method has a specific approach that determines the output it produces. A common distinction between methods is if they are gradient or perturbation based. *Gradient-based* methods backpropagate the signal from the output back towards the input. *Perturbation-based* methods perturb the input to the network and consider the effect of the perturbation on prediction. Another approach to interpretability technique involves mapping or approximating the complex network model to a more interpretable space. For example, some methods approximate the network predictions using a simpler, more interpretable model. Other methods use dimension reduction techniques to reduce high-dimensional activations down to interpretable 2-D or 3-D space.

The following table compares visualization interpretability techniques for deep learning models for image classification. For an example showing how to use visualization methods to investigate the predictions of an image classification network, see “Explore Network Predictions Using Deep Learning Visualization Techniques” on page 5-2.

Deep Learning Visualization Methods for Image Classification

Method	Example Visualization	Function	Locality	Approach	Resolution	Requires Tuning	Description
Activations		`activations`	Local	Activation visualization	Low	No	Visualizing activations is a simple way of understanding network behavior. Most convolutional neural networks learn to detect features like color and edges in their first convolutional layers. In deeper convolutional layers, the network learns to detect more complicated features. For more information, see “Visualize Activations of a Convolutional Neural Network” on page 5-141.
CAM		`cam`	Local	Gradient-based class activation heat map	Low	No	Class activation mapping (CAM) is a simple technique for generating visual explanations of the predictions of convolutional neural networks [1]. CAM uses the global average pooling layer in a convolutional neural network to generate a map that highlights which parts of an image the network is using with respect to a particular class label. For more information, see “Investigate Network Predictions Using Class Activation Mapping” on page 5-123.
Grad-CAM		`gradCAM`	Local	Gradient-based class activation heat map	Low	No	Gradient-weighted class activation mapping (Grad-CAM) is a generalization of the CAM method that uses the gradient of the classification score with respect to the convolutional features determined by the network to understand which parts of the image are most important for classification [2]. The places where the gradient is large are the places where the final score depends most on the data. Grad-CAM gives similar results to CAM without the architecture restrictions of CAM. For more information, see “Grad-CAM Reveals the Why Behind Deep Learning Decisions” on page 5-21 and “Explore Semantic Segmentation Network Using Grad-CAM” on page 5-66.

Method	Example Visualization	Function	Locality	Approach	Resolution	Requires Tuning	Description
Occlusion sensitivity		`occlusionSensitivity`	Local	Perturbation-based heat map	Low to medium	Yes	Occlusion sensitivity measures network sensitivity to small perturbations in input data. The method perturbs small areas of the input by replacing it with an occluding mask, typically a gray square. As the mask moves across the image, the technique measures the change in probability score for a given class. You can use occlusion sensitivity to highlight which parts of the image are most important to the classification. To get the best results from occlusion sensitivity, you must choose the right values for the `MaskSize` and `Stride` options. This tuning provides more flexibility to examine the input features at different length scales. For more information, see “Understand Network Predictions Using Occlusion” on page 5-24.
LIME		`imageLIME`	Local	Perturbation-based proxy model, feature importance	Low to high	Yes	The LIME technique approximates the classification behavior of a deep learning network using a simpler, more interpretable model, such as a linear model or a regression tree [3]. The simple model determines the importance of features of the input data, as a proxy for the importance of the features to the deep learning network. For more information, see “Understand Network Predictions Using LIME” on page 5-42 and “Investigate Spectrogram Classifications Using LIME” on page 5-49.

Method	Example Visualization	Function	Locality	Approach	Resolution	Requires Tuning	Description
Gradient attribution		No	Local	Gradient-based saliency map	High	No	Gradient attribution methods provide pixel-resolution maps showing which pixels are most important to the network classification decisions [4][5]. These methods compute the gradient of the class score with respect to the input pixels. Intuitively, the maps show which pixels most affect the class score when changed. The gradient attribution methods produce maps the same size as the input image. Therefore, gradient attribution maps have a high resolution, but they tend to be much noisier, as a well-trained deep network is not strongly dependent on the exact value of specific pixels. For more information, see “Investigate Classification Decisions Using Gradient Attribution Techniques” on page 5-31.
Deep dream		`deepDreamImage`	Global	Gradient-based activation maximization	Low to high	Yes	Deep Dream is a feature visualization technique that synthesizes images that strongly activate network layers [6]. By visualizing these images, you can highlight the image features learned by a network. These images are useful for understanding and diagnosing network behavior. For more information, see “Deep Dream Images Using GoogLeNet” on page 5-15.
t-SNE		`tsne`	Global	Dimension reduction	N/A	No	t-SNE is a dimension reduction technique that preserves distances so that points near each other in the high-dimension representation are also near each other in the low-dimensional representation [7]. You can use t-SNE to visualize how deep learning networks change the representation of input data as it passes through the network layers. For more information, see “View Network Behavior Using tsne” on page 5-129.

Method	Example Visualization	Function	Locality	Approach	Resolution	Requires Tuning	Description
Maximal and minimal activating images		No	Global	Gradient-based activation maximization	N/A	No	Visualizing images that strongly or weakly activate the network for each class is a simple way of understating your network. Images that strongly activate highlight what the network thinks a "typical" image from that class looks like. Images that weakly activate can help you to discover why your network makes incorrect classification predictions. For more information, see “Visualize Image Classifications Using Maximal and Minimal Activating Images” on page 5-163.

Interpretability Methods for Nonimage Data

Many interpretability focus on interpreting image classification or regression networks. Interpreting nonimage data is often more challenging due to the nonvisual nature of the data. To explore the activations of an LSTM network, use the `activations` and `tsne` functions. For an example showing how to explore the predictions of an LSTM network, see “Visualize Activations of LSTM Network” on page 5-152. To explore the behavior of a network trained on tabular features, use the `lime` and `shapley` functions. For an example showing how to interpret a feature input network, see “Interpret Deep Network Predictions on Tabular Data Using LIME” on page 5-59. For more information about interpreting machine learning models, see “Interpret Machine Learning Models” (Statistics and Machine Learning Toolbox).

Manage Deep Learning Experiments

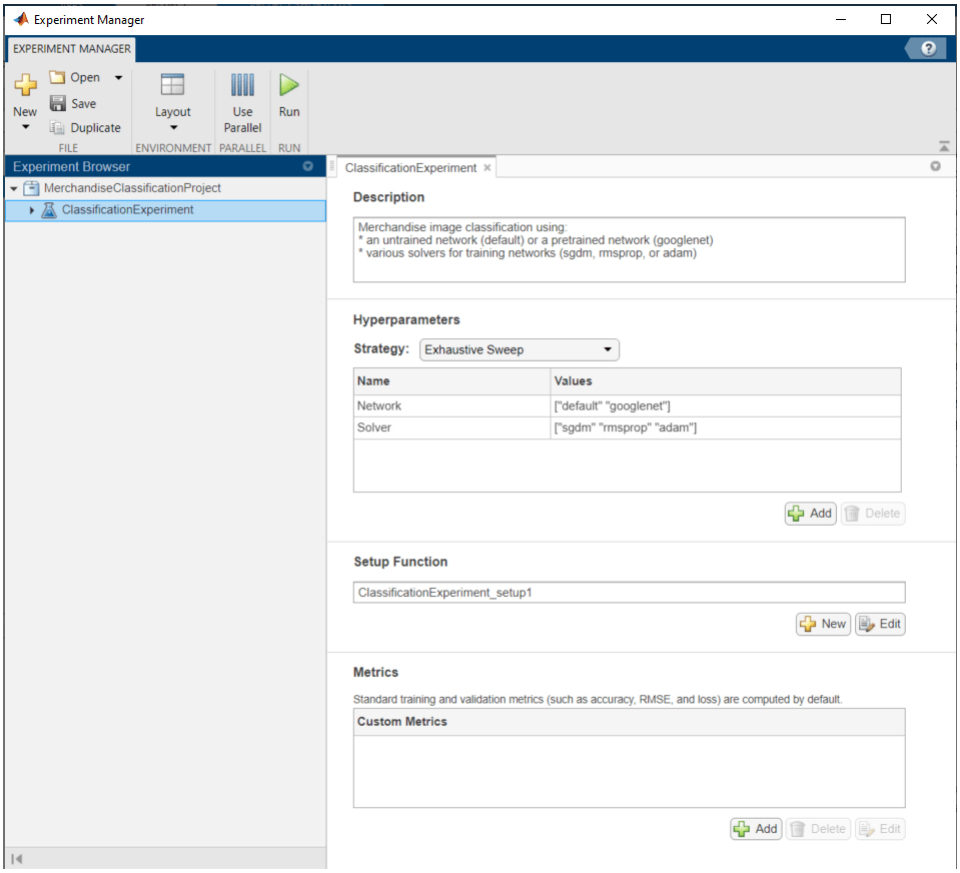
Create a Deep Learning Experiment for Classification

This example shows how to train a deep learning network for classification by using **Experiment Manager**. In this example, you train two networks to classify images of MathWorks merchandise into five classes. Each network is trained using three algorithms. In each case, a confusion matrix compares the true classes for a set of validation images with the classes predicted by the trained network. For more information on training a network for image classification, see “Train Deep Learning Network to Classify New Images” on page 3-6.

This experiment requires the Deep Learning Toolbox™ Model *for GoogLeNet Network* support package. Before you run the experiment, install this support package by calling the `googlenet` function and clicking the download link.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`ClassificationExperiment`).



Built-in training experiments consist of a description, a table of hyperparameters, a setup function, and a collection of metric functions to evaluate the results of the experiment. For more information, see “Configure Built-In Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Merchandise image classification using:
* an untrained network (default) or a pretrained network (googlenet)
* various solvers for training networks (sgdm, rmsprop, or adam)
```

The **Hyperparameters** section specifies the strategy (`Exhaustive Sweep`) and hyperparameter values to use for the experiment. When you run the experiment, Experiment Manager trains the network using every combination of hyperparameter values specified in the hyperparameter table. This example uses two hyperparameters:

- `Network` specifies the network to train. The options include `"default"` (the default network provided by the experiment template for image classification) and `"googlenet"` (a pretrained GoogLeNet network with modified layers for transfer learning).
- `Solver` indicates the algorithm used to train the network. The options include `"sgdm"` (stochastic gradient descent with momentum), `"rmsprop"` (root mean square propagation), and `"adam"` (adaptive moment estimation). For more information about these algorithms, see “Stochastic Gradient Descent”.

The **Setup Function** configures the training data, network architecture, and training options for the experiment. The input to the setup function is a structure with fields from the hyperparameter table. The setup function returns three outputs that you use to train a network for image classification problems. In this example, the setup function has three sections.

- **Load Training Data** defines image datastores containing the training and validation data. This example loads images from the file `MerchData.zip`. This small data set contains 75 images of MathWorks merchandise, belonging to five different classes. The images are of size 227-by-227-by-3. For more information on this data set, see “Image Data Sets” on page 19-118.

```
filename = "MerchData.zip";
dataFolder = fullfile(tempdir,"MerchData");
if ~exist(dataFolder,"dir")
    unzip(filename,tempdir);
end

imdsTrain = imageDatastore(dataFolder, ...
    IncludeSubfolders=true, ....
    LabelSource="foldernames");

numTrainingFiles = 0.7;
[imdsTrain,imdsValidation] = splitEachLabel(imdsTrain,numTrainingFiles);
```

- **Define Network Architecture** defines the architecture for a convolutional neural network for deep learning classification. In this example, the choice of network to train depends on the value of the hyperparameter `Network`.

```
switch params.Network
    case "default"
        inputSize = [227 227 3];
        numClasses = 5;
        layers = [
            imageInputLayer(inputSize)
            convolution2dLayer(5,20)
            batchNormalizationLayer
            reluLayer
            fullyConnectedLayer(numClasses)
            softmaxLayer
            classificationLayer];
    case "googlenet"
```

```
        inputSize = [224 224 3];
        numClasses = 5;
        imdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain);
        imdsValidation = augmentedImageDatastore(inputSize(1:2), ...
            imdsValidation);
        net = googlenet;
        layers = layerGraph(net);
        newLearnableLayer = fullyConnectedLayer(numClasses, ...
            Name="new_fc", ...
            WeightLearnRateFactor=10, ...
            BiasLearnRateFactor=10);
        layers = replaceLayer(layers,"loss3-classifier",newLearnableLayer);
        newClassLayer = classificationLayer(Name="new_classoutput");
        layers = replaceLayer(layers,"output",newClassLayer);
    otherwise
        error("Undefined network selection.");
end
```

- **Specify Training Options** defines a `trainingOptions` object for the experiment. The example trains the network for 8 epochs using the algorithm specified by the `Solver` entry in the hyperparameter table.

```
options = trainingOptions(params.Solver, ...
    MiniBatchSize=10, ...
    MaxEpochs=8, ...
    InitialLearnRate=1e-4, ...
    Shuffle="every-epoch", ...
    ValidationData=imdsValidation, ...
    ValidationFrequency=5, ...
    Verbose=false);
```

To inspect the setup function, under **Setup Function**, click **Edit**. The setup function opens in MATLAB® Editor. In addition, the code for the setup function appears in the appendix at the end of this example.

The **Metrics** section specifies optional functions that evaluate the results of the experiment. This example does not include any custom metric functions.

Run Experiment

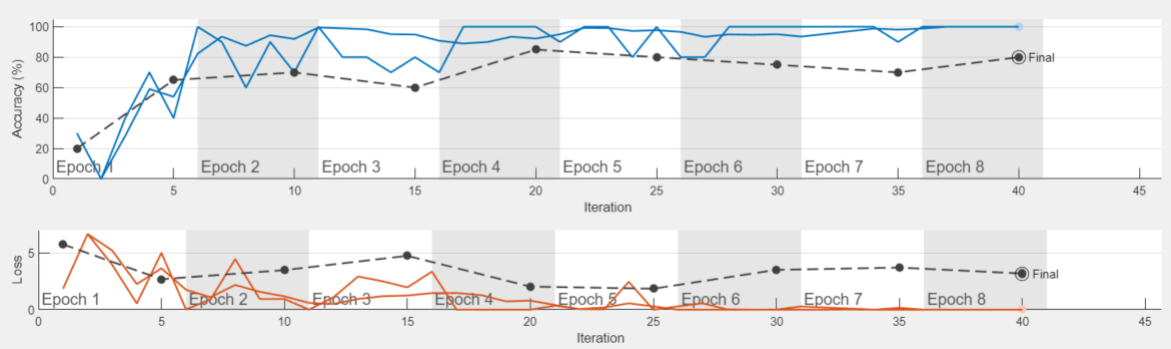
When you run the experiment, Experiment Manager trains the network defined by the setup function six times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox™, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16 and “GPU Support by Release” (Parallel Computing Toolbox).

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the accuracy and loss for each trial.

Trial	Status	Progress	Elapsed Time	Network	Solver	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss
1	Complete	100.0%	0 hr 0 min 7 sec	default	sgdm	100.0000	1.1921e-8	80.0000	3.1888
2	Complete	100.0%	0 hr 0 min 22 sec	googlenet	sgdm	100.0000	0.0495	95.0000	0.2479
3	Complete	100.0%	0 hr 0 min 8 sec	default	rmsprop	100.0000	0.0000	80.0000	2.6453
4	Complete	100.0%	0 hr 0 min 23 sec	googlenet	rmsprop	100.0000	0.0003	95.0000	0.2989
5	Complete	100.0%	0 hr 0 min 7 sec	default	adam	100.0000	0.0000	80.0000	2.5187
6	Complete	100.0%	0 hr 0 min 26 sec	googlenet	adam	100.0000	0.0003	90.0000	0.4894

While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial.



Evaluate Results

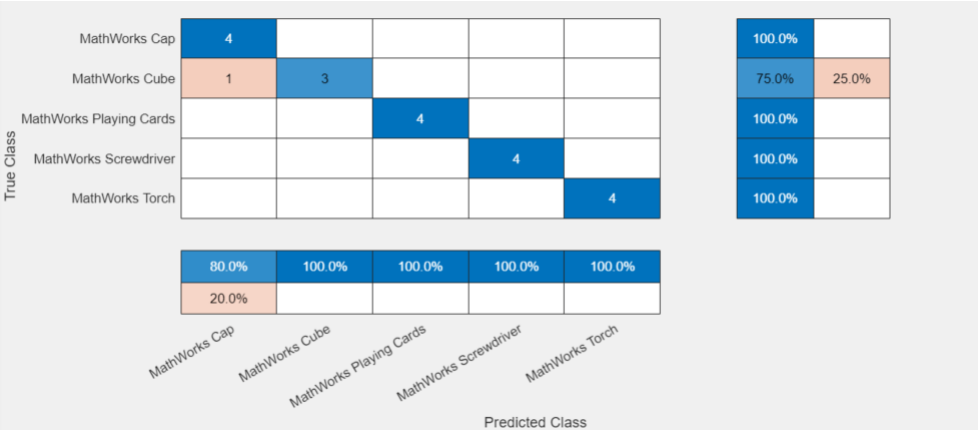
To find the best result for your experiment, sort the table of results by validation accuracy.

1. Point to the **Validation Accuracy** column.
2. Click the triangle icon.
3. Select **Sort in Descending Order**.

The trial with the highest validation accuracy appears at the top of the results table.

Trial	Status	Progress	Elapsed Time	Network	Solver	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss
2	Complete	100.0%	0 hr 0 min 22 sec	googlenet	sgdm	100.0000	0.0495	95.0000	0.2479
4	Complete	100.0%	0 hr 0 min 23 sec	googlenet	rmsprop	100.0000	0.0003	95.0000	0.2989
6	Complete	100.0%	0 hr 0 min 26 sec	googlenet	adam	100.0000	0.0003	90.0000	0.4894
1	Complete	100.0%	0 hr 0 min 7 sec	default	sgdm	100.0000	1.1921e-8	80.0000	3.1888
3	Complete	100.0%	0 hr 0 min 8 sec	default	rmsprop	100.0000	0.0000	80.0000	2.6453
5	Complete	100.0%	0 hr 0 min 7 sec	default	adam	100.0000	0.0000	80.0000	2.5187

To display the confusion matrix for this trial, select the top row in the results table and click **Confusion Matrix**.



To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **Validation Accuracy** cell of the best trial.
2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.

For more information, see “Sort, Filter, and Annotate Experiment Results”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix: Setup Function

This function configures the training data, network architecture, and training options for the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.

Output

- `imdsTrain` is an image datastore for the training data.
- `layers` is a layer graph that defines the neural network architecture.
- `options` is a `trainingOptions` object.

```
function [imdsTrain,layers,options] = ClassificationExperiment_setup1(params)

filename = "MerchData.zip";
dataFolder = fullfile(tempdir,"MerchData");
if ~exist(dataFolder,"dir")
```

```
    unzip(filename,tempdir);
end

imdsTrain = imageDatastore(dataFolder, ...
    IncludeSubfolders=true, ....
    LabelSource="foldernames");

numTrainingFiles = 0.7;
[imdsTrain,imdsValidation] = splitEachLabel(imdsTrain,numTrainingFiles);

switch params.Network
    case "default"
        inputSize = [227 227 3];
        numClasses = 5;

        layers = [
            imageInputLayer(inputSize)
            convolution2dLayer(5,20)
            batchNormalizationLayer
            reluLayer
            fullyConnectedLayer(numClasses)
            softmaxLayer
            classificationLayer];

    case "googlenet"
        inputSize = [224 224 3];
        numClasses = 5;

        imdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain);
        imdsValidation = augmentedImageDatastore(inputSize(1:2), ...
            imdsValidation);

        net = googlenet;
        layers = layerGraph(net);

        newLearnableLayer = fullyConnectedLayer(numClasses, ...
            Name="new_fc", ...
            WeightLearnRateFactor=10, ...
            BiasLearnRateFactor=10);
        layers = replaceLayer(layers,"loss3-classifier",newLearnableLayer);

        newClassLayer = classificationLayer(Name="new_classoutput");
        layers = replaceLayer(layers,"output",newClassLayer);

    otherwise
        error("Undefined network selection.");
end

options = trainingOptions(params.Solver, ...
    MiniBatchSize=10, ...
    MaxEpochs=8, ...
    InitialLearnRate=1e-4, ...
    Shuffle="every-epoch", ...
    ValidationData=imdsValidation, ...
    ValidationFrequency=5, ...
    Verbose=false);
```

```
end
```

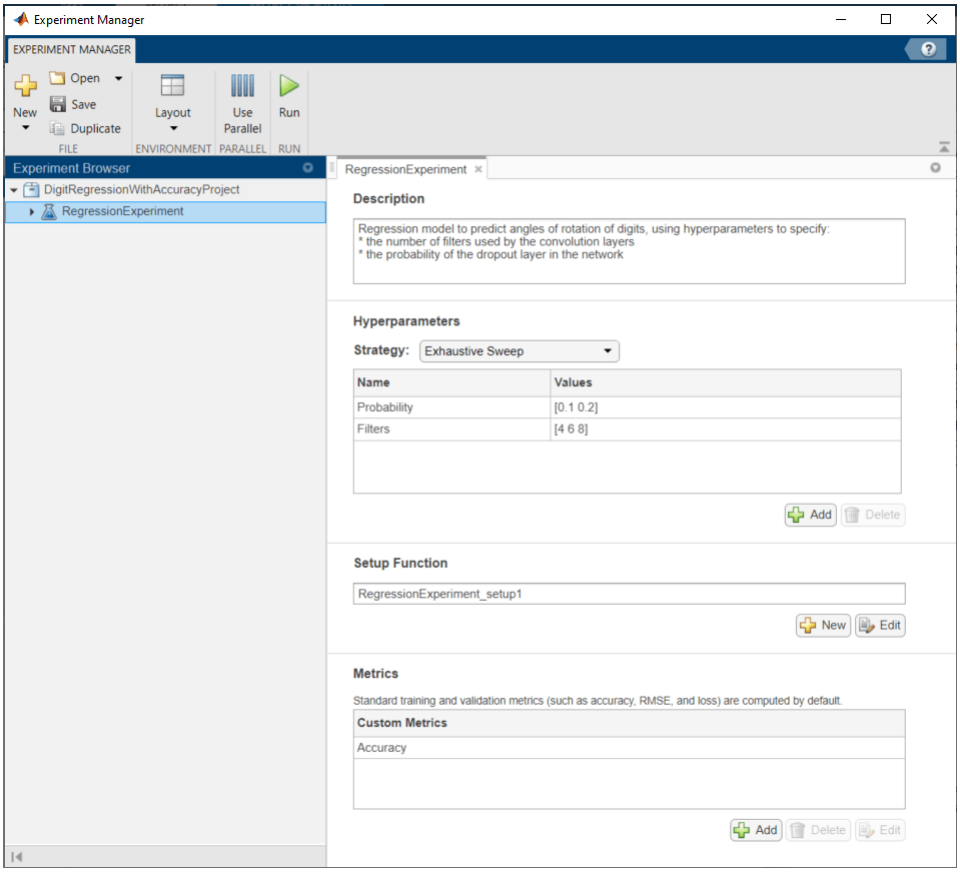
- “Evaluate Deep Learning Experiments by Using Metric Functions” on page 6-19
- “Create a Deep Learning Experiment for Regression” on page 6-9

Create a Deep Learning Experiment for Regression

This example shows how to train a deep learning network for regression by using **Experiment Manager**. In this example, you use a regression model to predict the angles of rotation of handwritten digits. A custom metric function determines the fraction of angle predictions within an acceptable error margin from the true angles. For more information on using a regression model, see “Train Convolutional Neural Network for Regression” on page 3-53.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`RegressionExperiment`).



Built-in training experiments consist of a description, a table of hyperparameters, a setup function, and a collection of metric functions to evaluate the results of the experiment. For more information, see “Configure Built-In Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Regression model to predict angles of rotation of digits, using hyperparameters to specify:
* the number of filters used by the convolution layers
* the probability of the dropout layer in the network
```

The **Hyperparameters** section specifies the strategy (`Exhaustive Sweep`) and hyperparameter values to use for the experiment. When you run the experiment, Experiment Manager trains the network using every combination of hyperparameter values specified in the hyperparameter table. This example uses two hyperparameters:

- `Probability` sets the probability of the dropout layer in the neural network. By default, the values for this hyperparameter are specified as `[0.1 0.2]`.
- `Filters` indicates the number of filters used by the first convolution layer in the neural network. In the subsequent convolution layers, the number of filters is a multiple of this value. By default, the values of this hyperparameter are specified as `[4 6 8]`.

The **Setup Function** configures the training data, network architecture, and training options for the experiment. The input to the setup function is a structure with fields from the hyperparameter table. The setup function returns four outputs that you use to train a network for image regression problems. The setup function has three sections.

- **Load Training Data** defines the training and validation data for the experiment as 4-D arrays. The training and validation data sets each contain 5000 images of digits from 0 to 9. The regression values correspond to the angles of rotation of the digits.

```
[XTrain,~,YTrain] = digitTrain4DArrayData;
[XValidation,~,YValidation] = digitTest4DArrayData;
```

- **Define Network Architecture** defines the architecture for a convolutional neural network for regression.

```
inputSize = [28 28 1];
numFilters = params.Filters;
layers = [
    imageInputLayer(inputSize)
    convolution2dLayer(3,numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer
    averagePooling2dLayer(2,Stride=2)
    convolution2dLayer(3,2*numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer
    averagePooling2dLayer(2,Stride=2)
    convolution2dLayer(3,4*numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer
    convolution2dLayer(3,4*numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer
    dropoutLayer(params.Probability)
    fullyConnectedLayer(1)
    regressionLayer];
```

- **Specify Training Options** defines a `trainingOptions` object for the experiment. The example trains the network for 30 epochs. The learning rate is initially 0.001 and drops by a factor of 0.1 after 20 epochs. The software trains the network on the training data and calculates the root mean squared error (RMSE) and loss on the validation data at regular intervals during training. The validation data is not used to update the network weights.

```
miniBatchSize = 128;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
```

```
options = trainingOptions("sgdm", ...
    MiniBatchSize=miniBatchSize, ...
    MaxEpochs=30, ...
    InitialLearnRate=1e-3, ...
    LearnRateSchedule="piecewise", ...
    LearnRateDropFactor=0.1, ...
    LearnRateDropPeriod=20, ...
    Shuffle="every-epoch", ...
    ValidationData={XValidation,YValidation}, ...
    ValidationFrequency=validationFrequency, ...
    Verbose=false);
```

To inspect the setup function, under **Setup Function**, click **Edit**. The setup function opens in MATLAB® Editor. In addition, the code for the setup function appears in Appendix 1 at the end of this example.

The **Metrics** section specifies optional functions that evaluate the results of the experiment. Experiment Manager evaluates these functions each time it finishes training the network. To inspect a metric function, select the name of the metric function and click **Edit**. The metric function opens in MATLAB Editor.

This example includes a metric function `Accuracy` that determines the percentage of angle predictions within an acceptable error margin from the true angles. By default, the function uses a threshold of 10 degrees. The code for the metric function appears in Appendix 2 at the end of this example.

Run Experiment

When you run the experiment, Experiment Manager trains the network defined by the setup function six times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox™, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16 and “GPU Support by Release” (Parallel Computing Toolbox).

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the RMSE and loss for each trial. The table also displays the accuracy of the trial, as determined by the custom metric function `Accuracy`.

Trial	Status	Progress	Elapsed Time	Probability	Filters	Training RMSE	Training Loss	Validation RMSE	Validation Loss	Accuracy
1	Complete	100.0%	0 hr 1 min 13 sec	0.1000	4.0000	4.6942	11.0176	5.5271	15.2746	93.6800

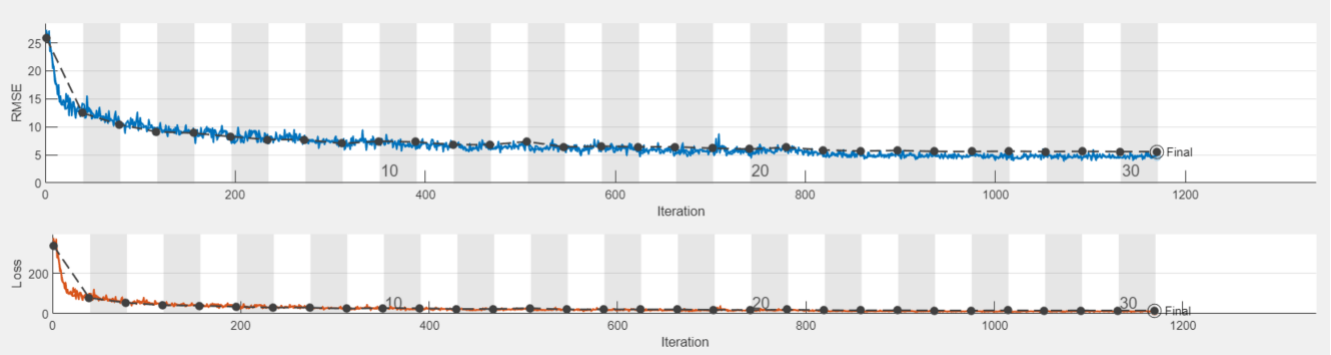
6	Complete	100.0%	0 hr 1 min 20 sec	0.2000	8.0000	4.2288	8.9413	4.4778	10.0253	97.0200

While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial.



Evaluate Results

To find the best result for your experiment, sort the table of results by accuracy.

1. Point to the **Accuracy** column.
2. Click the triangle icon.
3. Select **Sort in Descending Order**.

The trial with the highest accuracy appears at the top of the results table.

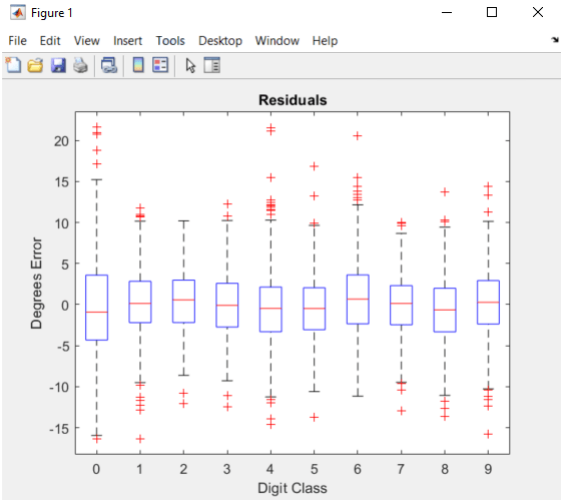
Trial	Status	Progress	Elapsed Time	Probability	Filters	Training RMSE	Training Loss	Validation RMSE	Validation Loss	Accuracy
5	Complete	100.0%	0 hr 1 min 18 sec	0.1000	8.0000	3.6132	6.5276	4.3334	9.3892	97.4800
6	Complete	100.0%	0 hr 1 min 20 sec	0.2000	8.0000	4.2288	8.9413	4.4778	10.0253	97.0200
3	Complete	100.0%	0 hr 1 min 24 sec	0.1000	6.0000	3.7716	7.1125	4.7295	11.1842	96.5000
4	Complete	100.0%	0 hr 1 min 17 sec	0.2000	6.0000	4.5593	10.3937	4.7918	11.4805	96.3000
1	Complete	100.0%	0 hr 1 min 13 sec	0.1000	4.0000	4.6942	11.0176	5.5271	15.2746	93.6800
2	Complete	100.0%	0 hr 1 min 19 sec	0.2000	4.0000	4.8882	11.9472	5.7182	16.3490	92.4400

To test the performance of an individual trial, export the trained network and display a box plot of the residuals for each digit class.

1. Select the trial with the highest accuracy.
2. On the **Experiment Manager** toolstrip, click **Export**.
3. In the dialog window, enter the name of a workspace variable for the exported network. The default name is `trainedNetwork`.
4. Use the exported network as the input to the function `plotResiduals`, which is listed in Appendix 3 at the end of this example. For instance, in the MATLAB Command Window, enter:

```
plotResiduals(trainedNetwork)
```

The function creates a residual box plot for each digit. The digit classes with highest accuracy have a mean close to zero and little variance.



To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **Accuracy** cell of the best trial.
2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.

For more information, see “Sort, Filter, and Annotate Experiment Results”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Setup Function

This function configures the training data, network architecture, and training options for the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.

Output

- `XTrain` is a 4-D array containing the training data.
- `YTrain` is a 1-D array containing the regression values for training,
- `layers` is a layer graph that defines the neural network architecture.
- `options` is a `trainingOptions` object.

```
function [XTrain,YTrain,layers,options] = RegressionExperiment_setup1(params)
```

```
[XTrain,~,YTrain] = digitTrain4DArrayData;
[XValidation,~,YValidation] = digitTest4DArrayData;

inputSize = [28 28 1];
numFilters = params.Filters;

layers = [
    imageInputLayer(inputSize)

    convolution2dLayer(3,numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer

    averagePooling2dLayer(2,Stride=2)

    convolution2dLayer(3,2*numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer

    averagePooling2dLayer(2,Stride=2)

    convolution2dLayer(3,4*numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer

    convolution2dLayer(3,4*numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer

    dropoutLayer(params.Probability)
    fullyConnectedLayer(1)
    regressionLayer];

miniBatchSize = 128;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
options = trainingOptions("sgdm", ...
    MiniBatchSize=miniBatchSize, ...
    MaxEpochs=30, ...
    InitialLearnRate=1e-3, ...
    LearnRateSchedule="piecewise", ...
    LearnRateDropFactor=0.1, ...
    LearnRateDropPeriod=20, ...
    Shuffle="every-epoch", ...
    ValidationData={XValidation,YValidation}, ...
    ValidationFrequency=validationFrequency, ...
    Verbose=false);

end
```

Appendix 2: Compute Accuracy of Regression Model

This function calculates the number of predictions within an acceptable error margin from the true angles.

```
function metricOutput = Accuracy(trialInfo)
```

```
[XValidation,~,YValidation] = digitTest4DArrayData;
YPredicted = predict(trialInfo.trainedNetwork,XValidation);
predictionError = YValidation - YPredicted;

thr = 10;
numCorrect = sum(abs(predictionError) < thr);
numValidationImages = numel(YValidation);

metricOutput = 100*numCorrect/numValidationImages;

end
```

Appendix 3: Display Box Plot of Residuals for Each Digit

This function creates a residual box plot for each digit.

```
function plotResiduals(net)

[XValidation,~,YValidation] = digitTest4DArrayData;
YPredicted = predict(net,XValidation);
predictionError = YValidation - YPredicted;
residualMatrix = reshape(predictionError,500,10);

figure
boxplot(residualMatrix,...
    'Labels',{'0','1','2','3','4','5','6','7','8','9'})
xlabel('Digit Class')
ylabel('Degrees Error')
title('Residuals')

end
```

- “Evaluate Deep Learning Experiments by Using Metric Functions” on page 6-19
- “Create a Deep Learning Experiment for Classification” on page 6-2

Use Experiment Manager to Train Networks in Parallel

By default, **Experiment Manager** runs one trial of your experiment at a time on a single CPU. If you have Parallel Computing Toolbox, you can configure your experiment to run multiple trials at the same time or to run a single trial at a time on multiple GPUs, on a cluster, or in the cloud.

Training Scenario	Recommendation
Run multiple trials at the same time using one parallel worker for each trial.	Set up your parallel environment and enable the **Use Parallel** option before running your experiment. Experiment Manager runs as many simultaneous trials as there are workers in your parallel pool. If you have multiple GPUs, parallel execution typically increases the speed of your experiment. However, if you have a single GPU, all workers share that GPU, so you do not get the training speed-up and you increase the chances of the GPU running out of memory.
Run a single trial at a time on multiple parallel workers.	**Built-In Training Experiments:** • In the experiment setup function, set the training option `ExecutionEnvironment` to `"multi-gpu"` or `"parallel"`. For more information, see "Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud" on page 7-2. • If you are using a partitionable datastore, enable background dispatching by setting the training option `DispatchInBackground` to `true`. For more information, see "Use Datastore for Parallel Training and Background Dispatching" on page 19-8. • Set up your parallel environment and disable the **Use Parallel** option before running your experiment.
	Custom Training Experiments: • In the experiment training function, set up your parallel environment and use an `spmd` block to define a custom parallel training loop. For more information, see "Train Network in Parallel with Custom Training Loop" on page 7-55. • Disable the **Use Parallel** option before running your experiment.

Tip To run an experiment in parallel using MATLAB Online, you must have access to a Cloud Center cluster. For more information, see "Use Parallel Computing Toolbox with Cloud Center Cluster in MATLAB Online" (Parallel Computing Toolbox).

Set Up Parallel Environment

Train on Multiple GPUs

If you have multiple GPUs, parallel execution typically increases the speed of your experiment. Using a GPU for deep learning requires Parallel Computing Toolbox and a supported GPU device. For more information, see "GPU Support by Release" (Parallel Computing Toolbox).

- For built-in training experiments, GPU support is automatic. By default, these experiments use a GPU if one is available.
- For custom training experiments, computations occur on a CPU by default. To train on a GPU, convert your data to `gpuArray` objects. To determine whether a usable GPU is available, call the `canUseGPU` function.

For best results, before you run your experiment, create a parallel pool with as many workers as GPUs. You can check the number of available GPUs by using the `gpuDeviceCount` function.

```
numGPUs = gpuDeviceCount("available");
parpool(numGPUs)
```

Train on Cluster or in Cloud

If your experiments take a long time to run on your local machine, you can accelerate training by using a computer cluster on your onsite network or by renting high-performance GPUs in the cloud. After you complete the initial setup, you can run your experiments with minimal changes to your code. Working on a cluster or in the cloud requires MATLAB Parallel Server™. For more information, see “Deep Learning in the Cloud” on page 7-10.

Run Multiple Trials in Parallel

To run multiple trials of your experiment in parallel, on the Experiment Manager toolstrip, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile.

Experiment Manager runs as many simultaneous trials as there are workers in your parallel pool. All other trials in your experiment are queued for later evaluation. A table of results displays the status and progress of each trial.

Trial	Status	Progress	Elapsed Time	myInitialLearnRate	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss
1	Complete	100.0%	0 hr 3 min 33 sec	0.0025	100.0000	0.0699	58.6400	1.2963
2	Complete	100.0%	0 hr 3 min 30 sec	0.0050	100.0000	0.0318	62.4800	1.3210
3	Running	30.7%	0 hr 0 min 56 sec	0.0075				
4	Running	30.7%	0 hr 0 min 56 sec	0.0100				
5	Queued	0.0%		0.0125				
6	Queued	0.0%		0.0150				

While the experiment is running, you can track its progress by displaying the training plot for each trial. You can also stop trials that appear to be underperforming. For more information, see “Stop and Restart Training”.

Note Experiment Manager does not support the execution of multiple trials in parallel when you set the training option `ExecutionEnvironment` to `"multi-gpu"` or `"parallel"` or when you enable the training option `DispatchInBackground`. Use these options to speed up your training only if you intend to run one trial of your experiment at a time. For more information, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2 and “Use Datastore for Parallel Training and Background Dispatching” on page 19-8.

Evaluate Deep Learning Experiments by Using Metric Functions

This example shows how to use metric functions to evaluate the results of an experiment. By default, when you run a built-in training experiment, **Experiment Manager** computes the loss, accuracy (for classification experiments), and root mean squared error (for regression experiments) for each trial in your experiment. To compute other measures, create your own metric function. For example, you can define metric functions to:

- Test the prediction performance of a trained network.
- Evaluate the training progress by computing the slope of the validation loss over the final epoch.
- Display the size of the network used in an experiment that uses different network architectures for each trial.

When each trial finishes training, Experiment Manager evaluates the metric functions and displays their values in the results table.

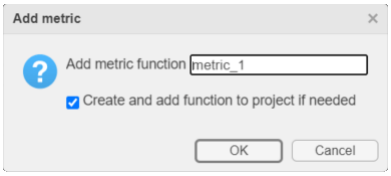
In this example, you train a network to classify images of handwritten digits. Two metric functions determine how well the trained network identifies the images of the numerals one and seven. For more information on using Experiment Manager to train a network for image classification, see “Image Classification by Sweeping Hyperparameters”.

Define Metric Functions

Add a metric function to a built-in training experiment.

1. In the **Experiment** pane, under **Metrics**, click **Add**.

2. In the **Add metric** dialog box, enter a name for the metric function and click **OK**. If you enter the name of a function that already exists in the project, Experiment Manager adds it to the experiment. Otherwise, Experiment Manager creates a function defined by a default template.



3. Select the name of the metric function and click **Edit**. The metric function opens in MATLAB® Editor.

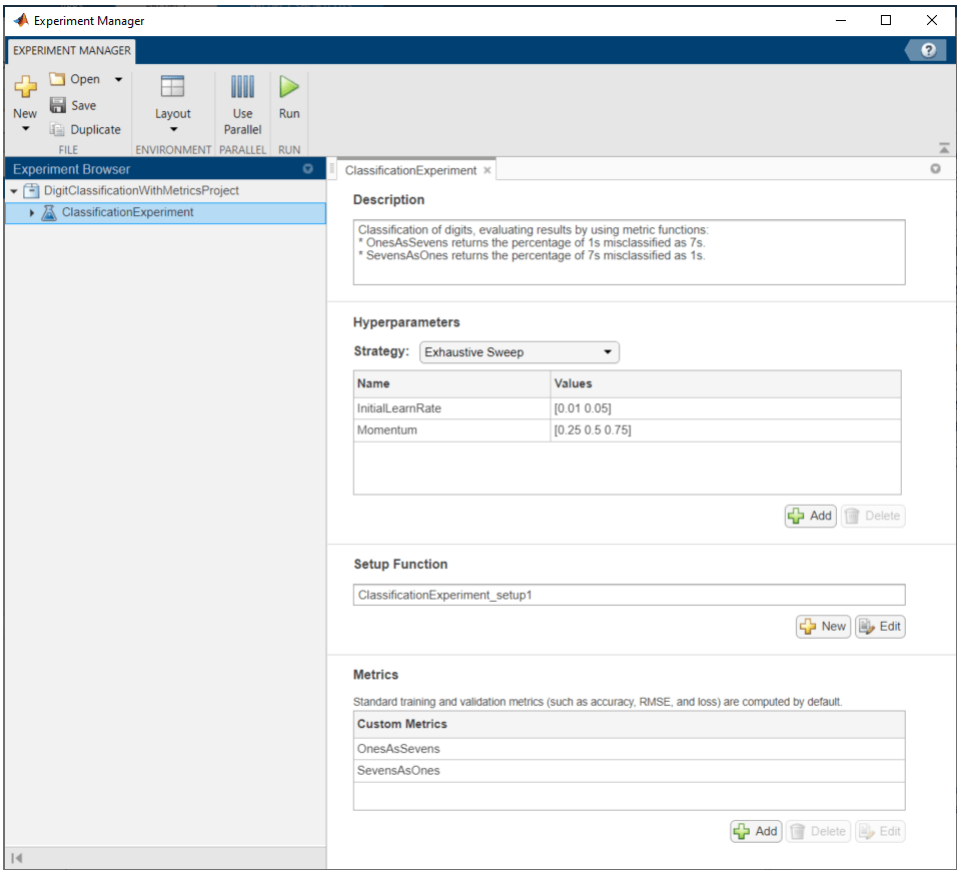
The input to a metric function is a structure with three fields:

- `trainedNetwork` is the `SeriesNetwork` object or `DAGNetwork` object returned by the `trainNetwork` function. For more information, see “net”.
- `trainingInfo` is a structure containing the training information returned by the `trainNetwork` function. For more information, see “info”.
- `parameters` is a structure with fields from the hyperparameter table.

The output of a custom metric function must be a scalar number, a logical value, or a string.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`ClassificationExperiment`).



Built-in training experiments consist of a description, a table of hyperparameters, a setup function, and a collection of metric functions to evaluate the results of the experiment. For more information, see “Configure Built-In Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Classification of digits, evaluating results by using metric functions:
* OnesAsSevens returns the percentage of 1s misclassified as 7s.
* SevensAsOnes returns the percentage of 7s misclassified as 1s.
```

The **Hyperparameters** section specifies the strategy (`Exhaustive Sweep`) and hyperparameter values to use for the experiment. When you run the experiment, Experiment Manager trains the network using every combination of hyperparameter values specified in the hyperparameter table. This example uses the hyperparameters `InitialLearnRate` and `Momentum`.

The **Setup Function** configures the training data, network architecture, and training options for the experiment. The input to the setup function is a structure with fields from the hyperparameter table. The setup function returns three outputs that you use to train a network for image classification problems. In this example, the setup function has three sections.

- **Load Training Data** defines image datastores containing the training and validation data. This example loads images from the Digits data set. For more information on this data set, see “Image Data Sets” on page 19-118.

```
digitDatasetPath = fullfile(toolboxdir("nnet"), ...
    "nndemos","nndatasets","DigitDataset");
imdsTrain = imageDatastore(digitDatasetPath, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");

numTrainingFiles = 750;
[imdsTrain,imdsValidation] = splitEachLabel(imdsTrain,numTrainingFiles);
```

- **Define Network Architecture** defines the architecture for a convolutional neural network for deep learning classification. This example uses the default classification network provided by the setup function template.

```
inputSize = [28 28 1];
numClasses = 10;
layers = [
    imageInputLayer(inputSize)
    convolution2dLayer(5,20)
    batchNormalizationLayer
    reluLayer
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

- **Specify Training Options** defines a `trainingOptions` object for the experiment. The example loads the values for the training options `'InitialLearnRate'` and `'Momentum'` from the hyperparameter table.

```
options = trainingOptions("sgdm", ...
    MaxEpochs=5, ...
    ValidationData=imdsValidation, ...
    ValidationFrequency=30, ...
    InitialLearnRate=params.InitialLearnRate, ...
    Momentum=params.Momentum, ...
    Verbose=false);
```

To inspect the setup function, under **Setup Function**, click **Edit**. The setup function opens in MATLAB® Editor. In addition, the code for the setup function appears in Appendix 1 at the end of this example.

The **Metrics** section specifies optional functions that evaluate the results of the experiment. Experiment Manager evaluates these functions each time it finishes training the network. To inspect a metric function, select the name of the metric function and click **Edit**. The metric function opens in MATLAB Editor.

This example includes two metric functions.

- `OnesAsSevens` returns the percentage of images of the numeral one that the trained network misclassifies as sevens.
- `SevensAsOnes` returns the percentage of images of the numeral seven that the trained network misclassifies as ones.

Each of these functions uses the trained network to classify the entire Digits data set. Then, the functions determine the number of images for which the actual label and the predicted label

disagree. For example, the function `OnesAsSevens` computes the number of images with an actual label of `'1'` and a predicted label of `'7'`. Similarly, the function `SevensAsOnes` computes the number of images with an actual label of `'7'` and a predicted label of `'1'`. The code for these metric functions appears in Appendix 2 and Appendix 3 at the end of this example.

Run Experiment

When you run the experiment, Experiment Manager trains the network defined by the setup function six times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox™, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16 and “GPU Support by Release” (Parallel Computing Toolbox).

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the metric function values for each trial.

Trial	Status	Progress	Elapsed Time	InitialLearnRate	Momentum	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss	OnesAsSevens	SevensAsOnes
1	Complete	100.0%	0 hr 0 min 59 sec	0.0100	0.2500	96.0938	0.2141	55.2000	1.3407	1.5000	2.6000

Evaluate Results

To find the best result for your experiment, sort the table of results. For example, find the trial with the smallest number of misclassified ones.

1. Point to the **OnesAsSevens** column.
2. Click the triangle icon.
3. Select **Sort in Ascending Order**.

Trial	Status	Progress	Elapsed Time	InitialLearnRate	Momentum	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss	OnesAsSevens	SevensAsOnes
5	Complete	100.0%	0 hr 1 min 2 sec	0.0100	0.7500	100.0000	0.0616	60.6000	1.2998	1.4000	1.5000
1	Complete	100.0%	0 hr 0 min 59 sec	0.0100	0.2500	96.0938	0.2141	55.2000	1.3407	1.5000	2.6000
3	Complete	100.0%	0 hr 1 min 3 sec	0.0100	0.5000	96.8750	0.1357	56.7600	1.3221	1.5000	2.1000
2	Complete	100.0%	0 hr 1 min 6 sec	0.0500	0.2500	96.8750	0.1272	56.6000	1.6953	2.2000	0.8000
4	Complete	100.0%	0 hr 1 min 3 sec	0.0500	0.5000	94.5313	0.1784	53.5600	2.3754	2.3000	0.9000
6	Complete	100.0%	0 hr 0 min 57 sec	0.0500	0.7500	82.8125	0.5932	47.9600	2.4599	2.5000	1.8000

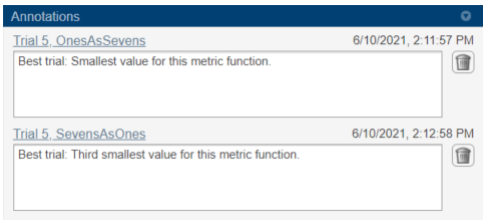
Similarly, find the trial with the smallest number of misclassified sevens by opening the drop-down menu for the **SevensAsOnes** column and selecting **Sort in Ascending Order**.

Trial	Status	Progress	Elapsed Time	InitialLearnRate	Momentum	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss	OnesAsSevens	SevensAsOnes
2	Complete	100.0%	0 hr 1 min 6 sec	0.0500	0.2500	96.8750	0.1272	56.6000	1.6953	2.2000	0.8000
4	Complete	100.0%	0 hr 1 min 3 sec	0.0500	0.5000	94.5313	0.1784	53.5600	2.3754	2.3000	0.9000
5	Complete	100.0%	0 hr 1 min 2 sec	0.0100	0.7500	100.0000	0.0616	60.6000	1.2998	1.4000	1.5000
6	Complete	100.0%	0 hr 0 min 57 sec	0.0500	0.7500	82.8125	0.5932	47.9600	2.4599	2.5000	1.8000
3	Complete	100.0%	0 hr 1 min 3 sec	0.0100	0.5000	96.8750	0.1357	56.7600	1.3221	1.5000	2.1000
1	Complete	100.0%	0 hr 0 min 59 sec	0.0100	0.2500	96.0938	0.2141	55.2000	1.3407	1.5000	2.6000

If no single trial minimizes both metric functions simultaneously, consider giving preference to a trial that ranks well for each metric. For instance, in these results, trial 5 ranks as one of the top three trials for each metric function.

To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **OnesAsSevens** cell of the best trial.
2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.
4. Repeat the previous steps for the **SevensAsOnes** cell.



For more information, see “Sort, Filter, and Annotate Experiment Results”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Setup Function

This function configures the training data, network architecture, and training options for the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.

Output

- `imdsTrain` is an image datastore for the training data.
- `layers` is a layer graph that defines the neural network architecture.
- `options` is a `trainingOptions` object.

```
function [imdsTrain,layers,options] = ClassificationExperiment_setup1(params)

digitDatasetPath = fullfile(toolboxdir("nnet"), ...
    "nndemos","nndatasets","DigitDataset");
imdsTrain = imageDatastore(digitDatasetPath, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");

numTrainingFiles = 750;
[imdsTrain,imdsValidation] = splitEachLabel(imdsTrain,numTrainingFiles);

inputSize = [28 28 1];
```

```
numClasses = 10;
layers = [
    imageInputLayer(inputSize)
    convolution2dLayer(5,20)
    batchNormalizationLayer
    reluLayer
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];

options = trainingOptions("sgdm", ...
    MaxEpochs=5, ...
    ValidationData=imdsValidation, ...
    ValidationFrequency=30, ...
    InitialLearnRate=params.InitialLearnRate, ...
    Momentum=params.Momentum, ...
    Verbose=false);

end
```

Appendix 2: Find Ones Misclassified as Sevens

This function determines the number of ones that are misclassified as sevens.

```
function metricOutput = OnesAsSevens(trialInfo)

actualValue = '1';
predValue = '7';

net = trialInfo.trainedNetwork;

digitDatasetPath = fullfile(toolboxdir("nnet"), ...
    "nndemos","nndatasets","DigitDataset");
imds = imageDatastore(digitDatasetPath, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");

YActual = imds.Labels;
YPred = classify(net,imds);

K = sum(YActual == actualValue & YPred == predValue);
N = sum(YActual == actualValue);

metricOutput = 100*K/N;

end
```

Appendix 3: Find Sevens Misclassified as Ones

This function determines the number of sevens that are misclassified as ones.

```
function metricOutput = SevensAsOnes(trialInfo)

actualValue = '7';
```

```
predValue = '1';

net = trialInfo.trainedNetwork;

digitDatasetPath = fullfile(toolboxdir("nnet"), ...
    "nndemos","nndatasets","DigitDataset");
imds = imageDatastore(digitDatasetPath, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");

YActual = imds.Labels;
YPred = classify(net,imds);

K = sum(YActual == actualValue & YPred == predValue);
N = sum(YActual == actualValue);

metricOutput = 100*K/N;

end
```

Tune Experiment Hyperparameters by Using Bayesian Optimization

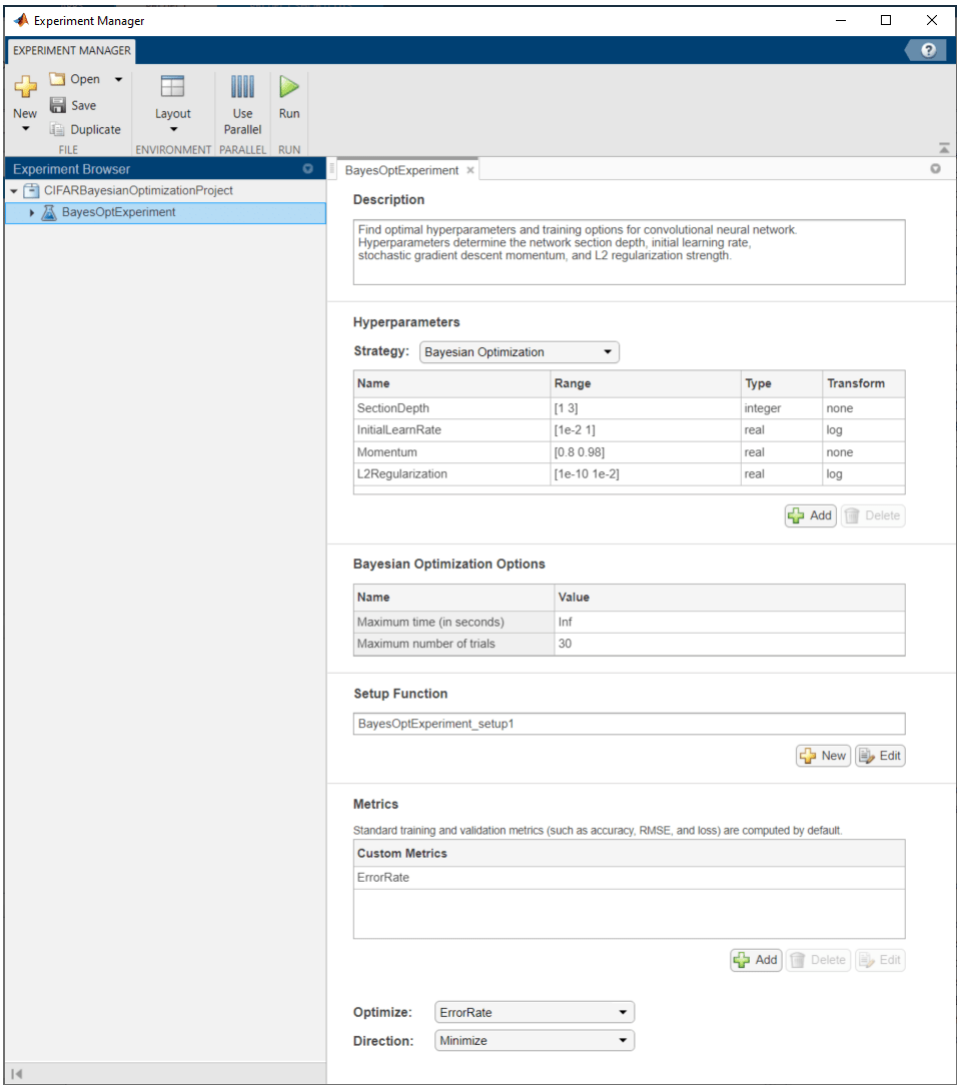
This example shows how to use Bayesian optimization in **Experiment Manager** to find optimal network hyperparameters and training options for convolutional neural networks. Bayesian optimization provides an alternative strategy to sweeping hyperparameters in an experiment. You specify a range of values for each hyperparameter and select a metric to optimize, and Experiment Manager searches for a combination of hyperparameters that optimizes your selected metric. Bayesian optimization requires Statistics and Machine Learning Toolbox™.

In this example, you train a network to classify images from the CIFAR-10 data set. The experiment uses Bayesian optimization to find the combination of hyperparameters that minimizes a custom metric function. The hyperparameters include options of the training algorithm, as well as parameters of the network architecture itself. The custom metric function determines the classification error on a randomly chosen test set. For more information on defining custom metrics in Experiment Manager, see “Evaluate Deep Learning Experiments by Using Metric Functions” on page 6-19.

Alternatively, you can find optimal hyperparameter values programmatically by calling the `bayesopt` function. For more information, see “Deep Learning Using Bayesian Optimization” on page 5-99.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`BayesOptExperiment`).



Built-in training experiments consist of a description, a table of hyperparameters, a setup function, and a collection of metric functions to evaluate the results of the experiment. Experiments that use Bayesian optimization include additional options to limit the duration of the experiment. For more information, see “Configure Built-In Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Find optimal hyperparameters and training options for convolutional neural network.
Hyperparamters determine the network section depth, initial learning rate,
stochastic gradient descent momentum, and L2 regularization strength.
```

The **Hyperparameters** section specifies the strategy (`Bayesian Optimization`) and hyperparameter options to use for the experiment. For each hyperparameter, specify these options:

- **Range** — Enter a two-element vector that gives the lower bound and upper bound of a real- or integer-valued hyperparameter, or a string array or cell array that lists the possible values of a categorical hyperparameter.

- **Type** — Select `real` (real-valued hyperparameter), `integer` (integer-valued hyperparameter), or `categorical` (categorical hyperparameter).
- **Transform** — Select `none` (no transform) or `log` (logarithmic transform). For `log`, the hyperparameter must be `real` or `integer` and positive. With this option, the hyperparameter is searched and modeled on a logarithmic scale.

When you run the experiment, Experiment Manager searches for the best combination of hyperparameters. Each trial in the experiment uses a new combination of hyperparameter values based on the results of the previous trials. This example uses these hyperparameters:

- `SectionDepth` — This parameter controls the depth of the network. The total number of layers in the network is `9*SectionDepth+7`. In the experiment setup function, the number of convolutional filters in each layer is proportional to `1/sqrt(SectionDepth)`, so the number of parameters and the required amount of computation for each iteration are roughly the same for different section depths.
- `InitialLearnRate` — If the learning rate is too low, then training takes a long time. If the learning rate is too high, then training can reach a suboptimal result or diverge. The best learning rate can depend on your data as well as the network you are training.
- `Momentum` — Stochastic gradient descent momentum adds inertia to the parameter updates by having the current update contain a contribution proportional to the update in the previous iteration. The inertial effect results in smoother parameter updates and a reduction of the noise inherent to stochastic gradient descent.
- `L2Regularization` — Use L2 regularization to prevent overfitting. Search the space of regularization strength to find a good value. Data augmentation and batch normalization also help regularize the network.

Under **Bayesian Optimization Options**, you can specify the duration of the experiment by entering the maximum time (in seconds) and the maximum number of trials to run. To best use the power of Bayesian optimization, perform at least 30 objective function evaluations.

The **Setup Function** configures the training data, network architecture, and training options for the experiment. The input to the setup function is a structure with fields from the hyperparameter table. The setup function returns three outputs that you use to train a network for image classification problems. In this example, the setup function has three sections.

- **Load Training Data** downloads and extracts images and labels from the CIFAR-10 data set. The data set is about 175 MB. Depending on your internet connection, the download process can take some time. For the training data, this example creates an `augmentedImageDatastore` by applying random translations and horizontal reflections. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images. To enable network validation, the example uses 5000 images with no augmentation. For more information on this data set, see “Image Data Sets” on page 19-118.

```
datadir = tempdir;
downloadCIFARData(datadir);

[XTrain,YTrain,XTest,YTest] = loadCIFARData(datadir);
idx = randperm(numel(YTest),5000);
XValidation = XTest(:,:,:,idx);
YValidation = YTest(idx);

imageSize = [32 32 3];
pixelRange = [-4 4];
```

```
imageAugmenter = imageDataAugmenter( ...
    RandXReflection=true, ...
    RandXTranslation=pixelRange, ...
    RandYTranslation=pixelRange);
augimdsTrain = augmentedImageDatastore(imageSize,XTrain,YTrain, ...
    DataAugmentation=imageAugmenter);
```

- **Define Network Architecture** defines the architecture for a convolutional neural network for deep learning classification. In this example, the network to train has three blocks produced by the helper function `convBlock`, which is listed in Appendix 2 at the end of this example. Each block contains `SectionDepth` identical convolutional layers. Each convolutional layer is followed by a batch normalization layer and a ReLU layer. The convolutional layers have added padding so that their spatial output size is always the same as the input size. Between the blocks, max pooling layers downsample the spatial dimensions by a factor of two. To ensure that the amount of computation required in each convolutional layer is roughly the same, the number of filters increases by a factor of two from one section to the next. The number of filters in each convolutional layer is proportional to `1/sqrt(SectionDepth)`, so that networks of different depths have roughly the same number of parameters and require about the same amount of computation per iteration.

```
numClasses = numel(unique(YTrain));
numF = round(16/sqrt(params.SectionDepth));
layers = [
    imageInputLayer(imageSize)
    convBlock(3,numF,params.SectionDepth)
    maxPooling2dLayer(3,Stride=2,Padding="same")
    convBlock(3,2*numF,params.SectionDepth)
    maxPooling2dLayer(3,Stride=2,Padding="same")
    convBlock(3,4*numF,params.SectionDepth)
    averagePooling2dLayer(8)
    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];
```

- **Specify Training Options** defines a `trainingOptions` object for the experiment using the values for the training options `'InitialLearnRate'`, `'Momentum'`, and `'L2Regularization'` generated by the Bayesian optimization algorithm. The example trains the network for a fixed number of epochs, validating once per epoch and lowering the learning rate by a factor of 10 during the last epochs to reduce the noise of the parameter updates and allow the network parameters to settle down closer to a minimum of the loss function.

```
miniBatchSize = 256;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
options = trainingOptions("sgdm", ...
    InitialLearnRate=params.InitialLearnRate, ...
    Momentum=params.Momentum, ...
    MaxEpochs=60, ...
    LearnRateSchedule="piecewise", ...
    LearnRateDropPeriod=40, ...
    LearnRateDropFactor=0.1, ...
    MiniBatchSize=miniBatchSize, ...
    L2Regularization=params.L2Regularization, ...
    Shuffle="every-epoch", ...
    Verbose=false, ...
    ValidationData={XValidation,YValidation}, ...
    ValidationFrequency=validationFrequency);
```

To inspect the setup function, under **Setup Function**, click **Edit**. The setup function opens in MATLAB® Editor. In addition, the code for the setup function appears in Appendix 1 at the end of this example.

The **Metrics** section specifies optional functions that evaluate the results of the experiment. Experiment Manager evaluates these functions each time it finishes training the network. To inspect a metric function, select the name of the metric function and click **Edit**. The metric function opens in MATLAB Editor.

This example includes the custom metric function `ErrorRate`. This function selects 5000 test images and labels at random, evaluates the trained network on these images, and calculates the proportion of images that the network misclassifies. The code for this function appears in Appendix 3 at the end of this example.

The **Optimize** and **Direction** fields indicate the metric that the Bayesian optimization algorithm uses as an objective function. For this experiment, Experiment Manager seeks to minimize the value of the `ErrorRate` metric.

Run Experiment

When you run the experiment, Experiment Manager searches for the best combination of hyperparameters with respect to the chosen metric. Each trial in the experiment uses a new combination of hyperparameter values based on the results of the previous trials. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox™, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16 and “GPU Support by Release” (Parallel Computing Toolbox).

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the metric function values for each trial. Experiment Manager indicates the trial with the optimal value for the selected metric. For example, in this experiment, the third trial produces the smallest error rate.

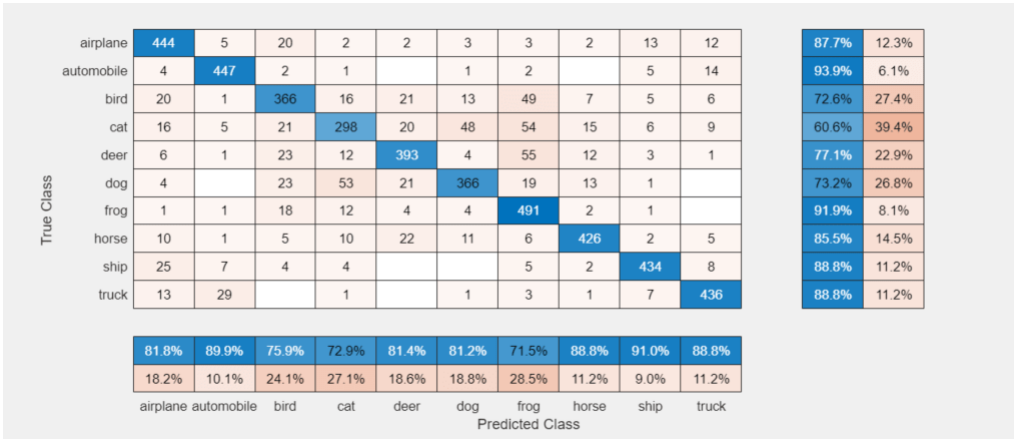
To determine the trial that optimizes the selected metric, Experiment Manager uses the best point criterion `'min-observed'`. For more information, see “Bayesian Optimization Algorithm” (Statistics and Machine Learning Toolbox) and `bestPoint` (Statistics and Machine Learning Toolbox).

Evaluate Results

To test the best trial in your experiment, first select the row in the results table with the lowest error rate.

To display the confusion matrix for the selected trial, click **Confusion Matrix**.



To perform additional computations, export the trained network to the workspace.

1. On the **Experiment Manager** toolstrip, click **Export**.
2. In the dialog window, enter the name of a workspace variable for the exported network. The default name is `trainedNetwork`.
3. Use the exported network as the input to the helper function `testSummary`, which is listed in Appendix 4 at the end of this example. For instance, in the MATLAB Command Window, enter:

```
testSummary(trainedNetwork)
```

This function evaluates the network in several ways:

- It predicts the labels of the entire test set and calculates the test error. Because Experiment Manager determines the best network without exposing the network to the entire test set, the test error can be higher than the value of the custom metric `ErrorRate`.
- It calculates the standard error (`testErrorSE`) and an approximate 95% confidence interval (`testError95CI`) of the generalization error rate by treating the classification of each image in the test set as an independent event with a certain probability of success. Using this assumption, the number of incorrectly classified images follows a binomial distribution. This method is often called the *Wald method*.
- It displays some test images together with their predicted classes and the probabilities of those classes.

The function displays a summary of these statistics in the MATLAB Command Window.

```
****************************************

Test error rate: 0.1776
Standard error: 0.0038
95% confidence interval: [0.1701, 0.1851]

****************************************
```

To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **ErrorRate** cell of the best trial.
2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.

For more information, see “Sort, Filter, and Annotate Experiment Results”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Setup Function

This function configures the training data, network architecture, and training options for the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.

Output

- `augimdsTrain` is an augmented image datastore for the training data.

- `layers` is a layer graph that defines the neural network architecture.
- `options` is a `trainingOptions` object.

```
function [augimdsTrain,layers,options] = BayesOptExperiment_setup1(params)

datadir = tempdir;
downloadCIFARData(datadir);

[XTrain,YTrain,XTest,YTest] = loadCIFARData(datadir);
idx = randperm(numel(YTest),5000);
XValidation = XTest(:,:,:,idx);
YValidation = YTest(idx);

imageSize = [32 32 3];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    RandXReflection=true, ...
    RandXTranslation=pixelRange, ...
    RandYTranslation=pixelRange);
augimdsTrain = augmentedImageDatastore(imageSize,XTrain,YTrain, ...
    DataAugmentation=imageAugmenter);

numClasses = numel(unique(YTrain));
numF = round(16/sqrt(params.SectionDepth));
layers = [
    imageInputLayer(imageSize)

    convBlock(3,numF,params.SectionDepth)
    maxPooling2dLayer(3,Stride=2,Padding="same")

    convBlock(3,2*numF,params.SectionDepth)
    maxPooling2dLayer(3,Stride=2,Padding="same")

    convBlock(3,4*numF,params.SectionDepth)
    averagePooling2dLayer(8)

    fullyConnectedLayer(numClasses)
    softmaxLayer
    classificationLayer];

miniBatchSize = 256;
validationFrequency = floor(numel(YTrain)/miniBatchSize);
options = trainingOptions("sgdm", ...
    InitialLearnRate=params.InitialLearnRate, ...
    Momentum=params.Momentum, ...
    MaxEpochs=60, ...
    LearnRateSchedule="piecewise", ...
    LearnRateDropPeriod=40, ...
    LearnRateDropFactor=0.1, ...
    MiniBatchSize=miniBatchSize, ...
    L2Regularization=params.L2Regularization, ...
    Shuffle="every-epoch", ...
    Verbose=false, ...
    ValidationData={XValidation,YValidation}, ...
    ValidationFrequency=validationFrequency);
```

```
end
```

Appendix 2: Create Block of Convolutional Layers

This function creates a block of `numConvLayers` convolutional layers, each with a specified `filterSize` and `numFilters` filters, and each followed by a batch normalization layer and a ReLU layer.

```
function layers = convBlock(filterSize,numFilters,numConvLayers)
layers = [
    convolution2dLayer(filterSize,numFilters,Padding="same")
    batchNormalizationLayer
    reluLayer];
layers = repmat(layers,numConvLayers,1);
end
```

Appendix 3: Compute Error Rate

This metric function takes as input a structure that contains the fields `trainedNetwork`, `trainingInfo`, and `parameters`.

- `trainedNetwork` is the `SeriesNetwork` object or `DAGNetwork` object returned by the `trainNetwork` function.
- `trainingInfo` is a structure containing the training information returned by the `trainNetwork` function.
- `parameters` is a structure with fields from the hyperparameter table.

The function selects 5000 test images and labels, evaluates the trained network on the test set, calculates the predicted image labels, and calculates the error rate on the test data.

```
function metricOutput = ErrorRate(trialInfo)

datadir = tempdir;
[~,~,XTest,YTest] = loadCIFARData(datadir);

idx = randperm(numel(YTest),5000);
XTest = XTest(:,:,:,idx);
YTest = YTest(idx);

YPredicted = classify(trialInfo.trainedNetwork,XTest);
metricOutput = 1 - mean(YPredicted == YTest);

end
```

Appendix 4: Summarize Test Statistics

This function computes the test error, standard error, and an approximate 95% confidence interval and displays a summary of these statistics in the MATLAB Command Window. The function also some test images together with their predicted classes and the probabilities of those classes.

```
function testSummary(net)

datadir = tempdir;
```

```
[~,~,XTest,YTest] = loadCIFARData(datadir);

[YPredicted,probs] = classify(net,XTest);
testError = 1 - mean(YPredicted == YTest);

NTest = numel(YTest);
testErrorSE = sqrt(testError*(1-testError)/NTest);
testError95CI = [testError - 1.96*testErrorSE, testError + 1.96*testErrorSE];

fprintf('\n*****************************************\n\n');
fprintf('Test error rate: %.4f\n',testError);
fprintf('Standard error: %.4f\n',testErrorSE);
fprintf('95%% confidence interval: [%.4f, %.4f]\n',testError95CI(1),testError95CI(2));
fprintf('\n*****************************************\n\n');

figure
idx = randperm(numel(YTest),9);
for i = 1:numel(idx)
    subplot(3,3,i)
    imshow(XTest(:,:,:,idx(i)));
    prob = num2str(100*max(probs(idx(i),:)),3);
    predClass = char(YPredicted(idx(i)));
    label = [predClass,', ',prob,'%'];
    title(label)
end
end
```

Try Multiple Pretrained Networks for Transfer Learning

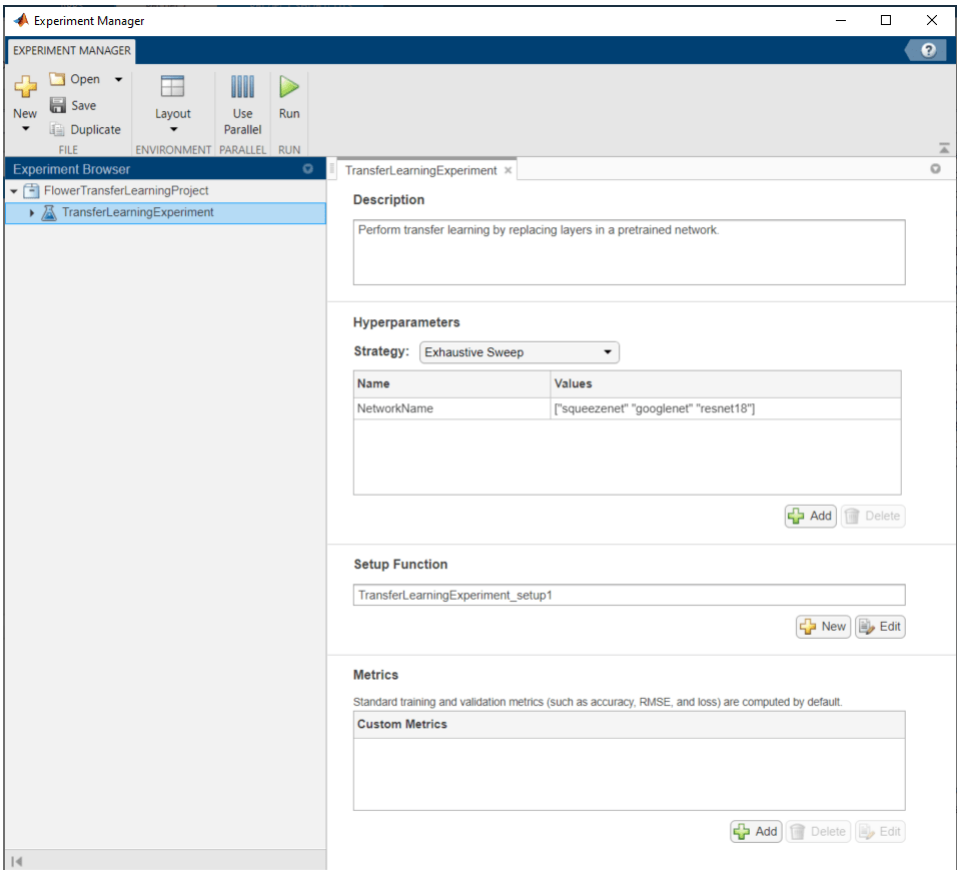
This example shows how to configure an experiment that replaces layers of different pretrained networks for transfer learning. Transfer learning is commonly used in deep learning applications. You can take a pretrained network and use it as a starting point to learn a new task. Fine-tuning a network with transfer learning is usually much faster and easier than training a network with randomly initialized weights from scratch. You can quickly transfer learned features to a new task using a smaller number of training images.

There are many pretrained networks available in Deep Learning Toolbox™. These pretrained networks have different characteristics that matter when choosing a network to apply to your problem. The most important characteristics are network accuracy, speed, and size. Choosing a network is generally a tradeoff between these characteristics. To compare the performance of different pretrained networks for your task, edit this experiment and specify which pretrained networks to use.

This experiment requires the Deep Learning Toolbox Model *for GoogLeNet Network* support package and the Deep Learning Toolbox Model *for ResNet-18 Network* support package. Before you run the experiment, install these support packages by calling the `googlenet` and `resnet18` functions and clicking the download links. For more information on other pretrained networks that you can download from the Add-On Explorer, see “Pretrained Deep Neural Networks” on page 1-8.

Open Experiment

First, open the example. **Experiment Manager** loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`TransferLearningExperiment`).



Built-in training experiments consist of a description, a table of hyperparameters, a setup function, and a collection of metric functions to evaluate the results of the experiment. For more information, see “Configure Built-In Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Perform transfer learning by replacing layers in a pretrained network.
```

The **Hyperparameters** section specifies the strategy (`Exhaustive Sweep`) and hyperparameter values to use for the experiment. When you run the experiment, Experiment Manager trains the network using every combination of hyperparameter values specified in the hyperparameter table. In this example, the hyperparameter `NetworkName` specifies the network to train and the value of the training option `'miniBatchSize'`.

The **Setup Function** configures the training data, network architecture, and training options for the experiment. The input to the setup function is a structure with fields from the hyperparameter table. The setup function returns three outputs that you use to train a network for image classification problems. In this example, the setup function:

- Loads a pretrained network corresponding to the hyperparameter `NetworkName`.

```
networkName = params.NetworkName;

switch networkName
    case "squeezenet"
```

```
        net = squeezenet;
        miniBatchSize = 128;
    case "googlenet"
        net = googlenet;
        miniBatchSize = 128;
    case "resnet18"
        net = resnet18;
        miniBatchSize = 128;
    case "mobilenetv2"
        net = mobilenetv2;
        miniBatchSize = 128;
    case "resnet50"
        net = resnet50;
        miniBatchSize = 128;
    case "resnet101"
        net = resnet101;
        miniBatchSize = 64;
    case "inceptionv3"
        net = inceptionv3;
        miniBatchSize = 64;
    case "inceptionresnetv2"
        net = inceptionresnetv2;
        miniBatchSize = 64;
    otherwise
        error("Undefined network selection.");
end
```

- Downloads and extracts the Flowers data set, which is about 218 MB. For more information on this data set, see “Image Data Sets” on page 19-118.

```
url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");

imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
    disp("Downloading Flower Dataset (218 MB)...")
    websave(filename,url);
    untar(filename,downloadFolder)
end

imds = imageDatastore(imageFolder, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");

[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9);
inputSize = net.Layers(1).InputSize;
augimdsTrain = augmentedImageDatastore(inputSize,imdsTrain);
augimdsValidation = augmentedImageDatastore(inputSize,imdsValidation);
```

- Replaces the learnable layers of the pretrained network to perform transfer learning. The helper function `findLayersToReplace`, which is listed in Appendix 2 at the end of this example, determines the layers in the network architecture to replace for transfer learning. For more information on the available pretrained networks, see “Pretrained Deep Neural Networks” on page 1-8.

```
lgraph = layerGraph(net);
[learnableLayer,classLayer] = findLayersToReplace(lgraph);
numClasses = numel(categories(imdsTrain.Labels));
```

```
if isa(learnableLayer,"nnet.cnn.layer.FullyConnectedLayer")
    newLearnableLayer = fullyConnectedLayer(numClasses, ...
        Name="new_fc", ...
        WeightLearnRateFactor=10, ...
        BiasLearnRateFactor=10);
elseif isa(learnableLayer,"nnet.cnn.layer.Convolution2DLayer")
    newLearnableLayer = convolution2dLayer(1,numClasses, ...
        Name="new_conv", ...
        WeightLearnRateFactor=10, ...
        BiasLearnRateFactor=10);
end

lgraph = replaceLayer(lgraph,learnableLayer.Name,newLearnableLayer);

newClassLayer = classificationLayer(Name="new_classoutput");
lgraph = replaceLayer(lgraph,classLayer.Name,newClassLayer);
```

- Defines a `trainingOptions` object for the experiment. The example trains the network for 10 epochs, using an initial learning rate of 0.0003 and validating the network every 5 epochs.

```
validationFrequencyEpochs = 5;

numObservations = augimdsTrain.NumObservations;
numIterationsPerEpoch = floor(numObservations/miniBatchSize);
validationFrequency = validationFrequencyEpochs * numIterationsPerEpoch;

options = trainingOptions("sgdm", ...
    MaxEpochs=10, ...
    MiniBatchSize=miniBatchSize, ...
    InitialLearnRate=3e-4, ...
    Shuffle="every-epoch", ...
    ValidationData=augimdsValidation, ...
    ValidationFrequency=validationFrequency, ...
    Verbose=false);
```

To inspect the setup function, under **Setup Function**, click **Edit**. The setup function opens in MATLAB® Editor. In addition, the code for the setup function appears in Appendix 1 at the end of this example.

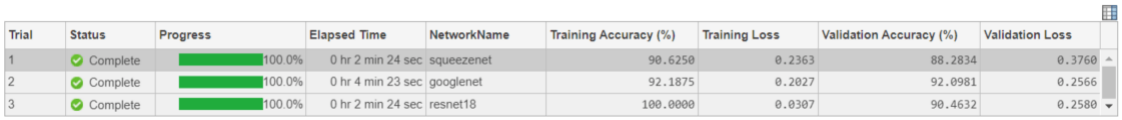
The **Metrics** section specifies optional functions that evaluate the results of the experiment. This example does not include any custom metric functions.

Run Experiment

When you run the experiment, Experiment Manager trains the network defined by the setup function six times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox™, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16 and “GPU Support by Release” (Parallel Computing Toolbox).

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the accuracy and loss for each trial. While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial. Click **Confusion Matrix** to display the confusion matrix for the validation data in each completed trial.



Trial	Status	Progress	Elapsed Time	NetworkName	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss
1	Complete	100.0%	0 hr 2 min 24 sec	squeezenet	90.6250	0.2363	88.2834	0.3760
2	Complete	100.0%	0 hr 4 min 23 sec	googlenet	92.1875	0.2027	92.0981	0.2566
3	Complete	100.0%	0 hr 2 min 24 sec	resnet18	100.0000	0.0307	90.4632	0.2580

When the experiment finishes, you can sort the results table by column, filter trials by using the **Filters** pane, or record observations by adding annotations. For more information, see “Sort, Filter, and Annotate Experiment Results”.

To test the performance of an individual trial, export the trained network or the training information for the trial. On the **Experiment Manager** toolstrip, select **Export** > **Trained Network** or **Export** > **Training Information**, respectively. For more information, see “net” and “info”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Setup Function

This function configures the training data, network architecture, and training options for the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.

Output

- `augimdsTrain` is an augmented image datastore for the training data.
- `lgraph` is a layer graph that defines the neural network architecture.
- `options` is a `trainingOptions` object.

```
function [augimdsTrain,lgraph,options] = TransferLearningExperiment_setup1(params)

networkName = params.NetworkName;

switch networkName
    case "squeezenet"
        net = squeezenet;
        miniBatchSize = 128;
    case "googlenet"
        net = googlenet;
        miniBatchSize = 128;
    case "resnet18"
        net = resnet18;
        miniBatchSize = 128;
    case "mobilenetv2"
        net = mobilenetv2;
        miniBatchSize = 128;
    case "resnet50"
```

```
        net = resnet50;
        miniBatchSize = 128;
    case "resnet101"
        net = resnet101;
        miniBatchSize = 64;
    case "inceptionv3"
        net = inceptionv3;
        miniBatchSize = 64;
    case "inceptionresnetv2"
        net = inceptionresnetv2;
        miniBatchSize = 64;
    otherwise
        error("Undefined network selection.");
end

url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");

imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
    disp("Downloading Flower Dataset (218 MB)...")
    websave(filename,url);
    untar(filename,downloadFolder)
end

imds = imageDatastore(imageFolder, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");

[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9);
inputSize = net.Layers(1).InputSize;
augimdsTrain = augmentedImageDatastore(inputSize,imdsTrain);
augimdsValidation = augmentedImageDatastore(inputSize,imdsValidation);

lgraph = layerGraph(net);
[learnableLayer,classLayer] = findLayersToReplace(lgraph);
numClasses = numel(categories(imdsTrain.Labels));

if isa(learnableLayer,"nnet.cnn.layer.FullyConnectedLayer")
    newLearnableLayer = fullyConnectedLayer(numClasses, ...
        Name="new_fc", ...
        WeightLearnRateFactor=10, ...
        BiasLearnRateFactor=10);
elseif isa(learnableLayer,"nnet.cnn.layer.Convolution2DLayer")
    newLearnableLayer = convolution2dLayer(1,numClasses, ...
        Name="new_conv", ...
        WeightLearnRateFactor=10, ...
        BiasLearnRateFactor=10);
end

lgraph = replaceLayer(lgraph,learnableLayer.Name,newLearnableLayer);

newClassLayer = classificationLayer(Name="new_classoutput");
lgraph = replaceLayer(lgraph,classLayer.Name,newClassLayer);

validationFrequencyEpochs = 5;
```

```
numObservations = augimdsTrain.NumObservations;
numIterationsPerEpoch = floor(numObservations/miniBatchSize);
validationFrequency = validationFrequencyEpochs * numIterationsPerEpoch;

options = trainingOptions("sgdm", ...
    MaxEpochs=10, ...
    MiniBatchSize=miniBatchSize, ...
    InitialLearnRate=3e-4, ...
    Shuffle="every-epoch", ...
    ValidationData=augimdsValidation, ...
    ValidationFrequency=validationFrequency, ...
    Verbose=false);

end
```

Appendix 2: Find Layers to Replace

This function finds the single classification layer and the preceding learnable (fully connected or convolutional) layer of the layer graph `lgraph`.

```
function [learnableLayer,classLayer] = findLayersToReplace(lgraph)

if ~isa(lgraph,"nnet.cnn.LayerGraph")
    error("Argument must be a LayerGraph object.")
end

src = string(lgraph.Connections.Source);
dst = string(lgraph.Connections.Destination);
layerNames = string({lgraph.Layers.Name}');

isClassificationLayer = arrayfun(@(l) ...
    (isa(l,"nnet.cnn.layer.ClassificationOutputLayer")|isa(l,"nnet.layer.ClassificationLayer")),
    lgraph.Layers);

if sum(isClassificationLayer) ~= 1
    error("Layer graph must have a single classification layer.")
end
classLayer = lgraph.Layers(isClassificationLayer);

currentLayerIdx = find(isClassificationLayer);
while true

    if numel(currentLayerIdx) ~= 1
        error("Layer graph must have a single learnable layer preceding the classification layer
    end

    currentLayerType = class(lgraph.Layers(currentLayerIdx));
    isLearnableLayer = ismember(currentLayerType, ...
        ["nnet.cnn.layer.FullyConnectedLayer","nnet.cnn.layer.Convolution2DLayer"]);

    if isLearnableLayer
        learnableLayer =  lgraph.Layers(currentLayerIdx);
        return
    end

    currentDstIdx = find(layerNames(currentLayerIdx) == dst);
```

```
    currentLayerIdx = find(src(currentDstIdx) == layerNames);
end
end
```

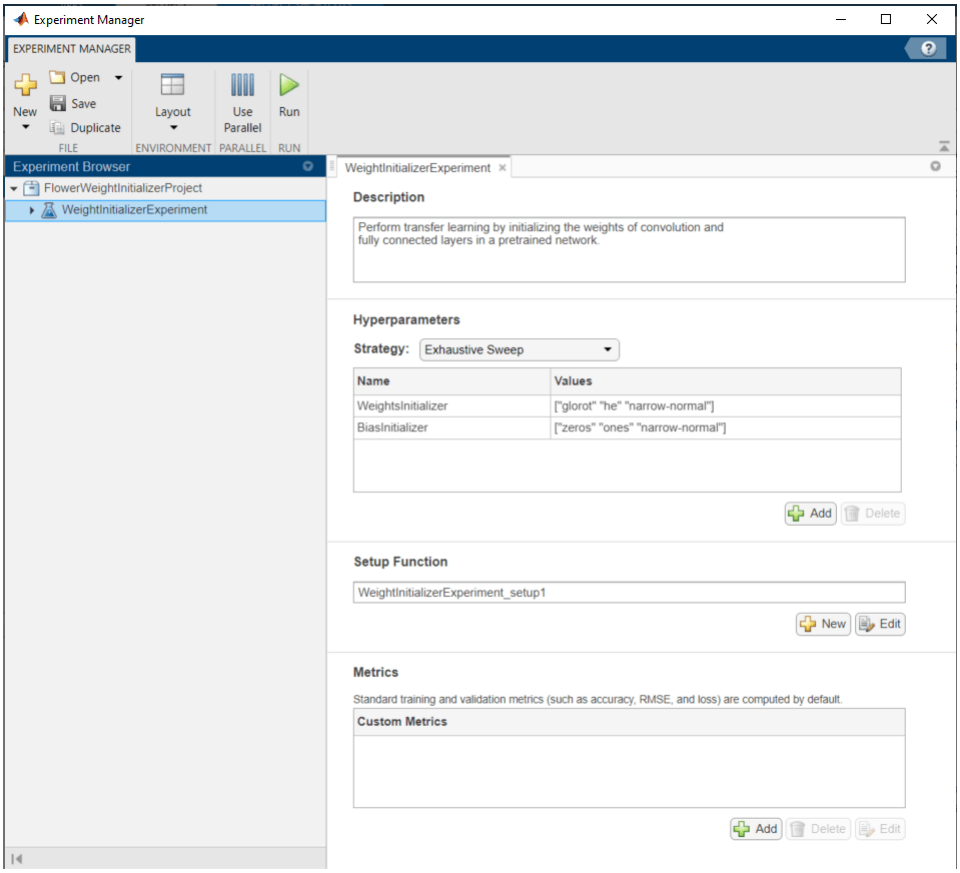
Experiment with Weight Initializers for Transfer Learning

This example shows how to configure an experiment that initializes the weights of convolution and fully connected layers using different weight initializers for training. To compare the performance of different weight initializers for your task, create an experiment using this example as a guide.

When training a deep learning network, the initialization of layer weights and biases can have a big impact on how well the network trains. The choice of initializer has a bigger impact on networks without batch normalization layers. For more information on weight initializers, see “Compare Layer Weight Initializers” on page 18-181.

Open Experiment

First, open the example. **Experiment Manager** loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`WeightInitializerExperiment`).



Built-in training experiments consist of a description, a table of hyperparameters, a setup function, and a collection of metric functions to evaluate the results of the experiment. For more information, see “Configure Built-In Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Perform transfer learning by initializing the weights of convolution and
fully connected layers in a pretrained network.
```

The **Hyperparameters** section specifies the strategy (`Exhaustive Sweep`) and hyperparameter values to use for the experiment. When you run the experiment, Experiment Manager trains the network using every combination of hyperparameter values specified in the hyperparameter table. This example uses the hyperparameters `WeightsInitializer` and `BiasInitializer` to specify the weight and bias initializers for the convolution and fully connected layers in a pretrained network. For more information about these initializers, see “`WeightsInitializer`” and “`BiasInitializer`”.

The **Setup Function** configures the training data, network architecture, and training options for the experiment. The input to the setup function is a structure with fields from the hyperparameter table. The setup function returns three outputs that you use to train a network for image classification problems. In this example, the setup function:

- Loads a pretrained GoogLeNet network.

```
lgraph = googlenet(Weights="none");
```

- Downloads and extracts the Flowers data set, which is about 218 MB. For more information on this data set, see “Image Data Sets” on page 19-118.

```
url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");

imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
    disp("Downloading Flower Dataset (218 MB)...")
    websave(filename,url);
    untar(filename,downloadFolder)
end

imds = imageDatastore(imageFolder, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");

[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9);
inputSize = net.Layers(1).InputSize;
augimdsTrain = augmentedImageDatastore(inputSize,imdsTrain);
augimdsValidation = augmentedImageDatastore(inputSize,imdsValidation);
```

- Initializes the input weight in the convolution and fully connected layers by using the initializers specified in the hyperparameter table. The auxiliary function `findLayersToReplace`, which is listed in Appendix 2 at the end of this example, determines the layers in the network architecture that can be modified for transfer learning.

```
numClasses = numel(categories(imdsTrain.Labels));
weightsInitializer = params.WeightsInitializer;
biasInitializer = params.BiasInitializer;

learnableLayer = findLayersToReplace(lgraph);
newLearnableLayer = fullyConnectedLayer(numClasses,Name="new_fc");
lgraph = replaceLayer(lgraph,learnableLayer.Name,newLearnableLayer);

for i = 1:numel(lgraph.Layers)
    layer = lgraph.Layers(i);
```

```
    if class(layer) == "nnet.cnn.layer.Convolution2DLayer" || ...
            class(layer) == "nnet.cnn.layer.FullyConnectedLayer"
        layerName = layer.Name;
        newLayer = layer;

        newLayer.WeightsInitializer = weightsInitializer;
        newLayer.BiasInitializer = biasInitializer;

        lgraph = replaceLayer(lgraph,layerName,newLayer);
    end
end
```

- Defines a `trainingOptions` object for the experiment. The example trains the network for 10 epochs, using a mini-batch size of 128 and validating the network every 5 epochs.

```
miniBatchSize = 128;
validationFrequencyEpochs = 5;

numObservations = augimdsTrain.NumObservations;
numIterationsPerEpoch = floor(numObservations/miniBatchSize);
validationFrequency = validationFrequencyEpochs * numIterationsPerEpoch;

options = trainingOptions("sgdm", ...
    MaxEpochs=10, ...
    MiniBatchSize=miniBatchSize, ...
    Shuffle="every-epoch", ...
    ValidationData=augimdsValidation, ...
    ValidationFrequency=validationFrequency, ...
    Verbose=false);
```

To inspect the setup function, under **Setup Function**, click **Edit**. The setup function opens in MATLAB® Editor. In addition, the code for the setup function appears in Appendix 1 at the end of this example.

The **Metrics** section specifies optional functions that evaluate the results of the experiment. This example does not include any custom metric functions.

Run Experiment

When you run the experiment, Experiment Manager trains the network defined by the setup function multiple times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox™, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16 and “GPU Support by Release” (Parallel Computing Toolbox).

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the accuracy and loss for each trial. While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial. Click **Confusion Matrix** to display the confusion matrix for the validation data in each completed trial.

Trial	Status	Progress	Elapsed Time	WeightsInitiali...	BiasInitializer	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss
1	Complete	100.0%	0 hr 5 min 37 sec	glorot	zeros	69.5313	0.8787	67.8474	0.8679
2	Complete	100.0%	0 hr 0 min 37 sec	he	zeros	16.4063	NaN	17.1662	NaN
3	Complete	100.0%	0 hr 5 min 44 sec	narrow-normal	zeros	17.1875	1.6165	24.5232	1.5998
4	Complete	100.0%	0 hr 5 min 30 sec	glorot	ones	26.5625	1.5956	24.5232	1.5998
5	Complete	100.0%	0 hr 0 min 38 sec	he	ones	16.4063	NaN	17.1662	NaN
6	Complete	100.0%	0 hr 5 min 13 sec	narrow-normal	ones	17.1875	1.6168	24.5232	1.5999
7	Complete	100.0%	0 hr 5 min 50 sec	glorot	narrow-normal	59.3750	1.0149	69.4823	0.7866
8	Complete	100.0%	0 hr 0 min 38 sec	he	narrow-normal	21.8750	NaN	17.1662	NaN
9	Complete	100.0%	0 hr 5 min 28 sec	narrow-normal	narrow-normal	26.5625	1.6006	24.5232	1.5998

Note that, for the trials that use the He weight initializer, Experiment Manager interrupts the training because the training and validation loss become undefined after a few iterations. Continuing the training for those trials does not produce any useful results.

When the experiment finishes, you can sort the results table by column, filter trials by using the **Filters** pane, or record observations by adding annotations. For more information, see “Sort, Filter, and Annotate Experiment Results”.

To test the performance of an individual trial, export the trained network or the training information for the trial. On the **Experiment Manager** toolstrip, select **Export** > **Trained Network** or **Export** > **Training Information**, respectively. For more information, see “net” and “info”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Setup Function

This function configures the training data, network architecture, and training options for the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.

Output

- `augimdsTrain` is an augmented image datastore object for the training data.
- `lgraph` is a layer graph that defines the neural network architecture.
- `options` is a `trainingOptions` object.

```
function [augimdsTrain,lgraph,options] = WeightInitializerExperiment_setup1(params)

lgraph = googlenet(Weights="none");

url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");
imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
    disp("Downloading Flower Dataset (218 MB)...")
    websave(filename,url);
    untar(filename,downloadFolder)
end
```

```
imds = imageDatastore(imageFolder, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9);
inputSize = lgraph.Layers(1).InputSize;
augimdsTrain = augmentedImageDatastore(inputSize,imdsTrain);
augimdsValidation = augmentedImageDatastore(inputSize,imdsValidation);

numClasses = numel(categories(imdsTrain.Labels));
weightsInitializer = params.WeightsInitializer;
biasInitializer = params.BiasInitializer;
learnableLayer = findLayersToReplace(lgraph);
newLearnableLayer = fullyConnectedLayer(numClasses,Name="new_fc");
lgraph = replaceLayer(lgraph,learnableLayer.Name,newLearnableLayer);
for i = 1:numel(lgraph.Layers)
    layer = lgraph.Layers(i);

    if class(layer) == "nnet.cnn.layer.Convolution2DLayer" || ...
            class(layer) == "nnet.cnn.layer.FullyConnectedLayer"
        layerName = layer.Name;
        newLayer = layer;

        newLayer.WeightsInitializer = weightsInitializer;
        newLayer.BiasInitializer = biasInitializer;

        lgraph = replaceLayer(lgraph,layerName,newLayer);
    end
end

miniBatchSize = 128;
validationFrequencyEpochs = 5;
numObservations = augimdsTrain.NumObservations;
numIterationsPerEpoch = floor(numObservations/miniBatchSize);
validationFrequency = validationFrequencyEpochs * numIterationsPerEpoch;
options = trainingOptions("sgdm", ...
    MaxEpochs=10, ...
    MiniBatchSize=miniBatchSize, ...
    Shuffle="every-epoch", ...
    ValidationData=augimdsValidation, ...
    ValidationFrequency=validationFrequency, ...
    Verbose=false);

end
```

Appendix 2: Find Layers to Replace

This function finds the single classification layer and the preceding learnable (fully connected or convolutional) layer of the layer graph `lgraph`.

```
function [learnableLayer,classLayer] = findLayersToReplace(lgraph)

if ~isa(lgraph,"nnet.cnn.LayerGraph")
    error("Argument must be a LayerGraph object.")
end

src = string(lgraph.Connections.Source);
```

```
dst = string(lgraph.Connections.Destination);
layerNames = string({lgraph.Layers.Name}');

isClassificationLayer = arrayfun(@(l) ...
    (isa(l,"nnet.cnn.layer.ClassificationOutputLayer")|isa(l,"nnet.layer.ClassificationLayer")),
    lgraph.Layers);

if sum(isClassificationLayer) ~= 1
    error("Layer graph must have a single classification layer.")
end
classLayer = lgraph.Layers(isClassificationLayer);

currentLayerIdx = find(isClassificationLayer);
while true

    if numel(currentLayerIdx) ~= 1
        error("Layer graph must have a single learnable layer preceding the classification layer
    end

    currentLayerType = class(lgraph.Layers(currentLayerIdx));
    isLearnableLayer = ismember(currentLayerType, ...
        ["nnet.cnn.layer.FullyConnectedLayer","nnet.cnn.layer.Convolution2DLayer"]);

    if isLearnableLayer
        learnableLayer =  lgraph.Layers(currentLayerIdx);
        return
    end

    currentDstIdx = find(layerNames(currentLayerIdx) == dst);
    currentLayerIdx = find(src(currentDstIdx) == layerNames);
end
end
```

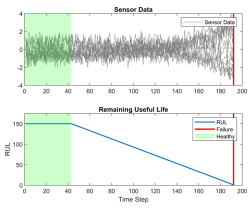
Choose Training Configurations for LSTM Using Bayesian Optimization

This example shows how to create a deep learning experiment to find optimal network hyperparameters and training options for long short-term memory (LSTM) networks using Bayesian optimization. In this example, you use **Experiment Manager** to train LSTM networks that predict the remaining useful life (RUL) of engines. The experiment uses the Turbofan Engine Degradation Simulation Data Set described in [1]. For more information on processing this data set for sequence-to-sequence regression, see “Sequence-to-Sequence Regression Using Deep Learning” on page 4-47.

Bayesian optimization provides an alternative strategy to sweeping hyperparameters in an experiment. You specify a range of values for each hyperparameter and select a metric to optimize, and Experiment Manager searches for a combination of hyperparameters that optimizes your selected metric. Bayesian optimization requires Statistics and Machine Learning Toolbox™. For more information, see “Tune Experiment Hyperparameters by Using Bayesian Optimization” on page 6-26.

RUL captures how many operational cycles an engine can make before failure. To focus on the sequence data from when the engines are close to failing, preprocess the data by clipping the responses at a specified threshold. This preprocessing operation allows the network to focus on predictor data behaviors close to failing by treating instances with higher RUL values as equal. For example, this figure shows the first response observation and the corresponding clipped response with a threshold of 150.

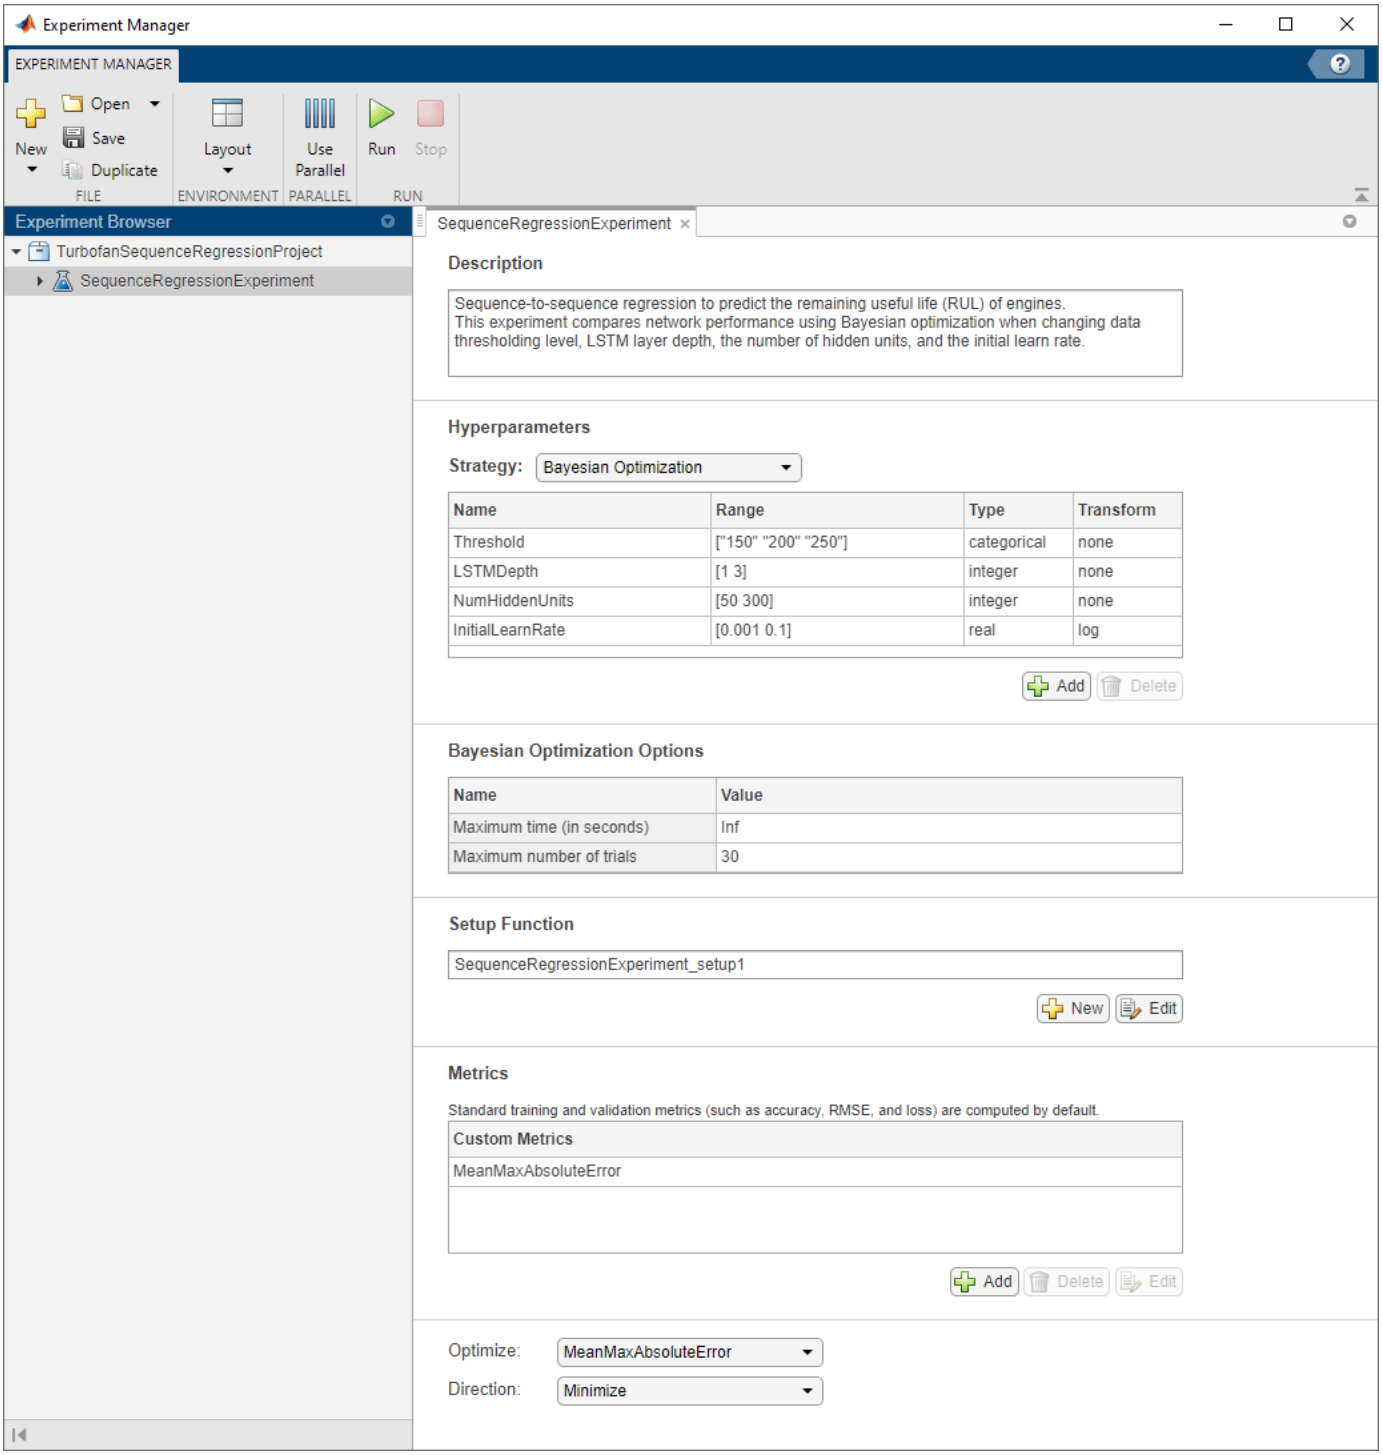


When you train a deep learning network, how you preprocess data, the number of layers and hidden units, and the initial learning rate in the network can affect the training behavior and performance of the network. Choosing the depth of an LSTM network involves balancing speed and accuracy. For example, deeper networks can be more accurate but take longer to train and converge [2].

By default, when you run a built-in training experiment for regression, Experiment Manager computes the loss and root mean squared error (RMSE) for each trial in your experiment. This example compares the performance of the network in each trial by using a custom metric that is specific to the problem data set. For more information on using custom metric functions, see “Evaluate Deep Learning Experiments by Using Metric Functions” on page 6-19.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment. To open the experiment, in the **Experiment Browser**, double-click the name of the experiment (`SequenceRegressionExperiment`).



Built-in training experiments consist of a description, a table of hyperparameters, a setup function, and a collection of metric functions to evaluate the results of the experiment. Experiments that use Bayesian optimization include additional options to limit the duration of the experiment. For more information, see “Configure Built-In Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Sequence-to-sequence regression to predict the remaining useful life (RUL) of engines.
This experiment compares network performance using Bayesian optimization when changing data
thresholding level, LSTM layer depth, the number of hidden units, and the initial learn rate.
```

The **Hyperparameter Table** specifies the strategy (`Bayesian Optimization`) and hyperparameter values to use for the experiment. For each hyperparameter, specify these options:

- **Range** — Enter a two-element vector that gives the lower bound and upper bound of a real- or integer-valued hyperparameter, or a string array or cell array that lists the possible values of a categorical hyperparameter.
- **Type** — Select `real` (real-valued hyperparameter), `integer` (integer-valued hyperparameter), or `categorical` (categorical hyperparameter).
- **Transform** — Select `none` (no transform) or `log` (logarithmic transform). For `log`, the hyperparameter must be `real` or `integer` and positive. With this option, the hyperparameter is searched and modeled on a logarithmic scale.

When you run the experiment, Experiment Manager searches for the best combination of hyperparameters. Each trial uses a new combination of the hyperparameter values based on the results of the previous trials. This example uses these hyperparameters:

- `Threshold` sets all response data above the threshold value to be equal to the threshold value. To prevent uniform response data, use threshold values greater or equal to 150. To limit the set of allowable values to 150, 200 and 250, the experiment models `Threshold` as a categorical hyperparameter.
- `LSTMDepth` indicates the number of LSTM layers used in the network. Specify this hyperparameter as an integer between 1 and 3.
- `NumHiddenUnits` determines the number of hidden units, or the amount of information stored at each time step, used in the network. Increasing the number of hidden units can result in overfitting the data and in a longer training time. Decreasing the number of hidden units can result in underfitting the data. Specify this hyperparameter as an integer between 50 and 300.
- `InitialLearnRate` specifies the initial learning rate used for training. If the learning rate is too low, then training takes a long time. If the learning rate is too high, then training can reach a suboptimal result or diverge. The best learning rate depends on your data as well as the network you are training. The experiment models this hyperparameter on a logarithmic scale because the range of values (0.001 to 0.1) spans several orders of magnitude.

Under **Bayesian Optimization Options**, you can specify the duration of the experiment by entering the maximum time (in seconds) and the maximum number of trials to run. To best use the power of Bayesian optimization, perform at least 30 objective function evaluations.

The **Setup Function** configures the training data, network architecture, and training options for the experiment. The input to the setup function is a structure with fields from the hyperparameter table. The setup function returns four outputs that you use to train a network for image regression problems. In this example, the setup function has three sections.

- **Load and Preprocess Data** downloads and extracts the Turbofan Engine Degradation Simulation Data Set from https://ti.arc.nasa.gov/tech/dash/groups/pcoe/prognostic-data-repository/ [3]. This section of the setup function also filters out constant valued features, normalizes the predictor data to have zero mean and unit variance, clips the response data by using the numerical value of the hyperparameter `Threshold`, and randomly selects training examples to use for validation.

```
dataFolder = fullfile(tempdir,"turbofan");

if ~exist(dataFolder,"dir")
    mkdir(dataFolder);
    oldDir = cd(dataFolder);
    filename = "CMAPSSData.zip";
    websave(filename,"https://ti.arc.nasa.gov/c/6/", ...
        weboptions("Timeout",Inf));
    unzip(filename,dataFolder);
    cd(oldDir);
end

filenameTrainPredictors = fullfile(dataFolder,"train_FD001.txt");
[XTrain,YTrain] = processTurboFanDataTrain(filenameTrainPredictors);

XTrain = helperFilter(XTrain);
XTrain = helperNormalize(XTrain);

thr = str2double(params.Threshold);
for i = 1:numel(YTrain)
    YTrain{i}(YTrain{i} > thr) = thr;
end

for i=1:numel(XTrain)
    sequence = XTrain{i};
    sequenceLengths(i) = size(sequence,2);
end

[~,idx] = sort(sequenceLengths,"descend");
XTrain = XTrain(idx);
YTrain = YTrain(idx);

idx = randperm(numel(XTrain),10);
XValidation = XTrain(idx);
XTrain(idx) = [];
YValidation = YTrain(idx);
YTrain(idx) = [];
```

- **Define Network Architecture** defines the architecture for an LSTM network for sequence-to-sequence regression. The network consists of LSTM layers followed by a fully connected layer of size 100 and a dropout layer with a dropout probability of 0.5. The hyperparameters `LSTMDepth` and `NumHiddenUnits` specify the number of LSTM layers and the number of hidden units for each layer.

```
numResponses = size(YTrain{1},1);
featureDimension = size(XTrain{1},1);
LSTMDepth = params.LSTMDepth;
numHiddenUnits = params.NumHiddenUnits;

layers = sequenceInputLayer(featureDimension);

for i = 1:LSTMDepth
    layers = [layers;lstmLayer(numHiddenUnits,OutputMode="sequence")];
end

layers = [layers
    fullyConnectedLayer(100)
    reluLayer()
    dropoutLayer(0.5)
```

```
    fullyConnectedLayer(numResponses)
    regressionLayer];
```

- **Specify Training Options** defines the training options for the experiment. Because deeper networks take longer to converge, the number of epochs is set to 300 to ensure all network depths converge. This example validates the network every 30 iterations. The initial learning rate equals the `InitialLearnRate` value from the hyperparameter table and drops by a factor of 0.2 every 15 epochs. With the training option `ExecutionEnvironment` set to `"auto"`, the experiment runs on a GPU if one is available. Otherwise, Experiment Manager uses the CPU. Because this example compares network depths and trains for many epochs, using a GPU speeds up training time considerably. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For more information, see “GPU Support by Release” (Parallel Computing Toolbox).

```
maxEpochs = 300;
miniBatchSize = 20;

options = trainingOptions("adam", ...
    ExecutionEnvironment="auto", ...
    MaxEpochs=maxEpochs, ...
    MiniBatchSize=miniBatchSize, ...
    ValidationData={XValidation,YValidation}, ...
    ValidationFrequency=30, ...
    InitialLearnRate=params.InitialLearnRate, ...
    LearnRateDropFactor=0.2, ...
    LearnRateDropPeriod=15, ...
    GradientThreshold=1, ...
    Shuffle="never", ...
    Verbose=false);
```

To inspect the setup function, under **Setup Function**, click **Edit**. The setup function opens in MATLAB Editor. In addition, the code for the setup function appears in Appendix 1 at the end of this example.

The **Metrics** section specifies optional functions that evaluate the results of the experiment. Experiment Manager evaluates these functions each time it finishes training the network. To inspect a metric function, select the name of the metric function and click **Edit**. The metric function opens in MATLAB Editor.

The prediction of the RUL of an engine requires careful consideration. If the prediction underestimates the RUL, engine maintenance might be scheduled before it is necessary. If the prediction overestimates the RUL, the engine might fail while in operation, resulting in high costs or safety concerns. To help mitigate these scenarios, this example includes a metric function `MeanMaxAbsoluteError` that identifies networks that underpredict or overpredict the RUL.

The `MeanMaxAbsoluteError` metric calculates the maximum absolute error, averaged across the entire training set. This metric calls the `predict` function to make a sequence of RUL predictions from the training set. Then, after calculating the maximum absolute error between each training response and predicted response sequence, the function computes the mean of all maximum absolute errors. This metric identifies the maximum deviations between the actual and predicted responses. The code for the metric function appears in Appendix 3 at the end of this example.

Run Experiment

When you run the experiment, Experiment Manager searches for the best combination of hyperparameters with respect to the chosen metric. Each trial in the experiment uses a new combination of hyperparameter values based on the results of the previous trials. By default,

Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox™, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16 and “GPU Support by Release” (Parallel Computing Toolbox).

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the metric function values for each trial. Experiment Manager indicates the trial with the optimal value for the selected metric. For example, in this experiment, the 17th trial produces the smallest maximum absolute error.

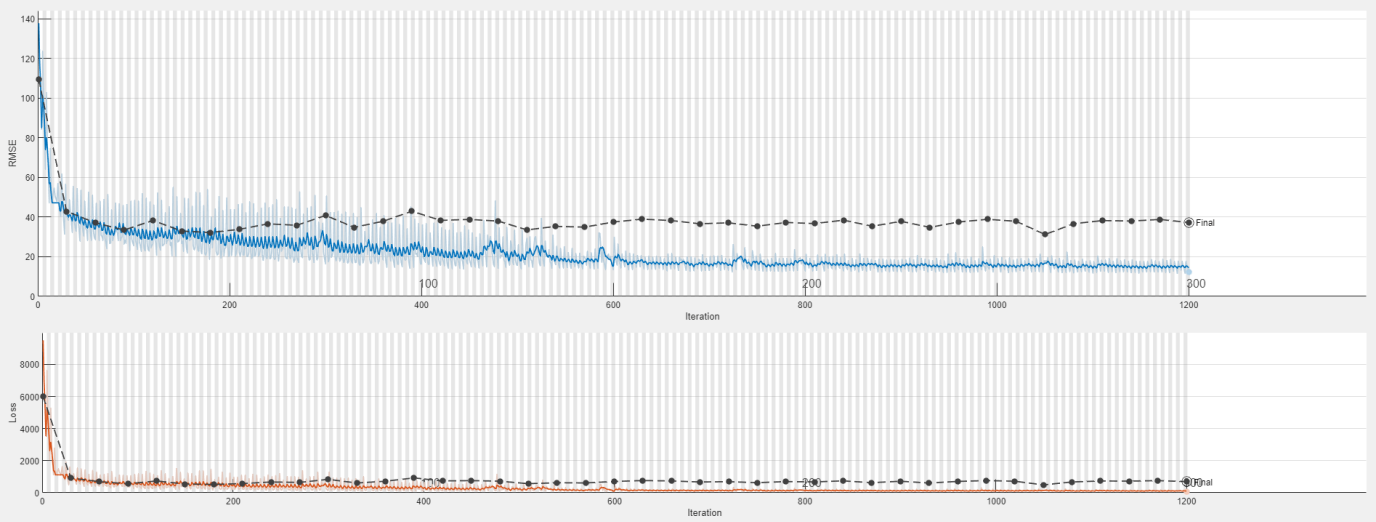
While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial. The elapsed time for a trial to complete training increases with network depth.



Evaluate Results

In the table of results, the **MeanMaxAbsoluteError** value quantifies how much the network underpredicts or overpredicts the RUL. The **Validation RMSE** value quantifies how well the network generalizes to unseen data. To find the best result for your experiment, sort the table of results and select the trial that has the lowest **MeanMaxAbsoluteError** and **Validation RMSE** values.

1. Point to the **MeanMaxAbsoluteError** column.
2. Click the triangle icon.
3. Select **Sort in Ascending Order**.

17	Complete	100.0%	0 hr 1 min 14 sec	250	2.0000	115.0000	0.0132	12.1981	74.3966	37.2713	694.5749	27.9796

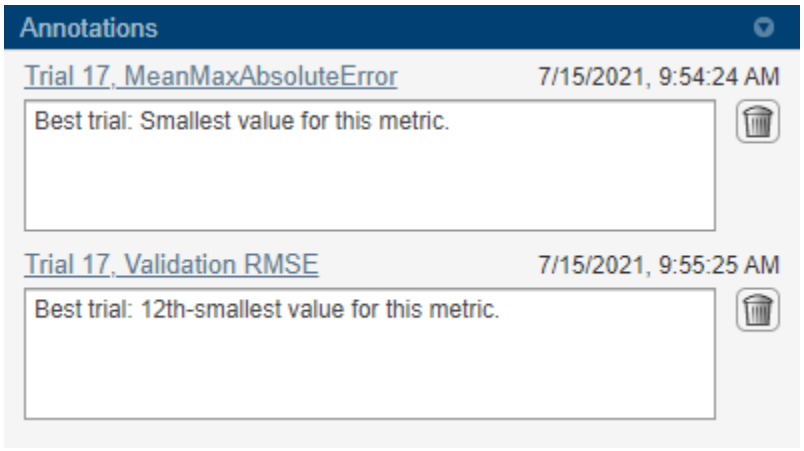
If no single trial minimizes both values, consider giving preference to a trial that ranks well for each value. For instance, in these results, trial 17 has the smallest **MeanMaxAbsoluteError** value and the

12th-smallest **Validation RMSE** value. Trials 3, 11, and 22 have smaller **Validation RMSE** values but larger **MeanMaxAbsoluteError** values.

To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **MeanMaxAbsoluteError** cell of the best trial.
2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.
4. Repeat the previous steps for the **Validation RMSE** cell.

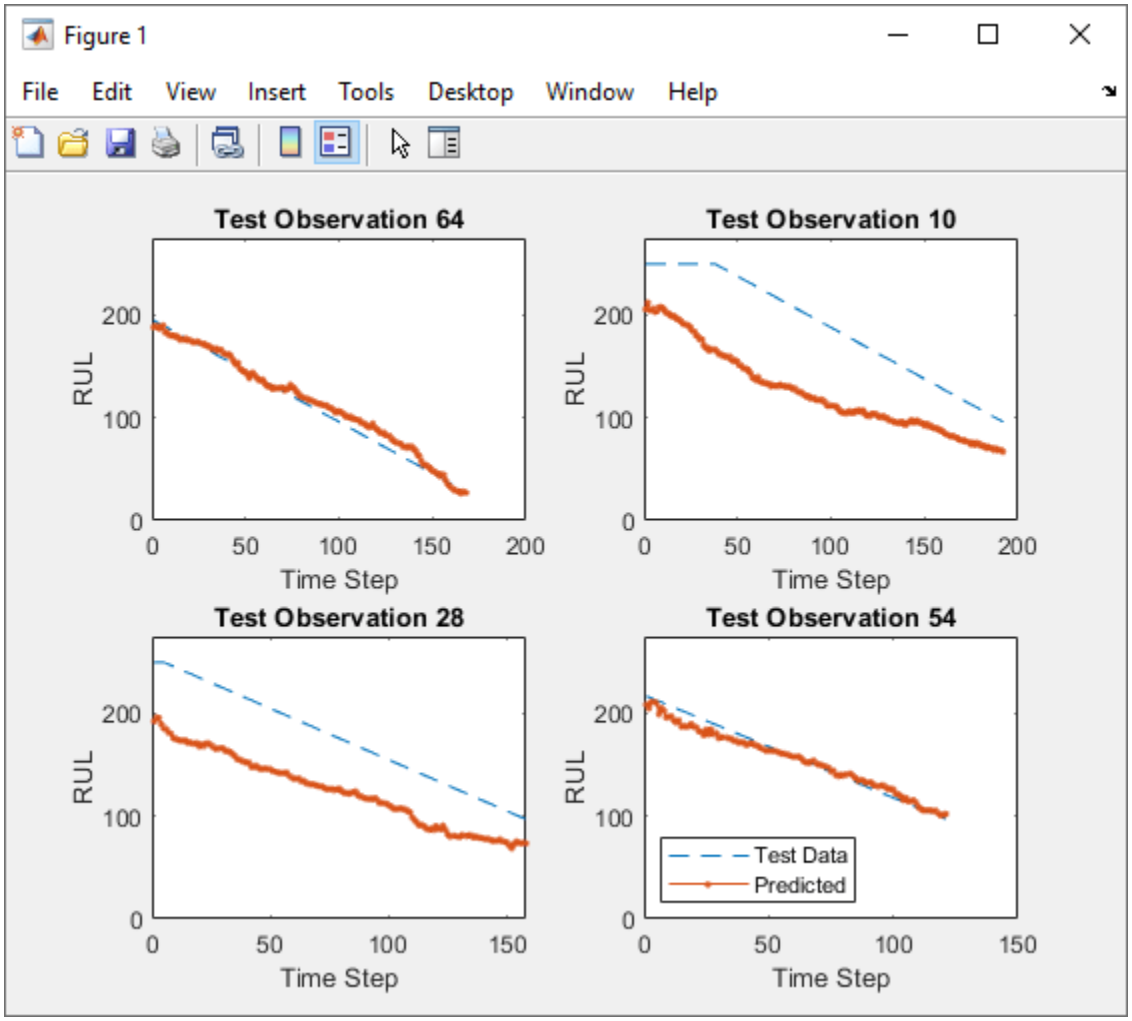


To test the performance of your best trial, export the trained network and display the predicted response sequence for several randomly chosen test sequences.

1. Select the best trial in your experiment.
2. On the **Experiment Manager** toolstrip, click **Export**.
3. In the dialog window, enter the name of a workspace variable for the exported network. The default name is `trainedNetwork`.
4. Use the exported network and the `Threshold` value of the network as inputs to the helper function `plotSequences`, which is listed in Appendix 4 at the end of this example. For instance, in the MATLAB Command Window, enter:

```
plotSequences(trainedNetwork,250)
```

The function plots the true and predicted response sequences of unseen test data.



Close Experiment

In the **Experiment Browser**, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Setup Function

This function configures the training data, network architecture, and training options for the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.

Output

- `XTrain` is a cell array containing the training data.
- `YTrain` is a cell array containing the regression values for training,
- `layers` is a layer graph that defines the neural network architecture.

- `options` is a `trainingOptions` object.

```
function [XTrain,YTrain,layers,options] = SequenceRegressionExperiment_setup1(params)

dataFolder = fullfile(tempdir,"turbofan");

if ~exist(dataFolder,"dir")
    mkdir(dataFolder);
    oldDir = cd(dataFolder);
    filename = "CMAPSSData.zip";
    websave(filename,"https://ti.arc.nasa.gov/c/6/", ...
        weboptions("Timeout",Inf));
    unzip(filename,dataFolder);
    cd(oldDir);
end

filenameTrainPredictors = fullfile(dataFolder,"train_FD001.txt");
[XTrain,YTrain] = processTurboFanDataTrain(filenameTrainPredictors);

XTrain = helperFilter(XTrain);
XTrain = helperNormalize(XTrain);

thr = str2double(params.Threshold);
for i = 1:numel(YTrain)
    YTrain{i}(YTrain{i} > thr) = thr;
end

for i=1:numel(XTrain)
    sequence = XTrain{i};
    sequenceLengths(i) = size(sequence,2);
end

[~,idx] = sort(sequenceLengths,"descend");
XTrain = XTrain(idx);
YTrain = YTrain(idx);

idx = randperm(numel(XTrain),10);
XValidation = XTrain(idx);
XTrain(idx) = [];
YValidation = YTrain(idx);
YTrain(idx) = [];

numResponses = size(YTrain{1},1);
featureDimension = size(XTrain{1},1);
LSTMDepth = params.LSTMDepth;
numHiddenUnits = params.NumHiddenUnits;

layers = sequenceInputLayer(featureDimension);

for i = 1:LSTMDepth
    layers = [layers;lstmLayer(numHiddenUnits,OutputMode="sequence")];
end

layers = [layers
    fullyConnectedLayer(100)
    reluLayer()
    dropoutLayer(0.5)
```

```
    fullyConnectedLayer(numResponses)
    regressionLayer];

maxEpochs = 300;
miniBatchSize = 20;

options = trainingOptions("adam", ...
    ExecutionEnvironment="auto", ...
    MaxEpochs=maxEpochs, ...
    MiniBatchSize=miniBatchSize, ...
    ValidationData={XValidation,YValidation}, ...
    ValidationFrequency=30, ...
    InitialLearnRate=params.InitialLearnRate, ...
    LearnRateDropFactor=0.2, ...
    LearnRateDropPeriod=15, ...
    GradientThreshold=1, ...
    Shuffle="never", ...
    Verbose=false);

end
```

Appendix 2: Filter and Normalize Predictive Maintenance Data

The helper function `helperFilter` filters the data by removing features with constant values. Features that remain constant for all time steps can negatively impact the training.

```
function [XTrain,XTest] = helperFilter(XTrain,XTest)
m = min([XTrain{:}],[],2);
M = max([XTrain{:}],[],2);
idxConstant = M == m;

for i = 1:numel(XTrain)
    XTrain{i}(idxConstant,:) = [];
    if nargin>1
        XTest{i}(idxConstant,:) = [];
    end
end
end
```

The helper function `helperNormalize` normalizes the training and test predictors to have zero mean and unit variance.

```
function [XTrain,XTest] = helperNormalize(XTrain,XTest)
mu = mean([XTrain{:}],2);
sig = std([XTrain{:}],0,2);

for i = 1:numel(XTrain)
    XTrain{i} = (XTrain{i} - mu) ./ sig;
    if nargin>1
        XTest{i} = (XTest{i} - mu) ./ sig;
    end
end
end
```

Appendix 3: Compute Mean of Maximum Absolute Errors

This metric function calculates the maximum absolute error of the trained network, averaged over the training set.

```
function metricOutput = MeanMaxAbsoluteError(trialInfo)

net = trialInfo.trainedNetwork;
thr = str2double(trialInfo.parameters.Threshold);

filenamePredictors = fullfile(tempdir,"turbofan","train_FD001.txt");
[XTrain,YTrain] = processTurboFanDataTrain(filenamePredictors);
XTrain = helperFilter(XTrain);
XTrain = helperNormalize(XTrain);

for i = 1:numel(YTrain)
    YTrain{i}(YTrain{i} > thr) = thr;
end

YPred = predict(net,XTrain,MiniBatchSize=1);

maxAbsErrors = zeros(1,numel(YTrain));
for i=1:numel(YTrain)
    absError = abs(YTrain{i}-YPred{i});
    maxAbsErrors(i) = max(absError);
end

metricOutput = mean(maxAbsErrors);

end
```

Appendix 4: Plot Predictive Maintenance Sequences

This function plots the true and predicted response sequences to allow you to evaluate the performance of your trained network. This function uses the helper functions `helperFilter` and `helperNormalize`, which are listed in Appendix 2.

```
function plotSequences(net,threshold)

filenameTrainPredictors = fullfile(tempdir,"turbofan","train_FD001.txt");
filenameTestPredictors = fullfile(tempdir,"turbofan","test_FD001.txt");
filenameTestResponses = fullfile(tempdir,"turbofan","RUL_FD001.txt");

[XTrain,YTrain] = processTurboFanDataTrain(filenameTrainPredictors);
[XTest,YTest] = processTurboFanDataTest(filenameTestPredictors,filenameTestResponses);

[XTrain,XTest] = helperFilter(XTrain,XTest);
[~,XTest] = helperNormalize(XTrain,XTest);

for i = 1:numel(YTrain)
  YTrain{i}(YTrain{i} > threshold) = threshold;
  YTest{i}(YTest{i} > threshold) = threshold;
end

YPred = predict(net,XTest,MiniBatchSize=1);

idx = randperm(100,4);
figure
for i = 1:numel(idx)
    subplot(2,2,i)
```

```
    plot(YTest{idx(i)},'--')
    hold on
    plot(YPred{idx(i)},'.-')
    hold off
    ylim([0 threshold+25])
    title("Test Observation " + idx(i))
    xlabel("Time Step")
    ylabel("RUL")
end
legend(["Test Data" "Predicted"],'Location','southwest')
end
```

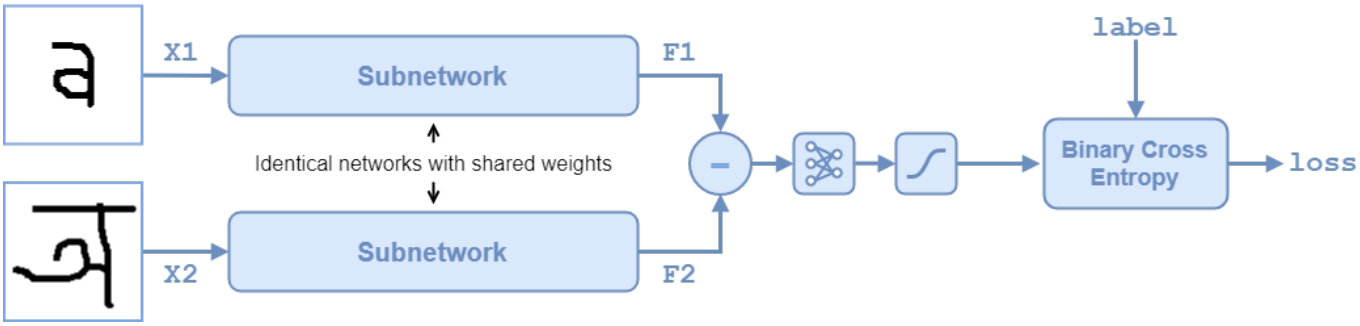
Run a Custom Training Experiment for Image Comparison

This example shows how to create a custom training experiment to train a Siamese network that identifies similar images of handwritten characters. For a custom training experiment, you explicitly define the training procedure used by **Experiment Manager**. In this example, you implement a custom training loop to train a Siamese network, a type of deep learning network that uses two or more identical subnetworks that have the same architecture and share the same parameters and weights. Some common applications for Siamese networks include facial recognition, signature verification, and paraphrase identification.

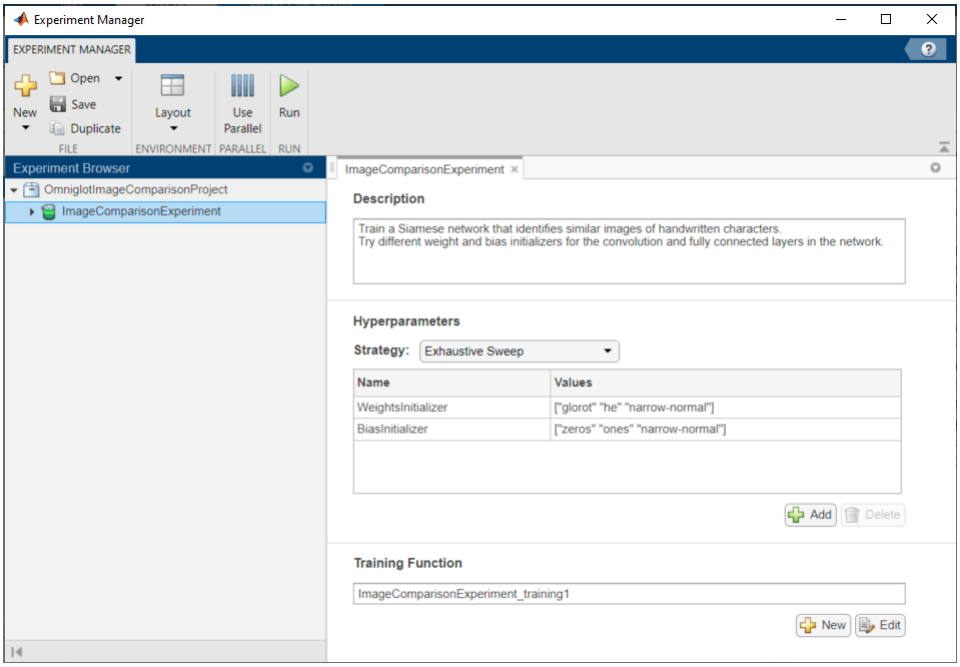
This diagram illustrates the Siamese network architecture in this example.



To compare two images, you pass each image through one of two identical subnetworks that share weights. The subnetworks convert each 105-by-105-by-1 image to a 4096-dimensional feature vector. Images of the same class have similar 4096-dimensional representations. The output feature vectors from each subnetwork are combined through subtraction and the result is passed through a `fullyconnect` operation with a single output. A sigmoid operation converts this value to a probability indicating that the images are similar (when the probability is close to 1) or dissimilar (when the probability is close to 0). The binary cross-entropy loss between the network prediction and the true label updates the network during training. For more information, see “Train a Siamese Network to Compare Images” on page 3-128.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`ImageComparisonExperiment`).



Custom training experiments consist of a description, a table of hyperparameters, and a training function. For more information, see “Configure Custom Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Train a Siamese network to identify similar and dissimilar images of handwritten characters.
Try different weight and bias initializers for the convolution and fully connected layers in the
```

The **Hyperparameters** section specifies the strategy (`Exhaustive Sweep`) and hyperparameter values to use for the experiment. When you run the experiment, Experiment Manager trains the network using every combination of hyperparameter values specified in the hyperparameter table. This example uses the hyperparameters `WeightsInitializer` and `BiasInitializer` to specify the weight and bias initializers, respectively, for the convolution and fully connected layers in each subnetwork. For more information about these initializers, see “`WeightsInitializer`” and “`BiasInitializer`”.

The **Training Function** specifies the training data, network architecture, training options, and training procedure used by the experiment. The input to the training function is a structure with fields from the hyperparameter table and an `experiments.Monitor` object that you can use to track the progress of the training, record values of the metrics used by the training, and produce training plots. The training function returns a structure that contains the trained network, the weights for the final `fullyconnect` operation for the network, and the execution environment used for training. Experiment Manager saves this output, so you can export it to the MATLAB workspace when the training is complete. The training function has five sections.

- **Initialize Output** sets the initial value of the network and `fullyconnect` weights to empty arrays to indicate that the training has not started. The experiment sets the execution environment to `"auto"`, so it trains and validates the network on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For more information, see “GPU Support by Release” (Parallel Computing Toolbox).

```
output.network = [];
output.weights = [];
output.executionEnvironment = "auto";
```

- **Load and Preprocess Training and Test Data** defines the training and test data for the experiment as `imageDatastore` objects. The experiment uses the Omniglot data set, which consists of character sets for 50 alphabets, divided into 30 sets for training and 20 sets for testing. For more information on this data set, see “Image Data Sets” on page 19-118.

```
monitor.Status = "Loading Training Data";

url = "https://github.com/brendenlake/omniglot/raw/master/python/images_background.zip";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"images_background.zip");

dataFolderTrain = fullfile(downloadFolder,"images_background");
if ~exist(dataFolderTrain,"dir")
    websave(filename,url);
    unzip(filename,downloadFolder);
end

imdsTrain = imageDatastore(dataFolderTrain, ...
    IncludeSubfolders=true, ...
    LabelSource="none");

files = imdsTrain.Files;
parts = split(files,filesep);
labels = join(parts(:,(end-2):(end-1)),'_');
imdsTrain.Labels = categorical(labels);

monitor.Status = "Loading Test Data";

url = "https://github.com/brendenlake/omniglot/raw/master/python/images_evaluation.zip";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"images_evaluation.zip");

dataFolderTest = fullfile(downloadFolder,"images_evaluation");
if ~exist(dataFolderTest,"dir")
    websave(filename,url);
    unzip(filename,downloadFolder);
end

imdsTest = imageDatastore(dataFolderTest, ...
    IncludeSubfolders=true, ...
    LabelSource="none");

files = imdsTest.Files;
parts = split(files,filesep);
labels = join(parts(:,(end-2):(end-1)),'_');
imdsTest.Labels = categorical(labels);
```

- **Define Network Architecture** defines the architecture for two identical subnetworks that accept 105-by-105-by-1 images and output a feature vector. The convolution and fully connected layers use the weights and bias initializers specified in the hyperparameter table. To train the network with a custom training loop and enable automatic differentiation, the training function converts the layer graph to a `dlnetwork` object. The weights for the final `fullyconnect` operation are initialized by sampling a random selection from a narrow normal distribution with standard deviation of 0.01.

```
monitor.Status = "Creating Network";

layers = [
    imageInputLayer([105 105 1],Name="input1",Normalization="none")
    convolution2dLayer(10,64,Name="conv1", ...
        WeightsInitializer=params.WeightsInitializer, ...
        BiasInitializer=params.BiasInitializer)
    reluLayer(Name="relu1")
    maxPooling2dLayer(2,Stride=2,Name="maxpool1")
    convolution2dLayer(7,128,Name="conv2", ...
        WeightsInitializer=params.WeightsInitializer, ...
        BiasInitializer=params.BiasInitializer)
    reluLayer(Name="relu2")
    maxPooling2dLayer(2,'Stride',2,Name="maxpool2")
    convolution2dLayer(4,128,'Name','conv3', ...
        WeightsInitializer=params.WeightsInitializer, ...
        BiasInitializer=params.BiasInitializer)
    reluLayer(Name="relu3")
    maxPooling2dLayer(2,'Stride',2,Name="maxpool3")
    convolution2dLayer(5,256,Name="conv4", ...
        WeightsInitializer=params.WeightsInitializer, ...
        BiasInitializer=params.BiasInitializer)
    reluLayer(Name="relu4")
    fullyConnectedLayer(4096,Name="fc1", ...
        WeightsInitializer=params.WeightsInitializer, ...
        BiasInitializer=params.BiasInitializer)];

lgraph = layerGraph(layers);
dlnet = dlnetwork(lgraph);

fcWeights = dlarray(0.01*randn(1,4096));
fcBias = dlarray(0.01*randn(1,1));
fcParams = struct(...
    "FcWeights",fcWeights,...
    "FcBias",fcBias);

output.network = dlnet;
output.weights = fcParams;
```

- **Specify Training Options** defines the training options used by the experiment. In this example, Experiment Manager trains the network with a mini-batch size of 180 for 1000 iterations, computing the accuracy of the network every 100 iterations. Training can take some time to run. For better results, consider increasing the training to 10,000 iterations.

```
numIterations = 1000;
miniBatchSize = 180;
validationFrequency = 100;
initialLearnRate = 6e-5;
gradientDecayFactor = 0.9;
squaredGradientDecayFactor = 0.99;
trailingAvgSubnet = [];
trailingAvgSqSubnet = [];
trailingAvgParams = [];
trailingAvgSqParams = [];
```

- **Train Model** defines the custom training loop used by the experiment. For each iteration, the custom training loop extracts a batch of image pairs and labels, converts the data to `dlarray` objects with underlying type single, and specifies the dimension labels `'SSCB'` (spatial, spatial,

channel, batch) for the image data and `'CB'` (channel, batch) for the labels. If you train on a GPU, the data is converted to `gpuArray` (Parallel Computing Toolbox) objects. Then, the training function evaluates the model gradients and updates the network parameters. To validate, the training function creates a set of five random mini-batches of test pairs, evaluates the network predictions, and calculates the average accuracy over the mini-batches. After each iteration of the custom training loop, the training function saves the trained network and the weights for the `fullyconnect` operation, records the training loss, and updates the training progress.

```
monitor.Metrics = ["TrainingLoss" "ValidationAccuracy"];
monitor.XLabel = "Iteration";
monitor.Status = "Training";

for iteration = 1:numIterations
    [X1,X2,pairLabels] = getSiameseBatch(imdsTrain,miniBatchSize);
    dlX1 = dlarray(single(X1),"SSCB");
    dlX2 = dlarray(single(X2),"SSCB");
    if (output.executionEnvironment == "auto" && canUseGPU) || ...
            output.executionEnvironment == "gpu"
        dlX1 = gpuArray(dlX1);
        dlX2 = gpuArray(dlX2);
    end
    [gradientsSubnet, gradientsParams,loss] = dlfeval(@modelGradients, ...
        dlnet,fcParams,dlX1,dlX2,pairLabels);
    lossValue = double(gather(extractdata(loss)));
    [dlnet,trailingAvgSubnet,trailingAvgSqSubnet] = ...
        adamupdate(dlnet,gradientsSubnet, ...
        trailingAvgSubnet,trailingAvgSqSubnet, ...
        iteration,initialLearnRate,gradientDecayFactor,squaredGradientDecayFactor);
    [fcParams,trailingAvgParams,trailingAvgSqParams] = ...
        adamupdate(fcParams,gradientsParams, ...
        trailingAvgParams,trailingAvgSqParams, ...
        iteration,initialLearnRate,gradientDecayFactor,squaredGradientDecayFactor);
    if ~rem(iteration,validationFrequency) || iteration == 1 || iteration == numIterations
        monitor.Status = "Validating";
        accuracy = zeros(1,5);
        accuracyBatchSize = 150;
        for i = 1:5
            [XAcc1,XAcc2,pairLabelsAcc] = getSiameseBatch(imdsTest,accuracyBatchSize);
            dlXAcc1 = dlarray(single(XAcc1),"SSCB");
            dlXAcc2 = dlarray(single(XAcc2),"SSCB");
            if (output.executionEnvironment == "auto" && canUseGPU) || ...
                    output.executionEnvironment == "gpu"
                dlXAcc1 = gpuArray(dlXAcc1);
                dlXAcc2 = gpuArray(dlXAcc2);
            end
            dlY = predictSiamese(dlnet,fcParams,dlXAcc1,dlXAcc2);
            Y = gather(extractdata(dlY));
            Y = round(Y);
            accuracy(i) = sum(Y == pairLabelsAcc)/accuracyBatchSize;
        end
        recordMetrics(monitor,iteration, ...
            ValidationAccuracy=mean(accuracy)*100);
        monitor.Status = "Training";
    end
    output.network = dlnet;
    output.weights = fcParams;
    recordMetrics(monitor,iteration, ...
```

```
        TrainingLoss=lossValue);
    monitor.Progress = (iteration/numIterations)*100;
    if monitor.Stop
        return;
    end
end
```

To inspect the training function, under **Training Function**, click **Edit**. The training function opens in MATLAB® Editor. In addition, the code for the training function appears in Appendix 1 at the end of this example.

Run Experiment

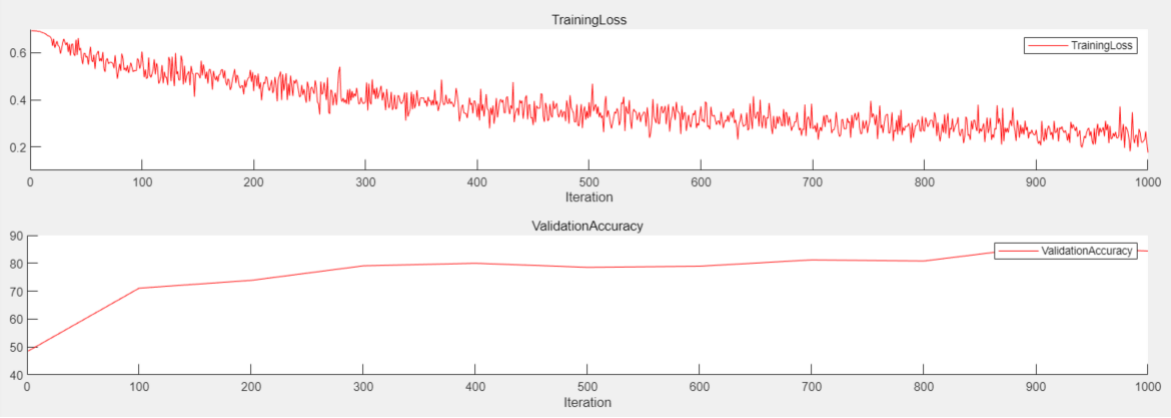
When you run the experiment, Experiment Manager trains the network defined by the training function multiple times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16.

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the training loss and validation accuracy for each trial.

Trial	Status	Progress	Elapsed Time	WeightsInitializer	BiasInitializer	TrainingLoss	ValidationAccuracy
1	Complete	100.0%	0 hr 13 min 16 sec	glorot	zeros	0.1753	84.4000
2	Complete	100.0%	0 hr 12 min 1 sec	he	zeros	0.1766	87.2000
3	Complete	100.0%	0 hr 12 min 18 sec	narrow-normal	zeros	0.2998	80.9333
4	Complete	100.0%	0 hr 12 min 28 sec	glorot	ones	0.2100	82.2667
5	Complete	100.0%	0 hr 12 min 42 sec	he	ones	0.2230	85.3333
6	Complete	100.0%	0 hr 12 min 24 sec	narrow-normal	ones	0.2904	79.4667
7	Complete	100.0%	0 hr 12 min 42 sec	glorot	narrow-normal	0.2280	81.6000
8	Complete	100.0%	0 hr 12 min 37 sec	he	narrow-normal	0.1971	89.2000
9	Complete	100.0%	0 hr 12 min 22 sec	narrow-normal	narrow-normal	0.2832	82.6667

While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial.



Evaluate Results

To find the best result for your experiment, sort the table of results by validation accuracy.

1. Point to the **ValidationAccuracy** column.
2. Click the triangle icon.
3. Select **Sort in Descending Order**.

The trial with the highest validation accuracy appears at the top of the results table.

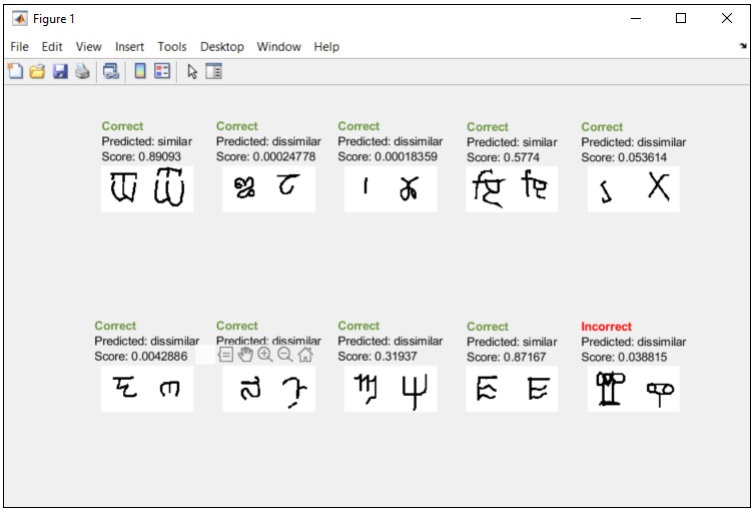
Trial	Status	Progress	Elapsed Time	WeightsInitializer	BiasInitializer	TrainingLoss	ValidationAccuracy
8	Complete	100.0%	0 hr 12 min 37 sec	he	narrow-normal	0.1971	89.2000
2	Complete	100.0%	0 hr 12 min 1 sec	he	zeros	0.1766	87.2000
5	Complete	100.0%	0 hr 12 min 42 sec	he	ones	0.2230	85.3333
1	Complete	100.0%	0 hr 13 min 16 sec	glorot	zeros	0.1753	84.4000
9	Complete	100.0%	0 hr 12 min 22 sec	narrow-normal	narrow-normal	0.2832	82.6667
4	Complete	100.0%	0 hr 12 min 28 sec	glorot	ones	0.2100	82.2667
7	Complete	100.0%	0 hr 12 min 42 sec	glorot	narrow-normal	0.2280	81.6000
3	Complete	100.0%	0 hr 12 min 18 sec	narrow-normal	zeros	0.2998	80.9333
6	Complete	100.0%	0 hr 12 min 24 sec	narrow-normal	ones	0.2904	79.4667

To visually check if the network correctly identifies similar and dissimilar pairs:

1. Select the trial with the highest accuracy.
2. On the **Experiment Manager** toolstrip, click **Export**.
3. In the dialog window, enter the name of a workspace variable for the exported training output. The default name is `trainingOutput`.
4. Test the network on a small batch of image pairs by calling the `displayTestSet` function, which is listed in Appendix 3 at the end of this example. Use the exported training output as the input to the function. For instance, in the MATLAB Command Window, enter:

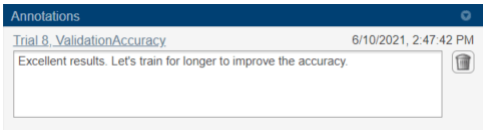
```
displayTestSet(trainingOutput)
```

The function displays 10 randomly selected pairs of test images with the prediction from the trained network, the probability score, and a label indicating whether the prediction is correct or incorrect.



To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **ValidationAccuracy** cell of the best trial.
2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.



For more information, see “Sort, Filter, and Annotate Experiment Results”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Training Function

This function specifies the training data, network architecture, training options, and training procedure used by the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.
- `monitor` is an `experiments.Monitor` object that you can use to track the progress of the training, update information fields in the results table, record values of the metrics used by the training, and produce training plots.

Output

- `output` is a structure that contains the trained network, the weights for the final `fullyconnect` operation for the network, and the execution environment used for training. Experiment Manager saves this output, so you can export it to the MATLAB workspace when the training is complete.

```
function output = ImageComparisonExperiment_training1(params,monitor)

output.network = [];
output.weights = [];
output.executionEnvironment = "auto";

monitor.Status = "Loading Training Data";

url = "https://github.com/brendenlake/omniglot/raw/master/python/images_background.zip";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"images_background.zip");

dataFolderTrain = fullfile(downloadFolder,"images_background");
if ~exist(dataFolderTrain,"dir")
    websave(filename,url);
    unzip(filename,downloadFolder);
end

imdsTrain = imageDatastore(dataFolderTrain, ...
    IncludeSubfolders=true, ...
```

```
    LabelSource="none");

files = imdsTrain.Files;
parts = split(files,filesep);

Appendix 2: Custom Training Helper Functions

The `modelGradients` function takes as input the Siamese `dlnetwork` object `net`, a pair of mini-batch input data `dlX1` and `dlX2`, and the label indicating whether they are similar or dissimilar. The function returns the gradients of the loss with respect to the learnable parameters in the network and the binary cross-entropy loss between the prediction and the ground truth.

```
function [gradientsSubnet,gradientsParams,loss] = modelGradients(dlnet,fcParams,dlX1,dlX2,pairLa
    Y = forwardSiamese(dlnet,fcParams,dlX1,dlX2);
    loss = binarycrossentropy(Y,pairLabels);
    [gradientsSubnet,gradientsParams] = dlgradient(loss,dlnet.Learnables,fcParams);
end
```

This function returns the binary cross-entropy loss value for a prediction from the network.

```
function loss = binarycrossentropy(Y,pairLabels)
    precision = underlyingType(Y);
    Y(Y < eps(precision)) = eps(precision);
    Y(Y > 1 - eps(precision)) = 1 - eps(precision);

     loss = -pairLabels.*log(Y) - (1 - pairLabels).*log(1 - Y);
     loss = sum(loss)/numel(pairLabels);
 end
```

This function defines how the subnetworks and the `fullyconnect` and `sigmoid` operations combine to form the complete Siamese network. The function accepts the network structure and two training images and returns a prediction of the probability of the pair being similar (closer to 1) or dissimilar (closer to 0).

```
function Y = forwardSiamese(dlnet,fcParams,dlX1,dlX2)
    F1 = forward(dlnet,dlX1);
    F1 = sigmoid(F1);

     F2 = forward(dlnet,dlX2);
     F2 = sigmoid(F2);

     Y = abs(F1 - F2);
     Y = fullyconnect(Y,fcParams.FcWeights,fcParams.FcBias);
     Y = sigmoid(Y);
 end
```

This function returns a randomly selected batch of paired images. On average, this function produces a balanced set of similar and dissimilar pairs.

```
function [X1,X2,pairLabels] = getSiameseBatch(imds,miniBatchSize)
    pairLabels = zeros(1,miniBatchSize);
    imgSize = size(readimage(imds,1));
    X1 = zeros([imgSize 1 miniBatchSize]);
    X2 = zeros([imgSize 1 miniBatchSize]);
    for i = 1:miniBatchSize
        choice = rand(1);
        if choice < 0.5
            [pairIdx1,pairIdx2,pairLabels(i)] = getSimilarPair(imds.Labels);
        else
            [pairIdx1,pairIdx2,pairLabels(i)] = getDissimilarPair(imds.Labels);
        end
        X1(:,:,:,i) = imds.readimage(pairIdx1);
        X2(:,:,:,i) = imds.readimage(pairIdx2);
    end
end
```

This function returns a random pair of indices for images that are in the same class and the similar pair label of 1.

```
function [pairIdx1,pairIdx2,label] = getSimilarPair(classLabel)
    classes = unique(classLabel);
    classChoice = randi(numel(classes));
    idxs = find(classLabel==classes(classChoice));
    pairIdxChoice = randperm(numel(idxs),2);
    pairIdx1 = idxs(pairIdxChoice(1));
    pairIdx2 = idxs(pairIdxChoice(2));
    label = 1;
end
```

This function returns a random pair of indices for images that are in different classes and the dissimilar pair label of 0.

```
function  [pairIdx1,pairIdx2,label] = getDissimilarPair(classLabel)
    classes = unique(classLabel);
    classesChoice = randperm(numel(classes),2);
    idxs1 = find(classLabel==classes(classesChoice(1)));
    idxs2 = find(classLabel==classes(classesChoice(2)));
```

```
    pairIdx1Choice = randi(numel(idxs1));
    pairIdx2Choice = randi(numel(idxs2));
    pairIdx1 = idxs1(pairIdx1Choice);
    pairIdx2 = idxs2(pairIdx2Choice);
    label = 0;
end
```

This function uses the trained network to make predictions about the similarity of two images.

```
function Y = predictSiamese(dlnet,fcParams,dlX1,dlX2)
    F1 = predict(dlnet,dlX1);
    F1 = sigmoid(F1);

     F2 = predict(dlnet,dlX2);
     F2 = sigmoid(F2);

     Y = abs(F1 - F2);
     Y = fullyconnect(Y,fcParams.FcWeights,fcParams.FcBias);
     Y = sigmoid(Y);
 end
```

Appendix 3: Display Pairs of Test Images

This function creates a small batch of image pairs to help you visually check if the network correctly identifies similar and dissimilar pairs. This function uses the helper functions `predictSiamese` and `predictSiamese`, which are listed in Appendix 2.

```
function displayTestSet(trainingOutput)

dlnet = trainingOutput.network;
fcParams = trainingOutput.weights;
executionEnvironment = trainingOutput.executionEnvironment;

downloadFolder = tempdir;
dataFolderTest = fullfile(downloadFolder,"images_evaluation");
imdsTest = imageDatastore(dataFolderTest, ...
    IncludeSubfolders=true, ...
    LabelSource="none");

files = imdsTest.Files;
parts = split(files,filesep);
labels = join(parts(:,(end-2):(end-1)),'_');
imdsTest.Labels = categorical(labels);

testBatchSize = 10;

[XTest1,XTest2,pairLabelsTest] = getSiameseBatch(imdsTest,testBatchSize);

dlXTest1 = dlarray(single(XTest1),"SSCB");
dlXTest2 = dlarray(single(XTest2),"SSCB");

if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
   dlXTest1 = gpuArray(dlXTest1);
   dlXTest2 = gpuArray(dlXTest2);
end

dlYScore = predictSiamese(dlnet,fcParams,dlXTest1,dlXTest2);
```

```
YScore = gather(extractdata(dlYScore));

YPred = round(YScore);

XTest1 = extractdata(dlXTest1);
XTest2 = extractdata(dlXTest2);

plotRatio = 16/9;
testingPlot = figure;
testingPlot.Position(3) = plotRatio*testingPlot.Position(4);
testingPlot.Visible = "on";

for i = 1:numel(pairLabelsTest)

    if YPred(i) == 1
        predLabel = "similar";
    else
        predLabel = "dissimilar" ;
    end

    if pairLabelsTest(i) == YPred(i)
        testStr = "\bf\color{darkgreen}Correct\rm\newline";
    else
        testStr = "\bf\color{red}Incorrect\rm\newline";
    end

    subplot(2,5,i)
    imshow([XTest1(:,:,:,i) XTest2(:,:,:,i)]);

    title(testStr + "\color{black}Predicted: " + predLabel + "\newlineScore: " + YScore(i));
end
```

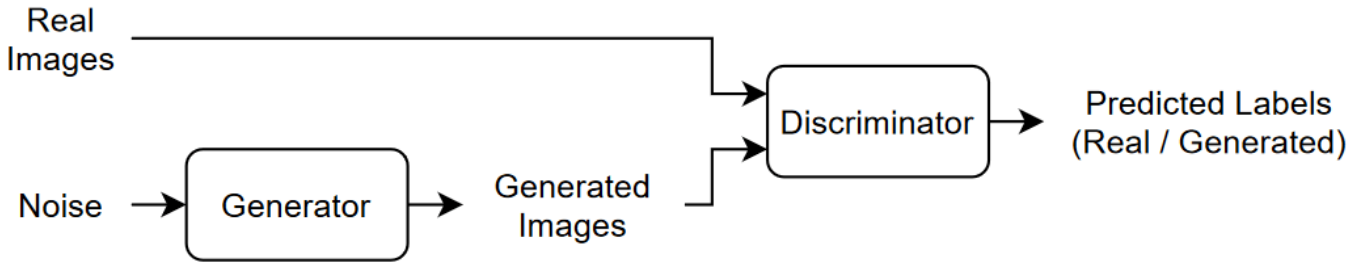
Use Experiment Manager to Train Generative Adversarial Networks (GANs)

This example shows how to create a custom training experiment to train a generative adversarial network (GAN) that generates images of flowers. For a custom training experiment, you explicitly define the training procedure used by **Experiment Manager**. In this example, you implement a custom training loop to train a GAN, a type of deep learning network that can generate data with similar characteristics as the input real data. A GAN consists of two networks that train together:

- Generator — Given a vector of random values (latent inputs) as input, this network generates data with the same structure as the training data.
- Discriminator — Given batches of data containing observations from both the training data, and generated data from the generator, this network attempts to classify the observations as "real" or "generated."



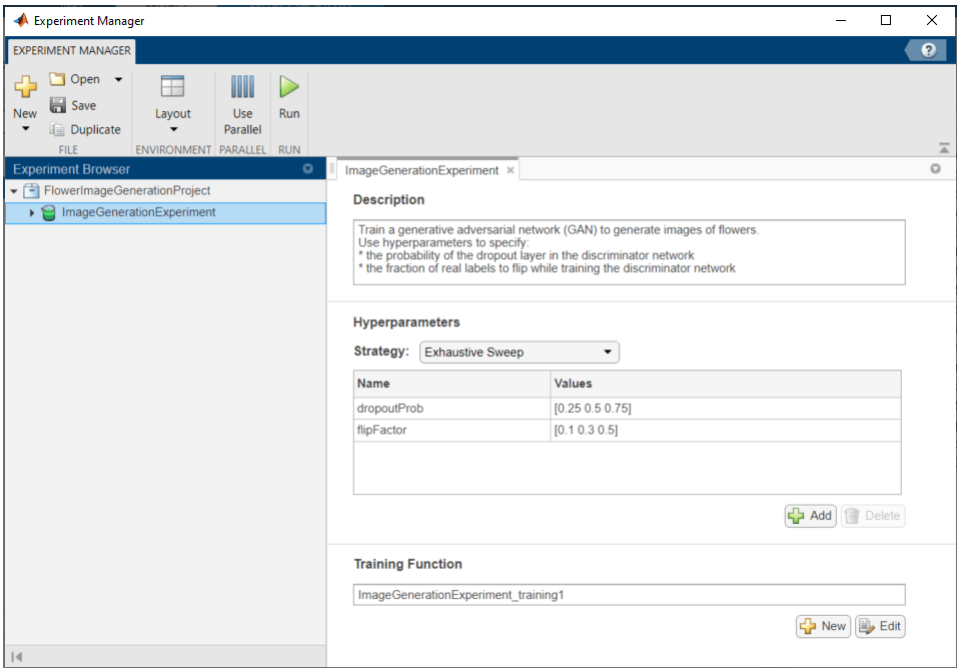
To train a GAN, train both networks simultaneously to maximize the performance of both networks:

- Train the generator to generate data that "fools" the discriminator. To optimize the performance of the generator, maximize the loss of the discriminator when given generated data. In other words, the objective of the generator is to generate data that the discriminator classifies as "real."
- Train the discriminator to distinguish between real and generated data. To optimize the performance of the discriminator, minimize the loss of the discriminator when given batches of both real and generated data. In other words, the objective of the discriminator is to not be "fooled" by the generator.

Ideally, these strategies result in a generator that generates convincingly realistic data and a discriminator that has learned strong feature representations that are characteristic of the training data. For more information, see “Train Generative Adversarial Network (GAN)” on page 3-76.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`ImageGenerationExperiment`).



Custom training experiments consist of a description, a table of hyperparameters, and a training function. For more information, see “Configure Custom Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Train a generative adversarial network (GAN) to generate images of flowers.
Use hyperparameters to specify:
* the probability of the dropout layer in the discriminator network
* the fraction of real labels to flip while training the discriminator network
```

The **Hyperparameters** section specifies the strategy (`Exhaustive Sweep`) and hyperparameter values to use for the experiment. When you run the experiment, Experiment Manager trains the network using every combination of hyperparameter values specified in the hyperparameter table. This example uses two hyperparameters:

- `dropoutProb` sets the probability of the dropout layer in the discriminator network. By default, the values for this hyperparameter are specified as `[0.25 0.5 0.75]`.
- `flipFactor` sets the fraction of real labels to flip when you train the discriminator network. The experiment uses this hyperparameter to add noise to the real data and better balance the learning of the discriminator and the generator. Otherwise, if the discriminator learns to discriminate between real and generated images too quickly, then the generator can fail to train. The values for this hyperparameter are specified as `[0.1 0.3 0.5]`.

The **Training Function** specifies the training data, network architecture, training options, and training procedure used by the experiment. The input to the training function is a structure with fields from the hyperparameter table and an `experiments.Monitor` object that you can use to track the progress of the training, record values of the metrics used by the training, and produce training plots. The training function returns a structure that contains the trained generator network, the trained discriminator network, and the execution environment used for training. Experiment Manager saves this output, so you can export it to the MATLAB workspace when the training is complete. The training function has six sections.

- **Initialize Output** sets the initial value of the networks to empty arrays to indicate that the training has not started. The experiment sets the execution environment to `"auto"`, so it trains the networks on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For more information, see "GPU Support by Release" (Parallel Computing Toolbox).

```
output.generator = [];
output.discriminator = [];
output.executionEnvironment = "auto";
```

- **Load Training Data** defines the training data for the experiment as an `imageDatastore` object. The experiment uses the Flowers data set, which contains 3670 images of flowers and is about 218 MB. For more information on this data set, see "Image Data Sets" on page 19-118.

```
monitor.Status = "Loading Data";

url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");

imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
    websave(filename,url);
    untar(filename,downloadFolder)
end

datasetFolder = fullfile(imageFolder);
imdsTrain = imageDatastore(datasetFolder, ...
    IncludeSubfolders=true);

augmenter = imageDataAugmenter(RandXReflection=true);
augimdsTrain = augmentedImageDatastore([64 64],imdsTrain, ...
    DataAugmentation=augmenter);
```

- **Define Generator Network** defines the architecture for the generator network as a layer graph that generates images from 1-by-1-by-100 arrays of random values. To train the network with a custom training loop and enable automatic differentiation, the training function converts the layer graph to a `dlnetwork` object.

```
monitor.Status = "Creating Generator";

filterSize = 5;
numFilters = 64;
numLatentInputs = 100;
projectionSize = [4 4 512];

layersGenerator = [
    featureInputLayer(numLatentInputs,Name="in")
    projectAndReshapeLayer(projectionSize,numLatentInputs,Name="proj")
    transposedConv2dLayer(filterSize,4*numFilters,Name="tconv1")
    batchNormalizationLayer(Name="bnorm1")
    reluLayer(Name="relu1")
    transposedConv2dLayer(filterSize,2*numFilters,Stride=2,Cropping="same",Name="tconv2")
    batchNormalizationLayer(Name="bnorm2")
    reluLayer(Name="relu2")
    transposedConv2dLayer(filterSize,numFilters,Stride=2,Cropping="same",Name="tconv3")
    batchNormalizationLayer(Name="bnorm3")
    reluLayer(Name="relu3")
```

```
    transposedConv2dLayer(filterSize,3,Stride=2,Cropping="same",Name="tconv4")
    tanhLayer(Name="tanh")];

lgraphGenerator = layerGraph(layersGenerator);
output.generator = dlnetwork(lgraphGenerator);
```

- **Define Discriminator Network** defines the architecture for the discriminator network as a layer graph that classifies real and generated 64-by-64-by-3 images. The dropout layer uses the dropout probability defined in the hyperparameter table. To train the network with a custom training loop and enable automatic differentiation, the training function converts the layer graph to a `dlnetwork` object.

```
monitor.Status = "Creating Discriminator";

filterSize = 5;
numFilters = 64;
inputSize = [64 64 3];
dropoutProb = params.dropoutProb;
scale = 0.2;

layersDiscriminator = [
    imageInputLayer(inputSize,Normalization="none",Name="in")
    dropoutLayer(dropoutProb,Name="dropout")
    convolution2dLayer(filterSize,numFilters,Stride=2,Padding="same",Name="conv1")
    leakyReluLayer(scale,Name="lrelu1")
    convolution2dLayer(filterSize,2*numFilters,Stride=2,Padding="same",Name="conv2")
    batchNormalizationLayer(Name="bn2")
    leakyReluLayer(scale,Name="lrelu2")
    convolution2dLayer(filterSize,4*numFilters,Stride=2,Padding="same",Name="conv3")
    batchNormalizationLayer(Name="bn3")
    leakyReluLayer(scale,Name="lrelu3")
    convolution2dLayer(filterSize,8*numFilters,Stride=2,Padding="same",Name="conv4")
    batchNormalizationLayer(Name="bn4")
    leakyReluLayer(scale,Name="lrelu4")
    convolution2dLayer(4,1,Name="conv5")];

lgraphDiscriminator = layerGraph(layersDiscriminator);
output.discriminator = dlnetwork(lgraphDiscriminator);
```

- **Specify Training Options** defines the training options used by the experiment. In this example, Experiment Manager trains the networks with a mini-batch size of 128 for 50 epochs using an initial learning rate of 0.0002, a gradient decay factor of 0.5, and a squared gradient decay factor of 0.999.

```
numEpochs = 50;
miniBatchSize = 128;
initialLearnRate = 0.0002;
gradientDecayFactor = 0.5;
squaredGradientDecayFactor = 0.999;
trailingAvgGenerator = [];
trailingAvgSqGenerator = [];
trailingAvgDiscriminator = [];
trailingAvgSqDiscriminator = [];
flipFactor = params.flipFactor;
```

- **Train Model** defines the custom training loop used by the experiment. The custom training loop uses `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch, the `minibatchqueue` object rescales the images in the range [-1,1], discards any partial mini-

batches with fewer than 128 observations, and formats the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. For each epoch, the custom training loop shuffles the datastore and loops over mini-batches of data. If you train on a GPU, the data is converted to `gpuArray` (Parallel Computing Toolbox) objects. Then, the training function evaluates the model gradients and updates the discriminator and generator network parameters. After each iteration of the custom training loop, the training function saves the trained networks and updates the training progress.

```
monitor.Metrics = ["scoreGenerator","scoreDiscriminator","scoreCombined"];
monitor.XLabel = "Iteration";
groupSubPlot(monitor,"Combined Score","scoreCombined");
groupSubPlot(monitor,"Generator and Discriminator Scores", ...
    ["scoreGenerator","scoreDiscriminator"]);
monitor.Status = "Training";
```

```
augimdsTrain.MiniBatchSize = miniBatchSize;
mbq = minibatchqueue(augimdsTrain,...
    MiniBatchSize=miniBatchSize,...
    PartialMiniBatch="discard",...
    MiniBatchFcn=@preprocessMiniBatch,...
    MiniBatchFormat="SSCB",...
    OutputEnvironment=output.executionEnvironment);
```

```
iteration = 0;
for epoch = 1:numEpochs
    shuffle(mbq);
    while hasdata(mbq)
        iteration = iteration + 1;
        dlX = next(mbq);
        Z = randn(numLatentInputs,miniBatchSize,"single");
        dlZ = dlarray(Z,"CB");
        if (output.executionEnvironment == "auto" && canUseGPU) || ...
                output.executionEnvironment == "gpu"
            dlZ = gpuArray(dlZ);
        end
        [gradientsGenerator,gradientsDiscriminator,stateGenerator,scoreGenerator,scoreDiscrimina
            dlfeval(@modelGradients,output.generator,output.discriminator,dlX,dlZ,flipFactor);
        output.generator.State = stateGenerator;
        [output.discriminator,trailingAvgDiscriminator,trailingAvgSqDiscriminator] = ...
            adamupdate(output.discriminator,gradientsDiscriminator, ...
            trailingAvgDiscriminator,trailingAvgSqDiscriminator,iteration, ...
            initialLearnRate,gradientDecayFactor,squaredGradientDecayFactor);
        [output.generator,trailingAvgGenerator,trailingAvgSqGenerator] = ...
            adamupdate(output.generator,gradientsGenerator, ...
            trailingAvgGenerator,trailingAvgSqGenerator,iteration, ...

        scoreDiscriminatorValue = ...
            double(gather(extractdata(scoreDiscriminator)));
        scoreCombinedValue = 1-2*max(abs(scoreDiscriminatorValue-0.5),abs(scoreGeneratorValue-0.5
        recordMetrics(monitor,iteration, ...
            scoreGenerator=scoreGeneratorValue, ...
            scoreDiscriminator=scoreDiscriminatorValue, ...
            scoreCombined=scoreCombinedValue);
        if monitor.Stop || isnan(scoreGeneratorValue) || isnan(scoreDiscriminatorValue)
            return;
```

```
        end
    end
    monitor.Progress = (epoch/numEpochs)*100;
end
```

Training GANs can be a challenging task because the generator and the discriminator networks compete against each other during the training. If one network learns too quickly, then the other network can fail to learn. To help you diagnose issues and monitor how well the generator and discriminator achieve their respective goals, this experiment displays a pair of scores in the training plot. The generator score `scoreGenerator` measures the likelihood that the discriminator can correctly distinguish generated images. The discriminator score `scoreDiscriminator` measures the likelihood that the discriminator can correctly distinguish all input images, assuming that the numbers of real and generated images passed to the discriminator are equal. In the ideal case, both scores are 0.5. Scores that are too close to zero or one can indicate that one network dominates the other. See “Monitor GAN Training Progress and Identify Common Failure Modes” on page 5-182.

To help you decide which trial produces the best results, this experiment combines the generator score and discriminator scores into a single numeric value, `scoreCombined`. This metric uses the *L*-∞ norm to determine how close the two networks are from the ideal scenario. It takes a value of one if both network scores equal 0.5, and zero if one of the network scores equals zero or one.

To inspect the training function, under **Training Function**, click **Edit**. The training function opens in MATLAB® Editor. In addition, the code for the training function appears in Appendix 1 at the end of this example.

Run Experiment

When you run the experiment, Experiment Manager trains the network defined by the training function multiple times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16.

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the training loss and validation accuracy for each trial.

Trial	Status	Progress	Elapsed Time	dropoutProb	flipFactor	scoreGenerator	scoreDiscriminator	scoreCombined
1	Complete	100.0%	0 hr 7 min 0 sec	0.2500	0.1000	0.2703	0.6532	0.5407
2	Complete	100.0%	0 hr 6 min 45 sec	0.5000	0.1000	0.2413	0.6581	0.4827
3	Complete	100.0%	0 hr 6 min 44 sec	0.7500	0.1000	0.3999	0.6095	0.7811
4	Complete	100.0%	0 hr 6 min 46 sec	0.2500	0.3000	0.3076	0.6068	0.6152
5	Complete	100.0%	0 hr 6 min 49 sec	0.5000	0.3000	0.3753	0.5412	0.7505

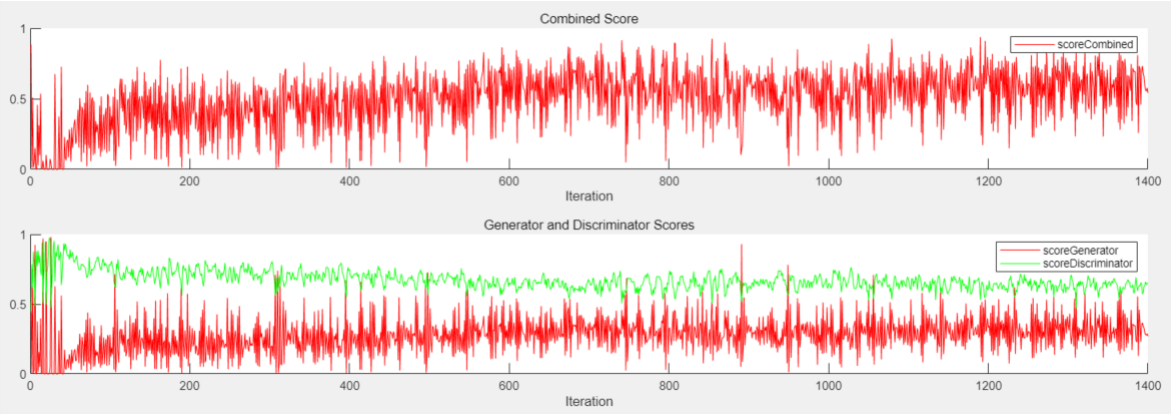
8	Complete	100.0%	0 hr 6 min 53 sec	0.5000	0.5000	0.1647	0.5504	0.3293
9	Complete	100.0%	0 hr 7 min 1 sec	0.7500	0.5000	0.1872	0.5548	0.3744

While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial.



Evaluate Results

To find the best result for your experiment, sort the table of results using the combined score.

1. Point to the **scoreCombined** column.
2. Click the triangle icon.
3. Select **Sort in Descending Order**.

The trial with the highest combined score appears at the top of the results table.

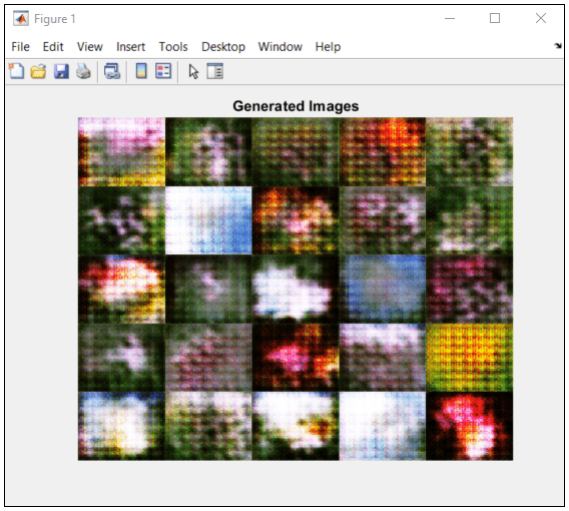
Trial	Status	Progress	Elapsed Time	dropoutProb	flipFactor	scoreGenerator	scoreDiscriminator	scoreCombined
3	Complete	100.0%	0 hr 6 min 44 sec	0.7500	0.1000	0.3999	0.6095	0.7811
5	Complete	100.0%	0 hr 6 min 49 sec	0.5000	0.3000	0.3753	0.5412	0.7505
4	Complete	100.0%	0 hr 6 min 46 sec	0.2500	0.3000	0.3076	0.6068	0.6152
6	Complete	100.0%	0 hr 6 min 50 sec	0.7500	0.3000	0.2782	0.6111	0.5564
1	Complete	100.0%	0 hr 7 min 0 sec	0.2500	0.1000	0.2703	0.6532	0.5407
2	Complete	100.0%	0 hr 6 min 45 sec	0.5000	0.1000	0.2413	0.6581	0.4827
7	Complete	100.0%	0 hr 6 min 53 sec	0.2500	0.5000	0.2335	0.5065	0.4670
9	Complete	100.0%	0 hr 7 min 1 sec	0.7500	0.5000	0.1872	0.5548	0.3744
8	Complete	100.0%	0 hr 6 min 53 sec	0.5000	0.5000	0.1647	0.5504	0.3293

Evaluate the quality of the GAN by generating and inspecting the images produced by the trained generator.

1. Select the trial with the highest combined score.
2. On the **Experiment Manager** toolstrip, click **Export**.
3. In the dialog window, enter the name of a workspace variable for the exported training output. The default name is `trainingOutput`.
4. Test the trained generator network by calling the `generateTestImages` function, which is listed in Appendix 3 at the end of this example. Use the exported training output as the input to the function. For instance, in the MATLAB Command Window, enter:

```
generateTestImages(trainingOutput)
```

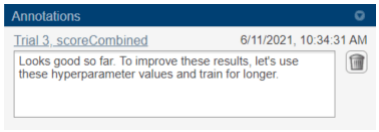
The function creates a batch of 25 random vectors to input to the generator network and displays the resulting images.



Using the combined score to sort your results might not identify the best trial in all cases. For best results, repeat this process for each trial with a high combined score, visually checking that the generator produces a variety of images without many duplicates. If the images have little diversity and some of them are almost identical, then your generator is likely affected by mode collapse. For more information, see “Mode Collapse” on page 5-184.

To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **scoreCombined** cell for the best trial.
2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.

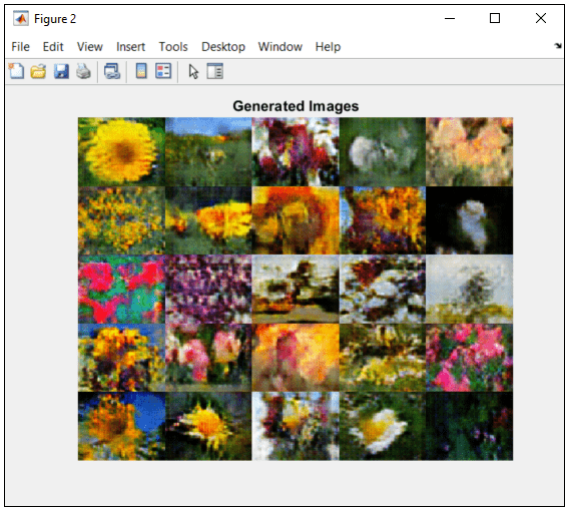


For more information, see “Sort, Filter, and Annotate Experiment Results”.

Rerun Experiment

After you identify the combination of hyperparameters that generates the best images, run the experiment a second time to train the network for a longer period of time.

1. Return to the experiment definition pane.
2. In the hyperparameter table, enter the hyperparameter values from your best trial. For example, to use the values from trial 3, change the value of `dropoutProb` to `0.75` and `flipFactor` to `0.1`.
3. Open the training function and specify a longer training time. Under **Specify Training Options**, change the value of `numEpochs` to `500`.
4. Run the experiment using the new hyperparameter values and training function. Experiment Manager runs a single trial. Training takes about 10 times longer than the previous trials.
5. When the experiment finishes, export the training output and run the `generateTestImages` function to test the new generator network. As before, visually check that the generator produces a variety of images without many duplicates.



Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Training Function

This function specifies the training data, network architecture, training options, and training procedure used by the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.
- `monitor` is an `experiments.Monitor` object that you can use to track the progress of the training, update information fields in the results table, record values of the metrics used by the training, and produce training plots.

Output

- `output` is a structure that contains the trained generator network, the trained discriminator network, and the execution environment used for training. Experiment Manager saves this output, so you can export it to the MATLAB workspace when the training is complete.

```
function output = ImageGenerationExperiment_training1(params,monitor)

output.generator = [];
output.discriminator = [];
output.executionEnvironment = "auto";

monitor.Status = "Loading Data";

url = "http://download.tensorflow.org/example_images/flower_photos.tgz";
downloadFolder = tempdir;
filename = fullfile(downloadFolder,"flower_dataset.tgz");

imageFolder = fullfile(downloadFolder,"flower_photos");
if ~exist(imageFolder,"dir")
```

```
    websave(filename,url);
    untar(filename,downloadFolder)
end

datasetFolder = fullfile(imageFolder);
imdsTrain = imageDatastore(datasetFolder, ...
    IncludeSubfolders=true);

        end
    end
    monitor.Progress = (epoch/numEpochs)*100;
end
end
```

Appendix 2: Custom Training Helper Functions

This function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array.
2. Rescale the images to be in the range [-1,1].

```
function X = preprocessMiniBatch(data)
    X = cat(4,data{:});
    X = rescale(X,-1,1,InputMin=0,InputMax=255);
end
```

This function takes as input the generator and discriminator `dlnetwork` objects (`dlnetGenerator` and `dlnetDiscriminator`), a mini-batch of input data (`dlX`), an array of random values (`dlZ`), and the percentage of real labels to flip (`flipFactor`), and returns the gradients of the loss with respect to the learnable parameters in the networks, the generator state, and the scores of the two networks. Because the discriminator output is not in the range [0,1], `modelGradients` applies the `sigmoid` function to convert this value into a probability.

```
function [gradientsGenerator,gradientsDiscriminator,stateGenerator,scoreGenerator,scoreDiscrimina
    modelGradients(dlnetGenerator,dlnetDiscriminator,dlX,dlZ,flipFactor)
    dlYPred = forward(dlnetDiscriminator,dlX);
    [dlXGenerated,stateGenerator] = forward(dlnetGenerator,dlZ);
    dlYPredGenerated = forward(dlnetDiscriminator,dlXGenerated);
    probGenerated = sigmoid(dlYPredGenerated);
    probReal = sigmoid(dlYPred);
    scoreDiscriminator = ((mean(probReal)+mean(1-probGenerated))/2);
    scoreGenerator = mean(probGenerated);
    numObservations = size(probReal,4);
    idx = randperm(numObservations,floor(flipFactor*numObservations));
    probReal(:,:,:,idx) = 1-probReal(:,:,:,idx);
    [lossGenerator,lossDiscriminator] = GANLoss(probReal,probGenerated);
    gradientsGenerator = dlgradient(lossGenerator, ...
        dlnetGenerator.Learnables,RetainData=true);
```

```
    gradientsDiscriminator = dlgradient(lossDiscriminator, ...
        dlnetDiscriminator.Learnables);
end
```

This function returns the loss for the discriminator and generator networks.

```
function [lossGenerator,lossDiscriminator] = ...
    GANLoss(probReal,probGenerated)
    lossDiscriminator = -mean(log(probReal))-mean(log(1-probGenerated));
    lossGenerator = -mean(log(probGenerated));
end
```

Appendix 3: Generate Test Images

This function creates a batch of 25 random vectors to input to the generator network and displays the resulting images. Use this function to visually check that the generator produces a variety of images without many duplicates. If the images have little diversity and some of them are almost identical, then your generator is likely affected by mode collapse.

```
function generateTestImages(trainingOutput)

dlnetGenerator = trainingOutput.generator;
executionEnvironment = trainingOutput.executionEnvironment;

numLatentInputs = 100;
numTestImages = 25;

ZTest = randn(numLatentInputs,numTestImages,"single");
dlZTest = dlarray(ZTest,"CB");

if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlZTest = gpuArray(dlZTest);
end

dlXGeneratedTest = predict(dlnetGenerator,dlZTest);

I = imtile(extractdata(dlXGeneratedTest));
I = rescale(I);
figure
image(I)
axis off
title("Generated Images")

end
```

Use Bayesian Optimization in Custom Training Experiments

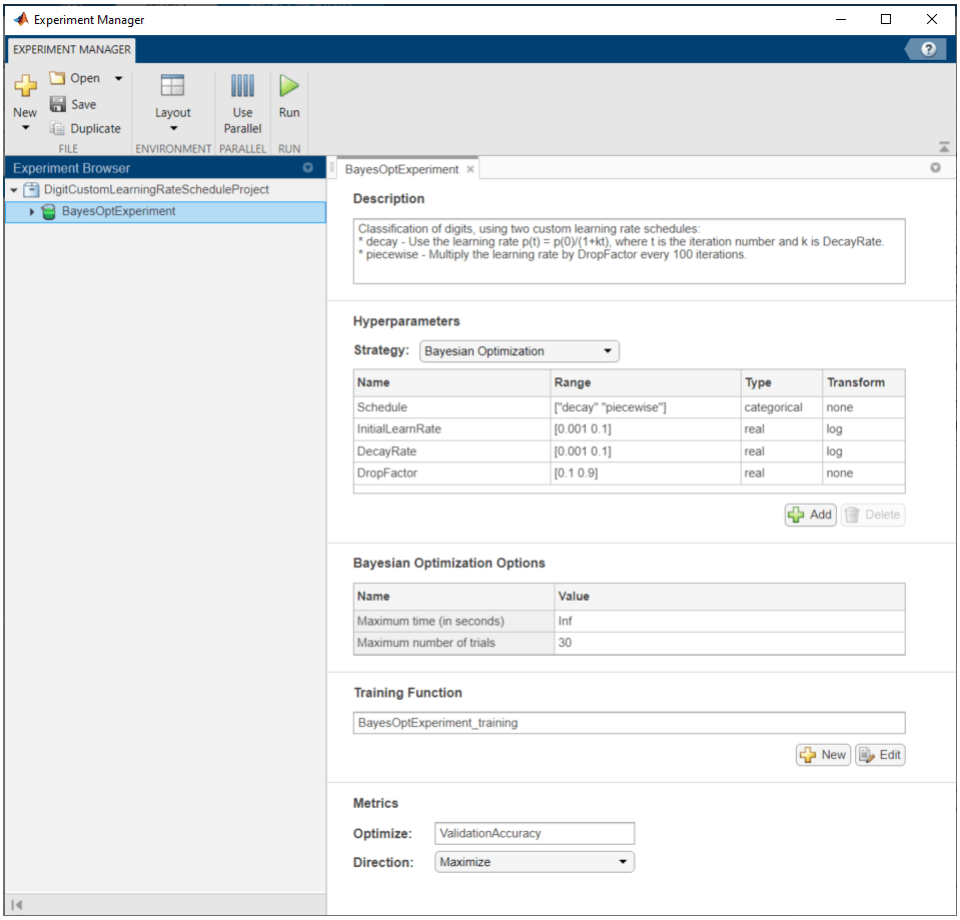
This example shows how to use Bayesian optimization to find optimal hyperparameter values for custom training experiments in **Experiment Manager**. Bayesian optimization provides an alternative strategy to sweeping hyperparameters in an experiment. You specify a range of values for each hyperparameter and select a metric to optimize, and Experiment Manager searches for a combination of hyperparameters that optimizes your selected metric. Bayesian optimization requires Statistics and Machine Learning Toolbox™.

In this example, you train a network to classify images of handwritten digits using a custom learning rate schedule. The experiment uses Bayesian optimization to find the type of schedule and the combination of hyperparameters that maximizes the validation accuracy. For more information on using a custom learning rate schedule, see “Train Network Using Custom Training Loop” on page 18-225 and “Piecewise Learn Rate Schedule” on page 18-217.

Alternatively, you can find optimal hyperparameter values programmatically by calling the `bayesopt` function. For more information, see “Deep Learning Using Bayesian Optimization” on page 5-99.

Open Experiment

First, open the example. Experiment Manager loads a project with a preconfigured experiment that you can inspect and run. To open the experiment, in the **Experiment Browser** pane, double-click the name of the experiment (`BayesOptExperiment`).



Custom training experiments consist of a description, a table of hyperparameters, and a training function. Experiments that use Bayesian optimization include additional options to limit the duration of the experiment. For more information, see “Configure Custom Training Experiment”.

The **Description** field contains a textual description of the experiment. For this example, the description is:

```
Classification of digits, using two custom learning rate schedules:
* decay - Use the learning rate p(t) = p(0)/(1+kt), where t is the iteration number and k is Deca
* piecewise - Multiply the learning rate by DropFactor every 100 iterations.
```

The **Hyperparameters** section specifies the strategy (`Bayesian Optimization`) and hyperparameter options to use for the experiment. For each hyperparameter, specify these options:

- **Range** — Enter a two-element vector that gives the lower bound and upper bound of a real- or integer-valued hyperparameter, or a string array or cell array that lists the possible values of a categorical hyperparameter.
- **Type** — Select `real` (real-valued hyperparameter), `integer` (integer-valued hyperparameter), or `categorical` (categorical hyperparameter).
- **Transform** — Select `none` (no transform) or `log` (logarithmic transform). For `log`, the hyperparameter must be `real` or `integer` and positive. With this option, the hyperparameter is searched and modeled on a logarithmic scale.

When you run the experiment, Experiment Manager searches for the best combination of hyperparameters. Each trial in the experiment uses a new combination of hyperparameter values based on the results of the previous trials. This example uses the hyperparameters `Schedule`, `InitialLearnRate`, `DecayRate`, and `DropFactor` to specify the custom learning rate schedule used for training. The options for `Schedule` are:

- `decay` — For each iteration, use the time-based learning rate $\rho_t = \frac{\rho_0}{1+kt}$, where t is the iteration number, ρ_0 is the initial learning rate specified by `InitialLearnRate`, and k is the decay rate specified by `DecayRate`. This option ignores the value of the hyperparameter `DropFactor`.
- `piecewise` — Start with the initial learning rate specified by `InitialLearnRate` and periodically drop the learning rate by multiplying by the drop factor specified by `DropFactor`. In this example, the learning rate drops every 100 iterations. This option ignores the value of the hyperparameter `DecayRate`.

The experiment models `InitialLearnRate` and `DecayRate` on a logarithmic scale because the range of values for these hyperparameters (`0.001` to `0.1`) spans several orders of magnitude. In contrast, the values for `DropFactor` range from `0.1` to `0.9`, so the experiment models `DropFactor` on a linear scale.

Under **Bayesian Optimization Options**, you can specify the duration of the experiment by entering the maximum time (in seconds) and the maximum number of trials to run. To best use the power of Bayesian optimization, perform at least 30 objective function evaluations.

The **Training Function** specifies the training data, network architecture, training options, and training procedure used by the experiment. The input to the training function is a structure with fields from the hyperparameter table and an `experiments.Monitor` object that you can use to track the progress of the training, record values of the metrics used by the training, and produce training plots. The training function returns a structure that contains the trained network, the training loss, the validation accuracy, and the execution environment used for training. Experiment Manager saves

this output, so you can export it to the MATLAB workspace when the training is complete. The training function has five sections.

- **Initialize Output** sets the initial value of the network, loss, and accuracy to empty arrays to indicate that the training has not started. The experiment sets the execution environment to `"auto"`, so it trains the network on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For more information, see "GPU Support by Release" (Parallel Computing Toolbox).

```
output.trainedNet = [];
output.trainingInfo.loss = [];
output.trainingInfo.accuracy = [];
output.executionEnvironment = "auto";
```

- **Load Training Data** defines the training and validation data for the experiment as augmented image datastores using the Digits data set. For each image in the training set, the experiment applies a random translation of up to 5 pixels on the horizontal and vertical axes. For more information on this data set, see "Image Data Sets" on page 19-118.

```
dataFolder = fullfile(toolboxdir("nnet"), ...
    "nndemos","nndatasets","DigitDataset");
imds = imageDatastore(dataFolder, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9,'randomize');
inputSize = [28 28 1];
pixelRange = [-5 5];
imageAugmenter = imageDataAugmenter( ...
    RandXTranslation = pixelRange, ...
    RandYTranslation = pixelRange);
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain, ...
    DataAugmentation = imageAugmenter);
augimdsValidation = augmentedImageDatastore(inputSize(1:2),imdsValidation);
classes = categories(imdsTrain.Labels);
numClasses = numel(classes);
```

- **Define Network Architecture** defines the architecture for the image classification network. To train the network with a custom training loop and enable automatic differentiation, the training function converts the layer graph to a `dlnetwork` object.

```
layers = [
    imageInputLayer(inputSize,Normalization="none",Name="input")
    convolution2dLayer(5,20,Name ="conv1")
    batchNormalizationLayer(Name="bn1")
    reluLayer(Name="relu1")
    convolution2dLayer(3,20,Padding="same",Name="conv2")
    batchNormalizationLayer(Name="bn2")
    reluLayer(Name="relu2")
    convolution2dLayer(3,20,Padding="same",Name="conv3")
    batchNormalizationLayer(Name="bn3")
    reluLayer(Name="relu3")
    fullyConnectedLayer(numClasses,Name="fc")
    softmaxLayer(Name="softmax")];
lgraph = layerGraph(layers);
dlnet = dlnetwork(lgraph);
```

- **Specify Training Options** defines the training options used by the experiment. In this example, Experiment Manager trains the networks with a mini-batch size of 128 for 10 epochs using the custom learning rate schedule defined by the hyperparameters.

```
numEpochs = 10;
miniBatchSize = 128;
momentum = 0.9;

learnRateSchedule = params.Schedule;
initialLearnRate = params.InitialLearnRate;
learnRateDecay = params.DecayRate;
learnRateDropFactor = params.DropFactor;
learnRateDropPeriod = 100;
learnRate = initialLearnRate;
```

- **Train Model** defines the custom training loop used by the experiment. The custom training loop uses `minibatchqueue` to process and manage the mini-batches of images. For each mini-batch, the `minibatchqueue` object converts the labels to one-hot encoded variables and formats the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. If you train on a GPU, the data is converted to `gpuArray` (Parallel Computing Toolbox) objects. For each epoch, the custom training loop shuffles the datastore, loops over mini-batches of data, and evaluates the model gradients, state, and loss. Then, the training function determines the learning rate for the selected schedule and updates the network parameters. After each iteration of the custom training loop, the training function computes the validation accuracy, saves the trained network, and updates the training progress.

```
monitor.Metrics = ["LearnRate" "TrainingLoss" "ValidationAccuracy"];
monitor.XLabel = "Iteration";

mbq = minibatchqueue(augimdsTrain,...
    MiniBatchSize=miniBatchSize,...
    MiniBatchFcn=@preprocessMiniBatch,...
    MiniBatchFormat={'SSCB',''},...
    OutputEnvironment=output.executionEnvironment);

iteration = 0;
velocity = [];
for epoch = 1:numEpochs
    shuffle(mbq);
    while hasdata(mbq)
        iteration = iteration + 1;
        [dlX, dlY] = next(mbq);
        [gradients,state,loss] = dlfeval(@modelGradients,dlnet,dlX,dlY);
        dlnet.State = state;
        switch learnRateSchedule
            case "decay"
                learnRate = initialLearnRate/(1 + learnRateDecay*iteration);
            case "piecewise"
                if mod(iteration,learnRateDropPeriod) == 0
                    learnRate = learnRate*learnRateDropFactor;
                end
        end
        recordMetrics(monitor,iteration, ...
            LearnRate=learnRate, ...
            TrainingLoss=loss);
        output.trainingInfo.loss = [output.trainingInfo.loss; iteration loss];
```

```
        [dlnet,velocity] = sgdmupdate(dlnet,gradients,velocity,learnRate,momentum);
        if monitor.Stop
            return;
        end
    end
    numOutputs = 1;
    mbqTest = minibatchqueue(augimdsValidation,numOutputs, ...
        MiniBatchSize=miniBatchSize, ...
        MiniBatchFcn=@preprocessMiniBatchPredictors, ...
        MiniBatchFormat="SSCB");
    predictions = modelPredictions(dlnet,mbqTest,classes);
    YTest = imdsValidation.Labels;
    accuracy = mean(predictions == YTest)*100.0;
    output.trainedNet = dlnet;
    monitor.Progress = (epoch*100.0)/numEpochs;
    recordMetrics(monitor,iteration, ...
        ValidationAccuracy=accuracy);
    output.trainingInfo.accuracy = [output.trainingInfo.accuracy; iteration accuracy];
end
```

To inspect the training function, under **Training Function**, click **Edit**. The training function opens in MATLAB® Editor. In addition, the code for the training function appears in Appendix 1 at the end of this example.

In the **Metrics** section, the **Optimize** and **Direction** fields indicate the metric that the Bayesian optimization algorithm uses as an objective function. For this experiment, Experiment Manager seeks to maximize the value of the validation accuracy.

Run Experiment

When you run the experiment, Experiment Manager trains the network defined by the training function multiple times. Each trial uses a different combination of hyperparameter values. By default, Experiment Manager runs one trial at a time. If you have Parallel Computing Toolbox, you can run multiple trials at the same time. For best results, before you run your experiment, start a parallel pool with as many workers as GPUs. For more information, see “Use Experiment Manager to Train Networks in Parallel” on page 6-16.

- To run one trial of the experiment at a time, on the Experiment Manager toolstrip, click **Run**.
- To run multiple trials at the same time, click **Use Parallel** and then **Run**. If there is no current parallel pool, Experiment Manager starts one using the default cluster profile. Experiment Manager then executes multiple simultaneous trials, depending on the number of parallel workers available.

A table of results displays the training loss and validation accuracy for each trial. Experiment Manager indicates the trial with the optimal value for the selected metric. For example, in this experiment, the third trial produces the greatest validation accuracy.

Trial	Status	Progress	Elapsed Time	Schedule	InitialLearnRate	DecayRate	DropFactor	LearnRate	TrainingLoss	ValidationAccuracy

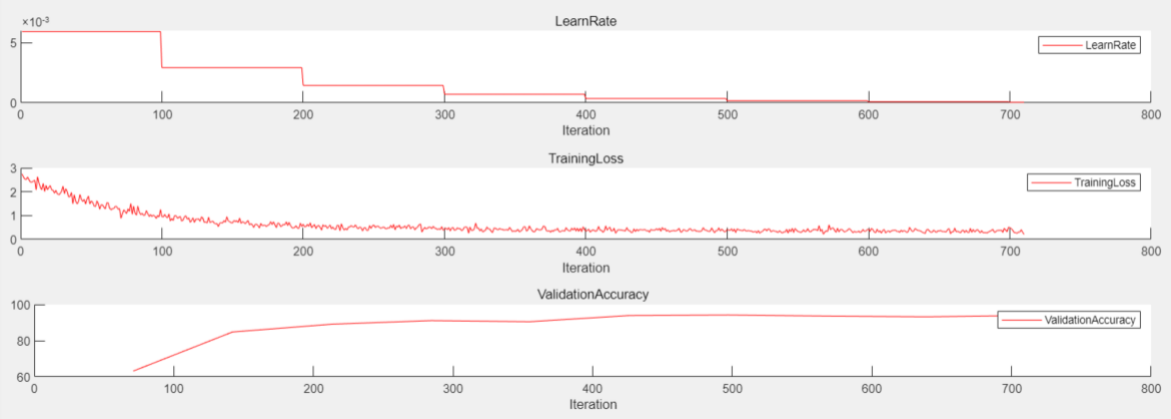
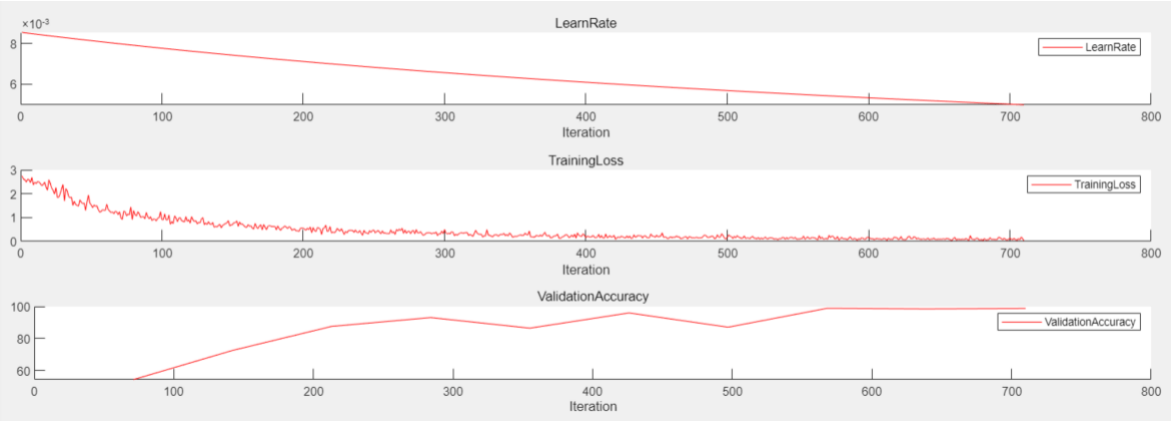
While the experiment is running, click **Training Plot** to display the training plot and track the progress of each trial. The training plot shows the learning rate, training loss, and validation accuracy for each trial. For example, this training plot is for a trial that uses a piecewise learning rate schedule.



In contrast, this training plot is for a trial that uses a time-based decay learning rate schedule.



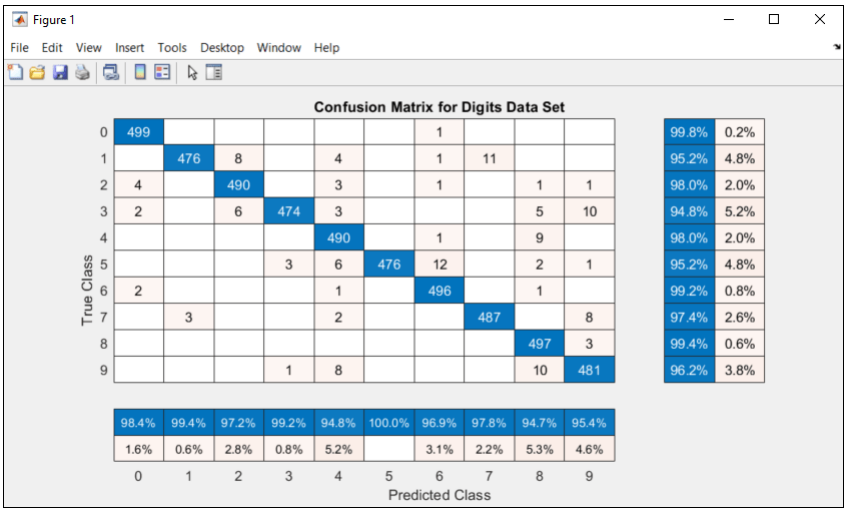
Evaluate Results

To test the best trial in your experiment, plot a confusion matrix.

1. In the results table, select the trial with the highest validation accuracy.
2. On the **Experiment Manager** toolstrip, click **Export**.
3. In the dialog window, enter the name of a workspace variable for the exported training output. The default name is `trainingOutput`.
4. Create a confusion matrix by calling the `drawConfusionMatrix` function, which is listed in Appendix 3 at the end of this example. As the input to the function, use the exported training output and the fraction of the Digits data set to use as a test set. For instance, in the MATLAB Command Window, enter:

```
drawConfusionMatrix(trainingOutput,0.5)
```

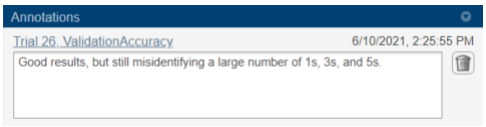
The function creates a confusion matrix using half of the images in the data set rotated by a small, random angle.



To record observations about the results of your experiment, add an annotation.

1. In the results table, right-click the **ValidationAccuracy** cell for the best trial.

2. Select **Add Annotation**.
3. In the **Annotations** pane, enter your observations in the text box.



For more information, see “Sort, Filter, and Annotate Experiment Results”.

Close Experiment

In the **Experiment Browser** pane, right-click the name of the project and select **Close Project**. Experiment Manager closes all of the experiments and results contained in the project.

Appendix 1: Training Function

This function specifies the training data, network architecture, training options, and training procedure used by the experiment.

Input

- `params` is a structure with fields from the Experiment Manager hyperparameter table.
- `monitor` is an `experiments.Monitor` object that you can use to track the progress of the training, update information fields in the results table, record values of the metrics used by the training, and produce training plots.

Output

- `output` is a structure that contains the trained network, the values of the training loss and validation accuracy, and the execution environment used for training. Experiment Manager saves this output, so you can export it to the MATLAB workspace when the training is complete.

```
function output = BayesOptExperiment_training(params,monitor)

output.trainedNet = [];
output.trainingInfo.loss = [];
output.trainingInfo.accuracy = [];
output.executionEnvironment = "auto";

dataFolder = fullfile(toolboxdir("nnet"), ...
    "nndemos","nndatasets","DigitDataset");
imds = imageDatastore(dataFolder, ...
    IncludeSubfolders=true, ...
    LabelSource="foldernames");
[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9,'randomize');
inputSize = [28 28 1];
pixelRange = [-5 5];
imageAugmenter = imageDataAugmenter( ...
    RandXTranslation = pixelRange, ...
    RandYTranslation = pixelRange);
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain, ...
    DataAugmentation = imageAugmenter);
augimdsValidation = augmentedImageDatastore(inputSize(1:2),imdsValidation);
classes = categories(imdsTrain.Labels);
```

```
numClasses = numel(classes);

layers = [
    imageInputLayer(inputSize,Normalization="none",Name="input")
    convolution2dLayer(5,20,Name ="conv1")
    batchNormalizationLayer(Name="bn1")
    reluLayer(Name="relu1")
    convolution2dLayer(3,20,Padding="same",Name="conv2")
    batchNormalizationLayer(Name="bn2")
    reluLayer(Name="relu2")
    convolution2dLayer(3,20,Padding="same",Name="conv3")
    batchNormalizationLayer(Name="bn3")
    reluLayer(Name="relu3")
    fullyConnectedLayer(numClasses,Name="fc")
    softmaxLayer(Name="softmax")];
lgraph = layerGraph(layers);
dlnet = dlnetwork(lgraph);

numEpochs = 10;
miniBatchSize = 128;
momentum = 0.9;

learnRateSchedule = params.Schedule;
initialLearnRate = params.InitialLearnRate;
learnRateDecay = params.DecayRate;
learnRateDropFactor = params.DropFactor;
learnRateDropPeriod = 100;
learnRate = initialLearnRate;

monitor.Metrics = ["LearnRate" "TrainingLoss" "ValidationAccuracy"];
monitor.XLabel = "Iteration";

mbq = minibatchqueue(augimdsTrain,...
    MiniBatchSize=miniBatchSize,...
    MiniBatchFcn=@preprocessMiniBatch,...
    MiniBatchFormat={'SSCB',''},...
    OutputEnvironment=output.executionEnvironment);

iteration = 0;
velocity = [];
for epoch = 1:numEpochs
    shuffle(mbq);

    while hasdata(mbq)
        iteration = iteration + 1;

        [dlX, dlY] = next(mbq);

        [gradients,state,loss] = dlfeval(@modelGradients,dlnet,dlX,dlY);
        dlnet.State = state;

        switch learnRateSchedule
            case "decay"
                learnRate = initialLearnRate/(1 + learnRateDecay*iteration);
            case "piecewise"
                if mod(iteration,learnRateDropPeriod) == 0
                    learnRate = learnRate*learnRateDropFactor;
                end
```

```
        end

        recordMetrics(monitor,iteration, ...
            LearnRate=learnRate, ...
            TrainingLoss=loss);
        output.trainingInfo.loss = [output.trainingInfo.loss; iteration loss];

        [dlnet,velocity] = sgdmupdate(dlnet,gradients,velocity,learnRate,momentum);

        if monitor.Stop
            return;
        end
    end

    numOutputs = 1;
    mbqTest = minibatchqueue(augimdsValidation,numOutputs, ...
        MiniBatchSize=miniBatchSize, ...
        MiniBatchFcn=@preprocessMiniBatchPredictors, ...
        MiniBatchFormat="SSCB");
    predictions = modelPredictions(dlnet,mbqTest,classes);
    YTest = imdsValidation.Labels;
    accuracy = mean(predictions == YTest)*100.0;

    output.trainedNet = dlnet;
    monitor.Progress = (epoch*100.0)/numEpochs;
    recordMetrics(monitor,iteration, ...
        ValidationAccuracy=accuracy);
    output.trainingInfo.accuracy = [output.trainingInfo.accuracy; iteration accuracy];
end
end
```

Appendix 2: Custom Training Helper Functions

The `modelGradients` function takes as input a `dlnetwork` object `dlnet` and a mini-batch of input data `dlX` with corresponding labels `Y`, and returns the gradients of the loss with respect to the learnable parameters in `dlnet`, the network state, and the loss. To compute the gradients automatically, use the `dlgradient` function.

```
function [gradients,state,loss] = modelGradients(dlnet,dlX,Y)
[dlYPred,state] = forward(dlnet,dlX);
loss = crossentropy(dlYPred,Y);
gradients = dlgradient(loss,dlnet.Learnables);
loss = double(gather(extractdata(loss)));
end
```

The `modelPredictions` function takes as input a `dlnetwork` object `dlnet`, a `minibatchqueue` of input data `mbq`, and the network classes, and computes the model predictions by iterating over all data in the `minibatchqueue` object. The function uses the `onehotdecode` function to find the predicted class with the highest score.

```
function predictions = modelPredictions(dlnet,mbq,classes)
predictions = [];
while hasdata(mbq)
    dlXTest = next(mbq);
    dlYPred = predict(dlnet,dlXTest);
    YPred = onehotdecode(dlYPred,classes,1)';
    predictions = [predictions; YPred];
```

```
end
end
```

The `preprocessMiniBatch` function preprocesses a mini-batch of predictors and labels using these steps:

1. Preprocess the images using the `preprocessMiniBatchPredictors` function.
2. Extract the label data from the incoming cell array and concatenate the data into a categorical array along the second dimension.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y] = preprocessMiniBatch(XCell,YCell)
X = preprocessMiniBatchPredictors(XCell);
Y = cat(2,YCell{1:end});
Y = onehotencode(Y,1);
end
```

The `preprocessMiniBatchPredictors` function preprocesses a mini-batch of predictors by extracting the image data from the input cell array and concatenating the data into a numeric array. For grayscale input, concatenating over the fourth dimension adds a third dimension to each image, for use as a singleton channel dimension.

```
function X = preprocessMiniBatchPredictors(XCell)
X = cat(4,XCell{1:end});
end
```

Appendix 3: Create Confusion Matrix

This function takes as input a trained network and the fraction of the Digits data set to use as a test set and creates a confusion matrix chart. This function uses the helper functions `modelPredictions` and `preprocessMiniBatchPredictors`, which are listed in Appendix 2.

```
function drawConfusionMatrix(trainingOutput,testSize)

dataFolder = fullfile(toolboxdir("nnet"), ...
    "nndemos","nndatasets","DigitDataset");
imds = imageDatastore(dataFolder, ...
    IncludeSubfolders=true, ....
    LabelSource="foldernames");
imdsTest = splitEachLabel(imds,testSize,"randomize");
inputSize = [28 28 1];
imageAugmenter = imageDataAugmenter(RandRotation=[-15 15]);
augimdsTest = augmentedImageDatastore(inputSize(1:2),imdsTest, ...
    DataAugmentation=imageAugmenter);
classes = categories(imdsTest.Labels);

trainedNet = trainingOutput.trainedNet;
numOutputs = 1;
miniBatchSize = 128;
mbqTest = minibatchqueue(augimdsTest,numOutputs, ...
    MiniBatchSize=miniBatchSize, ...
    MiniBatchFcn=@preprocessMiniBatchPredictors, ...
    MiniBatchFormat="SSCB");
predictedLabels = modelPredictions(trainedNet,mbqTest,classes);
trueLabels = imdsTest.Labels;
```

```
figure
confusionchart(trueLabels,predictedLabels, ...
    ColumnSummary="column-normalized", ...
    RowSummary="row-normalized", ...
    Title="Confusion Matrix for Digits Data Set");
cm = gcf;
cm.Position(3) = cm.Position(3)*1.5;

end
```

Keyboard Shortcuts for Experiment Manager

Use these keyboard shortcuts when working with Experiment Manager.

Shortcuts for General Navigation

Action	Shortcut
Show the access keys for the toolstrip	**Alt+E** Not supported on macOS systems.
Move forward through the different areas of the Experiment Manager app, including the toolstrip, Experiment Browser, and experiment or results panes.	**Ctrl+F6** On macOS systems, use **Command+F6** instead.
Move backward through the different areas of the Experiment Manager app, including the toolstrip, Experiment Browser, and experiment or results panes.	**Ctrl+Shift+F6** On macOS systems, use **Command+Shift+F6** instead.
Move forward through the different elements in the start page, toolstrip, experiment pane, or results pane	**Tab**
Move backward through the different elements in the start page, toolstrip, experiment pane, or results pane	**Shift+Tab**
Select the current option in the start page or a menu	**Enter**
Cancel the current action, for example, hide the access keys for the toolstrip or close a menu	**Esc**

Shortcuts for Experiment Browser

Use **Ctrl+F6** or **Ctrl+Shift+F6** to navigate to the Experiment Browser. Then press **Tab** to bring into focus the project, experiment, or result that is currently selected.

Action	Shortcut
Show the experiments in the project or the results for an experiment	**Right** arrow If the contents of the project or experiment are already visible, pressing the **Right** arrow selects the first experiment in the project or the first result for the experiment.
Hide the experiments in the project or the results for an experiment	**Left** arrow If the contents of an experiment are already hidden, pressing the **Left** arrow selects the project that contains the experiment.
Move to the next item in the browser	**Down** arrow

Action	Shortcut
Move to the previous item in the browser	**Up** arrow
Open an experiment or result	**Shift+F10** and select **Open** Not supported on macOS systems.
Rename an experiment or result	**F2** On macOS systems, use **Fn+F2** instead.

Shortcuts for Results Table

Use **Ctrl+F6** or **Ctrl+Shift+F6** to navigate to the results pane. Then press **Tab** to navigate down to the results table.

Action	Shortcut
Move to the next trial in the table	**Down** arrow
Move to the previous trial in the table	**Up** arrow
Move to the next column in the table	**Right** arrow
Move to the previous column in the table	**Left** arrow

Deep Learning in Parallel and the Cloud

Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud

In this section...

Training deep networks is computationally intensive and can take many hours of computing time; however, neural networks are inherently parallel algorithms. You can take advantage of this parallelism by running in parallel using high-performance GPUs and computer clusters.

It is recommended to train using a GPU or multiple GPUs. Only use single CPU or multiple CPUs if you do not have a GPU. CPUs are normally much slower that GPUs for both training and inference. Running on a single GPU typically offers much better performance than running on multiple CPU cores.

If you do not have a suitable GPU, you can rent high-performance GPUs and clusters in the cloud. For more information on hot to access MATLAB in the cloud for deep learning, see “Deep Learning in the Cloud” on page 7-10.

Using a GPU or parallel options requires Parallel Computing Toolbox. Using a GPU also requires a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Using a remote cluster also requires MATLAB Parallel Server.

Tip For `trainNetwork` workflows, GPU support is automatic. By default, the `trainNetwork` function uses a GPU if one is available. If you have access to a machine with multiple GPUs, specify the `ExecutionEnvironment` training option as `"multi-gpu"`.

To run custom training workflows, including `dlnetwork` workflows, on the GPU, use `minibatchqueue` to automatically convert data to `gpuArray` objects.

You can use parallel resources to scale up deep learning for a single network. You can also train multiple networks simultaneously. The following sections show the available options for deep learning in parallel in MATLAB:

- “Train Single Network in Parallel” on page 7-3
  - “Use Local Resources to Train Single Network in Parallel” on page 7-3
  - “Use Remote Cluster Resources to Train Single Network in Parallel” on page 7-4
  - “Use Deep Network Designer and Experiment Manager to Train Single Network in Parallel” on page 7-5
- “Train Multiple Networks in Parallel” on page 7-6
  - “Use Local or Remote Cluster Resources to Train Multiple Network in Parallel” on page 7-6
  - “Use Experiment Manager to Train Multiple Networks in Parallel” on page 7-7

- “Batch Deep Learning” on page 7-7

Note If you run MATLAB on a single remote machine for example, a cloud machine that you connect to via ssh or remote desktop protocol, then follow the steps for local resources. For more information on connecting to cloud resources, see “Deep Learning in the Cloud” on page 7-10.

Train Single Network in Parallel

Use Local Resources to Train Single Network in Parallel

The following table shows you the available options for training and inference with single network on your local workstation.

Resource	`trainNetwork` Workflows	Custom Training Workflows	Required Products
Single CPU	Automatic if no GPU is available. Training using a single CPU is not recommended.	Training using a single CPU is not recommended.	• MATLAB • Deep Learning Toolbox
Multiple CPU cores	Training using multiple CPU cores is not recommended if you have access to a GPU.	Training using multiple CPU cores is not recommended if you have access to a GPU.	• MATLAB • Deep Learning Toolbox • Parallel Computing Toolbox
Single GPU	Automatic. By default, training and inference run on the GPU if one is available. Alternatively, specify the `ExecutionEnvironment` training option as `"gpu"`	Use `minibatchqueue` to automatically convert data to `gpuArray` objects. For more information, see “Run Custom Training Loops on a GPU and in Parallel” on page 7-20 For an example, see “Train Network Using Custom Training Loop” on page 18-225.	

Resource	`trainNetwork` Workflows	Custom Training Workflows	Required Products
Multiple GPUs	Specify the `ExecutionEnvironment` training option as `"multi-gpu"`. For an example, see "Train Network Using Automatic Multi-GPU Support" on page 7-42.	Start a local parallel pool with as many workers as available GPUs. For more information, see "Deep Learning with MATLAB on Multiple GPUs" on page 7-13 Use `parpool` to execute training or inference with portion of a mini-batch on each worker. Convert each partial mini-batch of data to `gpuArray` objects. For training, aggregate gradients, loss and state parameters after each iteration. For more information, see "Run Custom Training Loops on a GPU and in Parallel" on page 7-20. For an example, see "Train Network in Parallel with Custom Training Loop" on page 7-55. Set the `executionEnvironment` variable to `"auto"` or `"gpu"`.	

Use Remote Cluster Resources to Train Single Network in Parallel

The following table shows you the available options for training and inference with single network on a remote cluster.

Resource	`trainNetwork` Workflows	Custom Training Workflows	Required Products
Multiple CPUs	Training using multiple CPU cores is not recommended if you have access to a GPU.	Training using multiple CPU cores is not recommended if you have access to a GPU.	• MATLAB • Deep Learning Toolbox • Parallel Computing Toolbox • MATLAB Parallel Server

Resource	`trainNetwork` Workflows	Custom Training Workflows	Required Products
Multiple GPUs	Specify the desired cluster as your default cluster profile. For more information, see "Manage Cluster Profiles and Automatic Pool Creation" on page 7-8 Specify the `ExecutionEnvironment` training option as `"parallel"`. For an example, see "Train Network in the Cloud Using Automatic Parallel Support" on page 7-28.	Start a parallel pool in the desired cluster with as many workers as available GPUs. For more information, see "Deep Learning with MATLAB on Multiple GPUs" on page 7-13 Use `parpool` to execute training or inference with a portion of a mini-batch on each worker. Convert each partial mini-batch of data to `gpuArray` objects. For training, aggregate gradients, loss and state parameters after each iteration. For more information, see "Run Custom Training Loops on a GPU and in Parallel" on page 7-20 For an example, see "Train Network in Parallel with Custom Training Loop" on page 7-55. Set the `executionEnvironment` variable to `"auto"` or `"gpu"`.	

Use Deep Network Designer and Experiment Manager to Train Single Network in Parallel

You can train a single network in parallel using Deep Network Designer. You can train using local resources or a remote cluster.

- To train locally using multiple GPUs, set the `ExectionEnvironment` option to `multi-gpu` in the Training Options dialog.
- To train using a remote cluster, set the `ExectionEnvironment` option to `parallel` in the Training Options dialog. If there is no current parallel pool, the software starts one using the default cluster profile. If the pool has access to GPUs, then only workers with a unique GPU perform training computation. If the pool does not have GPUs, then training takes place on all available CPU workers instead.

You can use Experiment Manager to run a single trial using multiple parallel workers. For more information, see "Use Experiment Manager to Train Networks in Parallel" on page 6-16.

Train Multiple Networks in Parallel

Use Local or Remote Cluster Resources to Train Multiple Network in Parallel

To train multiple networks in parallel, train each network on a different parallel worker. You can modify the network or training parameters on each worker to perform parameter sweeps in parallel.

Use `parfor` or `parfeval` to train a single network on each worker. To run in the background without blocking your local MATLAB, use `parfeval`. You can plot results using the `OutputFcn` training option.

You can run locally or using a remote cluster. Using a remote cluster requires MATLAB Parallel Server.

Resource	`trainNetwork` Workflows	Custom Training Workflows	Required Products
Multiple CPUs	Specify the desired cluster as your default cluster profile. For more information, see “Manage Cluster Profiles and Automatic Pool Creation” on page 7-8 Use `parfor` or `parfeval` to simultaneously execute training or inference on each worker. Specify the `ExecutionEnvironment` training option as `"cpu"` for each network. For examples, see • “Use parfor to Train Multiple Deep Learning Networks” on page 7-46 • “Use parfeval to Train Multiple Deep Learning Networks” on page 7-32	Specify the desired cluster as your default cluster profile. For more information, see “Manage Cluster Profiles and Automatic Pool Creation” on page 7-8 Use `parfor` or `parfeval` to simultaneously execute training or inference on each worker. For more information, see “Run Custom Training Loops on a GPU and in Parallel” on page 7-20	• MATLAB • Deep Learning Toolbox • Parallel Computing Toolbox • (optional) MATLAB Parallel Server

Resource	`trainNetwork` Workflows	Custom Training Workflows	Required Products
Multiple GPUs	Start a parallel pool in the desired cluster with as many workers as available GPUs. For more information, see "Deep Learning with MATLAB on Multiple GPUs" on page 7-13 Use `parfor` or `parfeval` to simultaneously execute a network on each worker. Specify the `ExecutionEnvironment` training option as `"gpu"` for each network. For examples, see • "Use parfor to Train Multiple Deep Learning Networks" on page 7-46 • "Use parfeval to Train Multiple Deep Learning Networks" on page 7-32	Start a parallel pool in the desired cluster with as many workers as available GPUs. For more information, see "Deep Learning with MATLAB on Multiple GPUs" on page 7-13 Use `parfor` or `parfeval` to simultaneously execute training or inference on each worker. For more information, see "Run Custom Training Loops on a GPU and in Parallel" on page 7-20 Convert each mini-batch of data to `gpuArray`. Use `minibatchqueue` and set `OutputEnvironment` property to `'gpu'` to automatically convert data to `gpuArray` objects.	

Use Experiment Manager to Train Multiple Networks in Parallel

You can use Experiment Manager to run trials on multiple parallel workers simultaneously. Set up your parallel environment and enable the **Use Parallel** option before running your experiment. Experiment Manager runs as many simultaneous trials as there are workers in your parallel pool. For more information, see "Use Experiment Manager to Train Networks in Parallel" on page 6-16.

Batch Deep Learning

You can offload deep learning computations to run in the background using the `batch` function. This means that you can continue using MATLAB while your computation runs in the background, or you can close your client MATLAB and fetch results later.

You can run batch jobs in a local or remote cluster. To offload your deep learning computations, use `batch` to submit a script or function that runs in the cluster. You can perform any kind of deep learning computation as a batch job, including parallel computations. For an example, see "Send Deep Learning Batch Job to Cluster" on page 7-39

To run in parallel, use a script or function that contains the same code that you would use to run in parallel locally or in a cluster. For example, your script or function can run `trainNetwork` using the

`"ExecutionEnvironment","parallel"` option, or run a custom training loop in parallel. Use `batch` to submit the script or function to the cluster and use the `Pool` option to specify the number of workers you want to use. For more information on running parallel computations with `batch`, see "Run Batch Parallel Jobs" (Parallel Computing Toolbox).

To run deep learning computation on multiple networks, it is recommended to submit a single batch job for each network. Doing so avoids the overhead required to start a parallel pool in the cluster and allows you to use the job monitor to observe the progress of each network computation individually.

You can submit multiple batch jobs. If the submitted jobs require more workers than are currently available in the cluster, then later jobs are queued until earlier jobs have finished. Queued jobs start when enough workers are available to run the job.

The default search paths of the workers might not be the same as that of your client MATLAB. To ensure that workers in the cluster have access to the needed files, such as code files, data files, or model files, specify paths to add to workers using the `AdditionalPaths` option.

To retrieve results after the job is finished, use the `fetchOutputs` function. `fetchOutputs` retrieves all variables in the batch worker workspace. When you submit batch jobs as a script, by default, workspace variables are copied from the client to workers. To avoid recursion of workspace variables, submit batch jobs as functions instead of as scripts.

You can use the `diary` to capture command line output while running batch jobs. This can be useful when executing the `trainNetwork` function with the `Verbose` option set to `true`.

Manage Cluster Profiles and Automatic Pool Creation

Parallel Computing Toolbox comes pre-configured with the cluster profile `local` for running parallel code on your local desktop machine. By default, MATLAB starts all parallel pools using the `local` cluster profile. If you want to run code on a remote cluster, you must start a parallel pool using the remote cluster profile. You can manage cluster profiles using the Cluster Profile Manager. For more information about managing cluster profiles, see "Discover Clusters and Use Cluster Profiles" (Parallel Computing Toolbox).

Some functions, including `trainNetwork`, `predict`, `classify`, `parfor`, and `parfeval` can automatically start a parallel pool. To take advantage of automatic parallel pool creation, set your desired cluster as the default cluster profile in the Cluster Profile Manager. Alternatively, you can create the pool manually and specify the desired cluster resource when you create the pool.

If you want to use multiple GPUs in a remote cluster to train multiple networks in parallel or for custom training loops, best practice is to manually start a parallel pool in the desired cluster with as many workers as available GPUs. For more information, see "Deep Learning with MATLAB on Multiple GPUs" on page 7-13.

Deep Learning Precision

For best performance, it is recommended to use a GPU for all deep learning workflows. Because single-precision and double-precision performance of GPUs can differ substantially, it is important to know in which precision computations are performed. Typically, GPUs offer much better performance for calculations in single precision.

If you only use a GPU for deep learning, then single-precision performance is one of the most important characteristics of a GPU. If you also use a GPU for other computations using Parallel

Computing Toolbox, then high double-precision performance is important. This is because many functions in MATLAB use double-precision arithmetic by default. For more information, see “Improve Performance Using Single Precision Calculations” (Parallel Computing Toolbox)

When you train a network using the `trainNetwork` function, or when you use prediction or validation functions with `DAGNetwork` and `SeriesNetwork` objects, the software performs these computations using single-precision, floating-point arithmetic. Functions for training, prediction, and validation include `trainNetwork`, `predict`, `classify`, and `activations`. The software uses single-precision arithmetic when you train networks using both CPUs and GPUs.

For custom training workflows, it is recommended to convert data to single precision for training and inference. If you use `minibatchqueue` to manage mini-batches, your data is converted to single precision by default.

Deep Learning in the Cloud

If you do not have a suitable GPU available for training your deep neural networks, you can speed up your deep learning applications with one or more high-performance GPUs in the cloud. Working in the cloud requires some initial setup, but using cloud resources can significantly reduce training time or allow you to train more networks in the same amount of time.

You can accelerate training using one or more GPUs on a single machine or using a cluster of machines with GPUs. Train a single network using multiple GPUs, or train multiple models at once.

After you set up MATLAB or MATLAB Parallel Server in your chosen cloud platform, you can perform deep learning with minimal changes to the code you run on your local machine. For more information about adapting your deep learning code for different parallel environments, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2.

Note If you run MATLAB on a single machine in the cloud and you connect via ssh or remote desktop protocol (RDP), then network execution and training uses the same code as if you were running on your local machine.

Using a GPU or parallel options requires Parallel Computing Toolbox. Using a GPU also requires a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Using a remote cluster also requires MATLAB Parallel Server.

Access MATLAB in the Cloud

MathWorks® provides several ways of accessing MATLAB in public clouds such as Amazon® Web Services (AWS®) and Azure® that are configurable depending on your needs. To utilize public cloud offerings, you must have an account with your chosen cloud platform.

These cloud offerings make it easy for you to run MATLAB in the cloud by using pre-configured machine templates. You do not have to install MATLAB yourself.

The following tables shows some of the options for accessing MATLAB in the cloud.

Type of Resource	Cloud Solution	Additional Information	Learn More
Single machine	MATLAB Deep Learning Container	• Run container anywhere, including in the cloud or local hardware. • Customize and save container image. • Includes commonly used toolboxes for deep learning applications and workflows.	• MATLAB Deep Learning Container on NVIDIA GPU Cloud for Amazon Web Services • MATLAB Deep Learning Container on NVIDIA GPU Cloud for NVIDIA DGX

Type of Resource	Cloud Solution	Additional Information	Learn More
	Azure Marketplace	• Fully customizable. • Configure region and network settings. • Deploy into existing cloud infrastructure.	Run MATLAB from Azure Marketplace
	Reference architecture templates for AWS and Azure	• Fully customizable. • Configure region and network settings. • Deploy into existing cloud infrastructure.	• Run MATLAB on Amazon Web Services (Windows) • Run MATLAB on Amazon Web Services (Linux) • Run MATLAB on Microsoft Azure using Reference Architecture (Windows) • Run MATLAB on Microsoft Azure using Reference Architecture(Linux)
Cluster	MathWorks Cloud Center	• Cloud Center creates and manages clusters in your AWS account. • Connect to Cloud Center clusters in MATLAB Online. For more information, see “Use Parallel Computing Toolbox with Cloud Center Cluster in MATLAB Online” (Parallel Computing Toolbox).	MathWorks Cloud Center
	Azure Marketplace	• Fully customizable. • Configure region and network settings. • Deploy into existing cloud infrastructure.	“Run MATLAB Parallel Server from Microsoft Azure Marketplace” (MATLAB Parallel Server)

Type of Resource	Cloud Solution	Additional Information	Learn More
	Reference architecture templates for AWS and Azure	• Fully customizable. • Configure region and network settings. • Deploy into existing cloud infrastructure.	• "Run MATLAB Parallel Server on Amazon Web Services" (MATLAB Parallel Server) • "Run MATLAB Parallel Server on Microsoft Azure Using Reference Architecture" (MATLAB Parallel Server)

Work with Big Data in the Cloud

Storing data in the cloud can make it easier for you to access for cloud applications without needing to upload or download large amounts of data each time you create cloud resources. Both AWS and Azure offer data storage services, such as AWS S3 and Azure Blob Storage, respectively.

To avoid the time and cost associated with transferring large quantities of data, it is recommended that you set up cloud resources for your deep learning applications using the same cloud provider and region that you use to store your data in the cloud.

To access data stored in the cloud from MATLAB, you must configure your machine with your access credentials. You can configure access from inside MATLAB using environment variables. For more information on how to set environment variables to access cloud data from your client MATLAB, see "Work with Remote Data". For more information on how to set environment variables on parallel workers in a remote cluster, see "Set Environment Variables on Workers" (Parallel Computing Toolbox).

For an example showing how to upload data to the cloud, see "Upload Deep Learning Data to the Cloud" on page 7-53.

Deep Learning with MATLAB on Multiple GPUs

MATLAB supports training a single deep neural network using multiple GPUs in parallel. This can be achieved using multiple GPUs on your local machine, or on a cluster or cloud using parallel workers with GPUs. Using multiple GPUs can speed up training significantly. To decide if you expect multi-GPU training to deliver a performance gain, consider the following factors:

- How long is the iteration on each GPU? If each GPU iteration is short, then the added overhead of communication between GPUs can dominate. Try increasing the computation per iteration by using a larger batch size.
- Are all the GPUs on a single machine? Communication between GPUs on different machines introduces a significant communication delay. You can mitigate this if you have suitable hardware. For more information, see “Advanced Support for Fast Multi-Node GPU Communication” on page 7-16.

Tip To train a single network using multiple GPUs on your local machine, you can simply specify the `ExecutionEnvironment` option as `"multi-gpu"` without changing the rest of your code. `trainNetwork` automatically uses your available GPUs for training computations.

When you train on a remote cluster, specify the `ExecutionEnvironment` option as `"parallel"`. If the cluster has access to one or more GPUs, then `trainNetwork` only uses the GPUs for training. Workers without a unique GPU are never used for training computation.

If you want to use more resources, you can scale up deep learning training to clusters or the cloud. To learn more about parallel options, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2. To try an example, see “Train Network in the Cloud Using Automatic Parallel Support” on page 7-28.

Using a GPU or parallel options requires Parallel Computing Toolbox. Using a GPU also requires a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Using a remote cluster also requires MATLAB Parallel Server.

Use Multiple GPUs in Local Machine

Note If you run MATLAB on a single machine in the cloud that you connect to via ssh or remote desktop protocol (RDP), then network execution and training uses the same code as if you were running on your local machine.

If you have access to a machine with multiple GPUs, you can simply specify the `ExecutionEnvironment` option as `"multi-gpu"`:

- For training using `trainNetwork`, use the `trainingOptions` function to set the `ExecutionEnvironment` name-value option to `"multi-gpu"`.
- For inference using `classify` and `predict`, set the `ExecutionEnvironment` name-value option to `"multi-gpu"`.

The `"multi-gpu"` option allows you to use multiple GPUs in a local parallel pool. If there is no current parallel pool, `trainNetwork`, `predict`, and `classify` automatically start a local parallel

pool using your default cluster profile settings. The pool has as many workers as the number of available GPUs.

For information on how to perform custom training using multiple GPUs in your local machine, see “Run Custom Training Loops on a GPU and in Parallel” on page 7-20.

Use Multiple GPUs in Cluster

For training and inference with multiple GPUs in a remote cluster, use the `"parallel"` option:

- For training using `trainNetwork`, use the `trainingOptions` function to set the `ExecutionEnvironment` name-value option to `"parallel"`.
- For inference using `classify` and `predict`, set the `ExecutionEnvironment` name-value option to `"parallel"`.

If there is no current parallel pool, `trainNetwork`, `predict`, and `classify` automatically start a parallel pool using your default cluster profile settings. If the pool has access to GPUs, then only workers with a unique GPU perform training computation. If the pool does not have GPUs, then training takes place on all available CPU workers instead.

For information on how to perform custom training using multiple GPUs in a remote cluster, see “Run Custom Training Loops on a GPU and in Parallel” on page 7-20.

Optimize Mini-Batch Size and Learning Rate

Convolutional neural networks are typically trained iteratively using mini-batches of images. This is because the whole dataset is usually too large to fit into GPU memory. For optimum performance, you can experiment with the mini-batch size by changing the `MiniBatchSize` name-value option using the `trainingOptions` function.

The optimal mini-batch size depends on your exact network, dataset, and GPU hardware. When training with multiple GPUs, each image batch is distributed between the GPUs. This effectively increases the total GPU memory available, allowing larger batch sizes. A recommended practice is to scale up the mini-batch size linearly with the number of GPUs, in order to keep the workload on each GPU constant. For example, if you are training on a single GPU using a mini-batch size of 64, and you want to scale up to training with four GPUs of the same type, you can increase the mini-batch size to 256 so that each GPU processes 64 observations per iteration.

Because increasing the mini-batch size improves the significance of each iteration, you can increase the learning rate. A good general guideline is to increase the learning rate proportionally to the increase in mini-batch size. Depending on your application, a larger mini-batch size and learning rate can speed up training without a decrease in accuracy, up to some limit.

Select Particular GPUs to Use for Training

If you do not want to use all of your GPUs, you can select the GPUs that you want to use for training and inference directly. Doing so can be useful to avoid training on a poor-performance GPU, for example, your display GPU.

If your GPUs are in your local machine, you can use the `gpuDeviceTable` and `gpuDeviceCount` functions to examine your GPU resources and determine the index of the GPUs you want to use.

For single GPU training with the `"auto"` or `"gpu"` options, by default, MATLAB uses the GPU device with index `1`. You can use a different GPU by selecting the device before you start training. Use `gpuDevice` to select the desired GPU using its index:

```
gpuDevice(index)
```

`trainNetwork`, `predict`, and `classify` automatically use the selected GPU when you set the `ExecutionEnvironment` option to `"auto"` or `"gpu"`.

For multiple GPU training with the `"multi-gpu"` option, by default, MATLAB uses all available GPUs in your local machine. If you want to exclude GPUs, you can start the parallel pool in advance and select the devices manually.

For example, suppose you have three GPUs but you only want to use the devices with indices `1` and `3`. You can use the following code to start a parallel pool with two workers and select one GPU on each worker.

```
useGPUs = [1 3];
parpool('local', numel(useGPUs));
spmd
    gpuDevice(useGPUs(labindex));
end
```

`trainNetwork`, `predict`, and `classify` automatically use the current parallel pool when you set the `ExecutionEnvironment` option to `"multi-gpu"` (or `"parallel"` for the same result).

Another option is to select workers using the `WorkerLoad` name-value argument in `trainingOptions`. For example:

```
parpool('local', 5);
opts = trainingOptions('sgdm', 'WorkerLoad', [1 1 1 0 1], ...)
```

In this case, the fourth worker is part of the pool but idle, which is not an ideal use of the parallel resources. It is more efficient to select GPUs for training manually using `gpuDevice`.

Train Multiple Networks on Multiple GPUs

If you want to train multiple models in parallel with one GPU each, start a parallel pool with one worker per available GPU, and train each network on a different worker. Use `parfor` or `parfeval` to simultaneously execute a network on each worker. Use the `trainingOptions` function to set the `ExecutionEnvironment` name-value option to `"gpu"` on each worker.

For example, use code of the following form to train multiple networks in parallel on all available GPUs:

```
options = trainingOptions("sgdm","ExecutionEnvironment","gpu");

parfor i=1:gpuDeviceCount("available")
    trainNetwork(…,options);
end
```

To run in the background without blocking your local MATLAB, use `parfeval`. For examples showing how to train multiple networks using `parfor` and `parfeval`, see

- “Use parfor to Train Multiple Deep Learning Networks” on page 7-46

- “Use parfeval to Train Multiple Deep Learning Networks” on page 7-32

Advanced Support for Fast Multi-Node GPU Communication

Some multi-GPU features in MATLAB, including `trainNetwork`, are optimized for direct communication via fast interconnects for improved performance.

If you have appropriate hardware connections, then data transfer between multiple GPUs uses fast peer-to-peer communication, including NVLink, if available.

If you are using a Linux compute cluster with fast interconnects between machines such as Infiniband, or fast interconnects between GPUs on different machines, such as GPUDirect RDMA, you might be able to take advantage of fast multi-node support in MATLAB. Enable this support on all the workers in your pool by setting the environment variable `PARALLEL_SERVER_FAST_MULTINODE_GPU_COMMUNICATION` to `1`. Set this environment variable in the Cluster Profile Manager.

This feature is part of the NVIDIA NCCL library for GPU communication. To configure it, you must set additional environment variables to define the network interface protocol, especially `NCCL_SOCKET_IFNAME`. For more information, see the NCCL documentation and in particular the section on NCCL Environment Variables.

Deep Learning with Big Data

Typically, training deep neural networks requires large amounts of data that often do not fit in memory. You do not need multiple computers to solve problems using data sets too large to fit in memory. Instead, you can divide your training data into mini-batches that contain a portion of the data set. By iterating over the mini-batches, networks can learn from large data sets without needing to load all data into memory at once.

If your data is too large to fit in memory, use a datastore to work with mini-batches of data for training and inference. MATLAB provides many different types of datastore tailored for different applications. For more information about datastores for different applications, see “Datastores for Deep Learning” on page 19-2.

`augmentedImageDatastore` is specifically designed to preprocess and augment batches of image data for machine learning and computer vision applications. For an example showing how to use `augmentedImageDatastore` to manage image data during training, see “Train Network with Augmented Images”

Work with Big Data in Parallel

If you want to use large amounts of data to train a network, it can be helpful to train in parallel. Doing so can reduce the time it takes to train a network, because you can train using multiple mini-batches at the same time.

It is recommended to train using a GPU or multiple GPUs. Only use single CPU or multiple CPUs if you do not have a GPU. CPUs are normally much slower that GPUs for both training and inference. Running on a single GPU typically offers much better performance than running on multiple CPU cores.

For more information about training in parallel, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2.

Preprocess Data in Background

When you train in parallel, you can fetch and preprocess your data in the background. This can be particularly useful if you want to preprocess your mini-batches during training, such as when using the `transform` function to apply a mini-batch preprocessing function to your datastore.

When you train a network using the `trainNetwork` function, you can fetch and preprocess data in the background by enabling background dispatch:

- Set the `DispatchInBackground` property of the datastore to `true`.
- Set the `'DispatchInBackground'` training option to `true` using the `trainingOptions` function.

During training, some workers are used for preprocessing data instead of network training computations. You can fine-tune the training computation and data dispatch loads between workers by specifying the `'WorkerLoad'` name-value argument using the `trainingOptions` function. For advanced options, you can try modifying the number of workers of the parallel pool.

You can use a built-in mini-batch datastore, such as `augmentedImageDatastore`, `denoisingImageDatastore`, or `pixelLabelImageDatastore`. You can also use a custom mini-

batch datastore with background dispatch enabled. For more information on creating custom mini-batch datastores, see “Develop Custom Mini-Batch Datastore” on page 19-36.

For more information about datastore requirement for background dispatching, see “Use Datastore for Parallel Training and Background Dispatching” on page 19-8

Work with Big Data in the Cloud

Storing data in the cloud can make it easier for you to access for cloud applications without needing to upload or download large amounts of data each time you create cloud resources. Both AWS and Azure offer data storage services, such as AWS S3 and Azure Blob Storage, respectively.

To avoid the time and cost associated with transferring large quantities of data, it is recommended that you set up cloud resources for your deep learning applications using the same cloud provider and region that you use to store your data in the cloud.

To access data stored in the cloud from MATLAB, you must configure your machine with your access credentials. You can configure access from inside MATLAB using environment variables. For more information on how to set environment variables to access cloud data from your client MATLAB, see “Work with Remote Data”. For more information on how to set environment variables on parallel workers in a remote cluster, see “Set Environment Variables on Workers” (Parallel Computing Toolbox).

For an example showing how to upload data to the cloud, see “Upload Deep Learning Data to the Cloud” on page 7-53.

For more information about deep learning in the cloud, see “Deep Learning in the Cloud” on page 7-10

Preprocess Data for Custom Training Loops

When you train a network using a custom training loop, you can process your data in the background by using `minibatchqueue` and enabling background dispatch. A `minibatchqueue` object iterates over a `datastore` to prepare mini-batches for custom training loops. Enable background dispatch when your mini-batches require heavy preprocessing.

To enable background dispatch, you must:

- Set the `DispatchInBackground` property of the datastore to `true`.
- Set the `DispatchInBackground` property of the `minibatchqueue` to `true`.

When you use this option, MATLAB opens a local parallel pool to use for preprocessing your data. Data preprocessing for custom training loops is supported when training using local resources only. For example, use this option when training using a single GPU in your local machine.

For more information about datastore requirements for background dispatching, see “Use Datastore for Parallel Training and Background Dispatching” on page 19-8

Run Custom Training Loops on a GPU and in Parallel

You can speed up your custom training loops by running on a GPU, in parallel using multiple GPUs, or on a cluster.

It is recommended to train using a GPU or multiple GPUs. Only use single CPU or multiple CPUs if you do not have a GPU. CPUs are normally much slower that GPUs for both training and inference. Running on a single GPU typically offers much better performance than running on multiple CPU cores.

Note This topic shows you how to perform custom training on GPUs, in parallel, and on the cloud. To learn about parallel and GPU workflows using the `trainNetwork` function, see:

- “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2
- “Deep Learning with MATLAB on Multiple GPUs” on page 7-13

Using a GPU or parallel options requires Parallel Computing Toolbox. Using a GPU also requires a supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox). Using a remote cluster also requires MATLAB Parallel Server.

Train Network on GPU

By default, custom training loops run on the CPU. Automatic differentiation using `dlgradient` and `dlfeval` supports running on the GPU when your data is on the GPU. To run a custom training loop on a GPU, simply convert your data to `gpuArray` during training.

You can use `minibatchqueue` to manage your data during training. `minibatchqueue` automatically prepares data for training, including custom preprocessing and converting data to `dlarray` and `gpuArray`. By default, `minibatchqueue` returns all mini-batch variables on the GPU if one is available. You can choose which variables to return on the GPU using the `OutputEnvironment` property.

For an example showing how to use `minibatchqueue` to train on the GPU, see “Train Network Using Custom Training Loop” on page 18-225.

Alternatively, you can manually convert your data to `gpuArray` within the training loop.

To easily specify the execution environment, create the variable `executionEnvironment` that contains either `"cpu"`, `"gpu"`, or `"auto"`.

```
executionEnvironment = "auto"
```

During training, after reading a mini-batch, check the execution environment option and convert the data to a `gpuArray` if necessary. The `canUseGPU` function checks for useable GPUs.

```
if (executionEnvironment == "auto" && canUseGPU) || executionEnvironment == "gpu"
    dlX = gpuArray(dlX);
end
```

Train Single Network in Parallel

When you train in parallel, each worker trains the network simultaneously using a portion of a mini-batch. This means that you must combine the gradients, loss, and any state parameters after each iteration, according to the proportion of the mini-batch processed by each worker.

You can train in parallel on your local machine, or on a remote cluster, for example, in the cloud. Start a parallel pool in the desired resources and partition your data between the workers. During training, combine the gradients, loss, and state after each iteration so that the learnable parameters on each worker update in synchronization. For an example showing how to perform custom training in parallel, see “Train Network in Parallel with Custom Training Loop” on page 7-55

Set Up Parallel Environment

It is recommended to train using a GPU or multiple GPUs. Only use single CPU or multiple CPUs if you do not have a GPU. CPUs are normally much slower that GPUs for both training and inference. Running on a single GPU typically offers much better performance than running on multiple CPU cores.

Set up the parallel environment that you want to use before training. Start a parallel pool using your desired resources. For training using multiple GPUs, start a parallel pool with as many workers as available GPUs. For best performance, MATLAB automatically assigns a different GPU to each worker.

If you are using your local machine, you can use `canUseGPU` and `gpuDeviceCount` to determine if you have GPUs available. For example, to check availabilities of GPUs and start a parallel pool with as many workers as available GPUs, use the following code:

```
if canUseGPU
    executionEnvironment = "gpu";
    numberOfGPUs = gpuDeviceCount("available");
    pool = parpool(numberOfGPUs);
else
    executionEnvironment = "cpu";
    pool = parpool;
end
```

If you are running using a remote cluster, for example, a cluster in the cloud, start a parallel pool with as many workers as the number of GPUs per machine multiplied by the number of machines.

For more information on selecting specific GPUs, see “Select Particular GPUs to Use for Training” on page 7-14.

Specify Mini-Batch Size and Partition Data

Specify the mini-batch size that you want to use during training. For GPU training, a recommended practice is to scale up the mini-batch size linearly with the number of GPUs, in order to keep the workload on each GPU constant. For example, if you are training on a single GPU using a mini-batch size of 64, and you want to scale up to training with four GPUs of the same type, you can increase the mini-batch size to 256 so that each GPU processes 64 observations per iteration.

You can use the following code to scale up the mini-batch size by the number of workers, where `N` is the number of workers in your parallel pool.

```
if executionEnvironment == "gpu"
    miniBatchSize = miniBatchSize .* N
end
```

If you want to use a mini-batch size that not exactly divisible by the number of workers in your parallel pool, then distribute the remainder across the workers.

```
workerMiniBatchSize = floor(miniBatchSize ./ repmat(N,1,N));
remainder = miniBatchSize - sum(workerMiniBatchSize);
workerMiniBatchSize = workerMiniBatchSize + [ones(1,remainder) zeros(1,N-remainder)]
```

At the start of training, shuffle your data. Partition your data so that each worker has access to a portion of the mini-batch. To partition a datastore, use the `partition` function.

You can use `minibatchqueue` to manage the data on each worker during training. `minibatchqueue` automatically prepares data for training, including custom preprocessing and converting data to `dlarray` and `gpuArray`. Create a minibatchqueue on each worker using the partitioned datastore. Set the `MiniBatchSize` property using the mini-batch sizes calculated for each worker.

At the start of each training iteration, use the `gop` function to check that all worker `minibatchqueue` objects can return data. If any worker runs out of data, training stops. If your overall mini-batch size is not exactly divisible by the number of workers and you do not discard partial mini-batches, some workers might run out of data before others.

Write your training code inside an `spmd` block, so that the training loop executes on each worker.

```
spmd
    % Reset and shuffle the datastore.
    reset(augimdsTrain);
    augimdsTrain = shuffle(augimdsTrain);

    % Partition datastore.
    workerImds = partition(augimdsTrain,N,labindex);

    % Create minibatchqueue using partitioned datastore on each worker
    workerMbq = minibatchqueue(workerImds,...
        "MiniBatchSize",workerMiniBatchSize(labindex),...
        "MiniBatchFcn",@preprocessMiniBatch);

    ...

    for epoch = 1:numEpochs

        % Reset and shuffle minibatchqueue on each worker.
        shuffle(workerMbq);

        % Loop over mini-batches.
        while gop(@and,hasdata(workerMbq))

            % Custom training loop
            ...

        end
        ...
    end
end
```

Aggregate Gradients

To ensure that the network on each worker learns from all data and not just the data on that worker, aggregate the gradients and use the aggregated gradients to update the network on each worker.

For example, suppose you are training the network `dlnet`, using the model gradients function `modelGradients`. Your training loop contains the following code for evaluating the gradient, loss, and statistics on each worker:

```
[workerGradients,dlworkerLoss,workerState] = dlfeval(@modelGradients,dlnet,dlworkerX,workerY);
```

`dlworkerX` and `workerY` are the predictor and true response on each worker, respectively.

To aggregate the gradients, use a weighted sum. Define a helper function to sum the gradients.

```
function gradients = aggregateGradients(dlgradients,factor)
    gradients = extractdata(dlgradients);
    gradients = gplus(factor*gradients);
end
```

Inside the training loop, use `dlupdate` to apply the function to the gradients of each learnable parameter.

```
workerGradients.Value = dlupdate(@aggregateGradients,workerGradients.Value,{workerNormalizationFa
```

Aggregate Loss and Accuracy

To find the network loss and accuracy, for example, to plot them during training to monitor training progress, aggregate the values of the loss and accuracy on all of the workers. Typically, the aggregated value is the sum of the value on each worker, weighted by the proportion of the mini-batch used on each worker. To aggregate the losses and accuracy each iteration, calculate the weight factor for each worker and use `gplus` to sum the values on each worker.

```
workerNormalizationFactor = workerMiniBatchSize(labindex)./miniBatchSize;
loss = gplus(workerNormalizationFactor*extractdata(dlworkerLoss));
accuracy = gplus(workerNormalizationFactor*extractdata(dlworkerAccuracy));
```

Aggregate Statistics

If your network contains layers that track the statistics of your training data, such as batch normalization layers, then you must aggregate the statistics across all workers after each training iteration. Doing so ensures that the network learns statistics that are representative of the entire training set.

You can identify the layers that contain statistics information before training. For example, if you are using a `dlnetwork` with batch normalization layers, you can use the following code to find the relevant layers.

```
batchNormLayers = arrayfun(@(l)isa(l,'nnet.cnn.layer.BatchNormalizationLayer'),dlnet.Layers);
batchNormLayersNames = string({dlnet.Layers(batchNormLayers).Name});
state = dlnet.State;
isBatchNormalizationStateMean = ismember(state.Layer,batchNormLayersNames) & state.Parameter == '
isBatchNormalizationStateVariance = ismember(state.Layer,batchNormLayersNames) & state.Parameter
```

Define a helper function to aggregate the statistics you are using. Batch normalization layers track the mean and variance of the input data. You can aggregate the mean on all the workers using a weighted average. To calculate the aggregated variance s_c^2, use a formula of the following form.

$$s_c^2 = \frac{1}{M}\sum_{j=1}^{N} m_j\left(s_j^2 + \left(\bar{x}_j - \bar{x}_c\right)^2\right)$$

N is the total number of workers, M is the total number of observations in a mini-batch, m_j is the number of observations processed on the jth worker, $\bar{x}_j$ and s_j^2 are the mean and variance statistics calculated on that worker, and $\bar{x}_c$ is the aggregated mean across all workers.

```
function state = aggregateState(state,factor,...
    isBatchNormalizationStateMean,isBatchNormalizationStateVariance)

    stateMeans = state.Value(isBatchNormalizationStateMean);
    stateVariances = state.Value(isBatchNormalizationStateVariance);

    for j = 1:numel(stateMeans)
        meanVal = stateMeans{j};
        varVal = stateVariances{j};

        % Calculate combined mean
        combinedMean = gplus(factor*meanVal);

        % Calculate combined variance terms to sum
        varTerm = factor.*(varVal + (meanVal - combinedMean).^2);

        % Update state
        stateMeans{j} = combinedMean;
        stateVariances{j} = gplus(varTerm);
    end

    state.Value(isBatchNormalizationStateMean) = stateMeans;
    state.Value(isBatchNormalizationStateVariance) = stateVariances;
end
```

Inside the training loop, use the helper function to update the state of the batch normalization layers with the combined mean and variance.

```
dlnet.State = aggregateState(workerState,workerNormalizationFactor,...
                isBatchNormalizationStateMean,isBatchNormalizationStateVariance);
```

Plot Results During Training

If you want to plot results during training, you can send data from the workers to the client using a `DataQueue` object.

To easily specify that the plot should be on or off, create the variable `plots` that contains either `"training-progress"` or `"none"`.

```
plots = "training-progress";
```

Before training, initialize the `DataQueue` and the animated line using the `animatedline` function.

```
if plots == "training-progress"
    figure
    lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
    ylim([0 inf])
    xlabel("Iteration")
    ylabel("Loss")
```

```
    grid on
end
```

Create the `DataQueue` object. Use `afterEach` to call the helper function `displayTrainingProgress` each time data is sent from the worker to the client.

```
Q = parallel.pool.DataQueue;
displayFcn = @(x) displayTrainingProgress(x,lineLossTrain);
afterEach(Q,displayFcn);
```

The `displayTrainingProgress` helper function contains the code used to add points to the animated line and display the training epoch and duration.

```
function displayTrainingProgress (data,line)
     addpoints(line,double(data(3)),double(data(2)))
     D = duration(0,0,data(4),'Format','hh:mm:ss');
     title("Epoch: " + data(1) + ", Elapsed: " + string(D))
     drawnow
end
```

Inside the training loop, at the end of each epoch, use the `DataQueue` to send the training data from the workers to the client. At the end of each iteration, the aggregated loss is the same on each worker, so you can send data from a single worker.

```
% Display training progress information.
if labindex == 1
   data = [epoch loss iteration toc(start)];
   send(Q,gather(data));
end
```

Train Multiple Networks in Parallel

To train multiple networks in parallel, start a parallel pool in your desired resources and use `parfor` to train a single network on each worker.

You can run locally or using a remote cluster. Using a remote cluster requires MATLAB Parallel Server. For more information about managing cluster resources, see “Discover Clusters and Use Cluster Profiles” (Parallel Computing Toolbox). If you have multiple GPUs and want to exclude some from training, you can choose the GPUs you use to train on. For more information on selecting specific GPUs, see “Select Particular GPUs to Use for Training” on page 7-14.

You can modify the network or training parameters on each worker to perform parameter sweeps in parallel. For example, in `networks` is an array of `dlnetwork` objects, you can use code of the following form to train multiple different networks using the same data.

```
parpool ("local",numNetworks);

parfor idx = 1:numNetworks
    iteration = 0;
    velocity = [];

    % Allocate one network per worker
    dlnet = networks(idx)

    % Loop over epochs.
    for epoch = 1:numEpochs
        % Shuffle data.
```

```
        shuffle(mbq);

        % Loop over mini-batches.
        while hasdata(mbq)
            iteration = iteration + 1;

            % Custom training loop
            ...

        end

    end

    % Send the trained networks back to the client.
    trainedNetworks{idx} = dlnet;
end
```

After `parfor` finishes, `trainedNetworks` contains the resulting networks trained by the workers.

Plot Results During Training

To monitor training progress on the workers, you can use a `DataQueue` to send data back from the workers.

To easily specify that the plot should be on or off, create the variable `plots` that contains either `"training-progress"` or `"none"`.

```
plots = "training-progress";
```

Before training, initialize the `DataQueue` and the animated lines using the `animatedline` function. Create a subplot for each network you are training.

```
if plots == "training-progress"
    f = figure;
    f.Visible = true;
    for i=1:numNetworks
        subplot(numNetworks,1,i)
        xlabel('Iteration');
        ylabel('loss');
        lines(i) = animatedline;
    end
end
```

Create the `DataQueue` object. Use `afterEach` to call the helper function `displayTrainingProgress` each time data is sent from the worker to the client.

```
Q = parallel.pool.DataQueue;
displayFcn = @(x) displayTrainingProgress(x,lines);
afterEach(Q,displayFcn);
```

The `displayTrainingProgress` helper function contains the code used to add points to the animated lines.

```
function displayTrainingProgress (data,lines)
     addpoints(lines(1),double(data(4)),double(data(3)))
     D = duration(0,0,data(5),'Format','hh:mm:ss');
     title("Epoch: " + data(2) + ", Elapsed: " + string(D))
     drawnow limitrate nocallbacks
end
```

Inside the training loop, at the end of each iteration, use the `DataQueue` to send the training data from the workers to the client. Send the `parfor` loop index as well as the training information so that the points are added to the correct line for each worker.

```
% Display training progress information.
data = [idx epoch loss iteration toc(start)];
send(Q,gather(data));
```

Use Experiment Manager to Train in Parallel

You can use Experiment Manager to run your custom training loops in parallel. You can either run multiple trails at the same time, or run a single trial at a time using parallel resources.

To run multiple trials at the same time using one parallel worker for each trial, set up your custom training experiment an enable the **Use Parallel** option before running your experiment.

To run a single trial at a time using multiple parallel workers, define your parallel environment in your experiment training function and use an `spmd` block to train the network in parallel. For more information on training a single network in parallel with a custom training loop, see “Train Single Network in Parallel” on page 7-21.

For more information on training in parallel using Experiment Manager, see “Use Experiment Manager to Train in Parallel” on page 7-27.

Train Network in the Cloud Using Automatic Parallel Support

This example shows how to train a convolutional neural network using MATLAB automatic support for parallel training. Deep learning training often takes hours or days. With parallel computing, you can speed up training using multiple graphical processing units (GPUs) locally or in a cluster in the cloud. If you have access to a machine with multiple GPUs, then you can complete this example on a local copy of the data. If you want to use more resources, then you can scale up deep learning training to the cloud. To learn more about your options for parallel training, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2. This example guides you through the steps to train a deep learning network in a cluster in the cloud using MATLAB automatic parallel support.

Requirements

Before you can run the example, you need to configure a cluster and upload data to the cloud. In MATLAB, you can create clusters in the cloud directly from the MATLAB Desktop. On the **Home** tab, in the **Parallel** menu, select **Create and Manage Clusters**. In the Cluster Profile Manager, click **Create Cloud Cluster**. Alternatively, you can use MathWorks Cloud Center to create and access compute clusters. For more information, see Getting Started with Cloud Center. After that, upload your data to an Amazon S3 bucket and access it directly from MATLAB. This example uses a copy of the CIFAR-10 data set that is already stored in Amazon S3. For instructions, see “Upload Deep Learning Data to the Cloud” on page 7-53.

Set Up Parallel Pool

Start a parallel pool in the cluster and set the number of workers to the number of GPUs in your cluster. If you specify more workers than GPUs, then the remaining workers are idle. This example assumes that the cluster you are using is set as the default cluster profile. Check the default cluster profile on the MATLAB **Home** tab, in **Parallel > Select a Default Cluster**.

```
numberOfWorkers = 8;
parpool(numberOfWorkers);
```

```
Starting parallel pool (parpool) using the 'MyClusterInTheCloud' profile ...
connected to 8 workers.
```

Load Data Set from the Cloud

Load the training and test data sets from the cloud using `imageDatastore`. In this example, you use a copy of the CIFAR-10 data set stored in Amazon S3. To ensure that the workers have access to the datastore in the cloud, make sure that the environment variables for the AWS credentials are set correctly. See “Upload Deep Learning Data to the Cloud” on page 7-53.

```
imdsTrain = imageDatastore('s3://cifar10cloud/cifar10/train', ...
 'IncludeSubfolders',true, ...
 'LabelSource','foldernames');

imdsTest = imageDatastore('s3://cifar10cloud/cifar10/test', ...
 'IncludeSubfolders',true, ...
 'LabelSource','foldernames');
```

Train the network with augmented image data by creating an `augmentedImageDatastore` object. Use random translations and horizontal reflections. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
imageSize = [32 32 3];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augmentedImdsTrain = augmentedImageDatastore(imageSize,imdsTrain, ...
    'DataAugmentation',imageAugmenter, ...
    'OutputSizeMode','randcrop');
```

Define Network Architecture and Training Options

Define a network architecture for the CIFAR-10 data set. To simplify the code, use convolutional blocks that convolve the input. The pooling layers downsample the spatial dimensions.

```
blockDepth = 4; % blockDepth controls the depth of a convolutional block
netWidth = 32; % netWidth controls the number of filters in a convolutional block

layers = [
    imageInputLayer(imageSize)

    convolutionalBlock(netWidth,blockDepth)
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(2*netWidth,blockDepth)
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(4*netWidth,blockDepth)
    averagePooling2dLayer(8)

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer
];
```

Define the training options. Train the network in parallel using the current cluster, by setting the execution environment to `parallel`. When you use multiple GPUs, you increase the available computational resources. Scale up the mini-batch size with the number of GPUs to keep the workload on each GPU constant. Scale the learning rate according to the mini-batch size. Use a learning rate schedule to drop the learning rate as the training progresses. Turn on the training progress plot to obtain visual feedback during training.

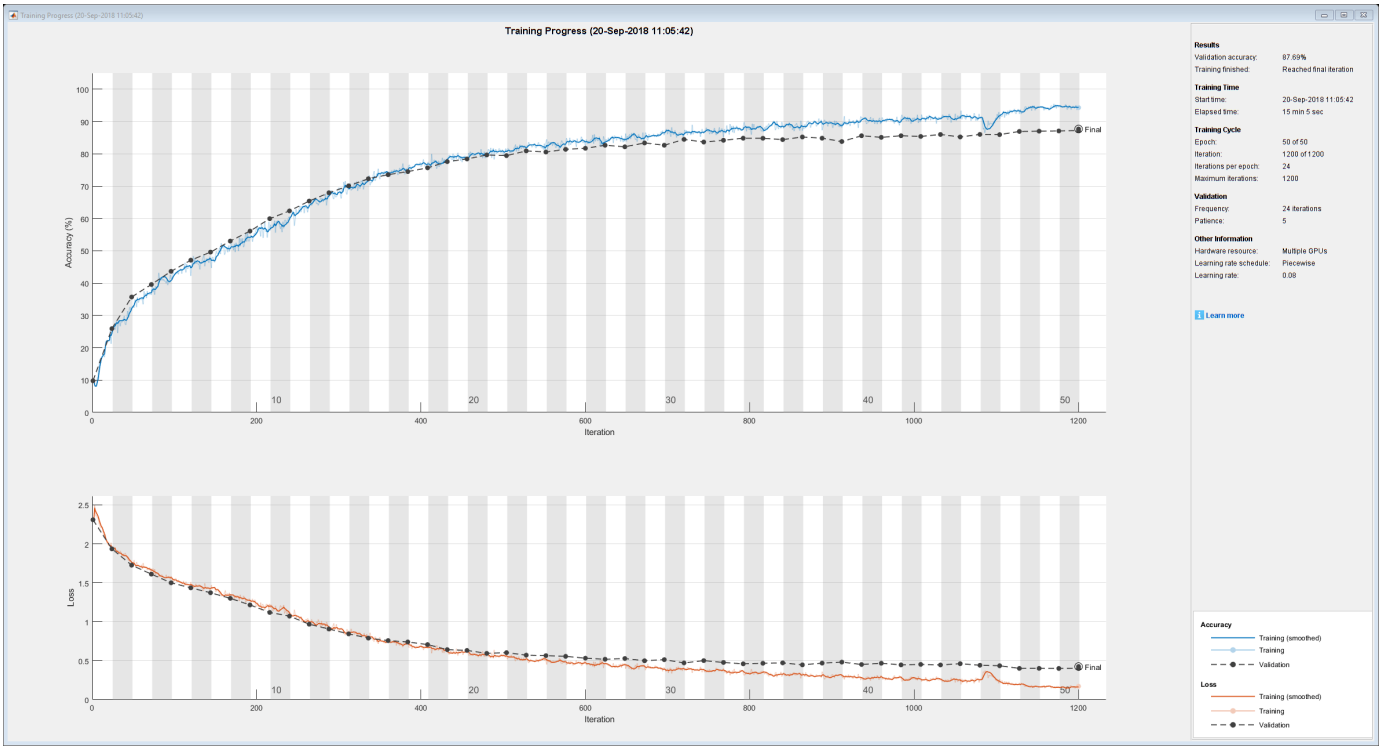
```
miniBatchSize = 256 * numberOfWorkers;
initialLearnRate = 1e-1 * miniBatchSize/256;

options = trainingOptions('sgdm', ...
    'ExecutionEnvironment','parallel', ... % Turn on automatic parallel support.
    'InitialLearnRate',initialLearnRate, ... % Set the initial learning rate.
    'MiniBatchSize',miniBatchSize, ... % Set the MiniBatchSize.
    'Verbose',false, ... % Do not send command line output.
    'Plots','training-progress', ... % Turn on the training progress plot.
    'L2Regularization',1e-10, ...
    'MaxEpochs',50, ...
    'Shuffle','every-epoch', ...
    'ValidationData',imdsTest, ...
    'ValidationFrequency',floor(numel(imdsTrain.Files)/miniBatchSize), ...
    'LearnRateSchedule','piecewise', ...
    'LearnRateDropFactor',0.1, ...
    'LearnRateDropPeriod',45);
```

Train Network and Use for Classification

Train the network in the cluster. During training, the plot displays the progress.

```
net = trainNetwork(augmentedImdsTrain,layers,options)
```



```
net =
  SeriesNetwork with properties:

    Layers: [43×1 nnet.cnn.layer.Layer]
```

Determine the accuracy of the network, by using the trained network to classify the test images on your local machine. Then compare the predicted labels to the actual labels.

```
YPredicted = classify(net,imdsTest);
accuracy = sum(YPredicted == imdsTest.Labels)/numel(imdsTest.Labels)
```

Define Helper Function

Define a function to create a convolutional block in the network architecture.

```
function layers = convolutionalBlock(numFilters,numConvLayers)
    layers = [
        convolution2dLayer(3,numFilters,'Padding','same')
        batchNormalizationLayer
        reluLayer
    ];
```

```
    layers = repmat(layers,numConvLayers,1);
end
```

Use parfeval to Train Multiple Deep Learning Networks

This example shows how to use `parfeval` to perform a parameter sweep on the depth of the network architecture for a deep learning network and retrieve data during training.

Deep learning training often takes hours or days, and searching for good architectures can be difficult. With parallel computing, you can speed up and automate your search for good models. If you have access to a machine with multiple graphical processing units (GPUs), you can complete this example on a local copy of the data set with a local parallel pool. If you want to use more resources, you can scale up deep learning training to the cloud. This example shows how to use `parfeval` to perform a parameter sweep on the depth of a network architecture in a cluster in the cloud. Using `parfeval` allows you to train in the background without blocking MATLAB, and provides options to stop early if results are satisfactory. You can modify the script to do a parameter sweep on any other parameter. Also, this example shows how to obtain feedback from the workers during computation by using `DataQueue`.

Requirements

Before you can run this example, you need to configure a cluster and upload your data to the Cloud. In MATLAB, you can create clusters in the cloud directly from the MATLAB Desktop. On the **Home** tab, in the **Parallel** menu, select **Create and Manage Clusters**. In the Cluster Profile Manager, click **Create Cloud Cluster**. Alternatively, you can use MathWorks Cloud Center to create and access compute clusters. For more information, see Getting Started with Cloud Center. For this example, ensure that your cluster is set as default on the MATLAB **Home** tab, in **Parallel > Select a Default Cluster**. After that, upload your data to an Amazon S3 bucket and use it directly from MATLAB. This example uses a copy of the CIFAR-10 data set that is already stored in Amazon S3. For instructions, see “Upload Deep Learning Data to the Cloud” on page 7-53.

Load Data Set from the Cloud

Load the training and test data sets from the cloud using `imageDatastore`. Split the training data set into training and validation sets, and keep the test data set to test the best network from the parameter sweep. In this example, you use a copy of the CIFAR-10 data set stored in Amazon S3. To ensure that the workers have access to the datastore in the cloud, make sure that the environment variables for the AWS credentials are set correctly. See “Upload Deep Learning Data to the Cloud” on page 7-53.

```
imds = imageDatastore('s3://cifar10cloud/cifar10/train', ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');

imdsTest = imageDatastore('s3://cifar10cloud/cifar10/test', ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');

[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9);
```

Train the network with augmented image data by creating an `augmentedImageDatastore` object. Use random translations and horizontal reflections. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
imageSize = [32 32 3];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
```

```
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augmentedImdsTrain = augmentedImageDatastore(imageSize,imdsTrain, ...
    'DataAugmentation',imageAugmenter, ...
    'OutputSizeMode','randcrop');
```

Train Several Networks Simultaneously

Define the training options. Set the mini-batch size and scale the initial learning rate linearly according to the mini-batch size. Set the validation frequency so that `trainNetwork` validates the network once per epoch.

```
miniBatchSize = 128;
initialLearnRate = 1e-1 * miniBatchSize/256;
validationFrequency = floor(numel(imdsTrain.Labels)/miniBatchSize);
options = trainingOptions('sgdm', ...
    'MiniBatchSize',miniBatchSize, ... % Set the mini-batch size
    'Verbose',false, ... % Do not send command line output.
    'InitialLearnRate',initialLearnRate, ... % Set the scaled learning rate.
    'L2Regularization',1e-10, ...
    'MaxEpochs',30, ...
    'Shuffle','every-epoch', ...
    'ValidationData',imdsValidation, ...
    'ValidationFrequency', validationFrequency);
```

Specify the depths for the network architecture on which to do a parameter sweep. Perform a parallel parameter sweep training several networks simultaneously using `parfeval`. Use a loop to iterate through the different network architectures in the sweep. Create the helper function `createNetworkArchitecture` at the end of the script, which takes an input argument to control the depth of the network and creates an architecture for CIFAR-10. Use `parfeval` to offload the computations performed by `trainNetwork` to a worker in the cluster. `parfeval` returns a future variable to hold the trained networks and training information when computations are done.

```
netDepths = 1:4;
for idx = 1:numel(netDepths)
    networksFuture(idx) = parfeval(@trainNetwork,2, ...
        augmentedImdsTrain,createNetworkArchitecture(netDepths(idx)),options);
end
```

```
Starting parallel pool (parpool) using the 'MyCluster' profile ...
Connected to the parallel pool (number of workers: 4).
```

`parfeval` does not block MATLAB, which means you can continue executing commands. In this case, obtain the trained networks and their training information by using `fetchOutputs` on `networksFuture`. The `fetchOutputs` function waits until the future variables finish.

```
[trainedNetworks,trainingInfo] = fetchOutputs(networksFuture);
```

Obtain the final validation accuracies of the networks by accessing the `trainingInfo` structure.

```
accuracies = [trainingInfo.FinalValidationAccuracy]
```

```
accuracies = 1×4

   72.5600   77.2600   79.4000   78.6800
```

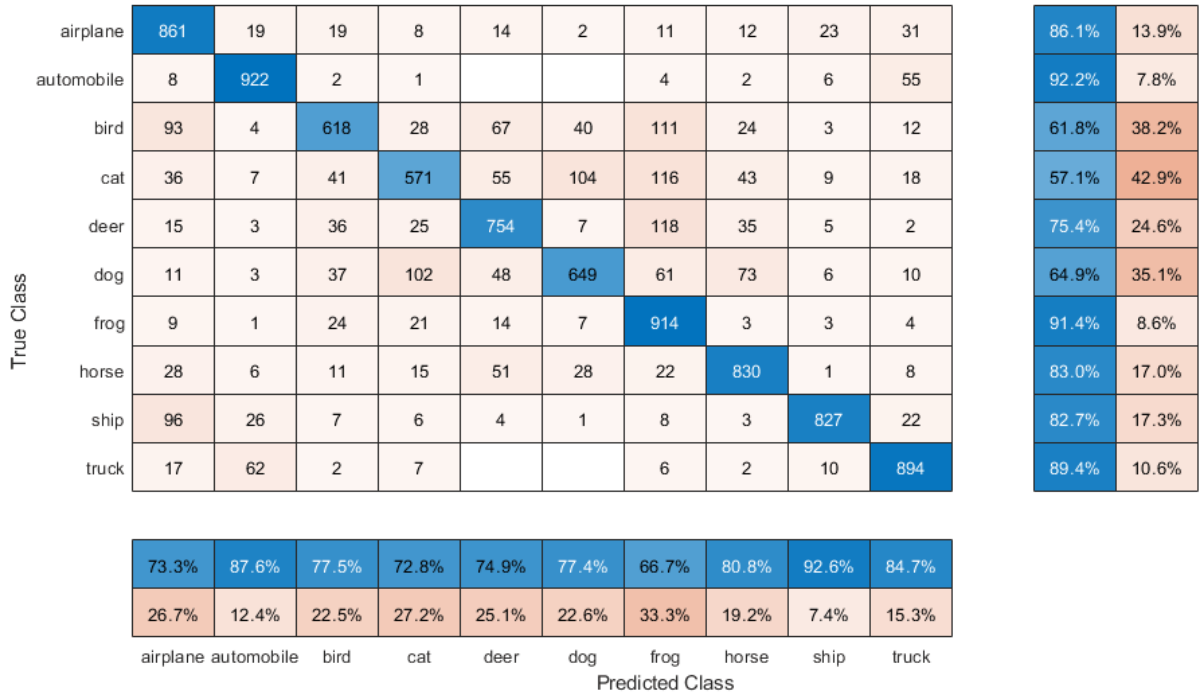
Select the best network in terms of accuracy. Test its performance against the test data set.

```
[~, I] = max(accuracies);
bestNetwork = trainedNetworks(I(1));
YPredicted = classify(bestNetwork,imdsTest);
accuracy = sum(YPredicted == imdsTest.Labels)/numel(imdsTest.Labels)
```

```
accuracy = 0.7840
```

Calculate the confusion matrix for the test data.

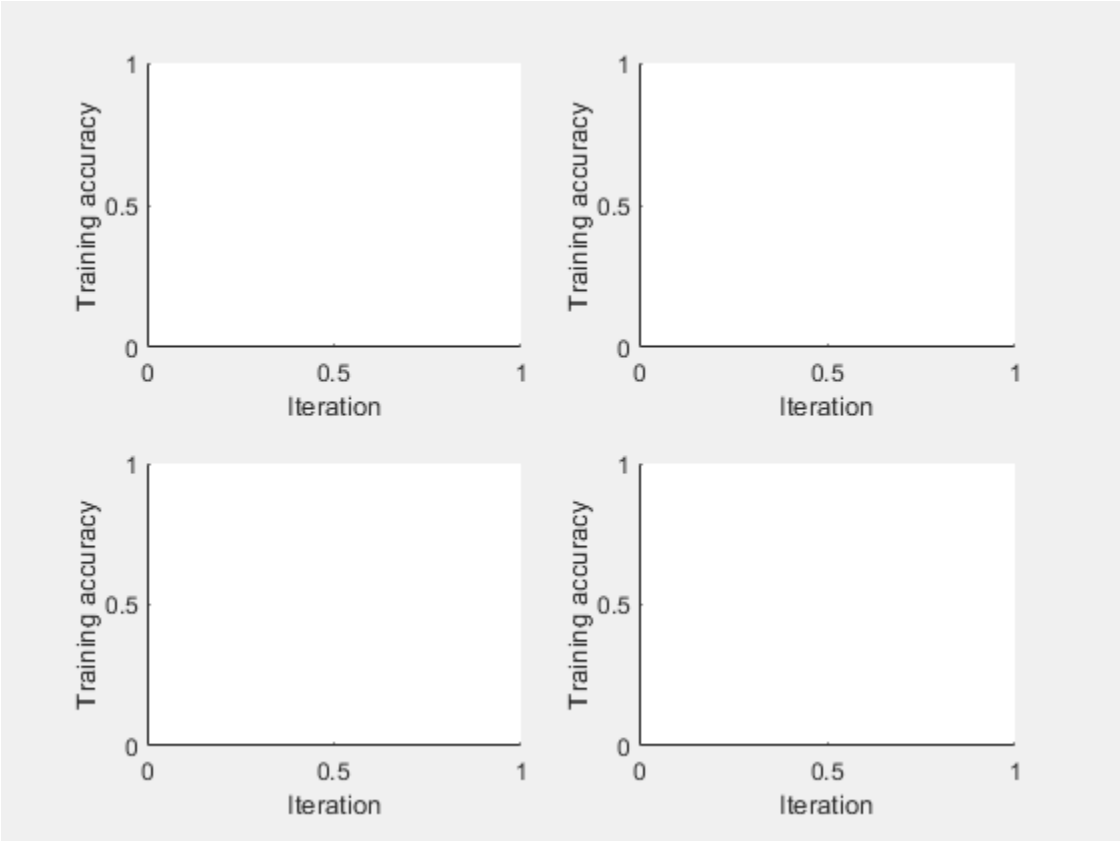
```
figure('Units','normalized','Position',[0.2 0.2 0.4 0.4]);
confusionchart(imdsTest.Labels,YPredicted,'RowSummary','row-normalized','ColumnSummary','column-n
```



Send Feedback Data During Training

Prepare and initialize plots that show the training progress in each of the workers. Use `animatedLine` for a convenient way to show changing data.

```
f = figure;
f.Visible = true;
for i=1:4
    subplot(2,2,i)
    xlabel('Iteration');
    ylabel('Training accuracy');
    lines(i) = animatedline;
end
```



Send the training progress data from the workers to the client by using `DataQueue`, and then plot the data. Update the plots each time the workers send training progress feedback by using `afterEach`. The parameter `opts` contains information about the worker, training iteration, and training accuracy.

```
D = parallel.pool.DataQueue;
afterEach(D, @(opts) updatePlot(lines, opts{:}));
```

Specify the depths for the network architecture on which to do a parameter sweep, and perform the parallel parameter sweep using `parfeval`. Allow the workers to access any helper function in this script, by adding the script to the current pool as an attached file. Define an output function in the training options to send the training progress from the workers to the client. The training options depend on the index of the worker and must be included inside the `for` loop.

```
netDepths = 1:4;
addAttachedFiles(gcp,mfilename);
for idx = 1:numel(netDepths)

    miniBatchSize = 128;
    initialLearnRate = 1e-1 * miniBatchSize/256; % Scale the learning rate according to the mini
    validationFrequency = floor(numel(imdsTrain.Labels)/miniBatchSize);

    options = trainingOptions('sgdm', ...
        'OutputFcn',@(state) sendTrainingProgress(D,idx,state), ... % Set an output function to s
        'MiniBatchSize',miniBatchSize, ... % Set the corresponding MiniBatchSize in the sweep.
        'Verbose',false, ... % Do not send command line output.
        'InitialLearnRate',initialLearnRate, ... % Set the scaled learning rate.
```

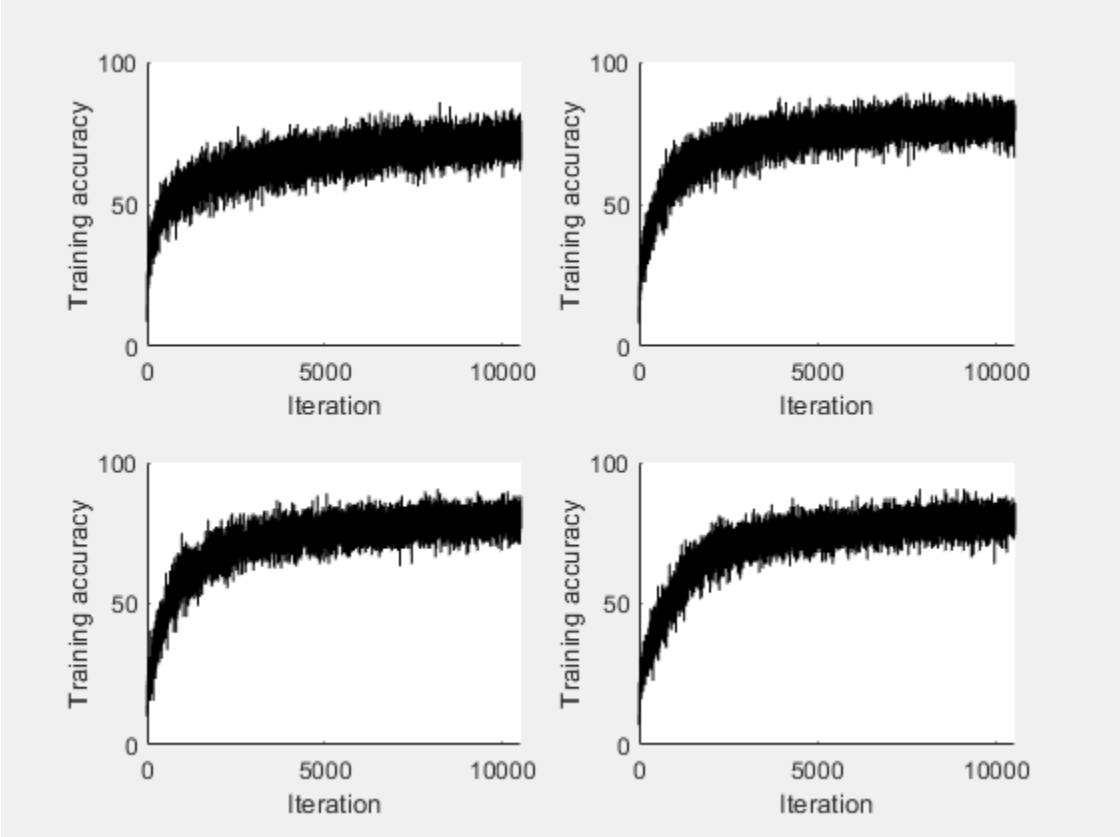
```
        'L2Regularization',1e-10, ...
        'MaxEpochs',30, ...
        'Shuffle','every-epoch', ...
        'ValidationData',imdsValidation, ...
        'ValidationFrequency', validationFrequency);

    networksFuture(idx) = parfeval(@trainNetwork,2, ...
        augmentedImdsTrain,createNetworkArchitecture(netDepths(idx)),options);
end
```

`parfeval` invokes `trainNetwork` on a worker in the cluster. Computations happen on the background, so you can continue working in MATLAB. If you want to stop a `parfeval` computation, you can call `cancel` on its corresponding future variable. For example, if you observe that a network is underperforming, you can cancel its future. When you do so, the next queued future variable starts its computations.

In this case, fetch the trained networks and their training information by invoking `fetchOutputs` on the future variables.

```
[trainedNetworks,trainingInfo] = fetchOutputs(networksFuture);
```



Obtain the final validation accuracy for each network.

```
accuracies = [trainingInfo.FinalValidationAccuracy]
```

```
accuracies = 1×4
```

```
   72.9200   77.4800   76.9200   77.0400
```

Helper Functions

Define a network architecture for the CIFAR-10 data set with a function, and use an input argument to adjust the depth of the network. To simplify the code, use convolutional blocks that convolve the input. The pooling layers downsample the spatial dimensions.

```
function layers = createNetworkArchitecture(netDepth)
imageSize = [32 32 3];
netWidth = round(16/sqrt(netDepth)); % netWidth controls the number of filters in a convolutiona

layers = [
    imageInputLayer(imageSize)

    convolutionalBlock(netWidth,netDepth)
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(2*netWidth,netDepth)
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(4*netWidth,netDepth)
    averagePooling2dLayer(8)

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer
    ];
end
```

Define a function to create a convolutional block in the network architecture.

```
function layers = convolutionalBlock(numFilters,numConvLayers)
layers = [
    convolution2dLayer(3,numFilters,'Padding','same')
    batchNormalizationLayer
    reluLayer
    ];

layers = repmat(layers,numConvLayers,1);
end
```

Define a function to send the training progress to the client through `DataQueue`.

```
function sendTrainingProgress(D,idx,info)
if info.State == "iteration"
    send(D,{idx,info.Iteration,info.TrainingAccuracy});
end
end
```

Define an update function to update the plots when a worker sends an intermediate result.

```
function updatePlot(lines,idx,iter,acc)
addpoints(lines(idx),iter,acc);
drawnow limitrate nocallbacks
end
```

Send Deep Learning Batch Job to Cluster

This example shows how to send deep learning training batch jobs to a cluster so that you can continue working or close MATLAB during training.

Training deep neural networks often takes hours or days. To use time efficiently, you can train neural networks as batch jobs and fetch the results from the cluster when they are ready. You can continue working in MATLAB while computations take place or close MATLAB and obtain the results later using the Job Monitor. This example sends the parallel parameter sweep in “Use parfor to Train Multiple Deep Learning Networks” on page 7-46 as a batch job. After the job is complete, you can fetch the trained networks and compare their accuracies.

Requirements

Before you can run this example, you need to configure a cluster and upload your data to the Cloud. In MATLAB, you can create clusters in the cloud directly from the MATLAB Desktop. On the **Home** tab, in the **Parallel** menu, select **Create and Manage Clusters**. In the Cluster Profile Manager, click **Create Cloud Cluster**. Alternatively, you can use MathWorks Cloud Center to create and access compute clusters. For more information, see Getting Started with Cloud Center. For this example, ensure that your cluster is set as default on the MATLAB **Home** tab, in **Parallel > Select a Default Cluster**. After that, upload your data to an Amazon S3 bucket and use it directly from MATLAB. This example uses a copy of the CIFAR-10 data set that is already stored in Amazon S3. For instructions, see “Upload Deep Learning Data to the Cloud” on page 7-53.

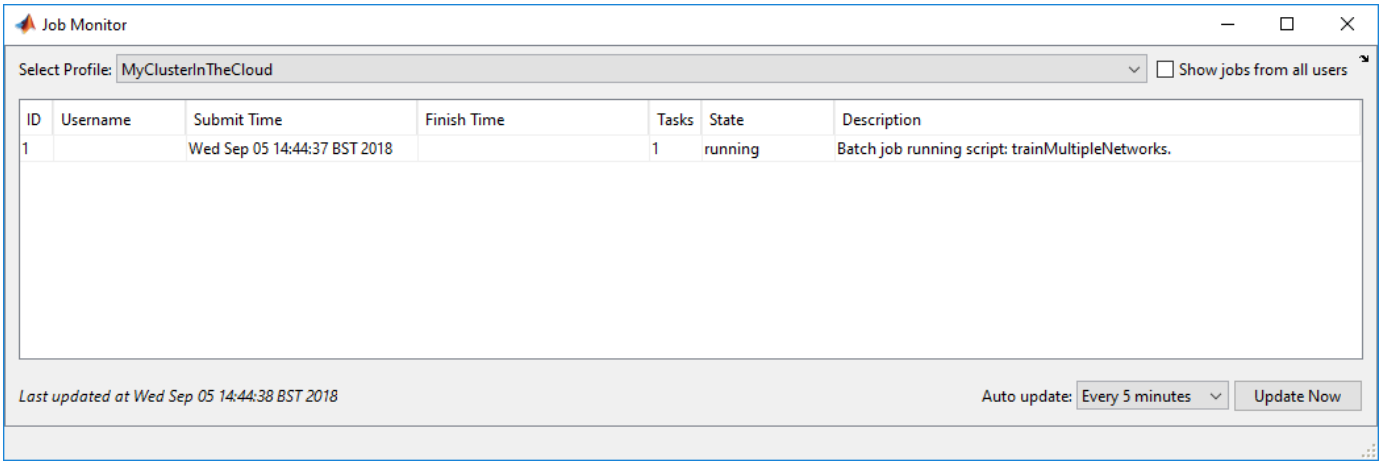
Submit Batch Job

Send a script as a batch job to the cluster by using the `batch` function. The cluster allocates one worker to execute the contents of your script. If the parallel code in the script benefits from extra workers, for example, it includes automatic parallel support or a parfor loop, you need to request the workers explicitly. `batch` uses one worker for the client running the script. You can specify more workers by using the 'Pool' name-value pair argument.

In this case, send the `trainMultipleNetworks` script to the cluster. This script contains the parallel parameter sweep in “Use parfor to Train Multiple Deep Learning Networks” on page 7-46. Because the script contains a `parfor` loop, specify 4 extra workers with the `Pool` name-value pair argument.

```
totalNumberOfWorkers = 5;
job1 = batch('trainMultipleNetworks', ...
    'Pool',totalNumberOfWorkers-1);
```

You can see the current status of your job in the cluster by checking the Job Monitor. In the **Environment** section on the **Home** tab, select **Parallel > Monitor Jobs** to open the Job Monitor.



You can submit additional jobs to the cluster. If the cluster is not available because it is running other jobs, any new job you submit remains queued until the cluster becomes available.

Fetch Results Programmatically

After submitting jobs to the cluster, you can continue working in MATLAB while computations take place. If the rest of your code depends on completion of a job, block MATLAB by using the `wait` command. In this case, wait for the job to finish.

```
wait(job1);
```

After the job finishes, fetch the results by using the `load` function. In this case, fetch the trained networks from the parallel parameter sweep in the submitted script and their accuracies.

```
load(job1,'accuracies');
accuracies
```

```
accuracies = 4×1

    0.8312
    0.8276
    0.8288
    0.8258
```

```
load(job1,'trainedNetworks');
trainedNetworks
```

```
trainedNetworks = 4×1 cell array
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
```

To load all the variables in the batch job, use the `load` function without arguments.

```
load(job1);
```

If you close MATLAB, you can still recover the job in the cluster to fetch the results either while the computation is taking place or after the computation is complete. Before closing MATLAB, make a note of the job ID and then retrieve the job later by using the `findJob` function.

To retrieve a job, first create a cluster object for your cluster by using the `parcluster` function. Then, provide the job ID to `findJob`. In this case, the job ID is `1`.

```
c = parcluster('MyClusterInTheCloud');
job = findJob(c,'ID',1);
```

Delete the job when you are done. The job is removed from the Job Monitor.

```
delete(job1);
```

Use Job Monitor to Fetch Results

When you submit batch jobs, all the computations happen in the cluster and you can safely close MATLAB. You can check the status of your jobs by using the Job Monitor in another MATLAB session.

When a job is done, you can retrieve the results from the Job Monitor. In the **Environment** section on the **Home** tab, select **Parallel > Monitor Jobs** to open the Job Monitor. Then right-click a job to display the context menu. From this menu, you can:

- Load the job into the workspace by clicking **Show Details**
- Load all variables in the job by clicking **Load Variables**
- Delete the job when you are done by clicking **Delete**

Train Network Using Automatic Multi-GPU Support

This example shows how to use multiple GPUs on your local machine for deep learning training using automatic parallel support. Training deep learning networks often takes hours or days. With parallel computing, you can speed up training using multiple GPUs. To learn more about options for parallel training, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” on page 7-2.

Requirements

Before you can run this example, you must download the CIFAR-10 data set to your local machine. The following code downloads the data set to your current directory. If you already have a local copy of CIFAR-10, then you can skip this section.

```
directory = pwd;
[locationCifar10Train,locationCifar10Test] = downloadCIFARToFolders(directory);
```

```
Downloading CIFAR-10 data set...done.
Copying CIFAR-10 to folders...done.
```

Load Data Set

Load the training and test data sets by using an `imageDatastore` object. In the following code, ensure that the location of the datastores points to CIFAR-10 in your local machine.

```
imdsTrain = imageDatastore(locationCifar10Train, ...
 'IncludeSubfolders',true, ...
 'LabelSource','foldernames');

imdsTest = imageDatastore(locationCifar10Test, ...
 'IncludeSubfolders',true, ...
 'LabelSource','foldernames');
```

To train the network with augmented image data, create an `augmentedImageDatastore` object. Use random translations and horizontal reflections. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
imageSize = [32 32 3];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
    'RandYTranslation',pixelRange);
augmentedImdsTrain = augmentedImageDatastore(imageSize,imdsTrain, ...
    'DataAugmentation',imageAugmenter);
```

Define Network Architecture and Training Options

Define a network architecture for the CIFAR-10 data set. To simplify the code, use convolutional blocks that convolve the input. The pooling layers downsample the spatial dimensions.

```
blockDepth = 4; % blockDepth controls the depth of a convolutional block.
netWidth = 32; % netWidth controls the number of filters in a convolutional block.

layers = [
    imageInputLayer(imageSize)

    convolutionalBlock(netWidth,blockDepth)
```

```
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(2*netWidth,blockDepth)
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(4*netWidth,blockDepth)
    averagePooling2dLayer(8)

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer
];
```

Define the training options. Train the network in parallel with multiple GPUs by setting the execution environment to `'multi-gpu'`. When you use multiple GPUs, you increase the available computational resources. Scale up the mini-batch size with the number of GPUs to keep the workload on each GPU constant. In this example, the number of GPUs is two. Scale the learning rate according to the mini-batch size. Use a learning rate schedule to drop the learning rate as the training progresses. Turn on the training progress plot to obtain visual feedback during training.

```
numGPUs = 2;
miniBatchSize = 256*numGPUs;
initialLearnRate = 1e-1*miniBatchSize/256;

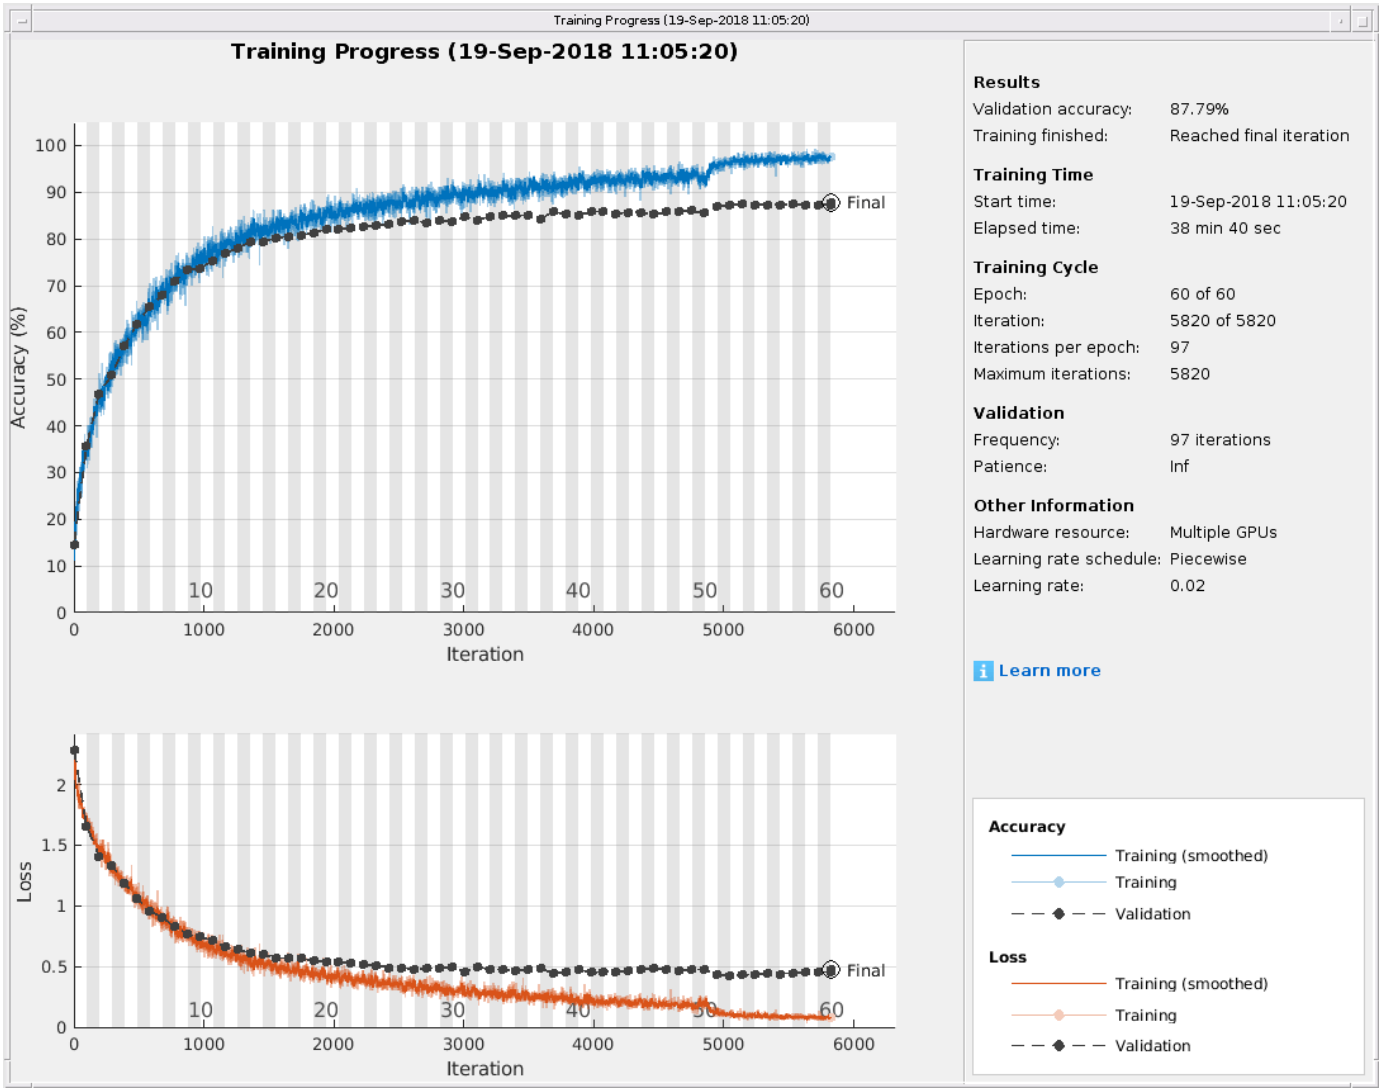
options = trainingOptions('sgdm', ...
    'ExecutionEnvironment','multi-gpu', ... % Turn on automatic multi-gpu support.
    'InitialLearnRate',initialLearnRate, ... % Set the initial learning rate.
    'MiniBatchSize',miniBatchSize, ... % Set the MiniBatchSize.
    'Verbose',false, ... % Do not send command line output.
    'Plots','training-progress', ... % Turn on the training progress plot.
    'L2Regularization',1e-10, ...
    'MaxEpochs',60, ...
    'Shuffle','every-epoch', ...
    'ValidationData',imdsTest, ...
    'ValidationFrequency',floor(numel(imdsTrain.Files)/miniBatchSize), ...
    'LearnRateSchedule','piecewise', ...
    'LearnRateDropFactor',0.1, ...
    'LearnRateDropPeriod',50);
```

Train Network and Use for Classification

Train the network. During training, the plot displays the progress.

```
net = trainNetwork(augmentedImdsTrain,layers,options)
```

```
Starting parallel pool (parpool) using the 'local' profile ...
Connected to the parallel pool (number of workers: 2).
```



```
net =
  SeriesNetwork with properties:

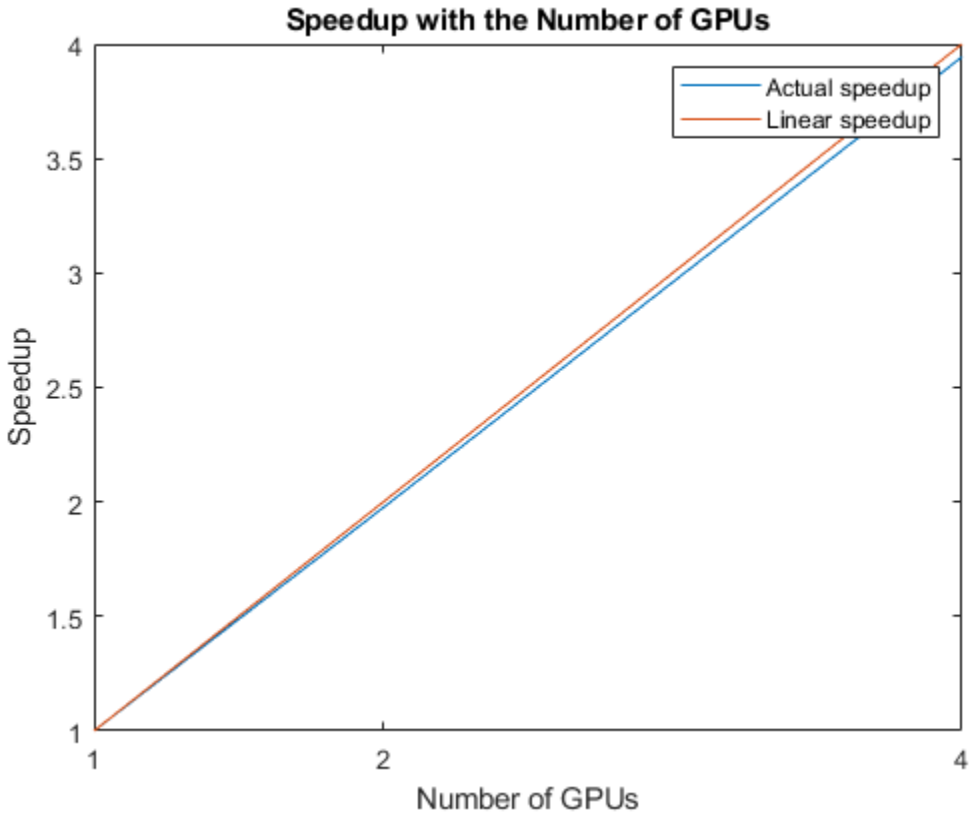
    Layers: [43×1 nnet.cnn.layer.Layer]
```

Determine the accuracy of the network by using the trained network to classify the test images on your local machine. Then compare the predicted labels to the actual labels.

```
YPredicted = classify(net,imdsTest);
accuracy = sum(YPredicted == imdsTest.Labels)/numel(imdsTest.Labels)
```

```
accuracy = 0.8779
```

Automatic multi-GPU support can speed up network training by taking advantage of several GPUs. The following plot shows the speedup in the overall training time with the number of GPUs on a Linux machine with four NVIDIA© TITAN Xp GPUs.



Define Helper Function

Define a function to create a convolutional block in the network architecture.

```
function layers = convolutionalBlock(numFilters,numConvLayers)
    layers = [
        convolution2dLayer(3,numFilters,'Padding','same')
        batchNormalizationLayer
        reluLayer];

    layers = repmat(layers,numConvLayers,1);
end
```

Use parfor to Train Multiple Deep Learning Networks

This example shows how to use a `parfor` loop to perform a parameter sweep on a training option.

Deep learning training often takes hours or days, and searching for good training options can be difficult. With parallel computing, you can speed up and automate your search for good models. If you have access to a machine with multiple graphical processing units (GPUs), you can complete this example on a local copy of the data set with a local parpool. If you want to use more resources, you can scale up deep learning training to the cloud. This example shows how to use a parfor loop to perform a parameter sweep on the training option `MiniBatchSize` in a cluster in the cloud. You can modify the script to do a parameter sweep on any other training option. Also, this example shows how to obtain feedback from the workers during computation using `DataQueue`. You can also send the script as a batch job to the cluster, so you can continue working or close MATLAB and fetch the results later. For more information, see “Send Deep Learning Batch Job to Cluster” on page 7-39.

Requirements

Before you can run this example, you need to configure a cluster and upload your data to the cloud. In MATLAB, you can create clusters in the cloud directly from the MATLAB Desktop. On the **Home** tab, in the **Parallel** menu, select **Create and Manage Clusters**. In the Cluster Profile Manager, click **Create Cloud Cluster**. Alternatively, you can use MathWorks Cloud Center to create and access compute clusters. For more information, see Getting Started with Cloud Center. For this example, ensure that your cluster is set as default on the MATLAB **Home** tab, in **Parallel > Select a Default Cluster**. After that, upload your data to an Amazon S3 bucket and use it directly from MATLAB. This example uses a copy of the CIFAR-10 data set that is already stored in Amazon S3. For instructions, see “Upload Deep Learning Data to the Cloud” on page 7-53.

Load the Data Set from the Cloud

Load the training and test data sets from the cloud using `imageDatastore`. Split the training data set into training and validation sets, and keep the test data set to test the best network from the parameter sweep. In this example you use a copy of the CIFAR-10 data set stored in Amazon S3. To ensure that the workers have access to the datastore in the cloud, make sure that the environment variables for the AWS credentials are set correctly. See “Upload Deep Learning Data to the Cloud” on page 7-53.

```
imds = imageDatastore('s3://cifar10cloud/cifar10/train', ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');

imdsTest = imageDatastore('s3://cifar10cloud/cifar10/test', ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');

[imdsTrain,imdsValidation] = splitEachLabel(imds,0.9);
```

Train the network with augmented image data, by creating an `augmentedImageDatastore` object. Use random translations and horizontal reflections. Data augmentation helps prevent the network from overfitting and memorizing the exact details of the training images.

```
imageSize = [32 32 3];
pixelRange = [-4 4];
imageAugmenter = imageDataAugmenter( ...
    'RandXReflection',true, ...
    'RandXTranslation',pixelRange, ...
```

```
    'RandYTranslation',pixelRange);
augmentedImdsTrain = augmentedImageDatastore(imageSize,imdsTrain, ...
    'DataAugmentation',imageAugmenter, ...
    'OutputSizeMode','randcrop');
```

Define Network Architecture

Define a network architecture for the CIFAR-10 data set. To simplify the code, use convolutional blocks that convolve the input. The pooling layers downsample the spatial dimensions.

```
imageSize = [32 32 3];
netDepth = 2; % netDepth controls the depth of a convolutional block
netWidth = 16; % netWidth controls the number of filters in a convolutional block

layers = [
    imageInputLayer(imageSize)

    convolutionalBlock(netWidth,netDepth)
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(2*netWidth,netDepth)
    maxPooling2dLayer(2,'Stride',2)
    convolutionalBlock(4*netWidth,netDepth)
    averagePooling2dLayer(8)

    fullyConnectedLayer(10)
    softmaxLayer
    classificationLayer
    ];
```

Train Several Networks Simultaneously

Specify the mini-batch sizes on which to do a parameter sweep. Allocate variables for the resulting networks and accuracy.

```
miniBatchSizes = [64 128 256 512];
numMiniBatchSizes = numel(miniBatchSizes);
trainedNetworks = cell(numMiniBatchSizes,1);
accuracies = zeros(numMiniBatchSizes,1);
```

Perform a parallel parameter sweep training several networks inside a `parfor` loop and varying the mini-batch size. The workers in the cluster train the networks simultaneously and send the trained networks and accuracies back when the training is complete. If you want to check that the training is working, set `Verbose` to `true` in the training options. Note that the workers compute independently, so the command line output is not in the same sequential order as the iterations.

```
parfor idx = 1:numMiniBatchSizes

    miniBatchSize = miniBatchSizes(idx);
    initialLearnRate = 1e-1 * miniBatchSize/256; % Scale the learning rate according to the mini

    % Define the training options. Set the mini-batch size.
    options = trainingOptions('sgdm', ...
        'MiniBatchSize',miniBatchSize, ... % Set the corresponding MiniBatchSize in the sweep.
        'Verbose',false, ... % Do not send command line output.
        'InitialLearnRate',initialLearnRate, ... % Set the scaled learning rate.
        'L2Regularization',1e-10, ...
        'MaxEpochs',30, ...
        'Shuffle','every-epoch', ...
```

```
        'ValidationData',imdsValidation, ...
        'LearnRateSchedule','piecewise', ...
        'LearnRateDropFactor',0.1, ...
        'LearnRateDropPeriod',25);

    % Train the network in a worker in the cluster.
    net = trainNetwork(augmentedImdsTrain,layers,options);

    % To obtain the accuracy of this network, use the trained network to
    % classify the validation images on the worker and compare the predicted labels to the
    % actual labels.
    YPredicted = classify(net,imdsValidation);
    accuracies(idx) = sum(YPredicted == imdsValidation.Labels)/numel(imdsValidation.Labels);

    % Send the trained network back to the client.
    trainedNetworks{idx} = net;
end
```

```
Starting parallel pool (parpool) using the 'MyClusterInTheCloud' profile ...
Connected to the parallel pool (number of workers: 4).
```

After `parfor` finishes, `trainedNetworks` contains the resulting networks trained by the workers. Display the trained networks and their accuracies.

```
trainedNetworks
```

```
trainedNetworks = 4×1 cell array
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
```

```
accuracies
```

```
accuracies = 4×1

    0.8188
    0.8232
    0.8162
    0.8050
```

Select the best network in terms of accuracy. Test its performance against the test data set.

```
[~, I] = max(accuracies);
bestNetwork = trainedNetworks{I(1)};
YPredicted = classify(bestNetwork,imdsTest);
accuracy = sum(YPredicted == imdsTest.Labels)/numel(imdsTest.Labels)
```

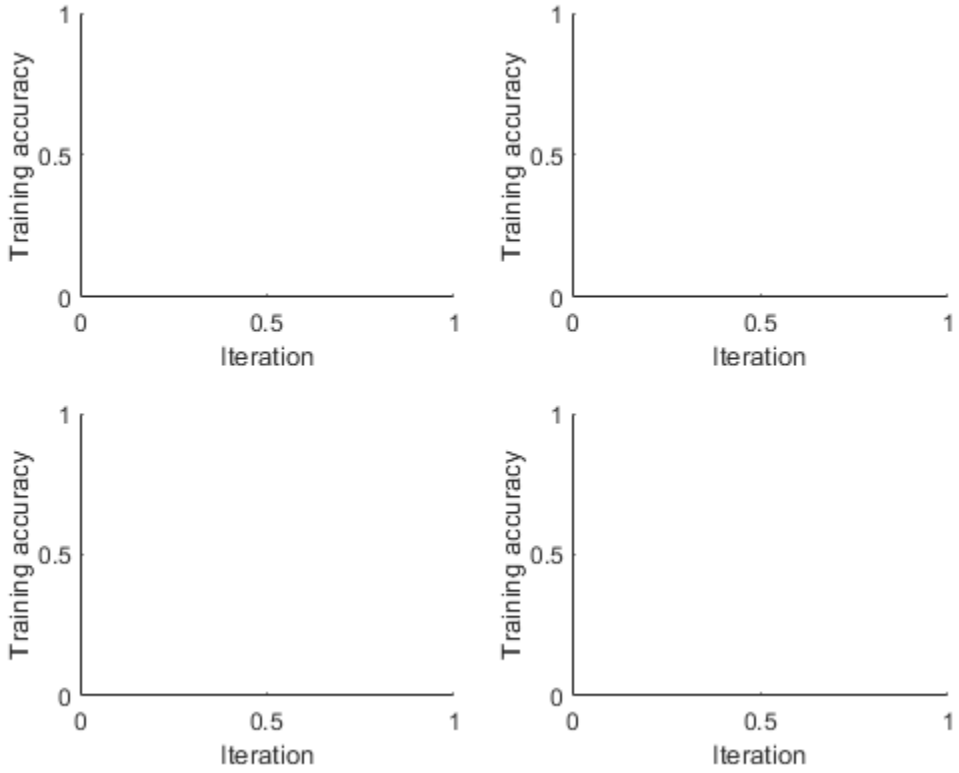
```
accuracy = 0.8173
```

Send Feedback Data During Training

Prepare and initialize plots that show the training progress in each of the workers. Use `animatedLine` for a convenient way to show changing data.

```
f = figure;
f.Visible = true;
```

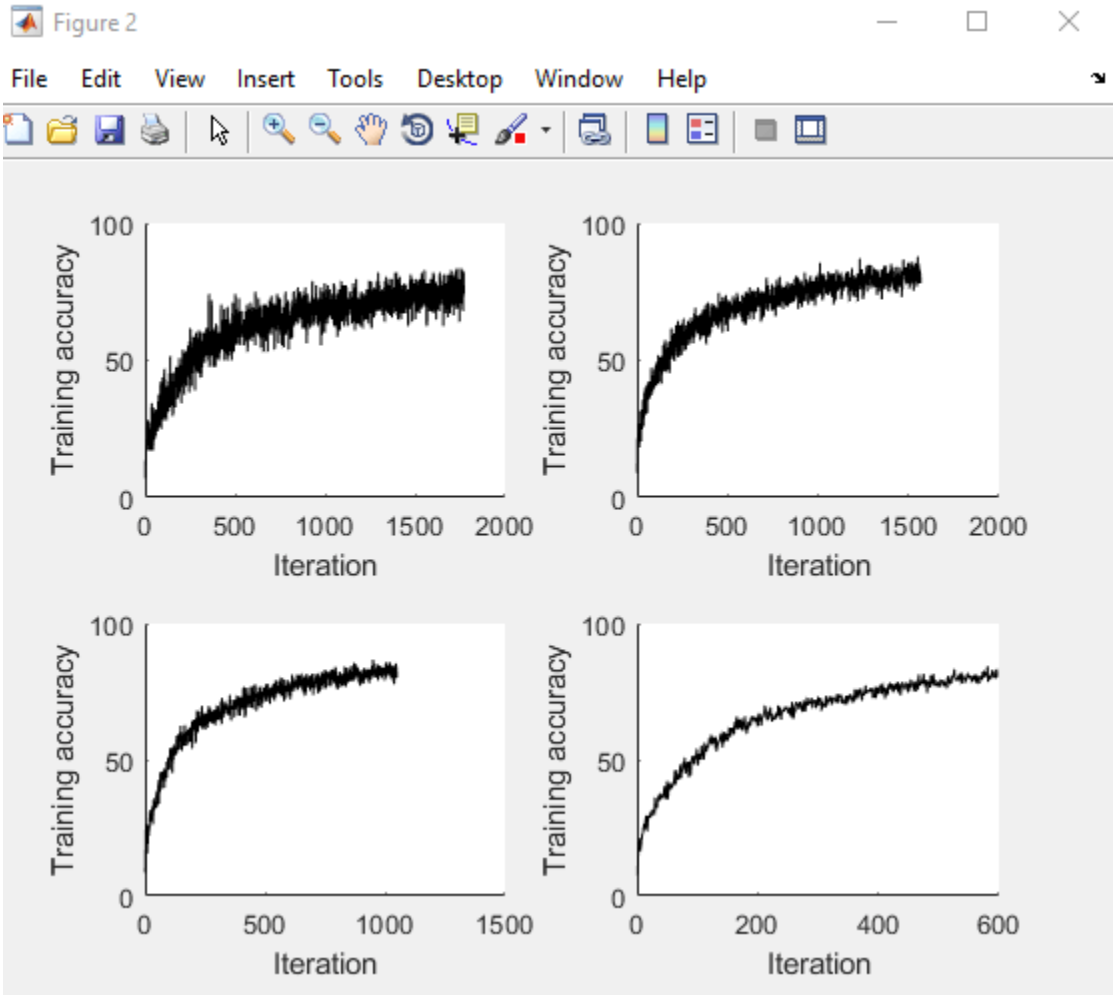
```
for i=1:4
    subplot(2,2,i)
    xlabel('Iteration');
    ylabel('Training accuracy');
    lines(i) = animatedline;
end
```



Send the training progress data from the workers to the client by using `DataQueue`, and then plot the data. Update the plots each time the workers send training progress feedback by using `afterEach`. The parameter `opts` contains information about the worker, training iteration, and training accuracy.

```
D = parallel.pool.DataQueue;
afterEach(D, @(opts) updatePlot(lines, opts{:}));
```

Perform a parallel parameter sweep training several networks inside a parfor loop with different mini-batch sizes. Note the use of `OutputFcn` in the training options to send the training progress to the client each iteration. This figure shows the training progress of four different workers during an execution of the following code.



```
parfor idx = 1:numel(miniBatchSizes)

    miniBatchSize = miniBatchSizes(idx);
    initialLearnRate = 1e-1 * miniBatchSize/256; % Scale the learning rate according to the miniB

    % Define the training options. Set an output function to send data back
    % to the client each iteration.
    options = trainingOptions('sgdm', ...
        'MiniBatchSize',miniBatchSize, ... % Set the corresponding MiniBatchSize in the sweep.
        'Verbose',false, ... % Do not send command line output.
        'InitialLearnRate',initialLearnRate, ... % Set the scaled learning rate.
        'OutputFcn',@(state) sendTrainingProgress(D,idx,state), ... % Set an output function to s
        'L2Regularization',1e-10, ...
        'MaxEpochs',30, ...
        'Shuffle','every-epoch', ...
        'ValidationData',imdsValidation, ...
        'LearnRateSchedule','piecewise', ...
        'LearnRateDropFactor',0.1, ...
        'LearnRateDropPeriod',25);

    % Train the network in a worker in the cluster. The workers send
    % training progress information during training to the client.
```

```
    net = trainNetwork(augmentedImdsTrain,layers,options);

    % To obtain the accuracy of this network, use the trained network to
    % classify the validation images on the worker and compare the predicted labels to the
    % actual labels.
    YPredicted = classify(net,imdsValidation);
    accuracies(idx) = sum(YPredicted == imdsValidation.Labels)/numel(imdsValidation.Labels);

    % Send the trained network back to the client.
    trainedNetworks{idx} = net;
end
```

```
Analyzing and transferring files to the workers ...done.
```

After `parfor` finishes, `trainedNetworks` contains the resulting networks trained by the workers. Display the trained networks and their accuracies.

```
trainedNetworks
```

```
trainedNetworks = 4×1 cell array
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
    {1×1 SeriesNetwork}
```

```
accuracies
```

```
accuracies = 4×1

    0.8214
    0.8172
    0.8132
    0.8084
```

Select the best network in terms of accuracy. Test its performance against the test data set.

```
[~, I] = max(accuracies);
bestNetwork = trainedNetworks{I(1)};
YPredicted = classify(bestNetwork,imdsTest);
accuracy = sum(YPredicted == imdsTest.Labels)/numel(imdsTest.Labels)
```

```
accuracy = 0.8187
```

Helper Functions

Define a function to create a convolutional block in the network architecture.

```
function layers = convolutionalBlock(numFilters,numConvLayers)
layers = [
    convolution2dLayer(3,numFilters,'Padding','same')
    batchNormalizationLayer
    reluLayer
    ];

layers = repmat(layers,numConvLayers,1);
end
```

Define a function to send the training progress to the client through `DataQueue`.

```
function sendTrainingProgress(D,idx,info)
if info.State == "iteration"
    send(D,{idx,info.Iteration,info.TrainingAccuracy});
end
end
```

Define an update function to update the plots when a worker sends an intermediate result.

```
function updatePlot(lines,idx,iter,acc)
addpoints(lines(idx),iter,acc);
drawnow limitrate nocallbacks
end
```

More About

- “Parallel for-Loops (parfor)” (Parallel Computing Toolbox)

Upload Deep Learning Data to the Cloud

This example shows how to upload data to an Amazon S3 bucket.

Before you can perform deep learning training in the cloud, you need to upload your data to the cloud. The example shows how to download the CIFAR-10 data set to your computer, and then upload the data to an Amazon S3 bucket for later use in MATLAB. The CIFAR-10 data set is a labeled image data set commonly used for benchmarking image classification algorithms. Before running this example, you need access to an Amazon Web Services (AWS) account. After you upload the data set to Amazon S3, you can try any of the examples in “Deep Learning in Parallel and in the Cloud”.

Download CIFAR-10 to Local Machine

Specify a local directory in which to download the data set. The following code creates a folder in your current directory containing all the images in the data set.

```
directory = pwd;
[trainDirectory,testDirectory] = downloadCIFARToFolders(directory);
```

```
Downloading CIFAR-10 data set...done.
Copying CIFAR-10 to folders...done.
```

Upload Local Data Set to Amazon S3 Bucket

To work with data in the cloud, you can upload to Amazon S3 and then use datastores to access the data in S3 from the workers in your cluster. The following steps describe how to upload the CIFAR-10 data set from your local machine to an Amazon S3 bucket.

1. For efficient file transfers to and from Amazon S3, download and install the AWS Command Line Interface tool from `https://aws.amazon.com/cli/`.

2. Specify your AWS Access Key ID, Secret Access Key, and Region of the bucket as system environment variables. Contact your AWS account administrator to obtain your keys.

For example, on Linux, macOS, or Unix, specify these variables:

```
export AWS_ACCESS_KEY_ID="YOUR_AWS_ACCESS_KEY_ID"
export AWS_SECRET_ACCESS_KEY="YOUR_AWS_SECRET_ACCESS_KEY"
export AWS_DEFAULT_REGION="us-east-1"
```

On Windows, specify these variables:

```
set AWS_ACCESS_KEY_ID="YOUR_AWS_ACCESS_KEY_ID"
set AWS_SECRET_ACCESS_KEY="YOUR_AWS_SECRET_ACCESS_KEY"
set AWS_DEFAULT_REGION="us-east-1"
```

To specify these environment variables permanently, set them in your user or system environment.

3. Create a bucket for your data by using either the AWS S3 web page or a command such as the following:

```
aws s3 mb s3://mynewbucket
```

4. Upload your data using a command such as the following:

```
aws s3 cp mylocaldatapath s3://mynewbucket --recursive
```

For example:

```
aws s3 cp path/to/CIFAR10/in/the/local/machine s3://MyExampleCloudData/cifar10/ --recursive
```

5. Copy your AWS credentials to your cluster workers by completing these steps in MATLAB:

a. In the **Environment** section on the **Home** tab, select **Parallel > Create and Manage Clusters**.

b. In the **Cluster Profile** pane of the Cluster Profile Manager, select your cloud cluster profile.

c. In the **Properties** tab, select the **EnvironmentVariables** property, scrolling as necessary to find the property.

d. At the bottom right of the window, click **Edit**.

e. Click in the box to the right of **EnvironmentVariables**, and then type these three variables, each on its own line: `AWS_ACCESS_KEY_ID`, `AWS_SECRET_ACCESS_KEY`, and `AWS_DEFAULT_REGION`.

f. At the bottom right of the window, click **Done**.

For information on how to create a cloud cluster, see “Create Cloud Cluster” (Parallel Computing Toolbox).

Use Data Set in MATLAB

After you store your data in Amazon S3, you can use datastores to access the data from your cluster workers. Simply create a datastore pointing to the URL of the S3 bucket. The following sample code shows how to use an `imageDatastore` to access an S3 bucket. Replace `'s3://MyExampleCloudData/cifar10/train'` with the URL of your S3 bucket.

```
imds = imageDatastore('s3://MyExampleCloudData/cifar10/train', ...
 'IncludeSubfolders',true, ...
 'LabelSource','foldernames');
```

With the CIFAR-10 data set now stored in Amazon S3, you can try any of the examples in “Deep Learning in Parallel and in the Cloud” that show how to use CIFAR-10 in different use cases.

Train Network in Parallel with Custom Training Loop

This example shows how to set up a custom training loop to train a network in parallel. In this example, parallel workers train on portions of the overall mini-batch. If you have a GPU, then training happens on the GPU. During training, a `DataQueue` object sends training progress information back to the MATLAB client.

Load Data Set

Load the digit data set and create an image datastore for the data set. Split the datastore into training and test datastores in a randomized way. Create an `augmentedImageDatastore` containing the training data.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet','nndemos', ...
    'nndatasets','DigitDataset');
imds = imageDatastore(digitDatasetPath, ...
    'IncludeSubfolders',true, ...
    'LabelSource','foldernames');

[imdsTrain,imdsTest] = splitEachLabel(imds,0.9,"randomized");

inputSize = [28 28 1];
augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain);
```

Determine the different classes in the training set.

```
classes = categories(imdsTrain.Labels);
numClasses = numel(classes);
```

Define Network

Define your network architecture and make it into a layer graph by using the `layerGraph` function. This network architecture includes batch normalization layers, which track the mean and variance statistics of the data set. When training in parallel, combine the statistics from all of the workers at the end of each iteration step, to ensure the network state reflects the whole mini-batch. Otherwise, the network state can diverge across the workers. If you are training stateful recurrent neural networks (RNNs), for example, using sequence data that has been split into smaller sequences to train networks containing LSTM or GRU layers, you must also manage the state between the workers.

```
layers = [
    imageInputLayer([28 28 1],'Name','input','Normalization','none')
    convolution2dLayer(5,20,'Name','conv1')
    batchNormalizationLayer('Name','bn1')
    reluLayer('Name','relu1')
    convolution2dLayer(3,20,'Padding',1,'Name','conv2')
    batchNormalizationLayer('Name','bn2')
    reluLayer('Name','relu2')
    convolution2dLayer(3,20,'Padding',1,'Name','conv3')
    batchNormalizationLayer('Name','bn3')
    reluLayer('Name','relu3')
    fullyConnectedLayer(numClasses,'Name','fc')];

lgraph = layerGraph(layers);
```

Create a `dlnetwork` object from the layer graph. `dlnetwork` objects allow for training with custom loops.

```
dlnet = dlnetwork(lgraph)
```

```
dlnet =
  dlnetwork with properties:

         Layers: [11×1 nnet.cnn.layer.Layer]
    Connections: [10×2 table]
     Learnables: [14×3 table]
          State: [6×3 table]
     InputNames: {'input'}
    OutputNames: {'fc'}
    Initialized: 1
```

Set Up Parallel Environment

Determine if GPUs are available for MATLAB to use with the `canUseGPU` function.

- If there are GPUs available, then train on the GPUs. Create a parallel pool with as many workers as GPUs.
- If there are no GPUs available, then train on the CPUs. Create a parallel pool with the default number of workers.

```
if canUseGPU
    executionEnvironment = "gpu";
    numberOfGPUs = gpuDeviceCount("available");
    pool = parpool(numberOfGPUs);
else
    executionEnvironment = "cpu";
    pool = parpool;
end
```

```
Starting parallel pool (parpool) using the 'local' profile ...
Connected to the parallel pool (number of workers: 4).
```

Get the number of workers in the parallel pool. Later in this example, you divide the workload according to this number.

```
N = pool.NumWorkers;
```

Train Model

Specify the training options.

```
numEpochs = 20;
miniBatchSize = 128;
velocity = [];
```

For GPU training, a recommended practice is to scale up the mini-batch size linearly with the number of GPUs, in order to keep the workload on each GPU constant. For more related advice, see “Deep Learning with MATLAB on Multiple GPUs” on page 7-13.

```
if executionEnvironment == "gpu"
    miniBatchSize = miniBatchSize .* N
end
```

```
miniBatchSize = 512
```

Calculate the mini-batch size for each worker by dividing the overall mini-batch size evenly among the workers. Distribute the remainder across the first workers.

```
workerMiniBatchSize = floor(miniBatchSize ./ repmat(N,1,N));
remainder = miniBatchSize - sum(workerMiniBatchSize);
workerMiniBatchSize = workerMiniBatchSize + [ones(1,remainder) zeros(1,N-remainder)]
```

```
workerMiniBatchSize = 1×4

   128   128   128   128
```

This network contains batch normalization layers that keep track of the mean and variance of the data the network is trained on. Since each worker processes a portion of each mini-batch during each iteration, the mean and variance must be aggregated across all the workers. Find the indices of the mean and variance state parameters of the batch normalization layers in the network state property.

```
batchNormLayers = arrayfun(@(l)isa(l,'nnet.cnn.layer.BatchNormalizationLayer'),dlnet.Layers);
batchNormLayersNames = string({dlnet.Layers(batchNormLayers).Name});
state = dlnet.State;
isBatchNormalizationStateMean = ismember(state.Layer,batchNormLayersNames) & state.Parameter == '
isBatchNormalizationStateVariance = ismember(state.Layer,batchNormLayersNames) & state.Parameter
```

Initialize the training progress plot.

```
figure
lineLossTrain = animatedline('Color',[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Iteration")
ylabel("Loss")
grid on
```

To send data back from the workers during training, create a `DataQueue` object. Use `afterEach` to set up a function, `displayTrainingProgress`, to call each time a worker sends data. `displayTrainingProgress` is a supporting function, defined at the end of this example, that displays the training progress information that comes from the workers.

```
Q = parallel.pool.DataQueue;
displayFcn = @(x) displayTrainingProgress(x,lineLossTrain);
afterEach(Q,displayFcn);
```

Train the model using a custom parallel training loop, as detailed in the following steps. To execute the code simultaneously on all the workers, use an `spmd` block. Within the `spmd` block, `labindex` gives the index of the worker currently executing the code.

Before training, partition the datastore for each worker by using the `partition` function. Use the partitioned datastore to create a `minibatchqueue` on each worker. For each mini-batch:

- Use the custom mini-batch preprocessing function `preprocessMiniBatch` (defined at the end of this example) to normalize the data, convert the labels to one-hot encoded variables, and determine the number of observations in the mini-batch.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels or the number of observations.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a

supported GPU device. For information on supported devices, see “GPU Support by Release” (Parallel Computing Toolbox) (Parallel Computing Toolbox).

For each epoch, reset and shuffle the datastore with the `reset` and `shuffle` functions. For each iteration in the epoch:

- Ensure that all workers have data available before beginning processing it in parallel, by performing a global `and` operation (`gop`) on the result of the `hasdata` function.
- Read a mini-batch from the `minibatchqueue` by using the `next` function.
- Compute the gradients and the loss of the network on each worker by calling `dlfeval` on the `modelGradients` function. The `dlfeval` function evaluates the helper function `modelGradients` with automatic differentiation enabled, so `modelGradients` can compute the gradients with respect to the loss in an automatic way. `modelGradients` is defined at the end of the example and returns loss and gradients given a network, mini-batch of data, and true labels.
- To obtain the overall loss, aggregate the losses on all workers. This example uses cross entropy for the loss function, and the aggregated loss is the sum of all losses. Before aggregating, normalize each loss by multiplying by the proportion of the overall mini-batch that the worker is working on. Use `gplus` to add all losses together and replicate the results across workers.
- To aggregate and update the gradients of all workers, use the `dlupdate` function with the `aggregateGradients` function. `aggregateGradients` is a supporting function defined at the end of this example. This function uses `gplus` to add together and replicate gradients across workers, following normalization according to the proportion of the overall mini-batch that each worker is working on.
- Aggregate the state of the network on all workers using the `aggregateState` function. `aggregateState` is a supporting function defined at the end of this example. The batch normalization layers in the network track the mean and variance of the data. Since the complete mini-batch is spread across multiple workers, aggregate the network state after each iteration to compute the mean and variance of the whole minibatch.
- After computing the final gradients, update the network learnable parameters with the `sgdmupdate` function.
- Send training progress information back to the client by using the `send` function with the `DataQueue`. Use only one worker to send data, because all workers have the same loss information. To ensure that data is on the CPU, so that a client machine without a GPU can access it, use `gather` on the `dlarray` before sending it.

```
start = tic;
spmd
    % Reset and shuffle the datastore.
    reset(augimdsTrain);
    augimdsTrain = shuffle(augimdsTrain);

    % Partition datastore.
    workerImds = partition(augimdsTrain,N,labindex);

    % Create minibatchqueue using partitioned datastore on each worker
    workerMbq = minibatchqueue(workerImds,3,...
        "MiniBatchSize",workerMiniBatchSize(labindex),...
        "MiniBatchFcn",@preprocessMiniBatch,...
        "MiniBatchFormat",{'SSCB','',''});

    workerVelocity = velocity;
```

```
    iteration = 0;

    for epoch = 1:numEpochs
        shuffle(workerMbq);

        % Loop over mini-batches.
        while gop(@and,hasdata(workerMbq))
            iteration = iteration + 1;

            % Read a mini-batch of data.
            [dlworkerX,workerY,workerNumObservations] = next(workerMbq);

            % Evaluate the model gradients and loss on the worker.
            [workerGradients,dlworkerLoss,workerState] = dlfeval(@modelGradients,dlnet,dlworkerX

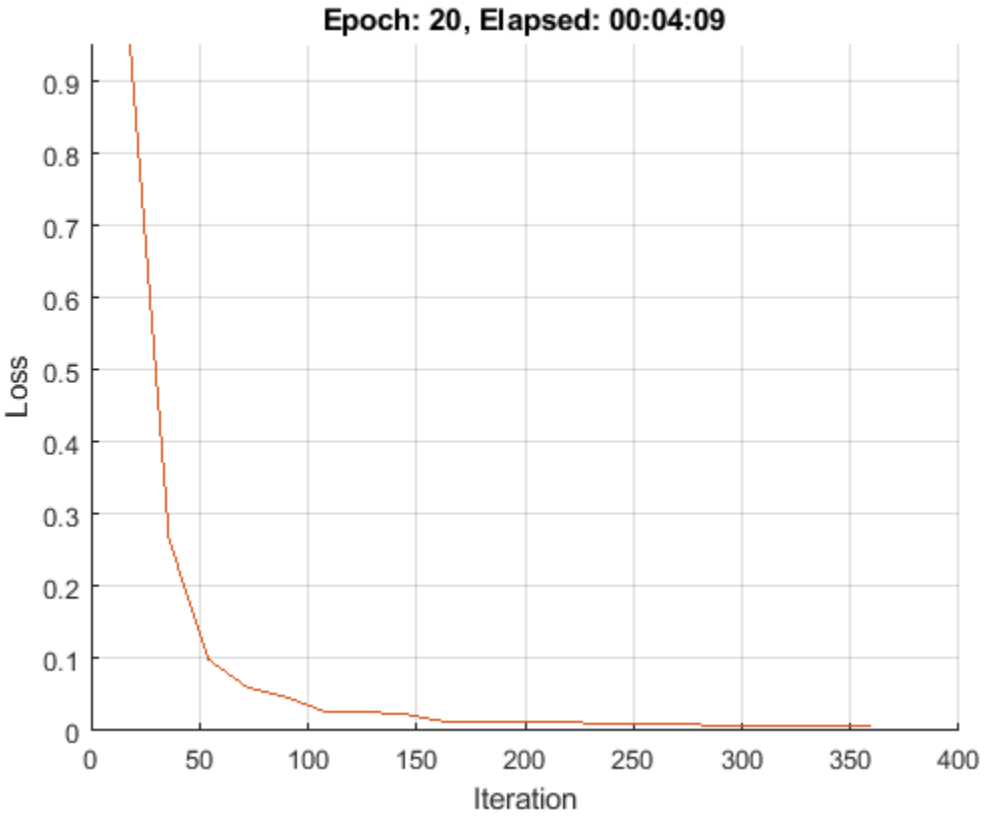
            % Aggregate the losses on all workers.
            workerNormalizationFactor = workerMiniBatchSize(labindex)./miniBatchSize;
            loss = gplus(workerNormalizationFactor*extractdata(dlworkerLoss));

            % Aggregate the network state on all workers
            dlnet.State = aggregateState(workerState,workerNormalizationFactor,...
                isBatchNormalizationStateMean,isBatchNormalizationStateVariance);

            % Aggregate the gradients on all workers.
            workerGradients.Value = dlupdate(@aggregateGradients,workerGradients.Value,{workerNo

            % Update the network parameters using the SGDM optimizer.
            [dlnet.Learnables,workerVelocity] = sgdmupdate(dlnet.Learnables,workerGradients,worke
        end

       % Display training progress information.
       if labindex == 1
           data = [epoch loss iteration toc(start)];
           send(Q,gather(data));
       end
    end
end
```



Test Model

After you train the network, you can test its accuracy.

Load the test images into memory by using `readall` on the test datastore, concatenate them, and normalize them.

```
XTest = readall(imdsTest);
XTest = cat(4,XTest{:});
XTest = single(XTest) ./ 255;
YTest = imdsTest.Labels;
```

After the training is complete, all workers have the same complete trained network. Retrieve any of them.

```
dlnetFinal = dlnet{1};
```

To classify images using a `dlnetwork` object, use the `predict` function on a `dlarray`.

```
dlYPredScores = predict(dlnetFinal,dlarray(XTest,'SSCB'));
```

From the predicted scores, find the class with the highest score with the `max` function. Before you do that, extract the data from the `dlarray` with the `extractdata` function.

```
[~,idx] = max(extractdata(dlYPredScores),[],1);
YPred = classes(idx);
```

To obtain the classification accuracy of the model, compare the predictions on the test set against the true labels.

```
accuracy = mean(YPred==YTest)
```

```
accuracy = 0.8960
```

Mini Batch Preprocessing Function

The `preprocessMiniBatch` function preprocesses a mini-batch of predictors and labels using the following steps:

1. Determine the number of observations in the mini-batch
2. Preprocess the images using the `preprocessMiniBatchPredictors` function.
3. Extract the label data from the incoming cell array and concatenate into a categorical array along the second dimension.
4. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y,numObs] = preprocessMiniBatch(XCell,YCell)

numObs = numel(YCell);

% Preprocess predictors.
X = preprocessMiniBatchPredictors(XCell);

% Extract label data from cell and concatenate.
Y = cat(2,YCell{1:end});

% One-hot encode labels.
Y = onehotencode(Y,1);

end
```

Mini-Batch Predictors Preprocessing Function

The `preprocessMiniBatchPredictors` function preprocesses a mini-batch of predictors by extracting the image data from the input cell array and concatenate into a numeric array. For grayscale input, concatenating over the fourth dimension adds a third dimension to each image, to use as a singleton channel dimension. The data are then normalized.

```
function X = preprocessMiniBatchPredictors(XCell)

% Concatenate.
X = cat(4,XCell{1:end});

% Normalize.
X =  X ./ 255;

end
```

Model Gradients Functions

Define a function, `modelGradients`, to compute the gradients of the loss with respect to the learnable parameters of the network. This function computes the network outputs for a mini-batch `X` with `forward` and `softmax` and calculates the loss, given the true outputs, using cross entropy.

When you call this function with `dlfeval`, automatic differentiation is enabled, and `dlgradient` can compute the gradients of the loss with respect to the learnables automatically.

```
function [dlgradients,dlloss,state] = modelGradients(dlnet,dlX,dlY)
    [dlYPred,state] = forward(dlnet,dlX);
    dlYPred = softmax(dlYPred);

    dlloss = crossentropy(dlYPred,dlY);
    dlgradients = dlgradient(dlloss,dlnet.Learnables);
end
```

Display Training Progress Function

Define a function to display training progress information that comes from the workers. The `DataQueue` in this example calls this function every time a worker sends data.

```
function displayTrainingProgress (data,line)
     addpoints(line,double(data(3)),double(data(2)))
     D = duration(0,0,data(4),'Format','hh:mm:ss');
     title("Epoch: " + data(1) + ", Elapsed: " + string(D))
     drawnow
end
```

Aggregate Gradients Function

Define a function that aggregates the gradients on all workers by adding them together. `gplus` adds together and replicates all the gradients on the workers. Before adding them together, normalize them by multiplying them by a factor that represents the proportion of the overall mini-batch that the worker is working on. To retrieve the contents of a `dlarray`, use `extractdata`.

```
function gradients = aggregateGradients(dlgradients,factor)
    gradients = extractdata(dlgradients);
    gradients = gplus(factor*gradients);
end
```

Aggregate State Function

Define a function that aggregates the network state on all workers. The network state contains the trained batch normalization statistics of the data set. Since each worker only sees a portion of the mini-batch, aggregate the network state so that the statistics are representative of the statistics across all the data. For each mini-batch, the combined mean is calculated as a weighted average of the mean across the workers for each iteration. The combined variance is calculated according to the following formula:

$$s_c^2 = \frac{1}{M}\sum_{j=1}^{N} m_j\left[s_j^2 + \left(\bar{x}_j - \bar{x}_c\right)^2\right]$$

where $N$is the total number of workers, $M$is the total number of observations in a mini-batch, m_j is the number of observations processed on the jth worker, $\bar{x}_j$ and s_j^2 are the mean and variance statistics calculated on that worker, and $\bar{x}_c$ is the combined mean across all workers.

```
function state = aggregateState(state,factor,...
    isBatchNormalizationStateMean,isBatchNormalizationStateVariance)

    stateMeans = state.Value(isBatchNormalizationStateMean);
    stateVariances = state.Value(isBatchNormalizationStateVariance);
```

```
    for j = 1:numel(stateMeans)
        meanVal = stateMeans{j};
        varVal = stateVariances{j};

        % Calculate combined mean
        combinedMean = gplus(factor*meanVal);

        % Calculate combined variance terms to sum
        varTerm = factor.*(varVal + (meanVal - combinedMean).^2);

        % Update state
        stateMeans{j} = combinedMean;
        stateVariances{j} = gplus(varTerm);
    end

    state.Value(isBatchNormalizationStateMean) = stateMeans;
    state.Value(isBatchNormalizationStateVariance) = stateVariances;
end
```

Train Network Using Federated Learning

This example shows how to train a network using federated learning. Federated learning is a technique that enables you to train a network in a distributed, decentralized way [1].

Federated learning allows you to train a model using data from different sources without moving the data to a central location, even if the individual data sources do not match the overall distribution of the data set. This is known as non-independent and identically distributed (non-IID) data. Federated learning can be especially useful when the training data is large, or when there are privacy concerns about transferring the training data.

Instead of distributing data, the federated learning technique trains multiple models, each in the same location as a data source. You can create a global model that has learned from all the data sources by periodically collecting and combining the learnable parameters of the locally trained models. In this way, you can train a global model without centrally processing any training data.

This example uses federated learning to train a classification model in parallel using a highly non-IID dataset. The model is trained using the digits data set, which consists of 10000 handwritten images of the numbers 0 to 9. The example runs in parallel using 10 workers, each processing images of a single digit. By averaging the learnable parameters of the networks after each round of training, the models on each worker improve performance across all classes, without ever processing data of the other classes.

While data privacy is one of the applications of federated learning, this example does not deal with the details of maintaining data privacy and security. This example demonstrates the basic federated learning algorithm.

Set Up Parallel Environment

Create a parallel pool with the same number of workers as classes in the data set. For this example, use a local parallel pool with 10 workers.

```
pool = parpool('local',10);
numWorkers = pool.NumWorkers;
```

Load Data Set

All data used in this example is initially stored in a centralized location. To make this data highly non-IID, you need to distribute the data among the workers according to class. To create validation and test data sets, transfer a portion of data from the workers to the client. After the data is correctly set up, with training data of individual classes on the workers and test and validation data of all classes on the client, there is no further transfer of data during training.

Specify the folder containing the image data.

```
digitDatasetPath = fullfile(matlabroot,'toolbox','nnet','nndemos',...
    'nndatasets','DigitDataset');
```

Distribute the data among the workers. Each worker receives images of only one digit, such that worker 1 receives all the images of the number 0, worker 2 receives images of the number 1, etc.

Images of each digit are stored in a separate folder with the name of that digit. On each worker, use the `fullfile` function to specify the path to a specific class folder. Then, create an `imageDatastore` that contains all images of that digit. Next, use the `splitEachLabel` function to

randomly separate 30% of the data for use in validation and testing. Finally, create an `augmentedImageDatastore` containing the training data.

```
inputSize = [28 28 1];
spmd
    digitDatasetPath = fullfile(digitDatasetPath,num2str(labindex - 1));
    imds = imageDatastore(digitDatasetPath,...
        'IncludeSubfolders',true,...
        'LabelSource','foldernames');
    [imdsTrain,imdsTestVal] = splitEachLabel(imds,0.7,"randomized");

    augimdsTrain = augmentedImageDatastore(inputSize(1:2),imdsTrain);
end
```

To test the performance of the combined global model during and after training, create test and validation datasets containing images from all classes. Combine the test and validation data from each worker into a single datastore. Then, split this datastore into two datastores that each contain 15% of the overall data - one for validating the network during training and the other for testing the network after training.

```
fileList = [];
labelList = [];

for i = 1:numWorkers
    tmp = imdsTestVal{i};

    fileList = cat(1,fileList,tmp.Files);
    labelList = cat(1,labelList,tmp.Labels);
end

imdsGlobalTestVal = imageDatastore(fileList);
imdsGlobalTestVal.Labels = labelList;

[imdsGlobalTest,imdsGlobalVal] = splitEachLabel(imdsGlobalTestVal,0.5,"randomized");

augimdsGlobalTest = augmentedImageDatastore(inputSize(1:2),imdsGlobalTest);
augimdsGlobalVal = augmentedImageDatastore(inputSize(1:2),imdsGlobalVal);
```

The data is now arranged such that each worker has data from a single class to train on, and the client holds validation and test data from all classes.

Define Network

Determine the number of classes in the data set.

```
classes = categories(imdsGlobalTest.Labels);
numClasses = numel(classes);
```

Define the network architecture.

```
layers = [
    imageInputLayer(inputSize,'Normalization','none','Name','input')
    convolution2dLayer(5,32,'Name','conv1')
    reluLayer('Name','relu1')
    maxPooling2dLayer(2,'Name','maxpool1')
    convolution2dLayer(5,64,'Name','conv2')
    reluLayer('Name','relu2')
    maxPooling2dLayer(2,'Name','maxpool2')
```

```
    fullyConnectedLayer(numClasses,'Name','fc')
    softmaxLayer('Name','softmax')];
```

Create a dlnetwork object from the layers.

```
dlnet = dlnetwork(layers)
```

```
dlnet =
  dlnetwork with properties:

         Layers: [9×1 nnet.cnn.layer.Layer]
    Connections: [8×2 table]
     Learnables: [6×3 table]
          State: [0×3 table]
     InputNames: {'input'}
    OutputNames: {'softmax'}
    Initialized: 1
```

Define Model Gradients Function

Create the function `modelGradients`, listed in the Model Gradients Function on page 7-0 section of this example, that takes a `dlnetwork` object and a mini-batch of input data with corresponding labels and returns the gradients of the loss with respect to the learnable parameters in the network and the corresponding loss.

Define Federated Averaging Function

Create the function `federatedAveraging`, listed in the the Federated Averaging Function on page 7-0 section of this example, that takes the learnable parameters of the networks on each worker and the normalization factor for each worker, and returns the averaged learnable parameters across all the networks. Use the average learnable parameters to update the global network and the network on each worker.

Define Compute Accuracy Function

Create the function `computeAccuracy`, listed in the Compute Accuracy Function on page 7-0 section of this example, that takes a `dlnetwork` object, a data set inside a `minibatchqueue` object, and the list of classes, and returns the accuracy of the predictions across all observations in the data set.

Specify Training Options

During training, the workers periodically communicate their network learnable parameters to the client, so that the client can update the global model. The training is divided into rounds. At the end of each round of training, the learnable parameters are averaged and the global model is updated. The worker models are then replaced with the new global model, and training continues on the workers.

Train for 300 rounds, with 5 epochs per round. Training for a small numer of epochs per round ensures that the networks on the workers do not diverge too far before they are averaged.

```
numRounds = 300;
numEpochsperRound = 5;
miniBatchSize = 100;
```

Specify the options for SGD optimization. Specify an initial learn rate of 0.001 and momentum 0.

```
learnRate = 0.001;
momentum = 0;
```

Train Model

Create a function handle to the custom mini-batch preprocessing function `preprocessMiniBatch` (defined in the Mini-Batch Preprocessing Function on page 7-0 section of this example).

On each worker, find the total number of training observations processed locally on that worker. Use this number to normalize the learnable parameters on each worker when you find the average learnable parameters after each communicaton round. This helps to balance the average if there is a difference between the amount of data on each worker.

On each worker, create a `minibatchqueue` object that processes and manages mini-batches of images during training. For each mini-batch:

- Preprocess the data using the custom mini-batch preprocessing function `preprocessMiniBatch` to convert the labels to one-hot encoded variables.
- Format the image data with the dimension labels `'SSCB'` (spatial, spatial, channel, batch). By default, the `minibatchqueue` object converts the data to `dlarray` objects with underlying type `single`. Do not add a format to the class labels.
- Train on a GPU if one is available. By default, the `minibatchqueue` object converts each output to a `gpuArray` if a GPU is available. Using a GPU requires Parallel Computing Toolbox™ and a supported GPU device. For information on supported devices, see GPU Support by Release (Parallel Computing Toolbox).

```
preProcess = @(x,y)preprocessMiniBatch(x,y,classes);

spmd
    sizeOfLocalDataset = augimdsTrain.NumObservations;

    mbq = minibatchqueue(augimdsTrain,...
        'MiniBatchSize',miniBatchSize,...
        'MiniBatchFcn',preProcess,...
        'MiniBatchFormat',{'SSCB',''});
end
```

Create a `minibatchqueue` object that manages the validation data to use during training. Use the same settings as the `minibatchqueue` on each worker.

```
mbqGlobalVal = minibatchqueue(augimdsGlobalVal,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn',preProcess,...
    'MiniBatchFormat',{'SSCB',''});
```

Initialize the training progress plot.

```
figure
lineAccuracyTrain = animatedline('Color',[0.85 0.325 0.098]);
ylim([0 inf])
xlabel("Communication rounds")
ylabel("Accuracy (Global)")
grid on
```

Initialize the velocity parameter for the SGDM solver.

```
velocity = [];
```

Initialize the global model. To start, the global model has the same initial parameters as the untrained network on each worker.

```
globalModel = dlnet;
```

Train the model using a custom training loop. For each communication round,

- Update the networks on the workers with the latest global network.
- Train the networks on the workers for five epochs.
- Find the average parameters of all the networks using the `federatedAveraging` function.
- Replace the global network parameters with the average value.
- Calculate the accuracy of the updated global network using the validation data.
- Display the training progress.

For each epoch, shuffle the data and loop over mini-batches of data. For each mini-batch:

- Evaluate the model gradients and loss using the `dlfeval` and `modelGradients` functions.
- Update the local network parameters using the `sgdmupdate` function.

```
start = tic;
for rounds = 1:numRounds

    spmd
        % Send global updated parameters to each worker.
        dlnet.Learnables.Value = globalModel.Learnables.Value;

        % Loop over epochs.
        for epoch = 1:numEpochsperRound
            % Shuffle data.
            shuffle(mbq);

            % Loop over mini-batches.
            while hasdata(mbq)

                % Read mini-batch of data.
                [dlX,dlT] = next(mbq);

                % Evaluate the model gradients, state, and loss using dlfeval and the
                % modelGradients function and update the network state.
                [gradients,loss] = dlfeval(@modelGradients,dlnet,dlX,dlT);

                % Update the network parameters using the SGDM optimizer.
                [dlnet,velocity] = sgdmupdate(dlnet,gradients,velocity,learnRate,momentum);

            end
        end

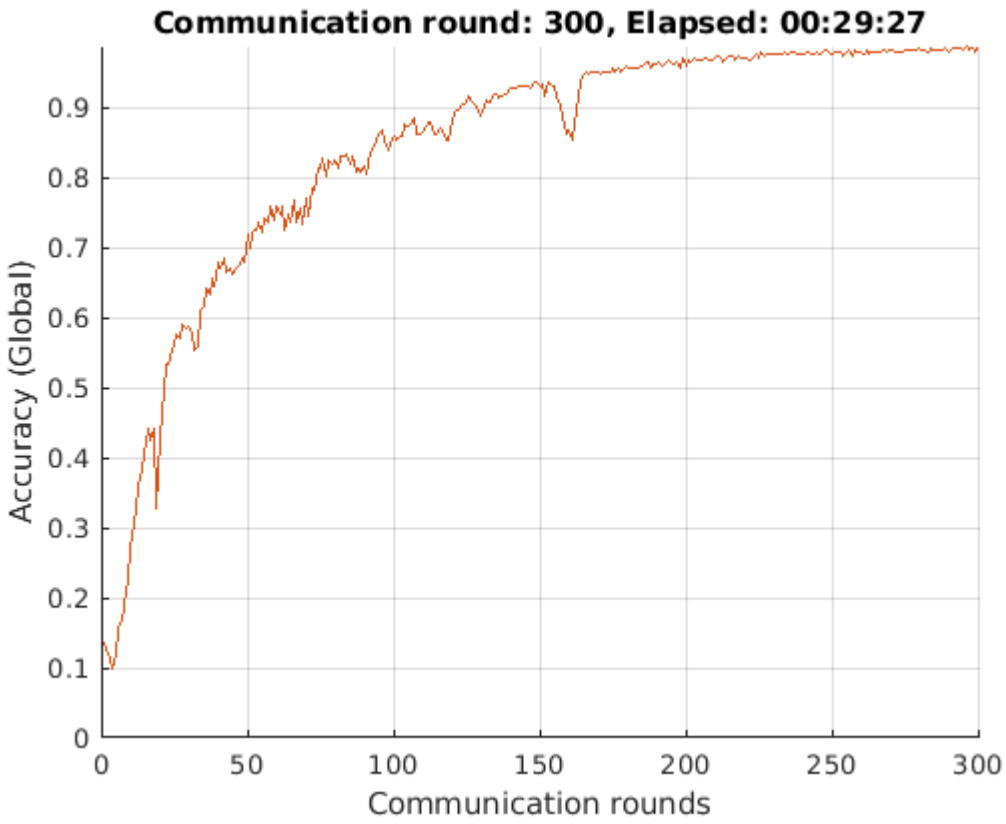
        % Collect updated learnable parameters on each worker.
        workerLearnables = dlnet.Learnables.Value;
    end

    % Find normalization factors for each worker based on ratio of data
    % processed on that worker.
    sizeOfAllDatasets = sum([sizeOfLocalDataset{:}]);
    normalizationFactor = [sizeOfLocalDataset{:}]/sizeOfAllDatasets;
```

```
    % Update the global model with new learnable parameters, normalized and
    % averaged across all workers.
    globalModel.Learnables.Value = federatedAveraging(workerLearnables,normalizationFactor);

    % Calculate the accuracy of the global model.
    accuracy = computeAccuracy(globalModel,mbqGlobalVal,classes);

    % Display the training progress of the global model.
    D = duration(0,0,toc(start),'Format','hh:mm:ss');
    addpoints(lineAccuracyTrain,rounds,double(accuracy))
    title("Communication round: " + rounds + ", Elapsed: " + string(D))
    drawnow
end
```



After the final round of training, update the network on each worker with the final average learnable parameters. This is important if you want to continue to use or train the network on the workers.

```
spmd
    dlnet.Learnables.Value = globalModel.Learnables.Value;
end
```

Test Model

Test the classification accuracy of the model by comparing the predictions on the test set with the true labels.

Create a `minibatchqueue` object that manages the test data. Use the same settings as the `minibatchqueue` objects used during training and validation.

```
mbqGlobalTest = minibatchqueue(augimdsGlobalTest,...
    'MiniBatchSize',miniBatchSize,...
    'MiniBatchFcn',preProcess,...
    'MiniBatchFormat','SSCB');
```

Use the `computePredictions` function to compute the predicted classes and calculate the accuracy of the predictions across all the test data.

```
accuracy = computeAccuracy(globalModel,mbqGlobalTest,classes)
```

```
accuracy = single
    0.9873
```

After you are done with your computations, you can delete your parallel pool. The `gcp` function returns the current parallel pool object so you can delete the pool.

```
delete(gcp('nocreate'));
```

Model Gradients Function

The `modelGradients` function takes a `dlnetwork` object `dlnet`, a mini-batch of input data `dlX` with corresponding labels `T` and returns the gradients of the loss with respect to the learnable parameters in `dlnet` and the loss. To compute the gradients automatically, use the `dlgradient` function. To compute predictions of the network during training, use the `forward` function.

```
function [gradients,loss] = modelGradients(dlnet,dlX,T)

    dlYPred = forward(dlnet,dlX);

    loss = crossentropy(dlYPred,T);
    gradients = dlgradient(loss,dlnet.Learnables);

end
```

Compute Accuracy Function

The `computePredictions` function takes a `dlnetwork` object `dlnet`, a `minibatchqueue` object `mbq`, and the list of classes, and returns the accuracy of all the predictions on the data set provided. To compute predictions of the network during validation or after training is finished, use the `predict` function.

```
function accuracy = computeAccuracy(dlnet,mbq,classes)

    correctPredictions = [];

    shuffle(mbq);
    while hasdata(mbq)

        [dlXTest,dlTTest] = next(mbq);

        TTest = onehotdecode(dlTTest,classes,1)';

        dlYPred = predict(dlnet,dlXTest);
        YPred = onehotdecode(dlYPred,classes,1)';
```

```
        correctPredictions = [correctPredictions; YPred == TTest];
    end

    predSum = sum(correctPredictions);
    accuracy = single(predSum./size(correctPredictions,1));

end
```

Mini-Batch Preprocessing Function

The preprocessMiniBatch function preprocesses the data using the following steps:

1. Extract the image data from the incoming cell array and concatenate into a numeric array. Concatenating the image data over the fourth dimension adds a third dimension to each image, to be used as a singleton channel dimension.
2. Extract the label data from the incoming cell arrays and concatenate into a categorical array along the second dimension.
3. One-hot encode the categorical labels into numeric arrays. Encoding into the first dimension produces an encoded array that matches the shape of the network output.

```
function [X,Y] = preprocessMiniBatch(XCell,YCell,classes)

    % Concatenate.
    X = cat(4,XCell{1:end});

    % Extract label data from cell and concatenate.
    Y = cat(2,YCell{1:end});

    % One-hot encode labels.
    Y = onehotencode(Y,1,'ClassNames',classes);

end
```

Federated Averaging Function

The function `federatedAveraging` function takes the learnable parameters of the networks on each worker and the normalization factor for each worker, and returns the averaged learnable parameters across all the networks. Use the average learnable parameters to update the global network and the network on each worker.

```
function learnables = federatedAveraging(workerLearnables,normalizationFactor)

    numWorkers = size(normalizationFactor,2);

    % Initialize container for averaged learnables with same size as existing
    % learnables. Use learnables of first worker network as an example.
    exampleLearnables = workerLearnables{1};
    learnables = cell(height(exampleLearnables),1);

    for i = 1:height(learnables)
        learnables{i} = zeros(size(exampleLearnables{i}),'like',(exampleLearnables{i}));
    end

    % Add the normalized learnable parameters of all workers to
    % calculate average values.
    for i = 1:numWorkers
        tmp = workerLearnables{i};
```

```
        for values = 1:numel(learnables)
            learnables{values} = learnables{values} + normalizationFactor(i).*tmp{values};
        end
    end

end
```

Computer Vision Examples

Gesture Recognition using Videos and Deep Learning

This example first shows how to perform gesture recognition using a pretrained SlowFast [1] on page 8-0 video classifier and then shows how to use transfer learning to train a classifier on a custom gesture recognition data set.

Overview

Vision-based human gesture recognition involves predicting a gesture, such as waving hello, sign language gestures, or clapping, using a set of video frames. One of the appealing features of gesture recognition is that they make it possible for humans to communicate with computers and devices without the need for an external input equipment such as a mouse or a remote control. Gesture recognition from videos has many applications, such as control of consumer electronics and mechanical systems, robot learning, and computer games. For example, online prediction of multiple actions for incoming videos from multiple cameras can be important for robot learning. Compared to image classification, human gesture recognition using videos is challenging to model because of the inaccurate ground truth data for video data sets, the variety of gestures that actors in a video can perform, the heavily class imbalanced data sets, and the large amount of data required to train a robust classifier from scratch. Deep learning techniques, such as SlowFast two pathway convolutional networks [1] on page 8-0 , have shown improved performance on smaller data sets using transfer learning with networks pretrained on large video activity recognition data sets.

Note: This example requires the Computer Vision Toolbox™ Model for SlowFast Video Classification. You can install the Computer Vision Toolbox Model for SlowFast Video Classification from Add-On Explorer. For more information about installing add-ons, see “Get and Manage Add-Ons”.

Perform Gesture Recognition Using a Pretrained Video Classifier

Download the pretrained SlowFast video classifier along with a video file on which to perform gesture recognition. The size of the downloaded zip file is around 245 MB.

```
downloadFolder = fullfile(tempdir,"gesture");
if ~isfolder(downloadFolder)
    mkdir(downloadFolder);
end

zipFile = "slowFastPretrained_fourClasses.zip";

if ~isfile(fullfile(downloadFolder,zipFile))
    disp('Downloading the pretrained network...');
    downloadURL = "https://ssd.mathworks.com/supportfiles/vision/data/" + zipFile;
    zipFile = fullfile(downloadFolder,zipFile);
    websave(zipFile,downloadURL);
    unzip(zipFile,downloadFolder);
    disp("Downloaded.")
end
```

```
Downloading the pretrained network...

Downloaded.
```

Load the pretrained SlowFast video classifier.

```
pretrainedDataFile = fullfile(downloadFolder,"slowFastPretrained_fourClasses.mat");
pretrained = load(pretrainedDataFile);
slowFastClassifier = pretrained.data.slowFast;
```

Display the class label names of the pretrained video classifier.

```
classes = slowFastClassifier.Classes
```

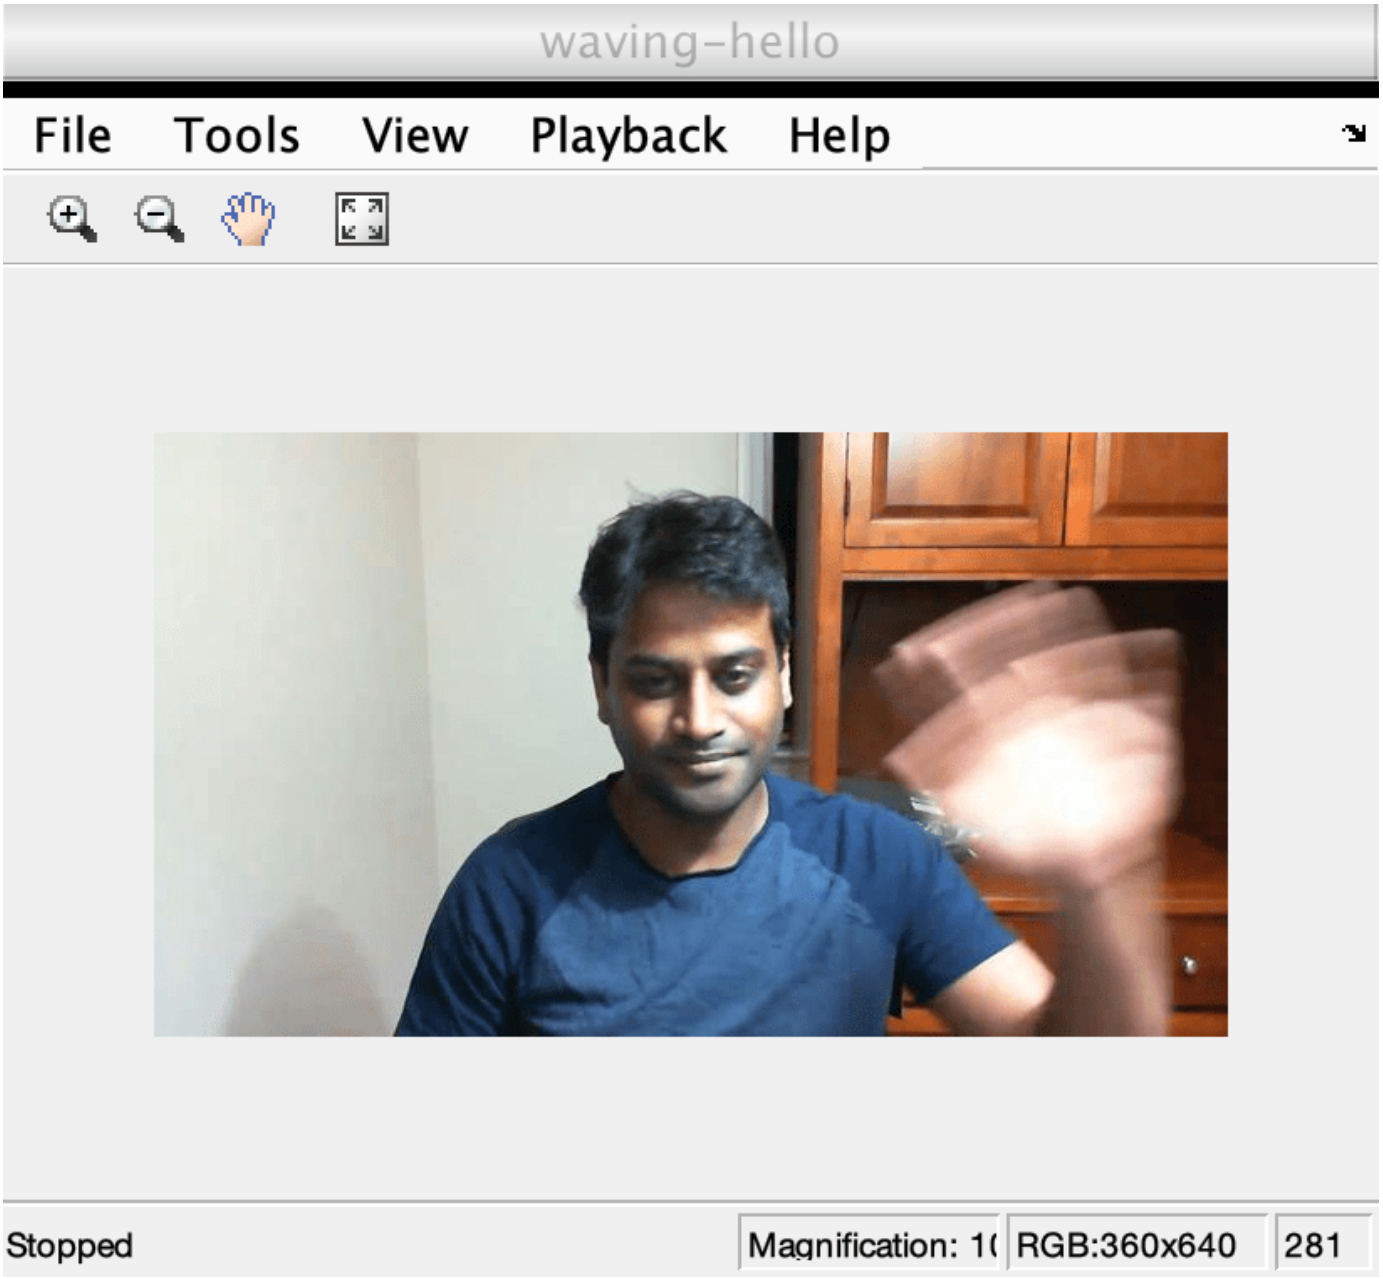
```
classes = 4×1 categorical
     clapping
     noAction
     somethingElse
     wavingHello
```

Read and display the video `waving-hello.avi` using `VideoReader` and `vision.VideoPlayer`.

```
videoFilename = fullfile(downloadFolder,"waving-hello.avi");

videoReader = VideoReader(videoFilename);
videoPlayer = vision.VideoPlayer;
videoPlayer.Name = "waving-hello";

while hasFrame(videoReader)
   frame = readFrame(videoReader);
   step(videoPlayer,frame);
end
release(videoPlayer);
```



Choose 10 randomly selected video sequences to classify the video, to uniformly cover the entirety of the file to find the action class that is predominant in the video.

```
numSequences = 10;
```

Classify the video file using the `classifyVideoFile` function.

```
[gestureLabel,score] = classifyVideoFile(slowFastClassifier,videoFilename,NumSequences=numSequenc
```

```
gestureLabel = categorical
     wavingHello
```

```
score = single
    0.4753
```

The classification can also be applied to a streaming video. To learn how to classify a streaming webcam video, see “Classify Streaming Webcam Video Using SlowFast Video Classifier” (Computer Vision Toolbox).

Train a Video Classifier for Gesture Recognition

This section of the example shows how the video classifier shown above is trained using transfer learning. Set the `doTraining` variable to `false` to use the pretrained video classifier without having to wait for training to complete. Alternatively, if you want to train the video classifier, set the `doTraining` variable to `true`.

```
doTraining = false;
```

Download Ground Truth Training Data

This example trains a SlowFast video classification network using downloadable gesture data set that contains four gestures: `"clapping"`,`"wavingHello"`,`"somethingElse"`, and `"noAction"`. The data set contains videos that are labeled using a Video Labeler and the corresponding ground truth data.

Create directories to store the ground truth training data.

```
groundTruthFolder = fullfile(downloadFolder,"groundTruthFolder");
if ~isfolder(groundTruthFolder)
    mkdir(groundTruthFolder);
end
```

Download the data set and extract the zip archive into the `downloadFolder`.

```
zipFile = 'videoClipsAndSceneLabels.zip';

if ~isfile(fullfile(groundTruthFolder,zipFile))
    disp('Downloading the ground truth training data...');
    downloadURL = "https://ssd.mathworks.com/supportfiles/vision/data/" + zipFile;
    zipFile = fullfile(groundTruthFolder,zipFile);
    websave(zipFile,downloadURL);
    unzip(zipFile,groundTruthFolder);
end
```

Extract Training Video Sequences

To train a video classifier, you need a collection of videos and its corresponding collection of scene labels. Use the helper function extractVideoScenes, defined at the end of this example, to extract labeled video scenes from the ground truth data and write them to disk as separate video files. To learn more about extracting training data from videos, see “Extract Training Data for Video Classification” (Computer Vision Toolbox).

```
groundTruthFolder = fullfile(downloadFolder,"groundTruthFolder");
trainingFolder = fullfile(downloadFolder,"videoScenes");

extractVideoScenes(groundTruthFolder,trainingFolder,classes);
```

A total of 40 video scenes are extracted from the downloaded ground truth data.

Load data set

This example uses a datastore to read the videos scenes and labels extracted from the ground truth data.

Specify the number of video frames the datastore should be configured to output for each time data is read from the datastore.

```
numFrames = 16;
```

A value of 16 is used here to balance memory usage and classification time. Common values to consider are 8, 16, 32, 64, or 128. Using more frames helps capture additional temporal information, but requires more memory. Empirical analysis is required to determine the optimal number of frames.

Next, specify the height and width of the frames the datastore should be configured to output. The datastore automatically resizes the raw video frames to the specified size to enable batch processing of multiple video sequences.

```
frameSize = [112,112];
```

A value of [112 112] is used to capture longer temporal relationships in the video scene which help classify gestures with long time durations. Common values for the size are [112 112], [224 224], or [256 256]. Smaller sizes enable the use of more video frames at the cost of memory usage, processing time, and spatial resolution. As with the number of frames, empirical analysis is required to determine the optimal values.

Specify the number of channels as 3, as the videos are RGB.

```
numChannels = 3;
```

Use the helper function, `createFileDatastore`, to configure a `FileDatastore` for loading the data. The helper function is listed at the end of this example.

```
isDataForTraining = true;
dsTrain = createFileDatastore(trainingFolder,numFrames,numChannels,classes,isDataForTraining);
```

Configure SlowFast Video Classifier for Transfer Learning

Create a SlowFast video classifier for transfer learning by using the `slowFastVideoClassifier` function. The `slowFastVideoClassifier` function creates a SlowFast video classifier object that is pretrained on the Kinetics-400 data set [2 on page 8-0].

Specify ResNet-50 as the base network convolution neural network 3D architecture for the SlowFast classifier.

```
baseNetwork = "resnet50-3d";
```

Specify the input size for the SlowFast video classifier.

```
inputSize = [frameSize,numChannels,numFrames];
```

Create a SlowFast video classifier by specifying the classes for the gesture data set and the network input size.

```
slowFast = slowFastVideoClassifier(baseNetwork,string(classes),InputSize=inputSize);
```

Specify a model name for the video classifier.

```
slowFast.ModelName = "Gesture Recognizer Using Deep Learning";
```

Augment and Preprocess Training Data

Data augmentation provides a way to use limited data sets for training. Augmentation on video data must be the same for a collection of frames based on the network input size. Minor changes, such as translation, cropping, or transforming an image, provide, new, distinct, and unique images that you can use to train a robust video classifier. Datastores are a convenient way to read and augment collections of data. Augment the training video data by using the `augmentVideo` supporting function, defined at the end of this example.

```
dsTrain = transform(dsTrain,@augmentVideo);
```

Preprocess the training video data to resize to the SlowFast video classifier input size, by using the `preprocessVideoClips`, defined at the end of this example. Specify the `InputNormalizationStatistics` property of the video classifier and input size to the preprocessing function as field values in a struct, `preprocessInfo`. The `InputNormalizationStatistics` property is used to rescale the video frames between 0 and 1, and then normalize the rescaled data using mean and standard deviation. The input size is used to resize the video frames using `imresize` based on the `SizingOption` value in the `info` struct. Alternatively, you could use `"randomcrop"` or `"centercrop"` as values for `SizingOption` to random crop or center crop the input data to the input size of the video classifier.

```
preprocessInfo.Statistics   = slowFast.InputNormalizationStatistics;
preprocessInfo.InputSize    = inputSize;
preprocessInfo.SizingOption = "resize";

dsTrain = transform(dsTrain,@(data)preprocessVideoClips(data,preprocessInfo));
```

Define Model Gradients Function

The `modelGradients` function, listed at the end of this example, takes as input the SlowFast video classifier `slowFast`, a mini-batch of input data `dlRGB`, and a mini-batch of ground truth label data `dlY`. The function returns the training loss value, the gradients of the loss with respect to the learnable parameters of the classifier, and the mini-batch accuracy of the classifier.

The loss is calculated by computing the cross-entropy loss of the predictions from video classifier. The output predictions of the network are probabilities between 0 and 1 for each of the classes.

$$predictions = forward(slowFast, dlRGB);$$

$$loss = crossentropy(predictions)$$

The accuracy of the classifier is calculated by comparing the classifier `predictions` to the ground truth label of the inputs, `dlY`.

Specify Training Options

Train with a mini-batch size of 5 for 600 iterations. Specify the iteration after which to save the model with the best mini-batch loss by using the `SaveBestAfterIteration` parameter.

Specify the cosine-annealing learning rate schedule [3 on page 8-0] parameters:

- A minimum learning rate of 1e-4.
- A maximum learning rate of 1e-3.

- Cosine number of iterations of 200, 300, and 400, after which the learning rate schedule cycle restarts. The option `CosineNumIterations` defines the width of each cosine cycle.

Specify the parameters for SGDM optimization. Initialize the SGDM optimization parameters at the beginning of the training:

- A momentum of 0.9.
- An initial velocity parameter initialized as `[]`.
- An L2 regularization factor of 0.0005.

Specify to dispatch the data in the background using a parallel pool. If `DispatchInBackground` is set to true, open a parallel pool with the specified number of parallel workers, and create a `DispatchInBackgroundDatastore`, provided as part of this example, that dispatches the data in the background to speed up training using asynchronous data loading and preprocessing. By default, this example uses a GPU if one is available. Otherwise, it uses a CPU. Using a GPU requires Parallel Computing Toolbox™ and a CUDA® enabled NVIDIA® GPU. For information about the supported compute capabilities, see “GPU Support by Release” (Parallel Computing Toolbox).

```
params.Classes = classes;
params.MiniBatchSize = 5;
params.NumIterations = 600;
params.CosineNumIterations = [100 200 300];
params.SaveBestAfterIteration = 400;
params.MinLearningRate = 1e-4;
params.MaxLearningRate = 1e-3;
params.Momentum = 0.9;
params.Velocity = [];
params.L2Regularization = 0.0005;
params.ProgressPlot = false;
params.Verbose = true;
params.DispatchInBackground = true;
params.NumWorkers = 12;
```

Train Video Classifier

Train the SlowFast video classifier using the video data.

For each epoch:

- Shuffle the data before looping over mini-batches of data.
- Use `minibatchqueue` to loop over the mini-batches. The supporting function `createMiniBatchQueue`, listed at the end of this example, uses the given training datastore to create a `minibatchqueue`.
- Display the loss and accuracy results for each epoch using the supporting function `displayVerboseOutputEveryEpoch`, listed at the end of this example.

For each mini-batch:

- Convert the video data and the labels to `dlarray` objects with the underlying type single.
- To enable processing the time dimension of the the video data using the SlowFast video classifier specify the temporal sequence dimension, `"T"`. Specify the dimension labels `"SSCTB"` (spatial, spatial, channel, temporal, batch) for the video data, and `"CB"` for the label data.

The `minibatchqueue` object uses the supporting function `batchVideo`, listed at the end of this example, to batch the RGB video data.

```
params.ModelFilename = "slowFastPretrained_fourClasses.mat";
if doTraining
    epoch = 1;
    bestLoss = realmax;
    accTrain = [];
    lossTrain = [];

    iteration = 1;
    start = tic;
    trainTime = start;
    shuffled = shuffleTrainDs(dsTrain);

    % Number of outputs is two: One for RGB frames, and one for ground truth labels.
    numOutputs = 2;
    mbq = createMiniBatchQueue(shuffled, numOutputs, params);

    % Use the initializeTrainingProgressPlot and initializeVerboseOutput
    % supporting functions, listed at the end of the example, to initialize
    % the training progress plot and verbose output to display the training
    % loss, training accuracy, and validation accuracy.
    plotters = initializeTrainingProgressPlot(params);
    initializeVerboseOutput(params);

    while iteration <= params.NumIterations

        % Iterate through the data set.
        [dlX1,dlY] = next(mbq);

        % Evaluate the model gradients and loss using dlfeval.
        [gradients,loss,acc,state] = ...
            dlfeval(@modelGradients,slowFast,dlX1,dlY);

        % Accumulate the loss and accuracies.
        lossTrain = [lossTrain, loss];
        accTrain = [accTrain, acc];

        % Update the network state.
        slowFast.State = state;

        % Update the gradients and parameters for the video classifier
        % using the SGDM optimizer.
        [slowFast,params.Velocity,learnRate] = ...
            updateLearnables(slowFast,gradients,params,params.Velocity,iteration);

        if ~hasdata(mbq) || iteration == params.NumIterations
            % Current epoch is complete. Do validation and update progress.
            trainTime = toc(trainTime);

            accTrain = mean(accTrain);
            lossTrain = mean(lossTrain);

            % Update the training progress.
            displayVerboseOutputEveryEpoch(params,start,learnRate,epoch,iteration,...
                accTrain,lossTrain,trainTime);
            updateProgressPlot(params,plotters,epoch,iteration,start,lossTrain,accTrain);

            % Save the trained video classifier and the parameters, that gave
            % the best training loss so far. Use the saveData supporting function,
```

```
            % listed at the end of this example.
            bestLoss = saveData(slowFast,bestLoss,iteration,lossTrain,params);
        end

        if ~hasdata(mbq) && iteration < params.NumIterations
            % Current epoch is complete. Initialize the training loss, accuracy
            % values, and minibatchqueue for the next epoch.
            accTrain = [];
            lossTrain = [];

            epoch = epoch + 1;
            trainTime = tic;
            shuffled = shuffleTrainDs(dsTrain);
            mbq = createMiniBatchQueue(shuffled, numOutputs, params);
        end

        iteration = iteration + 1;
    end

    % Display a message when training is complete.
    endVerboseOutput(params);

    disp("Model saved to: " + params.ModelFilename);
end
```

Evaluate the Trained Video Classifier

To evaluate the accuracy of the trained SlowFast video classifier, set the `isDataForTraining` variable to false and create a `fileDatastore`. Note that data augmentation is not applied to the evaluation data. Ideally, test and evaluation data should be representative of the original data and is left unmodified for unbiased evaluation.

```
isDataForTraining = false;
dsEval = createFileDatastore(trainingFolder,numFrames,numChannels,classes,isDataForTraining);
dsEval = transform(dsEval,@(data)preprocessVideoClips(data,preprocessInfo));
```

Load the best model saved during training or use the pretrained model.

```
if doTraining
    transferLearned = load(params.ModelFilename);
    slowFastClassifier = transferLearned.data.slowFast;
end
```

Create a `minibatchqueue` object to load batches of the test data.

```
numOutputs = 2;
mbq = createMiniBatchQueue(dsEval,numOutputs,params);
```

For each batch of evaluation data, make predictions using the SlowFast video classifier, and compute the prediction accuracy using a confusion matrix.

```
numClasses = numel(params.Classes);
cmat = sparse(numClasses,numClasses);

while hasdata(mbq)
    [dlVideo,dlY] = next(mbq);

    % Computer the predictions of the trained SlowFast
```

```
    % video classifier.
    dlYPred = predict(slowFastClassifier,dlVideo);
    dlYPred = squeezeIfNeeded(dlYPred,dlY);

    % Aggregate the confusion matrix by using the maximum
    % values of the prediction scores and the ground truth labels.
    [~,YTest] = max(dlY,[],1);
    [~,YPred] = max(dlYPred,[],1);
    cmat = aggregateConfusionMetric(cmat,YTest,YPred);
end
```

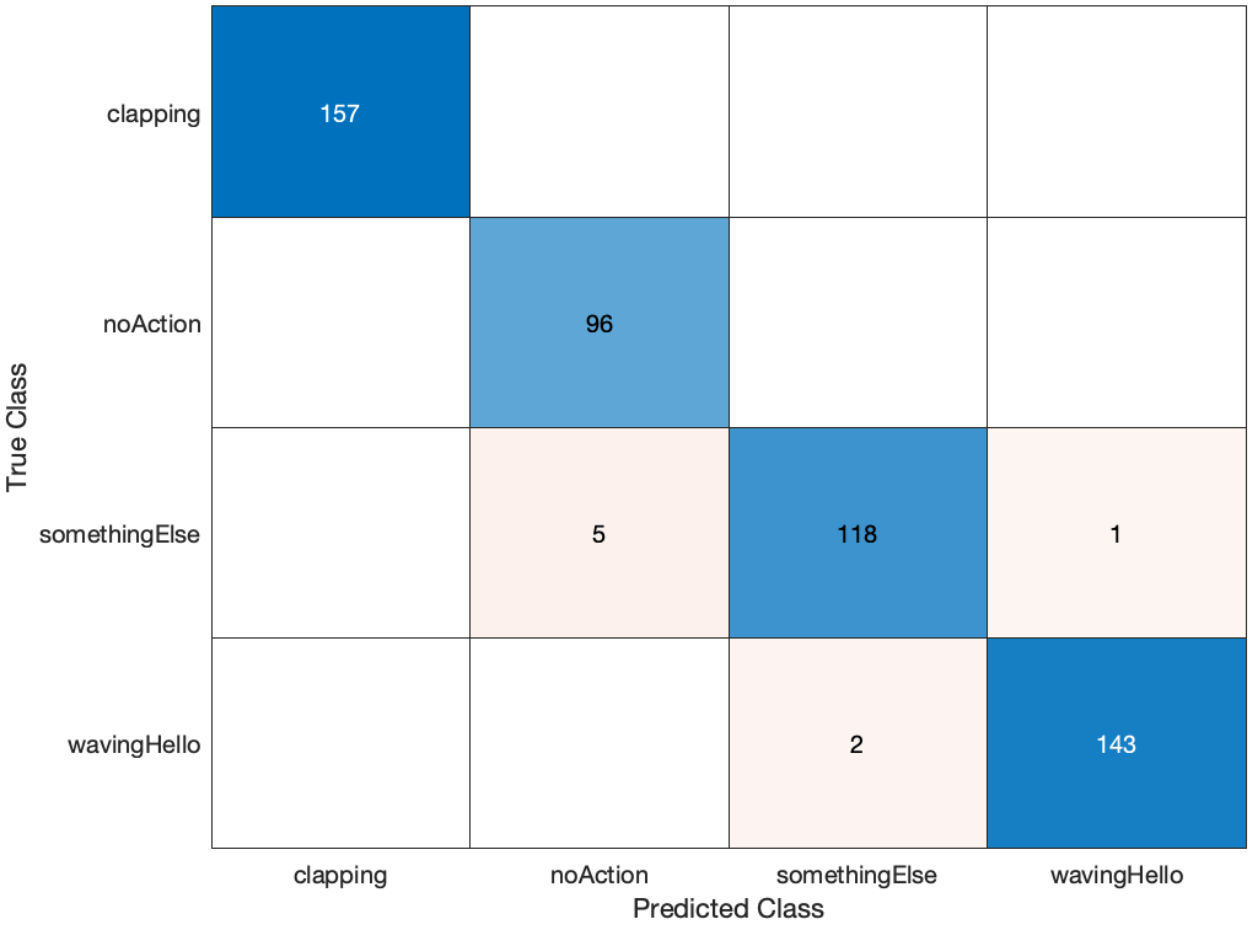
Compute the average clip classification accuracy for the trained SlowFast video classifier.

```
evalClipAccuracy = sum(diag(cmat))./sum(cmat,"all")
```

```
evalClipAccuracy = 0.9847
```

Display the confusion matrix.

```
figure
chart = confusionchart(cmat,classes);
```



The SlowFast video classifier that is pretrained on the Kinetics-400 data set [2 on page 8-0], provides strong performance for human gesture recognition on transfer learning. The above training was run on 24GB Titan-X GPU for about 60 minutes. When training from scratch on a small gesture recognition video data set, the training time and convergence takes much longer than the pretrained video classifier. Transer learning using the Kinetics-400 pretrained SlowFast video classifier also avoids overfitting the classifier when ran for larger number of epochs on such a small gesture recognition video data set. To learn more about video recognition using deep learning, see “Getting Started with Video Classification Using Deep Learning” (Computer Vision Toolbox).

Supporting Functions

`createFileDatastore`

The `createFileDatastore` function creates a `FileDatastore` object using the given folder name. The `FileDatastore` object reads the data in `'partialfile'` mode, so every read can return partially read frames from videos. This feature helps with reading large video files, if all of the frames do not fit in memory.

```
function datastore = createFileDatastore(trainingFolder,numFrames,numChannels,classes,isDataForT
    readFcn = @(f,u)readVideo(f,u,numFrames,numChannels,classes,isDataForTraining);
    datastore = fileDatastore(trainingFolder,...
        'IncludeSubfolders',true,...
        'FileExtensions','.avi',...
        'ReadFcn',readFcn,...
        'ReadMode','partialfile');
end
```

`shuffleTrainDs`

The `shuffleTrainDs` function shuffles the files present in the training datastore, `dsTrain`.

```
function shuffled = shuffleTrainDs(dsTrain)
shuffled = copy(dsTrain);
transformed = isa(shuffled, 'matlab.io.datastore.TransformedDatastore');
if transformed
    files = shuffled.UnderlyingDatastores{1}.Files;
else
    files = shuffled.Files;
end
n = numel(files);
shuffledIndices = randperm(n);
if transformed
    shuffled.UnderlyingDatastores{1}.Files = files(shuffledIndices);
else
    shuffled.Files = files(shuffledIndices);
end

reset(shuffled);

end
```

`readVideo`

The `readVideo` function reads video frames, and the corresponding label values for a given video file. During training, the read function reads the specific number of frames as per the network input size, with a randomly chosen starting frame. During testing, all the frames are sequentially read. The

video frames are resized to the required classifier network input size for training, and for testing and validation.

```
function [data,userdata,done] = readVideo(filename,userdata,numFrames,numChannels,classes,isDataF
    if isempty(userdata)
        userdata.reader      = VideoReader(filename);
        userdata.batchesRead = 0;

        userdata.label = getLabel(filename,classes);

        totalFrames = floor(userdata.reader.Duration * userdata.reader.FrameRate);
        totalFrames = min(totalFrames, userdata.reader.NumFrames);
        userdata.totalFrames = totalFrames;
        userdata.datatype = class(read(userdata.reader,1));
    end
    reader      = userdata.reader;
    totalFrames = userdata.totalFrames;
    label       = userdata.label;
    batchesRead = userdata.batchesRead;

    if isDataForTraining
        video = readForTraining(reader,numFrames,totalFrames);
    else
        video = readForEvaluation(reader,userdata.datatype,numChannels,numFrames,totalFrames);
    end

    data = {video, label};

    batchesRead = batchesRead + 1;

    userdata.batchesRead = batchesRead;

    if numFrames > totalFrames
        numBatches = 1;
    else
        numBatches = floor(totalFrames/numFrames);
    end
    % Set the done flag to true, if the reader has read all the frames or
    % if it is training.
    done = batchesRead == numBatches || isDataForTraining;
end
```

`readForTraining`

The `readForTraining` function reads the video frames for training the video classifier. The function reads the specific number of frames as per the network input size, with a randomly chosen starting frame. If there are not enough frames left over, the video sequence is repeated to pad the required number of frames.

```
function video = readForTraining(reader,numFrames,totalFrames)
    if numFrames >= totalFrames
        startIdx = 1;
        endIdx = totalFrames;
    else
        startIdx = randperm(totalFrames - numFrames + 1);
        startIdx = startIdx(1);
        endIdx = startIdx + numFrames - 1;
    end
```

```
    video = read(reader,[startIdx,endIdx]);
    if numFrames > totalFrames
        % Add more frames to fill in the network input size.
        additional = ceil(numFrames/totalFrames);
        video = repmat(video,1,1,1,additional);
        video = video(:,:,:,1:numFrames);
    end
end
```

readForEvaluation

The `readForEvaluation` function reads the video frames for evaluating the trained video classifier. The function reads the specific number of frames sequentially as per the network input size. If there are not enough frames left over, the video sequence is repeated to pad the required number of frames.

```
function video = readForEvaluation(reader,datatype,numChannels,numFrames,totalFrames)
    H = reader.Height;
    W = reader.Width;
    toRead = min([numFrames,totalFrames]);
    video = zeros([H,W,numChannels,toRead],datatype);
    frameIndex = 0;
    while hasFrame(reader) && frameIndex < numFrames
        frame = readFrame(reader);
        frameIndex = frameIndex + 1;
        video(:,:,:,frameIndex) = frame;
    end

    if frameIndex < numFrames
        video = video(:,:,:,1:frameIndex);
        additional = ceil(numFrames/frameIndex);
        video = repmat(video,1,1,1,additional);
        video = video(:,:,:,1:numFrames);
    end
end
```

getLabel

The `getLabel` function obtains the label name from the full path of a filename. The label for a file is the folder in which it exists. For example, for a file path such as `"/path/to/data set/clapping/video_0001.avi"`, the label name is `"clapping"`.

```
function label = getLabel(filename,classes)
    folder = fileparts(string(filename));
    [~,label] = fileparts(folder);
    label = categorical(string(label),string(classes));
end
```

augmentVideo

The `augmentVideo` function augments the video frames for training the video classifier. The function augments a video sequence with the same augmentation technique provided by the `augmentTransform` function.

```
function data = augmentVideo(data)
    numClips = size(data,1);
    for ii = 1:numClips
        video = data{ii,1};
```

```
        % HxWxC
        sz = size(video,[1,2,3]);
        % One augment fcn per clip
        augmentFcn = augmentTransform(sz);
        data{ii,1} = augmentFcn(video);
    end
end
```

augmentTransform

The `augmentTransform` function creates an augmentation method with random left-right flipping and scaling factors.

```
function augmentFcn = augmentTransform(sz)
% Randomly flip and scale the image.
tform = randomAffine2d('XReflection',true,'Scale',[1 1.1]);
rout = affineOutputView(sz,tform,'BoundsStyle','CenterOutput');

augmentFcn = @(data)augmentData(data,tform,rout);

    function data = augmentData(data,tform,rout)
        data = imwarp(data,tform,'OutputView',rout);
    end
end
```

preprocessVideoClips

The `preprocessVideoClips` function preprocesses the training video data to resize to the SlowFast video classifier input size. It takes the `InputNormalizationStatistics` and the `InputSize` properties of the video classifier in a struct, `info`. The `InputNormalizationStatistics` property is used to rescale the video frames between 0 and 1, and then normalize the rescaled data using mean and standard deviation. The input size is used to resize the video frames using `imresize` based on the `SizingOption` value in the `info` struct. Alternatively, you could use `"randomcrop"` or `"centercrop"` as values for `SizingOption` to random crop or center crop the input data to the input size of the video classifier.

```
function data = preprocessVideoClips(data, info)
    inputSize = info.InputSize(1:2);
    sizingOption = info.SizingOption;
    switch sizingOption
        case "resize"
            sizingFcn = @(x)imresize(x,inputSize);
        case "randomcrop"
            sizingFcn = @(x)cropVideo(x,@randomCropWindow2d,inputSize);
        case "centercrop"
            sizingFcn = @(x)cropVideo(x,@centerCropWindow2d,inputSize);
    end
    numClips = size(data,1);

    minValue  = info.Statistics.Min;
    maxValue  = info.Statistics.Max;
    meanValue = info.Statistics.Mean;
    stdValue  = info.Statistics.StandardDeviation;

    minValue  = reshape(minValue,1,1,3);
    maxValue  = reshape(maxValue,1,1,3);
    meanValue = reshape(meanValue,1,1,3);
```

```
    stdValue  = reshape(stdValue,1,1,3);

    for ii = 1:numClips
        video = data{ii,1};
        resized = sizingFcn(video);

        % Cast the input to single.
        resized = single(resized);

        % Rescale the input between 0 and 1.
        resized = rescale(resized,0,1,InputMin=minValue,InputMax=maxValue);

        % Normalize using mean and standard deviation.
        resized = resized - meanValue;
        resized = resized./stdValue;
        data{ii,1} = resized;
    end

    function outData = cropVideo(data,cropFcn,inputSize)
        imsz = size(data,[1,2]);
        cropWindow = cropFcn(imsz,inputSize);
        numBatches = size(data,4);
        sz = [inputSize, size(data,3),numBatches];
        outData = zeros(sz,'like',data);
        for b = 1:numBatches
            outData(:,:,:,b) = imcrop(data(:,:,:,b),cropWindow);
        end
    end
end
```

createMiniBatchQueue

The `createMiniBatchQueue` function creates a `minibatchqueue` object that provides `miniBatchSize` amount of data from the given datastore. It also creates a `DispatchInBackgroundDatastore` if a parallel pool is open.

```
function mbq = createMiniBatchQueue(datastore, numOutputs, params)
if params.DispatchInBackground && isempty(gcp('nocreate'))
    % Start a parallel pool, if DispatchInBackground is true, to dispatch
    % data in the background using the parallel pool.
    c = parcluster('local');
    c.NumWorkers = params.NumWorkers;
    parpool('local',params.NumWorkers);
end
p = gcp('nocreate');
if ~isempty(p)
    datastore = DispatchInBackgroundDatastore(datastore, p.NumWorkers);
end

inputFormat(1:numOutputs-1) = "SSCTB";
outputFormat = "CB";
mbq = minibatchqueue(datastore, numOutputs, ...
    "MiniBatchSize", params.MiniBatchSize, ...
    "MiniBatchFcn", @batchVideo, ...
    "MiniBatchFormat", [inputFormat,outputFormat]);
end
```

batchVideo

The `batchVideo` function batches the video, and the label data from cell arrays. It uses `onehotencode` function to encode ground truth categorical labels into one-hot arrays. The one-hot encoded array contains a `1` in the position corresponding to the class of the label, and `0` in every other position.

```
function [video,labels] = batchVideo(video,labels)
% Batch dimension: 5
video = cat(5,video{:});

% Batch dimension: 2
labels = cat(2,labels{:});

% Feature dimension: 1
labels = onehotencode(labels,1);
end
```

modelGradients

The `modelGradients` function takes as input a mini-batch of RGB data `dlRGB`, and the corresponding target `dlY`, and returns the corresponding loss, the gradients of the loss with respect to the learnable parameters, and the training accuracy. To compute the gradients, evaluate the `modelGradients` function using the `dlfeval` function in the training loop.

```
function [gradientsRGB,loss,acc,stateRGB] = modelGradients(slowFast,dlRGB,dlY)
[dlYPredRGB,stateRGB] = forward(slowFast,dlRGB);
dlYPred = squeezeIfNeeded(dlYPredRGB,dlY);

loss = crossentropy(dlYPred,dlY);

gradientsRGB = dlgradient(loss,slowFast.Learnables);

% Calculate the accuracy of the predictions.
[~,YTest] = max(dlY,[],1);
[~,YPred] = max(dlYPred,[],1);

acc = gather(extractdata(sum(YTest == YPred)./numel(YTest)));
end
```

squeezeIfNeeded

The `squeezeIfNeeded` function takes as the predicted scores, `dlYPred` and corresponding target `Y`, and returns the predicted scores `dlYPred`, after squeezing the singleton dimensions, if there are any.

```
function dlYPred = squeezeIfNeeded(dlYPred,Y)
if ~isequal(size(Y),size(dlYPred))
    dlYPred = squeeze(dlYPred);
    dlYPred = dlarray(dlYPred,dims(Y));
end
end
```

updateLearnables

The `updateLearnables` function updates the learnable parameters of the SlowFast video classifier with gradients and other parameters using SGDM optimization function `sgdmupdate`.

```
function [slowFast,velocity,learnRate] = updateLearnables(slowFast,gradients,params,velocity,ite
    % Determine the learning rate using the cosine-annealing learning rate schedule.
```

```
    learnRate = cosineAnnealingLearnRate(iteration, params);

    % Apply L2 regularization to the weights.
    learnables = slowFast.Learnables;
    idx = learnables.Parameter == "Weights";
    gradients(idx,:) = dlupdate(@(g,w) g + params.L2Regularization*w,gradients(idx,:),learnables

    % Update the network parameters using the SGDM optimizer.
    [slowFast, velocity] = sgdmupdate(slowFast,gradients,velocity,learnRate,params.Momentum);
end
```

cosineAnnealingLearnRate

The `cosineAnnealingLearnRate` function computes the learning rate based on the current iteration number, minimum learning rate, maximum learning rate, and number of iterations for annealing [3 on page 8-0].

```
function lr = cosineAnnealingLearnRate(iteration,params)
    if iteration == params.NumIterations
        lr = params.MinLearningRate;
        return;
    end
    cosineNumIter = [0, params.CosineNumIterations];
    csum = cumsum(cosineNumIter);
    block = find(csum >= iteration, 1,'first');
    cosineIter = iteration - csum(block - 1);
    annealingIteration = mod(cosineIter,cosineNumIter(block));
    cosineIteration = cosineNumIter(block);
    minR = params.MinLearningRate;
    maxR = params.MaxLearningRate;
    cosMult = 1 + cos(pi * annealingIteration / cosineIteration);
    lr = minR + ((maxR - minR) *  cosMult / 2);
end
```

aggregateConfusionMetric

The `aggregateConfusionMetric` function incrementally fills a confusion matrix based on the predicted results `YPred` and the expected results `YTest`.

```
function cmat = aggregateConfusionMetric(cmat,YTest,YPred)
YTest = gather(extractdata(YTest));
YPred = gather(extractdata(YPred));
[m,n] = size(cmat);
cmat = cmat + full(sparse(YTest,YPred,1,m,n));
end
```

saveData

The `saveData` function saves the given SlowFast video classifier, loss, and other training parameters to a MAT-file.

```
function bestLoss = saveData(slowFast,bestLoss,iteration,lossTrain,params)
if iteration >= params.SaveBestAfterIteration
    trainingLoss = extractdata(gather(lossTrain));
    if trainingLoss < bestLoss
        bestLoss = trainingLoss;
        slowFast = gatherFromGPUToSave(slowFast);
        data.BestLoss = bestLoss;
```

```
        data.slowFast = slowFast;
        data.Params = params;
        save(params.ModelFilename,'data');
    end
end
end
```

gatherFromGPUToSave

The `gatherFromGPUToSave` function gathers data from the GPU in order to save the model to disk.

```
function slowfast = gatherFromGPUToSave(slowfast)
if ~canUseGPU
    return;
end
slowfast.Learnables = gatherValues(slowfast.Learnables);
slowfast.State = gatherValues(slowfast.State);
    function tbl = gatherValues(tbl)
        for ii = 1:height(tbl)
            tbl.Value{ii} = gather(tbl.Value{ii});
        end
    end
end
```

extractVideoScenes

The `extractVideoScenes` function extracts training video data from a collection of videos and its corresponding collection of scene labels, by using the functions `sceneTimeRanges` and `writeVideoScenes`.

```
function extractVideoScenes(groundTruthFolder,trainingFolder,classes)
% If the video scenes are already extracted, no need to download
% the data set and extract video scenes.
if isfolder(trainingFolder)
    classFolders = fullfile(trainingFolder,string(classes));
    allClassFoldersFound = true;
    for ii = 1:numel(classFolders)
        if ~isfolder(classFolders(ii))
            allClassFoldersFound = false;
            break;
        end
    end
    if allClassFoldersFound
        return;
    end
end
if ~isfolder(groundTruthFolder)
    mkdir(groundTruthFolder);
end
downloadURL = "https://ssd.mathworks.com/supportfiles/vision/data/videoClipsAndSceneLabels.zip";

filename = fullfile(groundTruthFolder,"videoClipsAndSceneLabels.zip");
if ~exist(filename,'file')
    disp("Downloading the video clips and the corresponding scene labels to " + groundTruthFolde
    websave(filename,downloadURL);
end
% Unzip the contents to the download folder.
unzip(filename,groundTruthFolder);
```

```
labelDataFiles = dir(fullfile(groundTruthFolder,"*_labelData.mat"));
labelDataFiles = fullfile(groundTruthFolder,{labelDataFiles.name}');
numGtruth = numel(labelDataFiles);
% Load the label data information and create ground truth objects.
gTruth = groundTruth.empty(numGtruth,0);
for ii = 1:numGtruth
    ld = load(labelDataFiles{ii});
    videoFilename = fullfile(groundTruthFolder,ld.videoFilename);
    gds = groundTruthDataSource(videoFilename);
    gTruth(ii) = groundTruth(gds,ld.labelDefs,ld.labelData);
end
% Gather all the scene time ranges and the corresponding scene labels
% using the sceneTimeRanges function.
[timeRanges, sceneLabels] = sceneTimeRanges(gTruth);
% Specify the subfolder names for each duration as the scene label names.
foldernames = sceneLabels;
% Delete the folder if it already exists.
if isfolder(trainingFolder)
    rmdir(trainingFolder,'s');
end
% Video files are written to the folders specified by the folderNames input.
writeVideoScenes(gTruth,timeRanges,trainingFolder,foldernames);
end
```

`initializeTrainingProgressPlot`

The `initializeTrainingProgressPlot` function configures two plots for displaying the training loss, and the training accuracy.

```
function plotters = initializeTrainingProgressPlot(params)
if params.ProgressPlot
    % Plot the loss, training accuracy, and validation accuracy.
    figure

    % Loss plot
    subplot(2,1,1)
    plotters.LossPlotter = animatedline;
    xlabel("Iteration")
    ylabel("Loss")

    % Accuracy plot
    subplot(2,1,2)
    plotters.TrainAccPlotter = animatedline('Color','b');
    legend('Training Accuracy','Location','northwest');
    xlabel("Iteration")
    ylabel("Accuracy")
else
    plotters = [];
end
end
```

`updateProgressPlot`

The `updateProgressPlot` function updates the progress plot with loss and accuracy information during training.

```
function updateProgressPlot(params,plotters,epoch,iteration,start,lossTrain,accuracyTrain)
if params.ProgressPlot
```

```
    % Update the training progress.
    D = duration(0,0,toc(start),"Format","hh:mm:ss");
    title(plotters.LossPlotter.Parent,"Epoch: " + epoch + ", Elapsed: " + string(D));
    addpoints(plotters.LossPlotter,iteration,double(gather(extractdata(lossTrain))));
    addpoints(plotters.TrainAccPlotter,iteration,accuracyTrain);
    drawnow
end
end
```

initializeVerboseOutput

The `initializeVerboseOutput` function displays the column headings for the table of training values, which shows the epoch, mini-batch accuracy, and other training values.

```
function initializeVerboseOutput(params)
if params.Verbose
    disp(" ")
    if canUseGPU
        disp("Training on GPU.")
    else
        disp("Training on CPU.")
    end
    p = gcp('nocreate');
    if ~isempty(p)
        disp("Training on parallel cluster '" + p.Cluster.Profile + "'. ")
    end
    disp("NumIterations:" + string(params.NumIterations));
    disp("MiniBatchSize:" + string(params.MiniBatchSize));
    disp("Classes:" + join(string(params.Classes),","));
    disp("|=========================================================================================
    disp("| Epoch | Iteration | Time Elapsed | Mini-Batch | Mini-Batch |  Base Learning  | Train
    disp("|       |           |  (hh:mm:ss)  |  Accuracy  |    Loss    |      Rate       | (hh:m
    disp("|=========================================================================================
end
end
```

displayVerboseOutputEveryEpoch

The `displayVerboseOutputEveryEpoch` function displays the verbose output of the training values, such as the epoch, mini-batch accuracy, and mini-batch loss.

```
function displayVerboseOutputEveryEpoch(params,start,learnRate,epoch,iteration,...
                accTrain,lossTrain,trainTime)
    if params.Verbose
        D = duration(0,0,toc(start),'Format','hh:mm:ss');
        trainTime = duration(0,0,trainTime,'Format','hh:mm:ss');

        lossTrain = gather(extractdata(lossTrain));
        lossTrain = compose('%.4f',lossTrain);

        accTrain = composePadAccuracy(accTrain);

        learnRate = compose('%.13f',learnRate);

        disp("| " + ...
            pad(string(epoch),5,'both') + " | " + ...
            pad(string(iteration),9,'both') + " | " + ...
```

```
            pad(string(D),12,'both') + " | " + ...
            pad(string(accTrain),10,'both') + " | " + ...
            pad(string(lossTrain),10,'both') + " | " + ...
            pad(string(learnRate),13,'both') + " | " + ...
            pad(string(trainTime),10,'both') + " |")
    end

    function acc = composePadAccuracy(acc)
        acc = compose('%.2f',acc*100) + "%";
        acc = pad(string(acc),6,'left');
    end

end
```

`endVerboseOutput`

The `endVerboseOutput` function displays the end of verbose output during training.

```
function endVerboseOutput(params)
if params.Verbose
    disp("|=======================================================================================
end
end
```

Code Generation for Object Detection by Using Single Shot Multibox Detector

This example shows how to generate CUDA® code for an SSD network (ssdObjectDetector object) and take advantage of the NVIDIA® cuDNN and TensorRT libraries. An SSD network is based on a feed-forward convolutional neural network that detect multiple objects within the image in a single shot. SSD network can be thought of as having two sub-networks. A feature extraction network, followed by a detection network.

This example generates code for the network trained in the *Object Detection Using SSD Deep Learning* example from Computer Vision Toolbox™. For more information, see “Object Detection Using SSD Deep Learning” (Computer Vision Toolbox). The *Object Detection Using SSD Deep Learning* example uses ResNet-50 for feature extraction. The detection sub-network is a small CNN compared to the feature extraction network and is composed of a few convolutional layers and layers specific to SSD.

Third-Party Prerequisites

Required

This example generates CUDA MEX and has the following third-party requirements.

- CUDA enabled NVIDIA GPU and compatible driver.

Optional

For non-MEX builds such as static, dynamic libraries or executables, this example has the following additional requirements.

- NVIDIA toolkit.
- NVIDIA cuDNN library.
- Environment variables for the compilers and libraries. For more information, see “Third-Party Hardware” (GPU Coder) and “Setting Up the Prerequisite Products” (GPU Coder).

Verify GPU Environment

Use the `coder.checkGpuInstall` (GPU Coder) function to verify that the compilers and libraries necessary for running this example are set up correctly.

```
envCfg = coder.gpuEnvConfig('host');
envCfg.DeepLibTarget = 'cudnn';
envCfg.DeepCodegen = 1;
envCfg.Quiet = 1;
coder.checkGpuInstall(envCfg);
```

Get Pretrained DAGNetwork

```
net = getSSDNW();
```

The DAG network contains 180 layers including convolution, ReLU, and batch normalization layers, anchor box, SSD merge, focal loss, and other layers. To display an interactive visualization of the deep learning network architecture, use the `analyzeNetwork` function.

```
analyzeNetwork(net);
```

The `ssdObj_detect` Entry-Point Function

The ssdObj_detect.m entry-point function takes an image input and runs the detector on the image using the deep learning network saved in the `ssdResNet50VehicleExample_20a.mat` file. The function loads the network object from the `ssdResNet50VehicleExample_20a.mat` file into a persistent variable *ssdObj* and reuses the persistent object on subsequent detection calls.

```
type('ssdObj_detect.m')
```

```
function outImg = ssdObj_detect(in)

%   Copyright 2019-2021 The MathWorks, Inc.

persistent ssdObj;

if isempty(ssdObj)
    ssdObj = coder.loadDeepLearningNetwork('ssdResNet50VehicleExample_20a.mat');
end

% Pass in input
[bboxes,~,labels] = ssdObj.detect(in,'Threshold',0.7);

% Convert categorical labels to cell array of charactor vectors for
% execution
labels = cellstr(labels);

% Annotate detections in the image.
if ~isempty(labels)
    outImg = insertObjectAnnotation(in,'rectangle',bboxes,labels);
else
    outImg = in;
end
```

Run MEX Code Generation

To generate CUDA code for the ssdObj_detect.m entry-point function, create a GPU code configuration object for a MEX target and set the target language to C++. Use the `coder.DeepLearningConfig` (GPU Coder) function to create a `CuDNN` deep learning configuration object and assign it to the `DeepLearningConfig` property of the GPU code configuration object. Run the `codegen` command specifying an input size of [300,300,3]. This value corresponds to the input layer size of SSD Network.

```
cfg = coder.gpuConfig('mex');
cfg.TargetLang = 'C++';
cfg.DeepLearningConfig = coder.DeepLearningConfig('cudnn');
codegen -config cfg ssdObj_detect -args {ones(300,300,3,'uint8')} -report
```

```
Code generation successful: View report
```

Run Generated MEX

Set up the video file reader and read the input video. Create a video player to display the video and the output detections.

```
videoFile = 'highway_lanechange.mp4';
videoFreader = vision.VideoFileReader(videoFile,'VideoOutputDataType','uint8');
depVideoPlayer = vision.DeployableVideoPlayer('Size','Custom','CustomSize',[640 480]);
```

Read the video input frame-by-frame and detect the vehicles in the video using the detector.

```
cont = ~isDone(videoFreader);
while cont
    I = step(videoFreader);
    in = imresize(I,[300,300]);
    out = ssdObj_detect_mex(in);
    step(depVideoPlayer, out);
    % Exit the loop if the video player figure window is closed
    cont = ~isDone(videoFreader) && isOpen(depVideoPlayer);
end
```

Point Cloud Classification Using PointNet Deep Learning

This example shows how to train a PointNet network for point cloud classification.

Point cloud data is acquired by a variety of sensors, such as lidar, radar, and depth cameras. These sensors capture 3-D position information about objects in a scene, which is useful for many applications in autonomous driving and augmented reality. For example, discriminating vehicles from pedestrians is critical for planning the path of an autonomous vehicle. However, training robust classifiers with point cloud data is challenging because of the sparsity of data per object, object occlusions, and sensor noise. Deep learning techniques have been shown to address many of these challenges by learning robust feature representations directly from point cloud data. One of the seminal deep learning techniques for point cloud classification is PointNet [1 on page 8-0].

This example trains a PointNet classifier on the Sydney Urban Objects data set created by the University of Sydney [2 on page 8-0]. This data set provides a collection of point cloud data acquired from an urban environment using a lidar sensor. The data set has 100 labeled objects from 14 different categories, such as car, pedestrian, and bus.

Load data set

Download and extract the Sydney Urban Objects data set to a temporary directory.

```
downloadDirectory = tempdir;
datapath = downloadSydneyUrbanObjects(downloadDirectory);
```

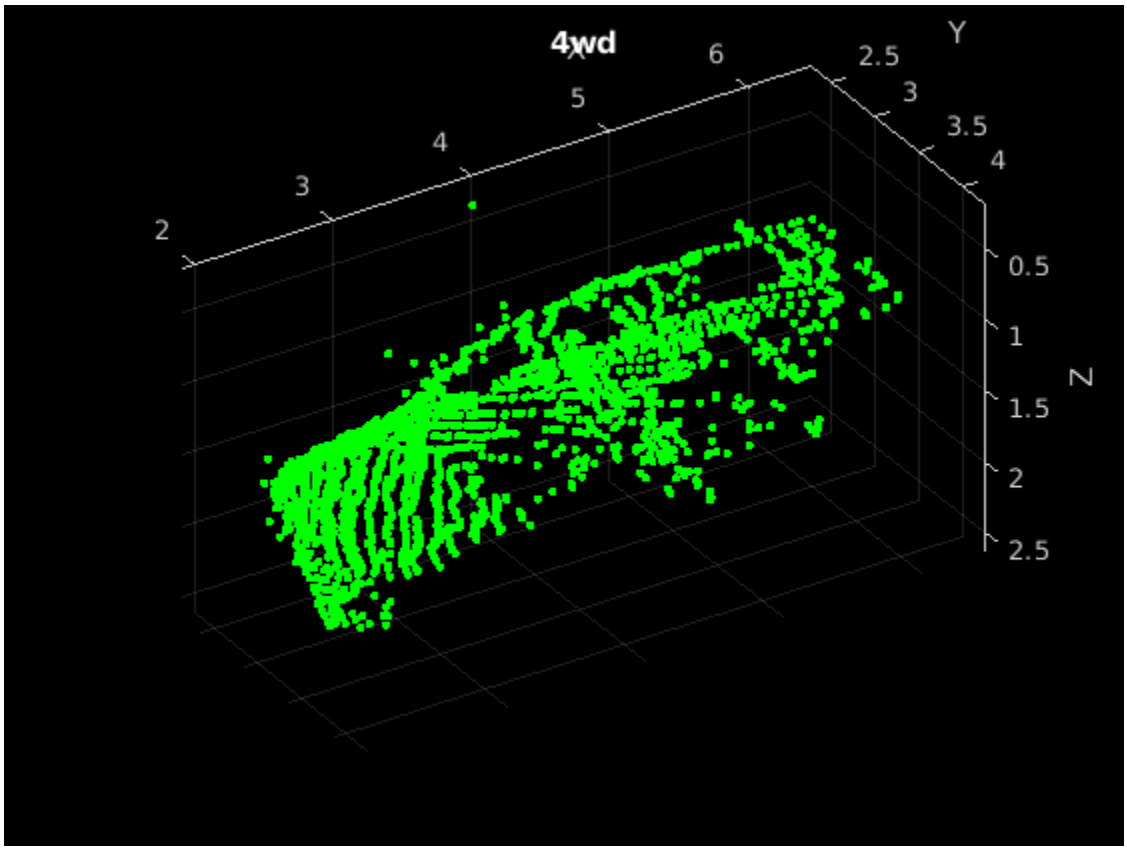
Load the downloaded training and validation data set using the `loadSydneyUrbanObjectsData` helper function listed at the end of this example. Use the first three data folds for training and the fourth for validation.

```
foldsTrain = 1:3;
foldsVal = 4;
dsTrain = loadSydneyUrbanObjectsData(datapath,foldsTrain);
dsVal = loadSydneyUrbanObjectsData(datapath,foldsVal);
```

Read one of the training samples and visualize it using `pcshow`.

```
data = read(dsTrain);
ptCloud = data{1,1};
label = data{1,2};

figure
pcshow(ptCloud.Location,[0 1 0],"MarkerSize",40,"VerticalAxisDir","down")
xlabel("X")
ylabel("Y")
zlabel("Z")
title(label)
```

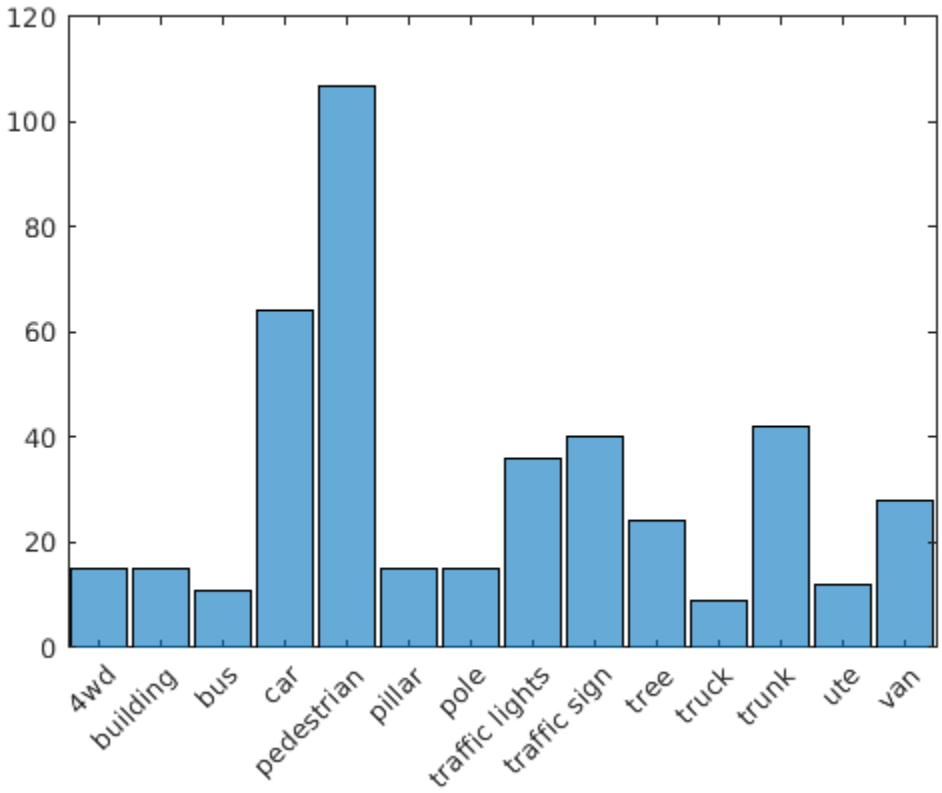


Read the labels and count the number of points assigned to each label to better understand the distribution of labels within the data set.

```
dsLabelCounts = transform(dsTrain,@(data){data{2} data{1}.Count});
labelCounts = readall(dsLabelCounts);
labels = vertcat(labelCounts{:,1});
counts = vertcat(labelCounts{:,2});
```

Next, use a histogram to visualize the class distribution.

```
figure
histogram(labels)
```



The label histogram shows that the data set is imbalanced and biased towards cars and pedestrians, which can prevent the training of a robust classifier. You can address class imbalance by oversampling the infrequent classes. For the Sydney Urban Objects data set, duplicating files corresponding to the infrequent classes is a simple method to address the class imbalance.

Group the files by label, count the number of observations per class, and use the `randReplicateFiles` helper function, listed at the end of this example, to randomly oversample the files to the desired number of observations per class.

```
rng(0)
[G,classes] = findgroups(labels);
numObservations = splitapply(@numel,labels,G);
desiredNumObservationsPerClass = max(numObservations);
files = splitapply(@(x){randReplicateFiles(x,desiredNumObservationsPerClass)},dsTrain.Files,G);
files = vertcat(files{:});
dsTrain.Files = files;
```

Data Augmentation

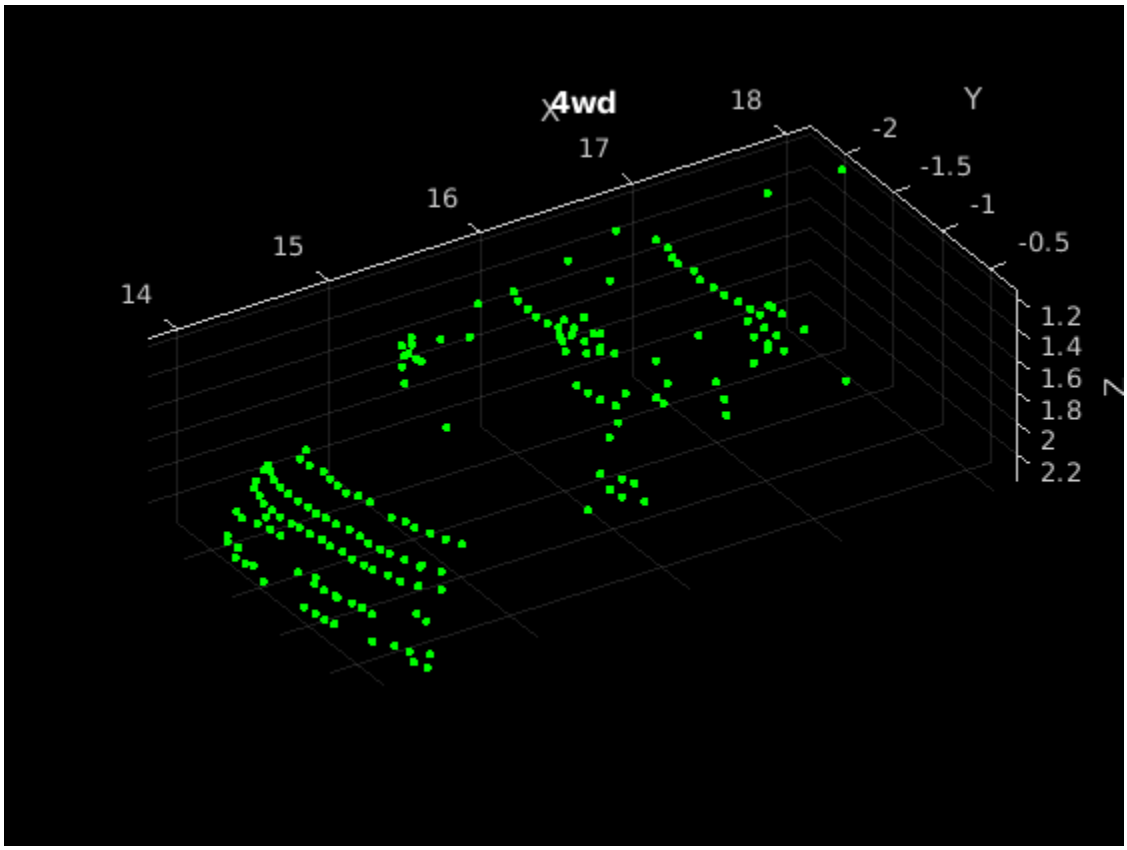
Duplicating the files to address class imbalance increases the likelihood of overfitting the network because much of the training data is identical. To offset this effect, apply data augmentation to the training data using the `transform` and `augmentPointCloud` helper function, which randomly rotates the point cloud, randomly removes points, and randomly jitters points with Gaussian noise.

```
dsTrain = transform(dsTrain,@augmentPointCloud);
```

Preview one of the augmented training samples.

```
data = preview(dsTrain);
ptCloud = data{1,1};
label = data{1,2};

figure
pcshow(ptCloud.Location,[0 1 0],"MarkerSize",40,"VerticalAxisDir","down")
xlabel("X")
ylabel("Y")
zlabel("Z")
title(label)
```



Note that because the data for measuring the performance of the trained network must be representative of the original data set, data augmentation is not applied to validation or test data.

Data Preprocessing

Two preprocessing steps are required to prepare the point cloud data for training and prediction.

First, to enable batch processing during training, select a fixed number of points from each point cloud. The optimal number of points depends on the data set and the number of points required to accurately capture the shape of the object. To help select the appropriate number of points, compute the minimum, maximum, and mean number of points per class.

```
minPointCount = splitapply(@min,counts,G);
maxPointCount = splitapply(@max,counts,G);
meanPointCount = splitapply(@(x)round(mean(x)),counts,G);

stats = table(classes,numObservations,minPointCount,maxPointCount,meanPointCount)
```

```
stats=14×5 table
       classes        numObservations    minPointCount    maxPointCount    meanPointCount
    ______________    _______________    _____________    _____________    ______________

    traffic sign               40               18              736             126
    tree                       24               53             2953             470
    truck                       9              445             3013            1376
    trunk                      42               32              766             241
    ute                        12               90             1380             580
    van                        28               91             5809            1125
```

Because of the large amount of intra-class and inter-class variability in the number of points per class, choosing a value that fits all classes is difficult. One heuristic is to choose enough points to adequately capture the shape of the objects while not increasing the computational cost by processing too many points. A value of 1024 provides a good tradeoff between these two facets. You can also select the optimal number of points based on empirical analysis. However, that is beyond the scope of this example. Use the `transform` function to select 1024 points in the training and validation sets.

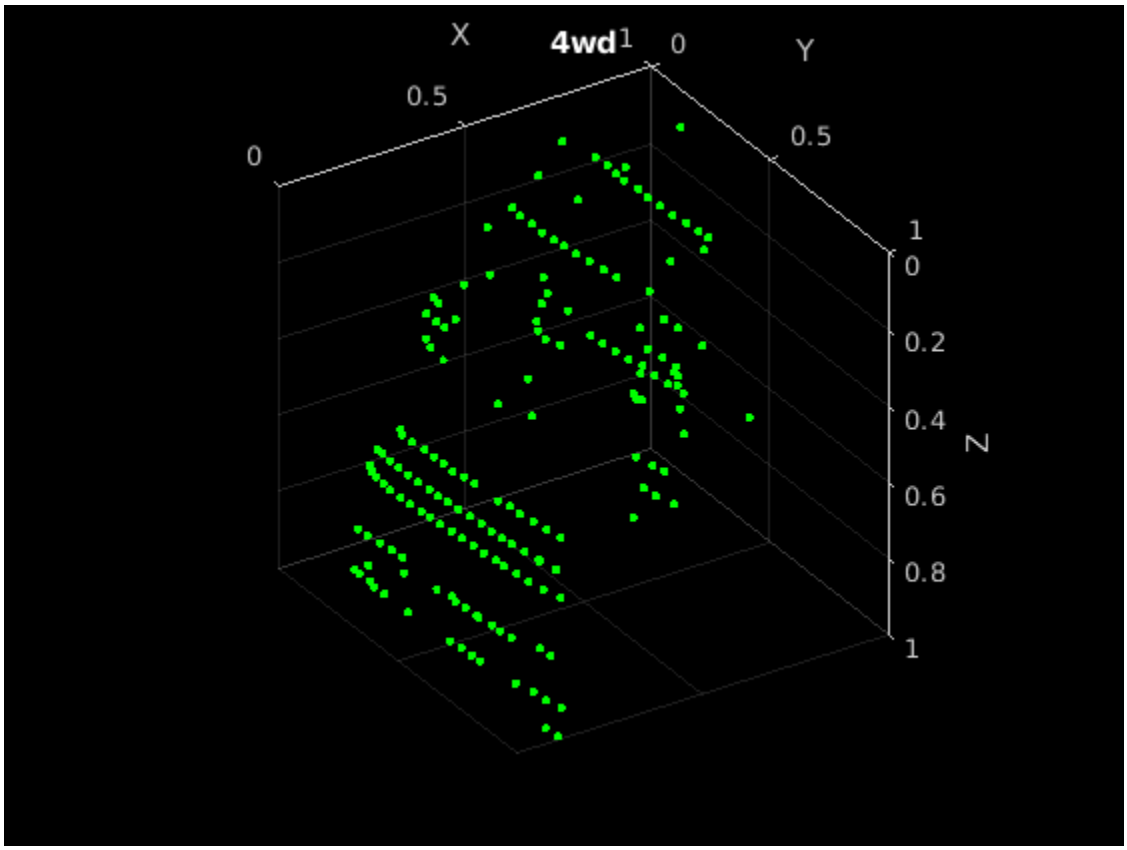
```
numPoints = 1024;
dsTrain = transform(dsTrain,@(data)selectPoints(data,numPoints));
dsVal = transform(dsVal,@(data)selectPoints(data,numPoints));
```

The last preprocessing step is to normalize the point cloud data between 0 and 1 to account for large differences in the range of data values. For example, objects closer to the lidar sensor have smaller values compared to objects that are further away. These differences can hinder the convergence of the network during training. Use `transform` to normalize the point cloud data in the training and validation sets.

```
dsTrain = transform(dsTrain,@preprocessPointCloud);
dsVal = transform(dsVal,@preprocessPointCloud);
```

Preview the augmented and preprocessed training data.

```
data = preview(dsTrain);
figure
pcshow(data{1,1},[0 1 0],"MarkerSize",40,"VerticalAxisDir","down");
xlabel("X")
ylabel("Y")
zlabel("Z")
title(data{1,2})
```



Define PointNet Model

The PointNet classification model consists of two components. The first component is a point cloud encoder that learns to encode sparse point cloud data into a dense feature vector. The second component is a classifier that predicts the categorical class of each encoded point cloud.

The PointNet encoder model is further composed of four models followed by a max operation.

1. Input transform model
2. Shared MLP model
3. Feature transform model
4. Shared MLP model

The shared MLP model is implemented using a series of convolution, batch normalization, and ReLU operations. The convolution operation is configured such that the weights are shared across the input point cloud. The transform model is composed of a shared MLP and a learnable transform matrix that is applied to each point cloud. The shared MLP and the max operation make the PointNet encoder invariant to the order in which the points are processed, while the transform model provides invariance to orientation changes.

Define PointNet Encoder Model Parameters

The shared MLP and transform models are parameterized by the number of input channels and the hidden channel sizes. The values chosen in this example are selected by tuning these hyperparameters on the Sydney Urban Objects data set. Note that if you want to apply PointNet to a different data set, you must perform additional hyperparameter tuning.

Set the input transform model input channel size to three and the hidden channel sizes to 64, 128, and 256 and use the `initializeTransform` helper function, listed at the end of this example, to initialize the model parameters.

```
inputChannelSize = 3;
hiddenChannelSize1 = [64,128];
hiddenChannelSize2 = 256;
[parameters.InputTransform, state.InputTransform] = initializeTransform(inputChannelSize,hiddenCh
```

Set the first shared MLP model input channel size to three and the hidden channel size to 64 and use the `initializeSharedMLP` helper function, listed at the end of this example, to initialize the model parameters.

```
inputChannelSize = 3;
hiddenChannelSize = [64 64];
[parameters.SharedMLP1,state.SharedMLP1] = initializeSharedMLP(inputChannelSize,hiddenChannelSize
```

Set the feature transformation model input channel size to 64 and hidden channel sizes to 64, 128, and 256 and use the `initializeTransform` helper function, listed at the end of this example, to initialize the model parameters.

```
inputChannelSize = 64;
hiddenChannelSize1 = [64,128];
hiddenChannelSize2 = 256;
[parameters.FeatureTransform, state.FeatureTransform] = initializeTransform(inputChannelSize,hidd
```

Set the second shared MLP model input channel size to 64 and the hidden channel size to 64 and use the `initializeSharedMLP` function, listed at the end of this example, to initialize the model parameters.

```
inputChannelSize = 64;
hiddenChannelSize = 64;
[parameters.SharedMLP2,state.SharedMLP2] = initializeSharedMLP(inputChannelSize,hiddenChannelSize
```

Define PointNet Classifier Model Parameters

The PointNet classifier model consists of a shared MLP, a fully connected operation, and a softmax activation. Set the classifier model input size to 64 and the hidden channel size to 512 and 256 and use the `initalizeClassifier` helper function, listed at the end of this example, to initialize the model parameters.

```
inputChannelSize = 64;
hiddenChannelSize = [512,256];
numClasses = numel(classes);
[parameters.ClassificationMLP, state.ClassificationMLP] = initializeClassificationMLP(inputChanne
```

Define PointNet Function

Create the function `pointnetClassifier`, listed in the Model Function section at the end of the example, to compute the outputs of the PointNet model. The function model takes as input the point cloud data, the learnable model parameters, the model state, and a flag that specifies whether the model returns outputs for training or prediction. The network returns the predictions for classifying the input point cloud.

Define Model Gradients Function

Create the function `modelGradients`, listed in the Model Gradients Function section of the example, that takes as input the model parameters, the model state, and a mini-batch of input data, and

returns the gradients of the loss with respect to the learnable parameters in the models and the corresponding loss.

Specify Training Options

Train for 10 epochs and load data in batches of 128. Set the initial learning rate to 0.002 and the L2 regularization factor to 0.01.

```
numEpochs = 10;
learnRate = 0.002;
miniBatchSize = 128;
l2Regularization = 0.01;
learnRateDropPeriod = 15;
learnRateDropFactor = 0.5;
```

Initialize the options for Adam optimization.

```
gradientDecayFactor = 0.9;
squaredGradientDecayFactor = 0.999;
```

Train PointNet

Train the model using a custom training loop.

Shuffle the data at the beginning of training.

For each iteration:

- Read a batch of data.
- Evaluate the model gradients.
- Apply L2 weight regularization.
- Use `adamupdate` to update the model parameters.
- Update the training progress plot.

At the end of each epoch, evaluate the model against the validation data set and collect confusion metrics to measure classification accuracy as training progresses.

After completing `learnRateDropPeriod` epochs, reduce the learning rate by a factor of `learnRateDropFactor`.

Initialize the moving average of the parameter gradients and the element-wise squares of the gradients used by the Adam optimizer.

```
avgGradients = [];
avgSquaredGradients = [];
```

Train the model if `doTraining` is true. Otherwise, load a pretrained network.

Note that training was verified on an NVIDIA Titan X with 12 GB of GPU memory. If your GPU has less memory, you may run out of memory during training. If this happens, lower the `miniBatchSize`. Training this network takes about 5 minutes. Depending on your GPU hardware, it can take longer.

```
doTraining = false;

if doTraining
```

```
% Create a minibatchqueue to batch data from training and validation
% datastores. Use the batchData function, listed at the end of the
% example, to batch the point cloud data and one-hot encode the label
% data.
numOutputsFromDSRead = 2;
mbqTrain = minibatchqueue(dsTrain,numOutputsFromDSRead,...
    "MiniBatchSize", miniBatchSize,...
    "MiniBatchFcn",@batchData,...
    "MiniBatchFormat",["SCSB" "BC"]);

mbqVal = minibatchqueue(dsVal,numOutputsFromDSRead,...
    "MiniBatchSize", miniBatchSize,...
    "MiniBatchFcn",@batchData,...
    "MiniBatchFormat",["SCSB" "BC"]);

% Use the configureTrainingProgressPlot function, listed at the end of the
% example, to initialize the training progress plot to display the training
% loss, training accuracy, and validation accuracy.
[lossPlotter, trainAccPlotter,valAccPlotter] = initializeTrainingProgressPlot;

numClasses = numel(classes);
iteration = 0;
start = tic;
for epoch = 1:numEpochs

    % Shuffle data every epoch.
    shuffle(mbqTrain);

    % Iterate through data set.
    while hasdata(mbqTrain)
        iteration = iteration + 1;

        % Read next batch of training data.
        [XTrain, YTrain] = next(mbqTrain);

        % Evaluate the model gradients and loss using dlfeval and the
        % modelGradients function.
        [gradients, loss, state, acc] = dlfeval(@modelGradients,XTrain,YTrain,parameters,sta

        % L2 regularization.
        gradients = dlupdate(@(g,p) g + l2Regularization*p,gradients,parameters);

        % Update the network parameters using the Adam optimizer.
        [parameters, avgGradients, avgSquaredGradients] = adamupdate(parameters, gradients,
            avgGradients, avgSquaredGradients, iteration,...
            learnRate,gradientDecayFactor, squaredGradientDecayFactor);

        % Update the training progress.
        D = duration(0,0,toc(start),"Format","hh:mm:ss");
        title(lossPlotter.Parent,"Epoch: " + epoch + ", Elapsed: " + string(D))
        addpoints(lossPlotter,iteration,double(gather(extractdata(loss))))
        addpoints(trainAccPlotter,iteration,acc);
        drawnow
    end

    % Evaluate the model on validation data.
    cmat = sparse(numClasses,numClasses);
    while hasdata(mbqVal)
```

```
            % Read next batch of validation data.
            [XVal, YVal] = next(mbqVal);

            % Compute label predictions.
            isTraining = false;
            YPred = pointnetClassifier(XVal,parameters,state,isTraining);

            % Choose prediction with highest score as the class label for
            % XTest.
            [~,YValLabel] = max(YVal,[],1);
            [~,YPredLabel] = max(YPred,[],1);

            % Collect confusion metrics.
            cmat = aggreateConfusionMetric(cmat,YValLabel,YPredLabel);
        end

        % Update training progress plot with average classification accuracy.
        acc = sum(diag(cmat))./sum(cmat,"all");
        addpoints(valAccPlotter,iteration,acc);

        % Upate the learning rate.
        if mod(epoch,learnRateDropPeriod) == 0
            learnRate = learnRate * learnRateDropFactor;
        end

        % Reset training and validation data queues.
        reset(mbqTrain);
        reset(mbqVal);
    end

else
    % Download pretrained model parameters, model state, and validation
    % results.
    pretrainedURL = 'https://ssd.mathworks.com/supportfiles/vision/data/pointnetSydneyUrbanObjec
    pretrainedResults = downloadPretrainedPointNet(pretrainedURL);

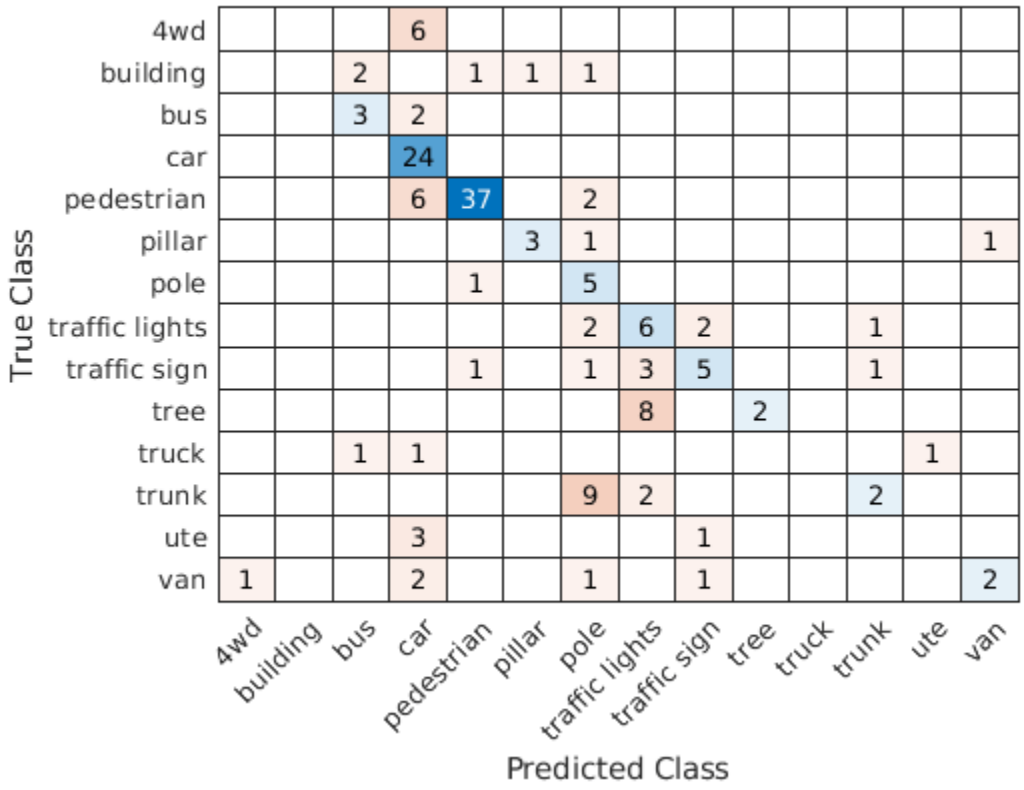
    parameters = pretrainedResults.parameters;
    state = pretrainedResults.state;
    cmat = pretrainedResults.cmat;

    % Move model parameters to the GPU if possible and convert to a dlarray.
    parameters = prepareForPrediction(parameters,@(x)dlarray(toDevice(x,canUseGPU)));

    % Move model state to the GPU if possible.
    state = prepareForPrediction(state,@(x)toDevice(x,canUseGPU));
end
```

Display the validation confusion matrix.

```
figure
chart = confusionchart(cmat,classes);
```



Compute the mean training and validation accuracy.

```
acc = sum(diag(cmat))./sum(cmat,"all")
```

```
acc = 0.5742
```

Due to the limited number of training samples in the Sydney Urban Objects data set, increasing the validation accuracy beyond 60% is challenging. The model easily overfits the training data in the absence of the augmentation defined in the `augmentPointCloudData` helper function. To improve the robustness of the PointNet classifier, additional training is required.

Classify Point Cloud Data Using PointNet

Load point cloud data with `pcread`, preprocess the point cloud using the same function used during training, and convert the result to a `dlarray`.

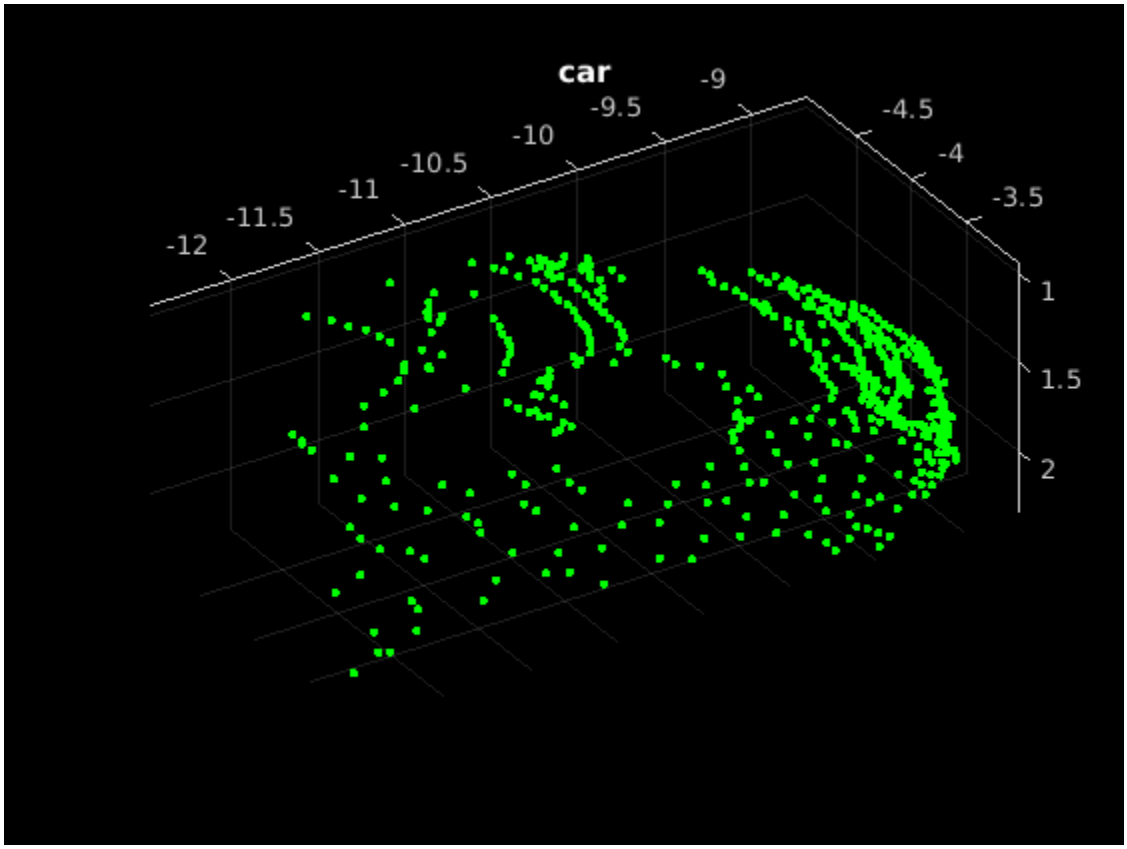
```
ptCloud = pcread("car.pcd");
X = preprocessPointCloud(ptCloud);
dlX = dlarray(X{1},"SCSB");
```

Predict point cloud labels with the `pointnetClassifier` model function.

```
YPred = pointnetClassifier(dlX,parameters,state,false);
[~,classIdx] = max(YPred,[],1);
```

Display the point cloud and the predicted label with the highest score.

```
figure
pcshow(ptCloud.Location,[0 1 0],"MarkerSize",40,"VerticalAxisDir","down")
title(classes(classIdx))
```



Model Gradients Function

The modelGradients function takes as input a mini-batch of data `dlX`, the corresponding target `dlY`, and the learnable parameters, and returns the gradients of the loss with respect to the learnable parameters and the corresponding loss. The loss includes a regularization term designed to ensure the feature transformation matrix predicted by the PointNet encoder is approximately orthogonal. To compute the gradients, evaluate the `modelGradients` function using the `dlfeval` function in the training loop.

```
function [gradients, loss, state, acc] = modelGradients(X,Y,parameters,state)

% Execute the model function.
isTraining = true;
[YPred,state,dlT] = pointnetClassifier(X,parameters,state,isTraining);

% Add regularization term to ensure feature transform matrix is
% approximately orthogonal.
K = size(dlT,1);
B = size(dlT, 4);
I = repelem(eye(K),1,1,1,B);
dlI = dlarray(I,"SSCB");
treg = mse(dlI,pagemtimes(dlT,permute(dlT,[2 1 3 4])));
factor = 0.001;
```

```
% Compute the loss.
loss = crossentropy(YPred,Y) + factor*treg;

% Compute the parameter gradients with respect to the loss.
gradients = dlgradient(loss, parameters);

% Compute training accuracy metric.
[~,YTest] = max(Y,[],1);
[~,YPred] = max(YPred,[],1);
acc = gather(extractdata(sum(YTest == YPred)./numel(YTest)));

end
```

PointNet Classifier Function

The `pointnetClassifier` function takes as input the point cloud data dlX, the learnable model parameters, the model state, and the flag isTraining, which specifies whether the model returns outputs for training or prediction. Then, the function invokes the PointNet encoder and a multilayer perceptron to extract classification features. During training, dropout is applied after each perceptron operation. After the last perceptron, a `fullyconnect` operation maps the classification features to the number of classes and a softmax activation is used to normalize the output into a probability distribution of labels. The probability distribution, the updated model state, and the feature transformation matrix predicted by the PointNet encoder are returned as outputs.

```
function [dlY,state,dlT] = pointnetClassifier(dlX,parameters,state,isTraining)

% Invoke the PointNet encoder.
[dlY,state,dlT] = pointnetEncoder(dlX,parameters,state,isTraining);

% Invoke the classifier.
p = parameters.ClassificationMLP.Perceptron;
s = state.ClassificationMLP.Perceptron;
for k = 1:numel(p)

    [dlY, s(k)] = perceptron(dlY,p(k),s(k),isTraining);

    % If training, apply inverted dropout with a probability of 0.3.
    if isTraining
        probability = 0.3;
        dropoutScaleFactor = 1 - probability;
        dropoutMask = ( rand(size(dlY), "like", dlY) > probability ) / dropoutScaleFactor;
        dlY = dlY.*dropoutMask;
    end

end
state.ClassificationMLP.Perceptron = s;

% Apply final fully connected and softmax operations.
weights = parameters.ClassificationMLP.FC.Weights;
bias = parameters.ClassificationMLP.FC.Bias;
dlY = fullyconnect(dlY,weights,bias);
dlY = softmax(dlY);
end
```

PointNet Encoder Function

The `pointnetEncoder` function processes the input dlX using an input transform, a shared MLP, a feature transform, a second shared MLP, and a max operation, and returns the result of the max operation.

```
function [dlY,state,T] = pointnetEncoder(dlX,parameters,state,isTraining)
% Input transform.
[dlY,state.InputTransform] = dataTransform(dlX,parameters.InputTransform,state.InputTransform,is

% Shared MLP.
[dlY,state.SharedMLP1.Perceptron] = sharedMLP(dlY,parameters.SharedMLP1.Perceptron,state.SharedMl

% Feature transform.
[dlY,state.FeatureTransform,T] = dataTransform(dlY,parameters.FeatureTransform,state.FeatureTrans

% Shared MLP.
[dlY,state.SharedMLP2.Perceptron] = sharedMLP(dlY,parameters.SharedMLP2.Perceptron,state.SharedMl

% Max operation.
dlY = max(dlY,[],1);
end
```

Shared Multilayer Perceptron Function

The shared multilayer `perceptron` function processes the input dlX using a series of perceptron operations and returns the result of the last perceptron.

```
function [dlY,state] = sharedMLP(dlX,parameters,state,isTraining)
dlY = dlX;
for k = 1:numel(parameters)
    [dlY, state(k)] = perceptron(dlY,parameters(k),state(k),isTraining);
end
end
```

Perceptron Function

The perceptron function processes the input dlX using a convolution, a batch normalization, and a relu operation and returns the output of the ReLU operation.

```
function [dlY,state] = perceptron(dlX,parameters,state,isTraining)
% Convolution.
W = parameters.Conv.Weights;
B = parameters.Conv.Bias;
dlY = dlconv(dlX,W,B);

% Batch normalization. Update batch normalization state when training.
offset = parameters.BatchNorm.Offset;
scale = parameters.BatchNorm.Scale;
trainedMean = state.BatchNorm.TrainedMean;
trainedVariance = state.BatchNorm.TrainedVariance;
if isTraining
    [dlY,trainedMean,trainedVariance] = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);

    % Update state.
    state.BatchNorm.TrainedMean = trainedMean;
    state.BatchNorm.TrainedVariance = trainedVariance;
else
```

```
    dlY = batchnorm(dlY,offset,scale,trainedMean,trainedVariance);
end

% ReLU.
dlY = relu(dlY);
end
```

Data Transform Function

The `dataTransform` function processes the input `dlX` using a shared MLP, a max operation, and another shared MLP to predict a transformation matrix T. The transformation matrix is applied to the input dlX using a batched matrix multiply operation. The function returns the result of the batched matrix multiply and the transformation matrix.

```
function [dlY,state,T] = dataTransform(dlX,parameters,state,isTraining)

% Shared MLP.
[dlY,state.Block1.Perceptron] = sharedMLP(dlX,parameters.Block1.Perceptron,state.Block1.Perceptr

% Max operation.
dlY = max(dlY,[],1);

% Shared MLP.
[dlY,state.Block2.Perceptron] = sharedMLP(dlY,parameters.Block2.Perceptron,state.Block2.Perceptr

% Transform net (T-Net). Apply last fully connected operation as W*X to
% predict tranformation matrix T.
dlY = squeeze(dlY); % N-by-B
T = parameters.Transform * stripdims(dlY); % K^2-by-B

% Reshape T into a square matrix.
K = sqrt(size(T,1));
T = reshape(T,K,K,1,[]); % [K K 1 B]
T = T + eye(K);

% Apply to input dlX using batch matrix multiply.
[C,B] = size(dlX,[3 4]);  % [M 1 K B]
dlX = reshape(dlX,[],C,1,B); % [M K 1 B]
Y = pagemtimes(dlX,T);
dlY = dlarray(Y,"SCSB");
end
```

Model Parameter Initialization Functions

`initializeTransform` Function

The `initializeTransform` function takes as input the channel size and the number of hidden channels for the two shared MLPs, and returns the initialized parameters in a struct. The parameters are initialized using He weight initialization [3 on page 8-0].

```
function [params,state] = initializeTransform(inputChannelSize,block1,block2)
[params.Block1,state.Block1] = initializeSharedMLP(inputChannelSize,block1);
[params.Block2,state.Block2] = initializeSharedMLP(block1(end),block2);

% Parameters for the transform matrix.
params.Transform = dlarray(zeros(inputChannelSize^2,block2(end)));
end
```

`initializeSharedMLP` Function

The initializeSharedMLP function takes as input the channel size and the hidden channel size, and returns the initialized parameters in a struct. The parameters are initialized using He weight initialization.

```
function [params,state] = initializeSharedMLP(inputChannelSize,hiddenChannelSize)
weights = initializeWeightsHe([1 1 inputChannelSize hiddenChannelSize(1)]);
bias = zeros(hiddenChannelSize(1),1,"single");
p.Conv.Weights = dlarray(weights);
p.Conv.Bias = dlarray(bias);

p.BatchNorm.Offset = dlarray(zeros(hiddenChannelSize(1),1,"single"));
p.BatchNorm.Scale = dlarray(ones(hiddenChannelSize(1),1,"single"));

s.BatchNorm.TrainedMean = zeros(hiddenChannelSize(1),1,"single");
s.BatchNorm.TrainedVariance = ones(hiddenChannelSize(1),1,"single");

params.Perceptron(1) = p;
state.Perceptron(1) = s;

for k = 2:numel(hiddenChannelSize)
    weights = initializeWeightsHe([1 1 hiddenChannelSize(k-1) hiddenChannelSize(k)]);
    bias = zeros(hiddenChannelSize(k),1,"single");
    p.Conv.Weights = dlarray(weights);
    p.Conv.Bias = dlarray(bias);

    p.BatchNorm.Offset = dlarray(zeros(hiddenChannelSize(k),1,"single"));
    p.BatchNorm.Scale = dlarray(ones(hiddenChannelSize(k),1,"single"));

    s.BatchNorm.TrainedMean = zeros(hiddenChannelSize(k),1,"single");
    s.BatchNorm.TrainedVariance = ones(hiddenChannelSize(k),1,"single");

    params.Perceptron(k) = p;
    state.Perceptron(k) = s;
end
end
```

`initializeClassificationMLP` Function

The `initializeClassificationMLP` function takes as input the channel size, the hidden channel size, and the number of classes and returns the initialized parameters in a struct. The shared MLP is initialized using He weight initialization and the final fully connected operation is initialized using random Gaussian values.

```
function [params,state] = initializeClassificationMLP(inputChannelSize,hiddenChannelSize,numClass
[params,state] = initializeSharedMLP(inputChannelSize,hiddenChannelSize);

weights = initializeWeightsGaussian([numClasses hiddenChannelSize(end)]);
bias = zeros(numClasses,1,"single");
params.FC.Weights = dlarray(weights);
params.FC.Bias = dlarray(bias);
end
```

`initializeWeightsHe` Function

The `initializeWeightsHe` function initializes parameters using He initialization.

```
function x = initializeWeightsHe(sz)
fanIn = prod(sz(1:3));
stddev = sqrt(2/fanIn);
x = stddev .* randn(sz);
end
```

`initializeWeightsGaussian` Function

The `initializeWeightsGaussian` function initializes parameters using Gaussian initialization with a standard deviation of 0.01.

```
function x = initializeWeightsGaussian(sz)
x = randn(sz,"single") .* 0.01;
end
```

Data Preprocessing Functions

`preprocessPointCloudData` Function

The `preprocessPointCloudData` function extracts the X, Y, Z point data from the input data and normalizes the data between 0 and 1. The function returns the normalized X, Y, Z data.

```
function data = preprocessPointCloud(data)

if ~iscell(data)
    data = {data};
end

numObservations = size(data,1);
for i = 1:numObservations
    % Scale points between 0 and 1.
    xlim = data{i,1}.XLimits;
    ylim = data{i,1}.YLimits;
    zlim = data{i,1}.ZLimits;

    xyzMin = [xlim(1) ylim(1) zlim(1)];
    xyzDiff = [diff(xlim) diff(ylim) diff(zlim)];

    data{i,1} = (data{i,1}.Location - xyzMin) ./ xyzDiff;
end
end
```

`selectPoints` Function

The `selectPoints` function samples the desired number of points. When the point cloud contains more than the desired number of points, the function uses `pcdownsample` to randomly select points. Otherwise, the function replicates data to produce the desired number of points.

```
function data = selectPoints(data,numPoints)
% Select the desired number of points by downsampling or replicating
% point cloud data.
numObservations = size(data,1);
for i = 1:numObservations
    ptCloud = data{i,1};
    if ptCloud.Count > numPoints
        percentage = numPoints/ptCloud.Count;
        data{i,1} = pcdownsample(ptCloud,"random",percentage);
    else
```

```
        replicationFactor = ceil(numPoints/ptCloud.Count);
        ind = repmat(1:ptCloud.Count,1,replicationFactor);
        data{i,1} = select(ptCloud,ind(1:numPoints));
    end
end
end
```

Data Augmentation Functions

The `augmentPointCloudData` function randomly rotates a point cloud about the z-axis, randomly drops 30% of the points, and randomly jitters the point location with Gaussian noise.

```
function data = augmentPointCloud(data)

numObservations = size(data,1);
for i = 1:numObservations

    ptCloud = data{i,1};

    % Rotate the point cloud about "up axis", which is Z for this data set.
    tform = randomAffine3d(...
        "XReflection", true,...
        "YReflection", true,...
        "Rotation",@randomRotationAboutZ);

    ptCloud = pctransform(ptCloud,tform);

    % Randomly drop out 30% of the points.
    if rand > 0.5
        ptCloud = pcdownsample(ptCloud,'random',0.3);
    end

    if rand > 0.5
        % Jitter the point locations with Gaussian noise with a mean of 0 and
        % a standard deviation of 0.02 by creating a random displacement field.
        D = 0.02 * randn(size(ptCloud.Location));
        ptCloud = pctransform(ptCloud,D);
    end

    data{i,1} = ptCloud;
end
end

function [rotationAxis,theta] = randomRotationAboutZ()
rotationAxis = [0 0 1];
theta = 2*pi*rand;
end
```

Supporting Functions

`aggregateConfusionMetric` Function

The `aggregateConfusionMetric` function incrementally fills a confusion matrix based on the predicted results `YPred` and the expected results `YTest`.

```
function cmat = aggreateConfusionMetric(cmat,YTest,YPred)
YTest = gather(extractdata(YTest));
YPred = gather(extractdata(YPred));
```

```
[m,n] = size(cmat);
cmat = cmat + full(sparse(YTest,YPred,1,m,n));
end
```

`initializeTrainingProgressPlot` Function

The `initializeTrainingProgressPlot` function configures two plots for displaying the training loss, training accuracy, and validation accuracy.

```
function [plotter,trainAccPlotter,valAccPlotter] = initializeTrainingProgressPlot()
% Plot the loss, training accuracy, and validation accuracy.
figure

% Loss plot
subplot(2,1,1)
plotter = animatedline;
xlabel("Iteration")
ylabel("Loss")

% Accuracy plot
subplot(2,1,2)
trainAccPlotter = animatedline('Color','b');
valAccPlotter = animatedline('Color','g');
legend('Training Accuracy','Validation Accuracy','Location','northwest');
xlabel("Iteration")
ylabel("Accuracy")
end
```

`replicateFiles` Function

The `replicateFiles` function randomly oversamples a set of files and returns a set of files with `numDesired` elements.

```
function files = randReplicateFiles(files,numDesired)
n = numel(files);
ind = randi(n,numDesired,1);
files = files(ind);
end
```

`downloadSydneyUrbanObjects` Function

The `downloadSydneyUrbanObjects` function downloads the data set and saves it to a temporary directory.

```
function datapath = downloadSydneyUrbanObjects(dataLoc)

if nargin == 0
    dataLoc = pwd;
end

dataLoc = string(dataLoc);

url = "http://www.acfr.usyd.edu.au/papers/data/";
name = "sydney-urban-objects-dataset.tar.gz";

datapath = fullfile(dataLoc,'sydney-urban-objects-dataset');
if ~exist(datapath,'dir')
    disp('Downloading Sydney Urban Objects data set...');
```

```
    untar(url+name,dataLoc);
end

end
```

`loadSydneyUrbanObjectsData` Function

The `loadSydneyUrbanObjectsData` function creates a datastore for loading point cloud and label data from the Sydney Urban Objects data set.

```
function ds = loadSydneyUrbanObjectsData(datapath,folds)

if nargin == 0
    return;
end

if nargin < 2
    folds = 1:4;
end

datapath = string(datapath);
path = fullfile(datapath,'objects',filesep);

% Add folds to datastore.
foldNames{1} = importdata(fullfile(datapath,'folds','fold0.txt'));
foldNames{2} = importdata(fullfile(datapath,'folds','fold1.txt'));
foldNames{3} = importdata(fullfile(datapath,'folds','fold2.txt'));
foldNames{4} = importdata(fullfile(datapath,'folds','fold3.txt'));
names = foldNames(folds);
names = vertcat(names{:});

fullFilenames = append(path,names);
ds = fileDatastore(fullFilenames,'ReadFcn',@extractTrainingData,'FileExtensions','.bin');
end
```

`batchData` Function

The `batchData` function collates data into batches and moves data to the GPU for processing.

```
function [X,Y] = batchData(ptCloud,labels)
X = cat(4,ptCloud{:});
labels = cat(1,labels{:});
Y = onehotencode(labels,2);
end
```

`extractTrainingData` Function

The extractTrainingData function extracts point cloud and label data from the Sydney Urban Objects data set.

```
function dataOut = extractTrainingData(fname)

[pointData,intensity] = readbin(fname);

[~,name] = fileparts(fname);
name = string(name);
name = extractBefore(name,'.');
name = replace(name,'_',' ');
```

```
labelNames = ["4wd","building","bus","car","pedestrian","pillar",...
    "pole","traffic lights","traffic sign","tree","truck","trunk","ute","van"];

label = categorical(name,labelNames);

dataOut = {pointCloud(pointData,'Intensity',intensity),label};

end
```

`readbin` Function

The `readbin` function reads the point cloud data from Sydney Urban Object binary files.

```
function [pointData,intensity] = readbin(fname)
% readbin Read point and intensity data from Sydney Urban Object binary
% files.

% names = ['t','intensity','id',...
%          'x','y','z',...
%          'azimuth','range','pid']
%
% formats = ['int64', 'uint8', 'uint8',...
%            'float32', 'float32', 'float32',...
%            'float32', 'float32', 'int32']

fid = fopen(fname, 'r');
c = onCleanup(@() fclose(fid));

fseek(fid,10,-1); % Move to the first X point location 10 bytes from beginning
X = fread(fid,inf,'single',30);
fseek(fid,14,-1);
Y = fread(fid,inf,'single',30);
fseek(fid,18,-1);
Z = fread(fid,inf,'single',30);

fseek(fid,8,-1);
intensity = fread(fid,inf,'uint8',33);

pointData = [X,Y,Z];
end
```

`downloadPretrainedPointNet` Function

The `downloadPretrainedPointNet` function downloads a pretrained pointnet model.

```
function data = downloadPretrainedPointNet(pretrainedURL)
% Download and load a pretrained pointnet model.
if ~exist('pointnetSydneyUrbanObjects.mat', 'file')
    if ~exist('pointnetSydneyUrbanObjects.zip', 'file')
        disp('Downloading pretrained detector (5 MB)...');
        websave('pointnetSydneyUrbanObjects.zip', pretrainedURL);
    end
    unzip('pointnetSydneyUrbanObjects.zip');
end
data = load("pointnetSydneyUrbanObjects.mat");
end
```

`prepareForPrediction` Function

The `prepareForPrediction` function is used to apply a user-defined function to nested structure data. It is a used to move model parameter and state data to the GPU.

```
function p = prepareForPrediction(p,fcn)

for i = 1:numel(p)
    p(i) = structfun(@(x)invoke(fcn,x),p(i),'UniformOutput',0);
end

    function data = invoke(fcn,data)
        if isstruct(data)
            data = prepareForPrediction(data,fcn);
        else
            data = fcn(data);
        end
    end
end

% Move data to the GPU.
function x = toDevice(x,useGPU)
if useGPU
    x = gpuArray(x);
end
end
```

Activity Recognition from Video and Optical Flow Data Using Deep Learning

This example first shows how to perform activity recognition using a pretrained Inflated 3-D (I3D) two-stream convolutional neural network based video classifier and then shows how to use transfer learning to train such a video classifier using RGB and optical flow data from videos [1] on page 8-0 .

Overview

Vision-based activity recognition involves predicting the action of an object, such as walking, swimming, or sitting, using a set of video frames. Activity recognition from video has many applications, such as human-computer interaction, robot learning, anomaly detection, surveillance, and object detection. For example, online prediction of multiple actions for incoming videos from multiple cameras can be important for robot learning. Compared to image classification, action recognition using videos is challenging to model because of the inaccurate ground truth data for video data sets, the variety of gestures that actors in a video can perform, the heavily class imbalanced datasets, and the large amount of data required to train a robust classifier from scratch. Deep learning techniques, such as I3D two-stream convolutional networks [1] on page 8-0 , R(2+1)D [4 on page 8-0], and SlowFast [5 on page 8-0] have shown improved performance on smaller datasets using transfer learning with networks pretrained on large video activity recognition datasets, such as Kinetics-400 [6 on page 8-0].

Note: This example requires the Computer Vision Toolbox™ Model for Inflated-3D Video Classification. You can install the Computer Vision Toolbox Model for Inflated-3D Video Classification from Add-On Explorer. For more information about installing add-ons, see “Get and Manage Add-Ons”.

Perform Activity Recognition Using a Pretrained Inflated-3D Video Classifier

Download the pretrained Inflated-3D video classifier along with a video file on which to perform activity recognition. The size of the downloaded zip file is around 89 MB.

```
downloadFolder = fullfile(tempdir,"hmdb51","pretrained","I3D");
if ~isfolder(downloadFolder)
    mkdir(downloadFolder);
end

filename = "activityRecognition-I3D-HMDB51-21b.zip";

zipFile = fullfile(downloadFolder,filename);
if ~isfile(zipFile)
    disp('Downloading the pretrained network...');
    downloadURL = "https://ssd.mathworks.com/supportfiles/vision/data/" + filename;
    websave(zipFile,downloadURL);
    unzip(zipFile,downloadFolder);
end
```

Load the pretrained Inflated-3D video classifier.

```
pretrainedDataFile = fullfile(downloadFolder,"inflated3d-FiveClasses-hmdb51.mat");
pretrained = load(pretrainedDataFile);
inflated3dPretrained = pretrained.data.inflated3d;
```

Display the class label names of the pretrained video classifier.

```
classes = inflated3dPretrained.Classes
```

```
classes = 5×1 categorical
     kiss
     laugh
     pick
     pour
     pushup
```

Read and display the video `pour.avi` using `VideoReader` and `vision.VideoPlayer`.

```
videoFilename = fullfile(downloadFolder, "pour.avi");

videoReader = VideoReader(videoFilename);
videoPlayer = vision.VideoPlayer;
videoPlayer.Name = "pour";

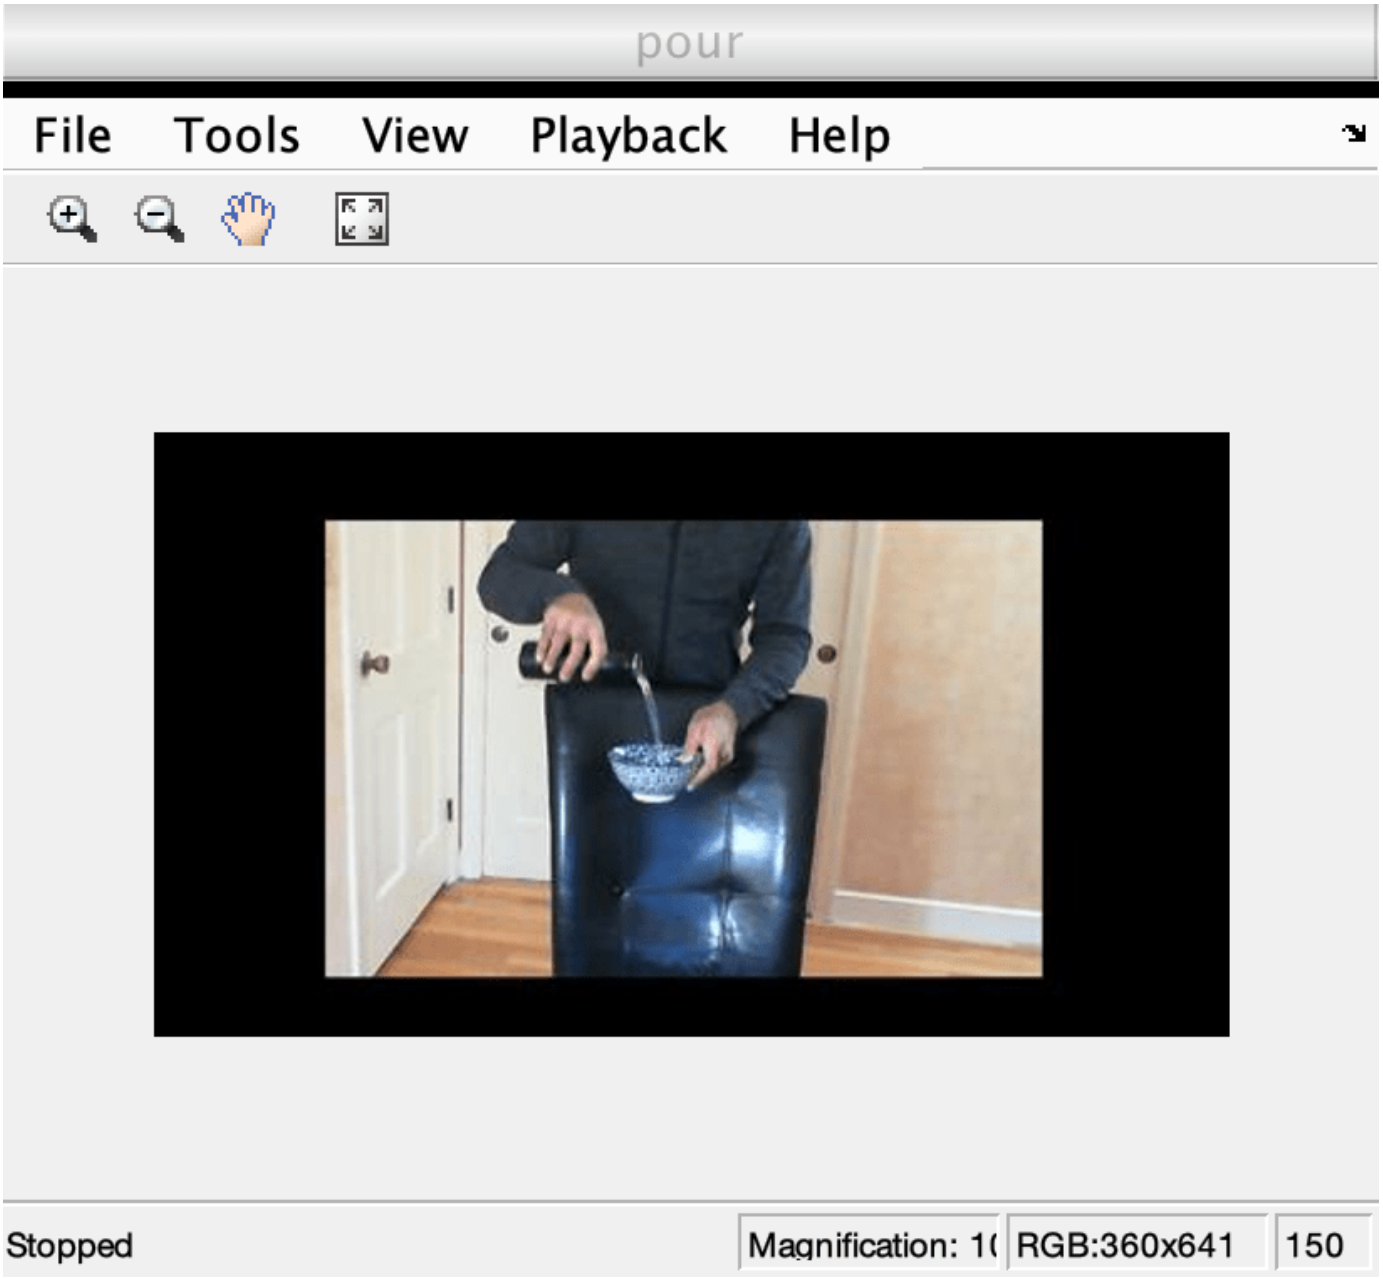
while hasFrame(videoReader)
   frame = readFrame(videoReader);
   % Resize the frame for display.
   frame = imresize(frame, 1.5);
   step(videoPlayer,frame);
end
release(videoPlayer);
```

Choose 10 randomly selected video sequences to classify the video, to uniformly cover the entirety of the file to find the action class that is predominant in the video.

```
numSequences = 10;
```

Classify the video file using the `classifyVideoFile` function.

```
[actionLabel,score] = classifyVideoFile(inflated3dPretrained, videoFilename, "NumSequences", numS
```



```
actionLabel = categorical
     pour

score = single
    0.4482
```

Train a Video Classifier for Gesture Recognition

This section of the example shows how the video classifier shown above is trained using transfer learning. Set the `doTraining` variable to `false` to use the pretrained video classifier without having

to wait for training to complete. Alternatively, if you want to train the video classifier, set the `doTraining` variable to `true`.

```
doTraining = false;
```

Download Training and Validation Data

This example trains an Inflated-3D (I3D) Video Classifier using the HMDB51 data set. Use the `downloadHMDB51` supporting function, listed at the end of this example, to download the HMDB51 data set to a folder named `hmdb51`.

```
downloadFolder = fullfile(tempdir,"hmdb51");
downloadHMDB51(downloadFolder);
```

After the download is complete, extract the RAR file `hmdb51_org.rar` to the `hmdb51` folder. Next, use the `checkForHMDB51Folder` supporting function, listed at the end of this example, to confirm that the downloaded and extracted files are in place.

```
allClasses = checkForHMDB51Folder(downloadFolder);
```

The data set contains about 2 GB of video data for 7000 clips over 51 classes, such as *drink*, *run*, and *shake hands*. Each video frame has a height of 240 pixels and a minimum width of 176 pixels. The number of frames ranges from 18 to approximately 1000.

To reduce training time, this example trains an activity recognition network to classify 5 action classes instead of all 51 classes in the data set. Set `useAllData` to `true` to train with all 51 classes.

```
useAllData = false;

if useAllData
    classes = allClasses;
end
dataFolder = fullfile(downloadFolder, "hmdb51_org");
```

Split the data set into a training set for training the classifier, and a test set for evaluating the classifier. Use 80% of the data for the training set and the rest for the test set. Use `folders2labels` and `splitlabels` to create label information from folders and split the data based on each label into training and test data sets by randomly selecting a proportion of files from each label.

```
[labels,files] = folders2labels(fullfile(dataFolder,string(classes)),...
    "IncludeSubfolders",true,...
    "FileExtensions",'.avi');

indices = splitlabels(labels,0.8,'randomized');

trainFilenames = files(indices{1});
testFilenames  = files(indices{2});
```

To normalize the input data for the network, the minimum and maximum values for the data set are provided in the MAT file `inputStatistics.mat`, attached to this example. To find the minimum and maximum values for a different data set, use the `inputStatistics` supporting function, listed at the end of this example.

```
inputStatsFilename = 'inputStatistics.mat';
if ~exist(inputStatsFilename, 'file')
    disp("Reading all the training data for input statistics...")
    inputStats = inputStatistics(dataFolder);
```

```
else
    d = load(inputStatsFilename);
    inputStats = d.inputStats;
end
```

Load Dataset

This example uses a datastore to read the videos scenes, the corresponding optical flow data, and the corresponding labels from the video files.

Specify the number of video frames the datastore should be configured to output for each time data is read from the datastore.

```
numFrames = 64;
```

A value of 64 is used here to balance memory usage and classification time. Common values to consider are 16, 32, 64, or 128. Using more frames helps capture additional temporal information, but requires more memory. You might need to lower this value depending on your system resources. Empirical analysis is required to determine the optimal number of frames.

Next, specify the height and width of the frames the datastore should be configured to output. The datastore automatically resizes the raw video frames to the specified size to enable batch processing of multiple video sequences.

```
frameSize = [112,112];
```

A value of [112 112] is used to capture longer temporal relationships in the video scene which help classify activities with long time durations. Common values for the size are [112 112], [224 224], or [256 256]. Smaller sizes enable the use of more video frames at the cost of memory usage, processing time, and spatial resolution. The minimum height and width of the video frames in the HMDB51 data set are 240 and 176, respectively. If you want to specify a frame size for the datastore to read that is larger than the minimum values, such as [256, 256], first resize the frames using `imresize`. As with the number of frames, empirical analysis is required to determine the optimal values.

Specify the number of channels as 3 for the RGB video subnetwork, and 2 for the optical flow subnetwork of the I3D video classifier. The two channels for optical flow data are the x and y components of velocity, V_x and V_y, respectively.

```
rgbChannels = 3;
flowChannels = 2;
```

Use the helper function, `createFileDatastore`, to configure two `FileDatastore` objects for loading the data, one for training and another for validation. The helper function is listed at the end of this example. Each datastore reads a video file to provide RGB data and the corresponding label information.

```
isDataForTraining = true;
dsTrain = createFileDatastore(trainFilenames,numFrames,rgbChannels,classes,isDataForTraining);

isDataForTraining = false;
dsVal = createFileDatastore(testFilenames,numFrames,rgbChannels,classes,isDataForTraining);
```

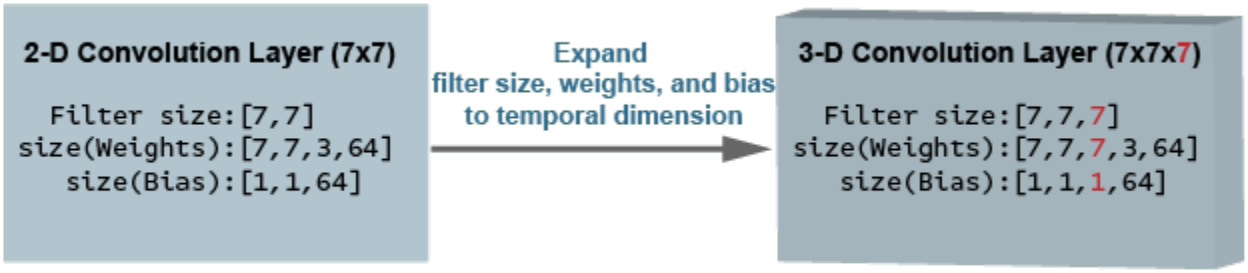
Define Network Architecture

I3D network

Using a 3-D CNN is a natural approach to extracting spatio-temporal features from videos. You can create an I3D network from a pretrained 2-D image classification network such as Inception v1 or

ResNet-50 by expanding 2-D filters and pooling kernels into 3-D. This procedure reuses the weights learned from the image classification task to bootstrap the video recognition task.

The following figure is a sample showing how to inflate a 2-D convolution layer to a 3-D convolution layer. The inflation involves expanding the filter size, weights, and bias by adding a third dimension (the temporal dimension).

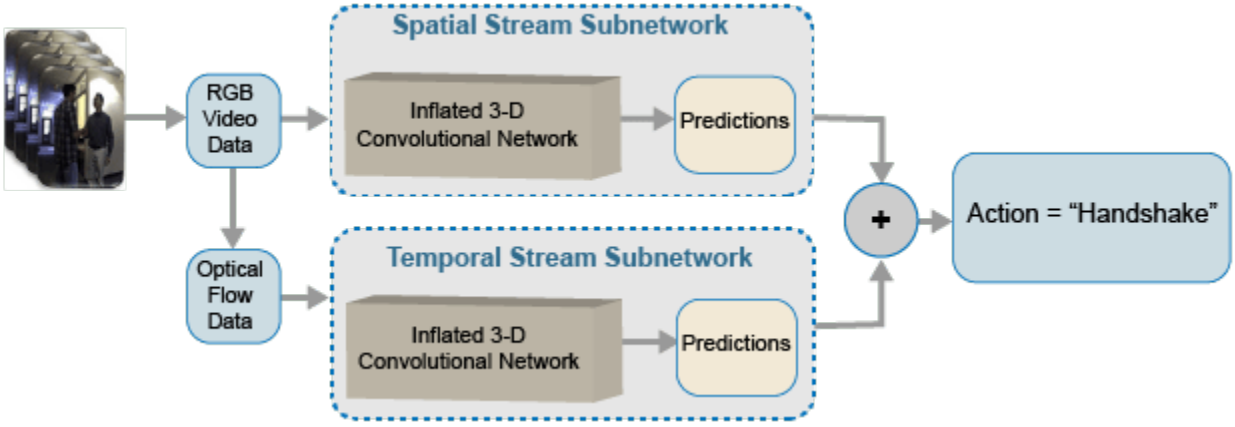


Two-Stream I3D Network

Video data can be considered to have two parts: a spatial component and a temporal component.

- The spatial component comprises information about the shape, texture, and color of objects in video. RGB data contains this information.
- The temporal component comprises information about the motion of objects across the frames and depicts important movements between the camera and the objects in a scene. Computing optical flow is a common technique for extracting temporal information from video.

A two-stream CNN incorporates a spatial subnetwork and a temporal subnetwork [2] on page 8-0 . A convolutional neural network trained on dense optical flow and a video data stream can achieve better performance with limited training data than with raw stacked RGB frames. The following illustration shows a typical two-stream I3D network.



Configure Inflated-3D (I3D) Video Classifier for Transfer Learning

In this example, you create an I3D video classifier based on the GoogLeNet architecture, a 3D Convolution Neural Network Video Classifier pretrained on the Kinetics-400 dataset.

Specify GoogLeNet as the backbone convolution neural network architecture for the I3D video classifier that contains two subnetworks, one for video data and another for optical flow data.

```
baseNetwork = "googlenet-video-flow";
```

Specify the input size for the Inflated-3D Video Classifier.

```
inputSize = [frameSize, rgbChannels, numFrames];
```

Obtain the minimum and maximum values for the RGB and optical flow data from the `inputStats` structure loaded from the `inputStatistics.mat` file. These values are needed to normalize the input data.

```
oflowMin = squeeze(inputStats.oflowMin)';
oflowMax = squeeze(inputStats.oflowMax)';
rgbMin   = squeeze(inputStats.rgbMin)';
rgbMax   = squeeze(inputStats.rgbMax)';

stats.Video.Min               = rgbMin;
stats.Video.Max               = rgbMax;
stats.Video.Mean              = [];
stats.Video.StandardDeviation = [];

stats.OpticalFlow.Min               = oflowMin(1:flowChannels);
stats.OpticalFlow.Max               = oflowMax(1:flowChannels);
stats.OpticalFlow.Mean              = [];
stats.OpticalFlow.StandardDeviation = [];
```

Create the I3D Video Classifier by using the `inflated3dVideoClassifier` function.

```
i3d = inflated3dVideoClassifier(baseNetwork,string(classes),...
    "InputSize",inputSize,...
    "InputNormalizationStatistics",stats);
```

Specify a model name for the video classifier.

```
i3d.ModelName = "Inflated-3D Activity Recognizer Using Video and Optical Flow";
```

Augment and Preprocess Training Data

Data augmentation provides a way to use limited data sets for training. Augmentation on video data must be the same for a collection of frames, i.e. a video sequence, based on the network input size. Minor changes, such as translation, cropping, or transforming an image, provide, new, distinct, and unique images that you can use to train a robust video classifier. Datastores are a convenient way to read and augment collections of data. Augment the training video data by using the `augmentVideo` supporting function, defined at the end of this example.

```
dsTrain = transform(dsTrain, @augmentVideo);
```

Preprocess the training video data to resize to the Inflated-3D Video Classifier input size, by using the `preprocessVideoClips`, defined at the end of this example. Specify the `InputNormalizationStatistics` property of the video classifier and input size to the preprocessing function as field values in a struct, `preprocessInfo`. The `InputNormalizationStatistics` property is used to rescale the video frames and optical flow data between -1 and 1. The input size is used to resize the video frames using `imresize` based on the `SizingOption` value in the `info` struct. Alternatively, you could use `"randomcrop"` or `"centercrop"` to random crop or center crop the input data to the input size of the video classifier. Note that data augmentation is not applied to the test and validation data. Ideally, test and validation data should be representative of the original data and is left unmodified for unbiased evaluation.

```
preprocessInfo.Statistics = i3d.InputNormalizationStatistics;
preprocessInfo.InputSize = inputSize;
preprocessInfo.SizingOption = "resize";
dsTrain = transform(dsTrain, @(data)preprocessVideoClips(data, preprocessInfo));
dsVal = transform(dsVal, @(data)preprocessVideoClips(data, preprocessInfo));
```

Define Model Gradients Function

Create the supporting function `modelGradients`, listed at the end of this example. The `modelGradients` function takes as input the I3D video classifier `i3d`, a mini-batch of input data `dlRGB` and `dlFlow`, and a mini-batch of ground truth label data `dlY`. The function returns the training loss value, the gradients of the loss with respect to the learnable parameters of the classifier, and the mini-batch accuracy of the classifier.

The loss is calculated by computing the average of the cross-entropy losses of the predictions from each of the subnetworks. The output predictions of the network are probabilities between 0 and 1 for each of the classes.

$$rgbLoss = crossentropy(rgbPrediction)$$

$$flowLoss = crossentropy(flowPrediction)$$

$$loss = mean([rgbLoss, flowLoss])$$

The accuracy of each of the classifier is calculated by taking the average of the RGB and optical flow predictions, and comparing it to the ground truth label of the inputs.

Specify Training Options

Train with a mini-batch size of 20 for 600 iterations. Specify the iteration after which to save the video classifier with the best validation accuracy by using the `SaveBestAfterIteration` parameter.

Specify the cosine-annealing learning rate schedule [3 on page 8-0] parameters:

- A minimum learning rate of 1e-4.
- A maximum learning rate of 1e-3.
- Cosine number of iterations of 100, 200, and 300, after which the learning rate schedule cycle restarts. The option `CosineNumIterations` defines the width of each cosine cycle.

Specify the parameters for SGDM optimization. Initialize the SGDM optimization parameters at the beginning of the training:

- A momentum of 0.9.
- An initial velocity parameter initialized as `[]`.
- An L2 regularization factor of 0.0005.

Specify to dispatch the data in the background using a parallel pool. If `DispatchInBackground` is set to true, open a parallel pool with the specified number of parallel workers, and create a `DispatchInBackgroundDatastore`, provided as part of this example, that dispatches the data in the background to speed up training using asynchronous data loading and preprocessing. By default, this example uses a GPU if one is available. Otherwise, it uses a CPU. Using a GPU requires Parallel Computing Toolbox™ and a CUDA® enabled NVIDIA® GPU. For information about the supported compute capabilities, see “GPU Support by Release” (Parallel Computing Toolbox).

```
params.Classes = classes;
params.MiniBatchSize = 20;
params.NumIterations = 600;
params.SaveBestAfterIteration = 400;
params.CosineNumIterations = [100, 200, 300];
params.MinLearningRate = 1e-4;
params.MaxLearningRate = 1e-3;
params.Momentum = 0.9;
params.VelocityRGB = [];
params.VelocityFlow = [];
params.L2Regularization = 0.0005;
params.ProgressPlot = true;
params.Verbose = true;
params.ValidationData = dsVal;
params.DispatchInBackground = false;
params.NumWorkers = 4;
```

Train I3D Video Classifier

Train the I3D video classifier using the RGB video data and optical flow data.

For each epoch:

- Shuffle the data before looping over mini-batches of data.
- Use `minibatchqueue` to loop over the mini-batches. The supporting function `createMiniBatchQueue`, listed at the end of this example, uses the given training datastore to create a `minibatchqueue`.
- Use the validation data `dsVal` to validate the networks.
- Display the loss and accuracy results for each epoch using the supporting function `displayVerboseOutputEveryEpoch`, listed at the end of this example.

For each mini-batch:

- Convert the video data or optical flow data and the labels to `dlarray` objects with the underlying type single.
- To enable processing the time dimension of the the video data using the I3D Video Classifier specify the temporal sequence dimension, `"T"`. Specify the dimension labels `"SSCTB"` (spatial, spatial, channel, temporal, batch) for the video data, and `"CB"` for the label data.

The `minibatchqueue` object uses the supporting function `batchVideoAndFlow`, listed at the end of this example, to batch the RGB video and optical flow data.

```
params.ModelFilename = "inflated3d-FiveClasses-hmdb51.mat";
if doTraining
    epoch     = 1;
    bestLoss  = realmax;

    accTrain     = [];
    accTrainRGB  = [];
    accTrainFlow = [];
    lossTrain    = [];

    iteration = 1;
    start     = tic;
    trainTime = start;
```

```
shuffled  = shuffleTrainDs(dsTrain);

% Number of outputs is three: One for RGB frames, one for optical flow
% data, and one for ground truth labels.
numOutputs = 3;
mbq        = createMiniBatchQueue(shuffled, numOutputs, params);

% Use the initializeTrainingProgressPlot and initializeVerboseOutput
% supporting functions, listed at the end of the example, to initialize
% the training progress plot and verbose output to display the training
% loss, training accuracy, and validation accuracy.
plotters = initializeTrainingProgressPlot(params);
initializeVerboseOutput(params);

while iteration <= params.NumIterations

    % Iterate through the data set.
    [dlVideo,dlFlow,dlY] = next(mbq);

    % Evaluate the model gradients and loss using dlfeval.
    [gradRGB,gradFlow,loss,acc,accRGB,accFlow,stateRGB,stateFlow] = ...
        dlfeval(@modelGradients,i3d,dlVideo,dlFlow,dlY);

    % Accumulate the loss and accuracies.
    lossTrain    = [lossTrain, loss];
    accTrain     = [accTrain, acc];
    accTrainRGB  = [accTrainRGB, accRGB];
    accTrainFlow = [accTrainFlow, accFlow];

    % Update the network state.
    i3d.VideoState       = stateRGB;
    i3d.OpticalFlowState = stateFlow;

    % Update the gradients and parameters for the RGB and optical flow
    % subnetworks using the SGDM optimizer.
    [i3d.VideoLearnables,params.VelocityRGB] = ...
        updateLearnables(i3d.VideoLearnables,gradRGB,params,params.VelocityRGB,iteration);
    [i3d.OpticalFlowLearnables,params.VelocityFlow,learnRate] = ...
        updateLearnables(i3d.OpticalFlowLearnables,gradFlow,params,params.VelocityFlow,itera

    if ~hasdata(mbq) || iteration == params.NumIterations
        % Current epoch is complete. Do validation and update progress.
        trainTime = toc(trainTime);

        [validationTime,cmat,lossValidation,accValidation,accValidationRGB,accValidationFlow
            doValidation(params, i3d);

        accTrain     = mean(accTrain);
        accTrainRGB  = mean(accTrainRGB);
        accTrainFlow = mean(accTrainFlow);
        lossTrain    = mean(lossTrain);

        % Update the training progress.
        displayVerboseOutputEveryEpoch(params,start,learnRate,epoch,iteration,...
            accTrain,accTrainRGB,accTrainFlow,...
            accValidation,accValidationRGB,accValidationFlow,...
            lossTrain,lossValidation,trainTime,validationTime);
        updateProgressPlot(params,plotters,epoch,iteration,start,lossTrain,accTrain,accValida
```

```
            % Save the trained video classifier and the parameters, that gave
            % the best validation loss so far. Use the saveData supporting function,
            % listed at the end of this example.
            bestLoss = saveData(i3d,bestLoss,iteration,cmat,lossTrain,lossValidation,...
                accTrain,accValidation,params);
        end

        if ~hasdata(mbq) && iteration < params.NumIterations
            % Current epoch is complete. Initialize the training loss, accuracy
            % values, and minibatchqueue for the next epoch.
            accTrain     = [];
            accTrainRGB  = [];
            accTrainFlow = [];
            lossTrain    = [];

            trainTime  = tic;
            epoch      = epoch + 1;
            shuffled   = shuffleTrainDs(dsTrain);
            numOutputs = 3;
            mbq        = createMiniBatchQueue(shuffled, numOutputs, params);

        end

        iteration = iteration + 1;
    end

    % Display a message when training is complete.
    endVerboseOutput(params);

    disp("Model saved to: " + params.ModelFilename);
end
```

Evaluate Trained Network

Use the test data set to evaluate the accuracy of the trained video classifier.

Load the best model saved during training or use the pretrained model.

```
if doTraining
    transferLearned = load(params.ModelFilename);
    inflated3dPretrained = transferLearned.data.inflated3d;
end
```

Create a `minibatchqueue` object to load batches of the test data.

```
numOutputs = 3;
mbq = createMiniBatchQueue(params.ValidationData, numOutputs, params);
```

For each batch of test data, make predictions using the RGB and optical flow networks, take the average of the predictions, and compute the prediction accuracy using a confusion matrix.

```
numClasses = numel(classes);
cmat = sparse(numClasses,numClasses);
while hasdata(mbq)
    [dlRGB, dlFlow, dlY] = next(mbq);

    % Pass the video input as RGB and optical flow data through the
```

```
    % two-stream I3D Video Classifier to get the separate predictions.
    [dlYPredRGB,dlYPredFlow] = predict(inflated3dPretrained,dlRGB,dlFlow);

    % Fuse the predictions by calculating the average of the predictions.
    dlYPred = (dlYPredRGB + dlYPredFlow)/2;

    % Calculate the accuracy of the predictions.
    [~,YTest] = max(dlY,[],1);
    [~,YPred] = max(dlYPred,[],1);

    cmat = aggregateConfusionMetric(cmat,YTest,YPred);
end
```

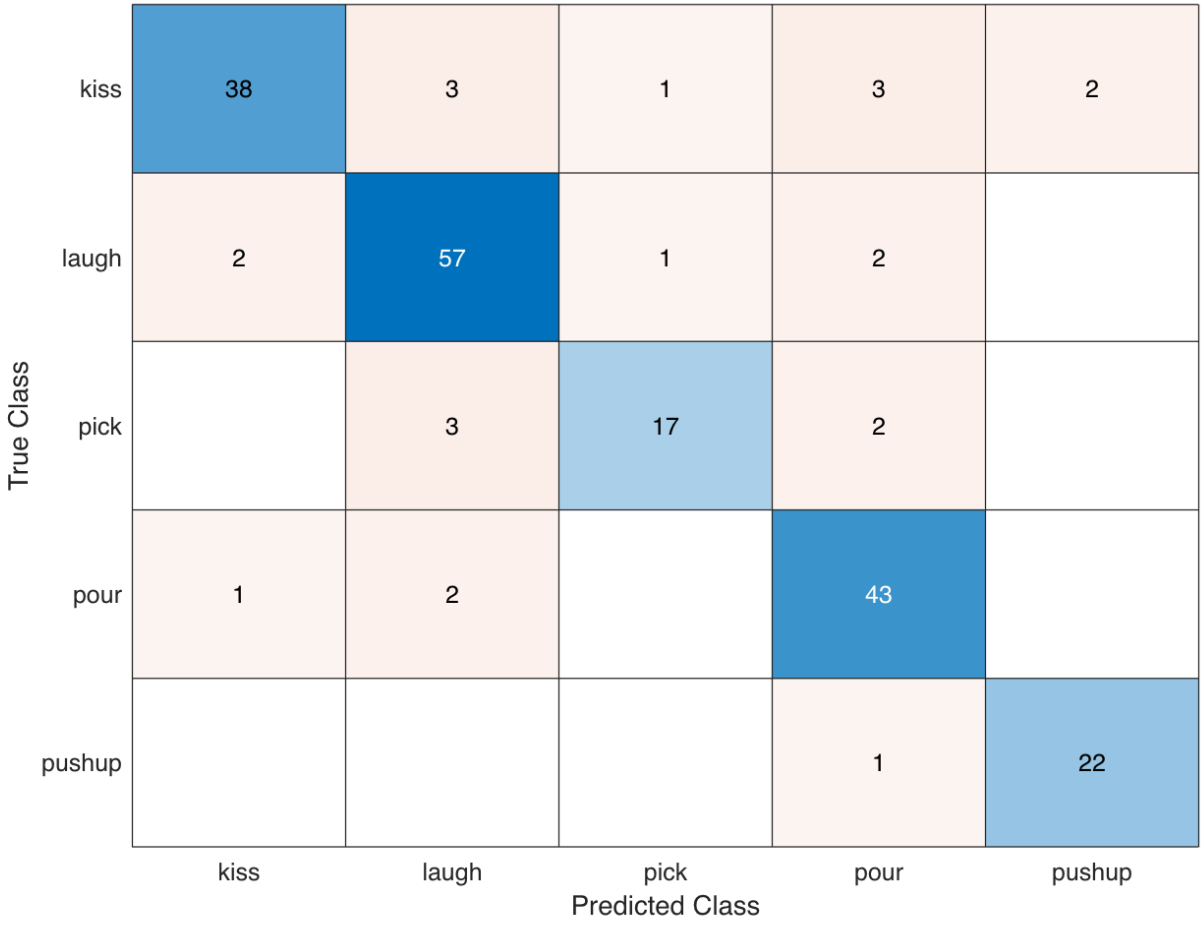
Compute the average classification accuracy for the trained networks.

```
accuracyEval = sum(diag(cmat))./sum(cmat,"all")
```

```
accuracyEval = 0.8850
```

Display the confusion matrix.

```
figure
chart = confusionchart(cmat,classes);
```



The Inflated-3D video classifier that is pretrained on the Kinetics-400 dataset, provides better performance for human activity recognition on transfer learning. The above training was run on 24GB Titan-X GPU for about 100 minutes. When training from scratch on a small activity recognition video dataset, the training time and convergence takes much longer than the pretrained video classifier. Transer learning using the Kinetics-400 pretrained Inflated-3D video classifier also avoids overfitting the classifier when ran for larger number of epochs. However, the SlowFast Video Classifier and R(2+1)D Video Classifier that are pretrained on the Kinetics-400 dataset provide better performance and faster convergence during training compared to the Inflated-3D Video Classifier. To learn more about video recognition using deep learning, see “Getting Started with Video Classification Using Deep Learning” (Computer Vision Toolbox).

Supporting Functions

`inputStatistics`

The `inputStatistics` function takes as input the name of the folder containing the HMDB51 data, and calculates the minimum and maximum values for the RGB data and the optical flow data. The minimum and maximum values are used as normalization inputs to the input layer of the networks. This function also obtains the number of frames in each of the video files to use later during training

and testing the network. In order to find the minimum and maximum values for a different data set, use this function with a folder name containing the data set.

```
function inputStats = inputStatistics(dataFolder)
    ds = createDatastore(dataFolder);
    ds.ReadFcn = @getMinMax;

    tic;
    tt = tall(ds);
    varnames = {'rgbMax','rgbMin','oflowMax','oflowMin'};
    stats = gather(groupsummary(tt,[],{'max','min'}, varnames));
    inputStats.Filename = gather(tt.Filename);
    inputStats.NumFrames = gather(tt.NumFrames);
    inputStats.rgbMax = stats.max_rgbMax;
    inputStats.rgbMin = stats.min_rgbMin;
    inputStats.oflowMax = stats.max_oflowMax;
    inputStats.oflowMin = stats.min_oflowMin;
    save('inputStatistics.mat','inputStats');
    toc;
end

function data = getMinMax(filename)
    reader = VideoReader(filename);
    opticFlow = opticalFlowFarneback;
    data = [];
    while hasFrame(reader)
        frame = readFrame(reader);
        [rgb,oflow] = findMinMax(frame,opticFlow);
        data = assignMinMax(data, rgb, oflow);
    end

    totalFrames = floor(reader.Duration * reader.FrameRate);
    totalFrames = min(totalFrames, reader.NumFrames);

    [labelName, filename] = getLabelFilename(filename);
    data.Filename = fullfile(labelName, filename);
    data.NumFrames = totalFrames;

    data = struct2table(data,'AsArray',true);
end

function data = assignMinMax(data, rgb, oflow)
    if isempty(data)
        data.rgbMax = rgb.Max;
        data.rgbMin = rgb.Min;
        data.oflowMax = oflow.Max;
        data.oflowMin = oflow.Min;
        return;
    end
    data.rgbMax = max(data.rgbMax, rgb.Max);
    data.rgbMin = min(data.rgbMin, rgb.Min);

    data.oflowMax = max(data.oflowMax, oflow.Max);
    data.oflowMin = min(data.oflowMin, oflow.Min);
end

function [rgbMinMax,oflowMinMax] = findMinMax(rgb, opticFlow)
    rgbMinMax.Max = max(rgb,[],[1,2]);
```

```
    rgbMinMax.Min = min(rgb,[],[1,2]);

    gray = rgb2gray(rgb);
    flow = estimateFlow(opticFlow,gray);
    oflow = cat(3,flow.Vx,flow.Vy,flow.Magnitude);

    oflowMinMax.Max = max(oflow,[],[1,2]);
    oflowMinMax.Min = min(oflow,[],[1,2]);
end

function ds = createDatastore(folder)
    ds = fileDatastore(folder,...
        'IncludeSubfolders', true,...
        'FileExtensions', '.avi',...
        'UniformRead', true,...
        'ReadFcn', @getMinMax);
    disp("NumFiles: " + numel(ds.Files));
end
```

createFileDatastore

The `createFileDatastore` function creates a `FileDatastore` object using the given file names. The `FileDatastore` object reads the data in `'partialfile'` mode, so every read can return partially read frames from videos. This feature helps with reading large video files, if all of the frames do not fit in memory.

```
function datastore = createFileDatastore(trainingFolder,numFrames,numChannels,classes,isDataForT
    readFcn = @(f,u)readVideo(f,u,numFrames,numChannels,classes,isDataForTraining);
    datastore = fileDatastore(trainingFolder,...
        'IncludeSubfolders',true,...
        'FileExtensions','.avi',...
        'ReadFcn',readFcn,...
        'ReadMode','partialfile');
end
```

shuffleTrainDs

The `shuffleTrainDs` function shuffles the files present in the training datastore `dsTrain`.

```
function shuffled = shuffleTrainDs(dsTrain)
shuffled = copy(dsTrain);
transformed = isa(shuffled, 'matlab.io.datastore.TransformedDatastore');
if transformed
    files = shuffled.UnderlyingDatastores{1}.Files;
else
    files = shuffled.Files;
end
n = numel(files);
shuffledIndices = randperm(n);
if transformed
    shuffled.UnderlyingDatastores{1}.Files = files(shuffledIndices);
else
    shuffled.Files = files(shuffledIndices);
end

reset(shuffled);
end
```

readVideo

The `readVideo` function reads video frames, and the corresponding label values for a given video file. During training, the read function reads the specific number of frames as per the network input size, with a randomly chosen starting frame. During testing, all the frames are sequentially read. The video frames are resized to the required classifier network input size for training, and for testing and validation.

```
function [data,userdata,done] = readVideo(filename,userdata,numFrames,numChannels,classes,isDataF
    if isempty(userdata)
        userdata.reader      = VideoReader(filename);
        userdata.batchesRead = 0;

        userdata.label = getLabel(filename,classes);

        totalFrames = floor(userdata.reader.Duration * userdata.reader.FrameRate);
        totalFrames = min(totalFrames, userdata.reader.NumFrames);
        userdata.totalFrames = totalFrames;
        userdata.datatype = class(read(userdata.reader,1));
    end
    reader      = userdata.reader;
    totalFrames = userdata.totalFrames;
    label       = userdata.label;
    batchesRead = userdata.batchesRead;

    if isDataForTraining
        video = readForTraining(reader, numFrames, totalFrames);
    else
        video = readForValidation(reader, userdata.datatype, numChannels, numFrames, totalFrames);
    end

    data = {video, label};

    batchesRead = batchesRead + 1;

    userdata.batchesRead = batchesRead;

    if numFrames > totalFrames
        numBatches = 1;
    else
        numBatches = floor(totalFrames/numFrames);
    end
    % Set the done flag to true, if the reader has read all the frames or
    % if it is training.
    done = batchesRead == numBatches || isDataForTraining;
end
```

readForTraining

The `readForTraining` function reads the video frames for training the video classifier. The function reads the specific number of frames as per the network input size, with a randomly chosen starting frame. If there are not enough frames left over, the video sequence is repeated to pad the required number of frames.

```
function video = readForTraining(reader, numFrames, totalFrames)
    if numFrames >= totalFrames
        startIdx = 1;
```

```
        endIdx = totalFrames;
    else
        startIdx = randperm(totalFrames - numFrames + 1);
        startIdx = startIdx(1);
        endIdx = startIdx + numFrames - 1;
    end
    video = read(reader,[startIdx,endIdx]);
    if numFrames > totalFrames
        % Add more frames to fill in the network input size.
        additional = ceil(numFrames/totalFrames);
        video = repmat(video,1,1,1,additional);
        video = video(:,:,:,1:numFrames);
    end
end
```

`readForValidation`

The `readForValidation` function reads the video frames for evaluating the trained video classifier. The function reads the specific number of frames sequentially as per the network input size. If there are not enough frames left over, the video sequence is repeated to pad the required number of frames.

```
function video = readForValidation(reader, datatype, numChannels, numFrames, totalFrames)
    H = reader.Height;
    W = reader.Width;
    toRead = min([numFrames,totalFrames]);
    video = zeros([H,W,numChannels,toRead], datatype);
    frameIndex = 0;
    while hasFrame(reader) && frameIndex < numFrames
        frame = readFrame(reader);
        frameIndex = frameIndex + 1;
        video(:,:,:,frameIndex) = frame;
    end

    if frameIndex < numFrames
        video = video(:,:,:,1:frameIndex);
        additional = ceil(numFrames/frameIndex);
        video = repmat(video,1,1,1,additional);
        video = video(:,:,:,1:numFrames);
    end
end
```

`getLabel`

The `getLabel` function obtains the label name from the full path of a filename. The label for a file is the folder in which it exists. For example, for a file path such as `"/path/to/dataset/clapping/video_0001.avi"`, the label name is `"clapping"`.

```
function label = getLabel(filename,classes)
    folder = fileparts(string(filename));
    [~,label] = fileparts(folder);
    label = categorical(string(label), string(classes));
end
```

`augmentVideo`

The `augmentVideo` function uses the augment transform function provided by the `augmentTransform` supporting function to apply the same augmentation across a video sequence.

```
function data = augmentVideo(data)
    numSequences = size(data,1);
    for ii = 1:numSequences
        video = data{ii,1};
        % HxWxC
        sz = size(video,[1,2,3]);
        % One augmentation per sequence
        augmentFcn = augmentTransform(sz);
        data{ii,1} = augmentFcn(video);
    end
end
```

augmentTransform

The `augmentTransform` function creates an augmentation method with random left-right flipping and scaling factors.

```
function augmentFcn = augmentTransform(sz)
% Randomly flip and scale the image.
tform = randomAffine2d('XReflection',true,'Scale',[1 1.1]);
rout = affineOutputView(sz,tform,'BoundsStyle','CenterOutput');

augmentFcn = @(data)augmentData(data,tform,rout);

    function data = augmentData(data,tform,rout)
        data = imwarp(data,tform,'OutputView',rout);
    end
end
```

preprocessVideoClips

The `preprocessVideoClips` function preprocesses the training video data to resize to the Inflated-3D Video Classifier input size. It takes the `InputNormalizationStatistics` and the `InputSize` properties of the video classifier in a struct, `info`. The `InputNormalizationStatistics` property is used to rescale the video frames and optical flow data between -1 and 1. The input size is used to resize the video frames using `imresize` based on the `SizingOption` value in the `info` struct. Alternatively, you could use `"randomcrop"` or `"centercrop"` as values for `SizingOption` to random crop or center crop the input data to the input size of the video classifier.

```
function preprocessed = preprocessVideoClips(data, info)
inputSize = info.InputSize(1:2);
sizingOption = info.SizingOption;
switch sizingOption
    case "resize"
        sizingFcn = @(x)imresize(x,inputSize);
    case "randomcrop"
        sizingFcn = @(x)cropVideo(x,@randomCropWindow2d,inputSize);
    case "centercrop"
        sizingFcn = @(x)cropVideo(x,@centerCropWindow2d,inputSize);
end
numClips = size(data,1);

rgbMin   = info.Statistics.Video.Min;
rgbMax   = info.Statistics.Video.Max;
oflowMin = info.Statistics.OpticalFlow.Min;
oflowMax = info.Statistics.OpticalFlow.Max;
```

```
numChannels = length(rgbMin);
rgbMin   = reshape(rgbMin, 1, 1, numChannels);
rgbMax   = reshape(rgbMax, 1, 1, numChannels);

numChannels = length(oflowMin);
oflowMin = reshape(oflowMin, 1, 1, numChannels);
oflowMax = reshape(oflowMax, 1, 1, numChannels);

preprocessed = cell(numClips, 3);
for ii = 1:numClips
    video   = data{ii,1};
    resized = sizingFcn(video);
    oflow   = computeFlow(resized,inputSize);

    % Cast the input to single.
    resized = single(resized);
    oflow   = single(oflow);

    % Rescale the input between -1 and 1.
    resized = rescale(resized,-1,1,"InputMin",rgbMin,"InputMax",rgbMax);
    oflow   = rescale(oflow,-1,1,"InputMin",oflowMin,"InputMax",oflowMax);

    preprocessed{ii,1} = resized;
    preprocessed{ii,2} = oflow;
    preprocessed{ii,3} = data{ii,2};
end
end

function outData = cropVideo(data, cropFcn, inputSize)
imsz = size(data,[1,2]);
cropWindow = cropFcn(imsz, inputSize);
numFrames = size(data,4);
sz = [inputSize, size(data,3), numFrames];
outData = zeros(sz, 'like', data);
for f = 1:numFrames
    outData(:,:,:,f) = imcrop(data(:,:,:,f), cropWindow);
end
end
```

`computeFlow`

The `computeFlow` function takes as input a video sequence, `videoFrames`, and computes the the corresponding optical flow data `opticalFlowData` using `opticalFlowFarneback`. The optical flow data contains two channels, which correspond to the *x*- and *y*- components of velocity.

```
function opticalFlowData = computeFlow(videoFrames, inputSize)
opticalFlow = opticalFlowFarneback;
numFrames = size(videoFrames,4);
sz = [inputSize, 2, numFrames];
opticalFlowData = zeros(sz, 'like', videoFrames);
for f = 1:numFrames
    gray = rgb2gray(videoFrames(:,:,:,f));
    flow = estimateFlow(opticalFlow,gray);

    opticalFlowData(:,:,:,f) = cat(3,flow.Vx,flow.Vy);
end
end
```

createMiniBatchQueue

The `createMiniBatchQueue` function creates a `minibatchqueue` object that provides `miniBatchSize` amount of data from the given datastore. It also creates a `DispatchInBackgroundDatastore` if a parallel pool is open.

```
function mbq = createMiniBatchQueue(datastore, numOutputs, params)
if params.DispatchInBackground && isempty(gcp('nocreate'))
    % Start a parallel pool, if DispatchInBackground is true, to dispatch
    % data in the background using the parallel pool.
    c = parcluster('local');
    c.NumWorkers = params.NumWorkers;
    parpool('local',params.NumWorkers);
end
p = gcp('nocreate');
if ~isempty(p)
    datastore = DispatchInBackgroundDatastore(datastore, p.NumWorkers);
end
inputFormat(1:numOutputs-1) = "SSCTB";
outputFormat = "CB";
mbq = minibatchqueue(datastore, numOutputs, ...
    "MiniBatchSize", params.MiniBatchSize, ...
    "MiniBatchFcn", @batchVideoAndFlow, ...
    "MiniBatchFormat", [inputFormat,outputFormat]);
end
```

batchVideoAndFlow

The `batchVideoAndFlow` function batches the video, optical flow, and label data from cell arrays. It uses `onehotencode` function to encode ground truth categorical labels into one-hot arrays. The one-hot encoded array contains a `1` in the position corresponding to the class of the label, and `0` in every other position.

```
function [video,flow,labels] = batchVideoAndFlow(video, flow, labels)
% Batch dimension: 5
video = cat(5,video{:});
flow = cat(5,flow{:});

% Batch dimension: 2
labels = cat(2,labels{:});

% Feature dimension: 1
labels = onehotencode(labels,1);
end
```

modelGradients

The `modelGradients` function takes as input a mini-batch of RGB data `dlRGB`, the corresponding optical flow data `dlFlow`, and the corresponding target `dlY`, and returns the corresponding loss, the gradients of the loss with respect to the learnable parameters, and the training accuracy. To compute the gradients, evaluate the `modelGradients` function using the `dlfeval` function in the training loop.

```
function [gradientsRGB,gradientsFlow,loss,acc,accRGB,accFlow,stateRGB,stateFlow] = modelGradients

% Pass video input as RGB and optical flow data through the two-stream
% network.
```

```
[dlYPredRGB,dlYPredFlow,stateRGB,stateFlow] = forward(i3d,dlRGB,dlFlow);

% Calculate fused loss, gradients, and accuracy for the two-stream
% predictions.
rgbLoss = crossentropy(dlYPredRGB,Y);
flowLoss = crossentropy(dlYPredFlow,Y);
% Fuse the losses.
loss = mean([rgbLoss,flowLoss]);

gradientsRGB = dlgradient(rgbLoss,i3d.VideoLearnables);
gradientsFlow = dlgradient(flowLoss,i3d.OpticalFlowLearnables);

% Fuse the predictions by calculating the average of the predictions.
dlYPred = (dlYPredRGB + dlYPredFlow)/2;

% Calculate the accuracy of the predictions.
[~,YTest] = max(Y,[],1);
[~,YPred] = max(dlYPred,[],1);

acc = gather(extractdata(sum(YTest == YPred)./numel(YTest)));

% Calculate the accuracy of the RGB and flow predictions.
[~,YTest] = max(Y,[],1);
[~,YPredRGB] = max(dlYPredRGB,[],1);
[~,YPredFlow] = max(dlYPredFlow,[],1);

accRGB = gather(extractdata(sum(YTest == YPredRGB)./numel(YTest)));
accFlow = gather(extractdata(sum(YTest == YPredFlow)./numel(YTest)));
end
```

`updateLearnables`

The `updateLearnables` function updates the provided `learnables` with gradients and other parameters using SGDM optimization function `sgdmupdate`.

```
function [learnables,velocity,learnRate] = updateLearnables(learnables,gradients,params,velocity
    % Determine the learning rate using the cosine-annealing learning rate schedule.
    learnRate = cosineAnnealingLearnRate(iteration, params);

    % Apply L2 regularization to the weights.
    idx = learnables.Parameter == "Weights";
    gradients(idx,:) = dlupdate(@(g,w) g + params.L2Regularization*w, gradients(idx,:), learnable

    % Update the network parameters using the SGDM optimizer.
    [learnables, velocity] = sgdmupdate(learnables, gradients, velocity, learnRate, params.Momen
end
```

`cosineAnnealingLearnRate`

The `cosineAnnealingLearnRate` function computes the learning rate based on the current iteration number, minimum learning rate, maximum learning rate, and number of iterations for annealing [3 on page 8-0].

```
function lr = cosineAnnealingLearnRate(iteration, params)
    if iteration == params.NumIterations
        lr = params.MinLearningRate;
        return;
    end
```

```
    cosineNumIter = [0, params.CosineNumIterations];
    csum = cumsum(cosineNumIter);
    block = find(csum >= iteration, 1,'first');
    cosineIter = iteration - csum(block - 1);
    annealingIteration = mod(cosineIter, cosineNumIter(block));
    cosineIteration = cosineNumIter(block);
    minR = params.MinLearningRate;
    maxR = params.MaxLearningRate;
    cosMult = 1 + cos(pi * annealingIteration / cosineIteration);
    lr = minR + ((maxR - minR) *  cosMult / 2);
end
```

aggregateConfusionMetric

The `aggregateConfusionMetric` function incrementally fills a confusion matrix based on the predicted results `YPred` and the expected results `YTest`.

```
function cmat = aggregateConfusionMetric(cmat,YTest,YPred)
YTest = gather(extractdata(YTest));
YPred = gather(extractdata(YPred));
[m,n] = size(cmat);
cmat = cmat + full(sparse(YTest,YPred,1,m,n));
end
```

doValidation

The `doValidation` function validates the video classifier using the validation data.

```
function [validationTime, cmat, lossValidation, accValidation, accValidationRGB, accValidationFl

validationTime = tic;

numOutputs = 3;
mbq = createMiniBatchQueue(params.ValidationData, numOutputs, params);

lossValidation = [];
numClasses = numel(params.Classes);
cmat = sparse(numClasses,numClasses);
cmatRGB = sparse(numClasses,numClasses);
cmatFlow = sparse(numClasses,numClasses);
while hasdata(mbq)

    [dlX1,dlX2,dlY] = next(mbq);

    [loss,YTest,YPred,YPredRGB,YPredFlow] = predictValidation(i3d,dlX1,dlX2,dlY);

    lossValidation = [lossValidation,loss];
    cmat = aggregateConfusionMetric(cmat,YTest,YPred);
    cmatRGB = aggregateConfusionMetric(cmatRGB,YTest,YPredRGB);
    cmatFlow = aggregateConfusionMetric(cmatFlow,YTest,YPredFlow);
end
lossValidation = mean(lossValidation);
accValidation = sum(diag(cmat))./sum(cmat,"all");
accValidationRGB = sum(diag(cmatRGB))./sum(cmatRGB,"all");
accValidationFlow = sum(diag(cmatFlow))./sum(cmatFlow,"all");

validationTime = toc(validationTime);
end
```

predictValidation

The `predictValidation` function calculates the loss and prediction values using the provided video classifier for RGB and optical flow data.

```
function [loss,YTest,YPred,YPredRGB,YPredFlow] = predictValidation(i3d,dlRGB,dlFlow,Y)

% Pass the video input through the two-stream Inflated-3D video classifier.
[dlYPredRGB,dlYPredFlow] = predict(i3d,dlRGB,dlFlow);

% Calculate the cross-entropy separately for the two-stream outputs.
rgbLoss = crossentropy(dlYPredRGB,Y);
flowLoss = crossentropy(dlYPredFlow,Y);

% Fuse the losses.
loss = mean([rgbLoss,flowLoss]);

% Fuse the predictions by calculating the average of the predictions.
dlYPred = (dlYPredRGB + dlYPredFlow)/2;

% Calculate the accuracy of the predictions.
[~,YTest] = max(Y,[],1);
[~,YPred] = max(dlYPred,[],1);

[~,YPredRGB] = max(dlYPredRGB,[],1);
[~,YPredFlow] = max(dlYPredFlow,[],1);

end
```

saveData

The `saveData` function saves the given Inflated-3d Video Classifier, accuracy, loss, and other training parameters to a MAT-file.

```
function bestLoss = saveData(inflated3d,bestLoss,iteration,cmat,lossTrain,lossValidation,...
                accTrain,accValidation,params)
if iteration >= params.SaveBestAfterIteration
    lossValidtion = extractdata(gather(lossValidation));
    if lossValidtion < bestLoss
        params = rmfield(params, 'VelocityRGB');
        params = rmfield(params, 'VelocityFlow');
        bestLoss = lossValidtion;
        inflated3d = gatherFromGPUToSave(inflated3d);
        data.BestLoss = bestLoss;
        data.TrainingLoss = extractdata(gather(lossTrain));
        data.TrainingAccuracy = accTrain;
        data.ValidationAccuracy = accValidation;
        data.ValidationConfmat= cmat;
        data.inflated3d = inflated3d;
        data.Params = params;
        save(params.ModelFilename, 'data');
    end
end
end
```

gatherFromGPUToSave

The `gatherFromGPUToSave` function gathers data from the GPU in order to save the video classifier to disk.

```
function classifier = gatherFromGPUToSave(classifier)
if ~canUseGPU
    return;
end
p = string(properties(classifier));
p = p(endsWith(p, ["Learnables","State"]));
for jj = 1:numel(p)
    prop = p(jj);
    classifier.(prop) = gatherValues(classifier.(prop));
end
    function tbl = gatherValues(tbl)
        for ii = 1:height(tbl)
            tbl.Value{ii} = gather(tbl.Value{ii});
        end
    end
end
```

checkForHMDB51Folder

The `checkForHMDB51Folder` function checks for the downloaded data in the download folder.

```
function classes = checkForHMDB51Folder(dataLoc)
hmdbFolder = fullfile(dataLoc, "hmdb51_org");
if ~isfolder(hmdbFolder)
    error("Download 'hmdb51_org.rar' file using the supporting function 'downloadHMDB51' before r
end

classes = ["brush_hair","cartwheel","catch","chew","clap","climb","climb_stairs",...
    "dive","draw_sword","dribble","drink","eat","fall_floor","fencing",...
    "flic_flac","golf","handstand","hit","hug","jump","kick","kick_ball",...
    "kiss","laugh","pick","pour","pullup","punch","push","pushup","ride_bike",...
    "ride_horse","run","shake_hands","shoot_ball","shoot_bow","shoot_gun",...
    "sit","situp","smile","smoke","somersault","stand","swing_baseball","sword",...
    "sword_exercise","talk","throw","turn","walk","wave"];
expectFolders = fullfile(hmdbFolder, classes);
if ~all(arrayfun(@(x)exist(x,'dir'),expectFolders))
    error("Download hmdb51_org.rar using the supporting function 'downloadHMDB51' before running
end
end
```

downloadHMDB51

The `downloadHMDB51` function downloads the data set and saves it to a directory.

```
function downloadHMDB51(dataLoc)

if nargin == 0
    dataLoc = pwd;
end
dataLoc = string(dataLoc);

if ~isfolder(dataLoc)
    mkdir(dataLoc);
```

```
end

dataUrl     = "http://serre-lab.clps.brown.edu/wp-content/uploads/2013/10/hmdb51_org.rar";
options     = weboptions('Timeout', Inf);
rarFileName = fullfile(dataLoc, 'hmdb51_org.rar');

% Download the RAR file and save it to the download folder.
if ~isfile(rarFileName)
    disp("Downloading hmdb51_org.rar (2 GB) to the folder:")
    disp(dataLoc)
    disp("This download can take a few minutes...")
    websave(rarFileName, dataUrl, options);
    disp("Download complete.")
    disp("Extract the hmdb51_org.rar file contents to the folder: ")
    disp(dataLoc)
end
end
```

initializeTrainingProgressPlot

The `initializeTrainingProgressPlot` function configures two plots for displaying the training loss, training accuracy, and validation accuracy.

```
function plotters = initializeTrainingProgressPlot(params)
if params.ProgressPlot
    % Plot the loss, training accuracy, and validation accuracy.
    figure

    % Loss plot
    subplot(2,1,1)
    plotters.LossPlotter = animatedline;
    xlabel("Iteration")
    ylabel("Loss")

    % Accuracy plot
    subplot(2,1,2)
    plotters.TrainAccPlotter = animatedline('Color','b');
    plotters.ValAccPlotter = animatedline('Color','g');
    legend('Training Accuracy','Validation Accuracy','Location','northwest');
    xlabel("Iteration")
    ylabel("Accuracy")
else
    plotters = [];
end
end
```

updateProgressPlot

The `updateProgressPlot` function updates the progress plot with loss and accuracy information during training.

```
function updateProgressPlot(params,plotters,epoch,iteration,start,lossTrain,accuracyTrain,accurac
if params.ProgressPlot

    % Update the training progress.
    D = duration(0,0,toc(start),"Format","hh:mm:ss");
    title(plotters.LossPlotter.Parent,"Epoch: " + epoch + ", Elapsed: " + string(D));
    addpoints(plotters.LossPlotter,iteration,double(gather(extractdata(lossTrain))));
```

```
    addpoints(plotters.TrainAccPlotter,iteration,accuracyTrain);
    addpoints(plotters.ValAccPlotter,iteration,accuracyValidation);
    drawnow
end
end
```

initializeVerboseOutput

The `initializeVerboseOutput` function displays the column headings for the table of training values, which shows the epoch, mini-batch accuracy, and other training values.

```
function initializeVerboseOutput(params)
if params.Verbose
    disp(" ")
    if canUseGPU
        disp("Training on GPU.")
    else
        disp("Training on CPU.")
    end
    p = gcp('nocreate');
    if ~isempty(p)
        disp("Training on parallel cluster '" + p.Cluster.Profile + "'. ")
    end
    disp("NumIterations:" + string(params.NumIterations));
    disp("MiniBatchSize:" + string(params.MiniBatchSize));
    disp("Classes:" + join(string(params.Classes), ","));
    disp("|=========================================================================================
    disp("| Epoch | Iteration | Time Elapsed |     Mini-Batch Accuracy    |    Validation Accurac
    disp("|       |           |  (hh:mm:ss)  |       (Avg:RGB:Flow)       |       (Avg:RGB:Flow)
    disp("|=========================================================================================
end
end
```

displayVerboseOutputEveryEpoch

The `displayVerboseOutputEveryEpoch` function displays the verbose output of the training values, such as the epoch, mini-batch accuracy, validation accuracy, and mini-batch loss.

```
function displayVerboseOutputEveryEpoch(params,start,learnRate,epoch,iteration,...
    accTrain,accTrainRGB,accTrainFlow,accValidation,accValidationRGB,accValidationFlow,lossTrain
if params.Verbose
    D = duration(0,0,toc(start),'Format','hh:mm:ss');
    trainTime = duration(0,0,trainTime,'Format','hh:mm:ss');
    validationTime = duration(0,0,validationTime,'Format','hh:mm:ss');

    lossValidation = gather(extractdata(lossValidation));
    lossValidation = compose('%.4f',lossValidation);

    accValidation = composePadAccuracy(accValidation);
    accValidationRGB = composePadAccuracy(accValidationRGB);
    accValidationFlow = composePadAccuracy(accValidationFlow);

    accVal = join([accValidation,accValidationRGB,accValidationFlow], " : ");

    lossTrain = gather(extractdata(lossTrain));
    lossTrain = compose('%.4f',lossTrain);

    accTrain = composePadAccuracy(accTrain);
```

```
    accTrainRGB = composePadAccuracy(accTrainRGB);
    accTrainFlow = composePadAccuracy(accTrainFlow);

    accTrain = join([accTrain,accTrainRGB,accTrainFlow], " : ");
    learnRate = compose('%.13f',learnRate);

    disp("| " + ...
        pad(string(epoch),5,'both') + " | " + ...
        pad(string(iteration),9,'both') + " | " + ...
        pad(string(D),12,'both') + " | " + ...
        pad(string(accTrain),26,'both') + " | " + ...
        pad(string(accVal),26,'both') + " | " + ...
        pad(string(lossTrain),10,'both') + " | " + ...
        pad(string(lossValidation),10,'both') + " | " + ...
        pad(string(learnRate),13,'both') + " | " + ...
        pad(string(trainTime),10,'both') + " | " + ...
        pad(string(validationTime),15,'both') + " |")
end

    function acc = composePadAccuracy(acc)
        acc = compose('%.2f',acc*100) + "%";
        acc = pad(string(acc),6,'left');
    end

end
```

`endVerboseOutput`

The `endVerboseOutput` function displays the end of verbose output during training.

```
function endVerboseOutput(params)
if params.Verbose
    disp("|========================================================================================
end
end
```

Import Pretrained ONNX YOLO v2 Object Detector

This example shows how to import a pretrained ONNX™ (Open Neural Network Exchange) you only look once (YOLO) v2 [1] on page 8-0 object detection network and use it to detect objects. After you import the network, you can deploy it to embedded platforms using GPU Coder™ or retrain it on custom data using transfer learning with `trainYOLOv2ObjectDetector`.

Download ONNX YOLO v2 Network

Download files related to the pretrained Tiny YOLO v2 network.

```
pretrainedURL = 'https://ssd.mathworks.com/supportfiles/vision/deeplearning/models/yolov2/tiny_yo
pretrainedNetTar = 'yolov2Tiny.tar';
if ~exist(pretrainedNetTar,'file')
    disp('Downloading pretrained network (58 MB)...');
    websave(pretrainedNetTar,pretrainedURL);
end
```

```
Downloading pretrained network (58 MB)...
```

Extract YOLO v2 Network

Untar the downloaded file to extract the Tiny YOLO v2 network. Load the `'Model.onnx'` model from `tiny_yolov2` folder, which is an ONNX YOLO v2 network pretrained on the PASCAL VOC data set. The network can detect objects from 20 different classes [4] on page 8-0 .

```
onnxfiles = untar(pretrainedNetTar);
pretrainedNet = 'tiny_yolov2/Model.onnx';
```

Import ONNX YOLO v2 Layers

Use the `importONNXLayers` function to import the downloaded network.

```
lgraph = importONNXLayers(pretrainedNet,'ImportWeights',true);
```

```
Warning: Imported layers have no output layer because ONNX files do not specify the network's ou
```

In this example you add an output layer to the imported layers, so you can ignore this warning. The Add YOLO v2 Transform and Output Layers on page 8-0 section shows how to add YOLO v2 output layer along with YOLO v2 Transform layer to the imported layers.

The network in this example contains no unsupported layers. Note that if the network you want to import has unsupported layers, the function imports them as placeholder layers. Before you can use your imported network, you must replace these layers. For more information on replacing placeholder layers, see `findPlaceholderLayers`.

Define YOLO v2 Anchor Boxes

YOLO v2 uses predefined anchor boxes to predict object location. The anchor boxes used in the imported network are defined in the Tiny YOLO v2 network configuration file [5] on page 8-0 . The ONNX anchors are defined with respect to the output size of the final convolution layer, which is 13-by-13. To use the anchors with `yolov2ObjectDetector`, resize the anchor boxes to the network input size, which is 416-by-416. The anchor boxes for `yolov2ObjectDetector` must be specified in the form [height, width].

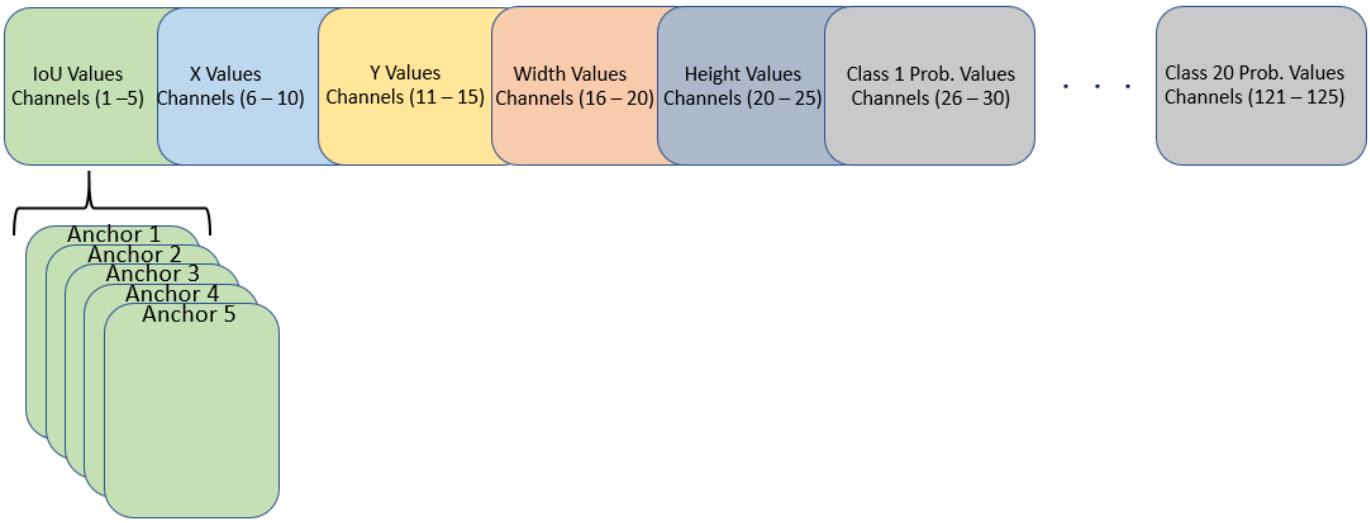
```
onnxAnchors = [1.08,1.19; 3.42,4.41; 6.63,11.38; 9.42,5.11; 16.62,10.52];
```

```
inputSize = lgraph.Layers(1,1).InputSize(1:2);
lastActivationSize = [13,13];
upScaleFactor = inputSize./lastActivationSize;
anchorBoxesTmp = upScaleFactor.* onnxAnchors;
anchorBoxes = [anchorBoxesTmp(:,2),anchorBoxesTmp(:,1)];
```

Reorder Detection Layer Weights

For efficient processing, you must reorder the weights and biases of the last convolution layer in the imported network to obtain the activations in the arrangement that `yolov2ObjectDetector` requires. `yolov2ObjectDetector` expects the 125 channels of the feature map of the last convolution layer in the following arrangement:

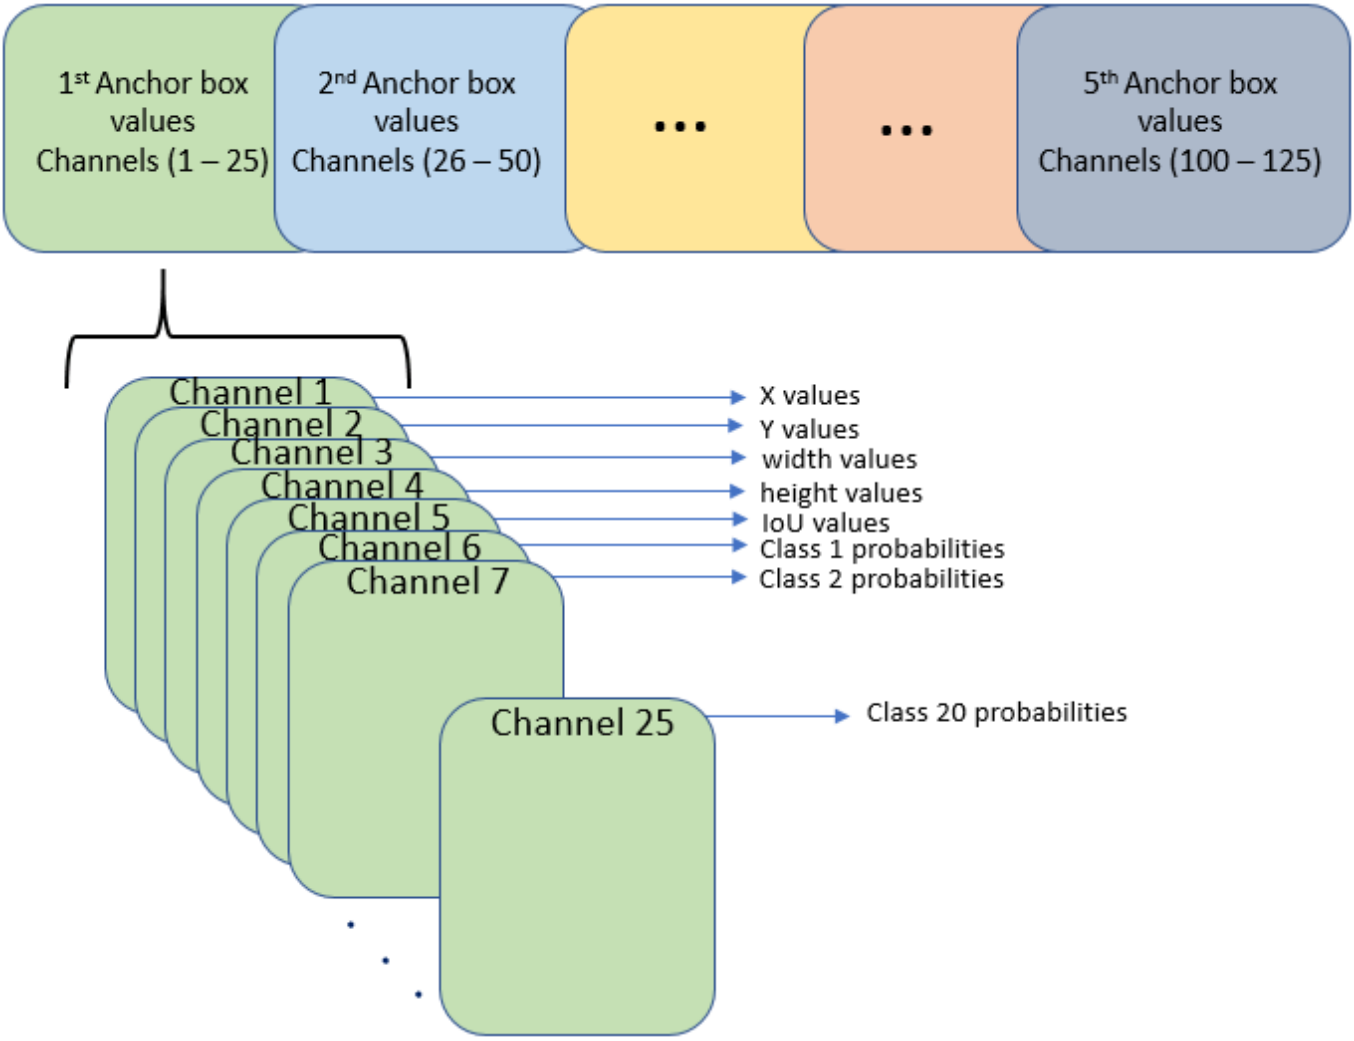
- Channels 1 to 5 - IoU values for five anchors
- Channels 6 to 10 - X values for five anchors
- Channels 11 to 15 - Y values for five anchors
- Channels 16 to 20 - Width values for five anchors
- Channels 21 to 25 - Height values for five anchors
- Channels 26 to 30 - Class 1 probability values for five anchors
- Channels 31 to 35 - Class 2 probability values for five anchors
- Channels 121 to 125 - Class 20 probability values for five anchors



However, in the last convolution layer, which is of size 13-by-13, the activations are arranged differently. Each of the 25 channels in the feature map corresponds to:

- Channel 1 - X values
- Channel 2 - Y values
- Channel 3 - Width values
- Channel 4 - Height values
- Channel 5 - IoU values
- Channel 6 - Class 1 probability values

- Channel 7 - Class 2 probability values
- Channel 25 - Class 20 probability values



Use the supporting function `rearrangeONNXWeights`, listed at the end of this example, to reorder the weights and biases of the last convolution layer in the imported network and obtain the activations in the format required by `yolov2ObjectDetector`.

```
weights = lgraph.Layers(end,1).Weights;
bias = lgraph.Layers(end,1).Bias;
layerName = lgraph.Layers(end,1).Name;

numAnchorBoxes = size(onnxAnchors,1);
[modWeights,modBias] = rearrangeONNXWeights(weights,bias,numAnchorBoxes);
```

Replace the weights and biases of the last convolution layer in the imported network with the new convolution layer using the reordered weights and biases.

```
filterSize = size(modWeights,[1 2]);
numFilters = size(modWeights,4);
```

```
modConvolution8 = convolution2dLayer(filterSize,numFilters,...
    'Name',layerName,'Bias',modBias,'Weights',modWeights);
lgraph = replaceLayer(lgraph,'convolution8',modConvolution8);
```

Add YOLO v2 Transform and Output Layers

A YOLO v2 detection network requires the YOLO v2 transform and YOLO v2 output layers. Create both of these layers, stack them in series, and attach the YOLO v2 transform layer to the last convolution layer.

```
classNames = tinyYOLOv2Classes;

layersToAdd = [
    yolov2TransformLayer(numAnchorBoxes,'Name','yolov2Transform');
    yolov2OutputLayer(anchorBoxes,'Classes',classNames,'Name','yolov2Output');
    ];

lgraph = addLayers(lgraph, layersToAdd);
lgraph = connectLayers(lgraph,layerName,'yolov2Transform');
```

The `ElementwiseAffineLayer` in the imported network duplicates the preprocessing step performed by `yolov2ObjectDetector`. Hence, remove the `ElementwiseAffineLayer` from the imported network.

```
yoloScaleLayerIdx = find(...
    arrayfun( @(x)isa(x,'nnet.onnx.layer.ElementwiseAffineLayer'), ...
    lgraph.Layers));

if ~isempty(yoloScaleLayerIdx)
    for i = 1:size(yoloScaleLayerIdx,1)
        layerNames {i} = lgraph.Layers(yoloScaleLayerIdx(i,1),1).Name;
    end
    lgraph = removeLayers(lgraph,layerNames);
    lgraph = connectLayers(lgraph,'Input_image','convolution');
end
```

Create YOLO v2 Object Detector

Assemble the layer graph using the `assembleNetwork` function and create a YOLO v2 object detector using the `yolov2ObjectDetector` function.

```
net = assembleNetwork(lgraph)
```

```
net =
  DAGNetwork with properties:

         Layers: [34×1 nnet.cnn.layer.Layer]
    Connections: [33×2 table]
     InputNames: {'Input_image'}
    OutputNames: {'yolov2Output'}
```

```
yolov2Detector = yolov2ObjectDetector(net)
```

```
yolov2Detector =
  yolov2ObjectDetector with properties:

            ModelName: 'importedNetwork'
```

```
           Network: [1×1 DAGNetwork]
    TrainingImageSize: [416 416]
         AnchorBoxes: [5×2 double]
          ClassNames: [aeroplane    bicycle    bird    boat    bottle    bus    car    cat    cl
```

Detect Objects Using Imported YOLO v2 Detector

Use the imported detector to detect objects in a test image. Display the results.

```
I = imread('highway.png');
% Convert image to BGR format.
Ibgr = cat(3,I(:,:,3),I(:,:,2),I(:,:,1));

More About

- “Export to and Import from ONNX” on page 1-15

Export YOLO v2 Object Detector to ONNX

This example shows how to export a YOLO v2 object detection network to ONNX™ (Open Neural Network Exchange) model format. After exporting the YOLO v2 network, you can import the network into other deep learning frameworks for inference. This example also presents the workflow that you can follow to perform inference using the imported ONNX model.

Export YOLO v2 Network

Export the detection network to ONNX and gather the metadata required to generate object detection results.

First, load a pretrained YOLO v2 object detector into the workspace.

```
input = load('yolov2VehicleDetector.mat');
net = input.detector.Network;
```

Next, obtain the YOLO v2 detector metadata to use for inference. The detector metadata includes the network input image size, anchor boxes, and activation size of last convolution layer.

Read the network input image size from the input YOLO v2 network.

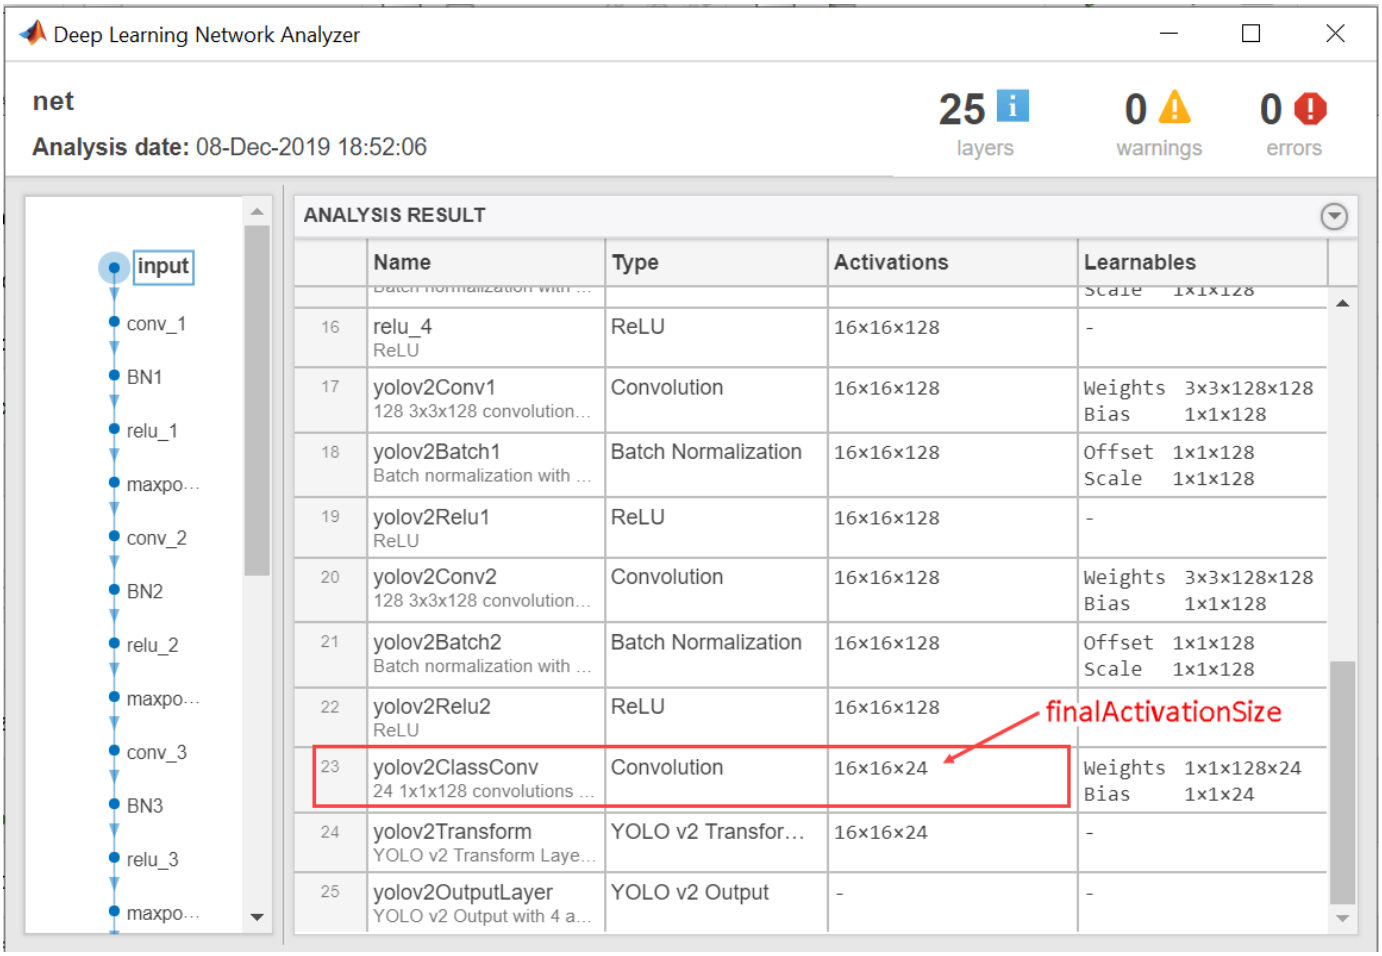
```
inputImageSize = net.Layers(1,1).InputSize;
```

Read the anchor boxes used for training from the input detector.

```
anchorBoxes = input.detector.AnchorBoxes;
```

Get the activation size of the last convolution layer in the input network by using the `analyzeNetwork` function.

```
analyzeNetwork(net);
```



```
finalActivationSize = [16 16 24];
```

Export to ONNX Model Format

Export the YOLO v2 object detection network as an ONNX format file by using the `exportONNXNetwork` function. Specify the file name as `yolov2.onnx`. The function saves the exported ONNX file to the current working folder.

```
filename = 'yolov2.onnx';
exportONNXNetwork(net,filename);
```

The `exportONNXNetwork` function maps the `yolov2TransformLayer` (Computer Vision Toolbox) and `yolov2OutputLayer` (Computer Vision Toolbox) in the input YOLO v2 network to the basic ONNX operator and identity operator, respectively. After you export the network, you can import the `yolov2.onnx` file into any deep learning framework that supports ONNX import.

Using the `exportONNXNetwork`, requires Deep Learning Toolbox™ and the Deep Learning Toolbox Converter for ONNX Model Format support package. If this support package is not installed, then the function provides a download link.

Object Detection Using Exported YOLO v2 Network

When exporting is complete, you can import the ONNX model into any deep learning framework and use the following workflow to perform object detection. Along with the ONNX network, this workflow

also requires the YOLO v2 detector metadata `inputImageSize`, `anchorBoxes`, and `finalActivationSize` obtained from the MATLAB workspace. The following code is a MATLAB implementation of the workflow that you must translate into the equivalent code for the framework of your choice.

Preprocess Input Image

Preprocess the image to use for inference. The image must be an RGB image and must be resized to the network input image size, and its pixel values must lie in the interval [0 1].

```
I = imread('highway.png');
resizedI = imresize(I,inputImageSize(1:2));
rescaledI = rescale(resizedI);
```

Pass Input and Run ONNX Model

Run the ONNX model in the deep learning framework of your choice with the preprocessed image as input to the imported ONNX model.

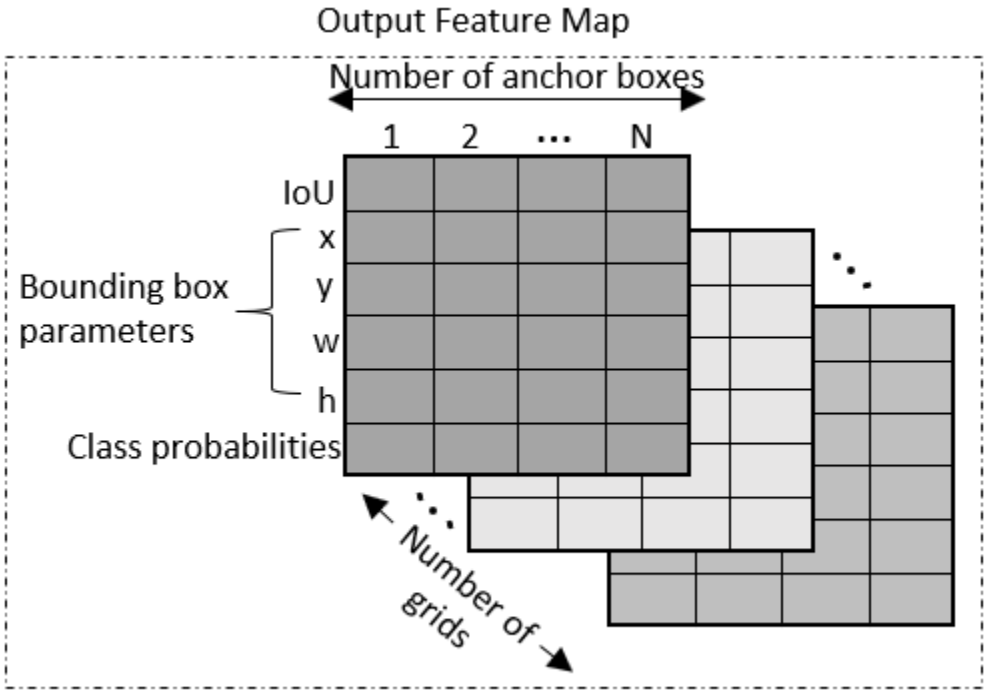
Extract Predictions from Output of ONNX Model

The model predicts the following:

- Intersection over union (IoU) with ground truth boxes
- `x`, `y`, `w`, and `h` bounding box parameters for each anchor box
- Class probabilities for each anchor box

The output of the ONNX model is a feature map that contains the predictions and is of size `predictionsPerAnchor`-by-`numAnchors`-by-`numGrids`.

- `numAnchors` is the number of anchor boxes.
- `numGrids` is the number of grids calculated as the product of the height and width of the last convolution layer.
- `predictionsPerAnchor` is the output predictions in the form [`IoU;x;y;w;h;class probabilities`].



- The first row in the feature map contains IoU predictions for each anchor box.
- The second and third rows in the feature map contain predictions for the centroid coordinates (x,y) of each anchor box.
- The fourth and fifth rows in the feature map contain the predictions for the width and height of each anchor box.
- The sixth row in the feature map contains the predictions for class probabilities of each anchor box.

Compute Final Detections

To compute final detections for the preprocessed test image, you must:

- Rescale the bounding box parameters with respect to the size of the input layer of the network.
- Compute object confidence scores from the predictions.
- Obtain predictions with high object confidence scores.
- Perform nonmaximum suppression.

As an implementation guide, use the code for `yolov2PostProcess` on page 8-0 function in Postprocessing Functions on page 8-0 .

```
[bboxes,scores,labels] = yolov2PostProcess(featureMap,inputImageSize,finalActivationsSize,anchorB
```

Display Detection Results

```
Idisp = insertObjectAnnotation(resizedI,'rectangle',bboxes,scores);
figure
imshow(Idisp)
```

Postprocessing Functions

```
function  [bboxes,scores,labels] = yolov2PostProcess(featureMap,inputImageSize,finalActivationsSi

% Extract prediction values from the feature map.
iouPred = featureMap(1,:,:);
xyPred = featureMap(2:3,:,:);
whPred = featureMap(4:5,:,:);
probPred = featureMap(6,:,:);

% Rescale the bounding box parameters.
bBoxes = rescaleBbox(xyPred,whPred,anchorBoxes,finalActivationsSize,inputImageSize);

% Rearrange the feature map as a two-dimensional matrix for efficient processing.
predVal = [bBoxes;iouPred;probPred];
predVal = reshape(predVal,size(predVal,1),[]);

% Compute object confidence scores from the rearranged prediction values.
[confScore,idx] = computeObjectScore(predVal);

% Obtain predictions with high object confidence scores.
[bboxPred,scorePred,classPred] = selectMaximumPredictions(confScore,idx,predVal);

% To get the final detections, perform nonmaximum suppression with an overlap threshold of 0.5.
[bboxes,scores,labels] = selectStrongestBboxMulticlass(bboxPred', scorePred', classPred','RatioTy

end

function bBoxes = rescaleBbox(xyPred,whPred,anchorBoxes,finalActivationsSize,inputImageSize)

% To rescale the bounding box parameters, compute the scaling factor by using the network paramet
scaleY = inputImageSize(1)/finalActivationsSize(1);
scaleX = inputImageSize(2)/finalActivationsSize(2);
scaleFactor = [scaleY scaleX];

bBoxes = zeros(size(xyPred,1)+size(whPred,1),size(anchors,1),size(xyPred,3),'like',xyPred);
for rowIdx=0:finalActivationsSize(1,1)-1
    for colIdx=0:finalActivationsSize(1,2)-1
        ind = rowIdx*finalActivationsSize(1,2)+colIdx+1;
        for anchorIdx = 1 : size(anchorBoxes,1)

            % Compute the center with respect to image.
            cx = (xyPred(1,anchorIdx,ind)+colIdx)* scaleFactor(1,2);
            cy = (xyPred(2,anchorIdx,ind)+rowIdx)* scaleFactor(1,1);

            % Compute the width and height with respect to the image.
            bw = whPred(1,anchorIdx,ind)* anchorBoxes(anchorIdx,1);
            bh = whPred(2,anchorIdx,ind)* anchorBoxes(anchorIdx,2);

            bBoxes(1,anchorIdx,ind) = (cx-bw/2);
            bBoxes(2,anchorIdx,ind) = (cy-bh/2);
            bBoxes(3,anchorIdx,ind) = bw;
```

```
            bBoxes(4,anchorIdx,ind) = bh;
        end
    end
end
end

function [confScore,idx] = computeObjectScore(predVal)
iouPred = predVal(5,:);
probPred = predVal(6:end,:);
[imax,idx] = max(probPred,[],1);
confScore = iouPred.*imax;
end

function [bboxPred,scorePred,classPred] = selectMaximumPredictions(confScore,idx,predVal)
% Specify the threshold for confidence scores.
confScoreId = confScore >= 0.5;
% Obtain the confidence scores greater than or equal to 0.5.
scorePred = confScore(:,confScoreId);
% Obtain the class IDs for predictions with confidence scores greater than
% or equal to 0.5.
classPred = idx(:,confScoreId);
% Obtain the bounding box parameters for predictions with confidence scores
% greater than or equal to 0.5.
bboxesXYWH = predVal(1:4,:);
bboxPred = bboxesXYWH(:,confScoreId);
end
```

Object Detection Using SSD Deep Learning

This example shows how to train a Single Shot Detector (SSD).

Overview

Deep learning is a powerful machine learning technique that automatically learns image features required for detection tasks. There are several techniques for object detection using deep learning such as Faster R-CNN, You Only Look Once (YOLO v2), and SSD. This example trains an SSD vehicle detector using the `trainSSDObjectDetector` function. For more information, see “Object Detection” (Computer Vision Toolbox).

Download Pretrained Detector

Download a pretrained detector to avoid having to wait for training to complete. If you want to train the detector, set the `doTraining` variable to true.

```
doTraining = false;
if ~doTraining && ~exist('ssdResNet50VehicleExample_20a.mat','file')
    disp('Downloading pretrained detector (44 MB)...');
    pretrainedURL = 'https://www.mathworks.com/supportfiles/vision/data/ssdResNet50VehicleExample
    websave('ssdResNet50VehicleExample_20a.mat',pretrainedURL);
end
```

```
Downloading pretrained detector (44 MB)...
```

Load Dataset

This example uses a small vehicle data set that contains 295 images. Many of these images come from the Caltech Cars 1999 and 2001 data sets, available at the Caltech Computational Vision website, created by Pietro Perona and used with permission. Each image contains one or two labeled instances of a vehicle. A small data set is useful for exploring the SSD training procedure, but in practice, more labeled images are needed to train a robust detector.

```
unzip vehicleDatasetImages.zip
data = load('vehicleDatasetGroundTruth.mat');
vehicleDataset = data.vehicleDataset;
```

The training data is stored in a table. The first column contains the path to the image files. The remaining columns contain the ROI labels for vehicles. Display the first few rows of the data.

```
vehicleDataset(1:4,:)
```

```
ans=4×2 table
              imageFilename                    vehicle
    ___________________________________    _______________

    {'vehicleImages/image_00001.jpg'}    {[220 136 35 28]}
    {'vehicleImages/image_00002.jpg'}    {[175 126 61 45]}
    {'vehicleImages/image_00003.jpg'}    {[108 120 45 33]}
    {'vehicleImages/image_00004.jpg'}    {[124 112 38 36]}
```

Split the data set into a training set for training the detector and a test set for evaluating the detector. Select 60% of the data for training. Use the rest for evaluation.

```
rng(0);
shuffledIndices = randperm(height(vehicleDataset));
```

```
idx = floor(0.6 * length(shuffledIndices) );
trainingData = vehicleDataset(shuffledIndices(1:idx),:);
testData = vehicleDataset(shuffledIndices(idx+1:end),:);
```

Use `imageDatastore` and `boxLabelDatastore` to load the image and label data during training and evaluation.

```
imdsTrain = imageDatastore(trainingData{:,'imageFilename'});
bldsTrain = boxLabelDatastore(trainingData(:,'vehicle'));

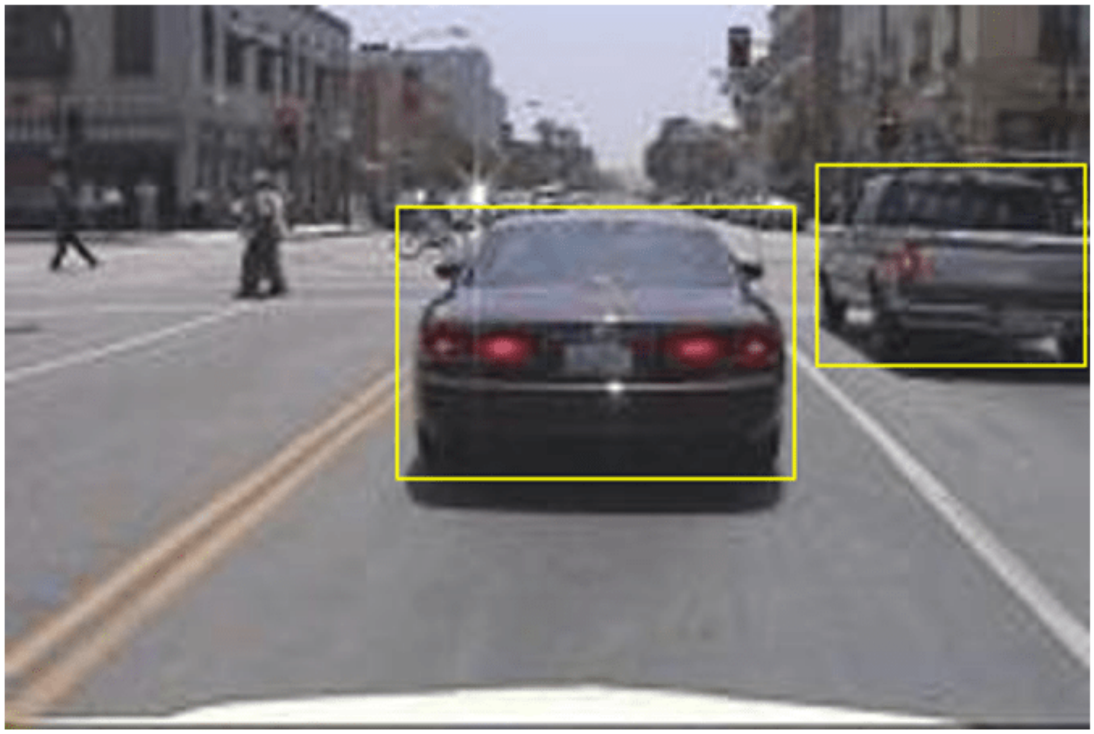
imdsTest = imageDatastore(testData{:,'imageFilename'});
bldsTest = boxLabelDatastore(testData(:,'vehicle'));
```

Combine image and box label datastores.

```
trainingData = combine(imdsTrain,bldsTrain);
testData = combine(imdsTest, bldsTest);
```

Display one of the training images and box labels.

```
data = read(trainingData);
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```



Create a SSD Object Detection Network

The SSD object detection network can be thought of as having two sub-networks. A feature extraction network, followed by a detection network.

The feature extraction network is typically a pretrained CNN (see “Pretrained Deep Neural Networks” on page 1-8 for more details). This example uses ResNet-50 for feature extraction. Other pretrained networks such as MobileNet v2 or ResNet-18 can also be used depending on application requirements. The detection sub-network is a small CNN compared to the feature extraction network and is composed of a few convolutional layers and layers specific to SSD.

Use the `ssdLayers` function to automatically modify a pretrained ResNet-50 network into a SSD object detection network. `ssdLayers` requires you to specify several inputs that parameterize the SSD network, including the network input size and the number of classes. When choosing the network input size, consider the size of the training images, and the computational cost incurred by processing data at the selected size. When feasible, choose a network input size that is close to the size of the training image. However, to reduce the computational cost of running this example, the network input size is chosen to be [300 300 3]. During training, `trainSSDObjectDetector` automatically resizes the training images to the network input size.

```
inputSize = [300 300 3];
```

Define number of object classes to detect.

```
numClasses = width(vehicleDataset)-1;
```

Create the SSD object detection network.

```
lgraph = ssdLayers(inputSize, numClasses, 'resnet50');
```

You can visualize the network using `analyzeNetwork` or `DeepNetworkDesigner` from Deep Learning Toolbox™. Note that you can also create a custom SSD network layer-by-layer. For more information, see “Create SSD Object Detection Network” (Computer Vision Toolbox).

Data Augmentation

Data augmentation is used to improve network accuracy by randomly transforming the original data during training. By using data augmentation, you can add more variety to the training data without actually having to increase the number of labeled training samples. Use `transform` to augment the training data by

- Randomly flipping the image and associated box labels horizontally.
- Randomly scale the image, associated box labels.
- Jitter image color.

Note that data augmentation is not applied to the test data. Ideally, test data should be representative of the original data and is left unmodified for unbiased evaluation.

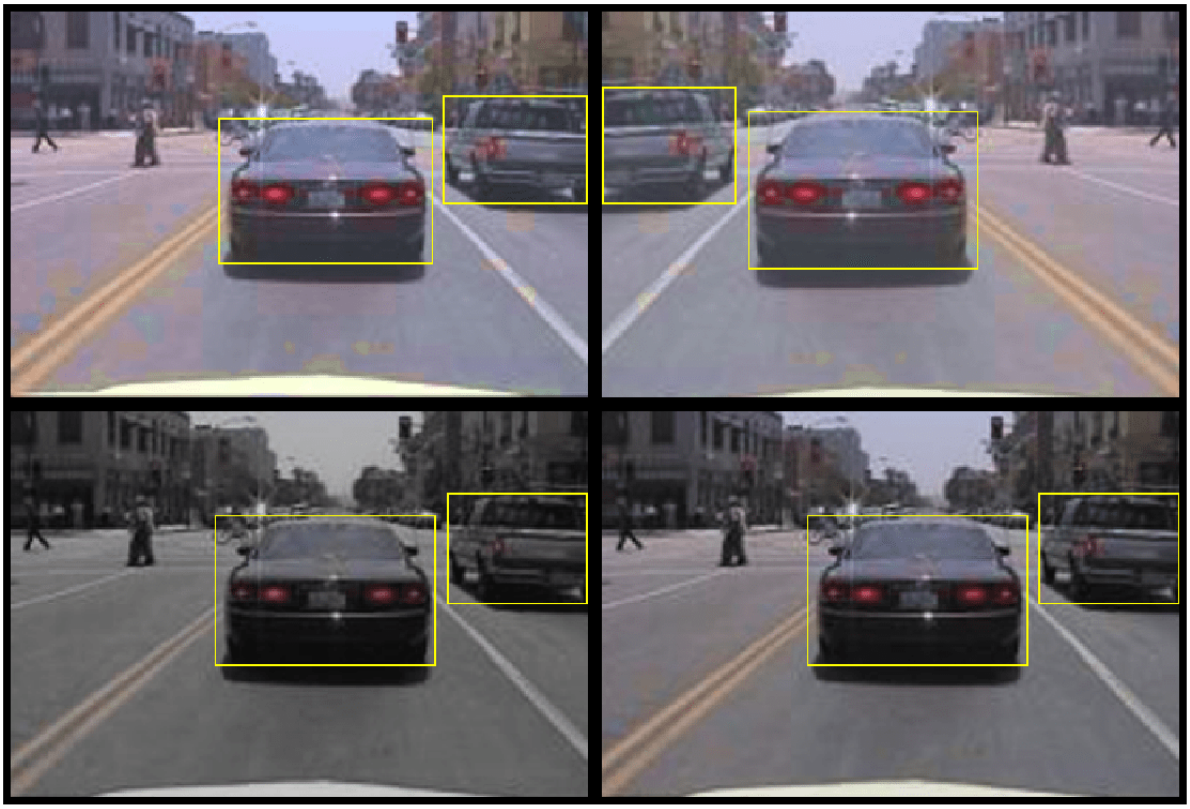
```
augmentedTrainingData = transform(trainingData,@augmentData);
```

Visualize augmented training data by reading the same image multiple times.

```
augmentedData = cell(4,1);
for k = 1:4
    data = read(augmentedTrainingData);
    augmentedData{k} = insertShape(data{1},'Rectangle',data{2});
```

```
    reset(augmentedTrainingData);
end

figure
montage(augmentedData,'BorderSize',10)
```



Preprocess Training Data

Preprocess the augmented training data to prepare for training.

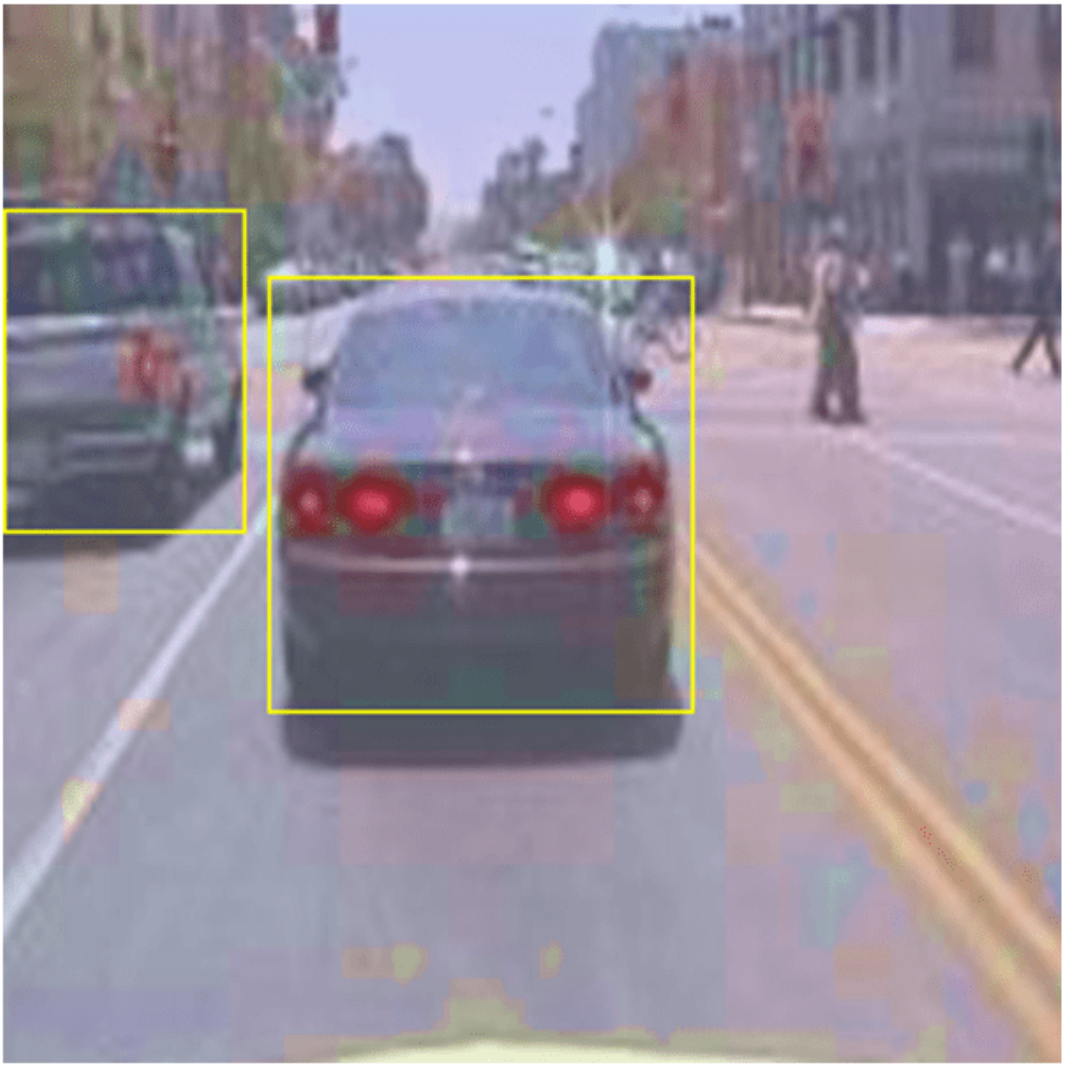
```
preprocessedTrainingData = transform(augmentedTrainingData,@(data)preprocessData(data,inputSize))
```

Read the preprocessed training data.

```
data = read(preprocessedTrainingData);
```

Display the image and bounding boxes.

```
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```



Train SSD Object Detector

Use `trainingOptions` to specify network training options. Set `'CheckpointPath'` to a temporary location. This enables the saving of partially trained detectors during the training process. If training is interrupted, such as by a power outage or system failure, you can resume training from the saved checkpoint.

```
options = trainingOptions('sgdm', ...
        'MiniBatchSize', 16, ....
        'InitialLearnRate',1e-1, ...
        'LearnRateSchedule', 'piecewise', ...
        'LearnRateDropPeriod', 30, ...
        'LearnRateDropFactor', 0.8, ...
        'MaxEpochs', 300, ...
```

```
        'VerboseFrequency', 50, ...
        'CheckpointPath', tempdir, ...
        'Shuffle','every-epoch');
```

Use `trainSSDObjectDetector` (Computer Vision Toolbox) function to train SSD object detector if `doTraining` to true. Otherwise, load a pretrained network.

```
if doTraining
    % Train the SSD detector.
    [detector, info] = trainSSDObjectDetector(preprocessedTrainingData,lgraph,options);
else
    % Load pretrained detector for the example.
    pretrained = load('ssdResNet50VehicleExample_20a.mat');
    detector = pretrained.detector;
end
```

This example is verified on an NVIDIA™ Titan X GPU with 12 GB of memory. If your GPU has less memory, you may run out of memory. If this happens, lower the '`MiniBatchSize`' using the `trainingOptions` function. Training this network took approximately 2 hours using this setup. Training time varies depending on the hardware you use.

As a quick test, run the detector on one test image.

```
data = read(testData);
I = data{1,1};
I = imresize(I,inputSize(1:2));
[bboxes,scores] = detect(detector,I, 'Threshold', 0.4);
```

Display the results.

```
I = insertObjectAnnotation(I,'rectangle',bboxes,scores);
figure
imshow(I)
```

Evaluate Detector Using Test Set

Evaluate the trained object detector on a large set of images to measure the performance. Computer Vision Toolbox™ provides object detector evaluation functions to measure common metrics such as average precision (`evaluateDetectionPrecision`) and log-average miss rates (`evaluateDetectionMissRate`). For this example, use the average precision metric to evaluate performance. The average precision provides a single number that incorporates the ability of the detector to make correct classifications (`precision`) and the ability of the detector to find all relevant objects (`recall`).

Apply the same preprocessing transform to the test data as for the training data. Note that data augmentation is not applied to the test data. Test data should be representative of the original data and be left unmodified for unbiased evaluation.

```
preprocessedTestData = transform(testData,@(data)preprocessData(data,inputSize));
```

Run the detector on all the test images.

```
detectionResults = detect(detector, preprocessedTestData, 'Threshold', 0.4);
```

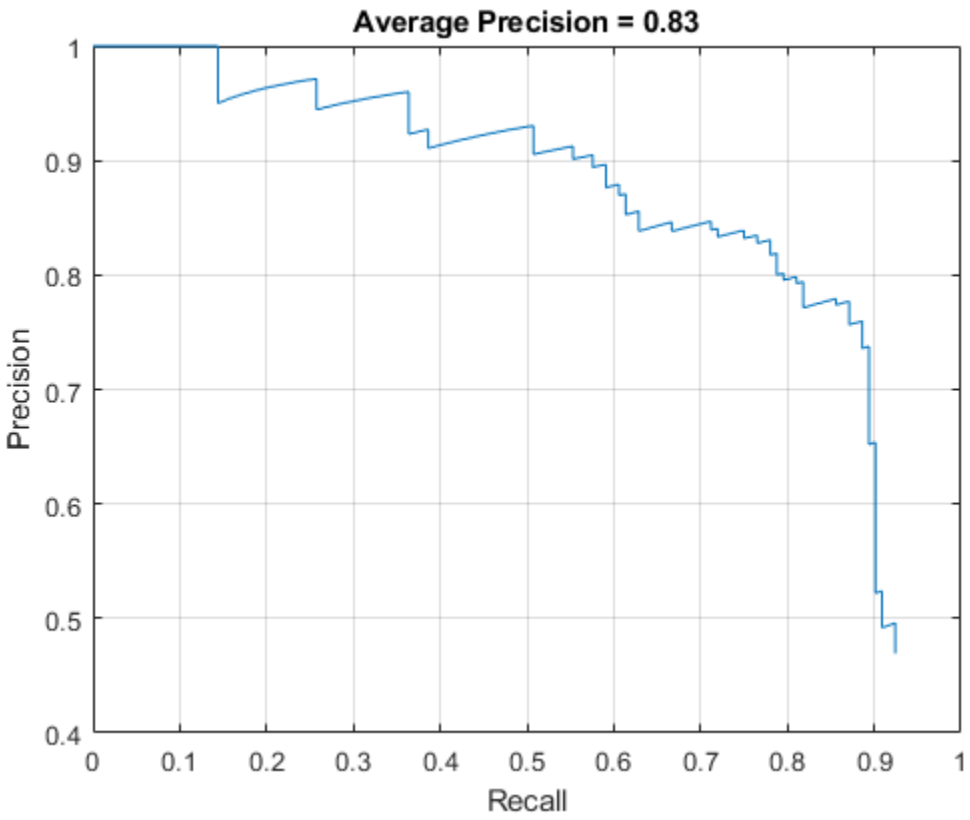
Evaluate the object detector using average precision metric.

```
[ap,recall,precision] = evaluateDetectionPrecision(detectionResults, preprocessedTestData);
```

The precision/recall (PR) curve highlights how precise a detector is at varying levels of recall. Ideally, the precision would be 1 at all recall levels. The use of more data can help improve the average precision, but might require more training time Plot the PR curve.

```
figure
plot(recall,precision)
```

```
xlabel('Recall')
ylabel('Precision')
grid on
title(sprintf('Average Precision = %.2f',ap))
```



Code Generation

Once the detector is trained and evaluated, you can generate code for the `ssdObjectDetector` using GPU Coder™. For more details, see "Code Generation for Object Detection by Using Single Shot Multibox Detector" (Computer Vision Toolbox) example.

Supporting Functions

```
function B = augmentData(A)
% Apply random horizontal flipping, and random X/Y scaling. Boxes that get
% scaled outside the bounds are clipped if the overlap is above 0.25. Also,
% jitter image color.
B = cell(size(A));

I = A{1};
sz = size(I);
if numel(sz)==3 && sz(3) == 3
    I = jitterColorHSV(I,...
        'Contrast',0.2,...
        'Hue',0,...
        'Saturation',0.1,...
        'Brightness',0.2);
end
```

```
% Randomly flip and scale image.
tform = randomAffine2d('XReflection',true,'Scale',[1 1.1]);
rout = affineOutputView(sz,tform,'BoundsStyle','CenterOutput');
B{1} = imwarp(I,tform,'OutputView',rout);

% Sanitize boxes, if needed.
A{2} = helperSanitizeBoxes(A{2}, sz);

% Apply same transform to boxes.
[B{2},indices] = bboxwarp(A{2},tform,rout,'OverlapThreshold',0.25);
B{3} = A{3}(indices);

% Return original data only when all boxes are removed by warping.
if isempty(indices)
    B = A;
end
end

function data = preprocessData(data,targetSize)
% Resize image and bounding boxes to the targetSize.
sz = size(data{1},[1 2]);
scale = targetSize(1:2)./sz;
data{1} = imresize(data{1},targetSize(1:2));

% Sanitize boxes, if needed.
data{2} = helperSanitizeBoxes(data{2}, sz);

% Resize boxes.
data{2} = bboxresize(data{2},scale);
end
```

Object Detection Using YOLO v3 Deep Learning

This example shows how to train a YOLO v3 on page 8-0 object detector.

Deep learning is a powerful machine learning technique that you can use to train robust object detectors. Several techniques for object detection exist, including Faster R-CNN, you only look once (YOLO) v2, and single shot detector (SSD). This example shows how to train a YOLO v3 object detector. YOLO v3 improves upon YOLO v2 by adding detection at multiple scales to help detect smaller objects. The loss function used for training is separated into mean squared error for bounding box regression and binary cross-entropy for object classification to help improve detection accuracy.

Note: This example requires the Computer Vision Toolbox™ Model for YOLO v3 Object Detection. You can install the Computer Vision Toolbox Model for YOLO v3 Object Detection from Add-On Explorer. For more information about installing add-ons, see “Get and Manage Add-Ons”.

Download Pretrained Network

Download a pretrained network using the helper function `downloadPretrainedYOLOv3Detector` to avoid having to wait for training to complete. If you want to train the network, set the `doTraining` variable to `true`.

```
doTraining = false;

if ~doTraining
    preTrainedDetector = downloadPretrainedYOLOv3Detector();
end
```

Load Data

This example uses a small labeled data set that contains 295 images. Many of these images come from the Caltech Cars 1999 and 2001 data sets, available at the Caltech Computational Vision website, created by Pietro Perona and used with permission. Each image contains one or two labeled instances of a vehicle. A small data set is useful for exploring the YOLO v3 training procedure, but in practice, more labeled images are needed to train a robust network.

Unzip the vehicle images and load the vehicle ground truth data.

```
unzip vehicleDatasetImages.zip
data = load('vehicleDatasetGroundTruth.mat');
vehicleDataset = data.vehicleDataset;

% Add the full path to the local vehicle data folder.
vehicleDataset.imageFilename = fullfile(pwd, vehicleDataset.imageFilename);
```

Note: In case of multiple classes, the data can also organized as three columns where the first column contains the image file names with paths, the second column contains the bounding boxes and the third column must be a cell vector that contains the label names corresponding to each bounding box. For more information on how to arrange the bounding boxes and labels, see `boxLabelDatastore` (Computer Vision Toolbox).

All the bounding boxes must be in the form `[x y width height]`. This vector specifies the upper left corner and the size of the bounding box in pixels.

Split the data set into a training set for training the network, and a test set for evaluating the network. Use 60% of the data for training set and the rest for the test set.

```
rng(0);
shuffledIndices = randperm(height(vehicleDataset));
idx = floor(0.6 * length(shuffledIndices));
trainingDataTbl = vehicleDataset(shuffledIndices(1:idx), :);
testDataTbl = vehicleDataset(shuffledIndices(idx+1:end), :);
```

Create an image datastore for loading the images.

```
imdsTrain = imageDatastore(trainingDataTbl.imageFilename);
imdsTest = imageDatastore(testDataTbl.imageFilename);
```

Create a datastore for the ground truth bounding boxes.

```
bldsTrain = boxLabelDatastore(trainingDataTbl(:, 2:end));
bldsTest = boxLabelDatastore(testDataTbl(:, 2:end));
```

Combine the image and box label datastores.

```
trainingData = combine(imdsTrain, bldsTrain);
testData = combine(imdsTest, bldsTest);
```

Use `validateInputData` to detect invalid images, bounding boxes or labels i.e.,

- Samples with invalid image format or containing NaNs
- Bounding boxes containing zeros/NaNs/Infs/empty
- Missing/non-categorical labels.

The values of the bounding boxes should be finite, positive, non-fractional, non-NaN and should be within the image boundary with a positive height and width. Any invalid samples must either be discarded or fixed for proper training.

```
validateInputData(trainingData);
validateInputData(testData);
```

Data Augmentation

Data augmentation is used to improve network accuracy by randomly transforming the original data during training. By using data augmentation, you can add more variety to the training data without actually having to increase the number of labeled training samples.

Use `transform` function to apply custom data augmentations to the training data. The `augmentData` helper function, listed at the end of the example, applies the following augmentations to the input data.

- Color jitter augmentation in HSV space
- Random horizontal flip
- Random scaling by 10 percent

```
augmentedTrainingData = transform(trainingData, @augmentData);
```

Read the same image four times and display the augmented training data.

```
% Visualize the augmented images.
augmentedData = cell(4,1);
for k = 1:4
    data = read(augmentedTrainingData);
```

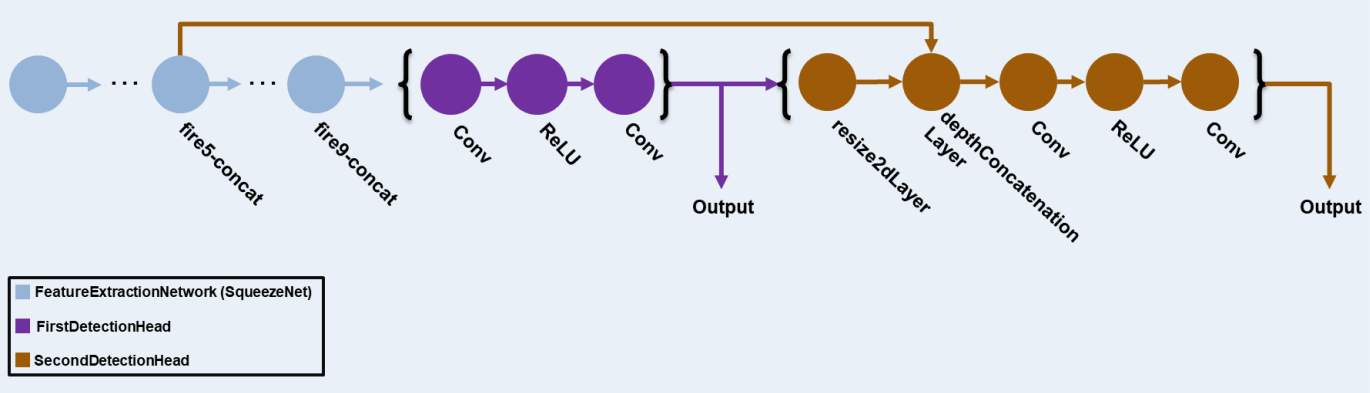
```
    augmentedData{k} = insertShape(data{1,1}, 'Rectangle', data{1,2});
    reset(augmentedTrainingData);
end
figure
montage(augmentedData, 'BorderSize', 10)
```

Define YOLO v3 Object Detector

The YOLO v3 detector in this example is based on SqueezeNet, and uses the feature extraction network in SqueezeNet with the addition of two detection heads at the end. The second detection head is twice the size of the first detection head, so it is better able to detect small objects. Note that you can specify any number of detection heads of different sizes based on the size of the objects that you want to detect. The YOLO v3 detector uses anchor boxes estimated using training data to have better initial priors corresponding to the type of data set and to help the detector learn to predict the boxes accurately. For information about anchor boxes, see “Anchor Boxes for Object Detection” (Computer Vision Toolbox).

The YOLO v3 network present in the YOLO v3 detector is illustrated in the following diagram.

You can use Deep Network Designer to create the network shown in the diagram.



Specify the network input size. When choosing the network input size, consider the minimum size required to run the network itself, the size of the training images, and the computational cost incurred by processing data at the selected size. When feasible, choose a network input size that is close to the size of the training image and larger than the input size required for the network. To reduce the computational cost of running the example, specify a network input size of [227 227 3].

```
networkInputSize = [227 227 3];
```

First, use `transform` to preprocess the training data for computing the anchor boxes, as the training images used in this example are bigger than 227-by-227 and vary in size. Specify the number of anchors as 6 to achieve a good tradeoff between number of anchors and mean IoU. Use the `estimateAnchorBoxes` function to estimate the anchor boxes. For details on estimating anchor boxes, see “Estimate Anchor Boxes From Training Data” (Computer Vision Toolbox). In case of using a pretrained YOLOv3 object detector, the anchor boxes calculated on that particular training dataset need to be specified. Note that the estimation process is not deterministic. To prevent the estimated anchor boxes from changing while tuning other hyperparameters set the random seed prior to estimation using rng.

```
rng(0)
trainingDataForEstimation = transform(trainingData, @(data)preprocessData(data, networkInputSize)
numAnchors = 6;
[anchors, meanIoU] = estimateAnchorBoxes(trainingDataForEstimation, numAnchors)
```

```
anchors = 6×2

    41    34
   163   130
    98    93
   144   125
    33    24
    69    66

meanIoU = 0.8507
```

Specify `anchorBoxes` to use in both the detection heads. `anchorBoxes` is a cell array of [Mx1], where M denotes the number of detection heads. Each detection head consists of a [Nx2] matrix of `anchors`, where N is the number of anchors to use. Select `anchorBoxes` for each detection head based on the feature map size. Use larger `anchors` at lower scale and smaller `anchors` at higher scale. To do so, sort the `anchors` with the larger anchor boxes first and assign the first three to the first detection head and the next three to the second detection head.

```
area = anchors(:, 1).*anchors(:, 2);
[~, idx] = sort(area, 'descend');
anchors = anchors(idx, :);
anchorBoxes = {anchors(1:3,:)
    anchors(4:6,:)
    };
```

Load the SqueezeNet network pretrained on Imagenet data set and then specify the class names. You can also choose to load a different pretrained network trained on COCO data set such as `tiny-yolov3-coco` or `darknet53-coco` or Imagenet data set such as MobileNet-v2 or ResNet-18. YOLO v3 performs better and trains faster when you use a pretrained network.

```
baseNetwork = squeezenet;
classNames = trainingDataTbl.Properties.VariableNames(2:end);
```

Next, create the `yolov3ObjectDetector` object by adding the detection network source. Choosing the optimal detection network source requires trial and error, and you can use `analyzeNetwork` to find the names of potential detection network source within a network. For this example, use the `fire9-concat` and `fire5-concat` layers as `DetectionNetworkSource`.

```
yolov3Detector = yolov3ObjectDetector(baseNetwork, classNames, anchorBoxes, 'DetectionNetworkSou
```

Alternatively, instead of the network created above using SqueezeNet, other pretrained YOLOv3 architectures trained using larger datasets like MS-COCO can be used to transfer learn the detector on custom object detection task. Transfer learning can be realized by changing the classNames and anchorBoxes.

Preprocess Training Data

Preprocess the augmented training data to prepare for training. The `preprocess` (Computer Vision Toolbox) method in `yolov3ObjectDetector` (Computer Vision Toolbox), applies the following preprocessing operations to the input data.

- Resize the images to the network input size by maintaining the aspect ratio.
- Scale the image pixels in the range `[0 1]`.

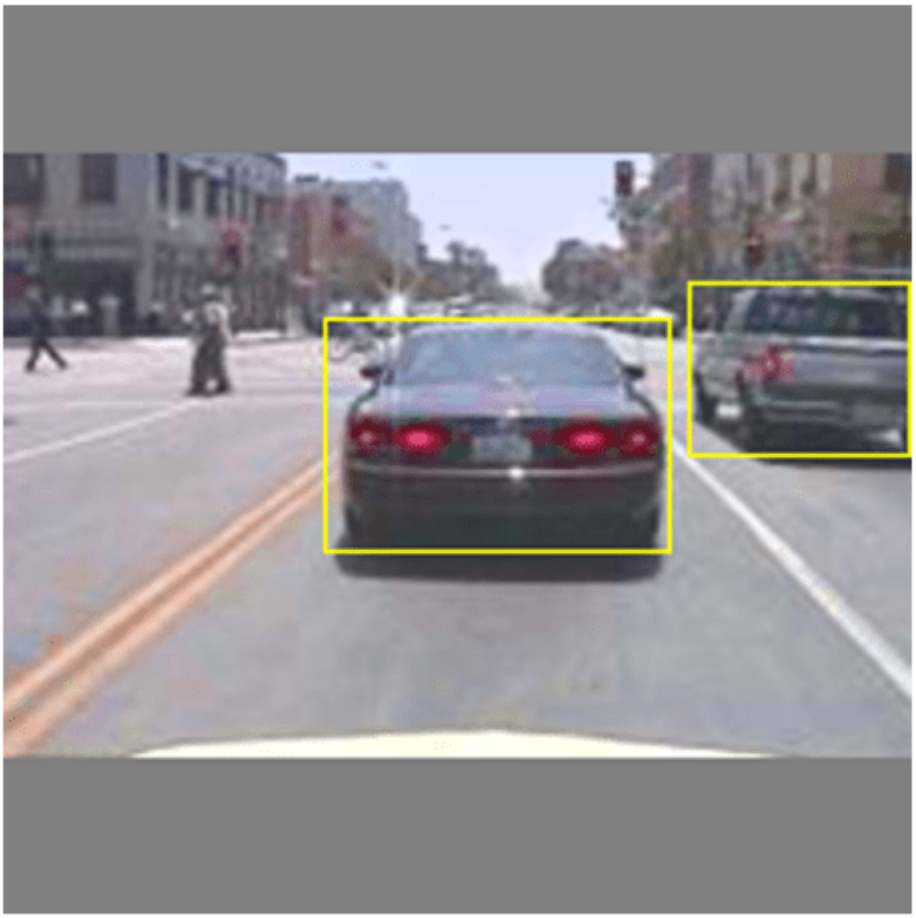
```
preprocessedTrainingData = transform(augmentedTrainingData, @(data)preprocess(yolov3Detector, da
```

Read the preprocessed training data.

```
data = read(preprocessedTrainingData);
```

Display the image with the bounding boxes.

```
I = data{1,1};
bbox = data{1,2};
annotatedImage = insertShape(I, 'Rectangle', bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```



Reset the datastore.

```
reset(preprocessedTrainingData);
```

Specify Training Options

Specify these training options.

- Set the number of epochs to be 80.
- Set the mini batch size as `8`. Stable training can be possible with higher learning rates when higher mini batch size is used. Although, this should be set depending on the available memory.
- Set the learning rate to 0.001.
- Set the warmup period as `1000` iterations. This parameter denotes the number of iterations to increase the learning rate exponentially based on the formula learningRate $\times \left(\frac{\text{iteration}}{\text{warmupPeriod}}\right)^4$. It helps in stabilizing the gradients at higher learning rates.

- Set the L2 regularization factor to 0.0005.
- Specify the penalty threshold as 0.5. Detections that overlap less than 0.5 with the ground truth are penalized.
- Initialize the velocity of gradient as `[]`. This is used by SGDM to store the velocity of gradients.

```
numEpochs = 80;
miniBatchSize = 8;
learningRate = 0.001;
warmupPeriod = 1000;
l2Regularization = 0.0005;
penaltyThreshold = 0.5;
velocity = [];
```

Train Model

Train on a GPU, if one is available. Using a GPU requires Parallel Computing Toolbox™ and a CUDA® enabled NVIDIA® GPU. For information about the supported compute capabilities, see “GPU Support by Release” (Parallel Computing Toolbox).

Use the `minibatchqueue` function to split the preprocessed training data into batches with the supporting function `createBatchData` which returns the batched images and bounding boxes combined with the respective class IDs. For faster extraction of the batch data for training, `dispatchInBackground` should be set to "true" which ensures the usage of parallel pool.

`minibatchqueue` automatically detects the availability of a GPU. If you do not have a GPU, or do not want to use one for training, set the `OutputEnvironment` parameter to `"cpu"`.

```
if canUseParallelPool
   dispatchInBackground = true;
else
   dispatchInBackground = false;
end

mbqTrain = minibatchqueue(preprocessedTrainingData, 2,...
        "MiniBatchSize", miniBatchSize,...
        "MiniBatchFcn", @(images, boxes, labels) createBatchData(images, boxes, labels, className
        "MiniBatchFormat", ["SSCB", ""],...
        "DispatchInBackground", dispatchInBackground,...
        "OutputCast", ["", "double"]);
```

Create the training progress plotter using supporting function `configureTrainingProgressPlotter` to see the plot while training the detector object with a custom training loop.

Finally, specify the custom training loop. For each iteration:

- Read data from the `minibatchqueue`. If it doesn't have any more data, reset the `minibatchqueue` and shuffle.
- Evaluate the model gradients using `dlfeval` and the `modelGradients` function. The function `modelGradients`, listed as a supporting function, returns the gradients of the loss with respect to the learnable parameters in `net`, the corresponding mini-batch loss, and the state of the current batch.
- Apply a weight decay factor to the gradients to regularization for more robust training.
- Determine the learning rate based on the iterations using the `piecewiseLearningRateWithWarmup` supporting function.

- Update the detector parameters using the `sgdmupdate` function.
- Update the `state` parameters of detector with the moving average.
- Display the learning rate, total loss, and the individual losses (box loss, object loss and class loss) for every iteration. These can be used to interpret how the respective losses are changing in each iteration. For example, a sudden spike in the box loss after few iterations implies that there are Inf or NaNs in the predictions.
- Update the training progress plot.

The training can also be terminated if the loss has saturated for few epochs.

```
if doTraining

    % Create subplots for the learning rate and mini-batch loss.
    fig = figure;
    [lossPlotter, learningRatePlotter] = configureTrainingProgressPlotter(fig);

    iteration = 0;
    % Custom training loop.
    for epoch = 1:numEpochs

        reset(mbqTrain);
        shuffle(mbqTrain);

        while(hasdata(mbqTrain))
            iteration = iteration + 1;

            [XTrain, YTrain] = next(mbqTrain);

            % Evaluate the model gradients and loss using dlfeval and the
            % modelGradients function.
            [gradients, state, lossInfo] = dlfeval(@modelGradients, yolov3Detector, XTrain, YTra

            % Apply L2 regularization.
            gradients = dlupdate(@(g,w) g + l2Regularization*w, gradients, yolov3Detector.Learnab

            % Determine the current learning rate value.
            currentLR = piecewiseLearningRateWithWarmup(iteration, epoch, learningRate, warmupPe

            % Update the detector learnable parameters using the SGDM optimizer.
            [yolov3Detector.Learnables, velocity] = sgdmupdate(yolov3Detector.Learnables, gradie

            % Update the state parameters of dlnetwork.
            yolov3Detector.State = state;

            % Display progress.
            displayLossInfo(epoch, iteration, currentLR, lossInfo);

            % Update training plot with new points.
            updatePlots(lossPlotter, learningRatePlotter, iteration, currentLR, lossInfo.totalLos
        end
    end
else
    yolov3Detector = preTrainedDetector;
end
```

Evaluate Model

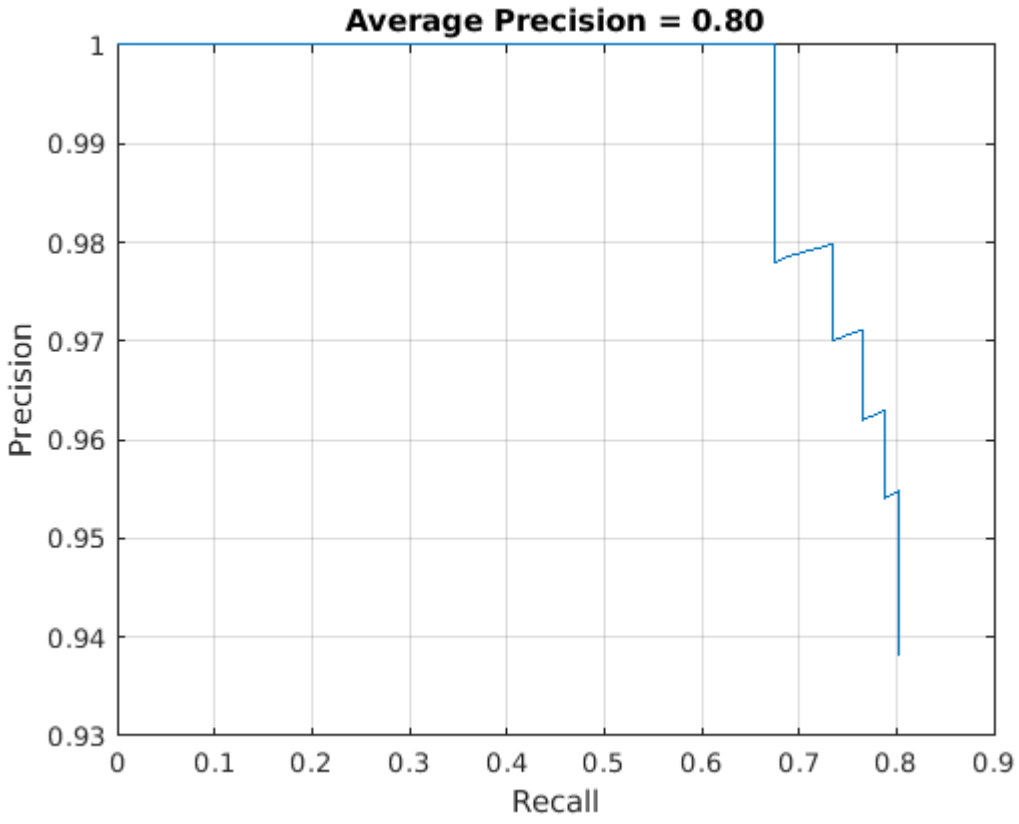
Computer Vision Toolbox™ provides object detector evaluation functions to measure common metrics such as average precision (`evaluateDetectionPrecision`) and log-average miss rates (`evaluateDetectionMissRate`). In this example, the average precision metric is used. The average precision provides a single number that incorporates the ability of the detector to make correct classifications (precision) and the ability of the detector to find all relevant objects (recall).

```
results = detect(yolov3Detector,testData,'MiniBatchSize',8);

% Evaluate the object detector using Average Precision metric.
[ap,recall,precision] = evaluateDetectionPrecision(results,testData);
```

The precision-recall (PR) curve shows how precise a detector is at varying levels of recall. Ideally, the precision is 1 at all recall levels.

```
% Plot precision-recall curve.
figure
plot(recall,precision)
xlabel('Recall')
ylabel('Precision')
grid on
title(sprintf('Average Precision = %.2f', ap))
```



Detect Objects Using YOLO v3

Use the detector for object detection.

```
% Read the datastore.
data = read(testData);

% Get the image.
I = data{1};

[bboxes,scores,labels] = detect(yolov3Detector,I);

% Display the detections on image.
I = insertObjectAnnotation(I,'rectangle',bboxes,scores);

figure
imshow(I)
```

Supporting Functions

Model Gradients Function

The function `modelGradients` takes the `yolov3ObjectDetector` object, a mini-batch of input data `XTrain` with corresponding ground truth boxes `YTrain`, the specified penalty threshold as input arguments and returns the gradients of the loss with respect to the learnable parameters in `yolov3ObjectDetector`, the corresponding mini-batch loss information, and the state of the current batch.

The model gradients function computes the total loss and gradients by performing these operations.

- Generate predictions from the input batch of images using the `forward` method.
- Collect predictions on the CPU for postprocessing.
- Convert the predictions from the YOLO v3 grid cell coordinates to bounding box coordinates to allow easy comparison with the ground truth data by using the `anchorBoxGenerator` method of `yolov3ObjectDetector`.

- Generate targets for loss computation by using the converted predictions and ground truth data. These targets are generated for bounding box positions (x, y, width, height), object confidence, and class probabilities. See the supporting function `generateTargets`.
- Calculates the mean squared error of the predicted bounding box coordinates with target boxes. See the supporting function `bboxOffsetLoss`.
- Determines the binary cross-entropy of the predicted object confidence score with target object confidence score. See the supporting function `objectnessLoss`.
- Determines the binary cross-entropy of the predicted class of object with the target. See the supporting function `classConfidenceLoss`.
- Computes the total loss as the sum of all losses.
- Computes the gradients of learnables with respect to the total loss.

```
function [gradients, state, info] = modelGradients(detector, XTrain, YTrain, penaltyThreshold)
inputImageSize = size(XTrain,1:2);

% Gather the ground truths in the CPU for post processing
YTrain = gather(extractdata(YTrain));

% Extract the predictions from the detector.
[gatheredPredictions, YPredCell, state] = forward(detector, XTrain);

% Generate target for predictions from the ground truth data.
[boxTarget, objectnessTarget, classTarget, objectMaskTarget, boxErrorScale] = generateTargets(gat
    YTrain, inputImageSize, detector.AnchorBoxes, penaltyThreshold);

% Compute the loss.
boxLoss = bboxOffsetLoss(YPredCell(:,[2 3 7 8]),boxTarget,objectMaskTarget,boxErrorScale);
objLoss = objectnessLoss(YPredCell(:,1),objectnessTarget,objectMaskTarget);
clsLoss = classConfidenceLoss(YPredCell(:,6),classTarget,objectMaskTarget);
totalLoss = boxLoss + objLoss + clsLoss;

info.boxLoss = boxLoss;
info.objLoss = objLoss;
info.clsLoss = clsLoss;
info.totalLoss = totalLoss;

% Compute gradients of learnables with regard to loss.
gradients = dlgradient(totalLoss, detector.Learnables);
end

function boxLoss = bboxOffsetLoss(boxPredCell, boxDeltaTarget, boxMaskTarget, boxErrorScaleTarget
% Mean squared error for bounding box position.
lossX = sum(cellfun(@(a,b,c,d) mse(a.*c.*d,b.*c.*d),boxPredCell(:,1),boxDeltaTarget(:,1),boxMask
lossY = sum(cellfun(@(a,b,c,d) mse(a.*c.*d,b.*c.*d),boxPredCell(:,2),boxDeltaTarget(:,2),boxMask
lossW = sum(cellfun(@(a,b,c,d) mse(a.*c.*d,b.*c.*d),boxPredCell(:,3),boxDeltaTarget(:,3),boxMask
lossH = sum(cellfun(@(a,b,c,d) mse(a.*c.*d,b.*c.*d),boxPredCell(:,4),boxDeltaTarget(:,4),boxMask
boxLoss = lossX+lossY+lossW+lossH;
end

function objLoss = objectnessLoss(objectnessPredCell, objectnessDeltaTarget, boxMaskTarget)
% Binary cross-entropy loss for objectness score.
objLoss = sum(cellfun(@(a,b,c) crossentropy(a.*c,b.*c,'TargetCategories','independent'),objectnes
end

function clsLoss = classConfidenceLoss(classPredCell, classTarget, boxMaskTarget)
```

```
% Binary cross-entropy loss for class confidence score.
clsLoss = sum(cellfun(@(a,b,c) crossentropy(a.*c,b.*c,'TargetCategories','independent'),classPred
end
```

Augmentation and Data Processing Functions

```
function data = augmentData(A)
% Apply random horizontal flipping, and random X/Y scaling. Boxes that get
% scaled outside the bounds are clipped if the overlap is above 0.25. Also,
% jitter image color.

data = cell(size(A));
for ii = 1:size(A,1)
    I = A{ii,1};
    bboxes = A{ii,2};
    labels = A{ii,3};
    sz = size(I);

    if numel(sz) == 3 && sz(3) == 3
        I = jitterColorHSV(I,...
            'Contrast',0.0,...
            'Hue',0.1,...
            'Saturation',0.2,...
            'Brightness',0.2);
    end

    % Randomly flip image.
    tform = randomAffine2d('XReflection',true,'Scale',[1 1.1]);
    rout = affineOutputView(sz,tform,'BoundsStyle','centerOutput');
    I = imwarp(I,tform,'OutputView',rout);

    % Apply same transform to boxes.
    [bboxes,indices] = bboxwarp(bboxes,tform,rout,'OverlapThreshold',0.25);
    labels = labels(indices);

    % Return original data only when all boxes are removed by warping.
    if isempty(indices)
        data(ii,:) = A(ii,:);
    else
        data(ii,:) = {I, bboxes, labels};
    end
end
end

function data = preprocessData(data, targetSize)
% Resize the images and scale the pixels to between 0 and 1. Also scale the
% corresponding bounding boxes.

for ii = 1:size(data,1)
    I = data{ii,1};
    imgSize = size(I);

    % Convert an input image with single channel to 3 channels.
    if numel(imgSize) < 3
        I = repmat(I,1,1,3);
    end
    bboxes = data{ii,2};
```

```
    I = im2single(imresize(I,targetSize(1:2)));
    scale = targetSize(1:2)./imgSize(1:2);
    bboxes = bboxresize(bboxes,scale);

    data(ii, 1:2) = {I, bboxes};
end
end

function [XTrain, YTrain] = createBatchData(data, groundTruthBoxes, groundTruthClasses, className
% Returns images combined along the batch dimension in XTrain and
% normalized bounding boxes concatenated with classIDs in YTrain

% Concatenate images along the batch dimension.
XTrain = cat(4, data{:,1});

% Get class IDs from the class names.
classNames = repmat({categorical(classNames')}, size(groundTruthClasses));
[~, classIndices] = cellfun(@(a,b)ismember(a,b), groundTruthClasses, classNames, 'UniformOutput'

Object Detection Using YOLO v2 Deep Learning

This example shows how to train a you only look once (YOLO) v2 object detector.

Deep learning is a powerful machine learning technique that you can use to train robust object detectors. Several techniques for object detection exist, including Faster R-CNN and you only look once (YOLO) v2. This example trains a YOLO v2 vehicle detector using the `trainYOLOv2ObjectDetector` function. For more information, see "Getting Started with YOLO v2" (Computer Vision Toolbox).

Download Pretrained Detector

Download a pretrained detector to avoid having to wait for training to complete. If you want to train the detector, set the `doTraining` variable to true.

```
doTraining = false;
if ~doTraining && ~exist('yolov2ResNet50VehicleExample_19b.mat','file')
    disp('Downloading pretrained detector (98 MB)...');
    pretrainedURL = 'https://www.mathworks.com/supportfiles/vision/data/yolov2ResNet50VehicleExar
    websave('yolov2ResNet50VehicleExample_19b.mat',pretrainedURL);
end
```

Load Dataset

This example uses a small vehicle dataset that contains 295 images. Many of these images come from the Caltech Cars 1999 and 2001 data sets, available at the Caltech Computational Vision website, created by Pietro Perona and used with permission. Each image contains one or two labeled instances of a vehicle. A small dataset is useful for exploring the YOLO v2 training procedure, but in practice, more labeled images are needed to train a robust detector. Unzip the vehicle images and load the vehicle ground truth data.

```
unzip vehicleDatasetImages.zip
data = load('vehicleDatasetGroundTruth.mat');
vehicleDataset = data.vehicleDataset;
```

The vehicle data is stored in a two-column table, where the first column contains the image file paths and the second column contains the vehicle bounding boxes.

```
% Display first few rows of the data set.
vehicleDataset(1:4,:)
```

```
ans=4×2 table
              imageFilename                vehicle
    ___________________________________    ___________

    {'vehicleImages/image_00001.jpg'}    {1×4 double}
    {'vehicleImages/image_00002.jpg'}    {1×4 double}
    {'vehicleImages/image_00003.jpg'}    {1×4 double}
    {'vehicleImages/image_00004.jpg'}    {1×4 double}
```

```
% Add the fullpath to the local vehicle data folder.
vehicleDataset.imageFilename = fullfile(pwd,vehicleDataset.imageFilename);
```

Split the dataset into training, validation, and test sets. Select 60% of the data for training, 10% for validation, and the rest for testing the trained detector.

```
rng(0);
shuffledIndices = randperm(height(vehicleDataset));
idx = floor(0.6 * length(shuffledIndices) );

trainingIdx = 1:idx;
trainingDataTbl = vehicleDataset(shuffledIndices(trainingIdx),:);

validationIdx = idx+1 : idx + 1 + floor(0.1 * length(shuffledIndices) );
validationDataTbl = vehicleDataset(shuffledIndices(validationIdx),:);

testIdx = validationIdx(end)+1 : length(shuffledIndices);
testDataTbl = vehicleDataset(shuffledIndices(testIdx),:);
```

Use `imageDatastore` and `boxLabelDatastore` to create datastores for loading the image and label data during training and evaluation.

```
imdsTrain = imageDatastore(trainingDataTbl{:,'imageFilename'});
bldsTrain = boxLabelDatastore(trainingDataTbl(:,'vehicle'));

imdsValidation = imageDatastore(validationDataTbl{:,'imageFilename'});
bldsValidation = boxLabelDatastore(validationDataTbl(:,'vehicle'));

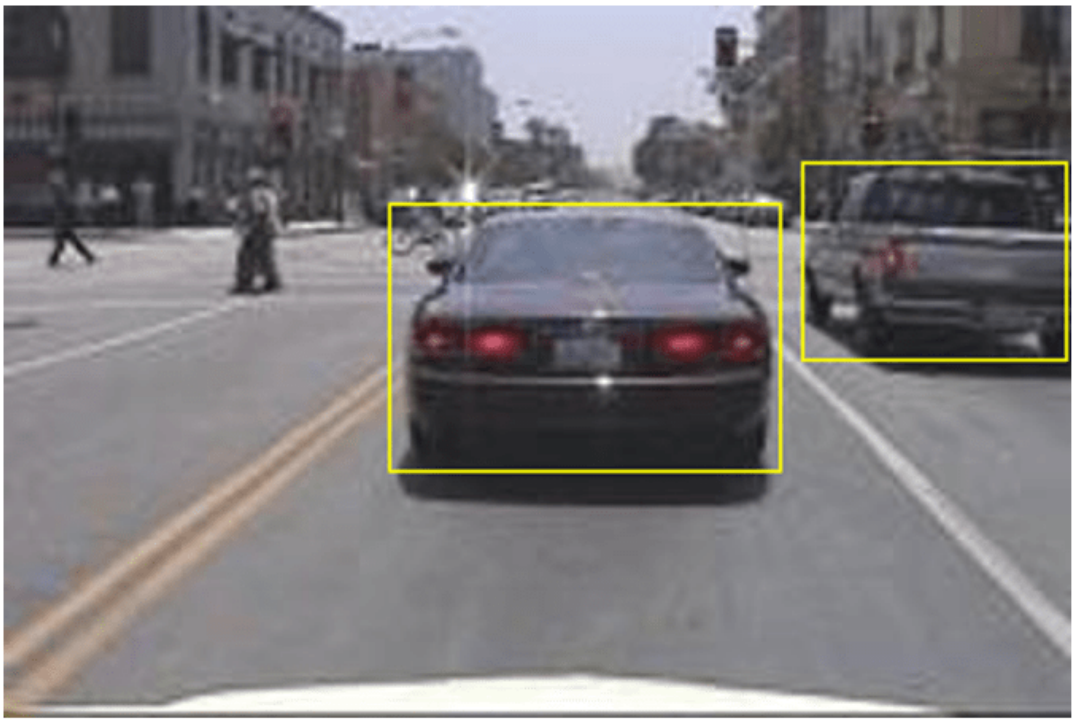
imdsTest = imageDatastore(testDataTbl{:,'imageFilename'});
bldsTest = boxLabelDatastore(testDataTbl(:,'vehicle'));
```

Combine image and box label datastores.

```
trainingData = combine(imdsTrain,bldsTrain);
validationData = combine(imdsValidation,bldsValidation);
testData = combine(imdsTest,bldsTest);
```

Display one of the training images and box labels.

```
data = read(trainingData);
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```



Create a YOLO v2 Object Detection Network

A YOLO v2 object detection network is composed of two subnetworks. A feature extraction network followed by a detection network. The feature extraction network is typically a pretrained CNN (for details, see “Pretrained Deep Neural Networks” on page 1-8). This example uses ResNet-50 for feature extraction. You can also use other pretrained networks such as MobileNet v2 or ResNet-18 can also be used depending on application requirements. The detection sub-network is a small CNN compared to the feature extraction network and is composed of a few convolutional layers and layers specific for YOLO v2.

Use the `yolov2Layers` (Computer Vision Toolbox) function to create a YOLO v2 object detection network automatically given a pretrained ResNet-50 feature extraction network. `yolov2Layers` requires you to specify several inputs that parameterize a YOLO v2 network:

- Network input size
- Anchor boxes
- Feature extraction network

First, specify the network input size and the number of classes. When choosing the network input size, consider the minimum size required by the network itself, the size of the training images, and the computational cost incurred by processing data at the selected size. When feasible, choose a network input size that is close to the size of the training image and larger than the input size required for the network. To reduce the computational cost of running the example, specify a network input size of [224 224 3], which is the minimum size required to run the network.

```
inputSize = [224 224 3];
```

Define the number of object classes to detect.

```
numClasses = width(vehicleDataset)-1;
```

Note that the training images used in this example are bigger than 224-by-224 and vary in size, so you must resize the images in a preprocessing step prior to training.

Next, use `estimateAnchorBoxes` (Computer Vision Toolbox) to estimate anchor boxes based on the size of objects in the training data. To account for the resizing of the images prior to training, resize the training data for estimating anchor boxes. Use `transform` to preprocess the training data, then define the number of anchor boxes and estimate the anchor boxes. Resize the training data to the input image size of the network using the supporting function `preprocessData`.

```
trainingDataForEstimation = transform(trainingData,@(data)preprocessData(data,inputSize));
numAnchors = 7;
[anchorBoxes, meanIoU] = estimateAnchorBoxes(trainingDataForEstimation, numAnchors)
```

```
anchorBoxes = 7×2

   162   136
    85    80
   149   123
    43    32
    65    63
   117   105
    33    27

meanIoU = 0.8472
```

For more information on choosing anchor boxes, see “Estimate Anchor Boxes From Training Data” (Computer Vision Toolbox) (Computer Vision Toolbox™) and “Anchor Boxes for Object Detection” (Computer Vision Toolbox).

Now, use `resnet50` to load a pretrained ResNet-50 model.

```
featureExtractionNetwork = resnet50;
```

Select `'activation_40_relu'` as the feature extraction layer to replace the layers after `'activation_40_relu'` with the detection subnetwork. This feature extraction layer outputs feature maps that are downsampled by a factor of 16. This amount of downsampling is a good trade-off between spatial resolution and the strength of the extracted features, as features extracted further down the network encode stronger image features at the cost of spatial resolution. Choosing the optimal feature extraction layer requires empirical analysis.

```
featureLayer = 'activation_40_relu';
```

Create the YOLO v2 object detection network.

```
lgraph = yolov2Layers(inputSize,numClasses,anchorBoxes,featureExtractionNetwork,featureLayer);
```

You can visualize the network using `analyzeNetwork` or Deep Network Designer from Deep Learning Toolbox™.

If more control is required over the YOLO v2 network architecture, use Deep Network Designer to design the YOLO v2 detection network manually. For more information, see “Design a YOLO v2 Detection Network” (Computer Vision Toolbox).

Data Augmentation

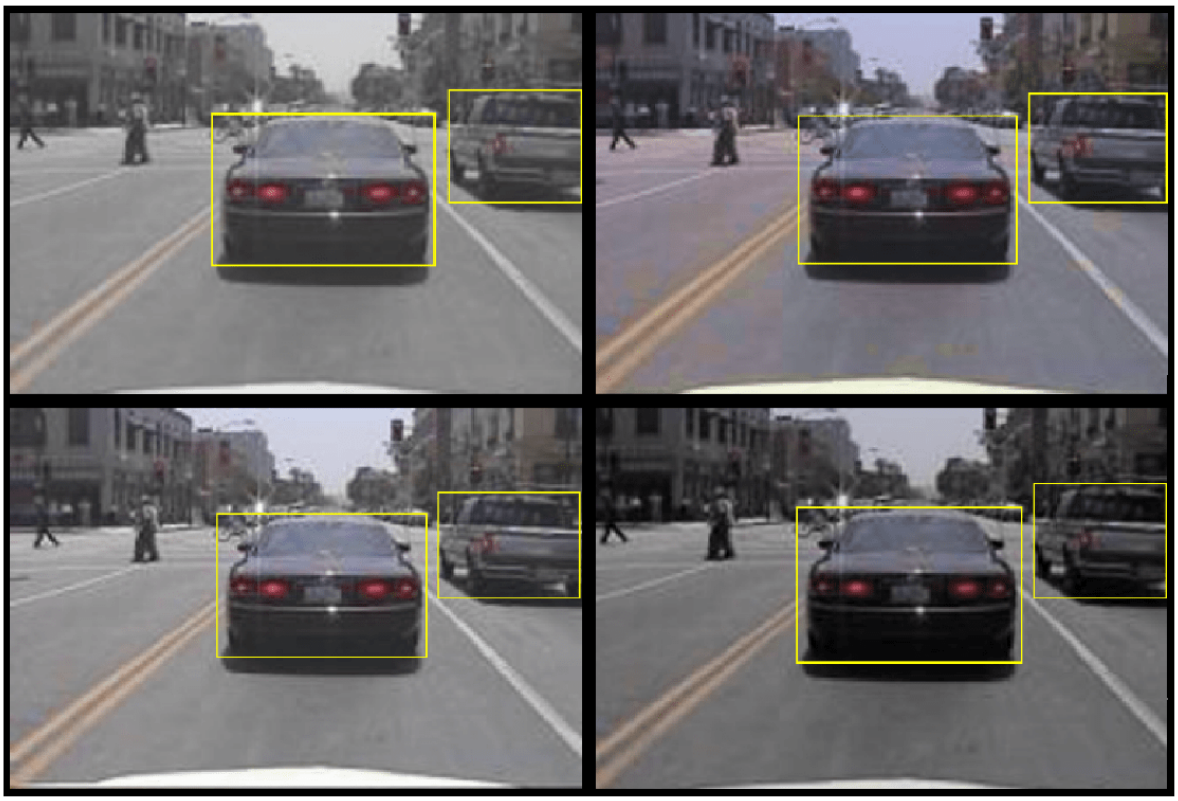
Data augmentation is used to improve network accuracy by randomly transforming the original data during training. By using data augmentation you can add more variety to the training data without actually having to increase the number of labeled training samples.

Use `transform` to augment the training data by randomly flipping the image and associated box labels horizontally. Note that data augmentation is not applied to the test and validation data. Ideally, test and validation data should be representative of the original data and is left unmodified for unbiased evaluation.

```
augmentedTrainingData = transform(trainingData,@augmentData);
```

Read the same image multiple times and display the augmented training data.

```
% Visualize the augmented images.
augmentedData = cell(4,1);
for k = 1:4
    data = read(augmentedTrainingData);
    augmentedData{k} = insertShape(data{1},'Rectangle',data{2});
    reset(augmentedTrainingData);
end
figure
montage(augmentedData,'BorderSize',10)
```



Preprocess Training Data

Preprocess the augmented training data, and the validation data to prepare for training.

```
preprocessedTrainingData = transform(augmentedTrainingData,@(data)preprocessData(data,inputSize))
preprocessedValidationData = transform(validationData,@(data)preprocessData(data,inputSize));
```

Read the preprocessed training data.

```
data = read(preprocessedTrainingData);
```

Display the image and bounding boxes.

```
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```

Train YOLO v2 Object Detector

Use `trainingOptions` to specify network training options. Set `'ValidationData'` to the preprocessed validation data. Set `'CheckpointPath'` to a temporary location. This enables the saving of partially trained detectors during the training process. If training is interrupted, such as by a power outage or system failure, you can resume training from the saved checkpoint.

```
options = trainingOptions('sgdm', ...
        'MiniBatchSize',16, ....
        'InitialLearnRate',1e-3, ...
        'MaxEpochs',20, ...
        'CheckpointPath',tempdir, ...
        'ValidationData',preprocessedValidationData);
```

Use `trainYOLOv2ObjectDetector` (Computer Vision Toolbox) function to train YOLO v2 object detector if `doTraining` is true. Otherwise, load the pretrained network.

```
if doTraining
    % Train the YOLO v2 detector.
```

```
    [detector,info] = trainYOLOv2ObjectDetector(preprocessedTrainingData,lgraph,options);
else
    % Load pretrained detector for the example.
    pretrained = load('yolov2ResNet50VehicleExample_19b.mat');
    detector = pretrained.detector;
end
```

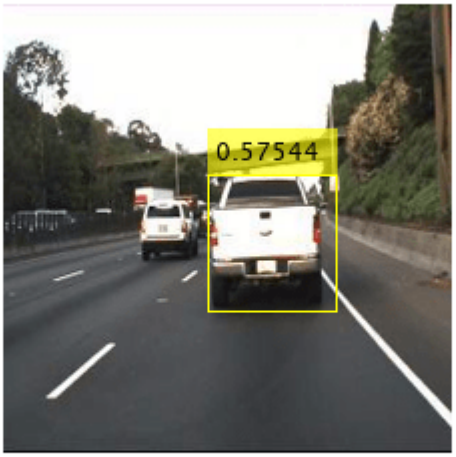
This example was verified on an NVIDIA™ Titan X GPU with 12 GB of memory. If your GPU has less memory, you may run out of memory. If this happens, lower the `'MiniBatchSize'` using the `trainingOptions` function. Training this network took approximately 7 minutes using this setup. Training time varies depending on the hardware you use.

As a quick test, run the detector on a test image. Make sure you resize the image to the same size as the training images.

```
I = imread('highway.png');
I = imresize(I,inputSize(1:2));
[bboxes,scores] = detect(detector,I);
```

Display the results.

```
I = insertObjectAnnotation(I,'rectangle',bboxes,scores);
figure
imshow(I)
```



Evaluate Detector Using Test Set

Evaluate the trained object detector on a large set of images to measure the performance. Computer Vision Toolbox™ provides object detector evaluation functions to measure common metrics such as average precision (`evaluateDetectionPrecision`) and log-average miss rates (`evaluateDetectionMissRate`). For this example, use the average precision metric to evaluate performance. The average precision provides a single number that incorporates the ability of the detector to make correct classifications (precision) and the ability of the detector to find all relevant objects (recall).

Apply the same preprocessing transform to the test data as for the training data. Note that data augmentation is not applied to the test data. Test data should be representative of the original data and be left unmodified for unbiased evaluation.

```
preprocessedTestData = transform(testData,@(data)preprocessData(data,inputSize));
```

Run the detector on all the test images.

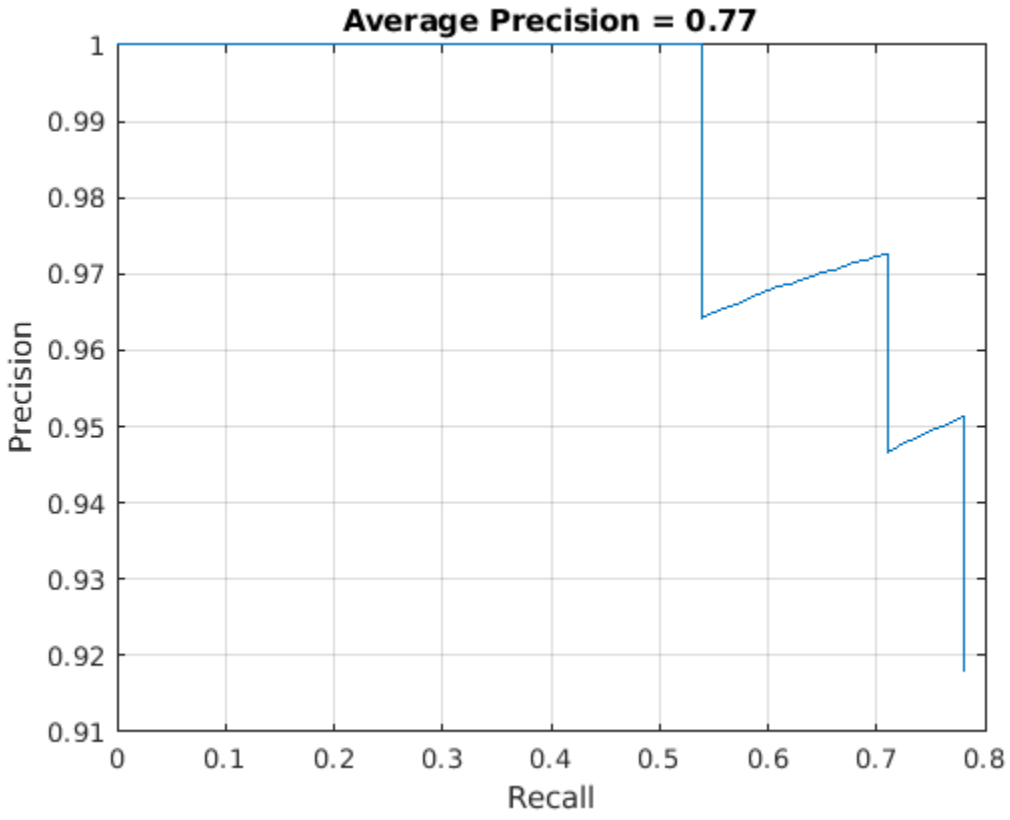
```
detectionResults = detect(detector, preprocessedTestData);
```

Evaluate the object detector using average precision metric.

```
[ap,recall,precision] = evaluateDetectionPrecision(detectionResults, preprocessedTestData);
```

The precision/recall (PR) curve highlights how precise a detector is at varying levels of recall. The ideal precision is 1 at all recall levels. The use of more data can help improve the average precision but might require more training time. Plot the PR curve.

```
figure
plot(recall,precision)
xlabel('Recall')
ylabel('Precision')
grid on
title(sprintf('Average Precision = %.2f',ap))
```



Code Generation

Once the detector is trained and evaluated, you can generate code for the `yolov2ObjectDetector` using GPU Coder™. See “Code Generation for Object Detection by Using YOLO v2” (GPU Coder) example for more details.

Supporting Functions

```
function B = augmentData(A)
% Apply random horizontal flipping, and random X/Y scaling. Boxes that get
% scaled outside the bounds are clipped if the overlap is above 0.25. Also,
% jitter image color.

B = cell(size(A));

I = A{1};
sz = size(I);
if numel(sz)==3 && sz(3) == 3
    I = jitterColorHSV(I,...
        'Contrast',0.2,...
        'Hue',0,...
        'Saturation',0.1,...
        'Brightness',0.2);
end

% Randomly flip and scale image.
tform = randomAffine2d('XReflection',true,'Scale',[1 1.1]);
rout = affineOutputView(sz,tform,'BoundsStyle','CenterOutput');
B{1} = imwarp(I,tform,'OutputView',rout);

% Sanitize box data, if needed.
A{2} = helperSanitizeBoxes(A{2}, sz);

% Apply same transform to boxes.
[B{2},indices] = bboxwarp(A{2},tform,rout,'OverlapThreshold',0.25);
B{3} = A{3}(indices);

% Return original data only when all boxes are removed by warping.
if isempty(indices)
    B = A;
end
end

function data = preprocessData(data,targetSize)
% Resize image and bounding boxes to the targetSize.
sz = size(data{1},[1 2]);
scale = targetSize(1:2)./sz;
data{1} = imresize(data{1},targetSize(1:2));

% Sanitize box data, if needed.
data{2} = helperSanitizeBoxes(data{2},sz);

% Resize boxes to new image size.
data{2} = bboxresize(data{2},scale);
end
```

Semantic Segmentation Using Deep Learning

This example shows how to train a semantic segmentation network using deep learning.

A semantic segmentation network classifies every pixel in an image, resulting in an image that is segmented by class. Applications for semantic segmentation include road segmentation for autonomous driving and cancer cell segmentation for medical diagnosis. To learn more, see “Getting Started with Semantic Segmentation Using Deep Learning” (Computer Vision Toolbox).

To illustrate the training procedure, this example trains Deeplab v3+ [1], one type of convolutional neural network (CNN) designed for semantic image segmentation. Other types of networks for semantic segmentation include fully convolutional networks (FCN), SegNet, and U-Net. The training procedure shown here can be applied to those networks too.

This example uses the CamVid dataset [2] from the University of Cambridge for training. This dataset is a collection of images containing street-level views obtained while driving. The dataset provides pixel-level labels for 32 semantic classes including car, pedestrian, and road.

Setup

This example creates the Deeplab v3+ network with weights initialized from a pre-trained Resnet-18 network. ResNet-18 is an efficient network that is well suited for applications with limited processing resources. Other pretrained networks such as MobileNet v2 or ResNet-50 can also be used depending on application requirements. For more details, see “Pretrained Deep Neural Networks” on page 1-8.

To get a pretrained Resnet-18, install `resnet18`. After installation is complete, run the following code to verify that the installation is correct.

```
resnet18();
```

In addition, download a pretrained version of DeepLab v3+. The pretrained model allows you to run the entire example without having to wait for training to complete.

```
pretrainedURL = 'https://www.mathworks.com/supportfiles/vision/data/deeplabv3plusResnet18CamVid.m
pretrainedFolder = fullfile(tempdir,'pretrainedNetwork');
pretrainedNetwork = fullfile(pretrainedFolder,'deeplabv3plusResnet18CamVid.mat');
if ~exist(pretrainedNetwork,'file')
    mkdir(pretrainedFolder);
    disp('Downloading pretrained network (58 MB)...');
    websave(pretrainedNetwork,pretrainedURL);
end
```

A CUDA-capable NVIDIA™ GPU is highly recommended for running this example. Use of a GPU requires Parallel Computing Toolbox™. For information about the supported compute capabilities, see “GPU Support by Release” (Parallel Computing Toolbox).

Download CamVid Dataset

Download the CamVid dataset from the following URLs.

```
imageURL = 'http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData/files/701_StillsRaw_full.zi
labelURL = 'http://web4.cs.ucl.ac.uk/staff/g.brostow/MotionSegRecData/data/LabeledApproved_full.z

outputFolder = fullfile(tempdir,'CamVid');
labelsZip = fullfile(outputFolder,'labels.zip');
imagesZip = fullfile(outputFolder,'images.zip');
```

```
if ~exist(labelsZip, 'file') || ~exist(imagesZip,'file')
    mkdir(outputFolder)

    disp('Downloading 16 MB CamVid dataset labels...');
    websave(labelsZip, labelURL);
    unzip(labelsZip, fullfile(outputFolder,'labels'));

    disp('Downloading 557 MB CamVid dataset images...');
    websave(imagesZip, imageURL);
    unzip(imagesZip, fullfile(outputFolder,'images'));
end
```

Note: Download time of the data depends on your Internet connection. The commands used above block MATLAB until the download is complete. Alternatively, you can use your web browser to first download the dataset to your local disk. To use the file you downloaded from the web, change the `outputFolder` variable above to the location of the downloaded file.

Load CamVid Images

Use `imageDatastore` to load CamVid images. The `imageDatastore` enables you to efficiently load a large collection of images on disk.

```
imgDir = fullfile(outputFolder,'images','701_StillsRaw_full');
imds = imageDatastore(imgDir);
```

Display one of the images.

```
I = readimage(imds,559);
I = histeq(I);
imshow(I)
```

Load CamVid Pixel-Labeled Images

Use `pixelLabelDatastore` (Computer Vision Toolbox) to load CamVid pixel label image data. A `pixelLabelDatastore` encapsulates the pixel label data and the label ID to a class name mapping.

We make training easier, we group the 32 original classes in CamVid to 11 classes. Specify these classes.

```
classes = [
    "Sky"
    "Building"
    "Pole"
    "Road"
    "Pavement"
    "Tree"
    "SignSymbol"
    "Fence"
    "Car"
    "Pedestrian"
    "Bicyclist"
    ];
```

To reduce 32 classes into 11, multiple classes from the original dataset are grouped together. For example, "Car" is a combination of "Car", "SUVPickupTruck", "Truck_Bus", "Train", and "OtherMoving". Return the grouped label IDs by using the supporting function `camvidPixelLabelIDs`, which is listed at the end of this example.

```
labelIDs = camvidPixelLabelIDs();
```

Use the classes and label IDs to create the `pixelLabelDatastore.`

```
labelDir = fullfile(outputFolder,'labels');
pxds = pixelLabelDatastore(labelDir,classes,labelIDs);
```

Read and display one of the pixel-labeled images by overlaying it on top of an image.

```
C = readimage(pxds,559);
cmap = camvidColorMap;
B = labeloverlay(I,C,'ColorMap',cmap);
imshow(B)
pixelLabelColorbar(cmap,classes);
```

Areas with no color overlay do not have pixel labels and are not used during training.

Analyze Dataset Statistics

To see the distribution of class labels in the CamVid dataset, use `countEachLabel` (Computer Vision Toolbox). This function counts the number of pixels by class label.

```
tbl = countEachLabel(pxds)
```

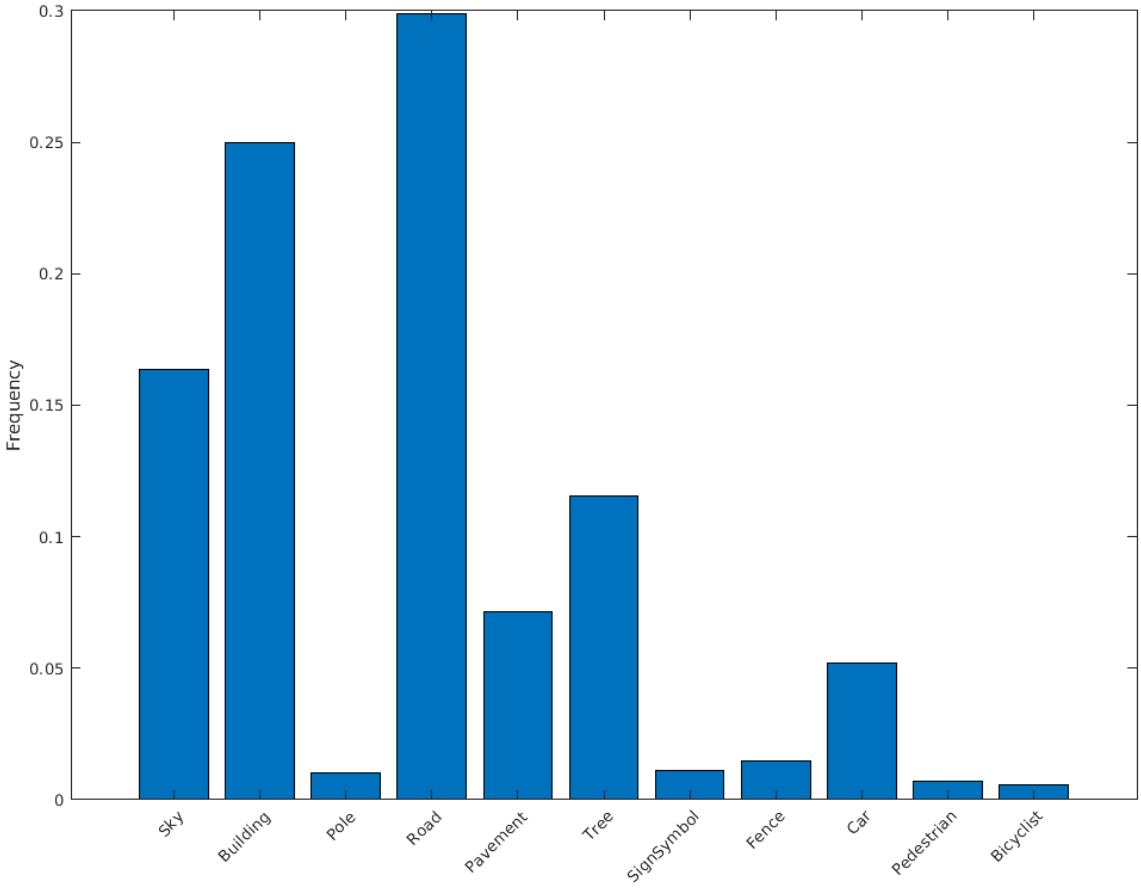
```
tbl=11×3 table
         Name          PixelCount    ImagePixelCount
    _______________    __________    _______________

    {'Sky'       }    7.6801e+07      4.8315e+08
    {'Building'  }    1.1737e+08      4.8315e+08
    {'Pole'      }    4.7987e+06      4.8315e+08
    {'Road'      }    1.4054e+08      4.8453e+08
    {'Pavement'  }    3.3614e+07      4.7209e+08
    {'Tree'      }    5.4259e+07       4.479e+08
    {'SignSymbol'}    5.2242e+06      4.6863e+08
    {'Fence'     }    6.9211e+06       2.516e+08
    {'Car'       }    2.4437e+07      4.8315e+08
    {'Pedestrian'}    3.4029e+06      4.4444e+08
    {'Bicyclist' }    2.5912e+06      2.6196e+08
```

Visualize the pixel counts by class.

```
frequency = tbl.PixelCount/sum(tbl.PixelCount);

bar(1:numel(classes),frequency)
xticks(1:numel(classes))
xticklabels(tbl.Name)
xtickangle(45)
ylabel('Frequency')
```



Ideally, all classes would have an equal number of observations. However, the classes in CamVid are imbalanced, which is a common issue in automotive data-sets of street scenes. Such scenes have more sky, building, and road pixels than pedestrian and bicyclist pixels because sky, buildings and roads cover more area in the image. If not handled correctly, this imbalance can be detrimental to the learning process because the learning is biased in favor of the dominant classes. Later on in this example, you will use class weighting to handle this issue.

The images in the CamVid data set are 720 by 960 in size. Image size is chosen such that a large enough batch of images can fit in memory during training on an NVIDIA™ Titan X with 12 GB of memory. You may need to resize the images to smaller sizes if your GPU does not have sufficient memory or reduce the training batch size.

Prepare Training, Validation, and Test Sets

Deeplab v3+ is trained using 60% of the images from the dataset. The rest of the images are split evenly in 20% and 20% for validation and testing respectively. The following code randomly splits the image and pixel label data into a training, validation and test set.

```
[imdsTrain, imdsVal, imdsTest, pxdsTrain, pxdsVal, pxdsTest] = partitionCamVidData(imds,pxds);
```

The 60/20/20 split results in the following number of training, validation and test images:

```
numTrainingImages = numel(imdsTrain.Files)
```

```
numTrainingImages = 421
```

```
numValImages = numel(imdsVal.Files)
```

```
numValImages = 140
```

```
numTestingImages = numel(imdsTest.Files)
```

```
numTestingImages = 140
```

Create the Network

Use the `deeplabv3plusLayers` function to create a DeepLab v3+ network based on ResNet-18. Choosing the best network for your application requires empirical analysis and is another level of hyperparameter tuning. For example, you can experiment with different base networks such as ResNet-50 or MobileNet v2, or you can try other semantic segmentation network architectures such as SegNet, fully convolutional networks (FCN), or U-Net.

```
% Specify the network image size. This is typically the same as the traing image sizes.
imageSize = [720 960 3];

% Specify the number of classes.
numClasses = numel(classes);

% Create DeepLab v3+.
lgraph = deeplabv3plusLayers(imageSize, numClasses, "resnet18");
```

Balance Classes Using Class Weighting

As shown earlier, the classes in CamVid are not balanced. To improve training, you can use class weighting to balance the classes. Use the pixel label counts computed earlier with `countEachLabel` (Computer Vision Toolbox) and calculate the median frequency class weights.

```
imageFreq = tbl.PixelCount ./ tbl.ImagePixelCount;
classWeights = median(imageFreq) ./ imageFreq
```

```
classWeights = 11×1

    0.3182
    0.2082
    5.0924
    0.1744
    0.7103
    0.4175
    4.5371
    1.8386
    1.0000
    6.6059
      ⋮
```

Specify the class weights using a `pixelClassificationLayer` (Computer Vision Toolbox).

```
pxLayer = pixelClassificationLayer('Name','labels','Classes',tbl.Name,'ClassWeights',classWeights
lgraph = replaceLayer(lgraph,"classification",pxLayer);
```

Select Training Options

The optimization algorithm used for training is stochastic gradient descent with momentum (SGDM). Use `trainingOptions` to specify the hyper-parameters used for SGDM.

```
% Define validation data.
dsVal = combine(imdsVal,pxdsVal);

% Define training options.
options = trainingOptions('sgdm', ...
    'LearnRateSchedule','piecewise',...
    'LearnRateDropPeriod',10,...
    'LearnRateDropFactor',0.3,...
    'Momentum',0.9, ...
    'InitialLearnRate',1e-3, ...
    'L2Regularization',0.005, ...
    'ValidationData',dsVal,...
    'MaxEpochs',30, ...
    'MiniBatchSize',8, ...
    'Shuffle','every-epoch', ...
    'CheckpointPath', tempdir, ...
    'VerboseFrequency',2,...
    'Plots','training-progress',...
    'ValidationPatience', 4);
```

The learning rate uses a piecewise schedule. The learning rate is reduced by a factor of 0.3 every 10 epochs. This allows the network to learn quickly with a higher initial learning rate, while being able to find a solution close to the local optimum once the learning rate drops.

The network is tested against the validation data every epoch by setting the `'ValidationData'` parameter. The `'ValidationPatience'` is set to 4 to stop training early when the validation accuracy converges. This prevents the network from overfitting on the training dataset.

A mini-batch size of 8 is used to reduce memory usage while training. You can increase or decrease this value based on the amount of GPU memory you have on your system.

In addition, `'CheckpointPath'` is set to a temporary location. This name-value pair enables the saving of network checkpoints at the end of every training epoch. If training is interrupted due to a system failure or power outage, you can resume training from the saved checkpoint. Make sure that the location specified by `'CheckpointPath'` has enough space to store the network checkpoints. For example, saving 100 Deeplab v3+ checkpoints requires ~6 GB of disk space because each checkpoint is 61 MB.

Data Augmentation

Data augmentation is used to improve network accuracy by randomly transforming the original data during training. By using data augmentation, you can add more variety to the training data without increasing the number of labeled training samples. To apply the same random transformation to both image and pixel label data use datastore `combine` and `transform`. First, combine `imdsTrain` and `pxdsTrain`.

```
dsTrain = combine(imdsTrain, pxdsTrain);
```

Next, use datastore `transform` to apply the desired data augmentation defined in the supporting function `augmentImageAndLabel`. Here, random left/right reflection and random X/Y translation of +/- 10 pixels is used for data augmentation.

```
xTrans = [-10 10];
yTrans = [-10 10];
dsTrain = transform(dsTrain, @(data)augmentImageAndLabel(data,xTrans,yTrans));
```

Note that data augmentation is not applied to the test and validation data. Ideally, test and validation data should be representative of the original data and is left unmodified for unbiased evaluation.

Start Training

Start training using `trainNetwork` if the `doTraining` flag is true. Otherwise, load a pretrained network.

Note: The training was verified on an NVIDIA™ Titan X with 12 GB of GPU memory. If your GPU has less memory, you may run out of memory during training. If this happens, try setting `'MiniBatchSize'` to 1 in `trainingOptions`, or reducing the network input and resizing the training data. Training this network takes about 5 hours. Depending on your GPU hardware, it can take even longer.

```
doTraining = false;
if doTraining
    [net, info] = trainNetwork(dsTrain,lgraph,options);
else
    data = load(pretrainedNetwork);
    net = data.net;
end
```

Test Network on One Image

As a quick sanity check, run the trained network on one test image.

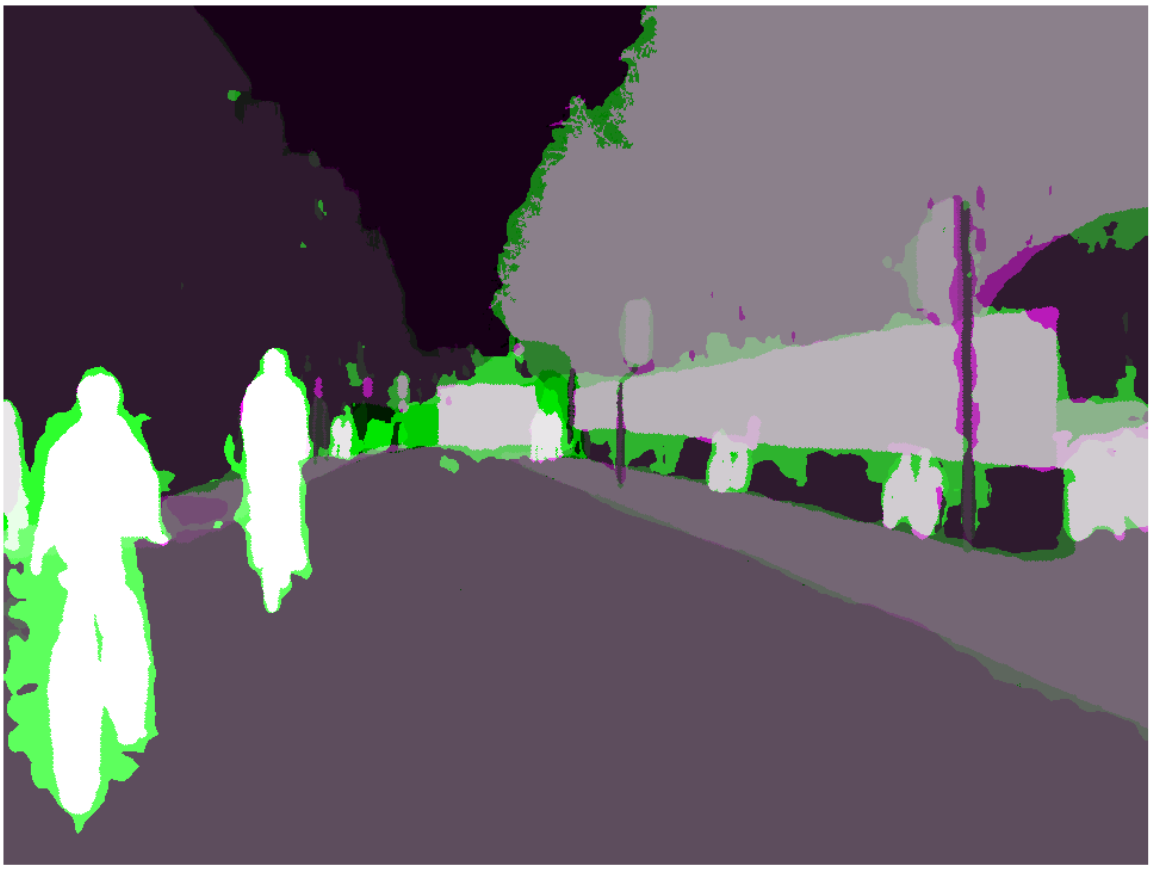
```
I = readimage(imdsTest,35);
C = semanticseg(I, net);
```

Display the results.

```
B = labeloverlay(I,C,'Colormap',cmap,'Transparency',0.4);
imshow(B)
pixelLabelColorbar(cmap, classes);
```

Compare the results in `C` with the expected ground truth stored in `pxdsTest`. The green and magenta regions highlight areas where the segmentation results differ from the expected ground truth.

```
expectedResult = readimage(pxdsTest,35);
actual = uint8(C);
expected = uint8(expectedResult);
imshowpair(actual, expected)
```



Visually, the semantic segmentation results overlap well for classes such as road, sky, and building. However, smaller objects like pedestrians and cars are not as accurate. The amount of overlap per class can be measured using the intersection-over-union (IoU) metric, also known as the Jaccard index. Use the `jaccard` (Image Processing Toolbox) function to measure IoU.

```
iou = jaccard(C,expectedResult);
table(classes,iou)
```

```
ans=11×2 table
      classes         iou
    ____________    _______

    "Sky"           0.91837
    "Building"      0.84479
    "Pole"          0.31203
    "Road"          0.93698
    "Pavement"      0.82838
    "Tree"          0.89636
    "SignSymbol"    0.57644
    "Fence"         0.71046
    "Car"           0.66688
    "Pedestrian"    0.48417
```

```
    "Bicyclist"     0.68431
```

The IoU metric confirms the visual results. Road, sky, and building classes have high IoU scores, while classes such as pedestrian and car have low scores. Other common segmentation metrics include the `dice` (Image Processing Toolbox) and the `bfscore` (Image Processing Toolbox) contour matching score.

Evaluate Trained Network

To measure accuracy for multiple test images, run`semanticseg` (Computer Vision Toolbox) on the entire test set. A mini-batch size of 4 is used to reduce memory usage while segmenting images. You can increase or decrease this value based on the amount of GPU memory you have on your system.

```
pxdsResults = semanticseg(imdsTest,net, ...
    'MiniBatchSize',4, ...
    'WriteLocation',tempdir, ...
    'Verbose',false);
```

`semanticseg` returns the results for the test set as a `pixelLabelDatastore` object. The actual pixel label data for each test image in `imdsTest` is written to disk in the location specified by the `'WriteLocation'` parameter. Use `evaluateSemanticSegmentation` (Computer Vision Toolbox) to measure semantic segmentation metrics on the test set results.

```
metrics = evaluateSemanticSegmentation(pxdsResults,pxdsTest,'Verbose',false);
```

`evaluateSemanticSegmentation` returns various metrics for the entire dataset, for individual classes, and for each test image. To see the dataset level metrics, inspect `metrics.DataSetMetrics` .

```
metrics.DataSetMetrics
```

```
ans=1×5 table
    GlobalAccuracy    MeanAccuracy    MeanIoU    WeightedIoU    MeanBFScore
    ______________    ____________    _______    ___________    ___________

       0.87695          0.85392       0.6302       0.80851        0.65051
```

The dataset metrics provide a high-level overview of the network performance. To see the impact each class has on the overall performance, inspect the per-class metrics using `metrics.ClassMetrics`.

```
metrics.ClassMetrics
```

```
ans=11×3 table
                  Accuracy      IoU      MeanBFScore
                  ________    _______    ___________

    Sky           0.93112     0.90209       0.8952
    Building      0.78453     0.76098      0.58511
    Pole          0.71586     0.21477      0.51439
    Road          0.93024     0.91465      0.76696
    Pavement      0.88466     0.70571      0.70919
    Tree          0.87377     0.76323      0.70875
    SignSymbol    0.79358     0.39309      0.48302
    Fence         0.81507     0.46484      0.48566
    Car           0.90956     0.76799      0.69233
```

```
    Pedestrian    0.87629      0.4366      0.60792
    Bicyclist     0.87844     0.60829      0.55089
```

Although the overall dataset performance is quite high, the class metrics show that underrepresented classes such as `Pedestrian`, `Bicyclist`, and `Car` are not segmented as well as classes such as `Road`, `Sky`, and `Building`. Additional data that includes more samples of the underrepresented classes might help improve the results.

Supporting Functions

```
function labelIDs = camvidPixelLabelIDs()
% Return the label IDs corresponding to each class.
%
% The CamVid dataset has 32 classes. Group them into 11 classes following
% the original SegNet training methodology [1].
%
% The 11 classes are:
%   "Sky" "Building", "Pole", "Road", "Pavement", "Tree", "SignSymbol",
%   "Fence", "Car", "Pedestrian",  and "Bicyclist".
%
% CamVid pixel label IDs are provided as RGB color values. Group them into
% 11 classes and return them as a cell array of M-by-3 matrices. The
% original CamVid class names are listed alongside each RGB value. Note
% that the Other/Void class are excluded below.

Semantic Segmentation Using Dilated Convolutions

Train a semantic segmentation network using dilated convolutions.

A semantic segmentation network classifies every pixel in an image, resulting in an image that is segmented by class. Applications for semantic segmentation include road segmentation for autonomous driving and cancer cell segmentation for medical diagnosis. To learn more, see “Getting Started with Semantic Segmentation Using Deep Learning” (Computer Vision Toolbox).

Semantic segmentation networks like DeepLab [1] make extensive use of dilated convolutions (also known as atrous convolutions) because they can increase the receptive field of the layer (the area of the input which the layers can see) without increasing the number of parameters or computations.

Load Training Data

The example uses a simple dataset of 32-by-32 triangle images for illustration purposes. The dataset includes accompanying pixel label ground truth data. Load the training data using an `imageDatastore` and a `pixelLabelDatastore`.

```
dataFolder = fullfile(toolboxdir('vision'),'visiondata','triangleImages');
imageFolderTrain = fullfile(dataFolder,'trainingImages');
labelFolderTrain = fullfile(dataFolder,'trainingLabels');
```

Create an `imageDatastore` for the images.

```
imdsTrain = imageDatastore(imageFolderTrain);
```

Create a `pixelLabelDatastore` for the ground truth pixel labels.

```
classNames = ["triangle" "background"];
labels = [255 0];
pxdsTrain = pixelLabelDatastore(labelFolderTrain,classNames,labels)
```

```
pxdsTrain =
  PixelLabelDatastore with properties:

                      Files: {200x1 cell}
                 ClassNames: {2x1 cell}
                   ReadSize: 1
                    ReadFcn: @readDatastoreImage
    AlternateFileSystemRoots: {}
```

Create Semantic Segmentation Network

This example uses a simple semantic segmentation network based on dilated convolutions.

Create a data source for training data and get the pixel counts for each label.

```
ds = combine(imdsTrain,pxdsTrain);
tbl = countEachLabel(pxdsTrain)
```

```
tbl=2×3 table
         Name          PixelCount    ImagePixelCount
    _______________    __________    _______________

    {'triangle'  }         10326       2.048e+05
```

```
    {'background'}    1.9447e+05       2.048e+05
```

The majority of pixel labels are for background. This class imbalance biases the learning process in favor of the dominant class. To fix this, use class weighting to balance the classes. You can use several methods to compute class weights. One common method is inverse frequency weighting where the class weights are the inverse of the class frequencies. This method increases the weight given to under represented classes. Calculate the class weights using inverse frequency weighting.

```
numberPixels = sum(tbl.PixelCount);
frequency = tbl.PixelCount / numberPixels;
classWeights = 1 ./ frequency;
```

Create a network for pixel classification by using an image input layer with an input size corresponding to the size of the input images. Next, specify three blocks of convolution, batch normalization, and ReLU layers. For each convolutional layer, specify 32 3-by-3 filters with increasing dilation factors and pad the inputs so they are the same size as the outputs by setting the `'Padding'` option to `'same'`. To classify the pixels, include a convolutional layer with K 1-by-1 convolutions, where K is the number of classes, followed by a softmax layer and a `pixelClassificationLayer` with the inverse class weights.

```
inputSize = [32 32 1];
filterSize = 3;
numFilters = 32;
numClasses = numel(classNames);

layers = [
    imageInputLayer(inputSize)

    convolution2dLayer(filterSize,numFilters,'DilationFactor',1,'Padding','same')
    batchNormalizationLayer
    reluLayer

    convolution2dLayer(filterSize,numFilters,'DilationFactor',2,'Padding','same')
    batchNormalizationLayer
    reluLayer

    convolution2dLayer(filterSize,numFilters,'DilationFactor',4,'Padding','same')
    batchNormalizationLayer
    reluLayer

    convolution2dLayer(1,numClasses)
    softmaxLayer
    pixelClassificationLayer('Classes',classNames,'ClassWeights',classWeights)];
```

Train Network

Specify the training options.

```
options = trainingOptions('sgdm', ...
    'MaxEpochs', 100, ...
    'MiniBatchSize', 64, ...
    'InitialLearnRate', 1e-3);
```

Train the network using `trainNetwork`.

```
net = trainNetwork(ds,layers,options);
```

```
Training on single CPU.
Initializing input data normalization.

|========================================================================================|
Training finished: Max epochs completed.
```

Test Network

Load the test data. Create an `imageDatastore` for the images. Create a `pixelLabelDatastore` for the ground truth pixel labels.

```
imageFolderTest = fullfile(dataFolder,'testImages');
imdsTest = imageDatastore(imageFolderTest);
labelFolderTest = fullfile(dataFolder,'testLabels');
pxdsTest = pixelLabelDatastore(labelFolderTest,classNames,labels);
```

Make predictions using the test data and trained network.

```
pxdsPred = semanticseg(imdsTest,net,'MiniBatchSize',32,'WriteLocation',tempdir);
```

```
Running semantic segmentation network
-------------------------------------
* Processed 100 images.
```

Evaluate the prediction accuracy using `evaluateSemanticSegmentation`.

```
metrics = evaluateSemanticSegmentation(pxdsPred,pxdsTest);
```

```
Evaluating semantic segmentation results
----------------------------------------
* Selected metrics: global accuracy, class accuracy, IoU, weighted IoU, BF score.
* Processed 100 images.
* Finalizing... Done.
* Data set metrics:

    GlobalAccuracy    MeanAccuracy    MeanIoU    WeightedIoU    MeanBFScore
    ______________    ____________    _______    ___________    ___________

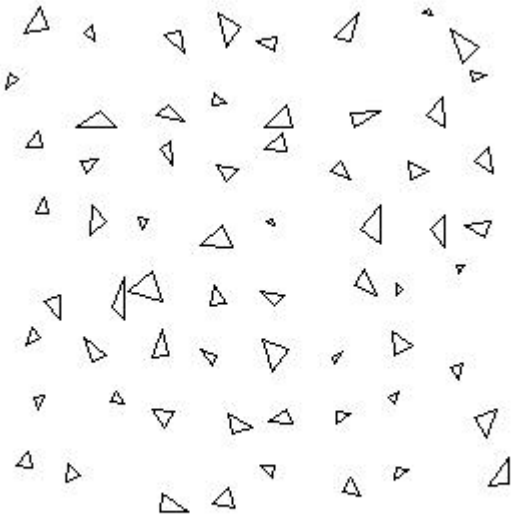
```

For more information on evaluating semantic segmentation networks, see `evaluateSemanticSegmentation` (Computer Vision Toolbox).

Segment New Image

Read and display the test image `triangleTest.jpg`.

```
imgTest = imread('triangleTest.jpg');
figure
imshow(imgTest)
```



Segment the test image using `semanticseg` and display the results using `labeloverlay`.

```
C = semanticseg(imgTest,net);
B = labeloverlay(imgTest,C);
figure
imshow(B)
```

Train Simple Semantic Segmentation Network in Deep Network Designer

This example shows how to create and train a simple semantic segmentation network using Deep Network Designer.

Semantic segmentation describes the process of associating each pixel of an image with a class label (such as *flower*, *person*, *road*, *sky*, *ocean*, or *car*). Applications for semantic segmentation include road segmentation for autonomous driving and cancer cell segmentation for medical diagnosis. To learn more, see “Getting Started with Semantic Segmentation Using Deep Learning” (Computer Vision Toolbox).

Preprocess Training Data

To train a semantic segmentation network, you need a collection of images and its corresponding collection of pixel-labeled images. A pixel-labeled image is an image where every pixel value represents the categorical label of that pixel. This example uses a simple data set of 32-by-32 images of triangles for illustration purposes. You can interactively label pixels and export the label data for computer vision applications using Image Labeler (Computer Vision Toolbox). For more information on creating training data for semantic segmentation applications, see “Label Pixels for Semantic Segmentation” (Computer Vision Toolbox).

Load the training data.

```
dataFolder  = fullfile(toolboxdir('vision'), ...
'visiondata','triangleImages');

imageDir = fullfile(dataFolder,'trainingImages');
labelDir = fullfile(dataFolder,'trainingLabels');
```

Create an `ImageDatastore` containing the images.

```
imds = imageDatastore(imageDir);
```

Create a `PixelLabelDatastore` containing the ground truth pixel labels. This data set has two classes: `"triangle"` and `"background"`.

```
classNames = ["triangle","background"];
labelIDs   = [255 0];

pxds = pixelLabelDatastore(labelDir,classNames,labelIDs);
```

Combine the image datastore and the pixel label datastore into a `CombinedDatastore` object using the `combine` function. A combined datastore maintains parity between the pair of images in the underlying datastores.

```
cds = combine(imds,pxds);
```

Build Network

Open Deep Network Designer.

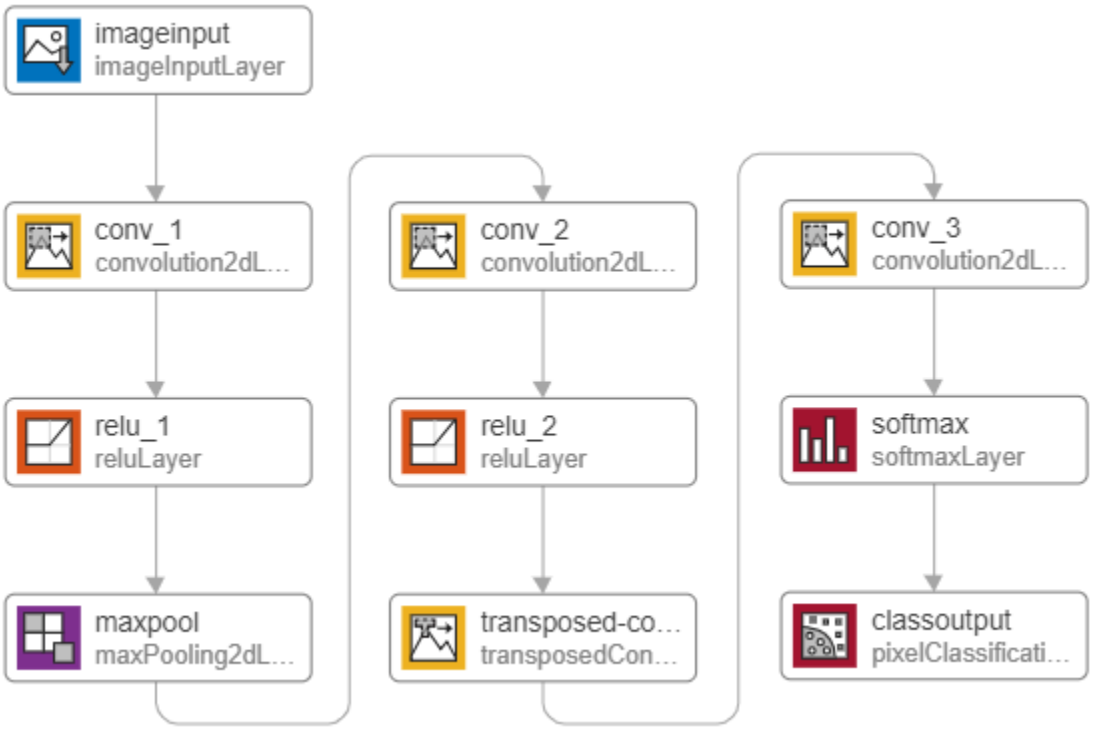
```
deepNetworkDesigner
```

In Deep Network Designer, you can build, edit, and train deep learning networks. Pause on **Blank Network** and click **New**.

Create a semantic segmentation network by dragging layers from the **Layer Library** to the **Designer** pane.

Connect the layers in this order:

1. `imageInputLayer` with `InputSize` set to `32,32,1`
2. `convolution2dLayer` with `FilterSize` set to `3,3`, `NumFilters` set to `64`, and `Padding` set to `1,1,1,1`
3. `reluLayer`
4. `maxPooling2dLayer` with `PoolSize` set to `2,2`, `Stride` set to `2,2`, and `Padding` set to `0,0,0,0`
5. `convolution2dLayer` with `FilterSize` set to `3,3`, `NumFilters` set to `64`, and `Padding` set to `1,1,1,1`
6. `reluLayer`
7. `transposedConv2dLayer` with `FilterSize` set to `4,4`, `NumFilters` set to `64`, `Stride` set to `2,2`, and `Cropping` set to `1,1,1,1`
8. `convolution2dLayer` with `FilterSize` set to `1,1`, `NumFilters` set to `2`, and `Padding` set to `0,0,0,0`
9. `softmaxLayer`
10. `pixelClassificationLayer`



You can also create this network at the command line and then import the network into Deep Network Designer using `deepNetworkDesigner(layers)`.

```
layers = [
    imageInputLayer([32 32 1])
```

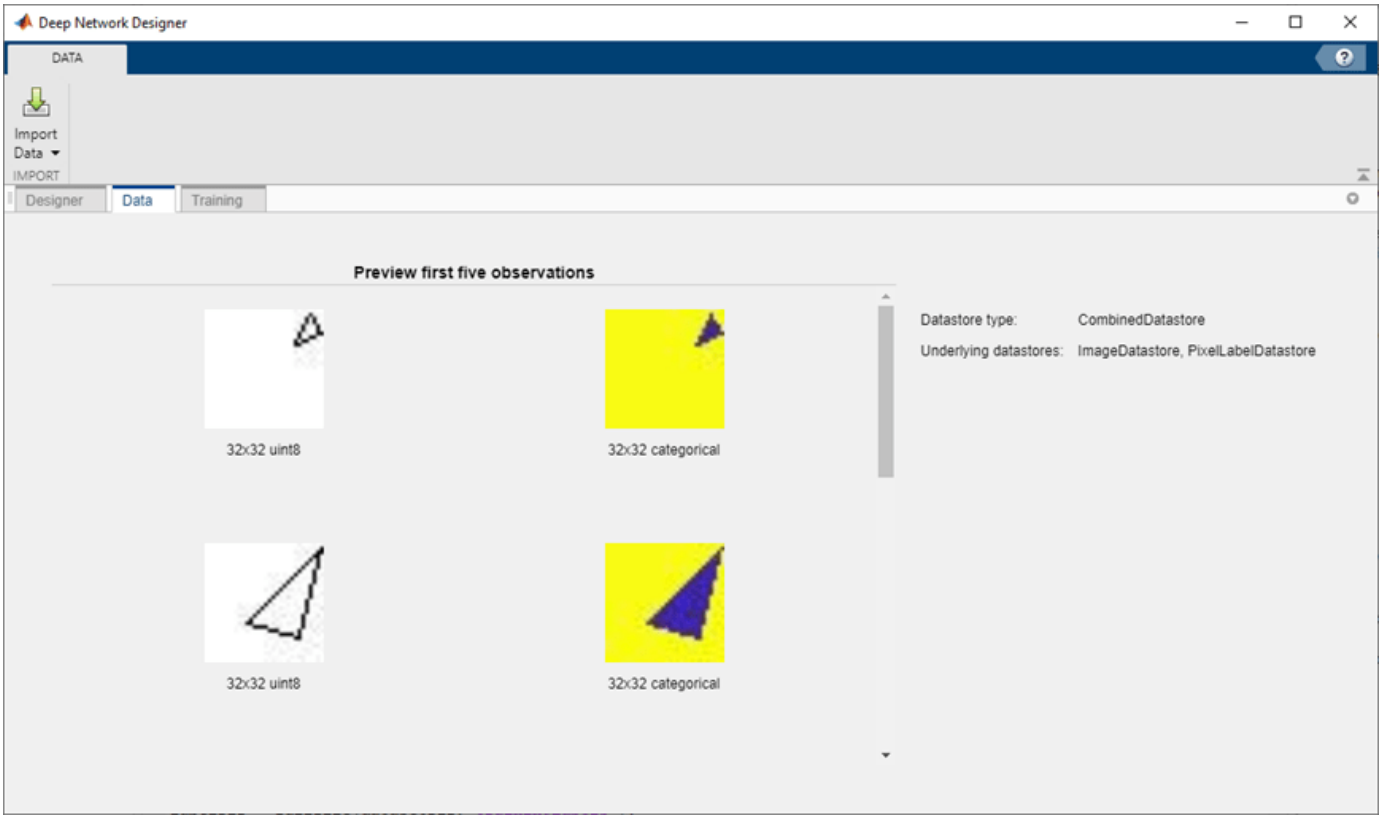
```
convolution2dLayer([3,3],64,'Padding',[1,1,1,1])
reluLayer
maxPooling2dLayer([2,2],'Stride',[2,2])
convolution2dLayer([3,3],64,'Padding',[1,1,1,1])
reluLayer
transposedConv2dLayer([4,4],64,'Stride',[2,2],'Cropping',[1,1,1,1])
convolution2dLayer([1,1],2)
softmaxLayer
pixelClassificationLayer
];
```

This network is a simple semantic segmentation network based on a downsampling and upsampling design. For more information on constructing a semantic segmentation network, see “Create a Semantic Segmentation Network” (Computer Vision Toolbox).

Import Data

To import the training datastore, on the **Data** tab, select **Import Data** > **Import Datastore**. Select the `CombinedDatastore` object `cds` as the training data. For the validation data, select `None`. Import the training data by clicking **Import**.

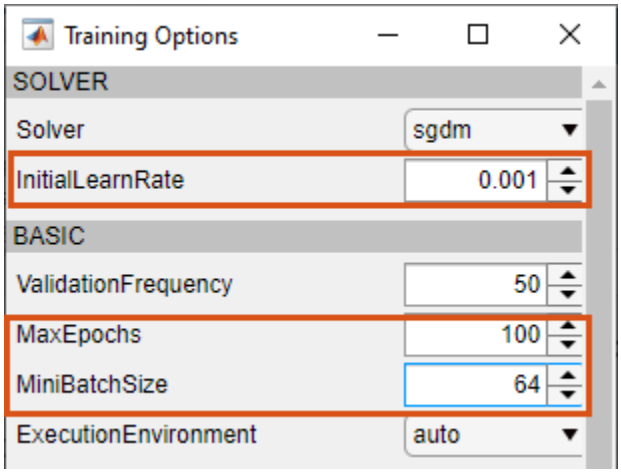
Deep Network Designer displays a preview of the imported semantic segmentation data. The preview displays the training images and the ground truth pixel labels. The network requires input images (left) and returns a classification for each pixel as either triangle or background (right).



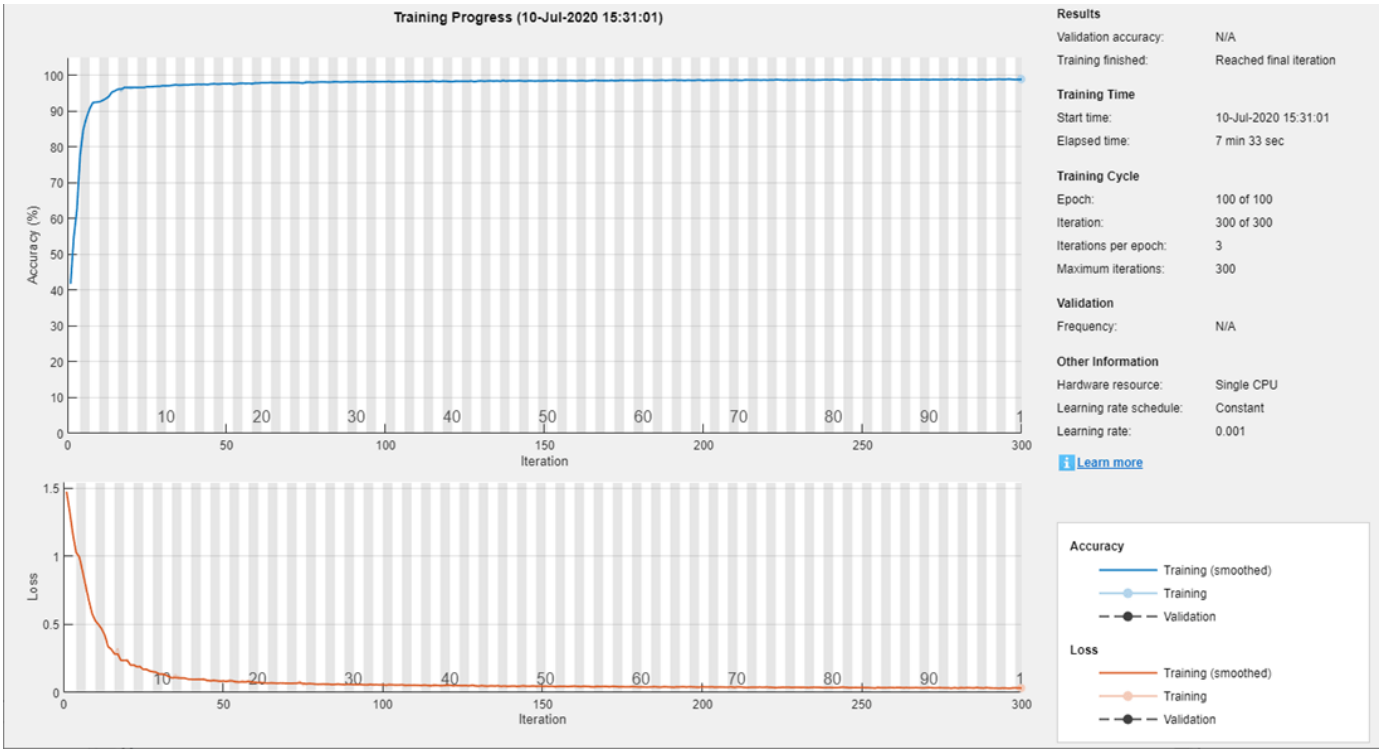
Train Network

Set the training options and train the network.

On the **Training** tab, click **Training Options**. Set **InitialLearnRate** to `0.001`, **MaxEpochs** to `100`, and **MiniBatchSize** to `64`. Set the training options by clicking **Close**.



Train the network by clicking **Train**.



Once training is complete, click **Export** to export the trained network to the workspace. The trained network is stored in the variable `trainedNetwork_1`.

Test Network

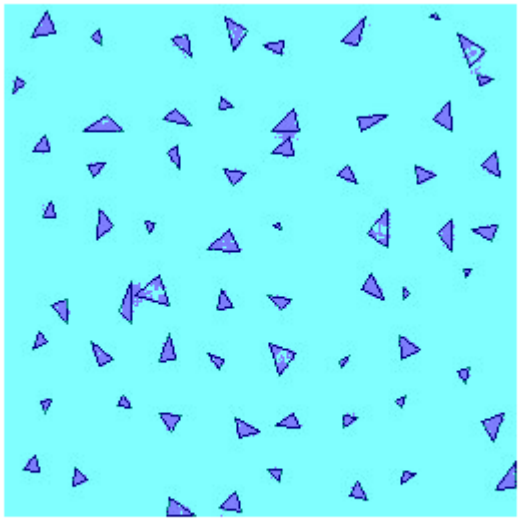
Make predictions using test data and the trained network.

Segment the test image using `semanticseg`. Display the labels over the image by using the `labeloverlay` function.

```
imgTest = imread('triangleTest.jpg');
testSeg = semanticseg(imgTest,trainedNetwork_1);
testImageSeg = labeloverlay(imgTest,testSeg);
```

Display the results.

```
figure
imshow(testImageSeg)
```



The network successfully labels the triangles in the test image.

The semantic segmentation network trained in this example is very simple. To construct more complex semantic segmentation networks, you can use the Computer Vision Toolbox functions `segnetLayers` (Computer Vision Toolbox), `deeplabv3plusLayers` (Computer Vision Toolbox), and `unetLayers` (Computer Vision Toolbox). For an example showing how to use the `deeplabv3plusLayers` function to create a DeepLab v3+ network, see "Semantic Segmentation With Deep Learning" (Computer Vision Toolbox).

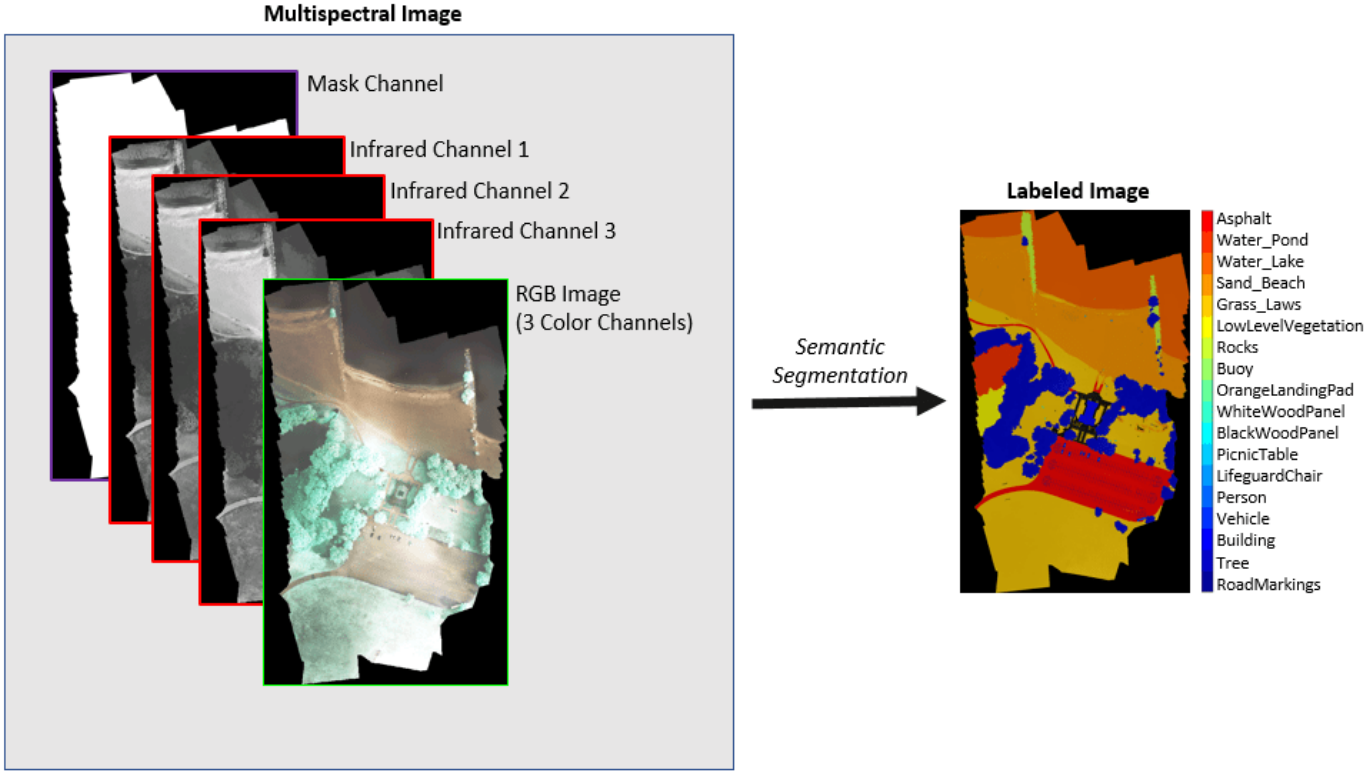
Semantic Segmentation of Multispectral Images Using Deep Learning

This example shows how to perform semantic segmentation of a multispectral image with seven channels using a U-Net.

Semantic segmentation involves labeling each pixel in an image with a class. One application of semantic segmentation is tracking deforestation, which is the change in forest cover over time. Environmental agencies track deforestation to assess and quantify the environmental and ecological health of a region.

Deep learning based semantic segmentation can yield a precise measurement of vegetation cover from high-resolution aerial photographs. One challenge is differentiating classes with similar visual characteristics, such as trying to classify a green pixel as grass, shrubbery, or tree. To increase classification accuracy, some data sets contain multispectral images that provide additional information about each pixel. For example, the Hamlin Beach State Park data set supplements the color images with three near-infrared channels that provide a clearer separation of the classes.



This example shows how to use deep-learning-based semantic segmentation techniques to calculate the percentage vegetation cover in a region from a set of multispectral images.

Download Data

This example uses a high-resolution multispectral data set to train the network [1 on page 8-0]. The image set was captured using a drone over the Hamlin Beach State Park, NY. The data contains labeled training, validation, and test sets, with 18 object class labels. The size of the data file is ~3.0 GB.

Download the MAT-file version of the data set using the `downloadHamlinBeachMSIData` helper function. This function is attached to the example as a supporting file.

```
imageDir = tempdir;
url = 'http://www.cis.rit.edu/~rmk6217/rit18_data.mat';
downloadHamlinBeachMSIData(url,imageDir);
```

Inspect Training Data

Load the data set into the workspace.

```
load(fullfile(imageDir,'rit18_data','rit18_data.mat'));
```

Examine the structure of the data.

```
whos train_data val_data test_data
```

```
  Name            Size                         Bytes  Class     Attributes

  test_data       7x12446x7654            1333663576  uint16
  train_data      7x9393x5642              741934284  uint16
  val_data        7x8833x6918              855493716  uint16
```

The multispectral image data is arranged as *numChannels*-by-*width*-by-*height* arrays. However, in MATLAB®, multichannel images are arranged as *width*-by-*height*-by-*numChannels* arrays. To reshape the data so that the channels are in the third dimension, use the helper function, `switchChannelsToThirdPlane`. This function is attached to the example as a supporting file.

```
train_data = switchChannelsToThirdPlane(train_data);
val_data   = switchChannelsToThirdPlane(val_data);
test_data  = switchChannelsToThirdPlane(test_data);
```

Confirm that the data has the correct structure.

```
whos train_data val_data test_data
```

```
  Name               Size                         Bytes  Class     Attributes

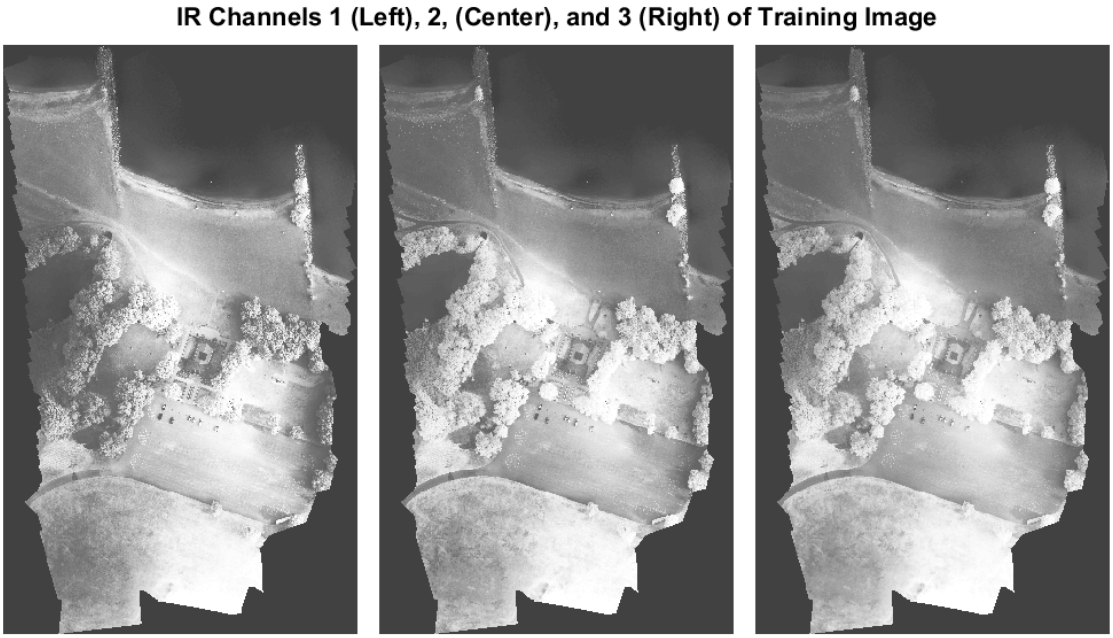
  test_data       12446x7654x7            1333663576  uint16
  train_data       9393x5642x7             741934284  uint16
  val_data         8833x6918x7             855493716  uint16
```

The RGB color channels are the 3rd, 2nd, and 1st image channels. Display the color component of the training, validation, and test images as a montage. To make the images appear brighter on the screen, equalize their histograms by using the `histeq` (Image Processing Toolbox) function.

```
figure
montage(...
    {histeq(train_data(:,:,[3 2 1])), ...
    histeq(val_data(:,:,[3 2 1])), ...
    histeq(test_data(:,:,[3 2 1]))}, ...
    'BorderSize',10,'BackgroundColor','white')
title('RGB Component of Training Image (Left), Validation Image (Center), and Test Image (Right)
```

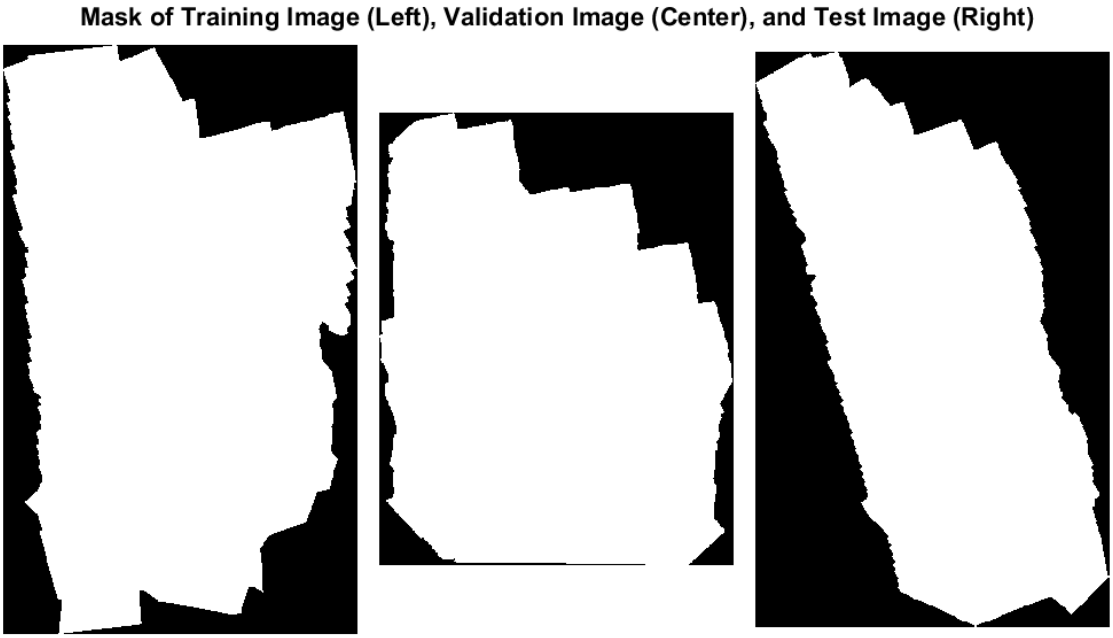
Display the last three histogram-equalized channels of the training data as a montage. These channels correspond to the near-infrared bands and highlight different components of the image based on their heat signatures. For example, the trees near the center of the second channel image show more detail than the trees in the other two channels.

```
figure
montage(...
    {histeq(train_data(:,:,4)), ...
    histeq(train_data(:,:,5)), ...
    histeq(train_data(:,:,6))}, ...
    'BorderSize',10,'BackgroundColor','white')
title('IR Channels 1 (Left), 2, (Center), and 3 (Right) of Training Image')
```



Channel 7 is a mask that indicates the valid segmentation region. Display the mask for the training, validation, and test images.

```
figure
montage(...
    {train_data(:,:,7), ...
    val_data(:,:,7), ...
    test_data(:,:,7)}, ...
    'BorderSize',10,'BackgroundColor','white')
title('Mask of Training Image (Left), Validation Image (Center), and Test Image (Right)')
```



The labeled images contain the ground truth data for the segmentation, with each pixel assigned to one of the 18 classes. Get a list of the classes with their corresponding IDs.

```
disp(classes)
```

```

Save the training data as a MAT file and the training labels as a PNG file.

```
save('train_data.mat','train_data');
imwrite(train_labels,'train_labels.png');
```

Create Random Patch Extraction Datastore for Training

Use a random patch extraction datastore to feed the training data to the network. This datastore extracts multiple corresponding random patches from an image datastore and pixel label datastore that contain ground truth images and pixel label data. Patching is a common technique to prevent running out of memory for large images and to effectively increase the amount of available training data.

Begin by storing the training images from `'train_data.mat'` in an `imageDatastore`. Because the MAT file format is a nonstandard image format, you must use a MAT file reader to enable reading the image data. You can use the helper MAT file reader, `matReader`, that extracts the first six channels from the training data and omits the last channel containing the mask. This function is attached to the example as a supporting file.

```
imds = imageDatastore('train_data.mat','FileExtensions','.mat','ReadFcn',@matReader);
```

Create a `pixelLabelDatastore` (Computer Vision Toolbox) to store the label patches containing the 18 labeled regions.

```
pixelLabelIds = 1:18;
pxds = pixelLabelDatastore('train_labels.png',classNames,pixelLabelIds);
```

Create a `randomPatchExtractionDatastore` (Image Processing Toolbox) from the image datastore and the pixel label datastore. Each mini-batch contains 16 patches of size 256-by-256 pixels. One thousand mini-batches are extracted at each iteration of the epoch.

```
dsTrain = randomPatchExtractionDatastore(imds,pxds,[256,256],'PatchesPerImage',16000);
```

The random patch extraction datastore `dsTrain` provides mini-batches of data to the network at each iteration of the epoch. Preview the datastore to explore the data.

```
inputBatch = preview(dsTrain);
disp(inputBatch)
```

```
        InputImage         ResponsePixelLabelImage

Create U-Net Network Layers

This example uses a variation of the U-Net network. In U-Net, the initial series of convolutional layers are interspersed with max pooling layers, successively decreasing the resolution of the input image. These layers are followed by a series of convolutional layers interspersed with upsampling operators, successively increasing the resolution of the input image [2 on page 8-0]. The name U-Net comes from the fact that the network can be drawn with a symmetric shape like the letter U.

This example modifies the U-Net to use zero-padding in the convolutions, so that the input and the output to the convolutions have the same size. Use the helper function, `createUnet`, to create a U-Net with a few preselected hyperparameters. This function is attached to the example as a supporting file.

```
inputTileSize = [256,256,6];
lgraph = createUnet(inputTileSize);
disp(lgraph.Layers)
```

```

```

Select Training Options

Train the network using stochastic gradient descent with momentum (SGDM) optimization. Specify the hyperparameter settings for SGDM by using the `trainingOptions` function.

Training a deep network is time-consuming. Accelerate the training by specifying a high learning rate. However, this can cause the gradients of the network to explode or grow uncontrollably, preventing the network from training successfully. To keep the gradients in a meaningful range, enable gradient clipping by specifying `'GradientThreshold'` as `0.05`, and specify `'GradientThresholdMethod'` to use the L2-norm of the gradients.

```
initialLearningRate = 0.05;
maxEpochs = 150;
minibatchSize = 16;
l2reg = 0.0001;

options = trainingOptions('sgdm',...
    'InitialLearnRate',initialLearningRate, ...
    'Momentum',0.9,...
    'L2Regularization',l2reg,...
    'MaxEpochs',maxEpochs,...
    'MiniBatchSize',minibatchSize,...
    'LearnRateSchedule','piecewise',...
    'Shuffle','every-epoch',...
    'GradientThresholdMethod','l2norm',...
    'GradientThreshold',0.05, ...
    'Plots','training-progress', ...
    'VerboseFrequency',20);
```

Train the Network

By default, the example downloads a pretrained version of U-Net for this dataset using the `downloadTrainedUnet` helper function. This function is attached to the example as a supporting file. The pretrained network enables you to run the entire example without having to wait for training to complete.

To train the network, set the `doTraining` variable in the following code to `true`. Train the model by using the `trainNetwork` function.

Train on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a CUDA® enabled NVIDIA® GPU. For more information, see “GPU Support by Release” (Parallel Computing Toolbox). Training takes about 20 hours on an NVIDIA Titan X.

```
doTraining = false;
if doTraining
```

```
    [net,info] = trainNetwork(dsTrain,lgraph,options);
    modelDateTime = string(datetime('now','Format',"yyyy-MM-dd-HH-mm-ss"));
    save(strcat("multispectralUnet-",modelDateTime,"-Epoch-",num2str(maxEpochs),".mat"),'net');

else
    trainedUnet_url = 'https://www.mathworks.com/supportfiles/vision/data/multispectralUnet.mat';
    downloadTrainedUnet(trainedUnet_url,imageDir);
    load(fullfile(imageDir,'trainedUnet','multispectralUnet.mat'));
end
```

You can now use the U-Net to semantically segment the multispectral image.

Predict Results on Test Data

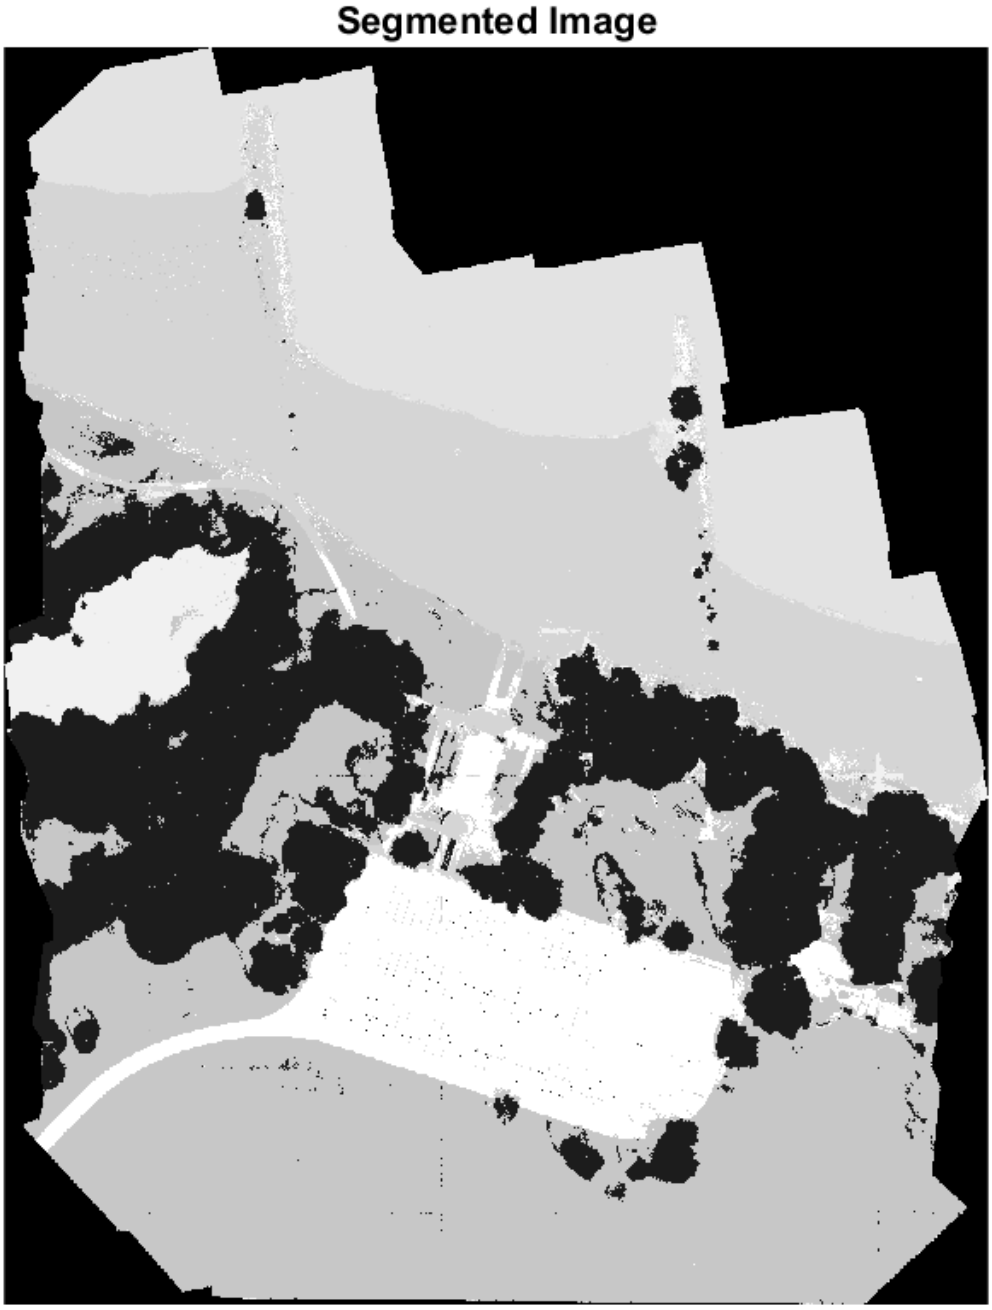
To perform the forward pass on the trained network, use the helper function, `segmentImage`, with the validation data set. This function is attached to the example as a supporting file. `segmentImage` performs segmentation on image patches using the `semanticseg` (Computer Vision Toolbox) function.

```
predictPatchSize = [1024 1024];
segmentedImage = segmentImage(val_data,net,predictPatchSize);
```

To extract only the valid portion of the segmentation, multiply the segmented image by the mask channel of the validation data.

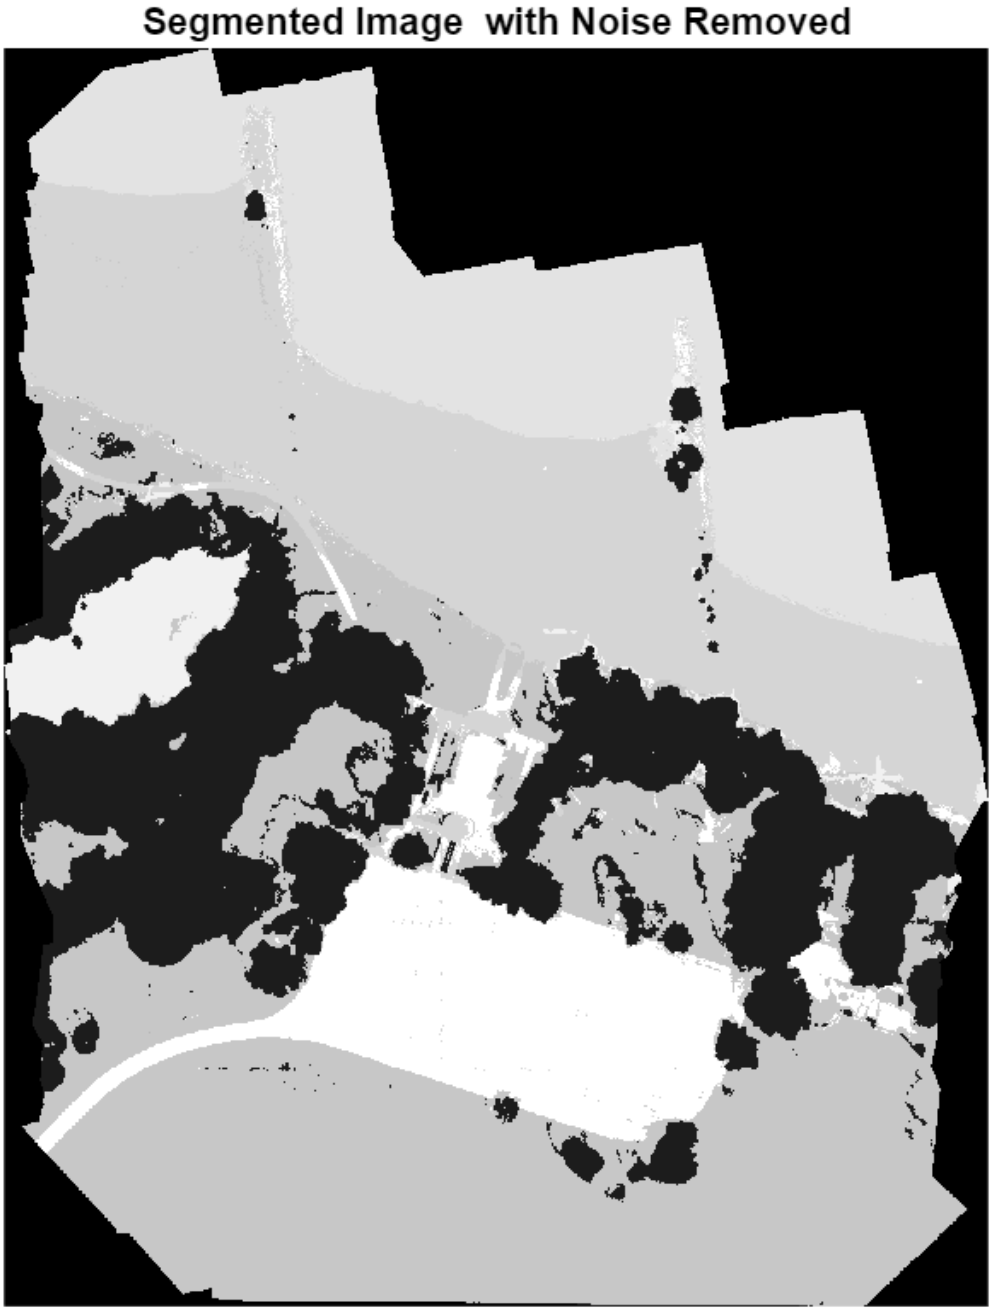
```
segmentedImage = uint8(val_data(:,:,7)~=0) .* segmentedImage;

figure
imshow(segmentedImage,[])
title('Segmented Image')
```



The output of semantic segmentation is noisy. Perform post image processing to remove noise and stray pixels. Use the `medfilt2` (Image Processing Toolbox) function to remove salt-and-pepper noise from the segmentation. Visualize the segmented image with the noise removed.

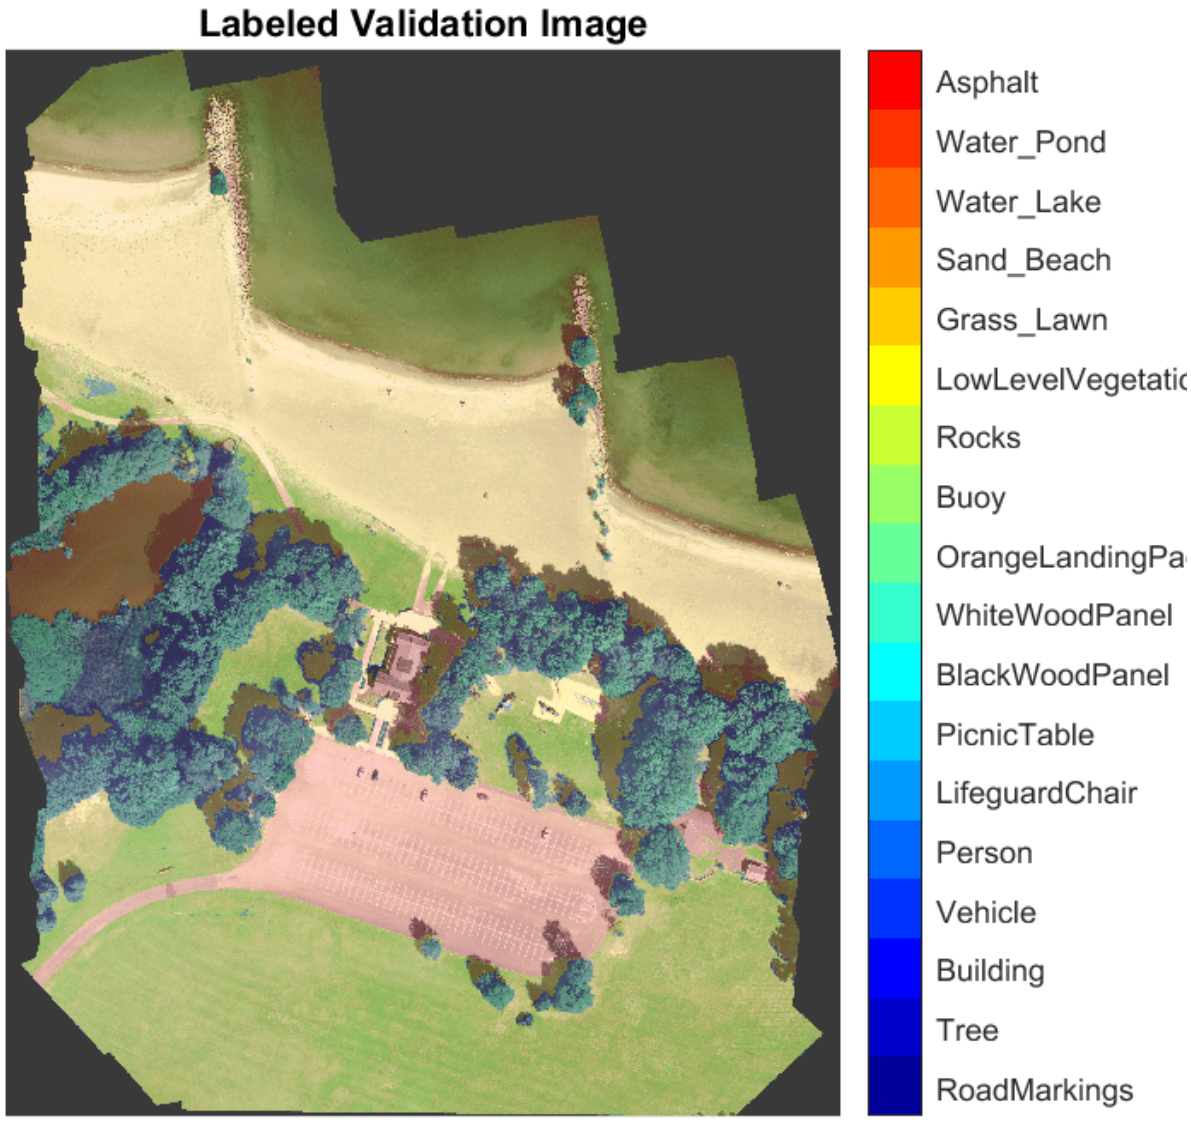
```
segmentedImage = medfilt2(segmentedImage,[7,7]);
imshow(segmentedImage,[]);
title('Segmented Image  with Noise Removed')
```



Overlay the segmented image on the histogram-equalized RGB validation image.

```
B = labeloverlay(histeq(val_data(:,:,[3 2 1])),segmentedImage,'Transparency',0.8,'Colormap',cmap)

figure
imshow(B)
title('Labeled Validation Image')
colorbar('TickLabels',cellstr(classNames),'Ticks',ticks,'TickLength',0,'TickLabelInterpreter','no
colormap(cmap)
```



Save the segmented image and ground truth labels as PNG files. These will be used to compute accuracy metrics.

```
imwrite(segmentedImage,'results.png');
imwrite(val_labels,'gtruth.png');
```

Quantify Segmentation Accuracy

Create a `pixelLabelDatastore` (Computer Vision Toolbox) for the segmentation results and the ground truth labels.

```
pxdsResults = pixelLabelDatastore('results.png',classNames,pixelLabelIds);
pxdsTruth = pixelLabelDatastore('gtruth.png',classNames,pixelLabelIds);
```

Measure the global accuracy of the semantic segmentation by using the `evaluateSemanticSegmentation` (Computer Vision Toolbox) function.

```
ssm = evaluateSemanticSegmentation(pxdsResults,pxdsTruth,'Metrics','global-accuracy');
```

```
Evaluating semantic segmentation results
----------------------------------------
* Selected metrics: global accuracy.
* Processed 1 images.
* Finalizing... Done.
* Data set metrics:

    GlobalAccuracy
    ______________

       0.90698
```

The global accuracy score indicates that just over 90% of the pixels are classified correctly.

Calculate Extent of Vegetation Cover

The final goal of this example is to calculate the extent of vegetation cover in the multispectral image.

Find the number of pixels labeled vegetation. The label IDs 2 ("Trees"), 13 ("LowLevelVegetation"), and 14 ("Grass_Lawn") are the vegetation classes. Also find the total number of valid pixels by summing the pixels in the ROI of the mask image.

```
vegetationClassIds = uint8([2,13,14]);
vegetationPixels = ismember(segmentedImage(:),vegetationClassIds);
validPixels = (segmentedImage~=0);

numVegetationPixels = sum(vegetationPixels(:));
numValidPixels = sum(validPixels(:));
```

Calculate the percentage of vegetation cover by dividing the number of vegetation pixels by the number of valid pixels.

```
percentVegetationCover = (numVegetationPixels/numValidPixels)*100;
fprintf('The percentage of vegetation cover is %3.2f%%.',percentVegetationCover);
```

```
The percentage of vegetation cover is 51.72%.
```

3-D Brain Tumor Segmentation Using Deep Learning

This example shows how to train a 3-D U-Net neural network and perform semantic segmentation of brain tumors from 3-D medical images.

Semantic segmentation involves labeling each pixel in an image or voxel of a 3-D volume with a class. This example illustrates the use of deep learning methods to perform binary semantic segmentation of brain tumors in magnetic resonance imaging (MRI) scans. In this binary segmentation, each pixel is labeled as tumor or background.

This example performs brain tumor segmentation using a 3-D U-Net architecture [1 on page 8-0]. U-Net is a fast, efficient and simple network that has become popular in the semantic segmentation domain.

One challenge of medical image segmentation is the amount of memory needed to store and process 3-D volumes. Training a network on the full input volume is impractical due to GPU resource constraints. This example solves the problem by training the network on image patches. The example uses an overlap-tile strategy to stitch test patches into a complete segmented test volume. The example avoids border artifacts by using the valid part of the convolution in the neural network [5 on page 8-0].

A second challenge of medical image segmentation is class imbalance in the data that hampers training when using conventional cross entropy loss. This example solves the problem by using a weighted multiclass Dice loss function [4 on page 8-0]. Weighting the classes helps to counter the influence of larger regions on the Dice score, making it easier for the network to learn how to segment smaller regions.

Download Training, Validation, and Test Data

This example uses the BraTS data set [2 on page 8-0]. The BraTS data set contains MRI scans of brain tumors, namely gliomas, which are the most common primary brain malignancies. The size of the data file is ~7 GB. If you do not want to download the BraTS data set, then go directly to the Download Pretrained Network and Sample Test Set on page 8-0 section in this example.

Create a directory to store the BraTS data set.

```
imageDir = fullfile(tempdir,'BraTS');
if ~exist(imageDir,'dir')
    mkdir(imageDir);
end
```

To download the BraTS data, go to the Medical Segmentation Decathlon website and click the "Download Data" link. Download the "Task01_BrainTumour.tar" file [3 on page 8-0]. Unzip the TAR file into the directory specified by the `imageDir` variable. When unzipped successfully, `imageDir` will contain a directory named `Task01_BrainTumour` that has three subdirectories: `imagesTr`, `imagesTs`, and `labelsTr`.

The data set contains 750 4-D volumes, each representing a stack of 3-D images. Each 4-D volume has size 240-by-240-by-155-by-4, where the first three dimensions correspond to height, width, and depth of a 3-D volumetric image. The fourth dimension corresponds to different scan modalities. The data set is divided into 484 training volumes with voxel labels and 266 test volumes, The test volumes do not have labels so this example does not use the test data. Instead, the example splits the 484 training volumes into three independent sets that are used for training, validation, and testing.

Preprocess Training and Validation Data

To train the 3-D U-Net network more efficiently, preprocess the MRI data using the helper function `preprocessBraTSdataset`. This function is attached to the example as a supporting file.

The helper function performs these operations:

- Crop the data to a region containing primarily the brain and tumor. Cropping the data reduces the size of data while retaining the most critical part of each MRI volume and its corresponding labels.
- Normalize each modality of each volume independently by subtracting the mean and dividing by the standard deviation of the cropped brain region.
- Split the 484 training volumes into 400 training, 29 validation, and 55 test sets.

Preprocessing the data can take about 30 minutes to complete.

```
sourceDataLoc = [imageDir filesep 'Task01_BrainTumour'];
preprocessDataLoc = fullfile(tempdir,'BraTS','preprocessedDataset');
preprocessBraTSdataset(preprocessDataLoc,sourceDataLoc);
```

Create Random Patch Extraction Datastore for Training and Validation

Use a random patch extraction datastore to feed the training data to the network and to validate the training progress. This datastore extracts random patches from ground truth images and corresponding pixel label data. Patching is a common technique to prevent running out of memory when training with arbitrarily large volumes.

Create an `imageDatastore` to store the 3-D image data. Because the MAT-file format is a nonstandard image format, you must use a MAT-file reader to enable reading the image data. You can use the helper MAT-file reader, `matRead`. This function is attached to the example as a supporting file.

```
volReader = @(x) matRead(x);
volLoc = fullfile(preprocessDataLoc,'imagesTr');
volds = imageDatastore(volLoc, ...
    'FileExtensions','.mat','ReadFcn',volReader);
```

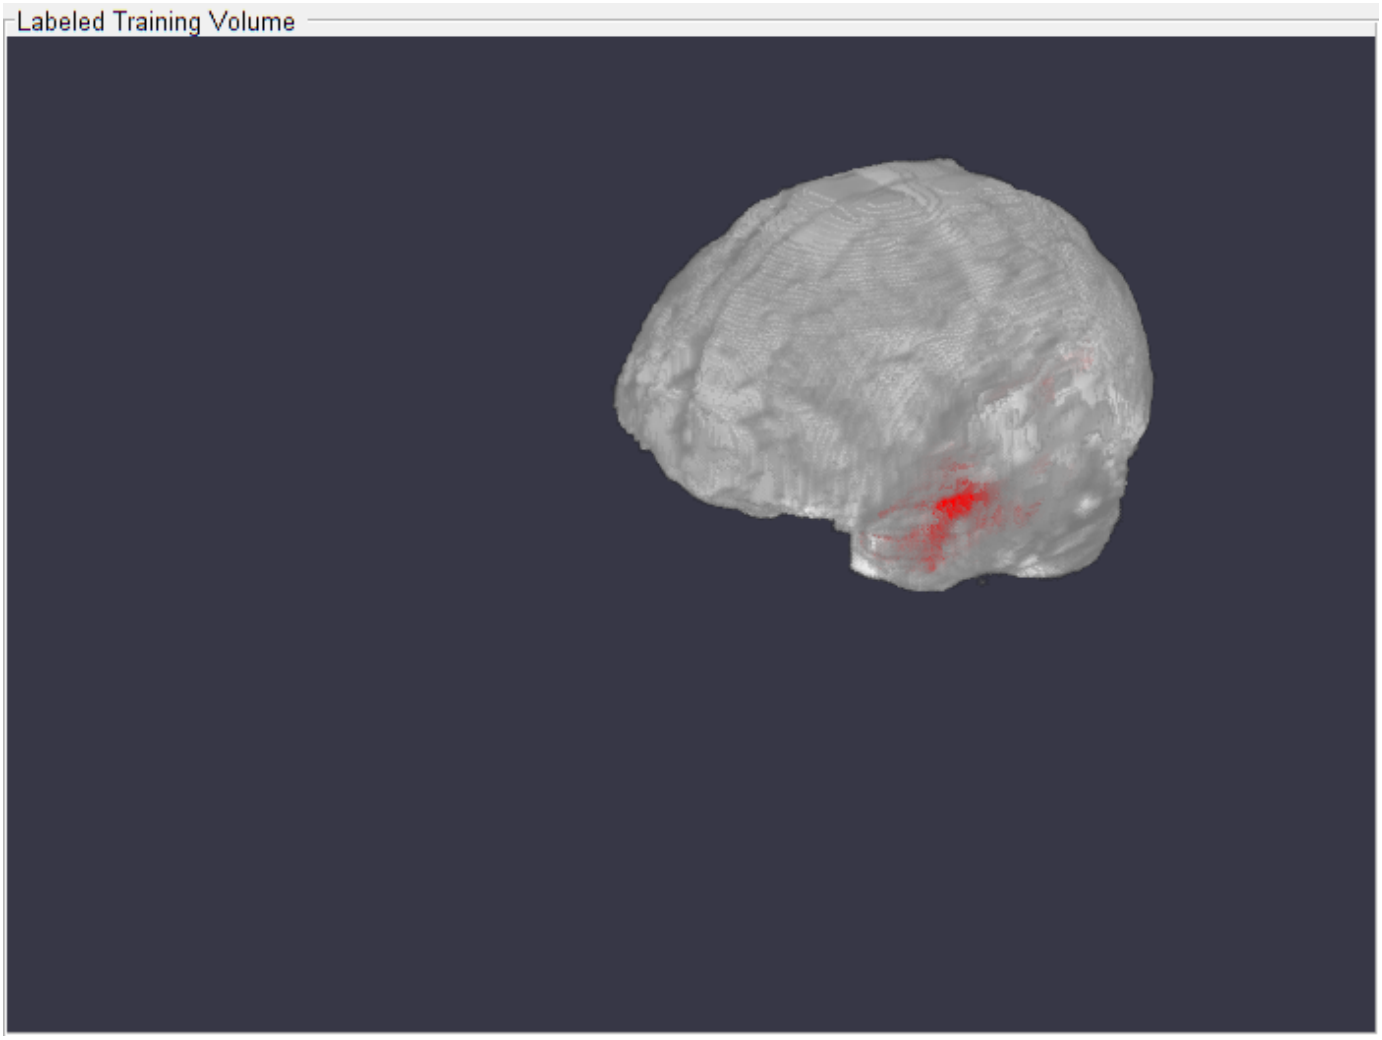
Create a `pixelLabelDatastore` (Computer Vision Toolbox) to store the labels.

```
lblLoc = fullfile(preprocessDataLoc,'labelsTr');
classNames = ["background","tumor"];
pixelLabelID = [0 1];
pxds = pixelLabelDatastore(lblLoc,classNames,pixelLabelID, ...
    'FileExtensions','.mat','ReadFcn',volReader);
```

Preview one image volume and label. Display the labeled volume using the `labelvolshow` (Image Processing Toolbox) function. Make the background fully transparent by setting the visibility of the background label (`1`) to `0`.

```
volume = preview(volds);
label = preview(pxds);

viewPnl = uipanel(figure,'Title','Labeled Training Volume');
hPred = labelvolshow(label,volume(:,:,:,1),'Parent',viewPnl, ...
    'LabelColor',[0 0 0;1 0 0]);
hPred.LabelVisibility(1) = 0;
```



Create a `randomPatchExtractionDatastore` (Image Processing Toolbox) that contains the training image and pixel label data. Specify a patch size of 132-by-132-by-132 voxels. Specify `'PatchesPerImage'` to extract 16 randomly positioned patches from each pair of volumes and labels during training. Specify a mini-batch size of 8.

```
patchSize = [132 132 132];
patchPerImage = 16;
miniBatchSize = 8;
patchds = randomPatchExtractionDatastore(volds,pxds,patchSize, ...
    'PatchesPerImage',patchPerImage);
patchds.MiniBatchSize = miniBatchSize;
```

Follow the same steps to create a `randomPatchExtractionDatastore` that contains the validation image and pixel label data. You can use validation data to evaluate whether the network is continuously learning, underfitting, or overfitting as time progresses.

```
volLocVal = fullfile(preprocessDataLoc,'imagesVal');
voldsVal = imageDatastore(volLocVal, ...
    'FileExtensions','.mat','ReadFcn',volReader);
```

```
lblLocVal = fullfile(preprocessDataLoc,'labelsVal');
pxdsVal = pixelLabelDatastore(lblLocVal,classNames,pixelLabelID, ...
    'FileExtensions','.mat','ReadFcn',volReader);

dsVal = randomPatchExtractionDatastore(voldsVal,pxdsVal,patchSize, ...
    'PatchesPerImage',patchPerImage);
dsVal.MiniBatchSize = miniBatchSize;
```

Set Up 3-D U-Net Layers

This example uses the 3-D U-Net network [1 on page 8-0]. In U-Net, the initial series of convolutional layers are interspersed with max pooling layers, successively decreasing the resolution of the input image. These layers are followed by a series of convolutional layers interspersed with upsampling operators, successively increasing the resolution of the input image. A batch normalization layer is introduced before each ReLU layer. The name U-Net comes from the fact that the network can be drawn with a symmetric shape like the letter U.

Create a default 3-D U-Net network by using the `unetLayers` (Computer Vision Toolbox) function. Specify two class segmentation. Also specify valid convolution padding to avoid border artifacts when using the overlap-tile strategy for prediction of the test volumes.

```
numChannels = 4;
inputPatchSize = [patchSize numChannels];
numClasses = 2;
[lgraph,outPatchSize] = unet3dLayers(inputPatchSize,numClasses,'ConvolutionPadding','valid');
```

Augment the training and validation data by using the `transform` function with custom preprocessing operations specified by the helper function `augmentAndCrop3dPatch`. This function is attached to the example as a supporting file.

The `augmentAndCrop3dPatch` function performs these operations:

1. Randomly rotate and reflect training data to make the training more robust. The function does not rotate or reflect validation data.
2. Crop response patches to the output size of the network, 44-by-44-by-44 voxels.

```
dataSource = 'Training';
dsTrain = transform(patchds,@(patchIn)augmentAndCrop3dPatch(patchIn,outPatchSize,dataSource));

dataSource = 'Validation';
dsVal = transform(dsVal,@(patchIn)augmentAndCrop3dPatch(patchIn,outPatchSize,dataSource));
```

To better segment smaller tumor regions and reduce the influence of larger background regions, this example uses a `dicePixelClassificationLayer` (Computer Vision Toolbox). Replace the pixel classification layer with the Dice pixel classification layer.

```
outputLayer = dicePixelClassificationLayer('Name','Output');
lgraph = replaceLayer(lgraph,'Segmentation-Layer',outputLayer);
```

The data has already been normalized in the Preprocess Training and Validation Data on page 8-0 section of this example. Data normalization in the `image3dInputLayer` is unnecessary, so replace the input layer with an input layer that does not have data normalization.

```
inputLayer = image3dInputLayer(inputPatchSize,'Normalization','none','Name','ImageInputLayer');
lgraph = replaceLayer(lgraph,'ImageInputLayer',inputLayer);
```

Alternatively, you can modify the 3-D U-Net network by using Deep Network Designer App from Deep Learning Toolbox™.

Plot the graph of the updated 3-D U-Net network.

```
analyzeNetwork(lgraph)
```

Specify Training Options

Train the network using the `adam` optimization solver. Specify the hyperparameter settings using the `trainingOptions` function. The initial learning rate is set to 5e-4 and gradually decreases over the span of training. You can experiment with the `MiniBatchSize` property based on your GPU memory. To maximize GPU memory utilization, favor large input patches over a large batch size. Note that batch normalization layers are less effective for smaller values of `MiniBatchSize`. Tune the initial learning rate based on the `MiniBatchSize`.

```
options = trainingOptions('adam', ...
    'MaxEpochs',50, ...
    'InitialLearnRate',5e-4, ...
    'LearnRateSchedule','piecewise', ...
    'LearnRateDropPeriod',5, ...
    'LearnRateDropFactor',0.95, ...
    'ValidationData',dsVal, ...
    'ValidationFrequency',400, ...
    'Plots','training-progress', ...
    'Verbose',false, ...
    'MiniBatchSize',miniBatchSize);
```

Download Pretrained Network and Sample Test Set

Download a pretrained version of 3-D U-Net and five sample test volumes and their corresponding labels from the BraTS data set [3 on page 8-0]. The pretrained model and sample data enable you to perform segmentation on test data without downloading the full data set or waiting for the network to train.

```
trained3DUnet_url = 'https://www.mathworks.com/supportfiles/vision/data/brainTumor3DUNetValid.ma
sampleData_url = 'https://www.mathworks.com/supportfiles/vision/data/sampleBraTSTestSetValid.tar

imageDir = fullfile(tempdir,'BraTS');
if ~exist(imageDir,'dir')
    mkdir(imageDir);
end

downloadTrained3DUnetSampleData(trained3DUnet_url,sampleData_url,imageDir);
```

Train Network

By default, the example loads a pretrained 3-D U-Net network. The pretrained network enables you to run the entire example without waiting for training to complete.

To train the network, set the `doTraining` variable in the following code to `true`. Train the model using the `trainNetwork` function.

Train on a GPU if one is available. Using a GPU requires Parallel Computing Toolbox™ and a CUDA® enabled NVIDIA® GPU. For more information, see “GPU Support by Release” (Parallel Computing Toolbox). Training takes about 30 hours on a multi-GPU system with 4 NVIDIA™ Titan Xp GPUs and can take even longer depending on your GPU hardware.

```
doTraining = false;
if doTraining
    modelDateTime = string(datetime('now','Format',"yyyy-MM-dd-HH-mm-ss"));
    [net,info] = trainNetwork(dsTrain,lgraph,options);
    save(strcat("trained3DUNet-",modelDateTime,"-Epoch-",num2str(options.MaxEpochs),".mat"),'net
else
    inputPatchSize = [132 132 132 4];
    outPatchSize = [44 44 44 2];
    load(fullfile(imageDir,'trained3DUNet','brainTumor3DUNetValid.mat'));
end
```

Perform Segmentation of Test Data

A GPU is highly recommended for performing semantic segmentation of the image volumes (requires Parallel Computing Toolbox™).

Select the source of test data that contains ground truth volumes and labels for testing. If you keep the `useFullTestSet` variable in the following code as `false`, then the example uses five volumes for testing. If you set the `useFullTestSet` variable to `true`, then the example uses 55 test images selected from the full data set.

```
useFullTestSet = false;
if useFullTestSet
    volLocTest = fullfile(preprocessDataLoc,'imagesTest');
    lblLocTest = fullfile(preprocessDataLoc,'labelsTest');
else
    volLocTest = fullfile(imageDir,'sampleBraTSTestSetValid','imagesTest');
    lblLocTest = fullfile(imageDir,'sampleBraTSTestSetValid','labelsTest');
    classNames = ["background","tumor"];
    pixelLabelID = [0 1];
end
```

The `voldsTest` variable stores the ground truth test images. The `pxdsTest` variable stores the ground truth labels.

```
volReader = @(x) matRead(x);
voldsTest = imageDatastore(volLocTest, ...
    'FileExtensions','.mat','ReadFcn',volReader);
pxdsTest = pixelLabelDatastore(lblLocTest,classNames,pixelLabelID, ...
    'FileExtensions','.mat','ReadFcn',volReader);
```

Use the overlap-tile strategy to predict the labels for each test volume. Each test volume is padded to make the input size a multiple of the output size of the network and compensates for the effects of valid convolution. The overlap-tile algorithm selects overlapping patches, predicts the labels for each patch by using the `semanticseg` (Computer Vision Toolbox) function, and then recombines the patches.

```
id = 1;
while hasdata(voldsTest)
    disp(['Processing test volume ' num2str(id)]);

    tempGroundTruth = read(pxdsTest);
    groundTruthLabels{id} = tempGroundTruth{1};
    vol{id} = read(voldsTest);

    % Use reflection padding for the test image.
    % Avoid padding of different modalities.
```

```
    volSize = size(vol{id},(1:3));
    padSizePre  = (inputPatchSize(1:3)-outPatchSize(1:3))/2;
    padSizePost = (inputPatchSize(1:3)-outPatchSize(1:3))/2 + (outPatchSize(1:3)-mod(volSize,outP
    volPaddedPre = padarray(vol{id},padSizePre,'symmetric','pre');
    volPadded = padarray(volPaddedPre,padSizePost,'symmetric','post');
    [heightPad,widthPad,depthPad,~] = size(volPadded);
    [height,width,depth,~] = size(vol{id});

    tempSeg = categorical(zeros([height,width,depth],'uint8'),[0;1],classNames);

    % Overlap-tile strategy for segmentation of volumes.
    for k = 1:outPatchSize(3):depthPad-inputPatchSize(3)+1
        for j = 1:outPatchSize(2):widthPad-inputPatchSize(2)+1
            for i = 1:outPatchSize(1):heightPad-inputPatchSize(1)+1
                patch = volPadded( i:i+inputPatchSize(1)-1,...
                    j:j+inputPatchSize(2)-1,...
                    k:k+inputPatchSize(3)-1,:);
                patchSeg = semanticseg(patch,net);
                tempSeg(i:i+outPatchSize(1)-1, ...
                    j:j+outPatchSize(2)-1, ...
                    k:k+outPatchSize(3)-1) = patchSeg;
            end
        end
    end

    % Crop out the extra padded region.
    tempSeg = tempSeg(1:height,1:width,1:depth);

    % Save the predicted volume result.
    predictedLabels{id} = tempSeg;
    id=id+1;
end
```

Compare Ground Truth Against Network Prediction

Select one of the test images to evaluate the accuracy of the semantic segmentation. Extract the first modality from the 4-D volumetric data and store this 3-D volume in the variable `vol3d`.

```
volId = 1;
vol3d = vol{volId}(:,:,:,1);
```

Display in a montage the center slice of the ground truth and predicted labels along the depth direction.

```
zID = size(vol3d,3)/2;
zSliceGT = labeloverlay(vol3d(:,:,zID),groundTruthLabels{volId}(:,:,zID));
zSlicePred = labeloverlay(vol3d(:,:,zID),predictedLabels{volId}(:,:,zID));

figure
montage({zSliceGT,zSlicePred},'Size',[1 2],'BorderSize',5)
title('Labeled Ground Truth (Left) vs. Network Prediction (Right)')
```

Display the ground-truth labeled volume using the `labelvolshow` (Image Processing Toolbox) function. Make the background fully transparent by setting the visibility of the background label (`1`) to `0`. Because the tumor is inside the brain tissue, make some of the brain voxels transparent, so that the tumor is visible. To make some brain voxels transparent, specify the volume threshold as a number in the range [0, 1]. All normalized volume intensities below this threshold value are fully

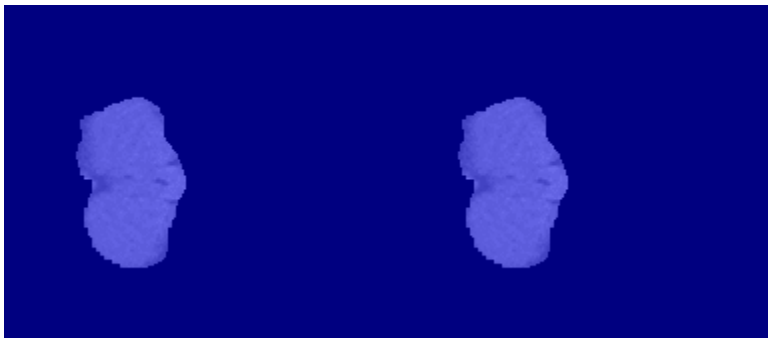
transparent. This example sets the volume threshold as less than 1 so that some brain pixels remain visible, to give context to the spatial location of the tumor inside the brain.

```
viewPnlTruth = uipanel(figure,'Title','Ground-Truth Labeled Volume');
hTruth = labelvolshow(groundTruthLabels{volId},vol3d,'Parent',viewPnlTruth, ...
    'LabelColor',[0 0 0;1 0 0],'VolumeThreshold',0.68);
hTruth.LabelVisibility(1) = 0;
```

For the same volume, display the predicted labels.

```
viewPnlPred = uipanel(figure,'Title','Predicted Labeled Volume');
hPred = labelvolshow(predictedLabels{volId},vol3d,'Parent',viewPnlPred, ...
    'LabelColor',[0 0 0;1 0 0],'VolumeThreshold',0.68);
hPred.LabelVisibility(1) = 0;
```

This image shows the result of displaying slices sequentially across the one of the volume. The labeled ground truth is on the left and the network prediction is on the right.



Quantify Segmentation Accuracy

Measure the segmentation accuracy using the `dice` (Image Processing Toolbox) function. This function computes the Dice similarity coefficient between the predicted and ground truth segmentations.

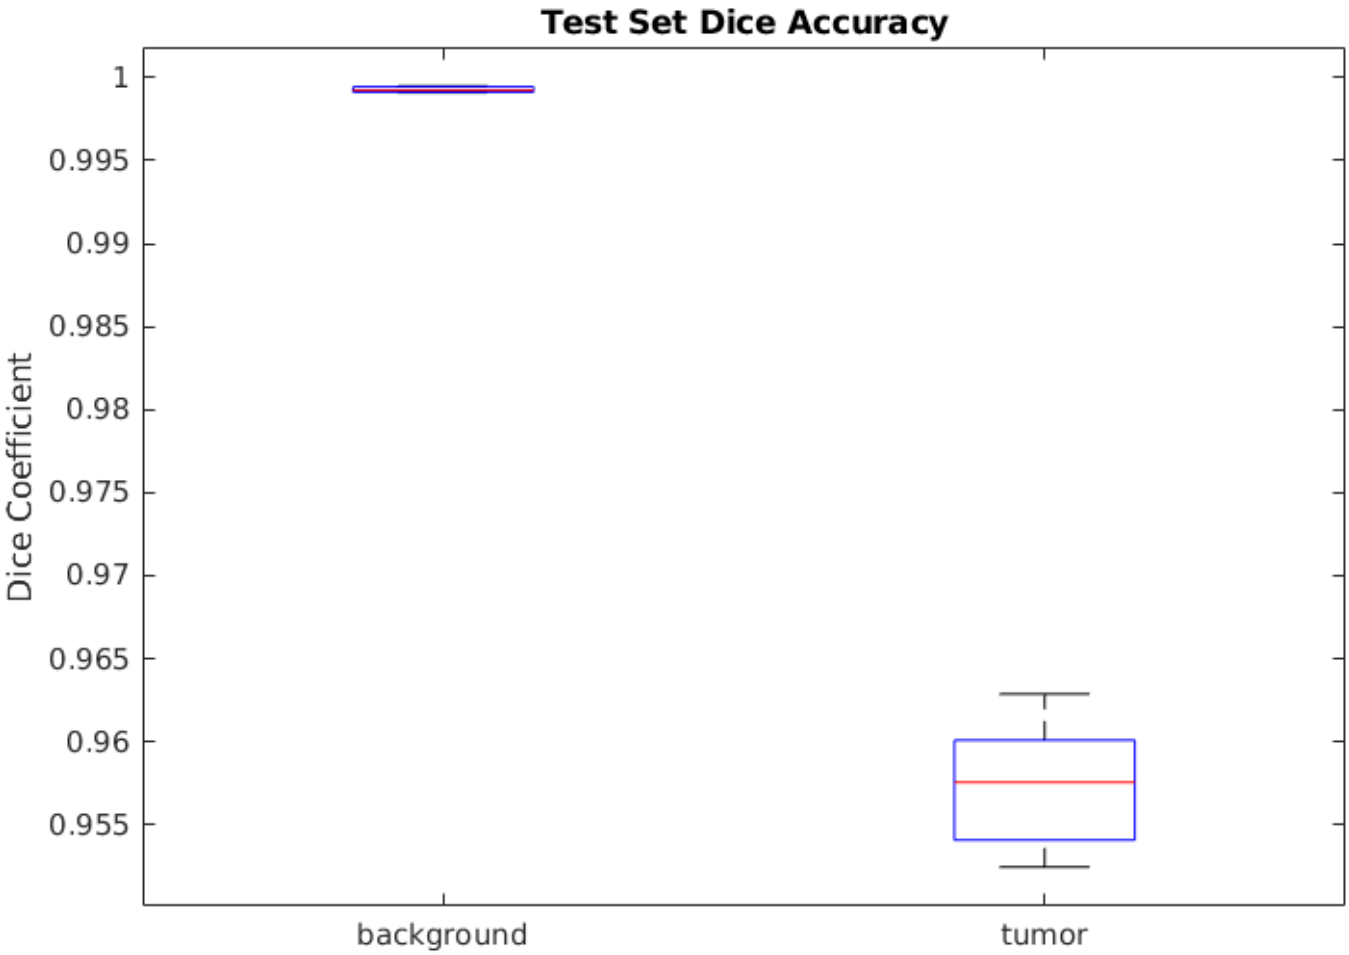
```
diceResult = zeros(length(voldsTest.Files),2);

for j = 1:length(vol)
    diceResult(j,:) = dice(groundTruthLabels{j},predictedLabels{j});
end
```

Calculate the average Dice score across the set of test volumes.

```
meanDiceBackground = mean(diceResult(:,1));
disp(['Average Dice score of background across ',num2str(j), ...
    ' test volumes = ',num2str(meanDiceBackground)])
meanDiceTumor = mean(diceResult(:,2));
disp(['Average Dice score of tumor across ',num2str(j), ...
    ' test volumes = ',num2str(meanDiceTumor)])
```

The figure shows a `boxplot` (Statistics and Machine Learning Toolbox) that visualizes statistics about the Dice scores across the set of five sample test volumes. The red lines in the plot show the median Dice value for the classes. The upper and lower bounds of the blue box indicate the 25th and 75th percentiles, respectively. Black whiskers extend to the most extreme data points not considered outliers.



If you have Statistics and Machine Learning Toolbox™, then you can use the `boxplot` function to visualize statistics about the Dice scores across all your test volumes. To create a `boxplot`, set the `createBoxplot` variable in the following code to `true`.

```
createBoxplot = false;
if createBoxplot
    figure
    boxplot(diceResult)
    title('Test Set Dice Accuracy')
    xticklabels(classNames)
    ylabel('Dice Coefficient')
end
```

Define Custom Pixel Classification Layer with Tversky Loss

This example shows how to define and create a custom pixel classification layer that uses Tversky loss.

This layer can be used to train semantic segmentation networks. To learn more about creating custom deep learning layers, see “Define Custom Deep Learning Layers” on page 18-9.

Tversky Loss

The Tversky loss is based on the Tversky index for measuring overlap between two segmented images [1 on page 8-0]. The Tversky index TI_c between one image Y and the corresponding ground truth T is given by

$$\mathrm{TI}_c = \frac{\sum_{m=1}^{M} Y_{cm} T_{cm}}{\sum_{m=1}^{M} Y_{cm} T_{cm} + \alpha \sum_{m=1}^{M} Y_{cm} T_{\bar{c}m} + \beta \sum_{m=1}^{M} Y_{\bar{c}m} T_{cm}}$$

- c corresponds to the class and $\bar{c}$ corresponds to not being in class c.
- M is the number of elements along the first two dimensions of Y.
- α and β are weighting factors that control the contribution that false positives and false negatives for each class make to the loss.

The loss L over the number of classes C is given by

$$L = \sum_{c=1}^{C} 1 - \mathrm{TI}_c$$

Classification Layer Template

Copy the classification layer template into a new file in MATLAB®. This template outlines the structure of a classification layer and includes the functions that define the layer behavior. The rest of the example shows how to complete the `tverskyPixelClassificationLayer`.

```
classdef tverskyPixelClassificationLayer < nnet.layer.ClassificationLayer

    properties
        % Optional properties
    end

    methods

         function loss = forwardLoss(layer, Y, T)
             % Layer forward loss function goes here
         end

     end
end
```

Declare Layer Properties

By default, custom output layers have the following properties:

- `Name` – Layer name, specified as a character vector or a string scalar. To include this layer in a layer graph, you must specify a nonempty unique layer name. If you train a series network with this layer and `Name` is set to `''`, then the software automatically assigns a name at training time.
- `Description` – One-line description of the layer, specified as a character vector or a string scalar. This description appears when the layer is displayed in a `Layer` array. If you do not specify a layer description, then the software displays the layer class name.
- `Type` – Type of the layer, specified as a character vector or a string scalar. The value of `Type` appears when the layer is displayed in a `Layer` array. If you do not specify a layer type, then the software displays `'Classification layer'` or `'Regression layer'`.

Custom classification layers also have the following property:

- `Classes` – Classes of the output layer, specified as a categorical vector, string array, cell array of character vectors, or `'auto'`. If `Classes` is `'auto'`, then the software automatically sets the classes at training time. If you specify a string array or cell array of character vectors `str`, then the software sets the classes of the output layer to `categorical(str,str)`. The default value is `'auto'`.

If the layer has no other properties, then you can omit the `properties` section.

The Tversky loss requires a small constant value to prevent division by zero. Specify the property, `Epsilon`, to hold this value. It also requires two variable properties `Alpha` and `Beta` that control the weighting of false positives and false negatives, respectively.

```
classdef tverskyPixelClassificationLayer < nnet.layer.ClassificationLayer

    properties(Constant)
       % Small constant to prevent division by zero.
       Epsilon = 1e-8;
    end

    properties
       % Default weighting coefficients for false positives and false negatives
       Alpha = 0.5;
       Beta = 0.5;
    end

    ...
end
```

Create Constructor Function

Create the function that constructs the layer and initializes the layer properties. Specify any variables required to create the layer as inputs to the constructor function.

Specify an optional input argument name to assign to the `Name` property at creation.

```
function layer = tverskyPixelClassificationLayer(name, alpha, beta)
    % layer =  tverskyPixelClassificationLayer(name) creates a Tversky
    % pixel classification layer with the specified name.

    % Set layer name
    layer.Name = name;

    % Set layer properties
    layer.Alpha = alpha;
```

```
    layer.Beta = beta;

    % Set layer description
    layer.Description = 'Tversky loss';
end
```

Create Forward Loss Function

Create a function named `forwardLoss` that returns the weighted cross entropy loss between the predictions made by the network and the training targets. The syntax for `forwardLoss` is `loss = forwardLoss(layer,Y,T)`, where `Y` is the output of the previous layer and `T` represents the training targets.

For semantic segmentation problems, the dimensions of `T` match the dimension of `Y`, where `Y` is a 4-D array of size `H`-by-`W`-by-`K`-by-`N`, where `K` is the number of classes, and `N` is the mini-batch size.

The size of `Y` depends on the output of the previous layer. To ensure that `Y` is the same size as `T`, you must include a layer that outputs the correct size before the output layer. For example, to ensure that `Y` is a 4-D array of prediction scores for `K` classes, you can include a fully connected layer of size `K` or a convolutional layer with `K` filters followed by a softmax layer before the output layer.

```
function loss = forwardLoss(layer, Y, T)
    % loss = forwardLoss(layer, Y, T) returns the Tversky loss between
    % the predictions Y and the training targets T.

    Pcnot = 1-Y;
    Gcnot = 1-T;
    TP = sum(sum(Y.*T,1),2);
    FP = sum(sum(Y.*Gcnot,1),2);
    FN = sum(sum(Pcnot.*T,1),2);

    numer = TP + layer.Epsilon;
    denom = TP + layer.Alpha*FP + layer.Beta*FN + layer.Epsilon;

    % Compute Tversky index
    lossTIc = 1 - numer./denom;
    lossTI = sum(lossTIc,3);

    % Return average Tversky index loss
    N = size(Y,4);
    loss = sum(lossTI)/N;

end
```

Backward Loss Function

As the `forwardLoss` function fully supports automatic differentiation, there is no need to create a function for the backward loss.

For a list of functions that support automatic differentiation, see “List of Functions with dlarray Support” on page 18-423.

Completed Layer

The completed layer is provided in `tverskyPixelClassificationLayer.m`.

```
classdef tverskyPixelClassificationLayer < nnet.layer.ClassificationLayer
    % This layer implements the Tversky loss function for training
```

```
% semantic segmentation networks.

end

methods

    function layer = tverskyPixelClassificationLayer(name, alpha, beta)
        % layer =  tverskyPixelClassificationLayer(name, alpha, beta) creates a Tversky
        % pixel classification layer with the specified name and properties alpha and beta.

        % Set layer name.
        layer.Name = name;

        layer.Alpha = alpha;
        layer.Beta = beta;

        % Set layer description.
        layer.Description = 'Tversky loss';
    end

    function loss = forwardLoss(layer, Y, T)
        % loss = forwardLoss(layer, Y, T) returns the Tversky loss between
        % the predictions Y and the training targets T.

        Pcnot = 1-Y;
        Gcnot = 1-T;
        TP = sum(sum(Y.*T,1),2);
        FP = sum(sum(Y.*Gcnot,1),2);
        FN = sum(sum(Pcnot.*T,1),2);

        numer = TP + layer.Epsilon;
        denom = TP + layer.Alpha*FP + layer.Beta*FN + layer.Epsilon;

        % Compute tversky index
        lossTIc = 1 - numer./denom;
        lossTI = sum(lossTIc,3);

        % Return average tversky index loss.
```

```
            N = size(Y,4);
            loss = sum(lossTI)/N;

        end
    end
end
```

GPU Compatibility

The MATLAB functions used in `forwardLoss` in `tverskyPixelClassificationLayer` all support `gpuArray` inputs, so the layer is GPU compatible.

Check Output Layer Validity

Create an instance of the layer.

```
layer = tverskyPixelClassificationLayer('tversky',0.7,0.3);
```

Check the validity of the layer by using `checkLayer`. Specify the valid input size to be the size of a single observation of typical input to the layer. The layer expects a H-by-W-by-K-by-N array inputs, where K is the number of classes, and N is the number of observations in the mini-batch.

```
numClasses = 2;
validInputSize = [4 4 numClasses];
checkLayer(layer,validInputSize, 'ObservationDimension',4)
```

```
Skipping GPU tests. No compatible GPU device found.

Skipping code generation compatibility tests. To check validity of the layer for code generation

Running nnet.checklayer.TestOutputLayerWithoutBackward
........
Done nnet.checklayer.TestOutputLayerWithoutBackward
__________

Test Summary:
     8 Passed, 0 Failed, 0 Incomplete, 2 Skipped.
     Time elapsed: 1.7623 seconds.
```

The test summary reports the number of passed, failed, incomplete, and skipped tests.

Use Custom Layer in Semantic Segmentation Network

Create a semantic segmentation network that uses the `tverskyPixelClassificationLayer`.

```
layers = [
    imageInputLayer([32 32 1])
    convolution2dLayer(3,64,'Padding',1)
    batchNormalizationLayer
    reluLayer
    maxPooling2dLayer(2,'Stride',2)
    convolution2dLayer(3,64,'Padding',1)
    reluLayer
    transposedConv2dLayer(4,64,'Stride',2,'Cropping',1)
    convolution2dLayer(1,2)
    softmaxLayer
    tverskyPixelClassificationLayer('tversky',0.3,0.7)];
```

Load training data for semantic segmentation using `imageDatastore` and `pixelLabelDatastore`.

```
dataSetDir = fullfile(toolboxdir('vision'),'visiondata','triangleImages');
imageDir = fullfile(dataSetDir,'trainingImages');
labelDir = fullfile(dataSetDir,'trainingLabels');

imds = imageDatastore(imageDir);

classNames = ["triangle" "background"];
labelIDs = [255 0];
pxds = pixelLabelDatastore(labelDir, classNames, labelIDs);
```

Associate the image and pixel label data by using datastore `combine`.

```
ds = combine(imds,pxds);
```

Set the training options and train the network.

```
options = trainingOptions('adam', ...
    'InitialLearnRate',1e-3, ...
    'MaxEpochs',100, ...
    'LearnRateDropFactor',5e-1, ...
    'LearnRateDropPeriod',20, ...
    'LearnRateSchedule','piecewise', ...
    'MiniBatchSize',50);

net = trainNetwork(ds,layers,options);
```

```
Training on single CPU.

Train Object Detector Using R-CNN Deep Learning

This example shows how to train an object detector using deep learning and R-CNN (Regions with Convolutional Neural Networks).

Overview

This example shows how to train an R-CNN object detector for detecting stop signs. R-CNN is an object detection framework, which uses a convolutional neural network (CNN) to classify image regions within an image [1]. Instead of classifying every region using a sliding window, the R-CNN detector only processes those regions that are likely to contain an object. This greatly reduces the computational cost incurred when running a CNN.

To illustrate how to train an R-CNN stop sign detector, this example follows the transfer learning workflow that is commonly used in deep learning applications. In transfer learning, a network trained on a large collection of images, such as ImageNet [2], is used as the starting point to solve a new classification or detection task. The advantage of using this approach is that the pretrained network has already learned a rich set of image features that are applicable to a wide range of images. This learning is transferable to the new task by fine-tuning the network. A network is fine-tuned by making small adjustments to the weights such that the feature representations learned for the original task are slightly adjusted to support the new task.

The advantage of transfer learning is that the number of images required for training and the training time are reduced. To illustrate these advantages, this example trains a stop sign detector using the transfer learning workflow. First a CNN is pretrained using the CIFAR-10 data set, which has 50,000 training images. Then this pretrained CNN is fine-tuned for stop sign detection using just 41 training images. Without pretraining the CNN, training the stop sign detector would require many more images.

Note: This example requires Computer Vision Toolbox™, Image Processing Toolbox™, Deep Learning Toolbox™, and Statistics and Machine Learning Toolbox™.

Using a CUDA-capable NVIDIA™ GPU is highly recommended for running this example. Use of a GPU requires the Parallel Computing Toolbox™. For information about the supported compute capabilities, see “GPU Support by Release” (Parallel Computing Toolbox).

Download CIFAR-10 Image Data

Download the CIFAR-10 data set [3]. This dataset contains 50,000 training images that will be used to train a CNN.

Download CIFAR-10 data to a temporary directory

```
cifar10Data = tempdir;

url = 'https://www.cs.toronto.edu/~kriz/cifar-10-matlab.tar.gz';

helperCIFAR10Data.download(url,cifar10Data);
```

Load the CIFAR-10 training and test data.

```
[trainingImages,trainingLabels,testImages,testLabels] = helperCIFAR10Data.load(cifar10Data);
```

Each image is a 32x32 RGB image and there are 50,000 training samples.

```
size(trainingImages)
```

```
ans = 1×4

          32          32           3       50000
```

CIFAR-10 has 10 image categories. List the image categories:

```
numImageCategories = 10;
categories(trainingLabels)
```

```
ans = 10×1 cell
    {'airplane'  }
    {'automobile'}
    {'bird'      }
    {'cat'       }
    {'deer'      }
    {'dog'       }
    {'frog'      }
    {'horse'     }
    {'ship'      }
    {'truck'     }
```

You can display a few of the training images using the following code.

```
figure
thumbnails = trainingImages(:,:,:,1:100);
montage(thumbnails)
```

Create A Convolutional Neural Network (CNN)

A CNN is composed of a series of layers, where each layer defines a specific computation. The Deep Learning Toolbox™ provides functionality to easily design a CNN layer-by-layer. In this example, the following layers are used to create a CNN:

- `imageInputLayer` - Image input layer
- `convolution2dLayer` - 2D convolution layer for Convolutional Neural Networks
- `reluLayer` - Rectified linear unit (ReLU) layer
- `maxPooling2dLayer` - Max pooling layer
- `fullyConnectedLayer` - Fully connected layer
- `softmaxLayer` - Softmax layer
- `classificationLayer` - Classification output layer for a neural network

The network defined here is similar to the one described in [4] and starts with an `imageInputLayer`. The input layer defines the type and size of data the CNN can process. In this example, the CNN is used to process CIFAR-10 images, which are 32x32 RGB images:

```
% Create the image input layer for 32x32x3 CIFAR-10 images.
[height,width,numChannels, ~] = size(trainingImages);

imageSize = [height width numChannels];
inputLayer = imageInputLayer(imageSize)
```

```
inputLayer =
  ImageInputLayer with properties:
```

```
                    Name: ''
               InputSize: [32 32 3]
   Hyperparameters
          DataAugmentation: 'none'
             Normalization: 'zerocenter'
    NormalizationDimension: 'auto'
                    Mean: []
```

Next, define the middle layers of the network. The middle layers are made up of repeated blocks of convolutional, ReLU (rectified linear units), and pooling layers. These 3 layers form the core building blocks of convolutional neural networks. The convolutional layers define sets of filter weights, which are updated during network training. The ReLU layer adds non-linearity to the network, which allow the network to approximate non-linear functions that map image pixels to the semantic content of the image. The pooling layers downsample data as it flows through the network. In a network with lots of layers, pooling layers should be used sparingly to avoid downsampling the data too early in the network.

```
% Convolutional layer parameters
filterSize = [5 5];
numFilters = 32;

middleLayers = [

% The first convolutional layer has a bank of 32 5x5x3 filters. A
% symmetric padding of 2 pixels is added to ensure that image borders
% are included in the processing. This is important to avoid
% information at the borders being washed away too early in the
% network.
convolution2dLayer(filterSize,numFilters,'Padding',2)

% Note that the third dimension of the filter can be omitted because it
% is automatically deduced based on the connectivity of the network. In
% this case because this layer follows the image layer, the third
% dimension must be 3 to match the number of channels in the input
% image.

% Next add the ReLU layer:
reluLayer()

% Follow it with a max pooling layer that has a 3x3 spatial pooling area
% and a stride of 2 pixels. This down-samples the data dimensions from
% 32x32 to 15x15.
maxPooling2dLayer(3,'Stride',2)

% Repeat the 3 core layers to complete the middle of the network.
convolution2dLayer(filterSize,numFilters,'Padding',2)
reluLayer()
maxPooling2dLayer(3, 'Stride',2)

convolution2dLayer(filterSize,2 * numFilters,'Padding',2)
reluLayer()
maxPooling2dLayer(3,'Stride',2)

]
```

```
middleLayers =
  9x1 Layer array with layers:
```

```
    1   ''   Convolution   32 5x5 convolutions with stride [1  1] and padding [2  2  2  2]
    2   ''   ReLU          ReLU
    3   ''   Max Pooling   3x3 max pooling with stride [2  2] and padding [0  0  0  0]
    4   ''   Convolution   32 5x5 convolutions with stride [1  1] and padding [2  2  2  2]
    5   ''   ReLU          ReLU
    6   ''   Max Pooling   3x3 max pooling with stride [2  2] and padding [0  0  0  0]
    7   ''   Convolution   64 5x5 convolutions with stride [1  1] and padding [2  2  2  2]
    8   ''   ReLU          ReLU
    9   ''   Max Pooling   3x3 max pooling with stride [2  2] and padding [0  0  0  0]
```

A deeper network may be created by repeating these 3 basic layers. However, the number of pooling layers should be reduced to avoid downsampling the data prematurely. Downsampling early in the network discards image information that is useful for learning.

The final layers of a CNN are typically composed of fully connected layers and a softmax loss layer.

```
finalLayers = [

% Add a fully connected layer with 64 output neurons. The output size of
% this layer will be an array with a length of 64.
fullyConnectedLayer(64)

% Add an ReLU non-linearity.
reluLayer

% Add the last fully connected layer. At this point, the network must
% produce 10 signals that can be used to measure whether the input image
% belongs to one category or another. This measurement is made using the
% subsequent loss layers.
fullyConnectedLayer(numImageCategories)

% Add the softmax loss layer and classification layer. The final layers use
% the output of the fully connected layer to compute the categorical
% probability distribution over the image classes. During the training
% process, all the network weights are tuned to minimize the loss over this
% categorical distribution.
softmaxLayer
classificationLayer
]
```

```
finalLayers =
  5x1 Layer array with layers:

    1   ''   Fully Connected         64 fully connected layer
    2   ''   ReLU                   ReLU
    3   ''   Fully Connected         10 fully connected layer
    4   ''   Softmax                softmax
    5   ''   Classification Output   crossentropyex
```

Combine the input, middle, and final layers.

```
layers = [
    inputLayer
    middleLayers
    finalLayers
    ]
```

```
layers =
  15x1 Layer array with layers:

     1   ''   Image Input             32x32x3 images with 'zerocenter' normalization
     2   ''   Convolution             32 5x5 convolutions with stride [1  1] and padding [2  2  2
     3   ''   ReLU                    ReLU
     4   ''   Max Pooling             3x3 max pooling with stride [2  2] and padding [0  0  0  0]
     5   ''   Convolution             32 5x5 convolutions with stride [1  1] and padding [2  2  2
     6   ''   ReLU                    ReLU
     7   ''   Max Pooling             3x3 max pooling with stride [2  2] and padding [0  0  0  0]
     8   ''   Convolution             64 5x5 convolutions with stride [1  1] and padding [2  2  2
     9   ''   ReLU                    ReLU
    10   ''   Max Pooling             3x3 max pooling with stride [2  2] and padding [0  0  0  0]
    11   ''   Fully Connected         64 fully connected layer
    12   ''   ReLU                    ReLU
    13   ''   Fully Connected         10 fully connected layer
    14   ''   Softmax                 softmax
    15   ''   Classification Output   crossentropyex
```

Initialize the first convolutional layer weights using normally distributed random numbers with standard deviation of 0.0001. This helps improve the convergence of training.

```
layers(2).Weights = 0.0001 * randn([filterSize numChannels numFilters]);
```

Train CNN Using CIFAR-10 Data

Now that the network architecture is defined, it can be trained using the CIFAR-10 training data. First, set up the network training algorithm using the `trainingOptions` function. The network training algorithm uses Stochastic Gradient Descent with Momentum (SGDM) with an initial learning rate of 0.001. During training, the initial learning rate is reduced every 8 epochs (1 epoch is defined as one complete pass through the entire training data set). The training algorithm is run for 40 epochs.

Note that the training algorithm uses a mini-batch size of 128 images. If using a GPU for training, this size may need to be lowered due to memory constraints on the GPU.

```
% Set the network training options
opts = trainingOptions('sgdm', ...
    'Momentum', 0.9, ...
    'InitialLearnRate', 0.001, ...
    'LearnRateSchedule', 'piecewise', ...
    'LearnRateDropFactor', 0.1, ...
    'LearnRateDropPeriod', 8, ...
    'L2Regularization', 0.004, ...
    'MaxEpochs', 40, ...
    'MiniBatchSize', 128, ...
    'Verbose', true);
```

Train the network using the `trainNetwork` function. This is a computationally intensive process that takes 20-30 minutes to complete. To save time while running this example, a pretrained network is loaded from disk. If you wish to train the network yourself, set the `doTraining` variable shown below to true.

Note that a CUDA-capable NVIDIA™ GPU is highly recommended for training.

```
% A trained network is loaded from disk to save time when running the
% example. Set this flag to true to train the network.
```

```
doTraining = false;

if doTraining
    % Train a network.
    cifar10Net = trainNetwork(trainingImages, trainingLabels, layers, opts);
else
    % Load pre-trained detector for the example.
    load('rcnnStopSigns.mat','cifar10Net')
end
```

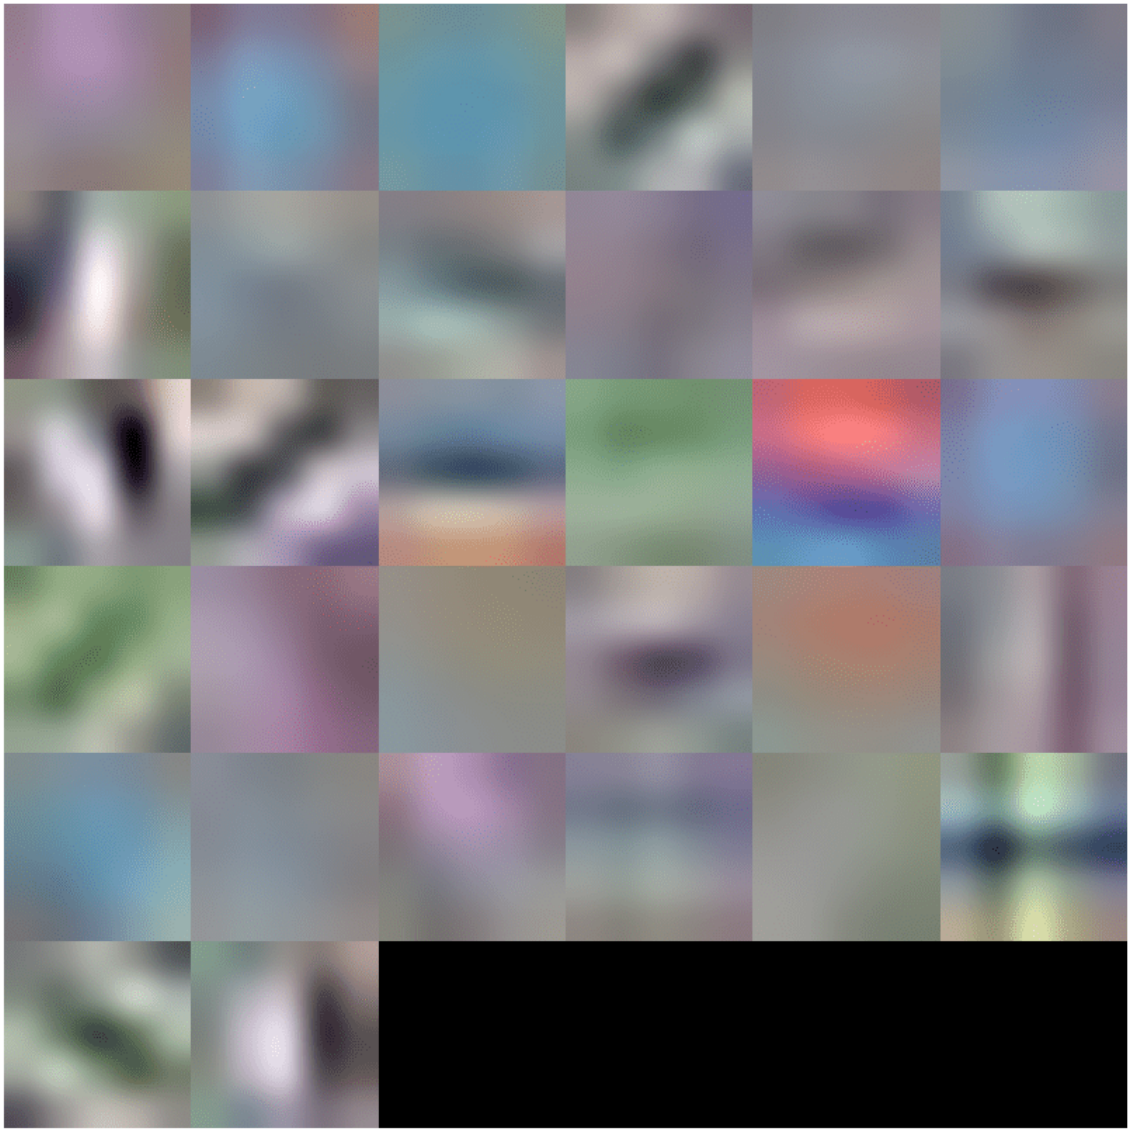
Validate CIFAR-10 Network Training

After the network is trained, it should be validated to ensure that training was successful. First, a quick visualization of the first convolutional layer's filter weights can help identify any immediate issues with training.

```
% Extract the first convolutional layer weights
w = cifar10Net.Layers(2).Weights;

% rescale the weights to the range [0, 1] for better visualization
w = rescale(w);

figure
montage(w)
```



The first layer weights should have some well defined structure. If the weights still look random, then that is an indication that the network may require additional training. In this case, as shown above, the first layer filters have learned edge-like features from the CIFAR-10 training data.

To completely validate the training results, use the CIFAR-10 test data to measure the classification accuracy of the network. A low accuracy score indicates additional training or additional training data is required. The goal of this example is not necessarily to achieve 100% accuracy on the test set, but to sufficiently train a network for use in training an object detector.

```
% Run the network on the test set.
YTest = classify(cifar10Net, testImages);
```

```
% Calculate the accuracy.
accuracy = sum(YTest == testLabels)/numel(testLabels)

accuracy = 0.7456
```

Further training will improve the accuracy, but that is not necessary for the purpose of training the R-CNN object detector.

Load Training Data

Now that the network is working well for the CIFAR-10 classification task, the transfer learning approach can be used to fine-tune the network for stop sign detection.

Start by loading the ground truth data for stop signs.

```
% Load the ground truth data
data = load('stopSignsAndCars.mat', 'stopSignsAndCars');
stopSignsAndCars = data.stopSignsAndCars;

% Update the path to the image files to match the local file system
visiondata = fullfile(toolboxdir('vision'),'visiondata');
stopSignsAndCars.imageFilename = fullfile(visiondata, stopSignsAndCars.imageFilename);

% Display a summary of the ground truth data
summary(stopSignsAndCars)

Variables:
    imageFilename: 41×1 cell array of character vectors
    stopSign: 41×1 cell
    carRear: 41×1 cell
    carFront: 41×1 cell
```

The training data is contained within a table that contains the image filename and ROI labels for stop signs, car fronts, and rears. Each ROI label is a bounding box around objects of interest within an image. For training the stop sign detector, only the stop sign ROI labels are needed. The ROI labels for car front and rear must be removed:

```
% Only keep the image file names and the stop sign ROI labels
stopSigns = stopSignsAndCars(:, {'imageFilename','stopSign'});

% Display one training image and the ground truth bounding boxes
I = imread(stopSigns.imageFilename{1});
I = insertObjectAnnotation(I,'Rectangle',stopSigns.stopSign{1},'stop sign','LineWidth',8);

figure
imshow(I)
```

Note that there are only 41 training images within this data set. Training an R-CNN object detector from scratch using only 41 images is not practical and would not produce a reliable stop sign detector. Because the stop sign detector is trained by fine-tuning a network that has been pre-trained on a larger dataset (CIFAR-10 has 50,000 training images), using a much smaller dataset is feasible.

Train R-CNN Stop Sign Detector

Finally, train the R-CNN object detector using `trainRCNNObjectDetector` (Computer Vision Toolbox). The input to this function is the ground truth table which contains labeled stop sign images, the pre-trained CIFAR-10 network, and the training options. The training function automatically modifies the original CIFAR-10 network, which classified images into 10 categories, into a network that can classify images into 2 classes: stop signs and a generic background class.

During training, the input network weights are fine-tuned using image patches extracted from the ground truth data. The 'PositiveOverlapRange' and 'NegativeOverlapRange' parameters control which image patches are used for training. Positive training samples are those that overlap with the ground truth boxes by 0.5 to 1.0, as measured by the bounding box intersection over union metric. Negative training samples are those that overlap by 0 to 0.3. The best values for these parameters should be chosen by testing the trained detector on a validation set.

For R-CNN training, **the use of a parallel pool of MATLAB workers is highly recommended to reduce training time**. `trainRCNNObjectDetector` automatically creates and uses a parallel pool based on your parallel preference settings. Ensure that the use of the parallel pool is enabled prior to training.

To save time while running this example, a pretrained network is loaded from disk. If you wish to train the network yourself, set the `doTraining` variable shown below to true.

Note that a CUDA-capable NVIDIA™ GPU is highly recommended for training.

```
% A trained detector is loaded from disk to save time when running the
% example. Set this flag to true to train the detector.
doTraining = false;

if doTraining

    % Set training options
    options = trainingOptions('sgdm', ...
        'MiniBatchSize', 128, ...
        'InitialLearnRate', 1e-3, ...
        'LearnRateSchedule', 'piecewise', ...
        'LearnRateDropFactor', 0.1, ...
        'LearnRateDropPeriod', 100, ...
        'MaxEpochs', 100, ...
        'Verbose', true);

    % Train an R-CNN object detector. This will take several minutes.
    rcnn = trainRCNNObjectDetector(stopSigns, cifar10Net, options, ...
    'NegativeOverlapRange', [0 0.3], 'PositiveOverlapRange',[0.5 1])
else
    % Load pre-trained network for the example.
    load('rcnnStopSigns.mat','rcnn')
end
```

Test R-CNN Stop Sign Detector

The R-CNN object detector can now be used to detect stop signs in images. Try it out on a test image:

```
% Read test image
testImage = imread('stopSignTest.jpg');

% Detect stop signs
[bboxes,score,label] = detect(rcnn,testImage,'MiniBatchSize',128)
```

```
bboxes = 1×4

   419   147    31    20

score = single
    0.9955

label = categorical categorical
     stopSign
```

The R-CNN object `detect` (Computer Vision Toolbox) method returns the object bounding boxes, a detection score, and a class label for each detection. The labels are useful when detecting multiple objects, e.g. stop, yield, or speed limit signs. The scores, which range between 0 and 1, indicate the confidence in the detection and can be used to ignore low scoring detections.

```
% Display the detection results
[score, idx] = max(score);

bbox = bboxes(idx, :);
annotation = sprintf('%s: (Confidence = %f)', label(idx), score);

outputImage = insertObjectAnnotation(testImage, 'rectangle', bbox, annotation);
```

```
figure
imshow(outputImage)
```

Debugging Tips

The network used within the R-CNN detector can also be used to process the entire test image. By directly processing the entire image, which is larger than the network's input size, a 2-D heat-map of classification scores can be generated. This is a useful debugging tool because it helps identify items in the image that are confusing the network, and may help provide insight into improving training.

```
% The trained network is stored within the R-CNN detector
rcnn.Network
```

```
ans =
  SeriesNetwork with properties:

    Layers: [15×1 nnet.cnn.layer.Layer]
```

Extract the `activations` from the softmax layer, which is the 14th layer in the network. These are the classification scores produced by the network as it scans the image.

```
featureMap = activations(rcnn.Network, testImage, 14);

% The softmax activations are stored in a 3-D array.
size(featureMap)
```

```
ans = 1×3

    43    78     2
```

The 3rd dimension in featureMap corresponds to the object classes.

```
rcnn.ClassNames
```

```
ans = 2×1 cell
    {'stopSign'  }
    {'Background'}
```

The stop sign feature map is stored in the first channel.

```
stopSignMap = featureMap(:, :, 1);
```

The size of the activations output is smaller than the input image due to the downsampling operations in the network. To generate a nicer visualization, resize `stopSignMap` to the size of the input image. This is a very crude approximation that maps activations to image pixels and should only be used for illustrative purposes.

```
% Resize stopSignMap for visualization
[height, width, ~] = size(testImage);
stopSignMap = imresize(stopSignMap, [height, width]);

% Visualize the feature map superimposed on the test image.
featureMapOnImage = imfuse(testImage, stopSignMap);

figure
imshow(featureMapOnImage)
```

The stop sign in the test image corresponds nicely with the largest peak in the network activations. This helps verify that the CNN used within the R-CNN detector has effectively learned to identify stop

signs. Had there been other peaks, this may indicate that the training requires additional negative data to help prevent false positives. If that's the case, then you can increase 'MaxEpochs' in the trainingOptions and re-train.

Summary

This example showed how to train an R-CNN stop sign object detector using a network trained with CIFAR-10 data. Similar steps may be followed to train other object detectors using deep learning.

Object Detection Using Faster R-CNN Deep Learning

This example shows how to train a Faster R-CNN (regions with convolutional neural networks) object detector.

Deep learning is a powerful machine learning technique that you can use to train robust object detectors. Several deep learning techniques for object detection exist, including Faster R-CNN and you only look once (YOLO) v2. This example trains a Faster R-CNN vehicle detector using the `trainFasterRCNNObjectDetector` function. For more information, see “Object Detection” (Computer Vision Toolbox).

Download Pretrained Detector

Download a pretrained detector to avoid having to wait for training to complete. If you want to train the detector, set the `doTraining` variable to true.

```
doTraining = false;
if ~doTraining && ~exist('fasterRCNNResNet50EndToEndVehicleExample.mat','file')
    disp('Downloading pretrained detector (118 MB)...');
    pretrainedURL = 'https://www.mathworks.com/supportfiles/vision/data/fasterRCNNResNet50EndToEn
    websave('fasterRCNNResNet50EndToEndVehicleExample.mat',pretrainedURL);
end
```

Load Data Set

This example uses a small labeled dataset that contains 295 images. Many of these images come from the Caltech Cars 1999 and 2001 data sets, available at the Caltech Computational Vision website, created by Pietro Perona and used with permission. Each image contains one or two labeled instances of a vehicle. A small dataset is useful for exploring the Faster R-CNN training procedure, but in practice, more labeled images are needed to train a robust detector. Unzip the vehicle images and load the vehicle ground truth data.

```
unzip vehicleDatasetImages.zip
data = load('vehicleDatasetGroundTruth.mat');
vehicleDataset = data.vehicleDataset;
```

The vehicle data is stored in a two-column table, where the first column contains the image file paths and the second column contains the vehicle bounding boxes.

Split the dataset into training, validation, and test sets. Select 60% of the data for training, 10% for validation, and the rest for testing the trained detector.

```
rng(0)
shuffledIndices = randperm(height(vehicleDataset));
idx = floor(0.6 * height(vehicleDataset));

trainingIdx = 1:idx;
trainingDataTbl = vehicleDataset(shuffledIndices(trainingIdx),:);

validationIdx = idx+1 : idx + 1 + floor(0.1 * length(shuffledIndices) );
validationDataTbl = vehicleDataset(shuffledIndices(validationIdx),:);

testIdx = validationIdx(end)+1 : length(shuffledIndices);
testDataTbl = vehicleDataset(shuffledIndices(testIdx),:);
```

Use `imageDatastore` and `boxLabelDatastore` to create datastores for loading the image and label data during training and evaluation.

```
imdsTrain = imageDatastore(trainingDataTbl{:,'imageFilename'});
bldsTrain = boxLabelDatastore(trainingDataTbl(:,'vehicle'));

imdsValidation = imageDatastore(validationDataTbl{:,'imageFilename'});
bldsValidation = boxLabelDatastore(validationDataTbl(:,'vehicle'));

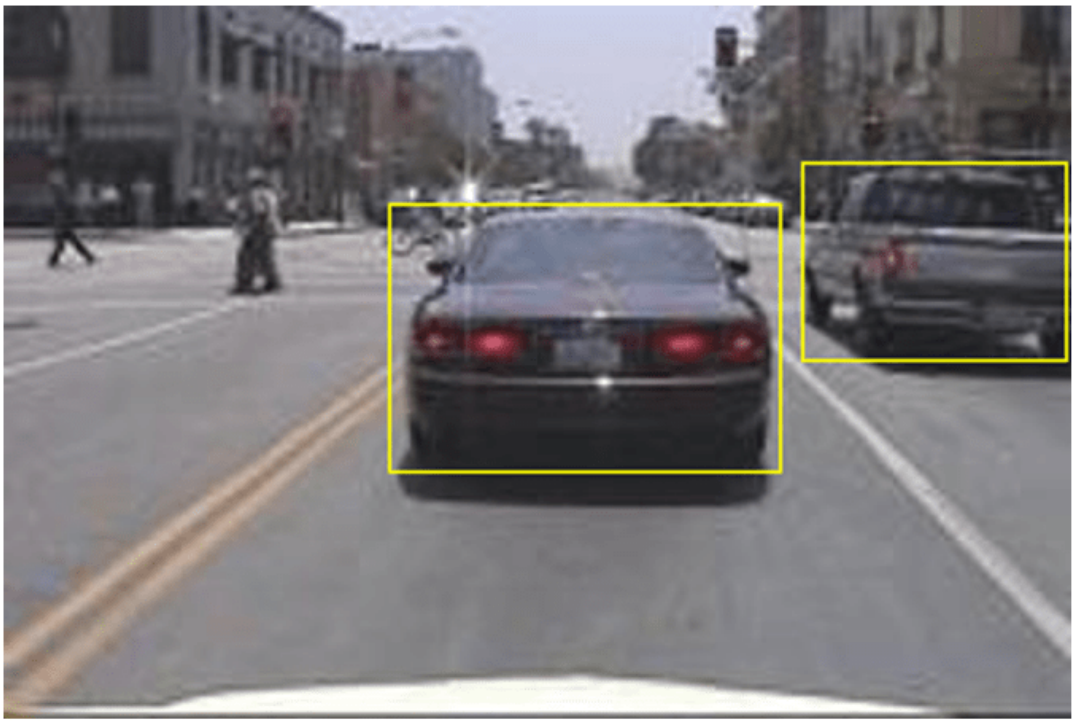
imdsTest = imageDatastore(testDataTbl{:,'imageFilename'});
bldsTest = boxLabelDatastore(testDataTbl(:,'vehicle'));
```

Combine image and box label datastores.

```
trainingData = combine(imdsTrain,bldsTrain);
validationData = combine(imdsValidation,bldsValidation);
testData = combine(imdsTest,bldsTest);
```

Display one of the training images and box labels.

```
data = read(trainingData);
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```



Create Faster R-CNN Detection Network

A Faster R-CNN object detection network is composed of a feature extraction network followed by two subnetworks. The feature extraction network is typically a pretrained CNN, such as ResNet-50 or Inception v3. The first subnetwork following the feature extraction network is a region proposal network (RPN) trained to generate object proposals - areas in the image where objects are likely to exist. The second subnetwork is trained to predict the actual class of each object proposal.

The feature extraction network is typically a pretrained CNN (for details, see “Pretrained Deep Neural Networks” on page 1-8). This example uses ResNet-50 for feature extraction. You can also use other pretrained networks such as MobileNet v2 or ResNet-18, depending on your application requirements.

Use `fasterRCNNLayers` to create a Faster R-CNN network automatically given a pretrained feature extraction network. `fasterRCNNLayers` requires you to specify several inputs that parameterize a Faster R-CNN network:

- Network input size
- Anchor boxes
- Feature extraction network

First, specify the network input size. When choosing the network input size, consider the minimum size required to run the network itself, the size of the training images, and the computational cost incurred by processing data at the selected size. When feasible, choose a network input size that is close to the size of the training image and larger than the input size required for the network. To reduce the computational cost of running the example, specify a network input size of [224 224 3], which is the minimum size required to run the network.

```
inputSize = [224 224 3];
```

Note that the training images used in this example are bigger than 224-by-224 and vary in size, so you must resize the images in a preprocessing step prior to training.

Next, use `estimateAnchorBoxes` to estimate anchor boxes based on the size of objects in the training data. To account for the resizing of the images prior to training, resize the training data for estimating anchor boxes. Use `transform` to preprocess the training data, then define the number of anchor boxes and estimate the anchor boxes.

```
preprocessedTrainingData = transform(trainingData, @(data)preprocessData(data,inputSize));
numAnchors = 3;
anchorBoxes = estimateAnchorBoxes(preprocessedTrainingData,numAnchors)
```

```
anchorBoxes = 3×2

    29    17
    46    39
   136   116
```

For more information on choosing anchor boxes, see“Estimate Anchor Boxes From Training Data” (Computer Vision Toolbox) (Computer Vision Toolbox™) and “Anchor Boxes for Object Detection” (Computer Vision Toolbox).

Now, use `resnet50` to load a pretrained ResNet-50 model.

```
featureExtractionNetwork = resnet50;
```

Select `'activation_40_relu'` as the feature extraction layer. This feature extraction layer outputs feature maps that are downsampled by a factor of 16. This amount of downsampling is a good trade-off between spatial resolution and the strength of the extracted features, as features extracted further down the network encode stronger image features at the cost of spatial resolution. Choosing the optimal feature extraction layer requires empirical analysis. You can use `analyzeNetwork` to find the names of other potential feature extraction layers within a network.

```
featureLayer = 'activation_40_relu';
```

Define the number of classes to detect.

```
numClasses = width(vehicleDataset)-1;
```

Create the Faster R-CNN object detection network.

```
lgraph = fasterRCNNLayers(inputSize,numClasses,anchorBoxes,featureExtractionNetwork,featureLayer
```

You can visualize the network using `analyzeNetwork` or Deep Network Designer from Deep Learning Toolbox™.

If more control is required over the Faster R-CNN network architecture, use Deep Network Designer to design the Faster R-CNN detection network manually. For more information, see “Getting Started with R-CNN, Fast R-CNN, and Faster R-CNN” (Computer Vision Toolbox).

Data Augmentation

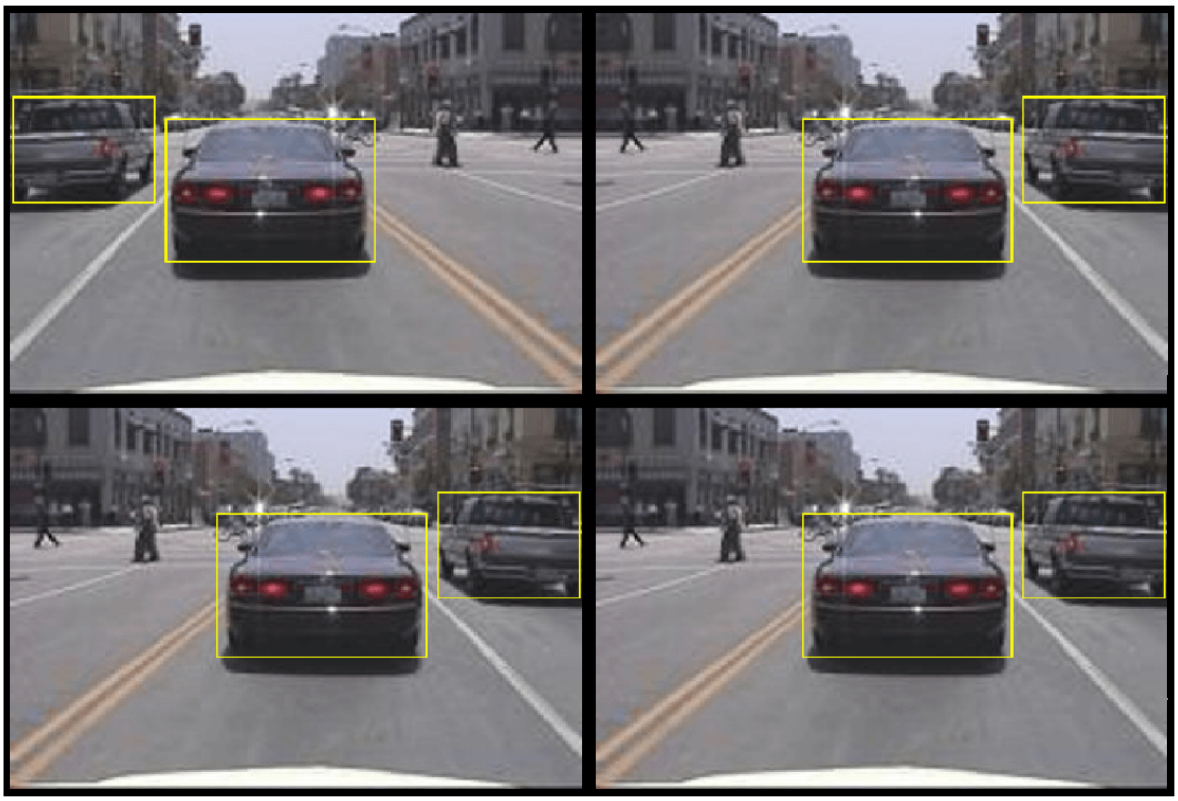
Data augmentation is used to improve network accuracy by randomly transforming the original data during training. By using data augmentation, you can add more variety to the training data without actually having to increase the number of labeled training samples.

Use `transform` to augment the training data by randomly flipping the image and associated box labels horizontally. Note that data augmentation is not applied to test and validation data. Ideally, test and validation data are representative of the original data and are left unmodified for unbiased evaluation.

```
augmentedTrainingData = transform(trainingData,@augmentData);
```

Read the same image multiple times and display the augmented training data.

```
augmentedData = cell(4,1);
for k = 1:4
    data = read(augmentedTrainingData);
    augmentedData{k} = insertShape(data{1},'Rectangle',data{2});
    reset(augmentedTrainingData);
end
figure
montage(augmentedData,'BorderSize',10)
```



Preprocess Training Data

Preprocess the augmented training data, and the validation data to prepare for training.

```
trainingData = transform(augmentedTrainingData,@(data)preprocessData(data,inputSize));
validationData = transform(validationData,@(data)preprocessData(data,inputSize));
```

Read the preprocessed data.

```
data = read(trainingData);
```

Display the image and box bounding boxes.

```
I = data{1};
bbox = data{2};
annotatedImage = insertShape(I,'Rectangle',bbox);
annotatedImage = imresize(annotatedImage,2);
figure
imshow(annotatedImage)
```

Train Faster R-CNN

Use `trainingOptions` to specify network training options. Set `'ValidationData'` to the preprocessed validation data. Set `'CheckpointPath'` to a temporary location. This enables the saving of partially trained detectors during the training process. If training is interrupted, such as by a power outage or system failure, you can resume training from the saved checkpoint.

```
options = trainingOptions('sgdm',...
    'MaxEpochs',10,...
    'MiniBatchSize',2,...
    'InitialLearnRate',1e-3,...
    'CheckpointPath',tempdir,...
    'ValidationData',validationData);
```

Use `trainFasterRCNNObjectDetector` to train Faster R-CNN object detector if `doTraining` is true. Otherwise, load the pretrained network.

```
if doTraining
    % Train the Faster R-CNN detector.
```

```
    % * Adjust NegativeOverlapRange and PositiveOverlapRange to ensure
    %   that training samples tightly overlap with ground truth.
    [detector, info] = trainFasterRCNNObjectDetector(trainingData,lgraph,options, ...
        'NegativeOverlapRange',[0 0.3], ...
        'PositiveOverlapRange',[0.6 1]);
else
    % Load pretrained detector for the example.
    pretrained = load('fasterRCNNResNet50EndToEndVehicleExample.mat');
    detector = pretrained.detector;
end
```

This example was verified on an Nvidia(TM) Titan X GPU with 12 GB of memory. Training the network took approximately 20 minutes. The training time varies depending on the hardware you use.

As a quick check, run the detector on one test image. Make sure you resize the image to the same size as the training images.

```
I = imread(testDataTbl.imageFilename{3});
I = imresize(I,inputSize(1:2));
[bboxes,scores] = detect(detector,I);
```

Display the results.

```
I = insertObjectAnnotation(I,'rectangle',bboxes,scores);
figure
imshow(I)
```

Evaluate Detector Using Test Set

Evaluate the trained object detector on a large set of images to measure the performance. Computer Vision Toolbox™ provides object detector evaluation functions to measure common metrics such as average precision (`evaluateDetectionPrecision`) and log-average miss rates (`evaluateDetectionMissRate`). For this example, use the average precision metric to evaluate performance. The average precision provides a single number that incorporates the ability of the

detector to make correct classifications (precision) and the ability of the detector to find all relevant objects (recall).

Apply the same preprocessing transform to the test data as for the training data.

```
testData = transform(testData,@(data)preprocessData(data,inputSize));
```

Run the detector on all the test images.

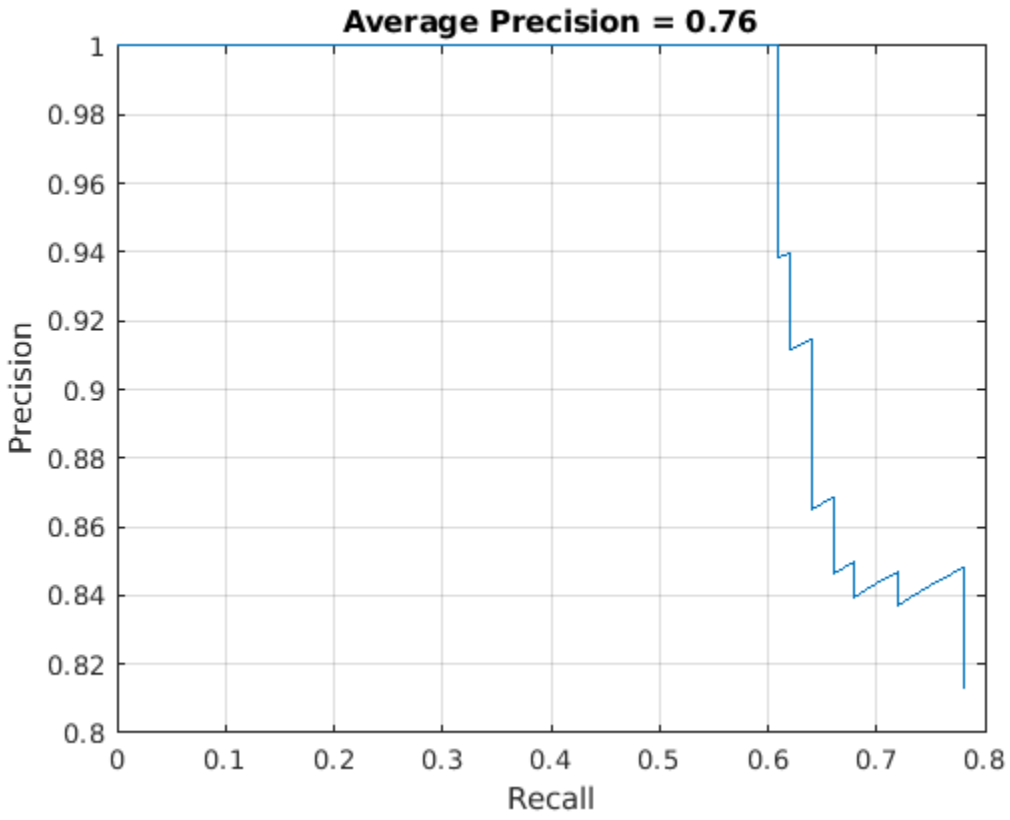
```
detectionResults = detect(detector,testData,'MinibatchSize',4);
```

Evaluate the object detector using the average precision metric.

```
[ap, recall, precision] = evaluateDetectionPrecision(detectionResults,testData);
```

The precision/recall (PR) curve highlights how precise a detector is at varying levels of recall. The ideal precision is 1 at all recall levels. The use of more data can help improve the average precision but might require more training time. Plot the PR curve.

```
figure
plot(recall,precision)
xlabel('Recall')
ylabel('Precision')
grid on
title(sprintf('Average Precision = %.2f', ap))
```



Supporting Functions

```
function data = augmentData(data)
% Randomly flip images and bounding boxes horizontally.
tform = randomAffine2d('XReflection',true);
sz = size(data{1});
rout = affineOutputView(sz,tform);
data{1} = imwarp(data{1},tform,'OutputView',rout);

% Sanitize box data, if needed.
data{2} = helperSanitizeBoxes(data{2}, sz);

% Warp boxes.
data{2} = bboxwarp(data{2},tform,rout);
end

function data = preprocessData(data,targetSize)
% Resize image and bounding boxes to targetSize.
sz = size(data{1},[1 2]);
scale = targetSize(1:2)./sz;
data{1} = imresize(data{1},targetSize(1:2));

% Sanitize box data, if needed.
data{2} = helperSanitizeBoxes(data{2}, sz);

% Resize boxes.
data{2} = bboxresize(data{2},scale);
end
```

Perform Instance Segmentation Using Mask R-CNN

This example shows how to segment individual instances of people and cars using a multiclass Mask region-based convolutional neural network (R-CNN).

Instance segmentation is a computer vision technique in which you detect and localize objects while simultaneously generating a segmentation map for each of the detected instances.

This example first shows how to perform instance segmentation using a pretrained Mask R-CNN that detects two classes. Then, you can optionally download a data set and train a multiclass Mask R-CNN using transfer learning.

Note: This example requires the Computer Vision Toolbox™ Model for Mask R-CNN. You can install the Computer Vision Toolbox Model for Mask R-CNN from the Add-On Explorer. For more information about installing add-ons, see “Get and Manage Add-Ons”.

Perform Instance Segmentation Using Pretrained Mask R-CNN

Download the pretrained Mask R-CNN. The network is stored as a `maskrcnn` (Computer Vision Toolbox) object.

```
dataFolder = fullfile(tempdir,"coco");
trainedMaskRCNN_url = 'https://www.mathworks.com/supportfiles/vision/data/maskrcnn_object_person_
helper.downloadTrainedMaskRCNN(trainedMaskRCNN_url,dataFolder);
```

```
Pretrained MaskRCNN network already exists.
```

```
pretrained = load(fullfile(dataFolder,'maskrcnn_object_person_car.mat'));
net = pretrained.net;
```

Read a test image that contains objects of the target classes.

```
imTest = imread('visionteam.jpg');
```

Segment the objects and their masks using the `segmentObjects` (Computer Vision Toolbox) function. The `segmentObjects` function performs these preprocessing steps on the input image before performing prediction:

1. Zero center the images using the COCO data set mean.
2. Resize the image to the input size of the network, while maintaining the aspect ratio (letter boxing).

```
[masks,labels,scores,boxes] = segmentObjects(net,imTest);
```

Visualize the predictions by overlaying the detected masks on the image using the `insertObjectMask` (Computer Vision Toolbox) function.

```
overlayedImage = insertObjectMask(imTest,masks);
imshow(overlayedImage)
```

Show the bounding boxes and labels on the objects.

```
showShape("rectangle",gather(boxes),"Label",labels,"LineColor",'r')
```

Download Training Data

The COCO 2014 train images data set [2] on page 8-0 consists of 82,783 images. The annotations data contains at least five captions corresponding to each image.

Create directories to store the COCO training images and annotation data.

```
imageFolder = fullfile(dataFolder,"images");
captionsFolder = fullfile(dataFolder,"annotations");
if ~exist(imageFolder,'dir')
    mkdir(imageFolder)
    mkdir(captionsFolder)
end
```

Download the COCO 2014 training images and captions from https://cocodataset.org/#download by clicking the "2014 Train images" and "2014 Train/Val annotations" links, respectively. Extract the image files into the folder specified by `imageFolder`. Extract the annotation files into the folder specified by `captionsFolder`.

```
annotationFile = fullfile(captionsFolder,"instances_train2014.json");
str = fileread(annotationFile);
```

Read and Preprocess Training Data

To train a Mask R-CNN, you need this data.

- RGB images that serve as input to the network, specified as *H*-by-*W*-by-3 numeric arrays.
- Bounding boxes for objects in the RGB images, specified as *NumObjects*-by-4 matrices, with rows in the format [*x y w h*]).
- Instance labels, specified as *NumObjects*-by-1 string vectors.

- Instance masks. Each mask is the segmentation of one instance in the image. The COCO data set specifies object instances using polygon coordinates formatted as *NumObjects*-by-2 cell arrays. Each row of the array contains the (*x*,*y*) coordinates of a polygon along the boundary of one instance in the image. However, the Mask R-CNN in this example requires binary masks specified as logical arrays of size *H*-by-*W*-by-*NumObjects*.

Initialize Training Data Parameters

```
trainClassNames = {'person', 'car'};
numClasses = length(trainClassNames);
imageSizeTrain = [800 800 3];
```

Format COCO Annotation Data as MAT Files

The COCO API for MATLAB enables you to access the annotation data. Download the COCO API for MATLAB from https://github.com/cocodataset/cocoapi by clicking the "Code" button and selecting "Download ZIP." Extract the `cocoapi-master` directory and its contents to the folder specified by `dataFolder`. If needed for your operating system, compile the gason parser by following the instructions in the `gason.m` file within the `MatlabAPI` subdirectory.

Specify the directory location for the COCO API for MATLAB and add the directory to the path.

```
cocoAPIDir = fullfile(dataFolder,"cocoapi-master","MatlabAPI");
addpath(cocoAPIDir);
```

Specify the folder in which to store the MAT files.

```
unpackAnnotationDir = fullfile(dataFolder,"annotations_unpacked","matFiles");
if ~exist(unpackAnnotationDir,'dir')
    mkdir(unpackAnnotationDir)
end
```

Extract the COCO annotations to MAT files using the `unpackAnnotations` helper function, which is attached to this example as a supporting file in the folder `helper`. Each MAT file corresponds to a single training image and contains the file name, bounding boxes, instance labels, and instance masks for each training image. The function converts object instances specified as polygon coordinates to binary masks using the `poly2mask` (Image Processing Toolbox) function.

```
helper.unpackAnnotations(trainClassNames,annotationFile,imageFolder,unpackAnnotationDir);
```

```
Loading and preparing annotations... DONE (t=9.11s).
Unpacking annotations into MAT files...
Done!
```

Create Datastore

The Mask R-CNN expects input data as a 1-by-4 cell array containing the RGB training image, bounding boxes, instance labels, and instance masks.

Create a file datastore with a custom read function, `cocoAnnotationMATReader`, that reads the content of the unpacked annotation MAT files, converts grayscale training images to RGB, and returns the data as a 1-by-4 cell array in the required format. The custom read function is attached to this example as a supporting file in the folder `helper`.

```
ds = fileDatastore(unpackAnnotationDir, ...
    'ReadFcn',@(x)helper.cocoAnnotationMATReader(x,imageFolder));
```

Preprocess the training images, bounding boxes, and instance masks to the size expected by the network using the `transform` function. The `transform` function processes the data using the operations specified in the `preprocessData` helper function. The helper function is attached to the example as a supporting file in the folder `helper`.

The `preprocessData` helper function performs these operations on the training images, bounding boxes, and instance masks:
