Financial Toolbox Product Description

Analyze financial data and develop financial models

Financial Toolbox provides functions for the mathematical modeling and statistical analysis of financial data. You can analyze, backtest, and optimize investment portfolios taking into account turnover, transaction costs, semi-continuous constraints, and minimum or maximum number of assets. The toolbox enables you to estimate risk, model credit scorecards, analyze yield curves, price fixed-income instruments and European options, and measure investment performance.

Stochastic differential equation (SDE) tools let you model and simulate a variety of stochastic processes. Time series analysis functions let you perform transformations or regressions with missing data and convert between different trading calendars and day-count conventions.

Expected Users

In general, this guide assumes experience working with financial derivatives and some familiarity with the underlying models.

In designing Financial Toolbox documentation, we assume that your title is like one of these:

- Analyst, quantitative analyst
- Risk manager
- Portfolio manager
- Asset allocator
- Financial engineer
- Trader
- Student, professor, or other academic

We also assume that your background, education, training, and responsibilities match some aspects of this profile:

- Finance, economics, perhaps accounting
- Engineering, mathematics, physics, other quantitative sciences
- Focus on quantitative approaches to financial problems

Analyze Sets of Numbers Using Matrix Functions

Introduction

Many financial analysis procedures involve *sets* of numbers; for example, a portfolio of securities at various prices and yields. Matrices, matrix functions, and matrix algebra are the most efficient ways to analyze sets of numbers and their relationships. Spreadsheets focus on individual cells and the relationships between cells. While you can think of a set of spreadsheet cells (a range of rows and columns) as a matrix, a matrix-oriented tool like MATLAB® software manipulates sets of numbers more quickly, easily, and naturally. For more information, see "Matrix Algebra Refresher" on page 1-7.

Key Definitions

Matrix

A rectangular array of numeric or algebraic quantities subject to mathematical operations; the regular formation of elements into rows and columns. Described as a "*m*-by-*n*" matrix, with *m* the number of rows and *n* the number of columns. The description is always "row-by-column." For example, here is a 2-by-3 matrix of two bonds (the rows) with different par values, coupon rates, and coupon payment frequencies per year (the columns) entered using MATLAB notation:

```
Bonds = [1000   0.06   2
          500   0.055  4]
```

Vector

A matrix with only one row or column. Described as a "1-by-*n*" or "*m*-by-1" matrix. The description is always "row-by-column." For example, here is a 1-by-4 vector of cash flows in MATLAB notation:

```
Cash = [1500   4470   5280   -1299]
```

Scalar

A 1-by-1 matrix; that is, a single number.

Referencing Matrix Elements

To reference specific matrix elements, use (row, column) notation. For example:

```
Bonds(1,2)
```

```
ans =

          0.06
```

```
Cash(3)
```

```
ans =

       5280.00
```

You can enlarge matrices using small matrices or vectors as elements. For example,

```
AddBond = [1000   0.065   2];
Bonds = [Bonds; AddBond]
```

adds another row to the matrix and creates

```
Bonds =

       1000   0.06    2
        500   0.055   4
       1000   0.065   2
```

Likewise,

```
Prices = [987.50
          475.00
          995.00]

Bonds = [Prices, Bonds]
```

adds another column and creates

```
Bonds =

    987.50   1000   0.06    2
    475.00    500   0.055   4
    995.00   1000   0.065   2
```

Finally, the colon (:) is important in generating and referencing matrix elements. For example, to reference the par value, coupon rate, and coupon frequency of the second bond:

```
BondItems = Bonds(2, 2:4)
```

```
BondItems =

    500.00   0.055   4
```

Transposing Matrices

Sometimes matrices are in the wrong configuration for an operation. In MATLAB, the apostrophe or prime character (') transposes a matrix: columns become rows, rows become columns. For example,

```
Cash = [1500   4470   5280   -1299]'
```

produces

```
Cash =

        1500
        4470
        5280
       -1299
```

Matrix Algebra Refresher

In this section...

Introduction

The explanations in the sections that follow should help refresh your skills for using matrix algebra and using MATLAB functions.

In addition, *Macro-Investment Analysis* by William Sharpe also provides an excellent explanation of matrix algebra operations using MATLAB. It is available on the web at:

```
https://www.stanford.edu/~wfsharpe/mia/mia.htm
```

Tip When you are setting up a problem, it helps to "talk through" the units and dimensions associated with each input and output matrix. In the example under "Multiplying Matrices" on page 1-8, one input matrix has five days' closing prices for three stocks, the other input matrix has shares of three stocks in two portfolios, and the output matrix therefore has five days' closing values for two portfolios. It also helps to name variables using descriptive terms.

Adding and Subtracting Matrices

Matrix addition and subtraction operate element-by-element. The two input matrices must have the same dimensions. The result is a new matrix of the same dimensions where each element is the sum or difference of each corresponding input element. For example, consider combining portfolios of different quantities of the same stocks ("shares of stocks A, B, and C [the rows] in portfolios P and Q [the columns] plus shares of A, B, and C in portfolios R and S").

```
Portfolios_PQ = [100   200
                 500   400
                 300   150];

Portfolios_RS = [175   125
                 200   200
                 100   500];

NewPortfolios = Portfolios_PQ + Portfolios_RS
```

```
NewPortfolios =

        275           325
        700           600
        400           650
```

Adding or subtracting a scalar and a matrix is allowed and also operates element-by-element.

```
SmallerPortf = NewPortfolios-10
```

```
SmallerPortf =
        265.00        315.00
        690.00        590.00
        390.00        640.00
```

Multiplying Matrices

Matrix multiplication does *not* operate element-by-element. It operates according to the rules of linear algebra. In multiplying matrices, it helps to remember this key rule: the inner dimensions must be the same. That is, if the first matrix is *m*-by-3, the second must be 3-by-*n*. The resulting matrix is *m*-by-*n*. It also helps to "talk through" the units of each matrix, as mentioned in "Analyze Sets of Numbers Using Matrix Functions" on page 1-4.

Matrix multiplication also is *not* commutative; that is, it is not independent of order. A*B does *not* equal B*A. The dimension rule illustrates this property. If A is 1-by-3 matrix and B is 3-by-1 matrix, A*B yields a scalar (1-by-1) matrix but B*A yields a 3-by-3 matrix.

Multiplying Vectors

Vector multiplication follows the same rules and helps illustrate the principles. For example, a stock portfolio has three different stocks and their closing prices today are:

```
ClosePrices = [42.5   15   78.875]
```

The portfolio contains these numbers of shares of each stock.

```
NumShares = [100
             500
             300]
```

To find the value of the portfolio, multiply the vectors

```
PortfValue = ClosePrices * NumShares
```

which yields:

```
PortfValue =

            3.5413e+004
```

The vectors are 1-by-3 and 3-by-1; the resulting vector is 1-by-1, a scalar. Multiplying these vectors thus means multiplying each closing price by its respective number of shares and summing the result.

To illustrate order dependence, switch the order of the vectors

```
Values = NumShares * ClosePrices
```

```
Values =

  1.0e+004 *

    0.4250    0.1500    0.7887
    2.1250    0.7500    3.9438
    1.2750    0.4500    2.3663
```

which shows the closing values of 100, 500, and 300 shares of each stock, not the portfolio value, and this is meaningless for this example.

Computing Dot Products of Vectors

In matrix algebra, if X and Y are vectors of the same length

$$Y = [y_1, y_2, \dots, y_n]$$
$$X = [x_1, x_2, \dots, x_n]$$

then the dot product

$$X \cdot Y = x_1 y_1 + x_2 y_2 + \dots + x_n y_n$$

is the scalar product of the two vectors. It is an exception to the commutative rule. To compute the dot product in MATLAB, use `sum(X .* Y)` or `sum(Y .* X)`. Be sure that the two vectors have the same dimensions. To illustrate, use the previous vectors.

```
Value = sum(NumShares .* ClosePrices')
```

```
Value =

      3.5413e+004
```

```
Value = sum(ClosePrices .* NumShares')
```

```
Value =

      3.5413e+004
```

As expected, the value in these cases matches the `PortfValue` computed previously.

Multiplying Vectors and Matrices

Multiplying vectors and matrices follows the matrix multiplication rules and process. For example, a portfolio matrix contains closing prices for a week. A second matrix (vector) contains the stock quantities in the portfolio.

```
WeekClosePr = [42.5     15      78.875
               42.125   15.5    78.75
               42.125   15.125  79
               42.625   15.25   78.875
               43       15.25   78.625];
PortQuan = [100
            500
            300];
```

To see the closing portfolio value for each day, simply multiply

```
WeekPortValue = WeekClosePr * PortQuan
```

```
WeekPortValue =

1.0e+004 *

    3.5412
    3.5587
    3.5475
    3.5550
    3.5513
```

The prices matrix is 5-by-3, the quantity matrix (vector) is 3-by-1, so the resulting matrix (vector) is 5-by-1.

Multiplying Two Matrices

Matrix multiplication also follows the rules of matrix algebra. In matrix algebra notation, if *A* is an *m*-by-*n* matrix and *B* is an *n*-by-*p* matrix

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ \vdots & \vdots & & \vdots \\ a_{i1} & a_{i2} & \cdots & a_{in} \\ \vdots & \vdots & & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}, \quad B = \begin{bmatrix} b_{11} & \cdots & b_{1j} & \cdots & b_{1p} \\ b_{21} & \cdots & b_{2j} & \cdots & b_{2p} \\ \vdots & & \vdots & & \vdots \\ b_{n1} & \cdots & b_{nj} & \cdots & b_{np} \end{bmatrix}$$

then *C* = *A***B* is an *m*-by-*p* matrix; and the element c_{ij} in the *i*th row and *j*th column of *C* is

$$c_{ij} = a_{i1}b_{1j} + a_{i2}b_{12} + \ldots + a_{in}b_{nj}\,.$$

To illustrate, assume that there are two portfolios of the same three stocks previously mentioned but with different quantities.

```
Portfolios = [100   200
              500   400
              300   150];
```

Multiplying the 5-by-3 week's closing prices matrix by the 3-by-2 portfolios matrix yields a 5-by-2 matrix showing each day's closing value for both portfolios.

```
PortfolioValues = WeekClosePr * Portfolios
```

```
PortfolioValues =

1.0e+004 *

    3.5412    2.6331
    3.5587    2.6437
    3.5475    2.6325
    3.5550    2.6456
    3.5513    2.6494
```

Monday's values result from multiplying each Monday closing price by its respective number of shares and summing the result for the first portfolio, then doing the same for the second portfolio. Tuesday's values result from multiplying each Tuesday closing price by its respective number of shares and summing the result for the first portfolio, then doing the same for the second portfolio. And so on, through the rest of the week. With one simple command, MATLAB quickly performs many calculations.

Multiplying a Matrix by a Scalar

Multiplying a matrix by a scalar is an exception to the dimension and commutative rules. It just operates element-by-element.

```
Portfolios = [100   200
              500   400
              300   150];

DoublePort = Portfolios * 2

DoublePort =
       200          400
      1000          800
       600          300
```

Dividing Matrices

Matrix division is useful primarily for solving equations, and especially for solving simultaneous linear equations (see “Solving Simultaneous Linear Equations” on page 1-11). For example, you want to solve for *X* in *A*X* = *B.*

In ordinary algebra, you would divide both sides of the equation by *A*, and *X* would equal *B/A*. However, since matrix algebra is not commutative *(A*X ≠ X*A)*, different processes apply. In formal matrix algebra, the solution involves matrix inversion. MATLAB, however, simplifies the process by providing two matrix division symbols, left and right (`\` and `/`). In general,

`X = A\B` solves for `X` in `A*X = B` and

`X = B/A` solves for `X` in `X*A = B`.

In general, matrix `A` must be a nonsingular square matrix; that is, it must be invertible and it must have the same number of rows and columns. (Generally, a matrix is invertible if the matrix times its inverse equals the identity matrix. To understand the theory and proofs, consult a textbook on linear algebra such as *Elementary Linear Algebra* by Hill listed in “Bibliography” on page A-2.) MATLAB gives a warning message if the matrix is singular or nearly so.

Solving Simultaneous Linear Equations

Matrix division is especially useful in solving simultaneous linear equations. Consider this problem: Given two portfolios of mortgage-based instruments, each with certain yields depending on the prime rate, how do you weight the portfolios to achieve certain annual cash flows? The answer involves solving two linear equations.

A linear equation is any equation of the form

$$a_1x + a_2y = b,$$

where a_1, a_2, and b are constants (with a_1 and a_2 not both 0), and x and y are variables. (It is a linear equation because it describes a line in the xy-plane. For example, the equation $2x + y = 8$ describes a line such that if $x = 2$, then $y = 4$.)

A system of linear equations is a set of linear equations that you usually want to solve at the same time; that is, simultaneously. A basic principle for exact answers in solving simultaneous linear equations requires that there be as many equations as there are unknowns. To get exact answers for x and y, there must be two equations. For example, to solve for x and y in the system of linear equations

$$\begin{aligned} 2x + y &= 13 \\ x - 3y &= -18, \end{aligned}$$

there must be two equations, which there are. Matrix algebra represents this system as an equation involving three matrices: *A* for the left-side constants, *X* for the variables, and *B* for the right-side constants

$$A = \begin{bmatrix} 2 & 1 \\ 1 & -3 \end{bmatrix}, \quad X = \begin{bmatrix} x \\ y \end{bmatrix}, \quad B = \begin{bmatrix} 13 \\ -18 \end{bmatrix},$$

where *A**X* = *B*.

Solving the system simultaneously means solving for *X*. Using MATLAB,

```
A = [2  1
     1 -3];

B = [13
    -18];

X = A \ B
```

solves for `X` in `A * X = B`.

```
X = [3 7]
```

So $x = 3$ and $y = 7$ in this example. In general, you can use matrix algebra to solve any system of linear equations such as

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \ldots + a_{1n}x_n &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \ldots + a_{2n}x_n &= b_2 \\ &\vdots \\ a_{m1}x_1 + a_{m2}x_2 + \ldots + a_{mn}x_n &= b_m \end{aligned}$$

by representing them as matrices

$$A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}, \quad X = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad B = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_m \end{bmatrix}$$

and solving for *X* in *A**X* = *B*.

To illustrate, consider this situation. There are two portfolios of mortgage-based instruments, M1 and M2. They have current annual cash payments of $100 and $70 per unit, respectively, based on today's prime rate. If the prime rate moves down one percentage point, their payments would be $80 and $40. An investor holds 10 units of M1 and 20 units of M2. The investor's receipts equal cash payments times units, or R = C * U, for each prime-rate scenario. As word equations:

	M1	M2
Prime flat:	$100 * 10 units	+ $70 * 20 units = $2400 receipts
Prime down:	$80 * 10 units	+ $40 * 20 units = $1600 receipts

As MATLAB matrices:

```
Cash = [100  70
         80  40];

Units = [10
        20];

Receipts = Cash * Units
```

```
Receipts =

       2400
       1600
```

Now the investor asks this question: Given these two portfolios and their characteristics, how many units of each should they hold to receive $7000 if the prime rate stays flat and $5000 if the prime drops one percentage point? Find the answer by solving two linear equations.

	M1	M2
Prime flat:	$100 * *x* units	+ $70 * *y* units = $7000 receipts
Prime down:	$80 * *x* units	+ $40 * *y* units = $5000 receipts

In other words, solve for U (units) in the equation R (receipts) = C (cash) * U (units). Using MATLAB left division

```
Cash = [100  70
         80  40];

Receipts = [7000
            5000];

Units = Cash \ Receipts
```

```
Units =

         43.7500
         37.5000
```

The investor should hold 43.75 units of portfolio M1 and 37.5 units of portfolio M2 to achieve the annual receipts desired.

Operating Element by Element

Finally, element-by-element arithmetic operations are called operations. To indicate a MATLAB array operation, precede the operator with a period (`.`). Addition and subtraction, and matrix multiplication and division by a scalar, are already array operations so no period is necessary. When using array operations on two matrices, the dimensions of the matrices must be the same. For example, given vectors of stock dividends and closing prices

```
Dividends = [1.90  0.40  1.56  4.50];
Prices = [25.625  17.75  26.125  60.50];

Yields = Dividends ./ Prices
Yields =

    0.0741    0.0225    0.0597    0.0744
```

Using Input and Output Arguments with Functions

In this section...

Input Arguments

Vector and Matrix Input

By design, MATLABsoftware can efficiently perform repeated operations on collections of data stored in vectors and matrices. MATLAB code that is written to operate simultaneously on different arrays is said to be vectorized. Vectorized code is not only clean and concise, but is also efficiently processed by MATLAB.

Because MATLAB is optimized for processing vectorized code, many Financial Toolbox functions accept either vector or matrix input arguments, rather than single (scalar) values.

One example of such a function is the `irr` function, which computes the internal rate of return of a cash flow stream. If you input a vector of cash flows from a single cash flow stream, then `irr` returns a scalar rate of return. If you input a matrix of cash flows from multiple cash flow streams, where each matrix column represents a different stream, then `irr` returns a vector of internal rates of return, where the columns correspond to the columns of the input matrix. Many other Financial Toolbox functions work similarly.

As an example, suppose that you make an initial investment of $100, from which you then receive by a series of annual cash receipts of $10, $20, $30, $40, and $50. This cash flow stream is stored in a vector

```
CashFlows = [-100 10 20 30 40 50]'
```

```
CashFlows =
  -100
    10
    20
    30
    40
    50
```

Use the `irr` function to compute the internal rate of return of the cash flow stream.

```
Rate = irr(CashFlows)
```

```
Rate =

    0.1201
```

For the single cash flow stream `CashFlows`, the function returns a scalar rate of return of `0.1201`, or 12.01%.

Now, use the `irr` function to compute internal rates of return for multiple cash flow streams.

```
Rate = irr([CashFlows CashFlows CashFlows])
Rate =

    0.1201    0.1201    0.1201
```

MATLAB performs the same computation on all the assets at once. For the three cash flow streams, the `irr` function returns a vector of three internal rates of return.

In the Financial Toolbox context, vectorized programming is useful in portfolio management. You can organize multiple assets into a single collection by placing data for each asset in a different matrix column or row, then pass the matrix to a Financial Toolbox function.

Character Vector Input

Enter MATLAB character vectors surrounded by single quotes (`'character vector'`).

A character vector is stored as a character array, one ASCII character per element. Thus, the date character vector is

```
DateCharacterVector = '9/16/2017'
```

This date character vector is actually a `1`-by-`9` vector. If you create a vector or matrix of character vectors, each character vector must have the same length. Using a column vector to create a vector of character vectors can allow you to visually check that all character vectors are the same length. If your character vectors are not the same length, use spaces or zeros to make them the same length, as in the following code.

```
DateFields = ['01/12/2017'
              '02/14/2017'
              '03/03/2017'
              '06/14/2017'
              '12/01/2017'];
```

`DateFields` is a `5`-by-`10` array of character vectors.

You cannot mix numbers and character vectors in a vector or matrix. If you input a vector or matrix that contains a mix of numbers and character vectors, MATLAB treats every entry as a character. As an example, input the following code

```
Item = [83  90  99 '14-Sep-1999']
```

```
Item =

SZc14-Sep-1999
```

The software understands the input not as a `1`-by-`4` vector, but as a `1`-by-`14` character array with the value `SZc14-Sep-1999`.

Output Arguments

Some functions return no arguments, some return just one, and some return multiple arguments. Functions that return multiple arguments use the syntax

```
[A, B, C] = function(input_arguments...)
```

to return arguments `A`, `B`, and `C`. If you omit all but one, the function returns the first argument. Thus, for this example if you use the syntax

```
X = function(input_arguments...)
```

the `function` returns a value for `A`, but not for `B` or `C`.

Some functions that return vectors accept only scalars as arguments. Such functions cannot accept vectors as arguments and return matrices, where each column in the output matrix corresponds to an entry in the input. Output vectors can be variable length.

For example, most functions that require asset life as an input, and return values corresponding to different periods over the asset life, cannot handle vectors or matrices as input arguments. These functions include `amortize`, `depfixdb`, `depgendb`, and `depsoyd`. For example, consider a car for which you want to compute the depreciation schedule. Use the `depfixdb` function to compute a stream of declining-balance depreciation values for the asset. Set the initial value of the asset and the lifetime of the asset. Note that in the returned vector, the asset lifetime determines the number of rows. Now consider a collection of cars with different lifetimes. Because `depfixdb` cannot output a matrix with an unequal number of rows in each column, `depfixdb` cannot accept a single input vector with values for each asset in the collection.

Performing Common Financial Tasks

Handle and Convert Dates

In this section...

Date Formats

Virtually all financial data derives from a time series, functions in Financial Toolbox have extensive date-handling capabilities. The toolbox functions support date or date-and-time formats as character vectors, datetime arrays, or serial date numbers.

- Date character vectors are text that represent date and time, which you can use with multiple formats. For example, `'dd-mmm-yyyy HH:MM:SS'`, `'dd-mmm-yyyy'`, and `'mm/dd/yyyy'` are all supported text formats for a date character vector. Most often, you work with date character vectors (such as `14-Sep-1999`) when dealing with dates.
- Datetime arrays, created using `datetime`, are the best data type for representing points in time. `datetime` values have flexible display formats and up to nanosecond precision, and can account for time zones, daylight saving time, and leap seconds. When `datetime` objects are used as inputs to other Financial Toolbox functions, the format of the input `datetime` object is preserved. For example:

```
originalDate = datetime('now','Format','yyyy-MM-dd HH:mm:ss');
  % Find the next business day
  b = busdate(originalDate)

b = 

  datetime

   2021-05-04 15:59:34
```

- Serial date numbers represent a calendar date as the number of days that have passed since a fixed base date. In MATLAB software, serial date number `1` is January 1,0000 A.D. Financial Toolbox works internally with serial date numbers (such as, `730377`). MATLAB also uses serial time to represent fractions of days beginning at midnight. For example, 6 p.m. equals `0.75` serial days, so 6:00 p.m. on `14-Sep-1999`, in MATLAB, is serial date number `730377.75`

Note If you specify a two-digit year, MATLAB assumes that the year lies within the 100-year period centered on the current year. See the function `datenum` for specific information. MATLAB internal date handling and calculations generate no ambiguous values. However, whenever possible, use serial date numbers or date character vectors containing four-digit years.

Many Financial Toolbox functions that require dates as input arguments accept date character vectors, datetime arrays, or serial date numbers. If you are dealing with a few dates at the MATLAB command-line level, date character vectors are more convenient. If you are using Financial Toolbox functions on large numbers of dates, as in analyzing large portfolios or cash flows, performance improves if you use datetime arrays or serial date numbers. For more information, see “Represent Dates and Times in MATLAB”.

Date Conversions

Financial Toolbox provides functions that convert date character vectors to or from serial date numbers. In addition, you can convert character vectors or serial date numbers to datetime arrays.

Functions that convert between date formats are:

`datedisp`	Displays a numeric matrix with date entries formatted as date character vectors.
`datenum`	Converts a date character vector to a serial date number.
`datestr`	Converts a serial date number to a date character vector.
`datetime`	Converts from date character vectors or serial date numbers to create a datetime array.
`datevec`	Converts a serial date number or date character vector to a date vector whose elements are `[Year Month Day Hour Minute Second]`.
`m2xdate`	Converts MATLAB serial date number to Excel® serial date number.
`x2mdate`	Converts Microsoft® Excel serial date number to MATLAB serial date number.

For more information, see “Convert Between Text and datetime or duration Values”.

Convert Between Datetime Arrays and Character Vectors

A date can be a character vector composed of fields related to a specific date and time. There are several ways to represent dates and times in several text formats. For example, all the following are character vectors represent August 23, 2010 at 04:35:42 PM:

```
'23-Aug-2010 04:35:06 PM'
'Wednesday, August 23'
'08/23/10 16:35'
'Aug 23 16:35:42.946'
```

A date character vector includes characters that separate the fields, such as the hyphen, space, and colon used here:

```
d = '23-Aug-2010 16:35:42'
```

Convert one or more date character vectors to a `datetime` array using the `datetime` function. For the best performance, specify the format of the input character vectors as an input to `datetime`.

Note The specifiers that `datetime` uses to describe date and time formats differ from the specifiers that the `datestr`, `datevec`, and `datenum` functions accept.

```
t = datetime(d,'InputFormat','dd-MMM-yyyy HH:mm:ss')
```

```
t =

   23-Aug-2010 16:35:42
```

Although the date string, `d`, and the `datetime` scalar, `t`, look similar, they are not equal. View the size and data type of each variable.

```
whos d t
```

```
    Name      Size             Bytes  Class       Attributes

  d         1x20                40   char
  t         1x1                121   datetime
```

Convert a `datetime` array to a character vector that uses `char` or `cellstr`. For example, convert the current date and time to a timestamp to append to a file name.

```
t = datetime('now','Format','yyyy-MM-dd''T''HHmmss')
```

```
t =

  datetime

   2016-12-11T125628
```

```
S = char(t);
filename = ['myTest_',S]
```

```
filename =

    'myTest_2016-12-11T125628'
```

Convert Serial Date Numbers to Datetime Arrays

Serial time can represent fractions of days beginning at midnight. For example, 6 p.m. equals `0.75` serial days, so the character vector `'31-Oct-2003, 6:00 PM'` in MATLAB is date number `731885.75`.

Convert one or more serial date numbers to a `datetime` array using the `datetime` function. Specify the type of date number that is being converted:

```
t = datetime(731885.75,'ConvertFrom','datenum')
```

```
t =

  datetime

   31-Oct-2003 18:00:00
```

Convert Datetime Arrays to Numeric Values

Some MATLAB functions accept numeric data types but not datetime values as inputs. To apply these functions to your date and time data, first, convert datetime values to meaningful numeric values, and then call the function. For example, the `log` function accepts `double` inputs but not `datetime` inputs. Suppose that you have a `datetime` array of dates spanning the course of a research study or experiment.

```
t = datetime(2014,6,18) + calmonths(1:4)
```

```
t = 

  1×4 datetime array

   18-Jul-2014   18-Aug-2014   18-Sep-2014   18-Oct-2014
```

Subtract the origin value. For example, the origin value can be the starting day of an experiment.

```
dt = t - datetime(2014,7,1)
```

```
dt = 

  1×4 duration array

    408:00:00   1152:00:00   1896:00:00   2616:00:00
```

`dt` is a `duration` array. Convert `dt` to a `double` array of values in units of years, days, hours, minutes, or seconds by using the `years`, `days`, `hours`, `minutes`, or `seconds` function, respectively.

```
x = hours(dt)
```

```
x = 

         408        1152        1896        2616
```

Pass the `double` array as the input to the `log` function.

```
y = log(x)
```

```
y = 

    6.0113    7.0493    7.5475    7.8694
```

Input Conversions with datenum

The `datenum` function is important for using Financial Toolbox software efficiently. `datenum` takes an input date character vector in any of several formats, with `'dd-mmm-yyyy'`, `'mm/dd/yyyy'`, or `'dd-mmm-yyyy, hh:mm:ss.ss'` formats being the most common. The input date character vector can have up to six fields formed by letters and numbers separated by any other characters, such that:

- The day field is an integer from `1` through `31`.
- The month field is either an integer from `1` through `12` or an alphabetical character vector with at least three characters.
- The year field is a nonnegative integer. If only two numbers are specified, then the year is assumed to lie within the 100-year period centered on the current year. If the year is omitted, the current year is the default.
- The hours, minutes, and seconds fields are optional. They are integers separated by colons or followed by `'am'` or `'pm'`.

For example, if the current year is 1999, then all these dates are equivalent:

```
'17-May-1999'
'17-May-99'
'17-may'
'May 17, 1999'
```

```
'5/17/99'
'5/17'
```

Also, both of these formats represent the same time.

```
'17-May-1999, 18:30'
'5/17/99/6:30 pm'
```

The default format for numbers-only input follows the US convention. Therefore, 3/6 is March 6, not June 3.

With datenum, you can convert dates into serial date format, store them in a matrix variable, and then later pass the variable to a function. Alternatively, you can use datenum directly in a function input argument list.

For example, consider the function bndprice that computes the price of a bond given the yield to maturity. First set up variables for the yield to maturity, coupon rate, and the necessary dates.

```
Yield       = 0.07;
CouponRate  = 0.08;
Settle      = datenum('17-May-2000');
Maturity    = datenum('01-Oct-2000');
```

Then call the function with the variables.

```
bndprice(Yield,CouponRate,Settle,Maturity)
```

```
ans =

  100.3503
```

Alternatively, convert date character vectors to serial date numbers directly in the function input argument list.

```
bndprice(0.07,0.08,datenum('17-May-2000'),...
datenum('01-Oct-2000'))
```

```
ans =

  100.3503
```

bndprice is an example of a function designed to detect the presence of date character vectors and make the conversion automatically. For functions like bndprice, date character vectors can be passed directly.

```
bndprice(0.07,0.08,'17-May-2000','01-Oct-2000')
```

```
ans =

  100.3503
```

The decision to represent dates as either date character vectors or serial date numbers is often a matter of convenience. For example, when formatting data for visual display or for debugging date-handling code, you can view dates more easily as date character vectors because serial date numbers are difficult to interpret. Alternately, serial date numbers are just another type of numeric data, which you can place in a matrix along with any other numeric data for convenient manipulation.

Remember that if you create a vector of input date character vectors, use a column vector, and be sure that all character vectors are the same length. To ensure that the character vectors are the same length, fill the character vectors with spaces or zeros. For more information, see “Character Vector Input” on page 1-16.

Output Conversions with datestr

The `datestr` function converts a serial date number to one of 19 different date character vector output formats showing date, time, or both. The default output for dates is a day-month-year character vector, for example, `24-Aug-2000`. The `datestr` function is useful for preparing output reports.

`datestr` Format	Description
`01-Mar-2000 15:45:17`	day-month-year hour:minute:second
`01-Mar-2000`	day-month-year
`03/01/00`	month/day/year
`Mar`	month, three letters
`M`	month, single letter
`3`	month number
`03/01`	month/day
`1`	day of month
`Wed`	day of week, three letters
`W`	day of week, single letter
`2000`	year, four numbers
`99`	year, two numbers
`Mar01`	month year
`15:45:17`	hour:minute:second
`03:45:17 PM`	hour:minute:second AM or PM
`15:45`	hour:minute
`03:45 PM`	hour:minute AM or PM
`Q1-99`	calendar quarter-year
`Q1`	calendar quarter

Current Date and Time

The `today` and `now` functions return serial date numbers for the current date, and the current date and time, respectively.

```
today
```

```
ans =

      736675
```

```
now
```

```
ans =

   7.3668e+05
```

The MATLAB function `date` returns a character vector for the current date.

```
date
```

```
ans =

    '11-Dec-2016'
```

Determining Specific Dates

Financial Toolbox provides many functions for determining specific dates. For example, assume that you schedule an accounting procedure for the last Friday of every month. Use the `lweekdate` function to return those dates for the year 2000. The input argument `6` specifies Friday.

```
Fridates = lweekdate(6,2000,1:12);
Fridays = datestr(Fridates)
```

```
Fridays =

  12×11 char array

    '28-Jan-2000'
    '25-Feb-2000'
    '31-Mar-2000'
    '28-Apr-2000'
    '26-May-2000'
    '30-Jun-2000'
    '28-Jul-2000'
    '25-Aug-2000'
    '29-Sep-2000'
    '27-Oct-2000'
    '24-Nov-2000'
    '29-Dec-2000'
```

Another example of needing specific dates could be that your company closes on Martin Luther King Jr. Day, which is the third Monday in January. You can use the `nweekdate` function to determine those specific dates for 2011 through 2014.

```
MLKDates = nweekdate(3,2,2011:2014,1);
MLKDays = datestr(MLKDates)
```

```
MLKDays =

  4×11 char array

    '17-Jan-2011'
    '16-Jan-2012'
    '21-Jan-2013'
    '20-Jan-2014'
```

Determining Holidays

Accounting for holidays and other nontrading days is important when you examine financial dates. Financial Toolbox provides the `holidays` function, which contains holidays and special nontrading days for the New York Stock Exchange from 1950 through 2030, inclusive. In addition, you can use `nyseclosures` to evaluate all known or anticipated closures of the New York Stock Exchange from

January 1, 1885, to December 31, 2050. `nyseclosures` returns a vector of serial date numbers corresponding to market closures between the dates `StartDate` and `EndDate`, inclusive.

In this example, use `holidays` to determine the standard holidays in the last half of 2012.

```
LHHDates = holidays('1-Jul-2012','31-Dec-2012');
LHHDays = datestr(LHHDates)
```

```
LHHDays =

  6×11 char array

    '04-Jul-2012'
    '03-Sep-2012'
    '29-Oct-2012'
    '30-Oct-2012'
    '22-Nov-2012'
    '25-Dec-2012'
```

You can then use the `busdate` function to determine the next business day in 2012 after these holidays.

```
LHNextDates = busdate(LHHDates);
LHNextDays = datestr(LHNextDates)
```

```
LHNextDays =

  6×11 char array

    '05-Jul-2012'
    '04-Sep-2012'
    '31-Oct-2012'
    '31-Oct-2012'
    '23-Nov-2012'
    '26-Dec-2012'
```

Determining Cash-Flow Dates

To determine cash-flow dates for securities with periodic payments, use `cfdates`. This function accounts for the coupons per year, the day-count basis, and the end-of-month rule. For example, you can determine the cash-flow dates for a security that pays four coupons per year on the last day of the month using an `actual/365` day-count basis. To do so, enter the settlement date, the maturity date, and the parameters for `Period`, `Basis`, and `EndMonthRule`.

```
PayDates = cfdates('14-Mar-2000','30-Nov-2001',4,3,1);
PayDays = datestr(PayDates)
```

```
PayDays =

  7×11 char array

    '31-May-2000'
    '31-Aug-2000'
    '30-Nov-2000'
    '28-Feb-2001'
    '31-May-2001'
    '31-Aug-2001'
    '30-Nov-2001'
```

Analyzing and Computing Cash Flows

In this section...

Introduction

Financial Toolbox cash-flow functions compute interest rates and rates of return, present or future values, depreciation streams, and annuities.

Some examples in this section use this income stream: an initial investment of $20,000 followed by three annual return payments, a second investment of $5,000, then four more returns. Investments are negative cash flows, return payments are positive cash flows.

```
Stream = [-20000,  2000,  2500,  3500, -5000,  6500,...
            9500,  9500,  9500];
```

Interest Rates/Rates of Return

Several functions calculate interest rates involved with cash flows. To compute the internal rate of return of the cash stream, execute the toolbox function `irr`

```
ROR = irr(Stream)
```

```
ROR =

    0.1172
```

The rate of return is 11.72%.

The internal rate of return of a cash flow may not have a unique value. Every time the sign changes in a cash flow, the equation defining `irr` can give up to two additional answers. An `irr` computation requires solving a polynomial equation, and the number of real roots of such an equation can depend on the number of sign changes in the coefficients. The equation for internal rate of return is

$$\frac{cf_1}{(1+r)} + \frac{cf_2}{(1+r)^2} + \ldots + \frac{cf_n}{(1+r)^n} + Investment = 0,$$

where *Investment* is a (negative) initial cash outlay at time 0, cf_n is the cash flow in the *n*th period, and *n* is the number of periods. `irr` finds the rate *r* such that the present value of the cash flow equals the initial investment. If all the cf_ns are positive there is only one solution. Every time there is a change of sign between coefficients, up to two additional real roots are possible.

Another toolbox rate function, `effrr`, calculates the effective rate of return given an annual interest rate (also known as nominal rate or annual percentage rate, APR) and number of compounding periods per year. To find the effective rate of a 9% APR compounded monthly, enter

```
Rate = effrr(0.09, 12)
```

```
Rate =

    0.0938
```

The Rate is 9.38%.

A companion function nomrr computes the nominal rate of return given the effective annual rate and the number of compounding periods.

Present or Future Values

The toolbox includes functions to compute the present or future value of cash flows at regular or irregular time intervals with equal or unequal payments: fvfix, fvvar, pvfix, and pvvar. The -fix functions assume equal cash flows at regular intervals, while the -var functions allow irregular cash flows at irregular periods.

Now compute the net present value of the sample income stream for which you computed the internal rate of return. This exercise also serves as a check on that calculation because the net present value of a cash stream at its internal rate of return should be zero. Enter

```
NPV = pvvar(Stream, ROR)
```

```
NPV =

   5.9117e-12
```

The NPV is very close to zero. The answer usually is not *exactly* zero due to rounding errors and the computational precision of the computer.

Note Other toolbox functions behave similarly. The functions that compute a bond's yield, for example, often must solve a nonlinear equation. If you then use that yield to compute the net present value of the bond's income stream, it usually does not *exactly* equal the purchase price, but the difference is negligible for practical applications.

Depreciation

The toolbox includes functions to compute standard depreciation schedules: straight line, general declining-balance, fixed declining-balance, and sum of years' digits. Functions also compute a complete amortization schedule for an asset, and return the remaining depreciable value after a depreciation schedule has been applied.

This example depreciates an automobile worth $15,000 over five years with a salvage value of $1,500. It computes the general declining balance using two different depreciation rates: 50% (or 1.5), and 100% (or 2.0, also known as double declining balance). Enter

```
Decline1 = depgendb(15000, 1500, 5, 1.5)
Decline2 = depgendb(15000, 1500, 5, 2.0)
```

which returns

```
Decline1 =
       4500.00       3150.00       2205.00       1543.50       2101.50
```

```
Decline2 =
      6000.00       3600.00       2160.00       1296.00        444.00
```

These functions return the actual depreciation amount for the first four years and the remaining depreciable value as the entry for the fifth year.

Annuities

Several toolbox functions deal with annuities. This first example shows how to compute the interest rate associated with a series of loan payments when only the payment amounts and principal are known. For a loan whose original value was $5000.00 and which was paid back monthly over four years at $130.00/month:

```
Rate = annurate(4*12, 130, 5000, 0, 0)
```

```
Rate =

    0.0094
```

The function returns a rate of 0.0094 monthly, or about 11.28% annually.

The next example uses a present-value function to show how to compute the initial principal when the payment and rate are known. For a loan paid at $300.00/month over four years at 11% annual interest

```
Principal = pvfix(0.11/12, 4*12, 300, 0, 0)
```

```
Principal =

   1.1607e+04
```

The function returns the original principal value of $11,607.43.

The final example computes an amortization schedule for a loan or annuity. The original value was $5000.00 and was paid back over 12 months at an annual rate of 9%.

```
[Prpmt, Intpmt, Balance, Payment] = ...
        amortize(0.09/12, 12, 5000, 0, 0);
```

This function returns vectors containing the amount of principal paid,

```
Prpmt = [399.76 402.76  405.78  408.82  411.89  414.97
         418.09 421.22  424.38  427.56  430.77  434.00]
```

the amount of interest paid,

```
Intpmt = [37.50 34.50  31.48  28.44  25.37  22.28
          19.17 16.03  12.88   9.69   6.49   3.26]
```

the remaining balance for each period of the loan,

```
Balance = [4600.24  4197.49  3791.71  3382.89  2971.01
           2556.03  2137.94  1716.72  1292.34   864.77
            434.00     0.00]
```

and a scalar for the monthly payment.

```
Payment = 437.26
```

Pricing and Computing Yields for Fixed-Income Securities

In this section...

Introduction

The Financial Toolbox product provides functions for computing accrued interest, price, yield, convexity, and duration of fixed-income securities. Various conventions exist for determining the details of these computations. The Financial Toolbox software supports conventions specified by the Securities Industry and Financial Markets Association (SIFMA), used in the US markets, the International Capital Market Association (ICMA), used mainly in the European markets, and the International Swaps and Derivatives Association (ISDA). For historical reasons, SIFMA is referred to in Financial Toolbox documentation as SIA and ISMA is referred to as International Capital Market Association (ICMA). Financial Instruments Toolbox™ supports additional functionality for pricing fixed-income securities. For more information, see “Price Interest-Rate Instruments” (Financial Instruments Toolbox).

Fixed-Income Terminology

Since terminology varies among texts on this subject, here are some basic definitions that apply to these Financial Toolbox functions.

The *settlement date* of a bond is the date when money first changes hands; that is, when a buyer pays for a bond. It need not coincide with the *issue date*, which is the date a bond is first offered for sale.

The *first coupon date* and *last coupon date* are the dates when the first and last coupons are paid, respectively. Although bonds typically pay periodic annual or semiannual coupons, the length of the first and last coupon periods may differ from the standard coupon period. The toolbox includes price and yield functions that handle these odd first and/or last periods.

Successive *quasi-coupon dates* determine the length of the standard coupon period for the fixed income security of interest, and do not necessarily coincide with actual coupon payment dates. The toolbox includes functions that calculate both actual and quasi-coupon dates for bonds with odd first and/or last periods.

Fixed-income securities can be purchased on dates that do not coincide with coupon payment dates. In this case, the bond owner is not entitled to the full value of the coupon for that period. When a bond is purchased between coupon dates, the buyer must compensate the seller for the pro-rata share of the coupon interest earned from the previous coupon payment date. This pro-rata share of the coupon payment is called *accrued interest*. The *purchase price*, the price paid for a bond, is the quoted market price plus accrued interest.

The *maturity date* of a bond is the date when the issuer returns the final face value, also known as the *redemption value* or *par value*, to the buyer. The *yield-to-maturity* of a bond is the nominal compound rate of return that equates the present value of all future cash flows (coupons and principal) to the current market price of the bond.

Period

The period of a bond refers to the frequency with which the issuer of a bond makes coupon payments to the holder.

Period of a Bond

Period Value	Payment Schedule
`0`	No coupons (Zero coupon bond)
`1`	Annual
`2`	Semiannual
`3`	Tri-annual
`4`	Quarterly
`6`	Bi-monthly
`12`	Monthly

Basis

The basis of a bond refers to the basis or day-count convention for a bond. Day count basis determines how interest accrues over time for various instruments and the amount transferred on interest payment dates. Basis is normally expressed as a fraction in which the numerator determines the number of days between two dates, and the denominator determines the number of days in the year.

For example, the numerator of *actual/actual* means that when determining the number of days between two dates, count the actual number of days; the denominator means that you use the actual number of days in the given year in any calculations (either 365 or 366 days depending on whether the given year is a leap year). The calculation of accrued interest for dates between payments also uses day count basis. Day count basis is a fraction of `Number of interest accrual days` / `Days in the relevant coupon period`.

Supported day count conventions and basis values are:

Basis Value	Day Count Convention
`0`	actual/actual (default) — Number of days in both a period and a year is the actual number of days. Also, another common actual/actual basis is basis `12`.

Basis Value	Day Count Convention
1	30/360 SIA — Year fraction is calculated based on a 360 day year with 30-day months, after applying the following rules: If the first date and the second date are the last day of February, the second date is changed to the 30th. If the first date falls on the 31st or is the last day of February, it is changed to the 30th. If after the preceding test, the first day is the 30th and the second day is the 31st, then the second day is changed to the 30th.
2	actual/360 — Number of days in a period is equal to the actual number of days, however the number of days in a year is 360.
3	actual/365 — Number of days in a period is equal to the actual number of days, however the number of days in a year is 365 (even in a leap year).
4	30/360 PSA — Number of days in every month is set to 30 (including February). If the start date of the period is either the 31st of a month or the last day of February, the start date is set to the 30th, while if the start date is the 30th of a month and the end date is the 31st, the end date is set to the 30th. The number of days in a year is 360.
5	30/360 ISDA — Number of days in every month is set to 30, except for February where it is the actual number of days. If the start date of the period is the 31st of a month, the start date is set to the 30th while if the start date is the 30th of a month and the end date is the 31st, the end date is set to the 30th. The number of days in a year is 360.
6	30E /360 — Number of days in every month is set to 30 except for February where it is equal to the actual number of days. If the start date or the end date of the period is the 31st of a month, that date is set to the 30th. The number of days in a year is 360.
7	actual/365 Japanese — Number of days in a period is equal to the actual number of days, except for leap days (29th February) which are ignored. The number of days in a year is 365 (even in a leap year).
8	actual/actual ICMA — Number of days in both a period and a year is the actual number of days and the compounding frequency is annual.
9	actual/360 ICMA — Number of days in a period is equal to the actual number of days, however the number of days in a year is 360 and the compounding frequency is annual.
10	actual/365 ICMA — Number of days in a period is equal to the actual number of days, however the number of days in a year is 365 (even in a leap year) and the compounding frequency is annual.
11	30/360 ICMA — Number of days in every month is set to 30, except for February where it is equal to the actual number of days. If the start date or the end date of the period is the 31st of a month, that date is set to the 30th. The number of days in a year is 360 and the compounding frequency is annual.
12	actual/365 ISDA — The day count fraction is calculated using the following formula: `(Actual number of days in period that fall in a leap year / 366)` + `(Actual number of days in period that fall in a normal year / 365)`. Basis 12 is also referred to as actual/actual ISDA.
13	bus/252 — The number of days in a period is equal to the actual number of business days. The number of business days in a year is 252.

Note Although the concept of day count sounds deceptively simple, the actual calculation of day counts can be complex. You can find a good discussion of day counts and the formulas for calculating them in Chapter 5 of Stigum and Robinson, *Money Market and Bond Calculations* in “Bibliography” on page A-2.

End-of-Month Rule

The *end-of-month rule* affects a bond's coupon payment structure. When the rule is in effect, a security that pays a coupon on the last actual day of a month will always pay coupons on the last day of the month. This means, for example, that a semiannual bond that pays a coupon on February 28 in nonleap years will pay coupons on August 31 in all years and on February 29 in leap years.

End-of-Month Rule

End-of-Month Rule Value	Meaning
`1` (default)	Rule in effect.
`0`	Rule not in effect.

Framework

Although not all Financial Toolbox functions require the same input arguments, they all accept the following common set of input arguments.

Common Input Arguments

Input	Meaning
`Settle`	Settlement date
`Maturity`	Maturity date
`Period`	Coupon payment period
`Basis`	Day-count basis
`EndMonthRule`	End-of-month payment rule
`IssueDate`	Bond issue date
`FirstCouponDate`	First coupon payment date
`LastCouponDate`	Last coupon payment date

Of the common input arguments, only `Settle` and `Maturity` are required. All others are optional. They are set to the default values if you do not explicitly set them. By default, the `FirstCouponDate` and `LastCouponDate` are nonapplicable. In other words, if you do not specify `FirstCouponDate` and `LastCouponDate`, the bond is assumed to have no odd first or last coupon periods. In this case, the bond is a standard bond with a coupon payment structure based solely on the maturity date.

Default Parameter Values

To illustrate the use of default values in Financial Toolbox functions, consider the `cfdates` function, which computes actual cash flow payment dates for a portfolio of fixed income securities regardless of whether the first and/or last coupon periods are normal, long, or short.

The complete calling syntax with the full input argument list is

```
CFlowDates = cfdates(Settle, Maturity, Period, Basis, ...
EndMonthRule, IssueDate, FirstCouponDate, LastCouponDate)
```

while the minimal calling syntax requires only settlement and maturity dates

```
CFlowDates = cfdates(Settle, Maturity)
```

Single Bond Example

As an example, suppose that you have a bond with these characteristics:

```
Settle          = '20-Sep-1999'
Maturity        = '15-Oct-2007'
Period          = 2
Basis           = 0
EndMonthRule    = 1
IssueDate       = NaN
FirstCouponDate = NaN
LastCouponDate  = NaN
```

`Period`, `Basis`, and `EndMonthRule` are set to their default values, and `IssueDate`, `FirstCouponDate`, and `LastCouponDate` are set to `NaN`.

Formally, a `NaN` is an IEEE® arithmetic standard for *Not-a-Number* and is used to indicate the result of an undefined operation (for example, zero divided by zero). However, `NaN` is also a convenient placeholder. In the SIA functions of Financial Toolbox software, `NaN` indicates the presence of a nonapplicable value. It tells the Financial Toolbox functions to ignore the input value and apply the default. Setting `IssueDate`, `FirstCouponDate`, and `LastCouponDate` to `NaN` in this example tells `cfdates` to assume that the bond has been issued before settlement and that no odd first or last coupon periods exist.

Having set these values, all these calls to `cfdates` produce the same result.

```
cfdates(Settle, Maturity)
cfdates(Settle, Maturity, Period)
cfdates(Settle, Maturity, Period, [])
cfdates(Settle, Maturity, [], Basis)
cfdates(Settle, Maturity, [], [])
cfdates(Settle, Maturity, Period, [], EndMonthRule)
cfdates(Settle, Maturity, Period, [], NaN)
cfdates(Settle, Maturity, Period, [], [], IssueDate)
cfdates(Settle, Maturity, Period, [], [], IssueDate, [], [])
cfdates(Settle, Maturity, Period, [], [], [], [],LastCouponDate)
cfdates(Settle, Maturity, Period, Basis, EndMonthRule, ...
IssueDate, FirstCouponDate, LastCouponDate)
```

Thus, leaving a particular input unspecified has the same effect as passing an empty matrix (`[]`) or passing a `NaN` – all three tell `cfdates` (and other Financial Toolbox functions) to use the default value for a particular input parameter.

Bond Portfolio Example

Since the previous example included only a single bond, there was no difference between passing an empty matrix or passing a `NaN` for an optional input argument. For a portfolio of bonds, however, using `NaN` as a placeholder is the only way to specify default acceptance for some bonds while explicitly setting nondefault values for the remaining bonds in the portfolio.

Now suppose that you have a portfolio of two bonds.

```
Settle   = '20-Sep-1999'
Maturity = ['15-Oct-2007'; '15-Oct-2010']
```

These calls to `cfdates` all set the coupon period to its default value (`Period = 2`) for both bonds.

```
cfdates(Settle, Maturity, 2)
cfdates(Settle, Maturity, [2 2])
cfdates(Settle, Maturity, [])
cfdates(Settle, Maturity, NaN)
cfdates(Settle, Maturity, [NaN NaN])
cfdates(Settle, Maturity)
```

The first two calls explicitly set `Period = 2`. Since `Maturity` is a `2`-by-`1` vector of maturity dates, `cfdates` knows that you have a two-bond portfolio.

The first call specifies a single (that is, scalar) 2 for `Period`. Passing a scalar tells `cfdates` to apply the scalar-valued input to all bonds in the portfolio. This is an example of implicit scalar-expansion. The settlement date has been implicit scalar-expanded as well.

The second call also applies the default coupon period by explicitly passing a two-element vector of 2's. The third call passes an empty matrix, which `cfdates` interprets as an invalid period, for which the default value is used. The fourth call is similar, except that a `NaN` has been passed. The fifth call passes two `NaN`'s, and has the same effect as the third. The last call passes the minimal input set.

Finally, consider the following calls to `cfdates` for the same two-bond portfolio.

```
cfdates(Settle, Maturity, [4 NaN])
cfdates(Settle, Maturity, [4 2])
```

The first call explicitly sets `Period = 4` for the first bond and implicitly sets the default `Period = 2` for the second bond. The second call has the same effect as the first but explicitly sets the periodicity for both bonds.

The optional input `Period` has been used for illustrative purpose only. The default-handling process illustrated in the examples applies to any of the optional input arguments.

Coupon Date Calculations

Calculating coupon dates, either actual or quasi dates, is notoriously complicated. Financial Toolbox software follows the SIA conventions in coupon date calculations.

The first step in finding the coupon dates associated with a bond is to determine the reference, or synchronization date (the *sync date*). Within the SIA framework, the order of precedence for determining the sync date is:

1. The first coupon date
2. The last coupon date
3. The maturity date

In other words, a Financial Toolbox function first examines the `FirstCouponDate` input. If `FirstCouponDate` is specified, coupon payment dates and quasi-coupon dates are computed with respect to `FirstCouponDate`; if `FirstCouponDate` is unspecified, empty (`[]`), or `NaN`, then the `LastCouponDate` is examined. If `LastCouponDate` is specified, coupon payment dates and quasi-coupon dates are computed with respect to `LastCouponDate`. If both `FirstCouponDate` and

LastCouponDate are unspecified, empty ([]), or NaN, the Maturity (a required input argument) serves as the synchronization date.

Yield Conventions

There are two yield and time factor conventions that are used in the Financial Toolbox software – these are determined by the input basis. Specifically, bases 0 to 7 are assumed to have semiannual compounding, while bases 8 to 12 are assumed to have annual compounding regardless of the period of the bond's coupon payments (including zero-coupon bonds). In addition, any yield-related sensitivity (that is, duration and convexity), when quoted on a periodic basis, follows this same convention. (See bndconvp, bndconvy, bnddurp, bnddury, and bndkrdur.)

Pricing Functions

This example shows how easily you can compute the price of a bond with an odd first period using the function bndprice. Assume that you have a bond with these characteristics:

```
Settle         = '11-Nov-1992';
Maturity       = '01-Mar-2005';
IssueDate      = '15-Oct-1992';
FirstCouponDate = '01-Mar-1993';
CouponRate     = 0.0785;
Yield          = 0.0625;
```

Allow coupon payment period (Period = 2), day-count basis (Basis = 0), and end-of-month rule (EndMonthRule = 1) to assume the default values. Also, assume that there is no odd last coupon date and that the face value of the bond is $100. Calling the function

```
[Price, AccruedInt] = bndprice(Yield, CouponRate, Settle, ...
Maturity, [], [], [], IssueDate, FirstCouponDate)
```

```
Price =

  113.5977

AccruedInt =

    0.5855
```

bndprice returns a price of $113.60 and accrued interest of $0.59.

Similar functions compute prices with regular payments, odd first and last periods, and prices of Treasury bills and discounted securities such as zero-coupon bonds.

Note bndprice and other functions use nonlinear formulas to compute the price of a security. For this reason, Financial Toolbox software uses Newton's method when solving for an independent variable within a formula. See any elementary numerical methods textbook for the mathematics underlying Newton's method.

Yield Functions

To illustrate toolbox yield functions, compute the yield of a bond that has odd first and last periods and settlement in the first period. First set up variables for settlement, maturity date, issue, first coupon, and a last coupon date.

```
Settle          = '12-Jan-2000';
Maturity        = '01-Oct-2001';
IssueDate       = '01-Jan-2000';
FirstCouponDate = '15-Jan-2000';
LastCouponDate  = '15-Apr-2000';
```

Assume a face value of $100. Specify a purchase price of $95.70, a coupon rate of 4%, quarterly coupon payments, and a 30/360 day-count convention (`Basis = 1`).

```
Price        = 95.7;
CouponRate   = 0.04;
Period       = 4;
Basis        = 1;
EndMonthRule = 1;
```

Calling the `bndyield` function

```
Yield = bndyield(Price, CouponRate, Settle, Maturity, Period,...
Basis, EndMonthRule, IssueDate, FirstCouponDate, LastCouponDate)
```

```
Yield =

    0.0659
```

The function returns a `Yield = 0.0659` (6.60%).

Fixed-Income Sensitivities

Financial Toolbox software supports the following options for managing interest-rate risk for one or more bonds:

- `bnddurp` and `bnddury` support duration and convexity analysis based on market quotes and assume parallel shifts in the bond yield curve.
- `bndkrdur` supports key rate duration based on a market yield curve and can model nonparallel shifts in the bond yield curve.

Calculating Duration and Convexity for Bonds

The toolbox includes functions to perform sensitivity analysis such as convexity and the Macaulay and modified durations for fixed-income securities. The Macaulay duration of an income stream, such as a coupon bond, measures how long, on average, the owner waits before receiving a payment. It is the weighted average of the times payments are made, with the weights at time `T` equal to the present value of the money received at time `T`. The modified duration is the Macaulay duration discounted by the per-period interest rate; that is, divided by (1+rate/frequency). The Macaulay duration is a measure of price sensitivity to yield changes. This duration is measured in years and is a weighted average-time-to-maturity of an instrument.

To illustrate, the following example computes the annualized Macaulay and modified durations, and the periodic Macaulay duration for a bond with settlement (12-Jan-2000) and maturity (01-Oct-2001) dates as above, a 5% coupon rate, and a 4.5% yield to maturity. For simplicity, any optional input arguments assume default values (that is, semiannual coupons, and day-count basis = 0 (actual/actual), coupon payment structure synchronized to the maturity date, and end-of-month payment rule in effect).

```
CouponRate = 0.05;
Yield = 0.045;
Settle  = '12-Jan-2000';
Maturity = '01-Oct-2001';

[ModDuration, YearDuration, PerDuration] = bnddury(Yield,...
CouponRate, Settle, Maturity)
```

```
ModDuration =

    1.6107

YearDuration =

    1.6470

PerDuration =

    3.2940
```

The durations are

```
ModDuration  = 1.6107 (years)
YearDuration = 1.6470 (years)
PerDuration  = 3.2940 (semiannual periods)
```

Note that the semiannual periodic Macaulay duration (PerDuration) is twice the annualized Macaulay duration (YearDuration).

Calculating Key Rate Durations for Bonds

Key rate duration enables you to evaluate the sensitivity and price of a bond to nonparallel changes in the spot or zero curve by decomposing the interest rate risk along the spot or zero curve. Key rate duration refers to the process of choosing a set of key rates and computing a duration for each rate. Specifically, for each key rate, while the other rates are held constant, the key rate is shifted up and down (and intermediate cash flow dates are interpolated), and then the present value of the security given the shifted curves is computed.

The calculation of bndkrdur supports:

$$krdur_i = \frac{(PV_{down} - PV_{up})}{(PV \times ShiftValue \times 2)}$$

Where *PV* is the current value of the instrument, *PV_up* and *PV_down* are the new values after the discount curve has been shocked, and *ShiftValue* is the change in interest rate. For example, if key rates of 3 months, 1, 2, 3, 5, 7, 10, 15, 20, 25, 30 years were chosen, then a 30-year bond might have corresponding key rate durations of:

3M	1Y	2Y	3Y	5Y	7Y	10Y	15Y	20Y	25Y	30Y
.01	.04	.09	.21	.4	.65	1.27	1.71	1.68	1.83	7.03

The key rate durations add up to approximately equal the duration of the bond.

For example, compute the key rate duration of the US Treasury Bond with maturity date of August 15, 2028 and coupon rate of 5.5%.

```
Settle = datenum('18-Nov-2008');
CouponRate = 5.500/100;
Maturity = datenum('15-Aug-2028');
Price = 114.83;
```

For the `ZeroData` information on the current spot curve for this bond, refer to https://www.treasury.gov/resource-center/data-chart-center/interest-rates/Pages/TextView.aspx?data=yield:

```
ZeroDates = daysadd(Settle ,[30 90 180 360 360*2 360*3 360*5 ...
360*7 360*10 360*20 360*30]);
ZeroRates = ([0.06 0.12 0.81 1.08 1.22 1.53 2.32 2.92 3.68 4.42 4.20]/100)';
```

Compute the key rate duration for a specific set of rates (choose this based on the maturities of the available hedging instruments):

```
krd = bndkrdur([ZeroDates ZeroRates],CouponRate,Settle,Maturity,'keyrates',[2 5 10 20])
```

```
krd =

    0.2865    0.8729    2.6451    8.5778
```

Note, the sum of the key rate durations approximately equals the duration of the bond:

```
[sum(krd) bnddurp(Price,CouponRate,Settle,Maturity)]
```

```
ans =

   12.3823   12.3919
```

Treasury Bills Defined

Treasury bills are short-term securities (issued with maturities of one year or less) sold by the United States Treasury. Sales of these securities are frequent, usually weekly. From time to time, the Treasury also offers longer duration securities called Treasury notes and Treasury bonds.

A Treasury bill is a discount security. The holder of the Treasury bill does not receive periodic interest payments. Instead, at the time of sale, a percentage discount is applied to the face value. At maturity, the holder redeems the bill for full face value.

The basis for Treasury bill interest calculation is actual/360. Under this system, interest accrues on the actual number of elapsed days between purchase and maturity, and each year contains 360 days.

Computing Treasury Bill Price and Yield

In this section...

Introduction

Financial Toolbox software provides the following suite of functions for computing price and yield on Treasury bills.

Treasury Bill Functions

Function	Purpose
tbilldisc2yield	Convert discount rate to yield.
tbillprice	Price Treasury bill given its yield or discount rate.
tbillrepo	Break-even discount of repurchase agreement.
tbillyield	Yield and discount of Treasury bill given its price.
tbillyield2disc	Convert yield to discount rate.
tbillval01	The value of 1 basis point (one hundredth of one percentage point, or 0.0001) given the characteristics of the Treasury bill, as represented by its settlement and maturity dates. You can relate the basis point to discount, money-market, or bond-equivalent yield.

For all functions with yield in the computation, you can specify yield as money-market or bond-equivalent yield. The functions all assume a face value of $100 for each Treasury bill.

Treasury Bill Repurchase Agreements

The following example shows how to compute the break-even discount rate. This is the rate that correctly prices the Treasury bill such that the profit from selling the tail equals 0.

```
Maturity = '26-Dec-2002';
InitialDiscount = 0.0161;
PurchaseDate = '26-Sep-2002';
SaleDate = '26-Oct-2002';
RepoRate = 0.0149;

BreakevenDiscount = tbillrepo(RepoRate, InitialDiscount, ...
PurchaseDate, SaleDate, Maturity)
```

```
BreakevenDiscount =

    0.0167
```

You can check the result of this computation by examining the cash flows in and out from the repurchase transaction. First compute the price of the Treasury bill on the purchase date (September 26).

```
PriceOnPurchaseDate = tbillprice(InitialDiscount, ...
PurchaseDate, Maturity, 3)

PriceOnPurchaseDate =

   99.5930
```

Next compute the interest due on the repurchase agreement.

```
RepoInterest = ...
RepoRate*PriceOnPurchaseDate*days360(PurchaseDate,SaleDate)/360

RepoInterest =

    0.1237
```

`RepoInterest` for a 1.49% 30-day term repurchase agreement (30/360 basis) is 0.1237.

Finally, compute the price of the Treasury bill on the sale date (October 26).

```
PriceOnSaleDate = tbillprice(BreakevenDiscount, SaleDate, ...
Maturity, 3)

PriceOnSaleDate =

   99.7167
```

Examining the cash flows, observe that the break-even discount causes the sum of the price on the purchase date plus the accrued 30-day interest to be equal to the price on sale date. The next table shows the cash flows.

Cash Flows from Repurchase Agreement

Date	Cash Out Flow		Cash In Flow	
9/26/2002	Purchase T-bill	99.593	Repo money	99.593
10/26/2002	Payment of repo	99.593	Sell T-bill	99.7168
	Repo interest	0.1238		
	Total	199.3098		199.3098

Treasury Bill Yields

Using the same data as before, you can examine the money-market and bond-equivalent yields of the Treasury bill at the time of purchase and sale. The function `tbilldisc2yield` can perform both computations at one time.

```
Maturity = '26-Dec-2002';
InitialDiscount = 0.0161;
PurchaseDate = '26-Sep-2002';
SaleDate = '26-Oct-2002';
RepoRate = 0.0149;
BreakevenDiscount = tbillrepo(RepoRate, InitialDiscount, ...
PurchaseDate, SaleDate, Maturity)

[BEYield, MMYield] = ...
tbilldisc2yield([InitialDiscount; BreakevenDiscount], ...
[PurchaseDate; SaleDate], Maturity)
```

```
BreakevenDiscount =

    0.0167

BEYield =

    0.0164
    0.0170

MMYield =

    0.0162
    0.0168
```

For the short Treasury bill (fewer than 182 days to maturity), the money-market yield is 360/365 of the bond-equivalent yield, as this example shows.

Term Structure of Interest Rates

In this section...

Introduction

The Financial Toolbox product contains several functions to derive and analyze interest rate curves, including data conversion and extrapolation, bootstrapping, and interest-rate curve conversion functions.

One of the first problems in analyzing the term structure of interest rates is dealing with market data reported in different formats. Treasury bills, for example, are quoted with bid and asked bank-discount rates. Treasury notes and bonds, on the other hand, are quoted with bid and asked prices based on $100 face value. To examine the full spectrum of Treasury securities, analysts must convert data to a single format. Financial Toolbox functions ease this conversion. This brief example uses only one security each; analysts often use 30, 100, or more of each.

First, capture Treasury bill quotes in their reported format

```
%         Maturity               Days  Bid     Ask     AskYield
TBill = [datenum('12/26/2000')  53    0.0503  0.0499  0.0510];
```

then capture Treasury bond quotes in their reported format

```
%        Coupon   Maturity           Bid       Ask       AskYield
TBond = [0.08875  datenum(2001,11,5) 103+4/32  103+6/32  0.0564];
```

and note that these quotes are based on a November 3, 2000 settlement date.

```
Settle = datenum('3-Nov-2000');
```

Next use the toolbox `tbl2bond` function to convert the Treasury bill data to Treasury bond format.

```
TBTBond = tbl2bond(TBill)
```

```
TBTBond =

   1.0e+05 *

         0    7.3085    0.0010    0.0010    0.0000
```

(The second element of `TBTBond` is the serial date number for December 26, 2000.)

Now combine short-term (Treasury bill) with long-term (Treasury bond) data to set up the overall term structure.

```
TBondsAll = [TBTBond; TBond]
```

```
TBondsAll =

   1.0e+05 *

         0    7.3085    0.0010    0.0010    0.0000
    0.0000    7.3116    0.0010    0.0010    0.0000
```

The Financial Toolbox software provides a second data-preparation function,`tr2bonds`, to convert the bond data into a form ready for the bootstrapping functions. `tr2bonds` generates a matrix of bond information sorted by maturity date, plus vectors of prices and yields.

```
[Bonds, Prices, Yields] = tr2bonds(TBondsAll)
```

```
Bonds =

   1.0e+05 *

    7.3085         0    0.0010         0         0    0.0000
    7.3116    0.0000    0.0010    0.0000         0    0.0000

Prices =

   99.2654
  103.1875

Yields =

    0.0510
    0.0564
```

Deriving an Implied Zero Curve

Using this market data, you can use one of the Financial Toolbox bootstrapping functions to derive an implied zero curve. Bootstrapping is a process whereby you begin with known data points and solve for unknown data points using an underlying arbitrage theory. Every coupon bond can be valued as a package of zero-coupon bonds which mimic its cash flow and risk characteristics. By mapping yields-to-maturity for each theoretical zero-coupon bond, to the dates spanning the investment horizon, you can create a theoretical zero-rate curve. The Financial Toolbox software provides two bootstrapping functions: `zbtprice` derives a zero curve from bond data and *prices*, and `zbtyield` derives a zero curve from bond data and *yields*. Using `zbtprice`

```
[ZeroRates, CurveDates] = zbtprice(Bonds, Prices, Settle)
```

```
ZeroRates =

     0.05
     0.06

CurveDates =

      730846
      731160
```

`CurveDates` gives the investment horizon.

```
datestr(CurveDates)
```

```
ans =

26-Dec-2000
05-Nov-2001
```

Use additional Financial Toolbox functions `zero2disc`, `zero2fwd`, and `zero2pyld` to construct discount, forward, and par yield curves from the zero curve, and vice versa.

```
[DiscRates, CurveDates] = zero2disc(ZeroRates, CurveDates, Settle);
[FwdRates, CurveDates] = zero2fwd(ZeroRates, CurveDates, Settle);
[PYldRates, CurveDates] = zero2pyld(ZeroRates, CurveDates, Settle);
```

Returns with Negative Prices

Once considered a mathematical impossibility, negative prices have become an established aspect of many financial markets. Negative prices arise in situations where investors determine that holding an asset entails more risk than the current value of the asset. For example, energy futures see negative prices because of costs associated with overproduction and limited storage capacity. In a different setting, central banks impose negative interest rates when national economies become deflationary, and the pricing of interest rate derivatives, traditionally based on positivity, have to be rethought (see “Work with Negative Interest Rates Using Functions” (Financial Instruments Toolbox)). A negative price encourages the buyer to take something from the seller, and the seller pays a fee for the service of divesting.

MathWorks® Computational Finance products support several functions for converting between price series *p*(*t*) and return series *r*(*t*). Price positivity is not a requirement. The returns computed from input negative prices can be unexpected, but they have mathematical meaning that can help you to understand price movements.

Negative Price Conversion

Financial Toolbox functions `ret2tick` and `tick2ret` support converting between price series *p*(*t*) and return series *r*(*t*).

For simple returns (default), the functions implement the formulas

$$r_s(t) = \frac{p_s(t)}{p_s(t-1)} - 1$$

$$p_s(t) = p_s(t-1)(r_s(t) + 1)\,.$$

For continuous returns, the functions implement the formulas

$$r_c(t) = \log\left(\frac{p_c(t)}{p_c(t-1)}\right)$$

$$p_c(t) = p_c(t-1)e^{r_c(t)}\,.$$

The functions `price2ret` and `ret2price` implement the same formulas, but they divide by Δ*t* in the return formulas and they multiply by Δ*t* in the price formulas. A positive factor of Δ*t* (enforced by required monotonic observation times) does not affect the behavior of the functions. Econometrics Toolbox™ calls simple returns *periodic*, and continuous returns are the default. Otherwise, the functionality between the set of functions is identical. This example concentrates on the Financial Toolbox functions.

In the simple return formula, $r_s(t)$ is the percentage change (*PC*) in $p_s(t-1)$ over the interval $[t-1,t]$

$$PC = \frac{p_s(t)}{p_s(t-1)} - 1$$

$$p_s(t) = p_s(t-1) + PC \cdot p_s(t-1)\,.$$

For positive prices, the range of *PC* is $(-1,\infty)$, that is, anything from a 100% loss (p_s: $p_s(t-1) \rightarrow 0$) to unlimited gain. The recursion in the second equation gives the subsequent prices; $p_s(t)$ is computed from $p_s(t-1)$ by adding a percentage of $p_s(t-1)$.

Furthermore, you can aggregate simple returns through time using the formula

$$\frac{p_s(T)}{p_s(1)} - 1 = \prod_{t=2}^{T} (r_s(t) + 1) - 1,$$

where the left-hand side represents the simple return over the entire interval $[0,T]$.

Continuous returns add 1 to PC to move the range to $(0,\infty)$, the domain of the real logarithm. Continuous returns have the time aggregation property

$$\log\left(\frac{p_c(T)}{p_c(1)} - 1\right) = \log\left(\prod_{t=2}^{T}\left(\frac{p_c(t)}{p_c(t-1)}\right)\right) = \sum_{t=2}^{T}\log\left(\frac{p_c(t)}{p_c(t-1)}\right) = \sum_{t=2}^{T} r_c(t)\,.$$

This transformation ensures additivity of compound returns.

If negative prices are allowed, the range of simple returns PC expands to $(-\infty,\infty)$, that is, anything from unlimited loss to unlimited gain. In the formula for continuous returns, logarithms of negative numbers are unavoidable. The logarithm of a negative number is not a mathematical problem because the complex logarithm (the MATLAB default) interprets negative numbers as complex numbers with phase angle $\pm\pi$, so that, for example,

$$-2 = 2e^{i\pi}$$

$$\log(- 2) = 2 + i\pi$$

If $x < 0$, $\log(x) = \log(|x|) \pm i\pi$. The log of a negative number has an imaginary part of $\pm\pi$. The log of 0 is undefined because the range of the exponential $e^{i\theta}$ is positive. Therefore, zero prices (that is, free exchanges) are unsupported.

Analysis of Negative Price Returns

To illustrate negative price inputs, consider the following price series and its simple returns.

```
p = [3; 1; -2; -1; 1]
```

```
p =

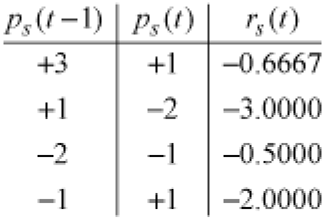
     3
     1
    -2
    -1
     1
```

```
rs = tick2ret(p)
```

```
rs =

   -0.6667
   -3.0000
   -0.5000
   -2.0000
```

This table summarizes the recursions.



$p_s(t-1)$	$p_s(t)$	$r_s(t)$
+3	+1	−0.6667
+1	−2	−3.0000
−2	−1	−0.5000
−1	+1	−2.0000

The returns have the correct size (66%, 300%, 50%, 200%), but do they have the correct sign? If you interpret negative returns as losses, as with the positive price series, the signs seem wrong—the last two returns should be gains (that is, if you interpret less negative to be a gain). However, if you interpret the negative returns by the formula

$$p_S(t) = p_S(t - 1) + PC \cdot p_S(t - 1),$$

which requires the signs, the last two negative percentage changes multiply *negative* prices $p_s(t - 1)$, which produces *positive* additions to $p_s(t - 1)$. Briefly, a negative return on a negative price produces a positive price movement. The returns are correct.

The round trip produced by `ret2tick` returns the original price series.

```
ps = ret2tick(rs,StartPrice=3)
```

```
ps =

     3
     1
    -2
    -1
     1
```

Also, the following computations shows that time aggregation holds.

```
p(5)/p(1) - 1
```

```
ans =

   -0.6667
```

```
prod(rs + 1) - 1
```

```
ans =

   -0.6667
```

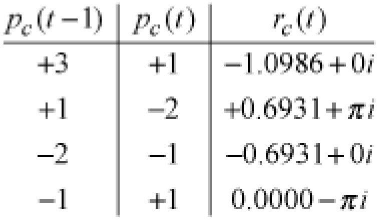
For continuous returns, negative price ratios $p_c(t)/p_c(t - 1)$ are interpreted as complex numbers with phase angles ±*π*, and the complex logarithm is invoked.

```
rc = tick2ret(p,Method="continuous")
```

```
rc =

  -1.0986 + 0.0000i
   0.6931 + 3.1416i
  -0.6931 + 0.0000i
   0.0000 - 3.1416i
```

This table summarizes the recursions.



$p_c(t-1)$	$p_c(t)$	$r_c(t)$
+3	+1	$-1.0986+0i$
+1	−2	$+0.6931+\pi i$
−2	−1	$-0.6931+0i$
−1	+1	$0.0000-\pi i$

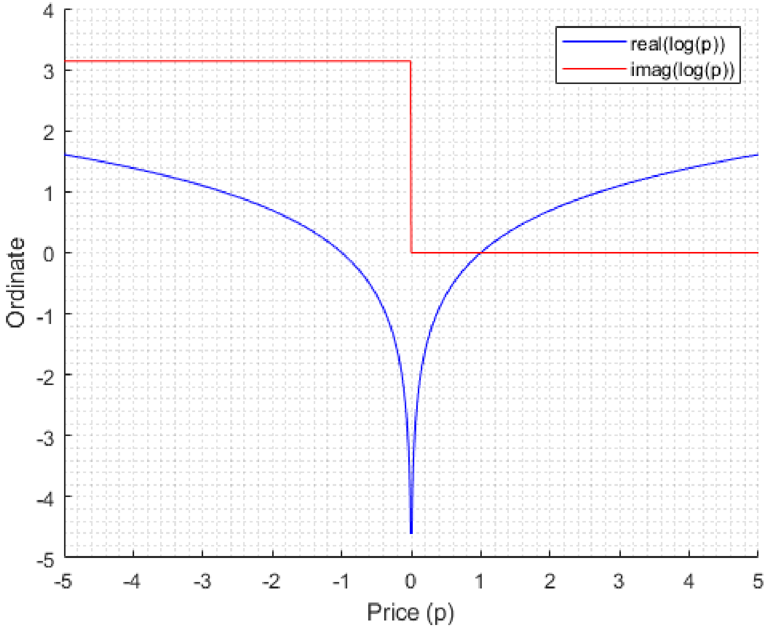
The real part shows the trend in the absolute price series. When $|p_c(t-1)| < |p_c(t)|$, that is, when prices move away from zero, $r_c(t)$ has a positive real part. When $|p_c(t-1)| > |p_c(t)|$, that is, when prices move toward zero, $r_c(t)$ has a negative real part. When $|p_c(t-1)| = |p_c(t)|$, that is, when the absolute size of the prices is unchanged, $r_c(t)$ has a zero real part. For positive price series, where the absolute series is the same as the series itself, the real part has its usual meaning.

The imaginary part shows changes of sign in the price series. When $p_c(t-1) > 0$ and $p_c(t) < 0$, that is, when prices move from investments to divestments, $r_c(t)$ has a positive imaginary part ($+\pi$). When $p_c(t-1) < 0$ and $p_c(t) > 0$, that is, when prices move from divestments to investments, $r_c(t)$ has a negative imaginary part ($-\pi$). When the sign of the prices is unchanged, $r_c(t)$ has a zero imaginary part. For positive price series, changes of sign are irrelevant, and the imaginary part conveys no information (0).

Visualization of Complex Returns

Complex continuous returns contain a lot of information. Visualizing the information can help you to interpret the complex returns. The following code plots the real and imaginary parts of the logarithm on either side of zero.

```
p = -5:0.01:5;
hold on
plot(p,real(log(p)),"b")
plot(p,imag(log(p)),"r")
xticks(-5:5)
xlabel("Price (p)")
ylabel("Ordinate")
legend(["real(log(p))" "imag(log(p))"],AutoUpdate=false)
grid minor
```



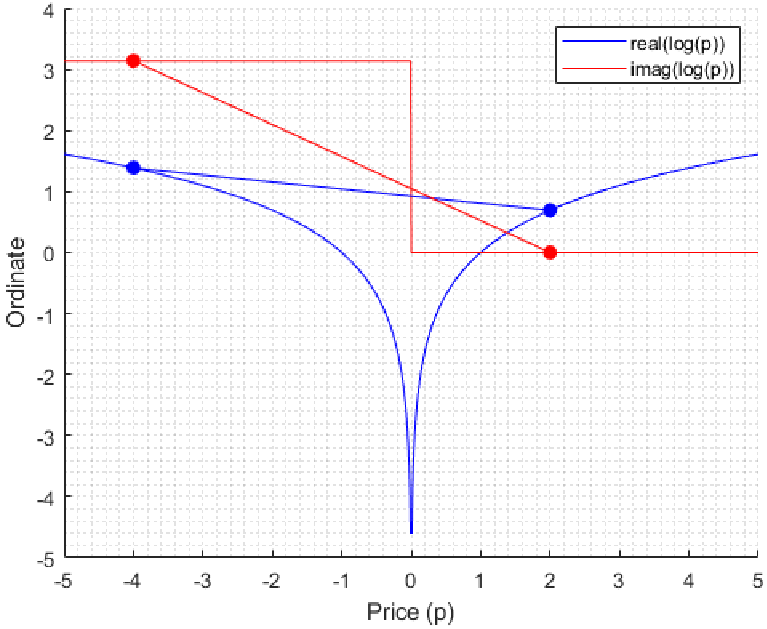
Due to the following identity

$$
\begin{aligned}
r_c(t) &= \log\left(\frac{p_c(t)}{p_c(t-1)}\right) \\
&= \log(p_c(t)) - \log(p_c(t-1)) \\
&= \underbrace{[\mathrm{real}(\log(p_c(t)) - \mathrm{real}(\log(p_c(t-1)))]}_{\text{blue curve}} + \underbrace{[\mathrm{imag}(\log(p_c(t))) - \mathrm{imag}(\log(p_c(t-1)))]}_{\text{red curve}} \cdot i,
\end{aligned}
$$

you can read the real part of a continuous return as a difference in ordinates on the blue graph, and you can read the imaginary part as a difference in ordinates on the red graph. Absolute price movements toward zero result in a negative real part and absolute price movements away from zero result in a positive real part. Likewise, changes of sign result in a jump of $\pm\pi$ in the imaginary part, with the sign change depending on the direction of the move.

For example, the plot below superimposes the real and imaginary parts of the logarithm at prices $p = -4$ and $p = 2$, with lines to help visualize their differences.

```
p = [-4; 2];
plot(p,real(log(p)),"bo-",MarkerFaceColor="b")
plot(p,imag(log(p)),"ro-",MarkerFaceColor="r")
hold off
```



If $p_c(t-1) = -4$ and $p_c(t) = 2$, the real part of $\log(p_c(t)) - \log(p_c(t-1))$ is negative (line slopes down), corresponding to a decrease in absolute price. The imaginary part is $0 - \pi = -\pi$, corresponding to a change of sign from negative to positive. If the direction of the price movement is reversed, so that $p_c(t-1) = 2$ and $p_c(t) = -4$, the positive difference in the real part corresponds to an increase in absolute price, and the positive difference in the imaginary part corresponds to a change of sign from positive to negative.

If you convert the continuous returns $r_c(t) = \log(p_c(t)/p_c(t-1))$ to simple returns $r_s = (p_s(t)/p_s(t-1) - 1)$ by the following computation, the result is the same simple returns series as before.

```
rs = exp(rc) - 1
```

```
rs =

  -0.6667 + 0.0000i
  -3.0000 + 0.0000i
  -0.5000 + 0.0000i
  -2.0000 - 0.0000i
```

You can complete the round trip, which results in the expected price series, by the computation

```
pc = ret2tick(rc,Method="continuous",StartPrice=3)
```

```
pc =

   3.0000 + 0.0000i
   1.0000 + 0.0000i
  -2.0000 + 0.0000i
  -1.0000 + 0.0000i
   1.0000 + 0.0000i
```

Conclusion

Complex continuous returns are a necessary intermediary when considering logarithms of negative price ratios. `tick2ret` computes a continuous complex extension of the function on the positive real axis. The logarithm maintains the additivity property, used when computing multiperiod returns.

Because the extensible logarithm implemented in MATLAB, current implementations of Computational Finance tools that accept prices and returns behave logically with negative prices. The interpretation of complex-valued results can be unfamiliar at first, but as shown, the results are meaningful and explicable.

More About

- "Work with Negative Interest Rates Using Functions" (Financial Instruments Toolbox)

Pricing and Analyzing Equity Derivatives

In this section...

Introduction

These toolbox functions compute prices, sensitivities, and profits for portfolios of options or other equity derivatives. They use the Black-Scholes model for European options and the binomial model for American options. Such measures are useful for managing portfolios and for executing collars, hedges, and straddles:

- A collar is an interest-rate option that guarantees that the rate on a floating-rate loan will not exceed a certain upper level nor fall below a lower level. It is designed to protect an investor against wide fluctuations in interest rates.
- A hedge is a securities transaction that reduces or offsets the risk on an existing investment position.
- A straddle is a strategy used in trading options or futures. It involves simultaneously purchasing put and call options with the same exercise price and expiration date, and it is most profitable when the price of the underlying security is very volatile.

Sensitivity Measures

There are six basic sensitivity measures associated with option pricing: delta, gamma, lambda, rho, theta, and vega — the "greeks." The toolbox provides functions for calculating each sensitivity and for implied volatility.

Delta

Delta of a derivative security is the rate of change of its price relative to the price of the underlying asset. It is the first derivative of the curve that relates the price of the derivative to the price of the underlying security. When delta is large, the price of the derivative is sensitive to small changes in the price of the underlying security.

Gamma

Gamma of a derivative security is the rate of change of delta relative to the price of the underlying asset; that is, the second derivative of the option price relative to the security price. When gamma is small, the change in delta is small. This sensitivity measure is important for deciding how much to adjust a hedge position.

Lambda

Lambda, also known as the elasticity of an option, represents the percentage change in the price of an option relative to a 1% change in the price of the underlying security.

Rho

Rho is the rate of change in option price relative to the risk-free interest rate.

Theta

Theta is the rate of change in the price of a derivative security relative to time. Theta is usually small or negative since the value of an option tends to drop as it approaches maturity.

Vega

Vega is the rate of change in the price of a derivative security relative to the volatility of the underlying security. When vega is large the security is sensitive to small changes in volatility. For example, options traders often must decide whether to buy an option to hedge against vega or gamma. The hedge selected usually depends upon how frequently one rebalances a hedge position and also upon the standard deviation of the price of the underlying asset (the volatility). If the standard deviation is changing rapidly, balancing against vega is preferable.

Implied Volatility

The implied volatility of an option is the standard deviation that makes an option price equal to the market price. It helps determine a market estimate for the future volatility of a stock and provides the input volatility (when needed) to the other Black-Scholes functions.

Analysis Models

Toolbox functions for analyzing equity derivatives use the Black-Scholes model for European options and the binomial model for American options. The Black-Scholes model makes several assumptions about the underlying securities and their behavior. The Black-Scholes model was the first complete mathematical model for pricing options, developed by Fischer Black and Myron Scholes. It examines market price, strike price, volatility, time to expiration, and interest rates. It is limited to only certain kinds of options.

The binomial model, on the other hand, makes far fewer assumptions about the processes underlying an option. A binomial model is a method of pricing options or other equity derivatives in which the probability over time of each possible price follows a binomial distribution. The basic assumption is that prices can move to only two values (one higher and one lower) over any short time period. For further explanation, see Options, Futures, and Other Derivatives by John Hull in “Bibliography” on page A-2.

Black-Scholes Model

Using the Black-Scholes model entails several assumptions:

- The prices of the underlying asset follow an Ito process. (See Hull on page A-3, page 222.)
- The option can be exercised only on its expiration date (European option).
- Short selling is permitted.
- There are no transaction costs.
- All securities are divisible.
- There is no riskless arbitrage (where arbitrage is the purchase of securities on one market for immediate resale on another market to profit from a price or currency discrepancy).
- Trading is a continuous process.
- The risk-free interest rate is constant and remains the same for all maturities.

If any of these assumptions is untrue, Black-Scholes may not be an appropriate model.

To illustrate toolbox Black-Scholes functions, this example computes the call and put prices of a European option and its delta, gamma, lambda, and implied volatility. The asset price is $100.00, the exercise price is $95.00, the risk-free interest rate is 10%, the time to maturity is 0.25 years, the volatility is 0.50, and the dividend rate is 0. Simply executing the toolbox functions

```
[OptCall, OptPut] = blsprice(100, 95, 0.10, 0.25, 0.50, 0)
[CallVal, PutVal] = blsdelta(100, 95, 0.10, 0.25, 0.50, 0)
GammaVal = blsgamma(100, 95, 0.10, 0.25, 0.50, 0)
VegaVal = blsvega(100, 95, 0.10, 0.25, 0.50, 0)
[LamCall, LamPut] = blslambda(100, 95, 0.10, 0.25, 0.50, 0)
```

```
OptCall =

   13.6953

OptPut =

    6.3497

CallVal =

    0.6665

PutVal =

   -0.3335

GammaVal =

    0.0145

VegaVal =

   18.1843

LamCall =

    4.8664

LamPut =

   -5.2528
```

To summarize:

- The option call price `OptCall` = $13.70
- The option put price `OptPut` = $6.35
- delta for a call `CallVal` = 0.6665 and delta for a put `PutVal` = -0.3335
- gamma `GammaVal` = 0.0145

- vega VegaVal = 18.1843
- lambda for a call LamCall = 4.8664 and lambda for a put LamPut = –5.2528

Now as a computation check, find the implied volatility of the option using the call option price from blsprice.

```
Volatility = blsimpv(100, 95, 0.10, 0.25, OptCall)
```

```
Volatility =

    0.5000
```

The function returns an implied volatility of 0.500, the original blsprice input.

Binomial Model

The binomial model for pricing options or other equity derivatives assumes that the probability over time of each possible price follows a binomial distribution. The basic assumption is that prices can move to only two values, one up and one down, over any short time period. Plotting the two values, and then the subsequent two values each, and then the subsequent two values each, and so on over time, is known as “building a binomial tree.”. This model applies to American options, which can be exercised any time up to and including their expiration date.

This example prices an American call option using a binomial model. Again, the asset price is $100.00, the exercise price is $95.00, the risk-free interest rate is 10%, and the time to maturity is 0.25 years. It computes the tree in increments of 0.05 years, so there are 0.25/0.05 = 5 periods in the example. The volatility is 0.50, this is a call (flag = 1), the dividend rate is 0, and it pays a dividend of $5.00 after three periods (an ex-dividend date). Executing the toolbox function

```
[StockPrice, OptionPrice] = binprice(100, 95, 0.10, 0.25,...
0.05,  0.50, 1, 0, 5.0, 3)
```

returns the tree of prices of the underlying asset

```
StockPrice =

  100.0000  111.2713  123.8732  137.9629  148.6915  166.2807

         0         0    1.3481    2.7402    5.5698   11.3211
         0         0         0         0         0         0
         0         0         0         0         0         0
         0         0         0         0         0         0
```

The output from the binomial function is a binary tree. Read the StockPrice matrix this way: column 1 shows the price for period 0, column 2 shows the up and down prices for period 1, column 3 shows the up-up, up-down, and down-down prices for period 2, and so on. Ignore the zeros. The

`OptionPrice` matrix gives the associated option value for each node in the price tree. Ignore the zeros that correspond to a zero in the price tree.

About Life Tables

Life tables are used for life insurance and work with the probability distribution of human mortality. This distribution, which is age-dependent, has several characteristic features that are consequences of biological, cultural, and behavioral factors. Usually, the practitioners of life studies use life tables that contain age-dependent series for specific demographics. The tables are in a standard format with standard notation that is specific to the life studies field. An example of a life table is shown in Table 1 from CDC life tables for the United States.

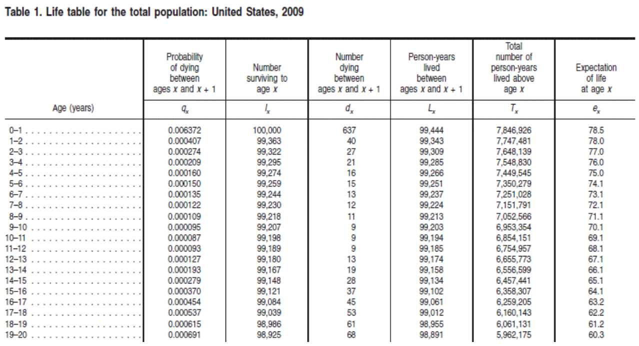

Table 1. Life table for the total population: United States, 2009

	Probability of dying between ages *x* and *x* + 1	Number surviving to age *x*	Number dying between ages *x* and *x* + 1	Person-years lived between ages *x* and *x* + 1	Total number of person-years lived above age *x*	Expectation of life at age *x*
Age (years)	q_x	l_x	d_x	L_x	T_x	e_x
0–1	0.006372	100,000	637	99,444	7,846,926	78.5
1–2	0.000407	99,363	40	99,343	7,747,481	78.0

13–14	0.000193	99,167	19	99,158	6,556,599	66.1
14–15	0.000279	99,148	28	99,134	6,457,441	65.1
15–16	0.000370	99,121	37	99,102	6,358,307	64.1
16–17	0.000454	99,084	45	99,061	6,259,205	63.2
17–18	0.000537	99,039	53	99,012	6,160,143	62.2
18–19	0.000615	98,986	61	98,955	6,061,131	61.2
19–20	0.000691	98,925	68	98,891	5,962,175	60.3

Often, these life tables can have numerous variations such as abridged tables (which pose challenges due to the granularity of the data) and different termination criteria (that can make it difficult to compare tables or to compute life expectancies).

Most raw life tables have one or more of the first three series in this table (q_x, l_x, and d_x) and the notation for these three series is standard in the field.

- The q_x series is basically the discrete hazard function for human mortality.
- The l_x series is the survival function multiplied by a radix of 100,000.
- The d_x series is the discrete probability density for the distribution as a function of age.

Financial Toolbox can handle arbitrary life table data supporting several standard models of mortality and provides various interpolation methods to calibrate and analyze the life table data.

Although primarily designed for life insurance applications, the life tables functions (`lifetableconv`, `lifetablefit`, and `lifetablegen` can also be used by social scientists, behavioral psychologists, public health officials, and medical researchers.

Life Tables Theory

Life tables are based on hazard functions and survival functions which are, in turn, derived from probability distributions. Specifically, given a continuous probability distribution, its cumulative distribution function is F(x) and its probability density function is f(x) = d F(x)/dx.

For the analysis of mortality, the random variable of interest X is the distribution of ages at which individuals die within a population. So, the probability that someone dies by age x is

$$\Pr[X \leq x] = F(x)$$

The survival function, ($s(x)$), which characterizes the probability that an individual lives beyond a specified age x > `0`, is

$$s(x) = Pr[X > x]$$
$$= 1 - F(x)$$

For a continuous probability distribution, the hazard function is a function of the survival function with

$$h(x) = \lim_{\Delta x \to 0} \frac{Pr[x \le X < x + \Delta x | X \ge x]}{\Delta x}$$
$$= -\frac{1}{s(x)}\frac{d(s(x))}{dx}$$

and the survival functions is a function of the hazard function with

$$s(x) = \exp\left(-\int_0^x h(\xi)d\xi\right)$$

Life table models generally specify either the hazard function or the survival function. However, life tables are discrete and work with discrete versions of the hazard and survival functions. Three series are used for life tables and the notation is the convention. The discrete hazard function is denoted as

$$q_x \approx h(x)$$
$$= 1 - \frac{s(x+1)}{s(x)}$$

which is the probability a person at age x dies by age $x + 1$ (where x is in years). The discrete survival function is presented in terms of an initial number of survivors at birth called the life table radix (which is usually 100,000 individuals) and is denoted as

$$l_x = l_0 s(x)$$

with radix l_0 = `100000`. This number, l_x, represents the number of individuals out of 100,000 at birth who are still alive at age x.

A third series is related to the probability density function which is the number of "standardized" deaths in a given year denoted as

$$d_x = l_x - l_{x+1}$$

Based on a few additional rules about how to initialize and terminate these series, any one series can be derived from any of the other series.

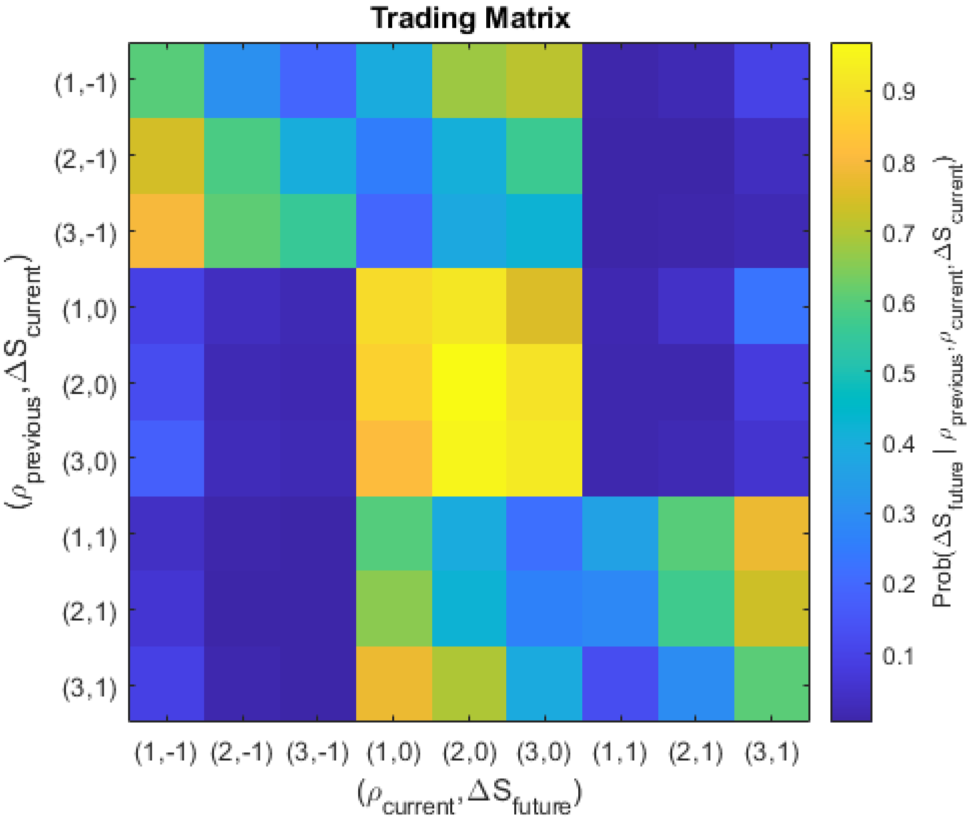
Machine Learning for Statistical Arbitrage: Introduction



Machine learning techniques for processing large amounts of data are broadly applicable in computational finance. The series of examples introduced in this topic provides a general workflow, illustrating how capabilities in MATLAB apply to a specific problem in financial engineering. The workflow is problem-oriented, exploratory, and guided by the data and the resulting analysis. The overall approach, however, is useful for constructing applications in many areas.

The workflow consists of these actions:

- Formulate a simple approach to algorithmic trading, through an analysis of market microstructure, with the goal of identifying real-time arbitrage opportunities.
- Use a large sample of exchange data to track order dynamics of a single security on a single day, selectively processing the data to develop relevant statistical measures.
- Create a model of intraday dynamics conditioned on a selection of hyperparameters introduced during feature engineering and development.
- Evaluate hyperparameter tunings using a supervising objective that computes cash returned on a model-based trading strategy.
- Optimize the trading strategy using different machine learning algorithms.
- Suggest modifications for further development.

The workflow is separated into three examples:

1. “Machine Learning for Statistical Arbitrage I: Data Management and Visualization” on page 2-50
2. “Machine Learning for Statistical Arbitrage II: Feature Engineering and Model Development” on page 2-60
3. “Machine Learning for Statistical Arbitrage III: Training, Tuning, and Prediction” on page 2-71

For more information about general workflows for machine learning, see:

- “Machine Learning in MATLAB”
- “Supervised Learning Workflow and Algorithms”

Machine Learning for Statistical Arbitrage I: Data Management and Visualization

This example shows techniques for managing, processing, and visualizing large amounts of financial data in MATLAB®. It is part of a series of related examples on machine learning for statistical arbitrage (see “Machine Learning Applications”).

Working with Big Data

Financial markets, with electronic exchanges such as NASDAQ executing orders on a timescale of milliseconds, generate vast amounts of data. Data streams can be mined for statistical arbitrage opportunities, but traditional methods for processing and storing dynamic analytic information can be overwhelmed by big data. Fortunately, new computational approaches have emerged, and MATLAB has an array of tools for implementing them.

Main computer memory provides high-speed access but limited capacity, whereas external storage offers low-speed access but potentially unlimited capacity. Computation takes place in memory. The computer recalls data and results from external storage.

Data Files

This example uses one trading day of NASDAQ exchange data [2] on one security (INTC) in a sample provided by LOBSTER [1] and included with Financial Toolbox™ in the zip file `LOBSTER_SampleFile_INTC_2012-06-21_5.zip`. Extract the contents of the zip file into your current folder. The expanded files, including two CSV files of data and the text file `LOBSTER_SampleFiles_ReadMe.txt`, consume 93.7 MB of memory.

```
unzip("LOBSTER_SampleFile_INTC_2012-06-21_5.zip");
```

The data describes the intraday evolution of the *limit order book* (LOB), which is the record of *market orders* (best price), *limit orders* (designated price), and resulting buys and sells. The data includes the precise time of these events, with orders tracked from arrival until cancellation or execution. At each moment in the trading day, orders on both the buy and sell side of the LOB exist at various *levels* away from the midprice between the lowest ask (order to sell) and the highest bid (order to buy).

Level 5 data (five levels away from the midprice on either side) is contained in two CSV files. Extract the trading date from the message file name.

```
MSGFileName = "INTC_2012-06-21_34200000_57600000_message_5.csv";   % Message file (description o
LOBFileName = "INTC_2012-06-21_34200000_57600000_orderbook_5.csv"; % Data file

[ticker,rem] = strtok(MSGFileName,'_');
date = strtok(rem,'_');
```

Data Storage

Daily data streams accumulate and need to be stored. A *datastore* is a repository for collections of data that are too big to fit in memory.

Use `tabularTextDatastore` to create datastores for the message and data files. Because the files contain data with different formats, create the datastores separately. Ignore generic column headers (for example, `VarName1`) by setting the `'ReadVariableNames'` name-value pair argument to `false`. Replace the headers with descriptive variable names obtained from

LOBSTER_SampleFiles_ReadMe.txt. Set the 'ReadSize' name-value pair argument to 'file' to allow similarly formatted files to be appended to existing datastores at the end of each trading day.

```
DSMSG = tabularTextDatastore(MSGFileName,'ReadVariableNames',false,'ReadSize','file');
DSMSG.VariableNames = ["Time","Type","OrderID","Size","Price","Direction"];

DSLOB = tabularTextDatastore(LOBFileName,'ReadVariableNames',false,'ReadSize','file');
DSLOB.VariableNames = ["AskPrice1","AskSize1","BidPrice1","BidSize1",...
                       "AskPrice2","AskSize2","BidPrice2","BidSize2",...
                       "AskPrice3","AskSize3","BidPrice3","BidSize3",...
                       "AskPrice4","AskSize4","BidPrice4","BidSize4",...
                       "AskPrice5","AskSize5","BidPrice5","BidSize5"];
```

Create a combined datastore by selecting Time and the level 3 data.

```
TimeVariable = "Time";
DSMSG.SelectedVariableNames = TimeVariable;

LOB3Variables = ["AskPrice1","AskSize1","BidPrice1","BidSize1",...
                 "AskPrice2","AskSize2","BidPrice2","BidSize2",...
                 "AskPrice3","AskSize3","BidPrice3","BidSize3"];
DSLOB.SelectedVariableNames = LOB3Variables;

DS = combine(DSMSG,DSLOB);
```

You can preview the first few rows in the combined datastore without loading data into memory.

```
DSPreview = preview(DS);
LOBPreview = DSPreview(:,1:5)
```

```
LOBPreview=8×5 table
    Time     AskPrice1    AskSize1    BidPrice1    BidSize1
    _____    _________    ________    _________    ________

    34200    2.752e+05       66       2.751e+05      400   
    34200    2.752e+05      166       2.751e+05      400   
    34200    2.752e+05      166       2.751e+05      400   
    34200    2.752e+05      166       2.751e+05      400   
    34200    2.752e+05      166       2.751e+05      300   
    34200    2.752e+05      166       2.751e+05      300   
    34200    2.752e+05      166       2.751e+05      300   
    34200    2.752e+05      166       2.751e+05      300   
```

The preview shows asks and bids *at the touch*, meaning the level 1 data, which is closest to the midprice. Time units are seconds after midnight, price units are dollar amounts times 10,000, and size units are the number of shares (see LOBSTER_SampleFiles_ReadMe.txt).

Tall Arrays and Timetables

Tall arrays work with out-of-memory data backed by a datastore using the MapReduce technique (see “Tall Arrays for Out-of-Memory Data”). When you use MapReduce, tall arrays remain unevaluated until you execute specific computations that use the data.

Set the execution environment for MapReduce to the local MATLAB session, instead of using Parallel Computing Toolbox™, by calling mapreducer(0). Then, create a tall array from the datastore DS by using tall. Preview the data in the tall array.

```
mapreducer(0)
DT = tall(DS);

DTPreview = DT(:,1:5)
```

```
DTPreview =

  Mx5 tall table

    Time     AskPrice1    AskSize1    BidPrice1    BidSize1
    _____    _________    ________    _________    ________

    34200    2.752e+05      66       2.751e+05      400
    34200    2.752e+05     166       2.751e+05      400
    34200    2.752e+05     166       2.751e+05      400
    34200    2.752e+05     166       2.751e+05      400
    34200    2.752e+05     166       2.751e+05      300
    34200    2.752e+05     166       2.751e+05      300
    34200    2.752e+05     166       2.751e+05      300
    34200    2.752e+05     166       2.751e+05      300
      :          :           :            :           :
      :          :           :            :           :
```

Timetables allow you to perform operations specific to time series (see “Create Timetables”). Because the LOB data consists of concurrent time series, convert DT to a tall timetable.

```
DT.Time = seconds(DT.Time); % Cast time as a duration from midnight.
DTT = table2timetable(DT);

DTTPreview = DTT(:,1:4)
```

```
DTTPreview =

  Mx4 tall timetable

      Time       AskPrice1    AskSize1    BidPrice1    BidSize1

```

Because all the data is in the datastore, the workspace uses little memory.

Preprocess and Evaluate Data

Tall arrays allow preprocessing, or *queuing*, of computations before they are evaluated, which improves memory management in the workspace.

Midprice S and imbalance index I are used to model LOB dynamics. To queue their computations, define them, and the time base, in terms of DTT.

```
timeBase = DTT.Time;
MidPrice = (DTT.BidPrice1 + DTT.AskPrice1)/2;

% LOB level 3 imbalance index:

lambda  = 0.5; % Hyperparameter
weights = exp(-(lambda)*[0 1 2]);
VAsk = weights(1)*DTT.AskSize1 + weights(2)*DTT.AskSize2 + weights(3)*DTT.AskSize3;
VBid = weights(1)*DTT.BidSize1 + weights(2)*DTT.BidSize2 + weights(3)*DTT.BidSize3;
ImbalanceIndex = (VBid-VAsk)./(VBid+VAsk);
```

The imbalance index is a weighted average of ask and bid volumes on either side of the midprice [3]. The imbalance index is a potential indicator of future price movements. The variable lambda is a *hyperparameter*, which is a parameter specified before training rather than estimated by the machine learning algorithm. A hyperparameter can influence the performance of the model. *Feature engineering* is the process of choosing domain-specific hyperparameters to use in machine learning algorithms. You can tune hyperparameters to optimize a trading strategy.

To bring preprocessed expressions into memory and evaluate them, use the gather function. This process is called *deferred evaluation*.

```
[t,S,I] = gather(timeBase,MidPrice,ImbalanceIndex);
```

```
Evaluating tall expression using the Local MATLAB Session:
- Pass 1 of 1: Completed in 2.8 sec
Evaluation completed in 3 sec
```

A single call to gather evaluates multiple preprocessed expressions with a single pass through the datastore.

Determine the sample size, which is the number of *ticks*, or updates, in the data.

```
numTicks = length(t)
```

```
numTicks = 581030
```

The daily LOB data contains 581,030 ticks.

Checkpoint Data

You can save both unevaluated and evaluated data to external storage for later use.

Prepend the time base with the date, and cast the result as a datetime array. Save the resulting datetime array, MidPrice, and ImbalanceIndex to a MAT-file in a specified location.

```
dateTimeBase = datetime(date) + timeBase;
Today = timetable(dateTimeBase,MidPrice,ImbalanceIndex)
```

```
Today =

  581,030x2 tall timetable

        dateTimeBase          MidPrice     ImbalanceIndex
    ____________________    __________    ______________

    21-Jun-2012 09:30:00    2.7515e+05         -0.205

             :                  :               :
             :                  :               :
```

```
location = fullfile(pwd,"ExchangeData",ticker,date);
write(location,Today,'FileType','mat')
```

```
Writing tall data to folder C:\TEMP\Bdoc23a_2213998_3568\ib570499\19\tp1e1da1c0\finance-ex97702888
Evaluating tall expression using the Local MATLAB Session:
- Pass 1 of 1: Completed in 3.5 sec
Evaluation completed in 3.8 sec
```

The file is written once, at the end of each trading day. The code saves the data to a file in a date-stamped folder. The series of ExchangeData subfolders serves as a historical data repository.

Alternatively, you can save workspace variables evaluated with gather directly to a MAT-file in the current folder.

```
save("LOBVars.mat","t","S","I")
```

In preparation for model validation later on, evaluate and add market order prices to the same file.

```
[MOBid,MOAsk] = gather(DTT.BidPrice1,DTT.AskPrice1);
```

```
Evaluating tall expression using the Local MATLAB Session:
- Pass 1 of 1: Completed in 2.4 sec
Evaluation completed in 2.4 sec
```

```
save("LOBVars.mat","MOBid","MOAsk","-append")
```

The remainder of this example uses only the unevaluated tall timetable DTT. Clear other variables from the workspace.

```
clearvars -except DTT
whos
```

```
  Name            Size            Bytes  Class    Attributes

  DTT       581,030x12             4746  tall
```

Data Visualization

To visualize large amounts of data, you must summarize, bin, or sample the data in some way to reduce the number of points plotted on the screen.

LOB Snapshot

One method of visualization is to evaluate only a selected subsample of the data. Create a snapshot of the LOB at a specific time of day (11 AM).

```
sampleTimeTarget = seconds(11*60*60);               % Seconds after midnight
sampleTimes = withtol(sampleTimeTarget,seconds(1)); % 1 second tolerance
sampleLOB = DTT(sampleTimes,:);

numTimes = gather(size(sampleLOB,1))
```

```
Evaluating tall expression using the Local MATLAB Session:
- Pass 1 of 1: Completed in 2.4 sec
Evaluation completed in 2.5 sec

numTimes = 23
```

There are 23 ticks within one second of 11 AM. For the snapshot, use the tick closest to the midtime.

```
sampleLOB = sampleLOB(round(numTimes/2),:);
sampleTime = sampleLOB.Time;

sampleBidPrices = [sampleLOB.BidPrice1,sampleLOB.BidPrice2,sampleLOB.BidPrice3];
sampleBidSizes  = [sampleLOB.BidSize1,sampleLOB.BidSize2,sampleLOB.BidSize3];
sampleAskPrices = [sampleLOB.AskPrice1,sampleLOB.AskPrice2,sampleLOB.AskPrice3];
sampleAskSizes  = [sampleLOB.AskSize1,sampleLOB.AskSize2,sampleLOB.AskSize3];

[sampleTime,sampleBidPrices,sampleBidSizes,sampleAskPrices,sampleAskSizes] = ...
    gather(sampleTime,sampleBidPrices,sampleBidSizes,sampleAskPrices,sampleAskSizes);
```

```
Evaluating tall expression using the Local MATLAB Session:
- Pass 1 of 2: Completed in 2.3 sec
- Pass 2 of 2: Completed in 2.6 sec
Evaluation completed in 5.4 sec
```

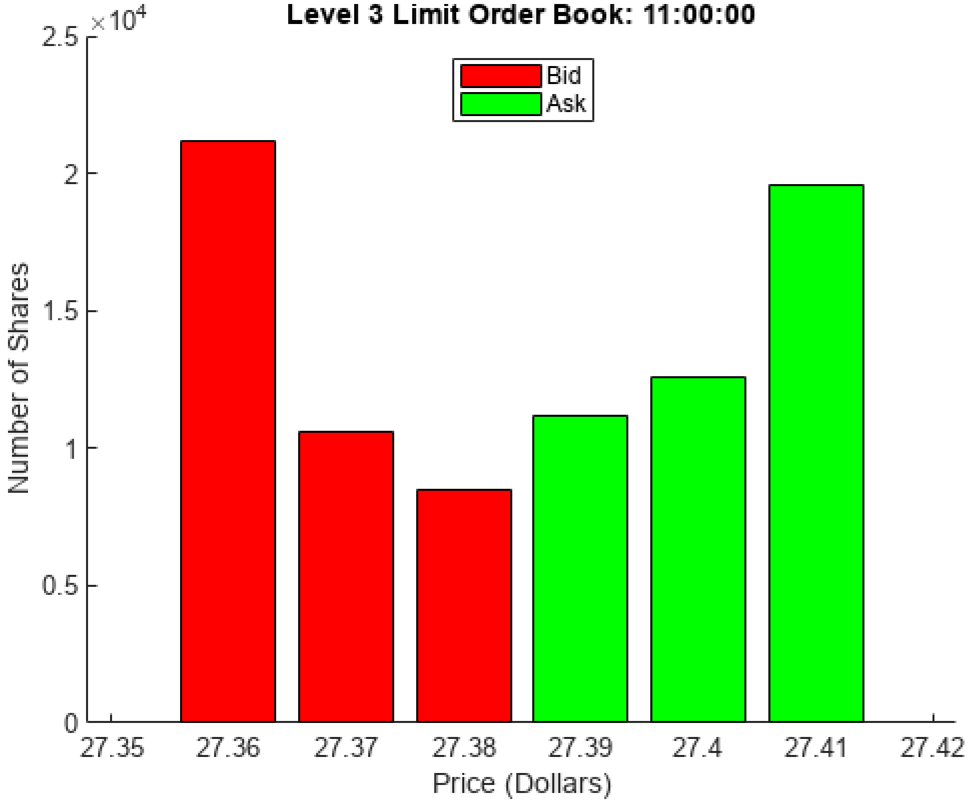
Visualize the limited data sample returned by `gather` by using `bar`.

```
figure
hold on

bar((sampleBidPrices/10000),sampleBidSizes,'r')
bar((sampleAskPrices/10000),sampleAskSizes,'g')
hold off

xlabel("Price (Dollars)")
ylabel("Number of Shares")
```

```
legend(["Bid","Ask"],'Location','North')
title(strcat("Level 3 Limit Order Book: ",datestr(sampleTime,"HH:MM:SS")))
```



Depth of Market

Some visualization functions work directly with tall arrays and do not require the use of `gather` (see “Visualization of Tall Arrays”). The functions automatically sample data to decrease pixel density. Visualize the level 3 intraday *depth of market,* which shows the time evolution of liquidity, by using `plot` with the tall timetable `DTT`.

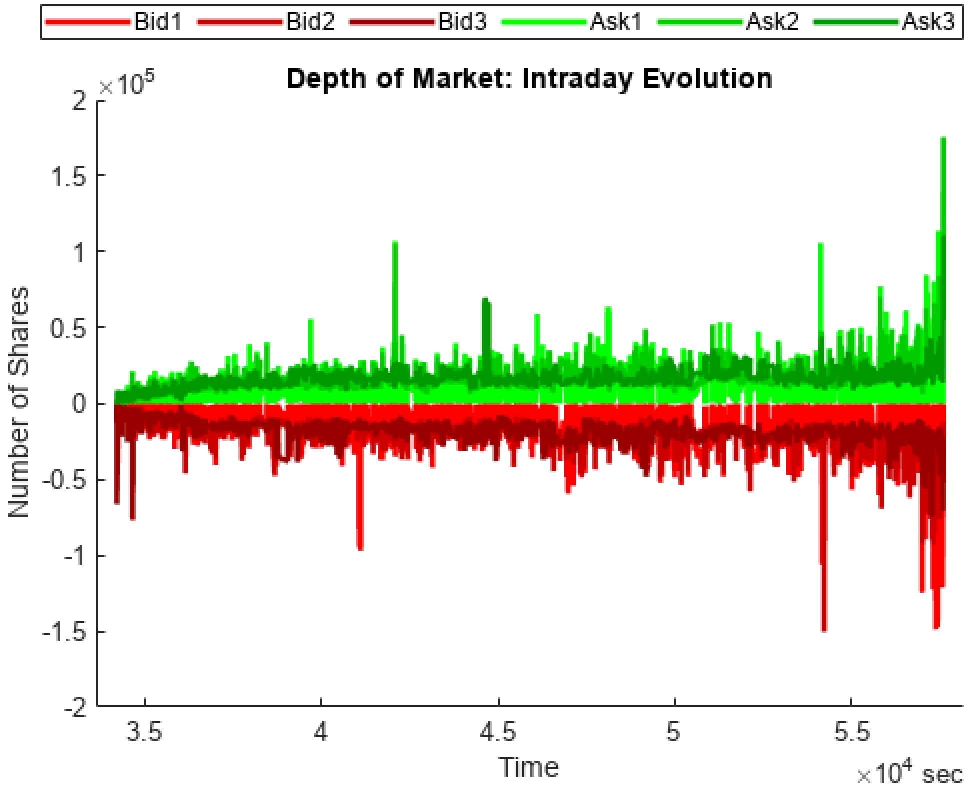
```
figure
hold on

plot(DTT.Time,-DTT.BidSize1,'Color',[1.0 0 0],'LineWidth',2)
plot(DTT.Time,-DTT.BidSize2,'Color',[0.8 0 0],'LineWidth',2)
plot(DTT.Time,-DTT.BidSize3,'Color',[0.6 0 0],'LineWidth',2)

plot(DTT.Time,DTT.AskSize1,'Color',[0 1.0 0],'LineWidth',2)
plot(DTT.Time,DTT.AskSize2,'Color',[0 0.8 0],'LineWidth',2)
plot(DTT.Time,DTT.AskSize3,'Color',[0 0.6 0],'LineWidth',2)

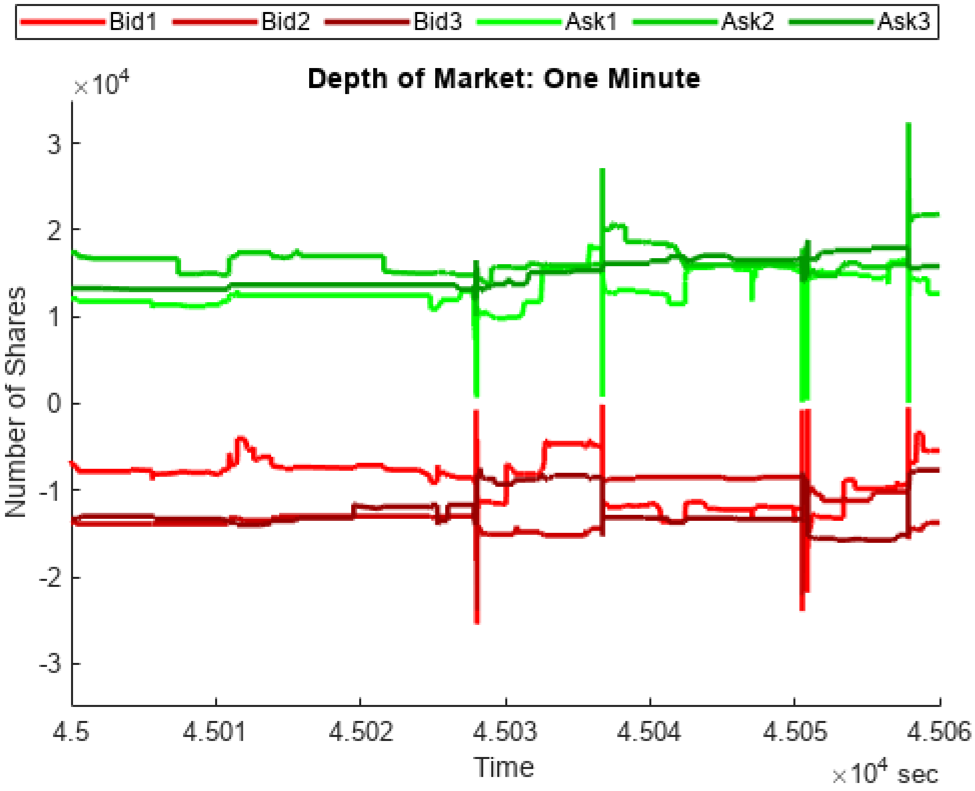
hold off

xlabel("Time")
ylabel("Number of Shares")
title("Depth of Market: Intraday Evolution")
legend(["Bid1","Bid2","Bid3","Ask1","Ask2","Ask3"],'Location','NorthOutside','Orientation','Hori
```



To display details, limit the time interval.

```
xlim(seconds([45000 45060]))
ylim([-35000 35000])
title("Depth of Market: One Minute")
```



Summary

This example introduces the basics of working with big data, both in and out of memory. It shows how to set up, combine, and update external datastores, then create tall arrays for preprocessing data without allocating variables in the MATLAB workspace. The `gather` function transfers data into the workspace for computation and further analysis. The example shows how to visualize the data through data sampling or by MATLAB plotting functions that work directly with out-of-memory data.

Machine Learning for Statistical Arbitrage II: Feature Engineering and Model Development

This example creates a continuous-time Markov model of limit order book (LOB) dynamics, and develops a strategy for algorithmic trading based on patterns observed in the data. It is part of a series of related examples on machine learning for statistical arbitrage (see “Machine Learning Applications”).

Exploratory Data Analysis

To predict the future behavior of a system, you need to discover patterns in historical data. The vast amount of data available from exchanges, such as NASDAQ, poses computational challenges while offering statistical opportunities. This example explores LOB data by looking for indicators of price momentum, following the approach in [4].

Raw Data

Load `LOBVars.mat`, the preprocessed LOB data set of the NASDAQ security INTC.

```
load LOBVars
```

The data set contains the following information for each order: the arrival time `t` (seconds from midnight), level 1 asking price `MOAsk`, level 1 bidding price `MOBid`, midprice `S`, and imbalance index `I`.

Create a plot that shows the intraday evolution of the LOB imbalance index `I` and midprice `S`.

```
figure

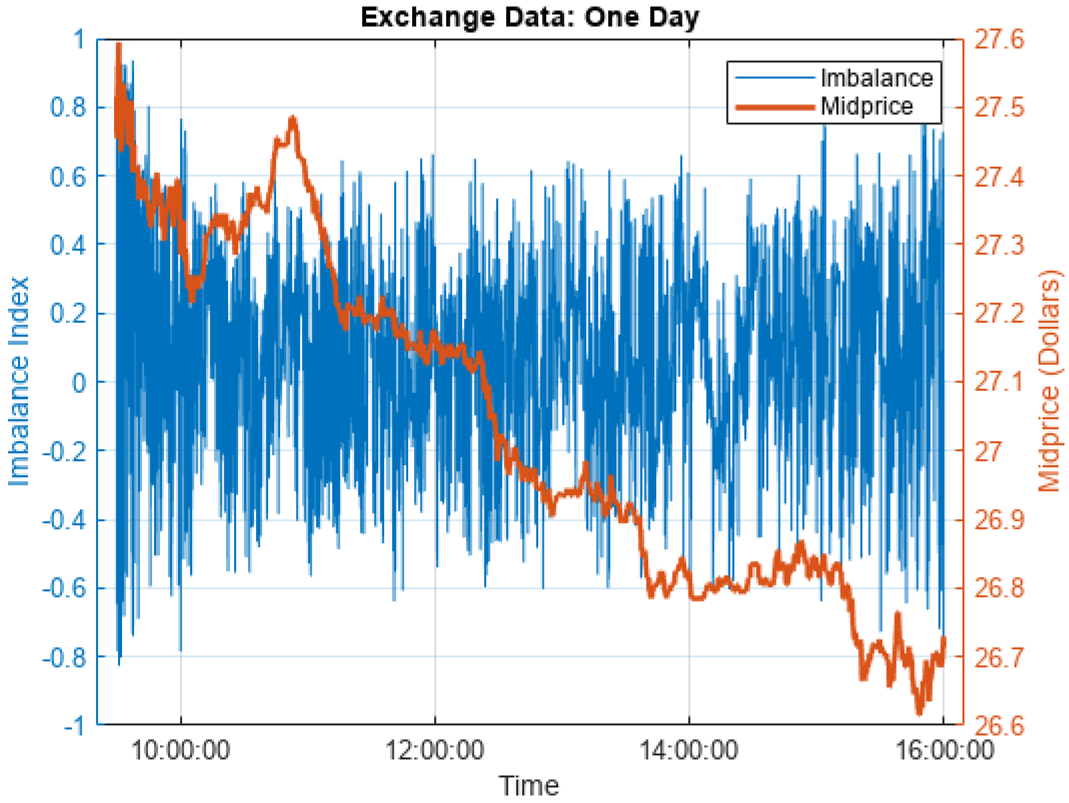
t.Format = "hh:mm:ss";

yyaxis left
plot(t,I)
ylabel("Imbalance Index")

yyaxis right
plot(t,S/10000,'LineWidth',2)
ylabel("Midprice (Dollars)")

xlabel("Time")

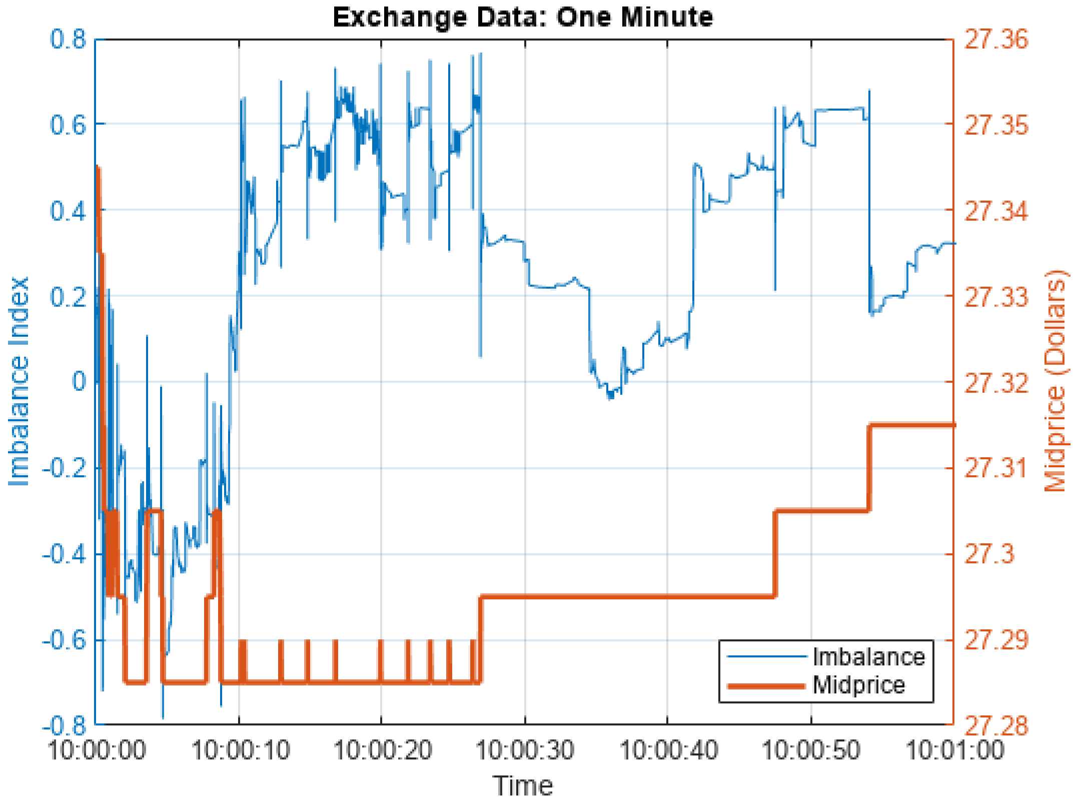
title('Exchange Data: One Day')
legend(["Imbalance","Midprice"],'Location','NE')
grid on
```



At this scale, the imbalance index gives no indication of future changes in the midprice.

To see more detail, limit the time scale to one minute.

```
timeRange = seconds([36000 36060]); % One minute after 10 AM, when prices were climbing
xlim(timeRange)
legend('Location','SE')
title("Exchange Data: One Minute")
```

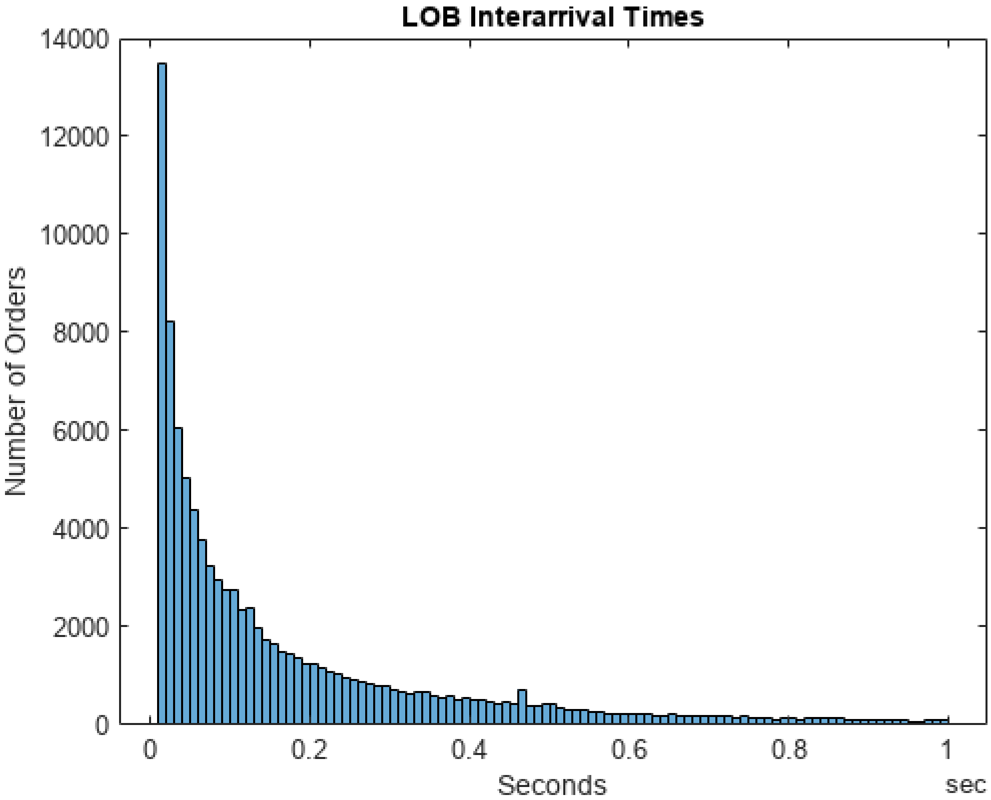


At this scale, sharp departures in the imbalance index align with corresponding departures in the midprice. If the relationship is predictive, meaning imbalances of a certain size forecast *future* price movements, then quantifying the relationship can provide statistical arbitrage opportunities.

Plot a histogram of the interarrival times in the LOB.

```
DT = diff(t); % Interarrival Times
DT.Format = "s";

figure
binEdges = seconds(0.01:0.01:1);
histogram(DT,binEdges)
xlabel("Seconds")
ylabel("Number of Orders")
title("LOB Interarrival Times")
```



Interarrival times follow the characteristic pattern of a Poisson process.

Compute the average wait time between orders by fitting an exponential distribution to the interarrival times.

```
DTAvg = expfit(DT)
```

```
DTAvg = duration
   0.040273 sec
```

Smoothed Data

The raw imbalance series I is erratic. To identify the most significant dynamic shifts, introduce a degree of smoothing dI, which is the number of backward ticks used to average the raw imbalance series.

```
dI = 10; % Hyperparameter
dTI = dI*DTAvg
```

```
dTI = duration
   0.40273 sec
```

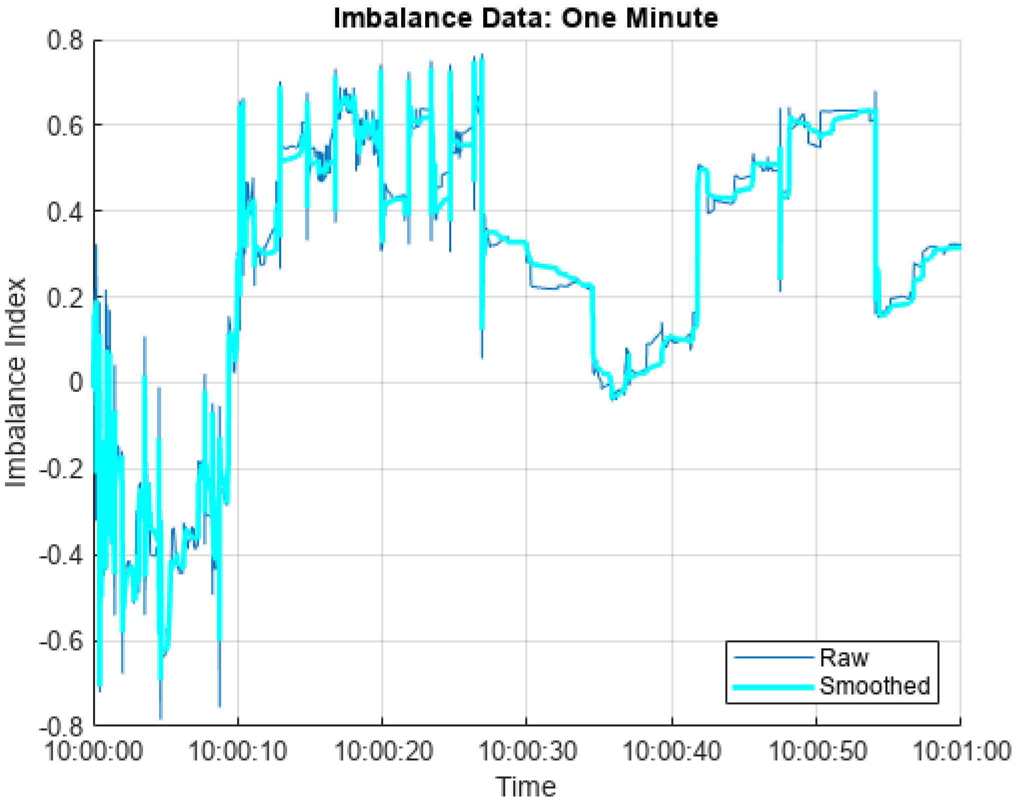
The setting corresponds to an interval of 10 ticks, or about 0.4 seconds on average. Smooth the imbalance indices over a trailing window.

```
sI = smoothdata(I,'movmean',[dI 0]);
```

Visualize the degree of smoothing to assess the volatility lost or retained.

```
figure
hold on
plot(t,I)
plot(t,sI,'c','LineWidth',2)
hold off

xlabel("Time")
xlim(timeRange)
ylabel("Imbalance Index")
title("Imbalance Data: One Minute")
legend(["Raw","Smoothed"],'Location','SE')
grid on
```



Discretized Data

To create a Markov model of the dynamics, collect the smoothed imbalance index `sI` into bins, discretizing it into a finite collection of states `rho` (ρ). The number of bins `numBins` is a hyperparameter.

```
numBins = 3; % Hyperparameter
binEdges = linspace(-1,1,numBins+1);
rho = discretize(sI,binEdges);
```

To model forecast performance, aggregate prices over a leading window. The number of ticks in a window `dS` is a hyperparameter.

```
dS = 20; % Hyperparameter
dTS = dS*DTAvg
```

```
dTS = duration
   0.80547 sec
```

The setting corresponds to an interval of 20 ticks, or about 0.8 seconds on average. Discretize price movements into three states DS (ΔS) given by the sign of the forward price change.

```
DS = NaN(size(S));
shiftS = S(dS+1:end);
DS(1:end-dS) = sign(shiftS-S(1:end-dS));
```

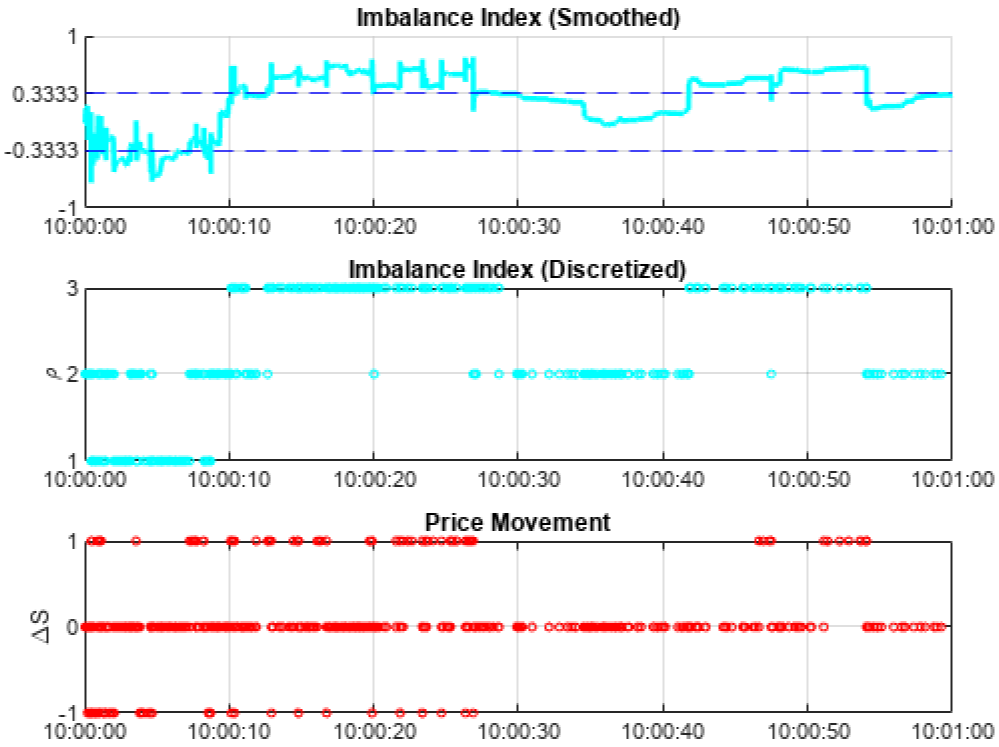
Visualize the discretized data.

```
figure

subplot(3,1,1)
hold on
plot(t,sI,'c','LineWidth',2)
for i = 2:numBins
    yline(binEdges(i),'b--');
end
hold off
xlim(timeRange)
ylim([-1 1])
yticks(binEdges)
title("Imbalance Index (Smoothed)")
grid on

subplot(3,1,2)
plot(t,rho,'co','MarkerSize',3)
xlim(timeRange)
ylim([1 numBins])
yticks(1:numBins)
ylabel("\rho")
title("Imbalance Index (Discretized)")
grid on

subplot(3,1,3)
plot(t,DS,'ro','MarkerSize',3)
xlim(timeRange)
ylim([-1 1])
yticks([-1 0 1])
ylabel("\DeltaS")
title("Price Movement")
grid on
```



Continuous Time Markov Process

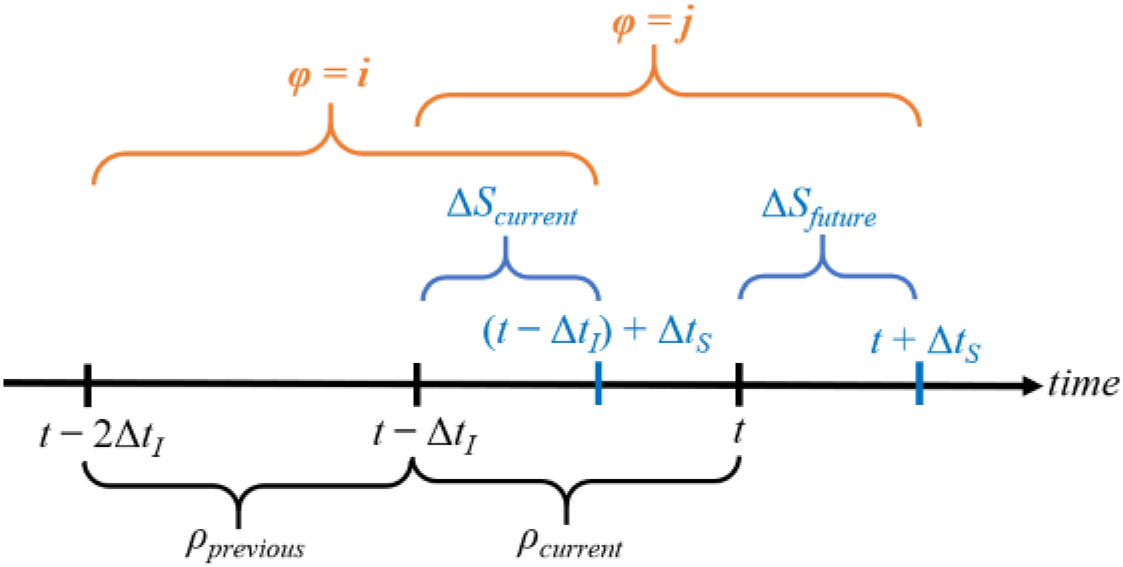
Together, the state of the LOB imbalance index `rho` (ρ) and the state of the forward price movement `DS` (ΔS) describe a two-dimensional continuous-time Markov chain (CTMC). The chain is modulated by the Poisson process of order arrivals, which signals any transition among the states.

To simplify the description, give the two-dimensional CTMC a one-dimensional encoding into states `phi` ($\varphi = (\rho, \Delta S)$).

```
numStates = 3*numBins; % numStates(DS)*numStates(rho)

phi = NaN(size(t));
for i = 1:length(t)
    switch DS(i)
        case -1
            phi(i) = rho(i);
        case 0
            phi(i) = rho(i) + numBins;
        case 1
            phi(i) = rho(i) + 2*numBins;
    end
end
```

Successive states of φ, and the component states ρ and ΔS, proceed as follows.



Hyperparameters dI (Δt_I) and dS (Δt_S) determine the size of a rolling state characterizing the dynamics. At time t, the process transitions from $\varphi = (\rho_{previous}, \Delta S_{current}) = i$ to $\varphi = (\rho_{current}, \Delta S_{future}) = j$ (or holds in the same state if $i = j$).

Estimate Process Parameters

Execution of the trading strategy at any time t is based on the probability of ΔS_{future} being in a particular state, conditional on the current and previous values of the other states. Following [3] and [4], determine empirical transition probabilities, and then assess them for predictive power.

```
% Transition counts

C = zeros(numStates);
for i = 1:length(phi)-dS-1
    C(phi(i),phi(i+1)) = C(phi(i),phi(i+1))+1;
end

% Holding times

H = diag(C);

% Transition rate matrix (infinitesimal generator)

G = C./H;
v = sum(G,2);
G = G + diag(-v);

% Transition probability matrix (stochastic for all dI)

P = expm(G*dI); % Matrix exponential
```

To obtain a trading matrix Q containing $\mathrm{Prob}(\Delta S_{future} \mid \rho_{previous}, \rho_{current}, \Delta S_{current})$ as in [4], apply Bayes' rule,

$$\mathrm{Prob}\left(\Delta S_{future}\,\middle|\,\rho_{previous},\rho_{current},\Delta S_{current}\right)=\frac{\mathrm{Prob}\left(\rho_{current},\Delta S_{future}\,\middle|\,\rho_{previous},\Delta S_{current}\right)}{\mathrm{Prob}\left(\rho_{current}\,\middle|\,\rho_{previous},\Delta S_{current}\right)}.$$

The numerator is the transition probability matrix `P`. Compute the denominator `PCond`.

```
PCond = zeros(size(P));
phiNums = 1:numStates;
modNums = mod(phiNums,numBins);
for i = phiNums
    for j = phiNums
        idx = (modNums == modNums(j));
        PCond(i,j) = sum(P(i,idx));
    end
end

Q = P./PCond;
```

Display `Q` in a table. Label the rows and columns with composite states $\varphi=(\rho,\Delta S)$.

```
binNames = string(1:numBins);
stateNames = ["("+binNames+",-1)","("+binNames+",0)","("+binNames+",1)"];
QTable = array2table(Q,'RowNames',stateNames,'VariableNames',stateNames)
```

```
QTable=9×9 table

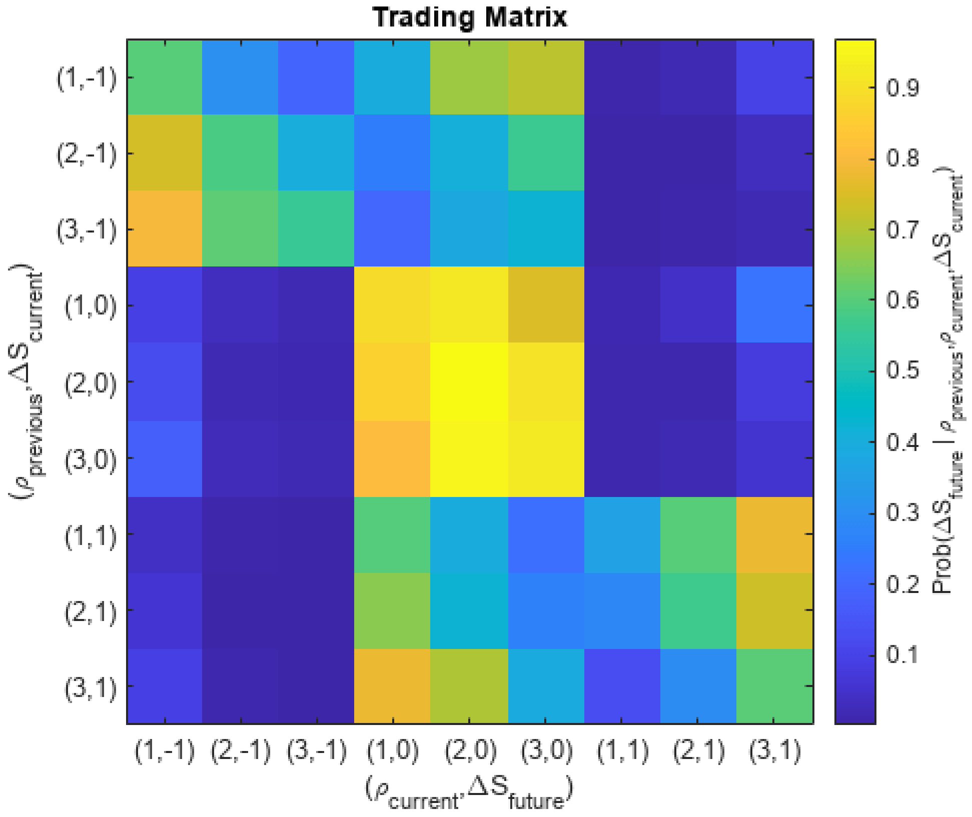
```

Rows are indexed by $(\rho_{previous},\Delta S_{current})$. Conditional probabilities for each of the three possible states of ΔS_{future} are read from the corresponding column, conditional on $\rho_{current}$.

Represent `Q` with a heatmap.

```
figure
imagesc(Q)
axis equal tight
hCB = colorbar;
hCB.Label.String = "Prob(\DeltaS_{future} | \rho_{previous},\rho_{current},\DeltaS_{current})";
xticks(phiNums)
xticklabels(stateNames)
xlabel("(\rho_{current},\DeltaS_{future})")
yticks(phiNums)
yticklabels(stateNames)
ylabel("(\rho_{previous},\DeltaS_{current})")
title("Trading Matrix")
```



The bright, central 3 x 3 square shows that in most transitions, tick to tick, no price change is expected ($\Delta S_{future} = 0$). Bright areas in the upper-left 3 x 3 square (downward price movements $\Delta S_{future} = -1$) and lower-right 3 x 3 square (upward price movements $\Delta S_{future} = +1$) show evidence of momentum, which can be leveraged in a trading strategy.

You can find arbitrage opportunities by thresholding `Q` above a specified trigger probability. For example:

```
trigger = 0.5;
QPattern = (Q > trigger)
```

```
QPattern = 9x9 logical array

   1   0   0   0   1   1   0   0   0
   1   1   0   0   0   1   0   0   0
   1   1   1   0   0   0   0   0   0
   0   0   0   1   1   1   0   0   0
   0   0   0   1   1   1   0   0   0
   0   0   0   1   1   1   0   0   0
   0   0   0   1   0   0   0   1   1
   0   0   0   1   0   0   0   1   1
   0   0   0   1   1   0   0   0   1
```

The entry in the (1,1) position shows a chance of more than 50% that a downward price movement ($\Delta S_{current} = -1$) will be followed by another downward price movement ($\Delta S_{future} = -1$), provided that the previous and current imbalance states ρ are both 1.

A Trading Strategy?

Q is constructed on the basis of both the available exchange data and the hyperparameter settings. Using Q to inform future trading decisions depends on the market continuing in the same statistical pattern. Whether the market exhibits momentum in certain states is a test of the weak-form *Efficient Market Hypothesis* (EMH). For heavily traded assets, such as the one used in this example (INTC), the EMH is likely to hold over extended periods, and arbitrage opportunities quickly disappear. However, failure of EMH can occur in some assets over short time intervals. A working trading strategy divides a portion of the trading day, short enough to exhibit a degree of statistical equilibrium, into a training period for estimating Q, using optimal hyperparameter settings and a validation period on which to trade. For an implementation of such a strategy, see “Machine Learning for Statistical Arbitrage III: Training, Tuning, and Prediction” on page 2-71.

Summary

This example begins with raw data on the LOB and transforms it into a summary (the Q matrix) of statistical arbitrage opportunities. The analysis uses the mathematics of continuous-time Markov chain models, first in recognizing the Poisson process of LOB interarrival times, then by discretizing data into two-dimensional states representing the instantaneous position of the market. A description of state transitions, derived empirically, leads to the possibility of an algorithmic trading strategy.

Machine Learning for Statistical Arbitrage III: Training, Tuning, and Prediction

This example uses Bayesian optimization to tune hyperparameters in the algorithmic trading model, supervised by the end-of-day return. It is part of a series of related examples on machine learning for statistical arbitrage (see “Machine Learning Applications”).

Load `LOBVars.mat`, the preprocessed LOB data set of the NASDAQ security INTC.

```
load LOBVars
```

The data set contains the following information for each order: the arrival time `t` (seconds from midnight), level 1 asking price `MOAsk`, level 1 bidding price `MOBid`, midprice `S`, and imbalance index `I`.

This example includes several supporting functions. To view them, open the example, and then expand the `LOBSupportingFiles` folder in the **Current Folder** pane.

Trading Strategy

The trading matrix `Q` contains probabilities of future price movements, given current and previous states `rho` of the limit order book (LOB) imbalance index `I` and the latest observed direction in prices `DS`.

View the supporting function `tradeOnQ.m`, which implements a simple trading strategy based on the pattern in `Q`.

```
function cash = tradeOnQ(Data,Q,n,N)

% Reference: Machine Learning for Statistical Arbitrage
%            Part II: Feature Engineering and Model Development

% Data

t = Data.t;
MOBid = Data.MOBid;
MOAsk = Data.MOAsk;
```

```
% States

[rho,DS] = getStates(Data,n,N);

% Start of trading

cash = 0;
assets = 0;

% Active trading

T = length(t);

for tt = 2:T-N  % Trading ticks

    % Get Q row, column indices of current state

    row = rho(tt-1)+n*(DS(tt-1)+1);
    downColumn = rho(tt);
    upColumn = rho(tt) + 2*n;

    % If predicting downward price move

    if Q(row,downColumn) > 0.5

        cash = cash + MOBid(tt); % Sell
        assets = assets - 1;

    % If predicting upward price move

    elseif Q(row,upColumn) > 0.5

        cash = cash - MOAsk(tt); % Buy
        assets = assets + 1;

    end

end

% End of trading (liquidate position)

if assets > 0

    cash = cash + assets*MOBid(T); % Sell off

elseif assets < 0

    cash = cash + assets*MOAsk(T); % Buy back

end
```

The algorithm uses predictions from `Q` to make decisions about trading at each tick. It illustrates the general mechanism of any optimized machine learning algorithm.

This strategy seeks to profit from expected price changes using market orders (best offer at the touch) of a single share at each tick, if an arbitrage opportunity arises. The strategy can be scaled up to larger trading volumes. Using the conditional probabilities obtained from Q, the tradeOnQ function takes one of these actions:

- Executes a buy if the probability of an upward forward price change is greater than 0.5.
- Executes a sell if the probability of an downward forward price change is greater than 0.5.

At the end of the trading day, the function liquidates the position at the touch.

The strategy requires Data with tick times t and the corresponding market order bid and ask prices MOBid and MOAsk, respectively. In real-time trading, data is provided by the exchange. This example evaluates the strategy by dividing the historical sample into *training* (calibration) and *validation* subsamples. The validation subsample serves as a proxy for real-time trading data. The strategy depends on Q, the trading matrix itself, which you estimate after you make a number of hyperparameter choices. The inputs n and N are hyperparameters to tune when you optimize the strategy.

Hyperparameters

The continuous-time Markov model and the resulting trading matrix Q depend on the values of four hyperparameters:

- lambda — The weighting parameter used to compute the imbalance index I
- dI — The number of backward ticks used to average I during smoothing
- numBins — The number of bins used to partition smoothed I for discretization
- dS — The number of forward ticks used to convert the prices S to discrete DS

In general, all four hyperparameters are tunable. However, to facilitate visualization, the example reduces the number of dimensions by tuning only numBins and N. The example:

- Fixes lambda
- Leaves numBins = n, where n is free to vary
- Equalizes the window lengths dI = dS = N, where N is free to vary

The restrictions do not significantly affect optimization outcomes. The optimization algorithm searches over the two-dimensional parameter space (n,N) for the configuration yielding the maximum return on trading.

Training and Validation Data

Machine learning requires a subsample on which to estimate Q and another subsample on which to evaluate the hyperparameter selections.

Specify a breakpoint to separate the data into training and validation subsamples. The breakpoint affects evaluation of the objective function, and is essentially another hyperparameter. However, because you do not tune the breakpoint, it is external to the optimization process.

```
bp = round((0.80)*length(t)); % Use 80% of data for training
```

Collect data in a timetable to pass to tradeOnQ.

```
Data = timetable(t,S,I,MOBid,MOAsk);
TData = Data(1:bp,:);       % Training data
VData = Data(bp+1:end,:);   % Validation data
```

Cross-Validation

Cross-validation describes a variety of techniques to assess how training results (here, computation of Q) generalize, with predictive reliability, to independent validation data (here, profitable trading). The goal of cross-validation is to flag problems in training results, like bias and overfitting. In the context of the trading strategy, overfitting refers to the time dependence, or nonstationarity, of Q. As Q changes over time, it becomes less effective in predicting future price movements. The key diagnostic issue is the degree to which Q changes, and at what rate, over a limited trading horizon.

With training and validation data in place, specify the hyperparameters and compare Q in the two subsamples. The supporting function makeQ.m provides the steps for making Q.

```
% Set specific hyperparameters

n = 3;  % Number of bins for I
N = 20; % Window lengths

% Compare Qs

QT = makeQ(TData,n,N);
QV = makeQ(VData,n,N);
QTVDiff = QT - QV
```

```
QTVDiff = 9×9

```

Differences between QT and QV appear minor, although they vary based on their position in the matrix. Identify trading inefficiencies, which result from indices (market states) where one matrix gives a trading cue (probability value > 0.5) and the other does not.

```
Inhomogeneity = (QT > 0.5 & QV < 0.5 ) | (QT < 0.5 & QV > 0.5 )
```

```
Inhomogeneity = 9x9 logical array

   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
   0   0   0   0   0   0   0   0   0
```

No significant inhomogeneities appear in the data with the given hyperparameter settings.

The severity of proceeding with a homogeneity assumption is not known *a priori*, and can emerge only from more comprehensive backtesting. Statistical tests are available, as described in [4] and [5], for example. During real-time trading, a rolling computation of `Q` over trailing training data of suitable size can provide the most reliable cues. Such an approach acknowledges inherent nonstationarity in the market.

Machine Learning

Machine learning refers to the general approach of effectively performing a task (for example, trading) in an automated fashion by detecting patterns (for example, computing `Q`) and making inferences based on available data. Often, data is dynamic and big enough to require specialized computational techniques. The evaluation process—tuning hyperparameters to describe the data and direct performance of the task—is ongoing.

In addition to the challenges of working with big data, the process of evaluating complex, sometimes black-box, objective functions is also challenging. Objective functions supervise hyperparameter evaluation. The trading strategy evaluates hyperparameter tunings by first computing `Q` on a training subsample, and then trading during an evaluation (real-time) subsample. The objective is to maximize profit, or minimize negative cash returned, over a space of suitably constrained configurations (`n`,`N`). This objective is a prototypical "expensive" objective function. *Bayesian optimization* is a type of machine learning suited to such objective functions. One of its principle advantages is the absence of costly derivative evaluations. To implement Bayesian optimization, use the Statistics and Machine Learning Toolbox™ function `bayesopt`.

The supporting function `optimizeTrading.m` uses `bayesopt` to optimize the trading strategy in `tradeOnQ`.

```
function results = optimizeTrading(TData,VData)

% Optimization variables

n = optimizableVariable('numBins',[1 10],'Type','integer');
N = optimizableVariable('numTicks',[1 50],'Type','integer');

% Objective function handle

f = @(x)negativeCash(x,TData,VData);

% Optimize

results = bayesopt(f,[n,N],...
                   'IsObjectiveDeterministic',true,...
                   'AcquisitionFunctionName','expected-improvement-plus',...
                   'MaxObjectiveEvaluations',25,...
                   'ExplorationRatio',2,...
                   'Verbose',0);

end % optimizeTrading

% Objective (local)
function loss = negativeCash(x,TData,VData)

n = x.numBins;
N = x.numTicks;

% Make trading matrix Q
```

```
Q = makeQ(TData,n,N);

% Trade on Q

cash = tradeOnQ(VData,Q,n,N);

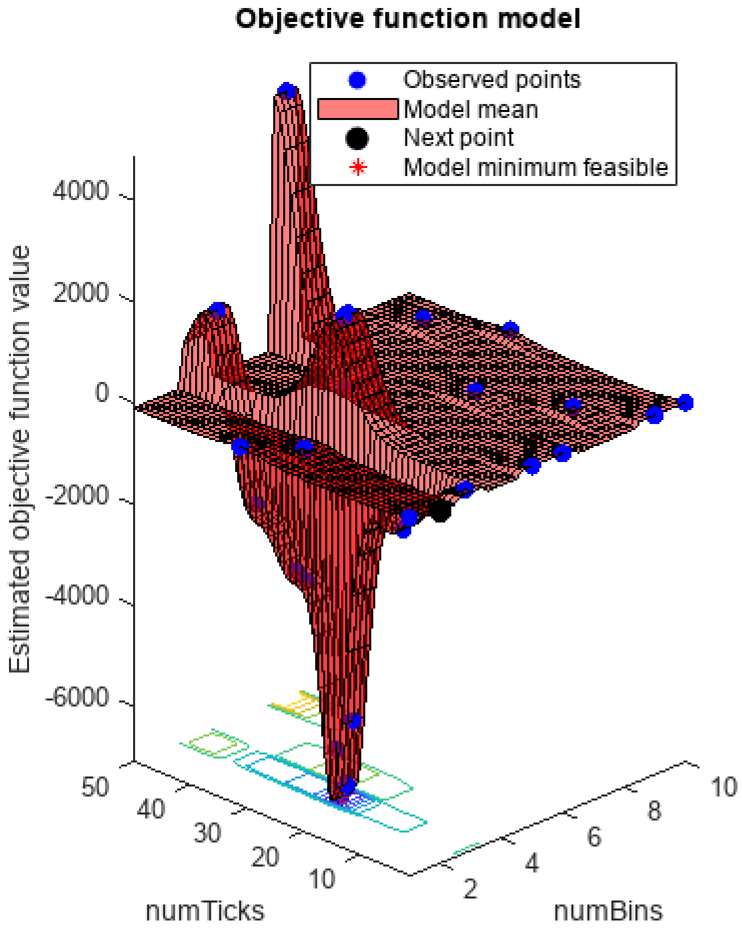
% Objective value

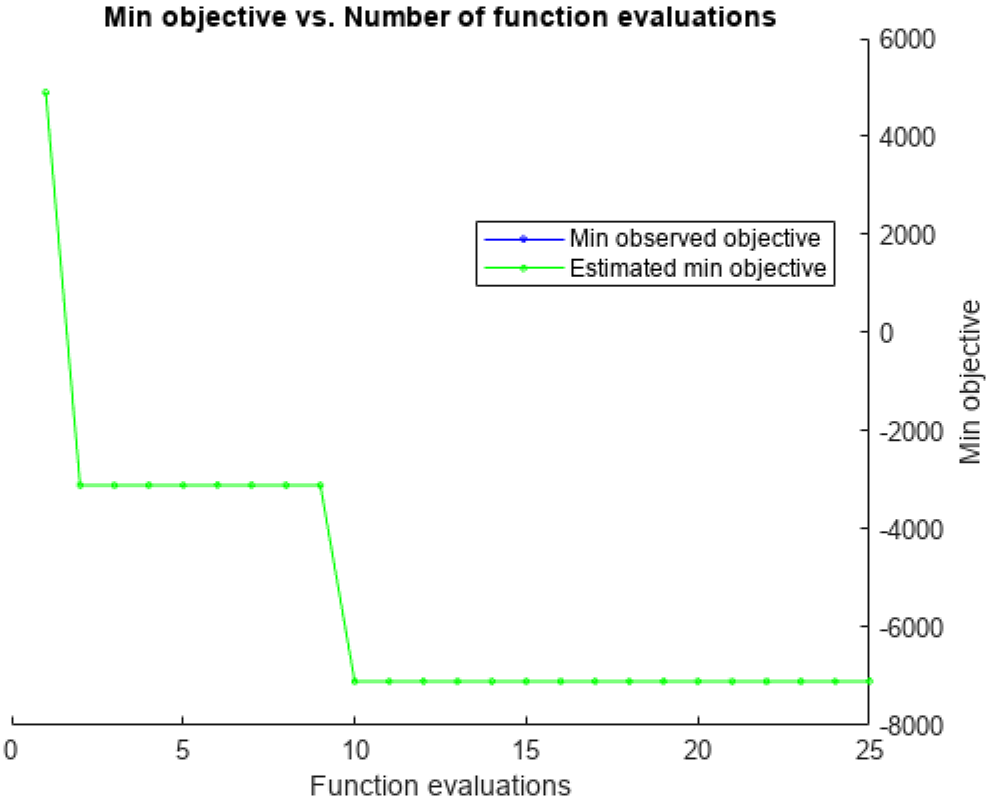
loss = -cash;

end % negativeCash
```

Optimize the trading strategy by passing the training and validation data to `optimizeTrading`.

```
rng(0) % For reproducibility
results = optimizeTrading(TData,VData);
```





The estimated minimum objective coincides with the minimum observed objective (the search is monotonic). Unlike derivative-based algorithms, `bayesopt` does not converge. As it tries to find the global minimum, `bayesopt` continues exploring until it reaches the specified number of iterations (25).

Obtain the best configuration by passing the `results` to `bestPoint`.

```
[Calibration,negReturn] = bestPoint(results,'Criterion','min-observed')
```

```
Calibration=1×2 table
    numBins    numTicks
    _______    ________

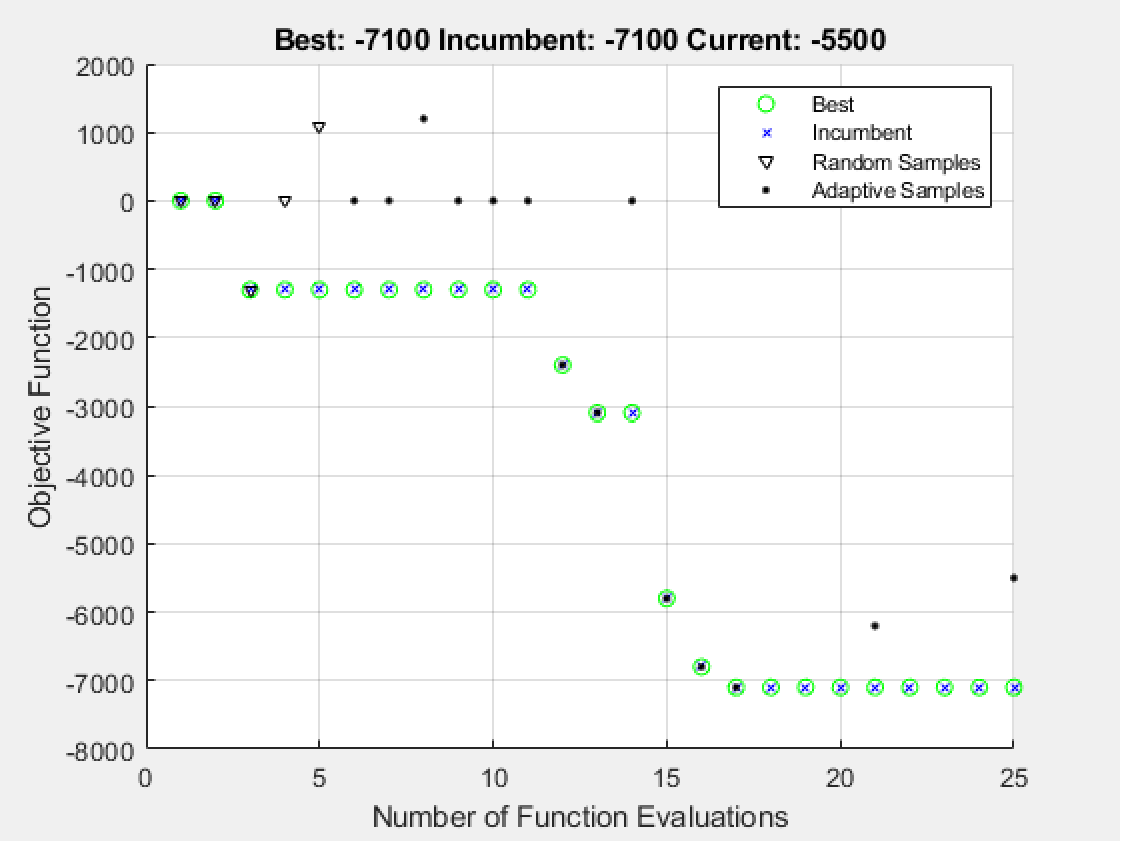
       3          24   

negReturn = -7100
```

Trading one share per tick, as directed by `Q`, the optimal strategy using (n,N) = (3,24) returns $0.71 over the final 20% of the trading day. Modifying the trading volume scales the return.

Another optimizer designed for expensive objectives is `surrogateopt` (Global Optimization Toolbox). It uses a different search strategy and can locate optima more quickly, depending on the objective. The supporting function `optimizeTrading2.m` uses `surrogateopt` instead of `bayesopt` to optimize the trading strategy in `tradeOnQ`.

```
rng(0) % For reproducibility
results2 = optimizeTrading2(TData,VData)
```



```
results2 = 1×2

     3    24
```

The results obtained with `surrogateopt` are the same as the `bayesopt` results. The plot contains information about the progress of the search that is specific to the `surrogateopt` algorithm.

Compute `Q` by passing the optimal hyperparameters and the entire data set to `makeQ`.

```
bestQ = makeQ(Data,3,24)
```

```
bestQ = 9×9

    0.3933    0.1868    0.1268    0.5887    0.7722    0.6665    0.0180    0.0410    0.2068
    0.5430    0.3490    0.2716    0.4447    0.6379    0.6518    0.0123    0.0131    0.0766
    0.6197    0.3897    0.3090    0.3705    0.5954    0.6363    0.0098    0.0150    0.0547
    0.1509    0.0440    0.0261    0.8217    0.8960    0.6908    0.0273    0.0601    0.2831
    0.1900    0.0328    0.0280    0.7862    0.9415    0.8316    0.0238    0.0257    0.1404
    0.2370    0.0441    0.0329    0.7391    0.9221    0.8745    0.0239    0.0338    0.0925
    0.1306    0.0234    0.0101    0.7861    0.6566    0.4168    0.0833    0.3200    0.5731
    0.1276    0.0169    0.0118    0.7242    0.6505    0.4712    0.1482    0.3326    0.5171
    0.1766    0.0282    0.0186    0.7216    0.7696    0.6185    0.1018    0.2023    0.3629
```

The trading matrix `bestQ` can be used as a starting point for the next trading day.

Summary

This example implements the optimized trading strategy developed in the first two related examples. Available data is split into training and validation subsamples and used, respectively, to compute the trading matrix `Q` and execute the resulting trading algorithm. The process is repeated over a space of hyperparameter settings using the global optimizers `bayesopt` and `surrogateopt`, both of which identify an optimal strategy yielding a positive return. The approach has many options for further customization.

Portfolio Analysis

Analyzing Portfolios

Portfolio managers concentrate their efforts on achieving the best possible trade-off between risk and return. For portfolios constructed from a fixed set of assets, the risk/return profile varies with the portfolio composition. Portfolios that maximize the return, given the risk, or, conversely, minimize the risk for the given return, are called *optimal*. Optimal portfolios define a line in the risk/return plane called the *efficient frontier*.

A portfolio may also have to meet additional requirements to be considered. Different investors have different levels of risk tolerance. Selecting the adequate portfolio for a particular investor is a difficult process. The portfolio manager can hedge the risk related to a particular portfolio along the efficient frontier with partial investment in risk-free assets. The definition of the capital allocation line, and finding where the final portfolio falls on this line, if at all, is a function of:

- The risk/return profile of each asset
- The risk-free rate
- The borrowing rate
- The degree of risk aversion characterizing an investor

Financial Toolbox software includes a set of portfolio optimization functions designed to find the portfolio that best meets investor requirements.

Warning `frontcon` has been removed. Use `Portfolio` instead.

`portopt` has been partially removed and will no longer accept `ConSet` or `varargin` arguments. `portopt` will only solve the portfolio problem for long-only fully invested portfolios. Use `Portfolio` instead.

Portfolio Optimization Functions

The portfolio optimization functions assist portfolio managers in constructing portfolios that optimize risk and return.

Capital Allocation	Description
`portalloc`	Computes the optimal risky portfolio on the efficient frontier, based on the risk-free rate, the borrowing rate, and the investor's degree of risk aversion. Also generates the capital allocation line, which provides the optimal allocation of funds between the risky portfolio and the risk-free asset.

Efficient Frontier Computation	Description
`frontier`	Computes portfolios along the efficient frontier for a given group of assets. Generates a surface of efficient frontiers showing how asset allocation influences risk and return over time.
`portopt`	Computes portfolios along the efficient frontier for a given group of assets. The computation is based on a set of user-specified linear constraints. Typically, these constraints are generated using the constraint specification functions described below. **Warning** `portopt` has been partially removed and will no longer accept `ConSet` or `varargin` arguments. `portopt` will only solve the portfolio problem for long-only fully invested portfolios. Use `Portfolio` instead. For more information on migrating `portopt` code to `Portfolio`, see “portopt Migration to Portfolio Object” on page 3-11.

Constraint Specification	Description
`portcons`	Generates the portfolio constraints matrix for a portfolio of asset investments using linear inequalities. The inequalities are of the type `A*Wts' <= b`, where `Wts` is a row vector of weights.
`portvrisk`	Portfolio value at risk (VaR) returns the maximum potential loss in the value of a portfolio over one period of time, given the loss probability level `RiskThreshold`.
`pcalims`	Asset minimum and maximum allocation. Generates a constraint set to fix the minimum and maximum weight for each individual asset.
`pcgcomp`	Group-to-group ratio constraint. Generates a constraint set specifying the maximum and minimum ratios between pairs of groups.
`pcglims`	Asset group minimum and maximum allocation. Generates a constraint set to fix the minimum and maximum total weight for each defined group of assets.
`pcpval`	Total portfolio value. Generates a constraint set to fix the total value of the portfolio.

Constraint Conversion	Description
`abs2active`	Transforms a constraint matrix expressed in absolute weight format to an equivalent matrix expressed in active weight format.
`active2abs`	Transforms a constraint matrix expressed in active weight format to an equivalent matrix expressed in absolute weight format.

Note An alternative to using these portfolio optimization functions is to use the Portfolio object (`Portfolio`) for mean-variance portfolio optimization. This object supports gross or net portfolio returns as the return proxy, the variance of portfolio returns as the risk proxy, and a portfolio set that is any combination of the specified constraints to form a portfolio set. For information on the workflow when using Portfolio objects, see “Portfolio Object Workflow” on page 4-17.

Portfolio Construction Examples

In this section...
"Introduction" on page 3-5
"Efficient Frontier Example" on page 3-5

Introduction

The efficient frontier computation functions require information about each asset in the portfolio. This data is entered into the function via two matrices: an expected return vector and a covariance matrix. The expected return vector contains the average expected return for each asset in the portfolio. The covariance matrix is a square matrix representing the interrelationships between pairs of assets. This information can be directly specified or can be estimated from an asset return time series with the function `ewstats`.

Note An alternative to using these portfolio optimization functions is to use the Portfolio object (`Portfolio`) for mean-variance portfolio optimization. This object supports gross or net portfolio returns as the return proxy, the variance of portfolio returns as the risk proxy, and a portfolio set that is any combination of the specified constraints to form a portfolio set. For information on the workflow when using Portfolio objects, see "Portfolio Object Workflow" on page 4-17.

Efficient Frontier Example

`frontcon` has been removed. To model the efficient frontier, use the `Portfolio` object instead. For example, using the `Portfolio` object, you can model an efficient frontier:

- "Obtaining Portfolios Along the Entire Efficient Frontier" on page 4-95
- "Obtaining Endpoints of the Efficient Frontier" on page 4-98
- "Obtaining Efficient Portfolios for Target Returns" on page 4-101

Portfolio Selection and Risk Aversion

In this section...

Introduction

One of the factors to consider when selecting the optimal portfolio for a particular investor is the degree of risk aversion. This level of aversion to risk can be characterized by defining the investor's indifference curve. This curve consists of the family of risk/return pairs defining the trade-off between the expected return and the risk. It establishes the increment in return that a particular investor requires to make an increment in risk worthwhile. Typical risk aversion coefficients range from 2.0 through 4.0, with the higher number representing lesser tolerance to risk. The equation used to represent risk aversion in Financial Toolbox software is

```
U = E(r) - 0.005*A*sig^2
```

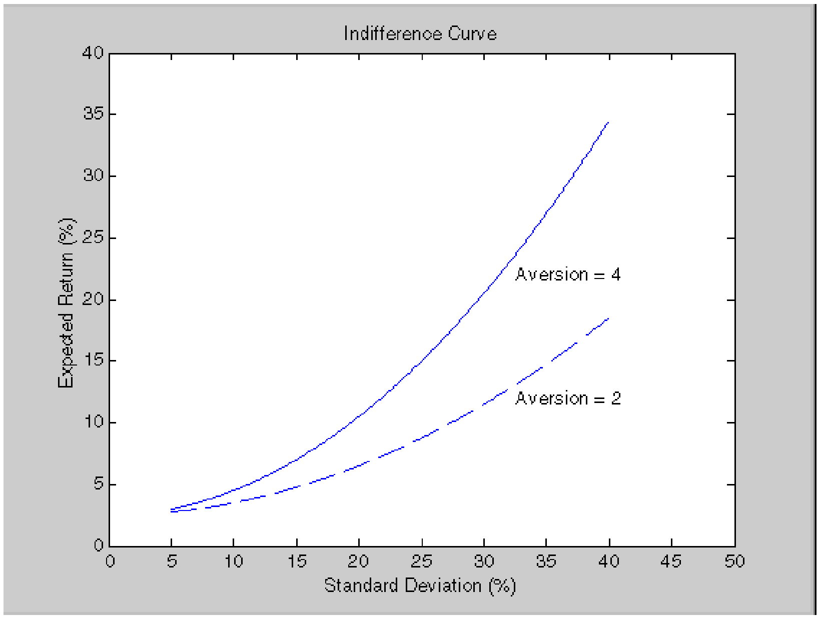
where:

`U` is the utility value.

`E(r)` is the expected return.

`A` is the index of investor's aversion.

`sig` is the standard deviation.



Note An alternative to using these portfolio optimization functions is to use the Portfolio object (`Portfolio`) for mean-variance portfolio optimization. This object supports gross or net portfolio returns as the return proxy, the variance of portfolio returns as the risk proxy, and a portfolio set that is any combination of the specified constraints to form a portfolio set. For information on the workflow when using Portfolio objects, see “Portfolio Object Workflow” on page 4-17.

Optimal Risky Portfolio

This example computes the optimal risky portfolio on the efficient frontier based on the risk-free rate, the borrowing rate, and the investor's degree of risk aversion. You do this with the function `portalloc`.

First generate the efficient frontier data using `portopt`.

```
ExpReturn = [0.1 0.2 0.15];

ExpCovariance  = [ 0.005   -0.010    0.004;
                  -0.010    0.040   -0.002;
                   0.004   -0.002    0.023];
```

Consider 20 different points along the efficient frontier.

```
NumPorts = 20;

[PortRisk, PortReturn, PortWts] = portopt(ExpReturn,...
ExpCovariance, NumPorts);
```

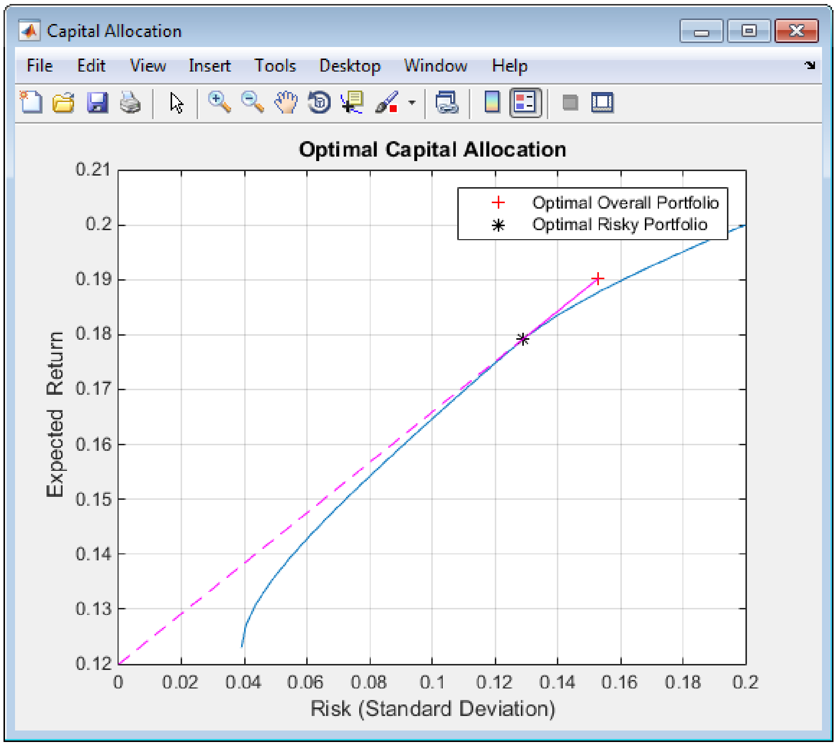
Calling `portopt`, while specifying output arguments, returns the corresponding vectors and arrays representing the risk, return, and weights for each of the portfolios along the efficient frontier. Use these as the first three input arguments to the function `portalloc`.

Now find the optimal risky portfolio and the optimal allocation of funds between the risky portfolio and the risk-free asset, using these values for the risk-free rate, borrowing rate, and investor's degree of risk aversion.

```
RisklessRate  =  0.08
BorrowRate    =  0.12
RiskAversion  =  3
```

Calling `portalloc` without specifying any output arguments gives a graph displaying the critical points.

```
portalloc(PortRisk, PortReturn, PortWts, RisklessRate,...
BorrowRate, RiskAversion);
```



Calling `portalloc` while specifying the output arguments returns the variance (`RiskyRisk`), the expected return (`RiskyReturn`), and the weights (`RiskyWts`) allocated to the optimal risky portfolio. It also returns the fraction (`RiskyFraction`) of the complete portfolio allocated to the risky portfolio, and the variance (`OverallRisk`) and expected return (`OverallReturn`) of the optimal overall portfolio. The overall portfolio combines investments in the risk-free asset and in the risky portfolio. The actual proportion assigned to each of these two investments is determined by the degree of risk aversion characterizing the investor.

```
[RiskyRisk, RiskyReturn, RiskyWts,RiskyFraction, OverallRisk,...
OverallReturn] = portalloc (PortRisk, PortReturn, PortWts,...
RisklessRate, BorrowRate, RiskAversion)
```

```
RiskyRisk =

    0.1288

RiskyReturn =

    0.1791

RiskyWts =

    0.0057    0.5879    0.4064

RiskyFraction =

    1.1869

OverallRisk =

    0.1529
```

```
OverallReturn =

    0.1902
```

The value of RiskyFraction exceeds 1 (100%), implying that the risk tolerance specified allows borrowing money to invest in the risky portfolio, and that no money is invested in the risk-free asset. This borrowed capital is added to the original capital available for investment. In this example, the customer tolerates borrowing 18.69% of the original capital amount.

portopt Migration to Portfolio Object

In this section...

Migrate portopt Without Output Arguments

This example shows how to migrate `portopt` without output arguments to a Portfolio object.

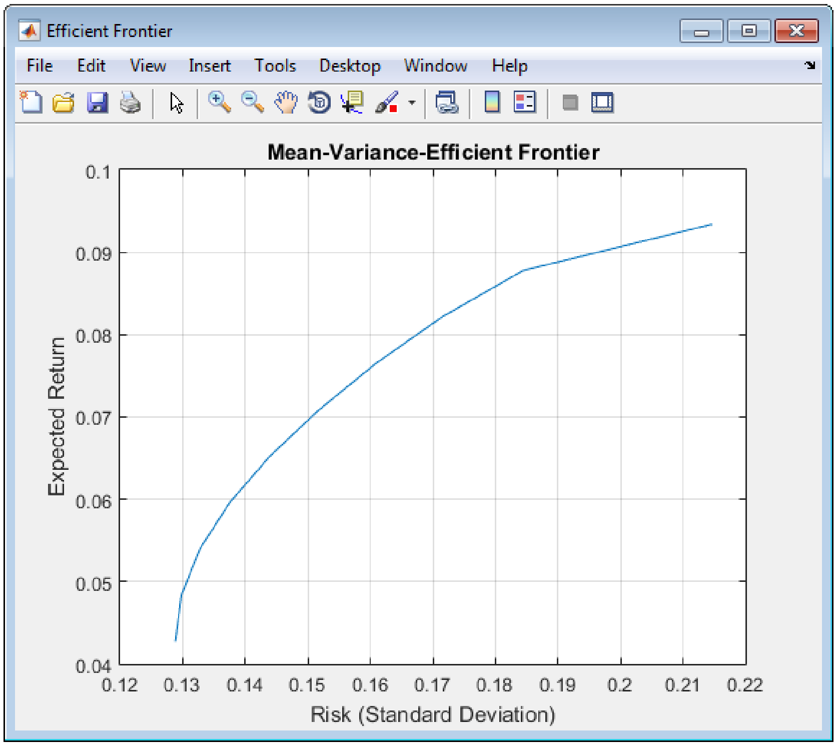
The basic `portopt` functionality is represented as:

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

portopt(ExpReturn, ExpCovariance, NumPorts);
```



To migrate a `portopt` syntax without output arguments to a Portfolio object:

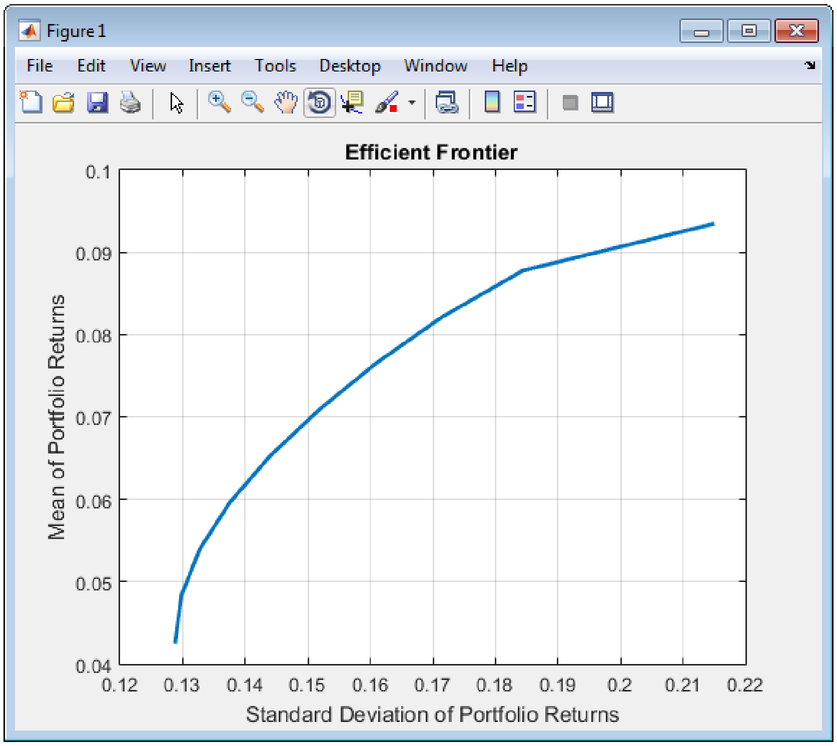
```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

p = Portfolio;
p = setAssetMoments(p, ExpReturn, ExpCovariance);
p = setDefaultConstraints(p);

plotFrontier(p, NumPorts);
```



Without output arguments, `portopt` plots the efficient frontier. The Portfolio object has similar behavior although the Portfolio object writes to the current figure window rather than create a new window each time a plot is generated.

Migrate portopt with Output Arguments

This example shows how to migrate `portopt` with output arguments to a Portfolio object.

With output arguments, the basic functionality of `portopt` returns portfolio moments and weights. Once the Portfolio object is set up, moments and weights are obtained in separate steps.

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

[PortRisk, PortReturn, PortWts] = portopt(ExpReturn, ExpCovariance, NumPorts);

display(PortWts);
```

```
PortWts =

    0.2103    0.2746    0.1157    0.1594    0.2400
    0.1744    0.2657    0.1296    0.2193    0.2110
    0.1386    0.2567    0.1436    0.2791    0.1821
    0.1027    0.2477    0.1575    0.3390    0.1532
    0.0668    0.2387    0.1714    0.3988    0.1242
    0.0309    0.2298    0.1854    0.4587    0.0953
         0    0.2168    0.1993    0.5209    0.0629
         0    0.1791    0.2133    0.5985    0.0091
         0    0.0557    0.2183    0.7260         0
         0         0         0    1.0000         0
```

To migrate a `portopt` syntax with output arguments:

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

p = Portfolio;
p = setAssetMoments(p, ExpReturn, ExpCovariance);
p = setDefaultConstraints(p);

PortWts = estimateFrontier(p, NumPorts);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

display(PortWts);
```

```
PortWts =

    0.2103    0.1744    0.1386    0.1027    0.0668    0.0309         0         0         0         0
    0.2746    0.2657    0.2567    0.2477    0.2387    0.2298    0.2168    0.1791    0.0557         0
    0.1157    0.1296    0.1436    0.1575    0.1714    0.1854    0.1993    0.2133    0.2183         0
    0.1594    0.2193    0.2791    0.3390    0.3988    0.4587    0.5209    0.5985    0.7260    1.0000
    0.2400    0.2110    0.1821    0.1532    0.1242    0.0953    0.0629    0.0091         0         0
```

The Portfolio object returns `PortWts` with portfolios going down columns, not across rows. Portfolio risks and returns are still in column format.

Migrate portopt for Target Returns Within Range of Efficient Portfolio Returns

This example shows how to migrate `portopt` target returns within range of efficient portfolio returns to a Portfolio object.

`portopt` can obtain portfolios with specific targeted levels of return but requires that the targeted returns fall within the range of efficient returns. The Portfolio object handles this by selecting portfolios at the ends of the efficient frontier.

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];
```

```
ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

TargetReturn = [ 0.05; 0.06; 0.07; 0.08; 0.09 ];

[PortRisk, PortReturn, PortWts] = portopt(ExpReturn, ExpCovariance, [], TargetReturn);

disp(' Efficient    Target');
disp([PortReturn, TargetReturn]);
```

```
 Efficient    Target
    0.0500    0.0500
    0.0600    0.0600
    0.0700    0.0700
    0.0800    0.0800
    0.0900    0.0900
```

To migrate a `portopt` syntax for target returns within range of efficient portfolio returns to a Portfolio object:

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

TargetReturn = [ 0.05; 0.06; 0.07; 0.08; 0.09 ];

p = Portfolio;
p = setAssetMoments(p, ExpReturn, ExpCovariance);
p = setDefaultConstraints(p);

PortWts = estimateFrontierByReturn(p, TargetReturn);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

disp(' Efficient    Target');
disp([PortReturn, TargetReturn]);
```

```
 Efficient    Target
    0.0500    0.0500
    0.0600    0.0600
    0.0700    0.0700
    0.0800    0.0800
    0.0900    0.0900
```

Migrate portopt for Target Return Outside Range of Efficient Portfolio Returns

This example shows how to migrate `portopt` target returns outside of range of efficient portfolio returns to a Portfolio object.

When the target return is outside of the range of efficient portfolio returns, `portopt` generates an error. The Portfolio object handles this effectively by selecting portfolios at the ends of the efficient frontier.

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

TargetReturn = [ 0.05; 0.06; 0.07; 0.08; 0.09; 0.10 ];

[PortRisk, PortReturn, PortWts] = portopt(ExpReturn, ExpCovariance, [], TargetReturn);

disp(' Efficient    Target');
disp([PortReturn, TargetReturn]);
```

```
> In portopt at 85
Error using portopt (line 297)
One or more requested returns are greater than the maximum achievable return of 0.093400.
```

To migrate a `portopt` syntax for target returns outside of the range of efficient portfolio returns to a Portfolio object:

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

TargetReturn = [ 0.05; 0.06; 0.07; 0.08; 0.09; 0.10 ];

p = Portfolio;
p = setAssetMoments(p, ExpReturn, ExpCovariance);
p = setDefaultConstraints(p);

PortWts = estimateFrontierByReturn(p, TargetReturn);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

disp(' Efficient    Target');
disp([PortReturn, TargetReturn]);
```

```
Warning: One or more target return values are outside the feasible range [
0.0427391, 0.0934 ].
    Will return portfolios associated with endpoints of the range for these
    values.

Migrate portopt Using portcons Output for ConSet

This example shows how to migrate `portopt` when the `ConSet` output from `portcons` is used with `portopt`.

`portopt` accepts as input the outputs from `portcons`, `pcalims`, `pcglims`, and `pcgcomp`. This example focuses on `portcons`. `portcons` sets up linear constraints for `portopt` in the form `A*Port <= b`. In a matrix `ConSet = [ A, b ]` and break into separate `A` and `b` arrays with `A = ConSet(:,1:end-1);` and `b = ConSet(:,end);`. In addition, to illustrate default problem with additional group constraints, consider three groups. Assets 2, 3, and 4 can constitute up to 80% of portfolio, Assets 1 and 2 can constitute up to 70% of portfolio, and Assets 3, 4, and 5 can constitute up to 90% of portfolio.

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];
```

```
ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

Groups = [ 0 1 1 1 0; 1 1 0 0 0; 0 0 1 1 1 ];
GroupBounds = [ 0, 0.8; 0, 0.7; 0, 0.9 ];

LowerGroup = GroupBounds(:,1);
UpperGroup = GroupBounds(:,2);

ConSet = portcons('default', 5, 'grouplims', Groups, LowerGroup, UpperGroup);

[PortRisk, PortReturn, PortWts] = portopt(ExpReturn, ExpCovariance, NumPorts, [], ConSet);

disp([PortRisk, PortReturn]);
```

```
Error using portopt (line 83)
In the current and future releases, portopt will no longer accept ConSet or varargin arguments.
'It will only solve the portfolio problem for long-only fully-invested portfolios.
To solve more general problems, use the Portfolio object.
See the release notes for details, including examples to make the conversion.
```

To migrate `portopt` to a Portfolio object when the `ConSet` output from `portcons` is used with `portopt`:

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

Groups = [ 0 1 1 1 0; 1 1 0 0 0; 0 0 1 1 1 ];
GroupBounds = [ 0, 0.8; 0, 0.7; 0, 0.9 ];

LowerGroup = GroupBounds(:,1);
UpperGroup = GroupBounds(:,2);

ConSet = portcons('default', 5, 'grouplims', Groups, LowerGroup, UpperGroup);

A = ConSet(:,1:end-1);
b = ConSet(:,end);

p = Portfolio;
p = setAssetMoments(p, ExpReturn, ExpCovariance);
p = setInequality(p, A, b);                   % implement group constraints here

PortWts = estimateFrontier(p, NumPorts);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

disp([PortRisk, PortReturn]);
```

```
0.1288    0.0427
0.1292    0.0465
0.1306    0.0503
0.1328    0.0540
0.1358    0.0578
0.1395    0.0615
0.1440    0.0653

```

The constraints are entered directly into the Portfolio object with the `setInequality` or `addInequality` functions.

Integrate Output from portcons, pcalims, pcglims, and pcgcomp with a Portfolio Object

This example shows how to integrate output from `pcalims`, `pcalims`, `pcglims`, or `pcgcomp` with a Portfolio object implementation.

`portcons`, `pcalims`, `pcglims`, and `pcgcomp` setup linear constraints for `portopt` in the form `A*Port <= b`. Although some functions permit two outputs, assume that the output is a single matrix `ConSet`. Break into separate `A` and `b` arrays with:

- `A = ConSet(:,1:end-1);`
- `b = ConSet(:,end);`

In addition, to illustrate default problem with additional group constraints, consider three groups:

- Assets 2, 3, and 4 can constitute up to 80% of portfolio.
- Assets 1 and 2 can constitute up to 70% of portfolio.
- Assets 3, 4, and 5 can constitute up to 90% of portfolio.

```
Groups = [ 0 1 1 1 0; 1 1 0 0 0; 0 0 1 1 1 ];
GroupBounds = [ 0, 0.8; 0, 0.7; 0, 0.9 ];
```

To integrate the `ConSet` output of `portcons` with a Portfolio object implementation:

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

Groups = [ 0 1 1 1 0; 1 1 0 0 0; 0 0 1 1 1 ];
GroupBounds = [ 0, 0.8; 0, 0.7; 0, 0.9 ];

LowerGroup = GroupBounds(:,1);
UpperGroup = GroupBounds(:,2);

ConSet = portcons('default', 5, 'grouplims', Groups, LowerGroup, UpperGroup);

A = ConSet(:,1:end-1);
b = ConSet(:,end);

p = Portfolio;
p = setAssetMoments(p, ExpReturn, ExpCovariance);
p = setDefaultConstraints(p);                % implement default constraints here
p = setInequality(p, A, b);                    % implement group constraints here

PortWts = estimateFrontier(p, NumPorts);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

disp([PortRisk, PortReturn]);
```

```
    0.1288    0.0427
    0.1292    0.0465
    0.1306    0.0503
    0.1328    0.0540
    0.1358    0.0578
    0.1395    0.0615
    0.1440    0.0653
    0.1504    0.0690
    0.1590    0.0728
    0.1806    0.0766
```

To integrate the output of `pcalims` and `pcglims` with a Portfolio object implementation:

```
ExpReturn = [ 0.0054; 0.0531; 0.0779; 0.0934; 0.0130 ];

ExpCovariance = [ 0.0569,  0.0092,  0.0039,  0.0070,  0.0022;
    0.0092,  0.0380,  0.0035,  0.0197,  0.0028;
    0.0039,  0.0035,  0.0997,  0.0100,  0.0070;
    0.0070,  0.0197,  0.0100,  0.0461,  0.0050;
    0.0022,  0.0028,  0.0070,  0.0050,  0.0573 ];

NumPorts = 10;

Groups = [ 0 1 1 1 0; 1 1 0 0 0; 0 0 1 1 1 ];
GroupBounds = [ 0, 0.8; 0, 0.7; 0, 0.9 ];

LowerGroup = GroupBounds(:,1);
UpperGroup = GroupBounds(:,2);

AssetMin = [ 0; 0; 0; 0; 0 ];
AssetMax = [ 0.8; 0.8; 0.8; 0.8; 0.8 ];

[Aa, ba] = pcalims(AssetMin, AssetMax);
[Ag, bg] = pcglims(Groups, LowerGroup, UpperGroup);

p = Portfolio;
p = setAssetMoments(p, ExpReturn, ExpCovariance);
p = setDefaultConstraints(p);               % implement default constraints first
p = addInequality(p, Aa, ba);               % implement bound constraints here
p = addInequality(p, Ag, bg);               % implement group constraints here

PortWts = estimateFrontier(p, NumPorts);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

disp([PortRisk, PortReturn]);

Constraint Specification Using a Portfolio Object

In this section...

Constraints for Efficient Frontier

This example computes the efficient frontier of portfolios consisting of three different assets, INTC, XON, and RD, given a list of constraints. The expected returns for INTC, XON, and RD are respectively as follows:

```
ExpReturn = [0.1 0.2 0.15];
```

The covariance matrix is

```
ExpCovariance  =  [ 0.005   -0.010    0.004;
                   -0.010    0.040   -0.002;
                    0.004   -0.002    0.023];
```

- Constraint 1

  - Allow short selling up to 10% of the portfolio value in any asset, but limit the investment in any one asset to 110% of the portfolio value.
- Constraint 2

  - Consider two different sectors, technology and energy, with the following table indicating the sector each asset belongs to.

Asset	INTC	XON	RD
Sector	Technology	Energy	Energy

Constrain the investment in the Energy sector to 80% of the portfolio value, and the investment in the Technology sector to 70%.

To solve this problem, use `Portfolio`, passing in a list of asset constraints. Consider eight different portfolios along the efficient frontier:

```
NumPorts = 8;
```

To introduce the asset bounds constraints specified in Constraint 1, create the matrix `AssetBounds`, where each column represents an asset. The upper row represents the lower bounds, and the lower row represents the upper bounds. Since the bounds are the same for each asset, only one pair of bounds is needed because of scalar expansion.

```
AssetBounds = [-0.1, 1.1];
```

Constraint 2 must be entered in two parts, the first part defining the groups, and the second part defining the constraints for each group. Given the information above, you can build a matrix of `1`s and `0`s indicating whether a specific asset belongs to a group. Each column represents an asset, and each row represents a group. This example has two groups: the technology group, and the energy group. Create the matrix `Groups` as follows.

```
Groups =  [0   1   1;
           1   0   0];
```

The `GroupBounds` matrix allows you to specify an upper and lower bound for each group. Each row in this matrix represents a group. The first column represents the minimum allocation, and the second column represents the maximum allocation to each group. Since the investment in the Energy sector is capped at 80% of the portfolio value, and the investment in the Technology sector is capped at 70%, create the `GroupBounds` matrix using this information.

```
GroupBounds = [0   0.80;
               0   0.70];
```

Now use `Portfolio` to obtain the vectors and arrays representing the risk, return, and weights for each of the eight portfolios computed along the efficient frontier. A budget constraint is added to ensure that the portfolio weights sum to 1.

```
p = Portfolio('AssetMean', ExpReturn, 'AssetCovar', ExpCovariance);
p = setBounds(p, AssetBounds(1), AssetBounds(2));
p = setBudget(p, 1, 1);
p = setGroups(p, Groups, GroupBounds(:,1), GroupBounds(:,2));

PortWts = estimateFrontier(p, NumPorts);

[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

PortRisk
PortReturn
PortWts
```

```
PortRisk =

    0.0416
    0.0499
    0.0624
    0.0767
    0.0920
    0.1100
    0.1378
    0.1716

PortReturn =

    0.1279
    0.1361
    0.1442
    0.1524
    0.1605
    0.1687
    0.1768
    0.1850

PortWts =

    0.7000    0.6031    0.4864    0.3696    0.2529    0.2000    0.2000    0.2000
    0.2582    0.3244    0.3708    0.4172    0.4636    0.5738    0.7369    0.9000
    0.0418    0.0725    0.1428    0.2132    0.2835    0.2262    0.0631   -0.1000
```

The outputs are represented as columns for the portfolio’s risk and return. Portfolio weights are identified as corresponding column vectors in a matrix.

Linear Constraint Equations

While the `Portfolio` object allows you to enter a fixed set of constraints related to minimum and maximum values for groups and individual assets, you often need to specify a larger and more general set of constraints when finding the optimal risky portfolio. `Portfolio` also addresses this need, by accepting an arbitrary set of constraints.

This example requires specifying the minimum and maximum investment in various groups.

Maximum and Minimum Group Exposure

Group	Minimum Exposure	Maximum Exposure
North America	0.30	0.75
Europe	0.10	0.55
Latin America	0.20	0.50
Asia	0.50	0.50

The minimum and maximum exposure in Asia is the same. This means that you require a fixed exposure for this group.

Also assume that the portfolio consists of three different funds. The correspondence between funds and groups is shown in the table below.

Group Membership

Group	Fund 1	Fund 2	Fund 3
North America	X	X	
Europe			X
Latin America	X		
Asia		X	X

Using the information in these two tables, build a mathematical representation of the constraints represented. Assume that the vector of weights representing the exposure of each asset in a portfolio is called `Wts = [W1 W2 W3]`.

Specifically

1.	$W1 + W2$	≥	0.30
2.	$W1 + W2$	≤	0.75
3.	$W3$	≥	0.10
4.	$W3$	≤	0.55
5.	$W1$	≥	0.20
6.	$W1$	≤	0.50
7.	$W2 + W3$	=	0.50

Since you must represent the information in the form `A*Wts <= b`, multiply equations 1, 3 and 5 by –1. Also turn equation 7 into a set of two inequalities: $W2 + W3 \geq 0.50$ and $W2 + W3 \leq 0.50$. (The intersection of these two inequalities is the equality itself.) Thus

1.	$-W1 - W2$	≤	-0.30
2.	$W1 + W2$	≤	0.75
3.	$-W3$	≤	-0.10
4.	$W3$	≤	0.55
5.	$-W1$	≤	-0.20
6.	$W1$	≤	0.50
7.	$-W2 - W3$	≤	-0.50
8.	$W2 + W3$	≤	0.50

Bringing these equations into matrix notation gives

```
A = [-1    -1     0;
      1     1     0;
      0     0    -1;
      0     0     1;
     -1     0     0;
      1     0     0;
      0    -1    -1;
      0     1     1]

b = [-0.30;
      0.75;
     -0.10;
      0.55;
     -0.20;
      0.50;
     -0.50;
      0.50]
```

One approach to solving this portfolio problem is to explicitly use the `setInequality` function:

```
p = Portfolio('AssetMean', ExpReturn, 'AssetCovar', ExpCovariance);
p = setBounds(p, AssetBounds(1), AssetBounds(2));
p = setBudget(p, 1, 1);
p = setInequality(p, A, b);
PortWts = estimateFrontier(p, NumPorts);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

PortRisk
PortReturn
PortWts
```

```
PortRisk =

    0.0586
    0.0586
    0.0586
    0.0586
    0.0586
    0.0586
    0.0586
    0.0586

PortReturn =

    0.1375
    0.1375
    0.1375
    0.1375
    0.1375
    0.1375
    0.1375
    0.1375

PortWts =

    0.5000    0.5000    0.5000    0.5000    0.5000    0.5000    0.5000    0.5000
    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500
    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500
```

In this case, the constraints allow only one optimum portfolio. Since eight portfolios were requested, all eight portfolios are the same. Note that the solution to this portfolio problem using the `setInequality` function is the same as using the `setGroups` function in the next example (“Specifying Group Constraints” on page 3-23).

Specifying Group Constraints

The example above (“Linear Constraint Equations” on page 3-21) defines a constraint matrix that specifies a set of typical scenarios. It defines groups of assets, specifies upper and lower bounds for total allocation in each of these groups, and it sets the total allocation of one group to a fixed value. Constraints like these are common occurrences. `Portfolio` object enables you to simplify the creation of the constraint matrix for these and other common portfolio requirements.

An alternative approach for solving the portfolio problem is to use the `Portfolio` object to define:

- A `Group` matrix, indicating the assets that belong to each group.
- A `GroupMin` vector, indicating the minimum bounds for each group.
- A `GroupMax` vector, indicating the maximum bounds for each group.

Based on the table Group Membership, build the `Group` matrix, with each row representing a group, and each column representing an asset.

```
Group = [1    1    0;
         0    0    1;
         1    0    0;
         0    1    1];
```

The table Maximum and Minimum Group Exposure has the information to build `GroupMin` and `GroupMax`.

```
GroupMin = [0.30  0.10  0.20  0.50];
GroupMax = [0.75  0.55  0.50  0.50];
```

Now use `Portfolio` and the `setInequality` function to obtain the vectors and arrays representing the risk, return, and weights for the portfolios computed along the efficient frontier.

```
p = Portfolio('AssetMean', ExpReturn, 'AssetCovar', ExpCovariance);
p = setBounds(p, AssetBounds(1), AssetBounds(2));
p = setBudget(p, 1, 1);
p = setGroups(p, Group, GroupMin, GroupMax);
PortWts = estimateFrontier(p, NumPorts);
[PortRisk, PortReturn] = estimatePortMoments(p, PortWts);

PortRisk
PortReturn
PortWts
```

```
PortRisk =

    0.0586
    0.0586
    0.0586
    0.0586
    0.0586
    0.0586
    0.0586
    0.0586

PortReturn =

    0.1375
    0.1375
    0.1375
    0.1375
    0.1375
    0.1375
    0.1375
    0.1375

PortWts =

    0.5000    0.5000    0.5000    0.5000    0.5000    0.5000    0.5000    0.5000
    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500
    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500    0.2500
```

In this case, the constraints allow only one optimum portfolio. Since eight portfolios were requested, all eight portfolios are the same. Note that the solution to this portfolio problem using the `setGroups` function is the same as using the `setInequality` function in the previous example (“Linear Constraint Equations” on page 3-21).

Active Returns and Tracking Error Efficient Frontier

Suppose that you want to identify an efficient set of portfolios that minimize the variance of the difference in returns with respect to a given target portfolio, subject to a given expected excess return. The mean and standard deviation of this excess return are often called the active return and active risk, respectively. Active risk is sometimes referred to as the tracking error. Since the objective is to track a given target portfolio as closely as possible, the resulting set of portfolios is sometimes referred to as the tracking error efficient frontier.

Specifically, assume that the target portfolio is expressed as an index weight vector, such that the index return series may be expressed as a linear combination of the available assets. This example illustrates how to construct a frontier that minimizes the active risk (tracking error) subject to attaining a given level of return. That is, it computes the tracking error efficient frontier.

One way to construct the tracking error efficient frontier is to explicitly form the target return series and subtract it from the return series of the individual assets. In this manner, you specify the expected mean and covariance of the active returns, and compute the efficient frontier subject to the usual portfolio constraints.

This example works directly with the mean and covariance of the absolute (unadjusted) returns but converts the constraints from the usual absolute weight format to active weight format.

Consider a portfolio of five assets with the following expected returns, standard deviations, and correlation matrix based on absolute weekly asset returns.

```
NumAssets    =  5;

ExpReturn    = [0.2074  0.1971  0.2669  0.1323  0.2535]/100;

Sigmas       = [2.6570  3.6297  3.9916  2.7145  2.6133]/100;

Correlations = [1.0000  0.6092  0.6321  0.5833  0.7304
                0.6092  1.0000  0.8504  0.8038  0.7176
                0.6321  0.8504  1.0000  0.7723  0.7236
                0.5833  0.8038  0.7723  1.0000  0.7225
                0.7304  0.7176  0.7236  0.7225  1.0000];
```

Convert the correlations and standard deviations to a covariance matrix using `corr2cov`.

```
ExpCovariance = corr2cov(Sigmas, Correlations);
```

Next, assume that the target index portfolio is an equally weighted portfolio formed from the five assets. The sum of index weights equals 1, satisfying the standard full investment budget equality constraint.

```
Index = ones(NumAssets, 1)/NumAssets;
```

Generate an asset constraint matrix using `portcons`. The constraint matrix `AbsConSet` is expressed in absolute format (unadjusted for the index), and is formatted as `[A b]`, corresponding to constraints of the form `A*w <= b`. Each row of `AbsConSet` corresponds to a constraint, and each column corresponds to an asset. Allow no short-selling and full investment in each asset (lower and upper bounds of each asset are 0 and 1, respectively). In particular, note that the first two rows correspond to the budget equality constraint; the remaining rows correspond to the upper/lower investment bounds.

```
AbsConSet = portcons('PortValue', 1, NumAssets, ...
'AssetLims', zeros(NumAssets,1), ones(NumAssets,1));
```

Now transform the absolute constraints to active constraints with `abs2active`.

```
ActiveConSet = abs2active(AbsConSet, Index);
```

An examination of the absolute and active constraint matrices reveals that they differ only in the last column (the columns corresponding to the `b` in `A*w <= b`).

```
[AbsConSet(:,end)  ActiveConSet(:,end)]
```

```
ans =

   -1.0000         0
    1.0000    0.8000
    1.0000    0.8000
    1.0000    0.8000
    1.0000    0.8000
    1.0000    0.8000
         0    0.2000
         0    0.2000
         0    0.2000
         0    0.2000
         0    0.2000
```

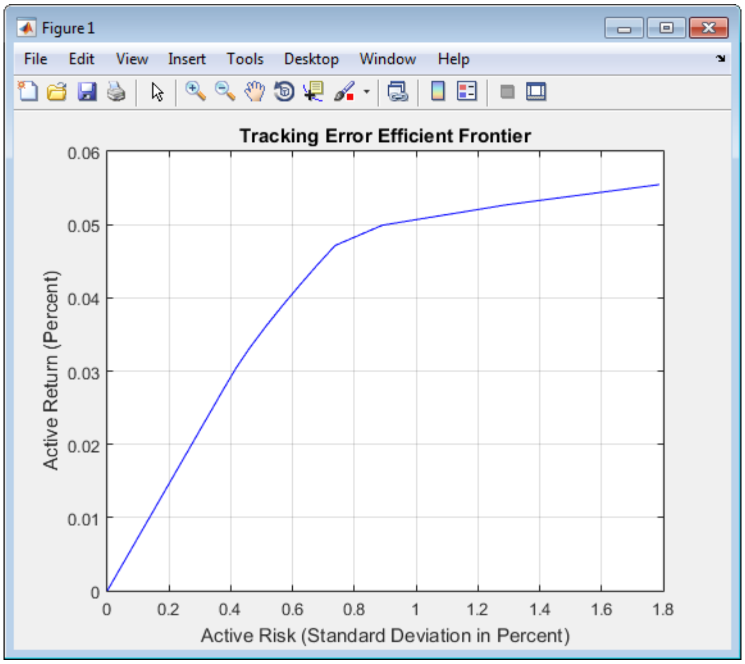
In particular, note that the sum-to-one absolute budget constraint becomes a sum-to-zero active budget constraint. The general transformation is as follows:

$$b_{active} = b_{absolute} - A \times Index \, .$$

Now construct the `Portfolio` object and plot the tracking error efficient frontier with 21 portfolios.

```
p = Portfolio('AssetMean', ExpReturn, 'AssetCovar', ExpCovariance);
p = p.setInequality(ActiveConSet(:,1:end-1), ActiveConSet(:,end));
[ActiveRisk, ActiveReturn] = p.plotFrontier(21);

plot(ActiveRisk*100, ActiveReturn*100, 'blue')
grid('on')
xlabel('Active Risk (Standard Deviation in Percent)')
ylabel('Active Return (Percent)')
title('Tracking Error Efficient Frontier')
```



Of particular interest is the lower-left portfolio along the frontier. This zero-risk/zero-return portfolio has a practical economic significance. It represents a full investment in the index portfolio itself. Each tracking error efficient portfolio (each row in the array `ActiveWeights`) satisfies the active budget constraint, and thus represents portfolio investment allocations with respect to the index portfolio. To convert these allocations to absolute investment allocations, add the index to each efficient portfolio.

```
ActiveWeights = p.estimateFrontier(21);
AbsoluteWeights = ActiveWeights + repmat(Index, 1, 21);
```

Mean-Variance Portfolio Optimization Tools

Portfolio Optimization Theory

In this section...

Portfolio Optimization Problems

Portfolio optimization problems involve identifying portfolios that satisfy three criteria:

- Minimize a proxy for risk.
- Match or exceed a proxy for return.
- Satisfy basic feasibility requirements.

Portfolios are points from a feasible set of assets that constitute an asset universe. A portfolio specifies either holdings or weights in each individual asset in the asset universe. The convention is to specify portfolios in terms of weights, although the portfolio optimization tools work with holdings as well.

The set of feasible portfolios is necessarily a nonempty, closed, and bounded set. The proxy for risk is a function that characterizes either the variability or losses associated with portfolio choices. The proxy for return is a function that characterizes either the gross or net benefits associated with portfolio choices. The terms “risk” and “risk proxy” and “return” and “return proxy” are interchangeable. The fundamental insight of Markowitz (see “Portfolio Optimization” on page A-5) is that the goal of the portfolio choice problem is to seek minimum risk for a given level of return and to seek maximum return for a given level of risk. Portfolios satisfying these criteria are efficient portfolios and the graph of the risks and returns of these portfolios forms a curve called the efficient frontier.

Portfolio Problem Specification

To specify a portfolio optimization problem, you need the following:

- Proxy for portfolio return (μ)
- Proxy for portfolio risk (σ)
- Set of feasible portfolios (X), called a portfolio set

Financial Toolbox has three objects to solve specific types of portfolio optimization problems:

- The `Portfolio` object supports mean-variance portfolio optimization (see Markowitz [46], [47] at “Portfolio Optimization” on page A-5). This object has either gross or net portfolio returns as the return proxy, the variance of portfolio returns as the risk proxy, and a portfolio set that is any combination of the specified constraints to form a portfolio set.
- The `PortfolioCVaR` object implements what is known as conditional value-at-risk portfolio optimization (see Rockafellar and Uryasev [48], [49] at “Portfolio Optimization” on page A-5), which is referred to as CVaR portfolio optimization. CVaR portfolio optimization works with the

same return proxies and portfolio sets as mean-variance portfolio optimization but uses conditional value-at-risk of portfolio returns as the risk proxy.

- The `PortfolioMAD` object implements what is known as mean-absolute deviation portfolio optimization (see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5), which is referred to as MAD portfolio optimization. MAD portfolio optimization works with the same return proxies and portfolio sets as mean-variance portfolio optimization but uses mean-absolute deviation portfolio returns as the risk proxy.

Return Proxy

The proxy for portfolio return is a function $\mu : X \rightarrow R$ on a portfolio set $X \subset R^n$ that characterizes the rewards associated with portfolio choices. Usually, the proxy for portfolio return has two general forms, gross and net portfolio returns. Both portfolio return forms separate the risk-free rate r_0 so that the portfolio $x \in X$ contains only risky assets.

Regardless of the underlying distribution of asset returns, a collection of S asset returns $y_1,...,y_S$ has a mean of asset returns

$$m = \frac{1}{S}\sum_{s=1}^{S} y_s,$$

and (sample) covariance of asset returns

$$C = \frac{1}{S-1}\sum_{s=1}^{S} (y_s - m)(y_s - m)^T .$$

These moments (or alternative estimators that characterize these moments) are used directly in mean-variance portfolio optimization to form proxies for portfolio risk and return.

Gross Portfolio Returns

The gross portfolio return for a portfolio $x \in X$ is

$$\mu(x) = r_0 + (m - r_0 1)^T x,$$

where:

r_0 is the risk-free rate (scalar).

m is the mean of asset returns (n vector).

If the portfolio weights sum to `1`, the risk-free rate is irrelevant. The properties in the `Portfolio` object to specify gross portfolio returns are:

- `RiskFreeRate` for r_0
- `AssetMean` for m

Net Portfolio Returns

The net portfolio return for a portfolio $x \in X$ is

$$\mu(x) = r_0 + (m - r_0 1)^T x - b^T \max\left\{0, x - x_0\right\} - s^T \max\left\{0, x_0 - x\right\},$$

where:

r_0 is the risk-free rate (scalar).

m is the mean of asset returns (n vector).

b is the proportional cost to purchase assets (n vector).

s is the proportional cost to sell assets (n vector).

You can incorporate fixed transaction costs in this model also. Though in this case, it is necessary to incorporate prices into such costs. The properties in the `Portfolio` object to specify net portfolio returns are:

- `RiskFreeRate` for r_0
- `AssetMean` for m
- `InitPort` for x_0
- `BuyCost` for b
- `SellCost` for s

Risk Proxy

The proxy for portfolio risk is a function $\sigma: X \rightarrow R$ on a portfolio set $X \subset R^n$ that characterizes the risks associated with portfolio choices.

Mean Variance

The mean variance of portfolio returns for a portfolio $x \in X$ is

$$Variance(x) = x^T C x$$

where C is the covariance of asset returns (`n`-by-`n` positive-semidefinite matrix).

The property in the `Portfolio` object to specify the variance of portfolio returns is `AssetCovar` for C.

Although the risk proxy in mean-variance portfolio optimization is the variance of portfolio returns, the square root, which is the standard deviation of portfolio returns, is often reported and displayed. Moreover, this quantity is often called the “risk” of the portfolio. For details, see Markowitz (“Portfolio Optimization” on page A-5).

Conditional Value-at-Risk

The conditional value-at-risk for a portfolio $x \in X$, which is also known as expected shortfall, is defined as

$$CVaR_\alpha(x) = \frac{1}{1-\alpha} \int_{f(x,y) \geq VaR_\alpha(x)} f(x,y)p(y)dy,$$

where:

α is the probability level such that $0 < \alpha < 1$.

f(x,y) is the loss function for a portfolio *x* and asset return *y*.

p(y) is the probability density function for asset return *y*.

VaR_α is the value-at-risk of portfolio *x* at probability level *α*.

The value-at-risk is defined as

$$VaR_\alpha(x) = \min\{\gamma: \Pr[f(x,Y) \le \gamma] \ge \alpha\}.$$

An alternative formulation for CVaR has the form:

$$CVaR_\alpha(x) = VaR_\alpha(x) + \frac{1}{1-\alpha}\int_{R^n} \max\{0, (f(x,y) - VaR_\alpha(x))\}p(y)dy$$

The choice for the probability level *α* is typically 0.9 or 0.95. Choosing *α* implies that the value-at-risk $VaR_\alpha(x)$ for portfolio *x* is the portfolio return such that the probability of portfolio returns falling below this level is (1 –*α*). Given $VaR_\alpha(x)$ for a portfolio *x*, the conditional value-at-risk of the portfolio is the expected loss of portfolio returns above the value-at-risk return.

Note Value-at-risk is a positive value for losses so that the probability level *α* indicates the probability that portfolio returns are below the negative of the value-at-risk.

To describe the probability distribution of returns, the `PortfolioCVaR` object takes a finite sample of return scenarios y_s, with $s = 1,...,S$. Each y_s is an *n* vector that contains the returns for each of the *n* assets under the scenario *s*. This sample of *S* scenarios is stored as a scenario matrix of size *S*-by-*n*. Then, the risk proxy for CVaR portfolio optimization, for a given portfolio $x \in X$ and $\alpha \in (0,1)$, is computed as

$$CVaR_\alpha(x) = VaR_\alpha(x) + \frac{1}{(1-\alpha)S}\sum_{s=1}^{S} \max\left\{0, -y_s^T x - VaR_\alpha(x)\right\}$$

The value-at-risk, $VaR_\alpha(x)$, is estimated whenever the CVaR is estimated. The loss function is $f(x, y_s) = -y_s^T x$, which is the portfolio loss under scenario *s*.

Under this definition, VaR and CVaR are sample estimators for VaR and CVaR based on the given scenarios. Better scenario samples yield more reliable estimates of VaR and CVaR.

For more information, see Rockafellar and Uryasev [48], [49], and Cornuejols and Tütüncü, [51], at “Portfolio Optimization” on page A-5.

Mean Absolute-Deviation

The mean-absolute-deviation (MAD) for a portfolio $x \in X$ is defined as

$$MAD(x) = \frac{1}{S}\sum_{s=1}^{S} \left|(y_s - m)^T x\right|$$

where:

y_s are asset returns with scenarios *s* = 1,...*S* (*S* collection of *n* vectors).

f(x,y) is the loss function for a portfolio *x* and asset return *y*.

m is the mean of asset returns (*n* vector).

such that

$$m = \frac{1}{S}\sum_{s=1}^{S} y_s$$

For more information, see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5.

Portfolio Set for Optimization Using Portfolio Objects

The final element for a complete specification of a portfolio optimization problem is the set of feasible portfolios, which is called a portfolio set. A portfolio set $X \subset R^n$ is specified by construction as the intersection of sets formed by a collection of constraints on portfolio weights. A portfolio set necessarily and sufficiently must be a nonempty, closed, and bounded set.

When setting up your portfolio set, ensure that the portfolio set satisfies these conditions. The most basic or “default” portfolio set requires portfolio weights to be nonnegative (using the lower-bound constraint) and to sum to `1` (using the budget constraint). The most general portfolio set handled by the portfolio optimization tools (`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` objects) can have any of these constraints:

- Linear inequality constraints
- Linear equality constraints
- `'Simple'` Bound constraints
- `'Conditional'` Bond constraints
- Budget constraints
- Group constraints
- Group ratio constraints
- Average turnover constraints
- One-way turnover constraints
- Tracking error constraints (only for `Portfolio` object)
- Cardinality constraints

Linear Inequality Constraints

Linear inequality constraints are general linear constraints that model relationships among portfolio weights that satisfy a system of inequalities. Use `setInequality` to set linear inequality constraints. Linear inequality constraints take the form

$$A_I x \leq b_I$$

where:

x is the portfolio (n vector).

A_I is the linear inequality constraint matrix (n_I-by-n matrix).

b_I is the linear inequality constraint vector (n_I vector).

n is the number of assets in the universe and n_I is the number of constraints.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify linear inequality constraints are:

- `AInequality` for A_I
- `bInequality` for b_I

- `NumAssets` for *n*

The default is to ignore these constraints.

Linear Equality Constraints

Linear equality constraints are general linear constraints that model relationships among portfolio weights that satisfy a system of equalities. Use `setEquality` to set linear equality constraints. Linear equality constraints take the form

$$A_E x = b_E$$

where:

x is the portfolio (n vector).

A_E is the linear equality constraint matrix (n_E-by-n matrix).

b_E is the linear equality constraint vector (n_E vector).

n is the number of assets in the universe and n_E is the number of constraints.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify linear equality constraints are:

- `AEquality` for A_E
- `bEquality` for b_E
- `NumAssets` for *n*

The default is to ignore these constraints.

'Simple' Bound Constraints

`'Simple'` Bound constraints are specialized linear constraints that confine portfolio weights to fall either above or below specific bounds. Use `setBounds` to specify bound constraints with a `'Simple'` `BoundType`. Since every portfolio set must be bounded, it is often a good practice, albeit not necessary, to set explicit bounds for the portfolio problem. To obtain explicit `'Simple'` bounds for a given portfolio set, use the `estimateBounds` function. Bound constraints take the form

$$l_B \le x \le u_B$$

where:

x is the portfolio (n vector).

l_B is the lower-bound constraint (n vector).

u_B is the upper-bound constraint (n vector).

n is the number of assets in the universe.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify bound constraints are:

- `LowerBound` for l_B
- `UpperBound` for u_B
- `NumAssets` for n

The default is to ignore these constraints.

The default portfolio optimization problem (see “Default Portfolio Problem” on page 4-16) has l_B = `0` with u_B set implicitly through a budget constraint.

'Conditional' Bound Constraints

`'Conditional'` Bound constraints, also called semicontinuous constraints, are mixed-integer linear constraints that confine portfolio weights to fall either above or below specific bounds *if* the asset is selected; otherwise, the value of the asset is zero. Use `setBounds` to specify bound constraints with a `'Conditional' BoundType`. To mathematically formulate this type of constraints, a binary variable v_i is needed. $v_i = 0$ indicates that asset i is not selected and v_i indicates that the asset was selected. Thus

$$l_i v_i \le x_i \le u_i v_i$$

where

x is the portfolio (n vector).

l is the conditional lower-bound constraint (n vector).

u is the conditional upper-bound constraint (n vector).

n is the number of assets in the universe.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify the bound constraint are:

- `LowerBound` for l_B
- `UpperBound` for u_B
- `NumAssets` for n

The default is to ignore this constraint.

Budget Constraints

Budget constraints are specialized linear constraints that confine the sum of portfolio weights to fall either above or below specific bounds. Use `setBudget` to set budget constraints. The constraints take the form

$$l_S \le 1^T x \le u_S$$

where:

x is the portfolio (n vector).

`1` is the vector of ones (n vector).

l_S is the lower-bound budget constraint (scalar).

u_S is the upper-bound budget constraint (scalar).

n is the number of assets in the universe.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify budget constraints are:

- `LowerBudget` for l_S
- `UpperBudget` for u_S
- `NumAssets` for n

The default is to ignore this constraint.

The default portfolio optimization problem (see “Default Portfolio Problem” on page 4-16) has $l_S = u_S = 1$, which means that the portfolio weights sum to `1`. If the portfolio optimization problem includes possible movements in and out of cash, the budget constraint specifies how far portfolios can go into cash. For example, if $l_S = 0$ and $u_S = 1$, then the portfolio can have 0–100% invested in cash. If cash is to be a portfolio choice, set `RiskFreeRate` (r_0) to a suitable value (see “Return Proxy” on page 4-4 and “Working with a Riskless Asset” on page 4-51).

Group Constraints

Group constraints are specialized linear constraints that enforce “membership” among groups of assets. Use `setGroups` to set group constraints. The constraints take the form

$$l_G \leq Gx \leq u_G$$

where:

x is the portfolio (n vector).

l_G is the lower-bound group constraint (n_G vector).

u_G is the upper-bound group constraint (n_G vector).

G is the matrix of group membership indexes (n_G-by-n matrix).

Each row of G identifies which assets belong to a group associated with that row. Each row contains either `0`s or `1`s with `1` indicating that an asset is part of the group or `0` indicating that the asset is not part of the group.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify group constraints are:

- `GroupMatrix` for G
- `LowerGroup` for l_G
- `UpperGroup` for u_G
- `NumAssets` for n

The default is to ignore these constraints.

Group Ratio Constraints

Group ratio constraints are specialized linear constraints that enforce relationships among groups of assets. Use `setGroupRatio` to set group ratio constraints. The constraints take the form

$$l_{Ri}(G_B x)_i \le (G_A x)_i \le u_{Ri}(G_B x)_i$$

for $i = 1,\ldots, n_R$ where:

x is the portfolio (n vector).

l_R is the vector of lower-bound group ratio constraints (n_R vector).

u_R is the vector matrix of upper-bound group ratio constraints (n_R vector).

G_A is the matrix of base group membership indexes (n_R-by-n matrix).

G_B is the matrix of comparison group membership indexes (n_R-by-n matrix).

n is the number of assets in the universe and n_R is the number of constraints.

Each row of G_A and G_B identifies which assets belong to a base and comparison group associated with that row.

Each row contains either `0`s or `1`s with `1` indicating that an asset is part of the group or `0` indicating that the asset is not part of the group.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify group ratio constraints are:

- `GroupA` for G_A
- `GroupB` for G_B
- `LowerRatio` for l_R
- `UpperRatio` for u_R
- `NumAssets` for n

The default is to ignore these constraints.

Average Turnover Constraints

Turnover constraint is a linear absolute value constraint that ensures estimated optimal portfolios differ from an initial portfolio by no more than a specified amount. Although portfolio turnover is defined in many ways, the turnover constraints implemented in Financial Toolbox compute portfolio turnover as the average of purchases and sales. Use `setTurnover` to set average turnover constraints. Average turnover constraints take the form

$$\frac{1}{2}1^T\left|x - x_0\right| \le \tau$$

where:

x is the portfolio (n vector).

`1` is the vector of ones (n vector).

x_0 is the initial portfolio (n vector).

τ is the upper bound for turnover (scalar).

n is the number of assets in the universe.

`Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object properties to specify the average turnover constraint are:

- `Turnover` for τ
- `InitPort` for x_0
- `NumAssets` for n

The default is to ignore this constraint.

One-Way Turnover Constraints

One-way turnover constraints ensure that estimated optimal portfolios differ from an initial portfolio by no more than specified amounts according to whether the differences are purchases or sales. Use `setOneWayTurnover` to set one-way turnover constraints. The constraints take the forms

$$1^T \max\{0, x - x_0\} \le \tau_B$$

$$1^T \max\{0, x_0 - x\} \le \tau_S$$

where:

x is the portfolio (n vector)

1 is the vector of ones (n vector).

x_0 is the Initial portfolio (n vector).

τ_B is the upper bound for turnover constraint on purchases (scalar).

τ_S is the upper bound for turnover constraint on sales (scalar).

To specify one-way turnover constraints, use the following properties in the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object:

- `BuyTurnover` for τ_B
- `SellTurnover` for τ_S
- `InitPort` for x_0

The default is to ignore this constraint.

Note The average turnover constraint (see “Working with Average Turnover Constraints Using Portfolio Object” on page 4-81) with τ is not a combination of the one-way turnover constraints with $\tau = \tau_B = \tau_S$.

Tracking Error Constraints

Tracking error constraint, within a portfolio optimization framework, is an additional constraint to specify the set of feasible portfolios known as a portfolio set. Use `setTrackingError` to set tracking error constraints. The tracking-error constraint has the form

$$(x - x_T)^T C(x - x_T) \leq \tau_T{}^2$$

where:

x is the portfolio (n vector).

x_T is the tracking portfolio against which risk is to be measured (n vector).

C is the covariance of asset returns.

τ_T is the upper bound for tracking error (scalar).

n is the number of assets in the universe.

`Portfolio` object properties to specify the average turnover constraint are:

- `TrackingPort` for x_T
- `TrackingError` for τ_T

The default is to ignore this constraint.

Note The tracking error constraints can be used with any of the other supported constraints in the `Portfolio` object without restrictions. However, since the portfolio set necessarily and sufficiently must be a non-empty compact set, the application of a tracking error constraint may result in an empty portfolio set. Use `estimateBounds` to confirm that the portfolio set is non-empty and compact.

Cardinality Constraints

Cardinality constraint limits the number of assets in the optimal allocation for an `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object . Use `setMinMaxNumAssets` to specify the `'MinNumAssets'` and `'MaxNumAssets'` constraints. To mathematically formulate this type of constraints, a binary variable v_i is needed. $v_i = 0$ indicates that asset i is not selected and $v_i = 1$ indicates that the asset was selected. Thus

$$MinNumAssets \leq \sum_{i=1}^{NumAssets} v_i \leq MaxNumAssets$$

The default is to ignore this constraint.

Default Portfolio Problem

The default portfolio optimization problem has a risk and return proxy associated with a given problem, and a portfolio set that specifies portfolio weights to be nonnegative and to sum to `1`. The lower bound combined with the budget constraint is sufficient to ensure that the portfolio set is nonempty, closed, and bounded. The default portfolio optimization problem characterizes a long-only investor who is fully invested in a collection of assets.

- For mean-variance portfolio optimization, it is sufficient to set up the default problem. After setting up the problem, data in the form of a mean and covariance of asset returns are then used to solve portfolio optimization problems.
- For conditional value-at-risk portfolio optimization, the default problem requires the additional specification of a probability level that must be set explicitly. Generally, “typical” values for this level are 0.90 or 0.95. After setting up the problem, data in the form of scenarios of asset returns are then used to solve portfolio optimization problems.
- For MAD portfolio optimization, it is sufficient to set up the default problem. After setting up the problem, data in the form of scenarios of asset returns are then used to solve portfolio optimization problems.

Portfolio Object Workflow

The `Portfolio` object workflow for creating and modeling a mean-variance portfolio is:

1. Create a Portfolio.

   Create a `Portfolio` object for mean-variance portfolio optimization. For more information, see “Creating the Portfolio Object” on page 4-24.
2. Estimate the mean and covariance for returns.

   Evaluate the mean and covariance for portfolio asset returns, including assets with missing data and financial time series data. For more information, see “Asset Returns and Moments of Asset Returns Using Portfolio Object” on page 4-41.
3. Specify the Portfolio Constraints.

   Define the constraints for portfolio assets such as linear equality and inequality, bound, budget, group, group ratio, turnover, tracking error, `'Conditional'` `BoundType`, and `MinNumAssets`, `MaxNumAssets` constraints. For more information, see “Working with Portfolio Constraints Using Defaults” on page 4-57 and “Working with 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints Using Portfolio Objects” on page 4-78.
4. Validate the Portfolio.

   Identify errors for the portfolio specification. For more information, see “Validate the Portfolio Problem for Portfolio Object” on page 4-90.
5. Estimate the efficient portfolios and frontiers.

   Analyze the efficient portfolios and efficient frontiers for a portfolio. For more information, see “Estimate Efficient Portfolios for Entire Efficient Frontier for Portfolio Object” on page 4-94 and “Estimate Efficient Frontiers for Portfolio Object” on page 4-118.

   Alternatively, you can estimate an optimal portfolio with a user-defined objective function for a `Portfolio` object. For details on using `estimateCustomObjectivePortfolio` to specify a user-defined objective function, see “Solver Guidelines for Custom Objective Problems Using Portfolio Objects” on page 4-115.
6. Postprocess the results.

   Use the efficient portfolios and efficient frontiers results to set up trades. For more information, see “Postprocessing Results to Set Up Tradable Portfolios” on page 4-126.

For an example of this workflow, see “Asset Allocation Case Study” on page 4-172 and “Portfolio Optimization Examples Using Financial Toolbox™” on page 4-152.

Portfolio Object

In this section...

Portfolio Object Properties and Functions

The `Portfolio` object implements mean-variance portfolio optimization. Every property and function of the `Portfolio` object is public, although some properties and functions are hidden. See `Portfolio` for the properties and functions of the `Portfolio` object. The `Portfolio` object is a value object where every instance of the object is a distinct version of the object. Since the `Portfolio` object is also a MATLAB object, it inherits the default functions associated with MATLAB objects.

Working with Portfolio Objects

The `Portfolio` object and its functions are an interface for mean-variance portfolio optimization. So, almost everything you do with the `Portfolio` object can be done using the associated functions. The basic workflow is:

1. Design your portfolio problem.
2. Use `Portfolio` to create the `Portfolio` object or use the various `set` functions to set up your portfolio problem.
3. Use estimate functions to solve your portfolio problem.

In addition, functions are available to help you view intermediate results and to diagnose your computations. Since MATLAB features are part of a `Portfolio` object, you can save and load objects from your workspace and create and manipulate arrays of objects. After settling on a problem, which, in the case of mean-variance portfolio optimization, means that you have either data or moments for asset returns and a collection of constraints on your portfolios, use `Portfolio` to set the properties for the `Portfolio` object. `Portfolio` lets you create an object from scratch or update an existing object. Since the `Portfolio` object is a value object, it is easy to create a basic object, then use functions to build upon the basic object to create new versions of the basic object. This is useful to compare a basic problem with alternatives derived from the basic problem. For details, see “Creating the Portfolio Object” on page 4-24.

Setting and Getting Properties

You can set properties of a `Portfolio` object using either `Portfolio` or various `set` functions.

Note Although you can also set properties directly, it is not recommended since error-checking is not performed when you set a property directly.

The Portfolio object supports setting properties with name-value pair arguments such that each argument name is a property and each value is the value to assign to that property. For example, to set the AssetMean and AssetCovar properties in an existing Portfolio object p with the values m and C, use the syntax:

```
p = Portfolio(p, 'AssetMean', m, 'AssetCovar', C);
```

In addition to Portfolio, which lets you set individual properties one at a time, groups of properties are set in a Portfolio object with various “set” and “add” functions. For example, to set up an average turnover constraint, use the setTurnover function to specify the bound on portfolio average turnover and the initial portfolio. To get individual properties from a Portfolio object, obtain properties directly or use an assortment of “get” functions that obtain groups of properties from a Portfolio object. The Portfolio object and the set functions have several useful features:

- Portfolio and the set functions try to determine the dimensions of your problem with either explicit or implicit inputs.
- Portfolio and the set functions try to resolve ambiguities with default choices.
- Portfolio and the set functions perform scalar expansion on arrays when possible.
- The associated Portfolio object functions try to diagnose and warn about problems.

Displaying Portfolio Objects

The Portfolio object uses the default display functions provided by MATLAB, where display and disp display a Portfolio object and its properties with or without the object variable name.

Saving and Loading Portfolio Objects

Save and load Portfolio objects using the MATLAB save and load commands.

Estimating Efficient Portfolios and Frontiers

Estimating efficient portfolios and efficient frontiers is the primary purpose of the portfolio optimization tools. An efficient portfolio are the portfolios that satisfy the criteria of minimum risk for a given level of return and maximum return for a given level of risk. A collection of “estimate” and “plot” functions provide ways to explore the efficient frontier. The “estimate” functions obtain either efficient portfolios or risk and return proxies to form efficient frontiers. At the portfolio level, a collection of functions estimates efficient portfolios on the efficient frontier with functions to obtain efficient portfolios:

- At the endpoints of the efficient frontier
- That attains targeted values for return proxies
- That attains targeted values for risk proxies
- Along the entire efficient frontier

These functions also provide purchases and sales needed to shift from an initial or current portfolio to each efficient portfolio. At the efficient frontier level, a collection of functions plot the efficient frontier and estimate either risk or return proxies for efficient portfolios on the efficient frontier. You can use the resultant efficient portfolios or risk and return proxies in subsequent analyses.

Arrays of Portfolio Objects

Although all functions associated with a `Portfolio` object are designed to work on a scalar `Portfolio` object, the array capabilities of MATLAB enable you to set up and work with arrays of `Portfolio` objects. The easiest way to do this is with the `repmat` function. For example, to create a 3-by-2 array of `Portfolio` objects:

```
p = repmat(Portfolio, 3, 2);
disp(p)
```

```
disp(p)
  3×2 Portfolio array with properties:

    BuyCost
    SellCost
    RiskFreeRate
    AssetMean
    AssetCovar
    TrackingError
    TrackingPort
    Turnover
    BuyTurnover
    SellTurnover
    Name
    NumAssets
    AssetList
    InitPort
    AInequality
    bInequality
    AEquality
    bEquality
    LowerBound
    UpperBound
    LowerBudget
    UpperBudget
    GroupMatrix
    LowerGroup
    UpperGroup
    GroupA
    GroupB
    LowerRatio
    UpperRatio
    MinNumAssets
    MaxNumAssets
    BoundType
```

After setting up an array of `Portfolio` objects, you can work on individual `Portfolio` objects in the array by indexing. For example:

```
p(i,j) = Portfolio(p(i,j), ... );
```

This example calls `Portfolio` for the `(i,j)` element of a matrix of `Portfolio` objects in the variable `p`.

If you set up an array of `Portfolio` objects, you can access properties of a particular `Portfolio` object in the array by indexing so that you can set the lower and upper bounds `lb` and `ub` for the (`i`,`j`,`k`) element of a 3-D array of `Portfolio` objects with

```
p(i,j,k) = setBounds(p(i,j,k),lb, ub);
```

and, once set, you can access these bounds with

```
[lb, ub] = getBounds(p(i,j,k));
```

`Portfolio` object functions work on only one `Portfolio` object at a time.

Subclassing Portfolio Objects

You can subclass the `Portfolio` object to override existing functions or to add new properties or functions. To do so, create a derived class from the `Portfolio` class. This gives you all the properties and functions of the `Portfolio` class along with any new features that you choose to add to your subclassed object. The `Portfolio` class is derived from an abstract class called `AbstractPortfolio`. Because of this, you can also create a derived class from `AbstractPortfolio` that implements an entirely different form of portfolio optimization using properties and functions of the `AbstractPortfolio` class.

Conventions for Representation of Data

The portfolio optimization tools follow these conventions regarding the representation of different quantities associated with portfolio optimization:

- Asset returns or prices are in matrix form with samples for a given asset going down the rows and assets going across the columns. In the case of prices, the earliest dates must be at the top of the matrix, with increasing dates going down.
- The mean and covariance of asset returns are stored in a vector and a matrix and the tools have no requirement that the mean must be either a column or row vector.
- Portfolios are in vector or matrix form with weights for a given portfolio going down the rows and distinct portfolios going across the columns.
- Constraints on portfolios are formed in such a way that a portfolio is a column vector.
- Portfolio risks and returns are either scalars or column vectors (for multiple portfolio risks and returns).

Creating the Portfolio Object

In this section...

To create a fully specified mean-variance portfolio optimization problem, instantiate the `Portfolio` object using `Portfolio`. For information on the workflow when using `Portfolio` objects, see "Portfolio Object Workflow" on page 4-17.

Syntax

Use `Portfolio` to create an instance of an object of the `Portfolio` class. You can use `Portfolio` in several ways. To set up a portfolio optimization problem in a `Portfolio` object, the simplest syntax is:

```
p = Portfolio;
```

This syntax creates a `Portfolio` object, `p`, such that all object properties are empty.

The `Portfolio` object also accepts collections of argument name-value pair arguments for properties and their values. The `Portfolio` object accepts inputs for public properties with the general syntax:

```
    p = Portfolio('property1', value1, 'property2', value2, ... );
```

If a `Portfolio` object already exists, the syntax permits the first (and only the first argument) of `Portfolio` to be an existing object with subsequent argument name-value pair arguments for properties to be added or modified. For example, given an existing `Portfolio` object in `p`, the general syntax is:

```
p = Portfolio(p, 'property1', value1, 'property2', value2, ... );
```

Input argument names are not case-sensitive, but must be completely specified. In addition, several properties can be specified with alternative argument names (see "Shortcuts for Property Names" on page 4-29). The `Portfolio` object detects problem dimensions from the inputs and, once set, subsequent inputs can undergo various scalar or matrix expansion operations that simplify the overall process to formulate a problem. In addition, a `Portfolio` object is a value object so that, given portfolio `p`, the following code creates two objects, `p` and `q`, that are distinct:

```
q = Portfolio(p, ...)
```

Portfolio Problem Sufficiency

A mean-variance portfolio optimization is completely specified with the `Portfolio` object if these two conditions are met:

- The moments of asset returns must be specified such that the property `AssetMean` contains a valid finite mean vector of asset returns and the property `AssetCovar` contains a valid symmetric positive-semidefinite matrix for the covariance of asset returns.

The first condition is satisfied by setting the properties associated with the moments of asset returns.

- The set of feasible portfolios must be a nonempty compact set, where a compact set is closed and bounded.

  The second condition is satisfied by an extensive collection of properties that define different types of constraints to form a set of feasible portfolios. Since such sets must be bounded, either explicit or implicit constraints can be imposed, and several functions, such as `estimateBounds`, provide ways to ensure that your problem is properly formulated.

Although the general sufficiency conditions for mean-variance portfolio optimization go beyond these two conditions, the `Portfolio` object implemented in Financial Toolbox implicitly handles all these additional conditions. For more information on the Markowitz model for mean-variance portfolio optimization, see “Portfolio Optimization” on page A-5.

Portfolio Function Examples

If you create a `Portfolio` object, `p`, with no input arguments, you can display it using `disp`:

```
p = Portfolio;
disp(p)
```

```
 Portfolio with properties:

          BuyCost: []
         SellCost: []
     RiskFreeRate: []
        AssetMean: []
       AssetCovar: []
    TrackingError: []
     TrackingPort: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
             Name: []
        NumAssets: []
        AssetList: []
         InitPort: []
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []
       LowerBound: []
       UpperBound: []
      LowerBudget: []
      UpperBudget: []
      GroupMatrix: []
       LowerGroup: []
       UpperGroup: []
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
     MinNumAssets: []
     MaxNumAssets: []
        BoundType: []
```

The approaches listed provide a way to set up a portfolio optimization problem with the `Portfolio` object. The `set` functions offer additional ways to set and modify collections of properties in the `Portfolio` object.

Using the Portfolio Function for a Single-Step Setup

You can use the `Portfolio` object to directly set up a “standard” portfolio optimization problem, given a mean and covariance of asset returns in the variables `m` and `C`:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

p = Portfolio('assetmean', m, 'assetcovar', C, ...
'lowerbudget', 1, 'upperbudget', 1, 'lowerbound', 0)
```

```
p = 

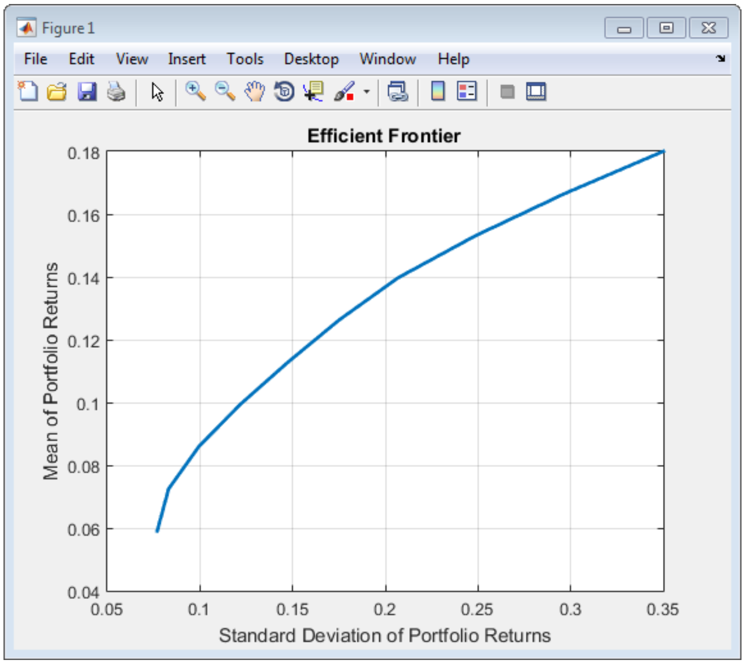
  Portfolio with properties:

          BuyCost: []
         SellCost: []
     RiskFreeRate: []
        AssetMean: [4×1 double]
       AssetCovar: [4×4 double]
    TrackingError: []
     TrackingPort: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
             Name: []
        NumAssets: 4
        AssetList: []
         InitPort: []
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []
       LowerBound: [4×1 double]
       UpperBound: []
      LowerBudget: 1
      UpperBudget: 1
      GroupMatrix: []
       LowerGroup: []
       UpperGroup: []
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
     MinNumAssets: []
     MaxNumAssets: []
        BoundType: []
```

The `LowerBound` property value undergoes scalar expansion since `AssetMean` and `AssetCovar` provide the dimensions of the problem.

You can use dot notation with the function `plotFrontier`.

```
p.plotFrontier
```



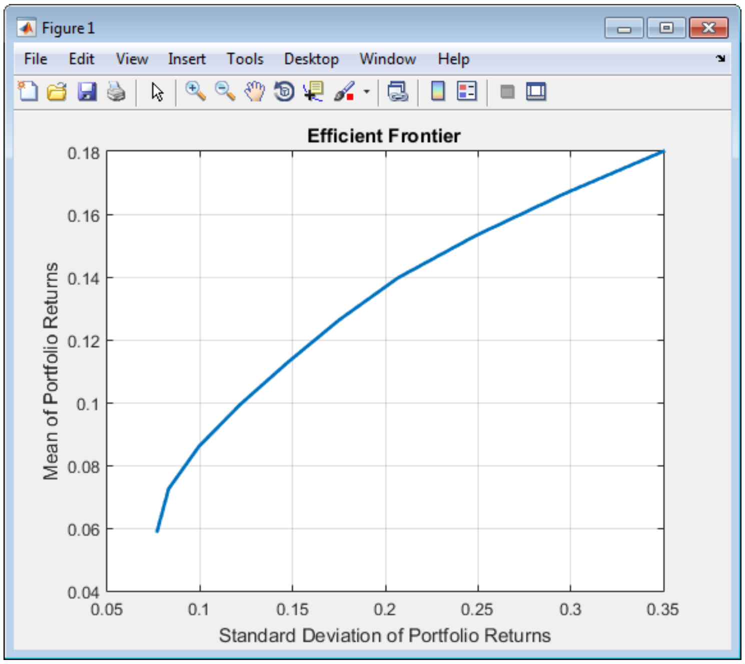
Using the Portfolio Function with a Sequence of Steps

An alternative way to accomplish the same task of setting up a “standard” portfolio optimization problem, given a mean and covariance of asset returns in the variables `m` and `C` (which also illustrates that argument names are not case-sensitive):

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = Portfolio(p, 'assetmean', m, 'assetcovar', C);
p = Portfolio(p, 'lowerbudget', 1, 'upperbudget', 1);
p = Portfolio(p, 'lowerbound', 0);

plotFrontier(p)
```

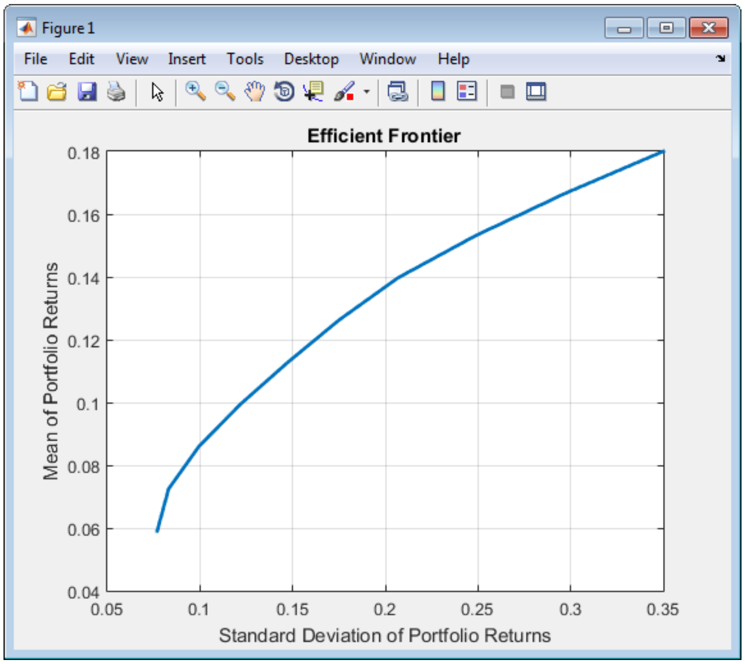


This way works because the calls to `Portfolio` are in this particular order. In this case, the call to initialize `AssetMean` and `AssetCovar` provides the dimensions for the problem. If you were to do this step last, you would have to explicitly dimension the `LowerBound` property as follows:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = Portfolio(p, 'LowerBound', zeros(size(m)));
p = Portfolio(p, 'LowerBudget', 1, 'UpperBudget', 1);
p = Portfolio(p, 'AssetMean', m, 'AssetCovar', C);

plotFrontier(p)
```



If you did not specify the size of `LowerBound` but, instead, input a scalar argument, the `Portfolio` object assumes that you are defining a single-asset problem and produces an error at the call to set asset moments with four assets.

Shortcuts for Property Names

The `Portfolio` object has shorter argument names that replace longer argument names associated with specific properties of the `Portfolio` object. For example, rather than enter `'assetcovar'`, the `Portfolio` object accepts the case-insensitive name `'covar'` to set the `AssetCovar` property in a `Portfolio` object. Every shorter argument name corresponds with a single property in the `Portfolio` object. The one exception is the alternative argument name `'budget'`, which signifies both the `LowerBudget` and `UpperBudget` properties. When `'budget'` is used, then the `LowerBudget` and `UpperBudget` properties are set to the same value to form an equality budget constraint.

Shortcuts for Property Names

Shortcut Argument Name	Equivalent Argument / Property Name
ae	AEquality
ai	AInequality
covar	AssetCovar
assetnames or assets	AssetList
mean	AssetMean
be	bEquality
bi	bInequality
group	GroupMatrix
lb	LowerBound
n or num	NumAssets
rfr	RiskFreeRate
ub	UpperBound
budget	UpperBudget and LowerBudget

For example, this call `Portfolio` uses these shortcuts for properties and is equivalent to the previous examples:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

p = Portfolio('mean', m, 'covar', C, 'budget', 1, 'lb', 0);
plotFrontier(p)
```

Direct Setting of Portfolio Object Properties

Although not recommended, you can set properties directly, however no error-checking is done on your inputs:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p.NumAssets = numel(m);
p.AssetMean = m;
p.AssetCovar = C;
p.LowerBudget = 1;
p.UpperBudget = 1;
p.LowerBound = zeros(size(m));

plotFrontier(p)
```

Common Operations on the Portfolio Object

In this section...

Naming a Portfolio Object

To name a `Portfolio` object, use the `Name` property. `Name` is informational and has no effect on any portfolio calculations. If the `Name` property is nonempty, `Name` is the title for the efficient frontier plot generated by `plotFrontier`. For example, if you set up an asset allocation fund, you could name the `Portfolio` object Asset Allocation Fund:

```
p = Portfolio('Name','Asset Allocation Fund');
disp(p.Name)
```

```
Asset Allocation Fund
```

Configuring the Assets in the Asset Universe

The fundamental quantity in the `Portfolio` object is the number of assets in the asset universe. This quantity is maintained in the `NumAssets` property. Although you can set this property directly, it is derived from other properties such as the mean of asset returns and the initial portfolio. In some instances, the number of assets may need to be set directly. This example shows how to set up a `Portfolio` object that has four assets:

```
p = Portfolio('NumAssets', 4);
disp(p.NumAssets)
```

```
4
```

After setting the `NumAssets` property, you cannot modify it (unless no other properties are set that depend on `NumAssets`). The only way to change the number of assets in an existing `Portfolio` object with a known number of assets is to create a new Portfolio object.

Setting Up a List of Asset Identifiers

When working with portfolios, you must specify a universe of assets. Although you can perform a complete analysis without naming the assets in your universe, it is helpful to have an identifier associated with each asset as you create and work with portfolios. You can create a list of asset identifiers as a cell vector of character vectors in the property `AssetList`. You can set up the list using the next two functions.

Setting Up Asset Lists Using the Portfolio Function

Suppose that you have a `Portfolio` object, `p`, with assets with symbols `'AA''`, `'BA'`, `'CAT'`, `'DD'`, and `'ETR'`. You can create a list of these asset symbols in the object using the `Portfolio` object:

```
p = Portfolio('assetlist', { 'AA', 'BA', 'CAT', 'DD', 'ETR' });
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

Notice that the property AssetList is maintained as a cell array that contains character vectors, and that it is necessary to pass a cell array into the Portfolio object to set AssetList. In addition, notice that the property NumAssets is set to 5 based on the number of symbols used to create the asset list:

```
disp(p.NumAssets)
```

```
5
```

Setting Up Asset Lists Using the setAssetList Function

You can also specify a list of assets using the setAssetList function. Given the list of asset symbols 'AA', 'BA', 'CAT', 'DD', and'ETR', you can use setAssetList with:

```
p = Portfolio;
p = setAssetList(p, { 'AA', 'BA', 'CAT', 'DD', 'ETR' });
disp(p.AssetList)
```

```
 'AA'    'BA'    'CAT'    'DD'    'ETR'
```

setAssetList also enables you to enter symbols directly as a comma-separated list without creating a cell array of character vectors. For example, given the list of assets symbols 'AA', 'BA', 'CAT', 'DD', and 'ETR', use setAssetList:

```
p = Portfolio;
p = setAssetList(p,'AA', 'BA', 'CAT', 'DD', 'ETR');
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

setAssetList has many additional features to create lists of asset identifiers. If you use setAssetList with just a Portfolio object, it creates a default asset list according to the name specified in the hidden public property defaultforAssetList (which is 'Asset' by default). The number of asset names created depends on the number of assets in the property NumAssets. If NumAssets is not set, then NumAssets is assumed to be 1.

For example, if a Portfolio object p is created with NumAssets = 5, then this code fragment shows the default naming behavior:

```
p = Portfolio('numassets',5);
p = setAssetList(p);
disp(p.AssetList)
```

```
'Asset1'    'Asset2'    'Asset3'    'Asset4'    'Asset5'
```

Suppose that your assets are, for example, ETFs and you change the hidden property defaultforAssetList to 'ETF', you can then create a default list for ETFs:

```
p = Portfolio('numassets',5);
p.defaultforAssetList = 'ETF';
p = setAssetList(p);
disp(p.AssetList)
```

```
'ETF1'    'ETF2'    'ETF3'    'ETF4'    'ETF5'
```

Truncating and Padding Asset Lists

If the NumAssets property is already set and you pass in too many or too few identifiers, the Portfolio object, and the setAssetList function truncate or pad the list with numbered default asset names that use the name specified in the hidden public property defaultforAssetList. If the list is truncated or padded, a warning message indicates the discrepancy. For example, assume that you have a Portfolio object with five ETFs and you only know the first three CUSIPs '921937835', '922908769', and '922042775'. Use this syntax to create an asset list that pads the remaining asset identifiers with numbered 'UnknownCUSIP' placeholders:

```
p = Portfolio('numassets',5);
p.defaultforAssetList = 'UnknownCUSIP';
p = setAssetList(p,'921937835', '922908769', '922042775');
disp(p.AssetList)
```

```
Warning: Input list of assets has 2 too few identifiers. Padding with numbered assets.
> In Portfolio.setAssetList at 121
    '921937835'    '922908769'    '922042775'    'UnknownCUSIP4'    'UnknownCUSIP5'
```

Alternatively, suppose that you have too many identifiers and need only the first four assets. This example illustrates truncation of the asset list using the Portfolio object:

```
p = Portfolio('numassets',4);
p = Portfolio(p, 'assetlist', { 'AGG', 'EEM', 'MDY', 'SPY', 'VEU' });
disp(p.AssetList)
```

```
Warning: AssetList has 1 too many identifiers. Using first 4 assets.
> In Portfolio.checkarguments at 434
  In Portfolio.Portfolio>Portfolio.Portfolio at 171
    'AGG'    'EEM'    'MDY'    'SPY'
```

The hidden public property uppercaseAssetList is a Boolean flag to specify whether to convert asset names to uppercase letters. The default value for uppercaseAssetList is false. This example shows how to use the uppercaseAssetList flag to force identifiers to be uppercase letters:

```
p = Portfolio;
p.uppercaseAssetList = true;
p = setAssetList(p,{ 'aa', 'ba', 'cat', 'dd', 'etr' });
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

Setting Up an Initial or Current Portfolio

In many applications, creating a new optimal portfolio requires comparing the new portfolio with an initial or current portfolio to form lists of purchases and sales. The Portfolio object property InitPort lets you identify an initial or current portfolio. The initial portfolio also plays an essential role if you have either transaction costs or turnover constraints. The initial portfolio need not be feasible within the constraints of the problem. This can happen if the weights in a portfolio have shifted such that some constraints become violated. To check if your initial portfolio is feasible, use the checkFeasibility function described in “Validating Portfolios” on page 4-91. Suppose that you have an initial portfolio in x0, then use the Portfolio object to set up an initial portfolio:

```
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = Portfolio('InitPort', x0);
disp(p.InitPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

As with all array properties, you can set InitPort with scalar expansion. This is helpful to set up an equally weighted initial portfolio of, for example, 10 assets:

```
p = Portfolio('NumAssets', 10, 'InitPort', 1/10);
disp(p.InitPort)
```

```
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
```

To clear an initial portfolio from your Portfolio object, use either the Portfolio object or the setInitPort function with an empty input for the InitPort property. If transaction costs or turnover constraints are set, it is not possible to clear the InitPort property in this way. In this case, to clear InitPort, first clear the dependent properties and then clear theInitPort property.

The InitPort property can also be set with setInitPort which lets you specify the number of assets if you want to use scalar expansion. For example, given an initial portfolio in x0, use setInitPort to set the InitPort property:

```
p = Portfolio;
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = setInitPort(p, x0);
disp(p.InitPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

To create an equally weighted portfolio of four assets, use setInitPort:

```
p = Portfolio;
p = setInitPort(p, 1/4, 4);
disp(p.InitPort)
```

```
 0.2500
 0.2500
 0.2500
 0.2500
```

Portfolio object functions that work with either transaction costs or turnover constraints also depend on the `InitPort` property. So, the `set` functions for transaction costs or turnover constraints permit the assignment of a value for the `InitPort` property as part of their implementation. For details, see "Working with Average Turnover Constraints Using Portfolio Object" on page 4-81, "Working with One-Way Turnover Constraints Using Portfolio Object" on page 4-84, and "Working with Transaction Costs" on page 4-53 for details. If either transaction costs or turnover constraints are used, then the `InitPort` property must have a nonempty value. Absent a specific value assigned through the `Portfolio` object or various `set` functions, the `Portfolio` object sets `InitPort` to `0` and warns if `BuyCost`, `SellCost`, or `Turnover` properties are set. The following example illustrates what happens if an average turnover constraint is specified with an initial portfolio:

```
p = Portfolio('Turnover', 0.3, 'InitPort', [ 0.3; 0.2; 0.2; 0.0 ]);
disp(p.InitPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

In contrast, this example shows what happens if an average turnover constraint is specified without an initial portfolio:

```
p = Portfolio('Turnover', 0.3);
disp(p.InitPort)
```

```
Warning: InitPort and NumAssets are empty and either transaction costs or turnover constraints specified.
Will set NumAssets = 1 and InitPort = 0.
> In Portfolio.checkarguments at 367
  In Portfolio.Portfolio>Portfolio.Portfolio at 171
     0
```

Setting Up a Tracking Portfolio

Given a benchmark or tracking portfolio, you can ensure that the risk of a portfolio relative to the benchmark portfolio is no greater than a specified amount. The `Portfolio` object property `TrackingPort` lets you identify a tracking portfolio. For more information on using a tracking portfolio with tracking error constraints, see “Working with Tracking Error Constraints Using Portfolio Object” on page 4-87.

The tracking error constraints can be used with any of the other supported constraints in the `Portfolio` object without restrictions. However, since the portfolio set necessarily and sufficiently must be a non-empty compact set, the application of a tracking error constraint can result in an empty portfolio set. Use `estimateBounds` to confirm that the portfolio set is non-empty and compact.

Suppose that you have an initial portfolio in `x0`, then use the `Portfolio` object to set up a tracking portfolio:

```
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = Portfolio('TrackingPort', x0);
disp(p.TrackingPort)
```

```
    0.3000
    0.2000
    0.2000
         0
```

As with all array properties, you can set `TrackingPort` with scalar expansion. This is helpful to set up an equally weighted tracking portfolio of, for example, 10 assets:

```
p = Portfolio('NumAssets', 10, 'TrackingPort', 1/10);
disp(p.TrackingPort)
```

```
    0.1000
    0.1000
    0.1000
    0.1000
    0.1000
    0.1000
    0.1000
    0.1000
    0.1000
    0.1000
```

To clear a tracking portfolio from your `Portfolio` object, use either the `Portfolio` object or the `setTrackingPort` function with an empty input for the `TrackingPort` property. If transaction costs or turnover constraints are set, it is not possible to clear the `TrackingPort` property in this way. In this case, to clear `TrackingPort`, first clear the dependent properties and then clear the`TrackingPort` property.

The `TrackingPort` property can also be set with `setTrackingPort` which lets you specify the number of assets if you want to use scalar expansion. For example, given an initial portfolio in `x0`, use `setTrackingPort` to set the `TrackingPort` property:

```
p = Portfolio;
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = setTrackingPort(p, x0);
disp(p.TrackingPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

To create an equally weighted portfolio of four assets, use `setTrackingPort`:

```
p = Portfolio;
p = setTrackingPort(p, 1/4, 4);
disp(p.TrackingPort)
```

```
 0.2500
 0.2500
 0.2500
 0.2500
```

Asset Returns and Moments of Asset Returns Using Portfolio Object

In this section...

Since mean-variance portfolio optimization problems require estimates for the mean and covariance of asset returns, the `Portfolio` object has several ways to set and get the properties `AssetMean` (for the mean) and `AssetCovar` (for the covariance). In addition, the return for a riskless asset is kept in the property `RiskFreeRate` so that all assets in `AssetMean` and `AssetCovar` are risky assets. For information on the workflow when using `Portfolio` objects, see “Portfolio Object Workflow” on page 4-17.

Assignment Using the Portfolio Function

Suppose that you have a mean and covariance of asset returns in variables `m` and `C`. The properties for the moments of asset returns are set using the `Portfolio` object:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0; 
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;
p = Portfolio('AssetMean', m, 'AssetCovar', C);
disp(p.NumAssets)
disp(p.AssetMean)
disp(p.AssetCovar)
```

```
      4

    0.0042
    0.0083
    0.0100
    0.0150

    0.0005    0.0003    0.0002         0
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
         0    0.0010    0.0028    0.0102
```

Notice that the Portfolio object determines the number of assets in `NumAssets` from the moments. The `Portfolio` object enables separate initialization of the moments, for example:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
```

```
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

p = Portfolio;
p = Portfolio(p, 'AssetMean', m);
p = Portfolio(p, 'AssetCovar', C);
[assetmean, assetcovar] = p.getAssetMoments

assetmean =

    0.0042
    0.0083
    0.0100
    0.0150

assetcovar =

    0.0005    0.0003    0.0002         0
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
         0    0.0010    0.0028    0.0102
```

The `getAssetMoments` function lets you get the values for `AssetMean` and `AssetCovar` properties at the same time.

Assignment Using the setAssetMoments Function

You can also set asset moment properties using the `setAssetMoments` function. For example, given the mean and covariance of asset returns in the variables `m` and `C`, the asset moment properties can be set:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

p = Portfolio;
p = setAssetMoments(p, m, C);
[assetmean, assetcovar] = getAssetMoments(p)

assetmean =

    0.0042
    0.0083
    0.0100
    0.0150

assetcovar =

    0.0005    0.0003    0.0002         0
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
         0    0.0010    0.0028    0.0102
```

Scalar Expansion of Arguments

Both the `Portfolio` object and the `setAssetMoments` function perform scalar expansion on arguments for the moments of asset returns. When using the `Portfolio` object, the number of assets must be already specified in the variable `NumAssets`. If `NumAssets` has not already been set, a scalar argument is interpreted as a scalar with `NumAssets` set to `1`. `setAssetMoments` provides an additional optional argument to specify the number of assets so that scalar expansion works with the correct number of assets. In addition, if either a scalar or vector is input for the covariance of asset returns, a diagonal matrix is formed such that a scalar expands along the diagonal and a vector becomes the diagonal. This example demonstrates scalar expansion for four jointly independent assets with a common mean `0.1` and common variance `0.03`:

```
p = Portfolio;
p = setAssetMoments(p, 0.1, 0.03, 4);
[assetmean, assetcovar] = getAssetMoments(p)

assetmean =

    0.1000
    0.1000
    0.1000
    0.1000

assetcovar =

    0.0300         0         0         0
         0    0.0300         0         0
         0         0    0.0300         0
         0         0         0    0.0300
```

If at least one argument is properly dimensioned, you do not need to include the additional `NumAssets` argument. This example illustrates a constant-diagonal covariance matrix and a mean of asset returns for four assets:

```
p = Portfolio;
p = setAssetMoments(p, [ 0.05; 0.06; 0.04; 0.03 ], 0.03);
[assetmean, assetcovar] = getAssetMoments(p)

assetmean =

    0.0500
    0.0600
    0.0400
    0.0300

assetcovar =

    0.0300         0         0         0
         0    0.0300         0         0
         0         0    0.0300         0
         0         0         0    0.0300
```

In addition, scalar expansion works with the `Portfolio` object if `NumAssets` is known, or is deduced from the inputs.

Estimating Asset Moments from Prices or Returns

Another way to set the moments of asset returns is to use the `estimateAssetMoments` function which accepts either prices or returns and estimates the mean and covariance of asset returns. Either prices or returns are stored as matrices with samples going down the rows and assets going across the columns. In addition, prices or returns can be stored in a `table` or `timetable` (see “Estimating Asset Moments from Time Series Data” on page 4-47). To illustrate using `estimateAssetMoments`, generate random samples of 120 observations of asset returns for four assets from the mean and covariance of asset returns in the variables `m` and `C` with `portsim`. The default behavior of `portsim` creates simulated data with estimated mean and covariance identical to the input moments `m` and `C`. In addition to a return series created by `portsim` in the variable `X`, a price series is created in the variable `Y`:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;
X = portsim(m', C, 120);
Y = ret2tick(X);
```

Note Portfolio optimization requires that you use total returns and not just price returns. So, "returns" should be total returns and "prices" should be total return prices.

Given asset returns and prices in variables `X` and `Y` from above, this sequence of examples demonstrates equivalent ways to estimate asset moments for the `Portfolio` object. A `Portfolio` object is created in `p` with the moments of asset returns set directly in the `Portfolio` object, and a second `Portfolio` object is created in `q` to obtain the mean and covariance of asset returns from asset return data in `X` using `estimateAssetMoments`:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

X = portsim(m', C, 120);
p = Portfolio('mean', m, 'covar', C);
q = Portfolio;
q = estimateAssetMoments(q, X);

[passetmean, passetcovar] = getAssetMoments(p)
[qassetmean, qassetcovar] = getAssetMoments(q)
```

```
passetmean =

    0.0042
    0.0083
    0.0100
    0.0150

passetcovar =

    0.0005    0.0003    0.0002         0
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
         0    0.0010    0.0028    0.0102

qassetmean =

    0.0042
    0.0083
    0.0100
    0.0150

qassetcovar =

    0.0005    0.0003    0.0002    0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
    0.0000    0.0010    0.0028    0.0102
```

Notice how either approach has the same moments. The default behavior of `estimateAssetMoments` is to work with asset returns. If, instead, you have asset prices in the variable `Y`, `estimateAssetMoments` accepts a name-value pair argument name `'DataFormat'` with a corresponding value set to `'prices'` to indicate that the input to the function is in the form of asset prices and not returns (the default value for the `'DataFormat'` argument is `'returns'`). This example compares direct assignment of moments in the `Portfolio` object `p` with estimated moments from asset price data in `Y` in the `Portfolio` object `q`:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

X = portsim(m', C, 120);
Y = ret2tick(X);

p = Portfolio('mean',m,'covar',C);

q = Portfolio;
q = estimateAssetMoments(q, Y, 'dataformat', 'prices');

[passetmean, passetcovar] = getAssetMoments(p)
[qassetmean, qassetcovar] = getAssetMoments(q)
```

```
passetmean =

    0.0042
    0.0083
    0.0100
    0.0150
```

```
passetcovar =

    0.0005    0.0003    0.0002         0
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
         0    0.0010    0.0028    0.0102

qassetmean =

    0.0042
    0.0083
    0.0100
    0.0150

qassetcovar =

    0.0005    0.0003    0.0002    0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
    0.0000    0.0010    0.0028    0.0102
```

Estimating Asset Moments with Missing Data

Often when working with multiple assets, you have missing data indicated by NaN values in your return or price data. Although “Multivariate Normal Regression” on page 9-2 goes into detail about regression with missing data, the estimateAssetMoments function has a name-value pair argument name 'MissingData' that indicates with a Boolean value whether to use the missing data capabilities of Financial Toolbox software. The default value for 'MissingData' is false which removes all samples with NaN values. If, however, 'MissingData' is set to true, estimateAssetMoments uses the ECM algorithm to estimate asset moments. This example illustrates how this works on price data with missing values:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

X = portsim(m', C, 120);
Y = ret2tick(X);
Y(1:20,1) = NaN;
Y(1:12,4) = NaN;

p = Portfolio('mean',m,'covar',C);

q = Portfolio;
q = estimateAssetMoments(q, Y, 'dataformat', 'prices');

r = Portfolio;
r = estimateAssetMoments(r, Y, 'dataformat', 'prices', 'missingdata', true);

[passetmean, passetcovar] = getAssetMoments(p)
[qassetmean, qassetcovar] = getAssetMoments(q)
[rassetmean, rassetcovar] = getAssetMoments(r)
```

```
passetmean =

    0.0042
    0.0083
    0.0100
    0.0150

passetcovar =

    0.0005    0.0003    0.0002         0
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
         0    0.0010    0.0028    0.0102

```

The Portfolio object p contains raw moments, the object q contains estimated moments in which NaN values are discarded, and the object r contains raw moments that accommodate missing values. Each time you run this example, you will get different estimates for the moments in q and r, and these will also differ from the moments in p.

Estimating Asset Moments from Time Series Data

The estimateAssetMoments function also accepts asset returns or prices stored in a table or timetable. estimateAssetMoments implicitly works with matrices of data or data in a table or timetable object using the same rules for whether the data are returns or prices.

To illustrate the use of a table and timetable, use array2table and array2timetable to create a table and a timetable that contain asset returns generated with portsim (see “Estimating Asset

Moments from Prices or Returns” on page 4-44). Two portfolio objects are then created with the `AssetReturns` based on a table and a timetable object.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

assetRetnScenarios = portsim(m', C, 120);
dates = datetime(datenum(2001,1:120,31), 'ConvertFrom', 'datenum');
assetsName = {'Bonds', 'LargeCap', 'SmallCap', 'Emerging'};
assetRetnTimeTable = array2timetable(assetRetnScenarios,'RowTimes',dates, 'VariableNames', assetsName);
assetRetnTable = array2table(assetRetnScenarios, 'VariableNames', assetsName);

% Create two Portfolio objects:
% p with predefined mean and covar: q with asset return scenarios to estimate mean and covar.
p = Portfolio('mean', m, 'covar', C);
q = Portfolio;

% estimate asset moments with timetable
q = estimateAssetMoments(q, assetRetnTimeTable);
[passetmean, passetcovar] = getAssetMoments(p)
[qassetmean, qassetcovar] = getAssetMoments(q)

% estimate asset moments with table
q = estimateAssetMoments(q, assetRetnTable);
[passetmean, passetcovar] = getAssetMoments(p)
[qassetmean, qassetcovar] = getAssetMoments(q)
```

```
passetmean =

    0.0042
    0.0083
    0.0100
    0.0150

passetcovar =

    0.0005    0.0003    0.0002         0

    0.0083
    0.0100
    0.0150

qassetcovar =

    0.0005    0.0003    0.0002   -0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
   -0.0000    0.0010    0.0028    0.0102

passetmean =
    0.0042
    0.0083
    0.0100
    0.0150

passetcovar =

    0.0005    0.0003    0.0002         0
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
         0    0.0010    0.0028    0.0102

qassetmean =

    0.0042
    0.0083
    0.0100
    0.0150

qassetcovar =

    0.0005    0.0003    0.0002   -0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0048    0.0028
   -0.0000    0.0010    0.0028    0.0102
```

As you can see, the moments match between th two portfolios. In addition, `estimateAssetMoments` also extracts asset names or identifiers from a `table` or `timetable` when the argument name `'GetAssetList'` set to `true` (its default value is `false`). If the `'GetAssetList'` value is `true`, the identifiers are used to set the `AssetList` property of the object. To show this, the formation of the `Portfolio` object `q` is repeated from the previous example with the `'GetAssetList'` flag set to `true` extracts the column labels from a table or timetable object:

```
q = estimateAssetMoments(q,assetRetnTable,'GetAssetList',true);
disp(q.AssetList)
```

```
'Bonds'    'LargeCap'    'SmallCap'    'Emerging'
```

Note if you set the `'GetAssetList'` flag set to `true` and your input data is in a matrix, `estimateAssetMoments` uses the default labeling scheme from `setAssetList` described in “Setting Up a List of Asset Identifiers” on page 4-32.

Working with a Riskless Asset

You can specify a riskless asset with the mean and covariance of asset returns in the AssetMean and AssetCovar properties such that the riskless asset has variance of 0 and is completely uncorrelated with all other assets. In this case, the Portfolio object uses a separate RiskFreeRate property that stores the rate of return of a riskless asset. Thus, you can separate your universe into a riskless asset and a collection of risky assets. For example, assume that your riskless asset has a return in the scalar variable r0, then the property for the RiskFreeRate is set using the Portfolio object:

```
r0 = 0.01/12;
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio('RiskFreeRate', r0, 'AssetMean', m, 'AssetCovar', C);
disp(p.RiskFreeRate)
```

```
 8.3333e-004
```

Note If your problem has a budget constraint such that your portfolio weights must sum to 1, then the riskless asset is irrelevant.

Working with Transaction Costs

The difference between net and gross portfolio returns is transaction costs. The net portfolio return proxy has distinct proportional costs to purchase and to sell assets which are maintained in the `Portfolio` object properties `BuyCost` and `SellCost`. Transaction costs are in units of total return and, as such, are proportional to the price of an asset so that they enter the model for net portfolio returns in return form. For example, suppose that you have a stock currently priced $40 and your usual transaction costs are five cents per share. Then the transaction cost for the stock is 0.05/40 = 0.00125 (as defined in “Net Portfolio Returns” on page 4-4). Costs are entered as positive values and credits are entered as negative values.

Setting Transaction Costs Using the Portfolio Function

To set up transaction costs, you must specify an initial or current portfolio in the `InitPort` property. If the initial portfolio is not set when you set up the transaction cost properties, `InitPort` is `0`. The properties for transaction costs can be set using the`Portfolio` object. For example, assume that purchase and sale transaction costs are in the variables `bc` and `sc` and an initial portfolio is in the variable `x0`, then transaction costs are set:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = Portfolio('BuyCost', bc, 'SellCost', sc, 'InitPort', x0);
disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)
```

```
    5

    0.0013
    0.0013
    0.0013
    0.0013
    0.0013

    0.0013
    0.0070
    0.0013

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

Setting Transaction Costs Using the setCosts Function

You can also set the properties for transaction costs using `setCosts`. Assume that you have the same costs and initial portfolio as in the previous example. Given a `Portfolio` object `p` with an initial portfolio already set, use `setCosts` to set up transaction costs:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];

p = Portfolio('InitPort', x0);
p = setCosts(p, bc, sc);

disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)

    5

    0.0013
    0.0013
    0.0013

    0.0013
    0.0070
    0.0013
    0.0013
    0.0024

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

You can also set up the initial portfolio's `InitPort` value as an optional argument to `setCosts` so that the following is an equivalent way to set up transaction costs:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];

p = Portfolio;
p = setCosts(p, bc, sc, x0);

disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)

    5

    0.0013
    0.0013
    0.0013
    0.0013
    0.0013

    0.0013
    0.0070
    0.0013
    0.0013
    0.0024

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

For an example of setting costs, see “Portfolio Analysis with Turnover Constraints” on page 4-204.

Setting Transaction Costs with Scalar Expansion

Both the `Portfolio` object and the `setCosts` function implement scalar expansion on the arguments for transaction costs and the initial portfolio. If the `NumAssets` property is already set in the `Portfolio` object, scalar arguments for these properties are expanded to have the same value across all dimensions. In addition, `setCosts` lets you specify `NumAssets` as an optional final argument. For example, assume that you have an initial portfolio `x0` and you want to set common transaction costs on all assets in your universe. You can set these costs in any of these equivalent ways:

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = Portfolio('InitPort', x0, 'BuyCost', 0.002, 'SellCost', 0.002);
```

or

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = Portfolio('InitPort', x0);
p = setCosts(p, 0.002, 0.002);
```

or

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = Portfolio;
p = setCosts(p, 0.002, 0.002, x0);
```

To clear costs from your `Portfolio` object, use either the `Portfolio` object or `setCosts` with empty inputs for the properties to be cleared. For example, you can clear sales costs from the `Portfolio` object `p` in the previous example:

```
p = Portfolio(p, 'SellCost', []);
```

Working with Portfolio Constraints Using Defaults

The final element for a complete specification of a portfolio optimization problem is the set of feasible portfolios, which is called a portfolio set. A portfolio set $X \subset R^n$ is specified by construction as the intersection of sets formed by a collection of constraints on portfolio weights. A portfolio set necessarily and sufficiently must be a nonempty, closed, and bounded set.

When setting up your portfolio set, ensure that the portfolio set satisfies these conditions. The most basic or “default” portfolio set requires portfolio weights to be nonnegative (using the lower-bound constraint) and to sum to `1` (using the budget constraint). For information on the workflow when using `Portfolio` objects, see “Portfolio Object Workflow” on page 4-17.

Setting Default Constraints for Portfolio Weights Using Portfolio Object

The “default” portfolio problem has two constraints on portfolio weights:

- Portfolio weights must be nonnegative.
- Portfolio weights must sum to `1`.

Implicitly, these constraints imply that portfolio weights are no greater than `1`, although this is a superfluous constraint to impose on the problem.

Setting Default Constraints Using the Portfolio Function

Given a portfolio optimization problem with `NumAssets` = `20` assets, use the `Portfolio` object to set up a default problem and explicitly set bounds and budget constraints:

```
p = Portfolio('NumAssets', 20, 'LowerBound', 0, 'Budget', 1);
disp(p)
```

```
  Portfolio with properties:

           GroupB: []
       LowerRatio: []
       UpperRatio: []
        BoundType: []
     MinNumAssets: []
     MaxNumAssets: []
```

Setting Default Constraints Using the setDefaultConstraints Function

An alternative approach is to use the `setDefaultConstraints` function. If the number of assets is already known in a `Portfolio` object, use `setDefaultConstraints` with no arguments to set up the necessary bound and budget constraints. Suppose that you have 20 assets to set up the portfolio set for a default problem:

```
p = Portfolio('NumAssets', 20);
p = setDefaultConstraints(p);
disp(p)
```

```
  Portfolio with properties:

          BuyCost: []
         SellCost: []
     RiskFreeRate: []
        AssetMean: []
       AssetCovar: []
    TrackingError: []
     TrackingPort: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
             Name: []
        NumAssets: 20
        AssetList: []
         InitPort: []
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []
       LowerBound: [20×1 double]
       UpperBound: []
      LowerBudget: 1
      UpperBudget: 1
      GroupMatrix: []
       LowerGroup: []
       UpperGroup: []
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
        BoundType: [0×0 categorical]
     MinNumAssets: []
     MaxNumAssets: []
```

If the number of assets is unknown, `setDefaultConstraints` accepts `NumAssets` as an optional argument to form a portfolio set for a default problem. Suppose that you have 20 assets:

```
p = Portfolio;
p = setDefaultConstraints(p, 20);
disp(p)
```

```
Portfolio with properties:

          BuyCost: []
         SellCost: []
     RiskFreeRate: []
        AssetMean: []
       AssetCovar: []
    TrackingError: []
     TrackingPort: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
             Name: []
        NumAssets: 20
        AssetList: []
         InitPort: []
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []

Working with 'Simple' Bound Constraints Using Portfolio Object

'Simple' bound constraints are optional linear constraints that maintain upper and lower bounds on portfolio weights (see “'Simple' Bound Constraints” on page 4-9). Although every portfolio set must be bounded, it is not necessary to specify a portfolio set with explicit bound constraints. For example, you can create a portfolio set with an implicit upper bound constraint or a portfolio set with average turnover constraints. The bound constraints have properties LowerBound for the lower-bound constraint and UpperBound for the upper-bound constraint. Set default values for these constraints using the setDefaultConstraints function (see “Setting Default Constraints for Portfolio Weights Using Portfolio Object” on page 4-57).

Setting 'Simple' Bounds Using the Portfolio Function

The properties for bound constraints are set through the Portfolio object. Suppose that you have a balanced fund with stocks that can range from 50% to 75% of your portfolio and bonds that can range from 25% to 50% of your portfolio. The bound constraints for a balanced fund are set with:

```
lb = [ 0.5; 0.25 ];
ub = [ 0.75; 0.5 ];
p = Portfolio('LowerBound', lb, 'UpperBound', ub, 'BoundType', 'Simple');
disp(p.NumAssets)
disp(p.LowerBound)
disp(p.UpperBound)
```

```
 2

 0.5000
 0.2500

 0.7500
 0.5000
```

To continue with this example, you must set up a budget constraint. For details, see “Working with Budget Constraints Using Portfolio Object” on page 4-64.

Setting 'Simple' Bounds Using the setBounds Function

You can also set the properties for bound constraints using setBounds. Suppose that you have a balanced fund with stocks that can range from 50% to 75% of your portfolio and bonds that can range from 25% to 50% of your portfolio. Given a Portfolio object p, use setBounds to set the bound constraints:

```
lb = [ 0.5; 0.25 ];
ub = [ 0.75; 0.5 ];
p = Portfolio;
p = setBounds(p, lb, ub,'BoundType', 'Simple');
disp(p.NumAssets)
disp(p.LowerBound)
disp(p.UpperBound)
```

```
  2

  0.5000
  0.2500
```

```
    0.7500
    0.5000
```

Setting 'Simple' Bounds Using the Portfolio Function or setBounds Function

Both the `Portfolio` object and `setBounds` function implement scalar expansion on either the `LowerBound` or `UpperBound` properties. If the `NumAssets` property is already set in the `Portfolio` object, scalar arguments for either property expand to have the same value across all dimensions. In addition, `setBounds` lets you specify `NumAssets` as an optional argument. Suppose that you have a universe of 500 assets and you want to set common bound constraints on all assets in your universe. Specifically, you are a long-only investor and want to hold no more than 5% of your portfolio in any single asset. You can set these bound constraints in any of these equivalent ways:

```
p = Portfolio('NumAssets', 500, 'LowerBound', 0, 'UpperBound', 0.05,'BoundType', 'Simple');
```

or

```
p = Portfolio('NumAssets', 500);
p = setBounds(p, 0, 0.05,'BoundType','Simple');
```

or

```
p = Portfolio;
p = setBounds(p, 0, 0.05, 'NumAssets', 500,'BoundType','Simple');
```

To clear bound constraints from your `Portfolio` object, use either the `Portfolio` object or `setBounds` with empty inputs for the properties to be cleared. For example, to clear the upper-bound constraint from the `Portfolio` object `p` in the previous example:

```
p = Portfolio(p, 'UpperBound', []);
```

Working with Budget Constraints Using Portfolio Object

The budget constraint is an optional linear constraint that maintains upper and lower bounds on the sum of portfolio weights (see “Budget Constraints” on page 4-10). Budget constraints have properties `LowerBudget` for the lower budget constraint and `UpperBudget` for the upper budget constraint. If you set up a portfolio optimization problem that requires portfolios to be fully invested in your universe of assets, you can set `LowerBudget` to be equal to `UpperBudget`. These budget constraints can be set with default values equal to `1` using `setDefaultConstraints` (see “Setting Default Constraints for Portfolio Weights Using Portfolio Object” on page 4-57).

Setting Budget Constraints Using the Portfolio Function

The properties for the budget constraint can also be set using the `Portfolio` object. Suppose that you have an asset universe with many risky assets and a riskless asset and you want to ensure that your portfolio never holds more than 1% cash, that is, you want to ensure that you are 99–100% invested in risky assets. The budget constraint for this portfolio can be set with:

```
p = Portfolio('LowerBudget', 0.99, 'UpperBudget', 1);
disp(p.LowerBudget)
disp(p.UpperBudget)
```

```
 0.9900

 1
```

Setting Budget Constraints Using the setBudget Function

You can also set the properties for a budget constraint using `setBudget`. Suppose that you have a fund that permits up to 10% leverage which means that your portfolio can be from 100% to 110% invested in risky assets. Given a `Portfolio` object `p`, use `setBudget` to set the budget constraints:

```
p = Portfolio;
p = setBudget(p, 1, 1.1);
disp(p.LowerBudget)
disp(p.UpperBudget)
```

```
 1

 1.1000
```

If you were to continue with this example, then set the `RiskFreeRate` property to the borrowing rate to finance possible leveraged positions. For details on the `RiskFreeRate` property, see “Working with a Riskless Asset” on page 4-51. To clear either bound for the budget constraint from your Portfolio object, use either the `Portfolio` object or `setBudget` with empty inputs for the properties to be cleared. For example, clear the upper-budget constraint from the `Portfolio` object `p` in the previous example with:

```
p = Portfolio(p, 'UpperBudget', []);
```

Working with Group Constraints Using Portfolio Object

Group constraints are optional linear constraints that group assets together and enforce bounds on the group weights (see “Group Constraints” on page 4-11). Although the constraints are implemented as general constraints, the usual convention is to form a group matrix that identifies membership of each asset within a specific group with Boolean indicators (either `true` or `false` or with `1` or `0`) for each element in the group matrix. Group constraints have properties `GroupMatrix` for the group membership matrix, `LowerGroup` for the lower-bound constraint on groups, and `UpperGroup` for the upper-bound constraint on groups.

Setting Group Constraints Using the Portfolio Function

The properties for group constraints are set through the `Portfolio` object. Suppose that you have a portfolio of five assets and want to ensure that the first three assets constitute no more than 30% of your portfolio, then you can set group constraints:

```
G = [ 1 1 1 0 0 ];
p = Portfolio('GroupMatrix', G, 'UpperGroup', 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

The group matrix `G` can also be a logical matrix so that the following code achieves the same result.

```
G = [ true true true false false ];
p = Portfolio('GroupMatrix', G, 'UpperGroup', 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

Setting Group Constraints Using the setGroups and addGroups Functions

You can also set the properties for group constraints using `setGroups`. Suppose that you have a portfolio of five assets and want to ensure that the first three assets constitute no more than 30% of your portfolio. Given a `Portfolio` object `p`, use `setGroups` to set the group constraints:

```
G = [ true true true false false ];
p = Portfolio;
p = setGroups(p, G, [], 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

In this example, you would set the `LowerGroup` property to be empty (`[]`).

Suppose that you want to add another group constraint to make odd-numbered assets constitute at least 20% of your portfolio. Set up an augmented group matrix and introduce infinite bounds for unconstrained group bounds or use the `addGroups` function to build up group constraints. For this example, create another group matrix for the second group constraint:

```
p = Portfolio;
G = [ true true true false false ];    % group matrix for first group constraint
p = setGroups(p, G, [], 0.3);
G = [ true false true false true ];    % group matrix for second group constraint
p = addGroups(p, G, 0.2);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.LowerGroup)
disp(p.UpperGroup)
```

```
 5

1     1     1     0     0
1     0     1     0     1

  -Inf
0.2000

0.3000
  Inf
```

`addGroups` determines which bounds are unbounded so you only need to focus on the constraints that you want to set.

The `Portfolio` object and `setGroups` and `addGroups` implement scalar expansion on either the `LowerGroup` or `UpperGroup` properties based on the dimension of the group matrix in the property `GroupMatrix`. Suppose that you have a universe of 30 assets with six asset classes such that assets 1–5, assets 6–12, assets 13–18, assets 19–22, assets 23–27, and assets 28–30 constitute each of your six asset classes and you want each asset class to fall from 0% to 25% of your portfolio. Let the following group matrix define your groups and scalar expansion define the common bounds on each group:

```
p = Portfolio;
G = blkdiag(true(1,5), true(1,7), true(1,6), true(1,4), true(1,5), true(1,3));
p = setGroups(p, G, 0, 0.25);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.LowerGroup)
disp(p.UpperGroup)
```

```

Working with Group Ratio Constraints Using Portfolio Object

Group ratio constraints are optional linear constraints that maintain bounds on proportional relationships among groups of assets (see “Group Ratio Constraints” on page 4-12). Although the constraints are implemented as general constraints, the usual convention is to specify a pair of group matrices that identify membership of each asset within specific groups with Boolean indicators (either `true` or `false` or with `1` or `0`) for each element in each of the group matrices. The goal is to ensure that the ratio of a base group compared to a comparison group fall within specified bounds. Group ratio constraints have properties:

- `GroupA` for the base membership matrix
- `GroupB` for the comparison membership matrix
- `LowerRatio` for the lower-bound constraint on the ratio of groups
- `UpperRatio` for the upper-bound constraint on the ratio of groups

Setting Group Ratio Constraints Using the Portfolio Function

The properties for group ratio constraints are set using the `Portfolio` object. For example, assume that you want the ratio of financial to nonfinancial companies in your portfolios to never go above 50%. Suppose that you have six assets with three financial companies (assets 1–3) and three nonfinancial companies (assets 4–6). To set group ratio constraints:

```
GA = [ 1 1 1 0 0 0 ];    % financial companies
GB = [ 0 0 0 1 1 1 ];    % nonfinancial companies
p = Portfolio('GroupA', GA, 'GroupB', GB, 'UpperRatio', 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

Group matrices GA and GB in this example can be logical matrices with `true` and `false` elements that yield the same result:

```
GA = [ true true true false false false ];    % financial companies
GB = [ false false false true true true ];    % nonfinancial companies
p = Portfolio('GroupA', GA, 'GroupB', GB, 'UpperRatio', 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

Setting Group Ratio Constraints Using the setGroupRatio and addGroupRatio Functions

You can also set the properties for group ratio constraints using `setGroupRatio`. For example, assume that you want the ratio of financial to nonfinancial companies in your portfolios to never go above 50%. Suppose that you have six assets with three financial companies (assets 1–3) and three nonfinancial companies (assets 4–6). Given a `Portfolio` object `p`, use `setGroupRatio` to set the group constraints:

```
GA = [ true true true false false false ];   % financial companies
GB = [ false false false true true true ];   % nonfinancial companies
p = Portfolio;
p = setGroupRatio(p, GA, GB, [], 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

In this example, you would set the `LowerRatio` property to be empty (`[]`).

Suppose that you want to add another group ratio constraint to ensure that the weights in odd-numbered assets constitute at least 20% of the weights in nonfinancial assets your portfolio. You can set up augmented group ratio matrices and introduce infinite bounds for unconstrained group ratio bounds, or you can use the `addGroupRatio` function to build up group ratio constraints. For this example, create another group matrix for the second group constraint:

```
p = Portfolio;
GA = [ true true true false false false ];   % financial companies
GB = [ false false false true true true ];   % nonfinancial companies
p = setGroupRatio(p, GA, GB, [], 0.5);

GA = [ true false true false true false ];   % odd-numbered companies
GB = [ false false false true true true ];   % nonfinancial companies
p = addGroupRatio(p, GA, GB, 0.2);

disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.LowerRatio)
disp(p.UpperRatio)
```

```
 6

1     1     1     0     0     0
1     0     1     0     1     0

0     0     0     1     1     1
0     0     0     1     1     1

  -Inf
0.2000

0.5000
  Inf
```

Notice that addGroupRatio determines which bounds are unbounded so you only need to focus on the constraints you want to set.

The Portfolio object, setGroupRatio, and addGroupRatio implement scalar expansion on either the LowerRatio or UpperRatio properties based on the dimension of the group matrices in GroupA and GroupB properties.

Working with Linear Equality Constraints Using Portfolio Object

Linear equality constraints are optional linear constraints that impose systems of equalities on portfolio weights (see “Linear Equality Constraints” on page 4-9). Linear equality constraints have properties AEquality, for the equality constraint matrix, and bEquality, for the equality constraint vector.

Setting Linear Equality Constraints Using the Portfolio Function

The properties for linear equality constraints are set using the Portfolio object. Suppose that you have a portfolio of five assets and want to ensure that the first three assets are 50% of your portfolio. To set this constraint:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = Portfolio('AEquality', A, 'bEquality', b);
disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)
```

```
5

1     1     1     0     0

0.5000
```

Setting Linear Equality Constraints Using the setEquality and addEquality Functions

You can also set the properties for linear equality constraints using setEquality. Suppose that you have a portfolio of five assets and want to ensure that the first three assets are 50% of your portfolio. Given a Portfolio object p, use setEquality to set the linear equality constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = Portfolio;
p = setEquality(p, A, b);
disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)
```

```
5

1     1     1     0     0

0.5000
```

Suppose that you want to add another linear equality constraint to ensure that the last three assets also constitute 50% of your portfolio. You can set up an augmented system of linear equalities or use addEquality to build up linear equality constraints. For this example, create another system of equalities:

```
p = Portfolio;
A = [ 1 1 1 0 0 ];    % first equality constraint
```

```
b = 0.5;
p = setEquality(p, A, b);

A = [ 0 0 1 1 1 ];    % second equality constraint
b = 0.5;
p = addEquality(p, A, b);

disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)

5

1     1     1     0     0
0     0     1     1     1

0.5000
0.5000
```

The `Portfolio` object, `setEquality`, and `addEquality` implement scalar expansion on the `bEquality` property based on the dimension of the matrix in the `AEquality` property.

Working with Linear Inequality Constraints Using Portfolio Object

Linear inequality constraints are optional linear constraints that impose systems of inequalities on portfolio weights (see “Linear Inequality Constraints” on page 4-8). Linear inequality constraints have properties AInequality for the inequality constraint matrix, and bInequality for the inequality constraint vector.

Setting Linear Inequality Constraints Using the Portfolio Function

The properties for linear inequality constraints are set using the Portfolio object. Suppose that you have a portfolio of five assets and you want to ensure that the first three assets are no more than 50% of your portfolio. To set up these constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = Portfolio('AInequality', A, 'bInequality', b);
disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0

0.5000
```

Setting Linear Inequality Constraints Using the setInequality and addInequality Functions

You can also set the properties for linear inequality constraints using setInequality. Suppose that you have a portfolio of five assets and you want to ensure that the first three assets constitute no more than 50% of your portfolio. Given a Portfolio object p, use setInequality to set the linear inequality constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = Portfolio;
p = setInequality(p, A, b);
disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0

0.5000
```

Suppose that you want to add another linear inequality constraint to ensure that the last three assets constitute at least 50% of your portfolio. You can set up an augmented system of linear inequalities or use the addInequality function to build up linear inequality constraints. For this example, create another system of inequalities:

```
p = Portfolio;
A = [ 1 1 1 0 0 ];    % first inequality constraint
b = 0.5;
p = setInequality(p, A, b);

A = [ 0 0 -1 -1 -1 ];    % second inequality constraint
b = -0.5;
p = addInequality(p, A, b);

disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0
0     0    -1    -1    -1

0.5000
-0.5000
```

The `Portfolio` object, `setInequality`, and `addInequality` implement scalar expansion on the `bInequality` property based on the dimension of the matrix in the `AInequality` property.

Working with 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints Using Portfolio Objects

When any one, or any combination of `'Conditional'` `BoundType`, `MinNumAssets`, or `MaxNumAssets` constraints are active, the portfolio problem is formulated by adding `NumAssets` binary variables, where `0` indicates not invested, and `1` is invested. For example, to explain the `'Conditional'` `BoundType` and `MinNumAssets` and `MaxNumAssets` constraints, assume that your portfolio has a universe of 100 assets that you want to invest:

- `'Conditional'` `BoundType` (also known as semicontinuous constraints), set by `setBounds`, is often used in situations where you do not want to invest small values. A standard example is a portfolio optimization problem where many small allocations are not attractive because of transaction costs. Instead, you prefer fewer instruments in the portfolio with larger allocations. This situation can be handled using`'Conditional'` `BoundType` constraints for a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object.

  For example, the weight you invest in each asset is either `0` or between `[0.01, 0.5]`. Generally, a semicontinuous variable *x* is a continuous variable between bounds [`lb`, `ub`] that also can assume the value `0`, where `lb` > `0`, `lb` ≤ `ub`. Applying this to portfolio optimization requires that very small or large positions should be avoided, that is values that fall in (`0`, `lb`) or are more than `ub`.
- `MinNumAssets` and `MaxNumAssets` (also known as cardinality constraints), set by `setMinMaxNumAssets`, limit the number of assets in a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object. For example, if you have 100 assets in your portfolio and you want the number of assets allocated in the portfolio to be from 40 through 60. Using `MinNumAssets` and `MaxNumAssets` you can limit the number of assets in the optimized portfolio, which allows you to limit transaction and operational costs or to create an index tracking portfolio.

Setting 'Conditional' BoundType Constraints Using the setBounds Function

Use `setBounds` with a `'conditional'` `BoundType` to set *xi* = `0` or `0.02` <= *xi* <= `0.5` for all *i*=1,...`NumAssets`:

```
p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar);
p = setBounds(p, 0.02, 0.5,'BoundType', 'Conditional', 'NumAssets', 3)
```

```
p = 
  Portfolio with properties:

Setting the Limits on the Number of Assets Invested Using the setMinMaxNumAssets Function

You can also set the `MinNumAssets` and `MaxNumAssets` properties to define a limit on the number of assets invested using `setMinMaxNumAssets`. For example, by setting `MinNumAssets=MaxNumAssets=2`, only two of the three assets are invested in the portfolio.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;

Working with Average Turnover Constraints Using Portfolio Object

The turnover constraint is an optional linear absolute value constraint (see “Average Turnover Constraints” on page 4-12) that enforces an upper bound on the average of purchases and sales. The turnover constraint can be set using the `Portfolio` object or the `setTurnover` function. The turnover constraint depends on an initial or current portfolio, which is assumed to be zero if not set when the turnover constraint is set. The turnover constraint has properties `Turnover`, for the upper bound on average turnover, and `InitPort`, for the portfolio against which turnover is computed.

Setting Average Turnover Constraints Using the Portfolio Function

The properties for the turnover constraints are set using the `Portfolio` object. Suppose that you have an initial portfolio of 10 assets in a variable `x0` and you want to ensure that average turnover is no more than 30%. To set this turnover constraint:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio('Turnover', 0.3, 'InitPort', x0);
disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```
10

0.3000

0.0700
0.1000
0.1000
0.1500
0.1100
0.0800
0.1000
```

Note if the `NumAssets` or `InitPort` properties are not set before or when the turnover constraint is set, various rules are applied to assign default values to these properties (see “Setting Up an Initial or Current Portfolio” on page 4-36).

Setting Average Turnover Constraints Using the setTurnover Function

You can also set properties for portfolio turnover using `setTurnover` to specify both the upper bound for average turnover and an initial portfolio. Suppose that you have an initial portfolio of 10 assets in a variable `x0` and want to ensure that average turnover is no more than 30%. Given a `Portfolio` object `p`, use `setTurnover` to set the turnover constraint with and without the initial portfolio being set previously:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio('InitPort', x0);
p = setTurnover(p, 0.3);

disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```

```

For an example of setting turnover, see “Portfolio Analysis with Turnover Constraints” on page 4-204.

setTurnover implements scalar expansion on the argument for the initial portfolio. If the NumAssets property is already set in the Portfolio object, a scalar argument for InitPort expands to have the same value across all dimensions. In addition, setTurnover lets you specify NumAssets as an optional argument. To clear turnover from your Portfolio object, use the Portfolio object or setTurnover with empty inputs for the properties to be cleared.

Working with One-Way Turnover Constraints Using Portfolio Object

One-way turnover constraints are optional constraints (see “One-Way Turnover Constraints” on page 4-13) that enforce upper bounds on net purchases or net sales. One-way turnover constraints can be set using the `Portfolio` object or the `setOneWayTurnover` function. One-way turnover constraints depend upon an initial or current portfolio, which is assumed to be zero if not set when the turnover constraints are set. One-way turnover constraints have properties `BuyTurnover`, for the upper bound on net purchases, `SellTurnover`, for the upper bound on net sales, and `InitPort`, for the portfolio against which turnover is computed.

Setting One-Way Turnover Constraints Using the Portfolio Function

The Properties for the one-way turnover constraints are set using the `Portfolio` object. Suppose that you have an initial portfolio with 10 assets in a variable `x0` and you want to ensure that turnover on purchases is no more than 30% and turnover on sales is no more than 20% of the initial portfolio. To set these turnover constraints:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio('BuyTurnover', 0.3, 'SellTurnover', 0.2, 'InitPort', x0);
disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```
    10

    0.3000

    0.2000

    0.1000
    0.1500
    0.1100
    0.0800
    0.1000
```

If the `NumAssets` or `InitPort` properties are not set before or when the turnover constraint is set, various rules are applied to assign default values to these properties (see “Setting Up an Initial or Current Portfolio” on page 4-36).

Setting Turnover Constraints Using the setOneWayTurnover Function

You can also set properties for portfolio turnover using `setOneWayTurnover` to specify the upper bounds for turnover on purchases (`BuyTurnover`) and sales (`SellTurnover`) and an initial portfolio. Suppose that you have an initial portfolio of 10 assets in a variable `x0` and want to ensure that turnover on purchases is no more than 30% and that turnover on sales is no more than 20% of the initial portfolio. Given a `Portfolio` object `p`, use `setOneWayTurnover` to set the turnover constraints with and without the initial portfolio being set previously:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio('InitPort', x0);
p = setOneWayTurnover(p, 0.3, 0.2);

disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```
    10

    0.1000
    0.1500
    0.1100
    0.0800
    0.1000
```

or

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio;
p = setOneWayTurnover(p, 0.3, 0.2, x0);
disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```
    10

    0.3000

    0.2000

    0.1200
    0.0900
    0.0800
    0.0700
    0.1000
    0.1000
    0.1500
    0.1100
    0.0800
    0.1000
```

`setOneWayTurnover` implements scalar expansion on the argument for the initial portfolio. If the `NumAssets` property is already set in the `Portfolio` object, a scalar argument for `InitPort` expands to have the same value across all dimensions. In addition, `setOneWayTurnover` lets you specify `NumAssets` as an optional argument. To remove one-way turnover from your `Portfolio` object, use the `Portfolio` object or `setOneWayTurnover` with empty inputs for the properties to be cleared.

Working with Tracking Error Constraints Using Portfolio Object

Tracking error constraints are optional constraints (see “Tracking Error Constraints” on page 4-14) that measure the risk relative to a portfolio called a tracking portfolio. Tracking error constraints can be set using the `Portfolio` object or the `setTrackingError` function.

The tracking error constraint is an optional quadratic constraint that enforces an upper bound on tracking error, which is the relative risk between a portfolio and a designated tracking portfolio. For more information, see “Tracking Error Constraints” on page 4-14.

The tracking error constraint can be set using the `Portfolio` object or the `setTrackingPort` and `setTrackingError` functions. The tracking error constraint depends on a tracking portfolio, which is assumed to be zero if not set when the tracking error constraint is set. The tracking error constraint has properties `TrackingError`, for the upper bound on tracking error, and `TrackingPort`, for the portfolio against which tracking error is computed.

Note The initial portfolio in the `Portfolio` object property `InitPort` is distinct from the tracking portfolio in the `Portfolio` object property `TrackingPort`.

Setting Tracking Error Constraints Using the Portfolio Function

The properties for the tracking error constraints are set using the `Portfolio` object. Suppose that you have a tracking portfolio of 10 assets in a variable *x0* and you want to ensure that the tracking error of any portfolio on the efficient frontier is no more than 8% relative to this portfolio. To set this constraint:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio('TrackingError', 0.08, 'TrackingPort', x0);
disp(p.NumAssets)
disp(p.TrackingError)
disp(p.TrackingPort)
```

```

```

If the `NumAssets` or `TrackingPort` properties are not set before or when the tracking error constraint is set, various rules are applied to assign default values to these properties (see “Setting Up a Tracking Portfolio” on page 4-39).

Setting Tracking Error Constraints Using the setTrackingError Function

You can also set properties for portfolio tracking error using the `setTrackingError` function to specify both the upper bound for tracking error and a designated tracking portfolio. Suppose that you have a tracking portfolio of 10 assets in a variable x0 and want to ensure that tracking error is no more than 8%. Given a Portfolio object p, use setTrackingError to set the tracking error constraint with and without the initial portfolio being set previously:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio('TrackingPort', x0);
p = setTrackingError(p, 0.08);

disp(p.NumAssets)
disp(p.TrackingError)
disp(p.TrackingPort)
```

```
    10

    0.0800

    0.1200
    0.0900
    0.0800
    0.0700
    0.1000
    0.1000
    0.1500
    0.1100
    0.0800
    0.1000
```

or

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = Portfolio('TrackingPort', x0);
p = setTrackingError(p, 0.08, x0);

disp(p.NumAssets)
disp(p.TrackingError)
disp(p.TrackingPort)
```

```
    10

    0.0800

    0.1200
    0.0900
    0.0800
    0.0700
    0.1000
    0.1000
    0.1500
    0.1100
    0.0800
    0.1000
```

If the NumAssets or TrackingPort properties are not set before or when the tracking error constraint is set, various rules are applied to assign default values to these properties (see “Setting Up a Tracking Portfolio” on page 4-39).

setTrackingError implements scalar expansion on the argument for the tracking portfolio. If the NumAssets property is already set in the Portfolio object, a scalar argument for TrackingPort expands to have the same value across all dimensions. In addition, setTrackingError lets you specify NumAssets as an optional argument. To clear tracking error from your Portfolio object, use the Portfolio object or setTrackingError with empty inputs for the properties to be cleared.

Validate the Portfolio Problem for Portfolio Object

In this section...
"Validating a Portfolio Set" on page 4-90
"Validating Portfolios" on page 4-91

Sometimes, you may want to validate either your inputs to, or outputs from, a portfolio optimization problem. Although most error checking that occurs during the problem setup phase catches most difficulties with a portfolio optimization problem, the processes to validate portfolio sets and portfolios are time consuming and are best done offline. So, the portfolio optimization tools have specialized functions to validate portfolio sets and portfolios. For information on the workflow when using `Portfolio` objects, see "Portfolio Object Workflow" on page 4-17.

Validating a Portfolio Set

Since it is necessary and sufficient that your portfolio set must be a nonempty, closed, and bounded set to have a valid portfolio optimization problem, the `estimateBounds` function lets you examine your portfolio set to determine if it is nonempty and, if nonempty, whether it is bounded. Suppose that you have the following portfolio set which is an empty set because the initial portfolio at `0` is too far from a portfolio that satisfies the budget and turnover constraint:

```
p = Portfolio('NumAssets', 3, 'Budget', 1);
p = setTurnover(p, 0.3, 0);
```

If a portfolio set is empty, `estimateBounds` returns `NaN` bounds and sets the `isbounded` flag to `[]`:

```
[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

   NaN
   NaN
   NaN

ub =

   NaN
   NaN
   NaN

isbounded =

     []
```

Suppose that you create an unbounded portfolio set as follows:

```
p = Portfolio('AInequality', [1 -1; 1 1 ], 'bInequality', 0);
[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

  -Inf
  -Inf
```

```
ub =

   1.0e-08 *

   -0.3712
       Inf

isbounded =

  logical

   0
```

In this case, `estimateBounds` returns (possibly infinite) bounds and sets the `isbounded` flag to `false`. The result shows which assets are unbounded so that you can apply bound constraints as necessary.

Finally, suppose that you created a portfolio set that is both nonempty and bounded. `estimateBounds` not only validates the set, but also obtains tighter bounds which are useful if you are concerned with the actual range of portfolio choices for individual assets in your portfolio set:

```
p = Portfolio;
p = setBudget(p, 1,1);
p = setBounds(p, [ -0.1; 0.2; 0.3; 0.2 ], [ 0.5; 0.3; 0.9; 0.8 ]);

[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

   -0.1000
    0.2000
    0.3000
    0.2000

ub =

    0.3000
    0.3000
    0.7000
    0.6000

isbounded =

  logical

   1
```

In this example, all but the second asset has tighter upper bounds than the input upper bound implies.

Validating Portfolios

Given a portfolio set specified in a `Portfolio` object, you often want to check if specific portfolios are feasible with respect to the portfolio set. This can occur with, for example, initial portfolios and with portfolios obtained from other procedures. The `checkFeasibility` function determines whether a collection of portfolios is feasible. Suppose that you perform the following portfolio optimization and want to determine if the resultant efficient portfolios are feasible relative to a modified problem.

First, set up a problem in the `Portfolio` object `p`, estimate efficient portfolios in `pwgt`, and then confirm that these portfolios are feasible relative to the initial problem:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
pwgt = estimateFrontier(p);

checkFeasibility(p, pwgt)
```

```
ans =

     1     1     1     1     1     1     1     1     1     1
```

Next, set up a different portfolio problem that starts with the initial problem with an additional a turnover constraint and an equally weighted initial portfolio:

```
q = setTurnover(p, 0.3, 0.25);
checkFeasibility(q, pwgt)
```

```
ans =

     0     0     0     1     1     0     0     0     0     0
```

In this case, only two of the 10 efficient portfolios from the initial problem are feasible relative to the new problem in Portfolio object `q`. Solving the second problem using `checkFeasibility` demonstrates that the efficient portfolio for `Portfolio` object `q` is feasible relative to the initial problem:

```
qwgt = estimateFrontier(q);
checkFeasibility(p, qwgt)
```

```
ans =

     1     1     1     1     1     1     1     1     1     1
```

Estimate Efficient Portfolios for Entire Efficient Frontier for Portfolio Object

There are two ways to look at a portfolio optimization problem and this depends on what is your goal:

- To estimate efficient portfolios, see “Obtaining Portfolios Along the Entire Efficient Frontier” on page 4-95.
- To estimate efficient frontiers, see “Estimate Efficient Frontiers for Portfolio Object” on page 4-118.

For information on the workflow when using `Portfolio` objects, see “Portfolio Object Workflow” on page 4-17.

Obtaining Portfolios Along the Entire Efficient Frontier

The most basic way to obtain optimal portfolios is to obtain points over the entire range of the efficient frontier.

Given a portfolio optimization problem in a `Portfolio` object, the `estimateFrontier` function computes efficient portfolios spaced evenly according to the return proxy from the minimum to maximum return efficient portfolios. The number of portfolios estimated is controlled by the hidden property `defaultNumPorts` which is set to `10`. A different value for the number of portfolios estimated is specified as an input argument to `estimateFrontier`. This example shows the default number of efficient portfolios over the entire range of the efficient frontier.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
pwgt = estimateFrontier(p);

disp(pwgt)
```

```
    0.8891    0.7215    0.5540    0.3865    0.2190    0.0515         0         0         0
    0.0369    0.1289    0.2209    0.3129    0.4049    0.4969    0.4049    0.2314    0.0579
    0.0404    0.0567    0.0730    0.0893    0.1056    0.1219    0.1320    0.1394    0.1468
    0.0336    0.0929    0.1521    0.2113    0.2705    0.3297    0.4630    0.6292    0.7953    1.0
```

If you want only four portfolios, you can use `estimateFrontier` with `NumPorts` specified as `4`.

```
pwgt = estimateFrontier(p, 4);
disp(pwgt)
```

```
    0.8891    0.3865         0         0
    0.0369    0.3129    0.4049         0
    0.0404    0.0893    0.1320         0
    0.0336    0.2113    0.4630    1.0000
```

Starting from the initial portfolio, `estimateFrontier` also returns purchases and sales to get from your initial portfolio to each efficient portfolio on the efficient frontier. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontier(p);

display(pwgt)
```

```
pwgt = 4×10

    0.8891    0.7215    0.5540    0.3865    0.2190    0.0515         0         0         0
    0.0369    0.1289    0.2209    0.3129    0.4049    0.4969    0.4049    0.2314    0.0579
    0.0404    0.0567    0.0730    0.0893    0.1056    0.1219    0.1320    0.1394    0.1468
    0.0336    0.0929    0.1521    0.2113    0.2705    0.3297    0.4630    0.6292    0.7953    1.0
```

```
display(pbuy)
```

```
pbuy = 4×10

    0.5891    0.4215    0.2540    0.0865         0         0         0         0         0
         0         0         0    0.0129    0.1049    0.1969    0.1049         0         0
         0         0         0         0         0         0         0         0         0
         0         0    0.0521    0.1113    0.1705    0.2297    0.3630    0.5292    0.6953    0.9
```

```
display(psell)
```

```
psell = 4×10

         0         0         0         0    0.0810    0.2485    0.3000    0.3000    0.3000    0.3
    0.2631    0.1711    0.0791         0         0         0         0    0.0686    0.2421    0.3
    0.1596    0.1433    0.1270    0.1107    0.0944    0.0781    0.0680    0.0606    0.0532    0.2
    0.0664    0.0071         0         0         0         0         0         0         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Endpoints of the Efficient Frontier

Often when using a `Portfolio` object, you might be interested in the endpoint portfolios for the efficient frontier. Suppose that you want to determine the range of returns from minimum to maximum to refine a search for a portfolio with a specific target return. Use the `estimateFrontierLimits` function to obtain the endpoint portfolios.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
pwgt = estimateFrontierLimits(p);

disp(pwgt)
```

```
    0.8891         0
    0.0369         0
    0.0404         0
    0.0336    1.0000
```

The `estimatePortMoments` function shows the range of risks and returns for efficient portfolios:

```
[prsk, pret] = estimatePortMoments(p, pwgt);
disp([prsk, pret])
```

```
    0.0769    0.0590
    0.3500    0.1800
```

Starting from an initial portfolio, `estimateFrontierLimits` also returns purchases and sales to get from the initial portfolio to the endpoint portfolios on the efficient frontier. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierLimits(p);

display(pwgt)
```

```
pwgt = 4×2

    0.8891         0
    0.0369         0
    0.0404         0
    0.0336    1.0000
```

```
display(pbuy)
```

```
pbuy = 4×2

    0.5891         0
         0         0
         0         0
         0    0.9000
```

```
display(psell)
```

```
psell = 4×2

         0    0.3000
    0.2631    0.3000
    0.1596    0.2000
    0.0664         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Efficient Portfolios for Target Returns

To obtain efficient portfolios that have targeted portfolio returns, the `estimateFrontierByReturn` function accepts one or more target portfolios returns and obtains efficient portfolios with the specified returns. For example, assume that you have a universe of four assets where you want to obtain efficient portfolios with target portfolio returns of 6%, 9%, and 12%:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
pwgt = estimateFrontierByReturn(p, [0.06, 0.09, 0.12]);

display(pwgt)
```

```
pwgt =

    0.8772    0.5032    0.1293
    0.0434    0.2488    0.4541
    0.0416    0.0780    0.1143
    0.0378    0.1700    0.3022
```

Sometimes, you can request a return for which no efficient portfolio exists. Based on the previous example, suppose that you want a portfolio with a 5% return (which is the return of the first asset). A portfolio that is fully invested in the first asset, however, is inefficient. `estimateFrontierByReturn` warns if your target returns are outside the range of efficient portfolio returns and replaces it with the endpoint portfolio of the efficient frontier closest to your target return:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio;
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
pwgt = estimateFrontierByReturn(p, [0.05, 0.09, 0.12]);

display(pwgt)
```

```
Warning: One or more target return values are outside the feasible range [ 0.0590468, 0.18 ].
    Will return portfolios associated with endpoints of the range for these values.
> In Portfolio.estimateFrontierByReturn at 70

pwgt =

    0.8891    0.5032    0.1293
    0.0369    0.2488    0.4541
    0.0404    0.0780    0.1143
    0.0336    0.1700    0.3022
```

The best way to avoid this situation is to bracket your target portfolio returns with `estimateFrontierLimits` and `estimatePortReturn` (see “Obtaining Endpoints of the Efficient Frontier” on page 4-98 and “Obtaining Portfolio Risks and Returns” on page 4-118).

```
pret = estimatePortReturn(p, p.estimateFrontierLimits);

display(pret)

pret =

    0.0590
    0.1800
```

This result indicates that efficient portfolios have returns that range between 5.9% and 18%.

If you have an initial portfolio, `estimateFrontierByReturn` also returns purchases and sales to get from your initial portfolio to the target portfolios on the efficient frontier. For example, given an initial portfolio in `pwgt0`, to obtain purchases and sales with target returns of 6%, 9%, and 12%:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierByReturn(p, [0.06, 0.09, 0.12]);

display(pwgt)
display(pbuy)
display(psell)

pwgt =

    0.8772    0.5032    0.1293
    0.0434    0.2488    0.4541
    0.0416    0.0780    0.1143
    0.0378    0.1700    0.3022

pbuy =

    0.5772    0.2032         0
         0         0    0.1541
         0         0         0
         0    0.0700    0.2022

psell =

         0         0    0.1707
    0.2566    0.0512         0
    0.1584    0.1220    0.0857
    0.0622         0         0
```

If you do not have an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Efficient Portfolios for Target Risks

To obtain efficient portfolios that have targeted portfolio risks, the `estimateFrontierByRisk` function accepts one or more target portfolio risks and obtains efficient portfolios with the specified risks. Suppose that you have a universe of four assets where you want to obtain efficient portfolios with target portfolio risks of 12%, 14%, and 16%.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

 p = Portfolio;
 p = setAssetMoments(p, m, C);
 p = setDefaultConstraints(p);
 pwgt = estimateFrontierByRisk(p, [0.12, 0.14, 0.16]);

 display(pwgt)
```

```
pwgt =

    0.3984    0.2659    0.1416
    0.3064    0.3791    0.4474
    0.0882    0.1010    0.1131
    0.2071    0.2540    0.2979
```

Sometimes, you can request a risk for which no efficient portfolio exists. Based on the previous example, suppose that you want a portfolio with 7% risk (individual assets in this universe have risks ranging from 8% to 35%). It turns out that a portfolio with 7% risk cannot be formed with these four assets. `estimateFrontierByRisk` warns if your target risks are outside the range of efficient portfolio risks and replaces it with the endpoint of the efficient frontier closest to your target risk:

```
pwgt = estimateFrontierByRisk(p, 0.07)
```

```
Warning: One or more target risk values are outside the feasible range [ 0.0769288, 0.35 ].
    Will return portfolios associated with endpoints of the range for these values.
> In Portfolio.estimateFrontierByRisk at 82

pwgt =

    0.8891
    0.0369
    0.0404
    0.0336
```

The best way to avoid this situation is to bracket your target portfolio risks with `estimateFrontierLimits` and `estimatePortRisk` (see “Obtaining Endpoints of the Efficient Frontier” on page 4-98 and “Obtaining Portfolio Risks and Returns” on page 4-118).

```
prsk = estimatePortRisk(p, p.estimateFrontierLimits);

display(prsk)
```

```
prsk =

    0.0769
    0.3500
```

This result indicates that efficient portfolios have risks that range from 7.7% to 35%.

Starting with an initial portfolio, `estimateFrontierByRisk` also returns purchases and sales to get from your initial portfolio to the target portfolios on the efficient frontier. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales from the example with target risks of 12%, 14%, and 16%:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierByRisk(p, [0.12, 0.14, 0.16]);

display(pwgt)
display(pbuy)
display(psell)
```

```
pwgt =

    0.3984    0.2659    0.1416
    0.3064    0.3791    0.4474
    0.0882    0.1010    0.1131
    0.2071    0.2540    0.2979

pbuy =

    0.0984         0         0
    0.0064    0.0791    0.1474
         0         0         0
    0.1071    0.1540    0.1979

psell =

         0    0.0341    0.1584
         0         0         0
    0.1118    0.0990    0.0869
         0         0         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Efficient Portfolio That Maximizes Sharpe Ratio

Portfolios that maximize the Sharpe ratio are portfolios on the efficient frontier that satisfy several theoretical conditions in finance. Such portfolios are called tangency portfolios since the tangent line from the risk-free rate to the efficient frontier taps the efficient frontier at portfolios that maximize the Sharpe ratio.

The Sharpe ratio is defined as the ratio

$$\frac{\mu(x) - r_0}{\sqrt{\sum(x)}}$$

where $x \in R^n$and $r_0$is the risk-free rate (μ and Σ proxies for the portfolio return and risk). For more information, see “Portfolio Optimization Theory” on page 4-3.

To obtain efficient portfolios that maximizes the Sharpe ratio, the `estimateMaxSharpeRatio` function accepts a `Portfolio` object and obtains efficient portfolios that maximize the Sharpe Ratio. Suppose that you have a universe with four risky assets and a riskless asset and you want to obtain a portfolio that maximizes the Sharpe ratio, where, in this example, r_0 is the return for the riskless asset.

```
r0 = 0.03;
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

p = Portfolio('RiskFreeRate', r0);
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
pwgt = estimateMaxSharpeRatio(p);

display(pwgt)
```

```
pwgt = 4×1

    0.4251
    0.2917
    0.0856
    0.1977
```

If you start with an initial portfolio, `estimateMaxSharpeRatio` also returns purchases and sales to get from your initial portfolio to the portfolio that maximizes the Sharpe ratio. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateMaxSharpeRatio(p);

display(pwgt)
```

```
pwgt = 4×1

    0.4251
    0.2917
    0.0856
    0.1977
```

```
display(pbuy)
```

```
pbuy = 4×1

    0.1251
         0
         0
    0.0977
```

```
display(psell)
```

```
psell = 4×1

         0
    0.0083
    0.1144
         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that you initial portfolio is `0`.

Choosing and Controlling the Solver for Mean-Variance Portfolio Optimization

The default solver for mean-variance portfolio optimization is `lcprog`, which implements a linear complementarity programming (LCP) algorithm. Although `lcprog` works for most problems, you can adjust arguments to control the algorithm. Alternatively, the mean-variance portfolio optimization tools let you use any of the variations of `quadprog` from Optimization Toolbox™ software. Like Optimization Toolbox, which uses the `interior-point-convex` algorithm as the default algorithm for `quadprog`, the portfolio optimization tools also use the `interior-point-convex` algorithm as the default. For details about `quadprog` and quadratic programming algorithms and options, see “Quadratic Programming Algorithms”.

Using 'lcprog' and 'quadprog'

To modify either `lcprog` or to specify `quadprog` as your solver, use the `setSolver` function to set the hidden properties `solverType` and `solverOptions` that specify and control the solver. Because the solver properties are hidden, you cannot set these options using the `Portfolio` object. The default solver is `lcprog` so you do not need to use `setSolver` to specify this solver. To use `quadprog`, you can set the default `interior-point-convex` algorithm of `quadprog` using this code:

```
p = Portfolio;
p = setSolver(p, 'quadprog');
display(p.solverType)
display(p.solverOptions)
```

```
quadprog options:

   Options used by current Algorithm ('interior-point-convex'):
   (Other available algorithms: 'active-set', 'trust-region-reflective')

   Set properties:
              Algorithm: 'interior-point-convex'
                Display: 'off'
    OptimalityTolerance: 1.0000e-12

   Default properties:
    ConstraintTolerance: 1.0000e-08
           LinearSolver: 'auto'
          MaxIterations: 200
          StepTolerance: 1.0000e-12
```

You can switch back to `lcprog` with this code:

```
p = setSolver(p, 'lcprog');
display(p.solverType);
display(p.solverOptions)
```

```
lcprog
     MaxIter: []
    TieBreak: []
      TolPiv: 5.0000e-08
```

In both cases, `setSolver` sets up default options associated with either solver. If you want to specify additional options associated with a given solver, `setSolver` accepts these options with name-value arguments in the function call. For example, if you intend to use quadprog and want to use the 'trust-region-reflective' algorithm, call setSolver with this code:

```
p = Portfolio;
p = setSolver(p, 'quadprog', 'Algorithm', 'trust-region-reflective');
display(p.solverOptions)
```

```
  quadprog options:

   Options used by current Algorithm ('trust-region-reflective'):
   (Other available algorithms: 'active-set', 'interior-point-convex')

   Set properties:
              Algorithm: 'trust-region-reflective'

   Default properties:
                Display: 'final'
      FunctionTolerance: 'default dependent on problem'
     HessianMultiplyFcn: []
          MaxIterations: 'default dependent on problem'
    OptimalityTolerance: 'default dependent on problem'
          StepTolerance: 2.2204e-14
    SubproblemAlgorithm: 'cg'
               TypicalX: 'ones(numberOfVariables,1)'
```

In addition, if you want to specify any of the options for quadprog that you typically set through optimoptions from Optimization Toolbox, setSolver accepts an optimoptions object as the second argument. For example, you can start with the default options for quadprog set by setSolver and then change the algorithm to 'trust-region-reflective' with no displayed output:

```
p = Portfolio;
options = optimoptions('quadprog', 'Algorithm', 'trust-region-reflective', 'Display', 'off');
p = setSolver(p, 'quadprog', options);
display(p.solverOptions.Algorithm)
display(p.solverOptions.Display)
```

```
trust-region-reflective
off
```

Using the Mixed Integer Nonlinear Programming (MINLP) Solver

The mixed integer nonlinear programming (MINLP) solver, configured using setSolverMINLP, enables you to specify associated solver options for portfolio optimization for a Portfolio object. The MINLP solver is used when any one, or any combination of 'Conditional' BoundType, MinNumAssets, or MaxNumAssets constraints are active. In this case, you formulate the portfolio problem by adding NumAssets binary variables, where 0 indicates not invested, and 1 is invested. For more information on using 'Conditional' BoundType, see setBounds. For more information on specifying MinNumAssets and MaxNumAssets, see setMinMaxNumAssets.

When using the estimate functions with a Portfolio object where 'Conditional' BoundType, MinNumAssets, or MaxNumAssets constraints are active, the mixed integer nonlinear programming (MINLP) solver is automatically used.

Solver Guidelines for Portfolio Objects

The following table provides guidelines for using setSolver and setSolverMINLP.

Portfolio Problem	Portfolio Function	Type of Optimization Problem	Main Solver	Helper Solver
Portfolio without tracking error constraints	`estimateFrontierByRisk`	Optimizing a portfolio for a certain risk level introduces a nonlinear constraint. Therefore, this problem has a linear objective with linear and nonlinear constraints.	`'fmincon'` using `setSolver`	For `'min'`: quadratic objective, `'quadprog'` or `'lcprog'` using `setSolver` For `'max'`: linear objective, `'linprog'` or `'lcprog'` using `setSolver`
Portfolio without tracking error constraints	`estimateFrontierByReturn`	Quadratic objective with linear constraints	`'quadprog'` or `'lcprog'` using `setSolver`	For `‘min’`: quadratic objective, `'quadprog'` or `'lcprog'` using `setSolver` For `‘max’`: linear objective, `'linprog'` or `'lcprog'` using `setSolver`
Portfolio without tracking error constraints	`estimateFrontierLimits`	Quadratic or linear objective with linear constraints	For `‘min’`: quadratic objective, `'quadprog'` or `'lcprog'` using `setSolver` For `‘max’`: linear objective, `'linprog'` or `'lcprog'` using `setSolver`	Not applicable
Portfolio without tracking error constraints	`estimateMaxSharpeRatio`	Quadratic objective with linear constraints	`'quadprog'` using `setSolver`	Because `estimateMaxSharpeRatio` internally calls `estimateFrontierLimits`, all solvers needed by `estimateFrontierLimits` are the helper solvers

Portfolio Problem	Portfolio Function	Type of Optimization Problem	Main Solver	Helper Solver
Portfolio with tracking error constraints	`estimateFrontierByRisk`	Linear objective with linear and nonlinear constraints	`'fmincon'` using `setSolver`	Not applicable
Portfolio with tracking error constraints	`estimateFrontierByReturn`	Linear objective with linear and nonlinear constraints	`'fmincon'` using `setSolver`	Not applicable
Portfolio with tracking error constraints	`estimateFrontierLimits`	Quadratic (minimum risk problem) or linear (maximum return problem) objective with linear and nonlinear constraints	`'fmincon'` using `setSolver`	Not applicable
Portfolio with tracking error constraints	`estimateMaxSharpeRatio`	Quadratic objective with linear and nonlinear constraints	`'fmincon'` using `setSolver`	Not applicable
Portfolio with active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierByRisk`	The problem is formulated by introducing `NumAssets` binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see `setSolverMINLP`.	Mixed integer nonlinear programming solver (MINLP) using `setSolverMINLP`	`'quadprog'` or `'fmincon'` are used when the `estimate` functions reduce the problem into NLP. These two solvers can be configured through `setSolver`.

Portfolio Problem	Portfolio Function	Type of Optimization Problem	Main Solver	Helper Solver
Portfolio with active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierByReturn`	The problem is formulated by introducing `NumAssets` binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see `setSolverMINLP`.	Mixed integer nonlinear programming solver (MINLP) using `setSolverMINLP`	`'quadprog'` or `'fmincon'` are used when the `estimate` functions reduce the problem into NLP. These two solvers can be configured through `setSolver`.
Portfolio with active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierLimits`	The problem is formulated by introducing `NumAssets` binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see `setSolverMINLP`.	Mixed integer nonlinear programming solver (MINLP) using `setSolverMINLP`	`'quadprog'` or `'fmincon'` are used when the `estimate` functions reduce the problem into NLP. These two solvers can be configured through `setSolver`.

Estimate Efficient Frontiers for Portfolio Object

Whereas “Estimate Efficient Portfolios for Entire Efficient Frontier for Portfolio Object” on page 4-94 focused on estimation of efficient portfolios, this section focuses on the estimation of efficient frontiers. For information on the workflow when using `Portfolio` objects, see “Portfolio Object Workflow” on page 4-17.

Obtaining Portfolio Risks and Returns

Given any portfolio and, in particular, efficient portfolios, the functions `estimatePortReturn`, `estimatePortRisk`, and `estimatePortMoments` provide estimates for the return (or return proxy), risk (or the risk proxy), and, in the case of mean-variance portfolio optimization, the moments of expected portfolio returns. Each function has the same input syntax but with different combinations of outputs. Suppose that you have this following portfolio optimization problem that gave you a collection of portfolios along the efficient frontier in `pwgt`:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = Portfolio('AssetMean', m, 'AssetCovar', C, 'InitPort', pwgt0);
p = setDefaultConstraints(p);
pwgt = estimateFrontier(p);
```

Given `pwgt0` and `pwgt`, use the portfolio risk and return estimation functions to obtain risks and returns for your initial portfolio and the portfolios on the efficient frontier:

```
[prsk0, pret0] = estimatePortMoments(p, pwgt0);
[prsk, pret] = estimatePortMoments(p, pwgt);
```

or

```
prsk0 = estimatePortRisk(p, pwgt0);
pret0 = estimatePortReturn(p, pwgt0);
prsk = estimatePortRisk(p, pwgt);
pret = estimatePortReturn(p, pwgt);
```

In either case, you obtain these risks and returns:

```
display(prsk0)
display(pret0)
display(prsk)
display(pret)
```

```
prsk0 =

    0.1103

pret0 =

    0.0870

prsk =
    0.0769
    0.0831
    0.0994
    0.1217
    0.1474
    0.1750
    0.2068
    0.2487
    0.2968
    0.3500

pret =

    0.0590
    0.0725
    0.0859
    0.0994
    0.1128
    0.1262
    0.1397
    0.1531
    0.1666
    0.1800
```

The returns and risks are at the periodicity of the moments of asset returns so that, if you have values for `AssetMean` and `AssetCovar` in terms of monthly returns, the estimates for portfolio risk and return are in terms of monthly returns as well. In addition, the estimate for portfolio risk in the mean-variance case is the standard deviation of portfolio returns, not the variance of portfolio returns.

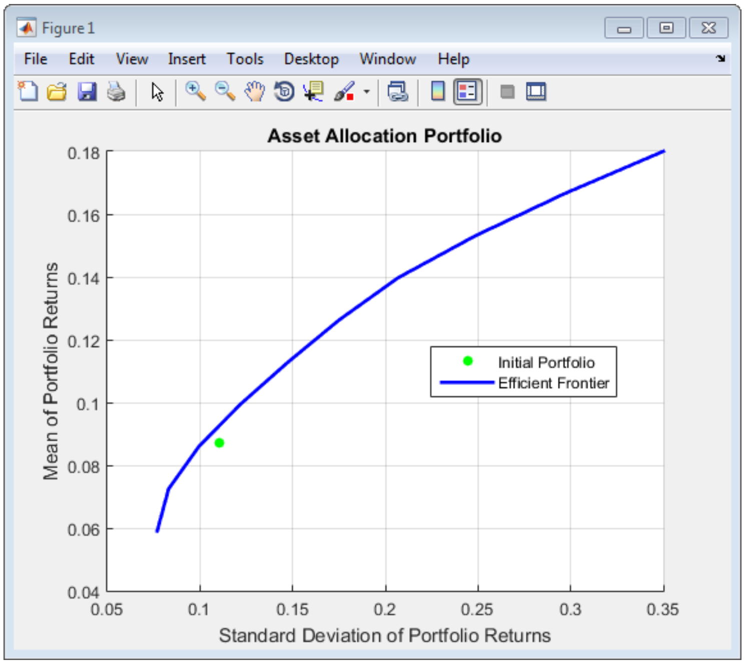
Plotting the Efficient Frontier for a Portfolio Object

The plotFrontier function creates a plot of the efficient frontier for a given portfolio optimization problem. This function accepts several types of inputs and generates a plot with an optional possibility to output the estimates for portfolio risks and returns along the efficient frontier. plotFrontier has four different ways that it can be used. In addition to a plot of the efficient frontier, if you have an initial portfolio in the InitPort property, plotFrontier also displays the return versus risk of the initial portfolio on the same plot. If you have a well-posed portfolio optimization problem set up in a Portfolio object and you use plotFrontier, you get a plot of the efficient frontier with the default number of portfolios on the frontier (the default number is 10 and is maintained in the hidden property defaultNumPorts). This example illustrates a typical use of plotFrontier to create a new plot:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = Portfolio('Name', 'Asset Allocation Portfolio', 'InitPort', pwgt0);
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
plotFrontier(p)
```



The Name property appears as the title of the efficient frontier plot if you set it in the Portfolio object. Without an explicit name, the title on the plot would be “Efficient Frontier.” If you want to obtain a specific number of portfolios along the efficient frontier, use plotFrontier with the number of portfolios that you want. Suppose that you have the Portfolio object from the previous example and you want to plot 20 portfolios along the efficient frontier and to obtain 20 risk and return values for each portfolio:

```
[prsk, pret] = plotFrontier(p, 20);
display([pret, prsk])
```

```

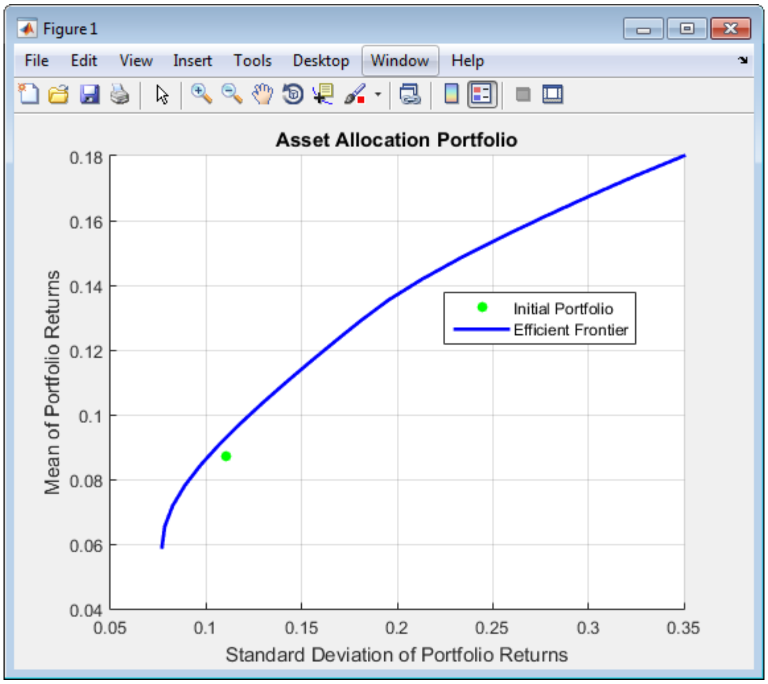
Plotting Existing Efficient Portfolios

If you already have efficient portfolios from any of the "estimateFrontier" functions (see “Estimate Efficient Portfolios for Entire Efficient Frontier for Portfolio Object” on page 4-94), pass them into `plotFrontier` directly to plot the efficient frontier:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = Portfolio('Name', 'Asset Allocation Portfolio', 'InitPort', pwgt0);
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
pwgt = estimateFrontier(p, 20);
plotFrontier(p, pwgt)
```



Plotting Existing Efficient Portfolio Risks and Returns

If you already have efficient portfolio risks and returns, you can use the interface to `plotFrontier` to pass them into `plotFrontier` to obtain a plot of the efficient frontier:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = Portfolio('Name', 'Asset Allocation Portfolio', 'InitPort', pwgt0);
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
[prsk, pret] = estimatePortMoments(p, p.estimateFrontier(20));
plotFrontier(p, prsk, pret)
```

Postprocessing Results to Set Up Tradable Portfolios

After obtaining efficient portfolios or estimates for expected portfolio risks and returns, use your results to set up trades to move toward an efficient portfolio. For information on the workflow when using `Portfolio` objects, see “Portfolio Object Workflow” on page 4-17.

Setting Up Tradable Portfolios

Suppose that you set up a portfolio optimization problem and obtained portfolios on the efficient frontier. Use the `dataset` object from Statistics and Machine Learning Toolbox™ to form a blotter that lists your portfolios with the names for each asset. For example, suppose that you want to obtain five portfolios along the efficient frontier. You can set up a blotter with weights multiplied by 100 to view the allocations for each portfolio:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

 p = Portfolio('InitPort', pwgt0);
 p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');
 p = setAssetMoments(p, m, C);
 p = setDefaultConstraints(p);
 pwgt = estimateFrontier(p, 5);

 pnames = cell(1,5);
   for i = 1:5
       pnames{i} = sprintf('Port%d',i);
   end

 Blotter = dataset([{100*pwgt},pnames],'obsnames',p.AssetList);
 display(Blotter)
```

```
Blotter = 

                          Port1     Port2     Port3     Port4     Port5
    Bonds                 88.906    51.216    13.525         0      0  
    Large-Cap Equities    3.6875    24.387    45.086    27.479      0  
    Small-Cap Equities    4.0425    7.7088    11.375    13.759      0  
    Emerging Equities      3.364    16.689    30.014    58.762    100  
```

This result indicates that you would invest primarily in bonds at the minimum-risk/minimum-return end of the efficient frontier (`Port1`), and that you would invest completely in emerging equity at the maximum-risk/maximum-return end of the efficient frontier (`Port5`). You can also select a particular efficient portfolio, for example, suppose that you want a portfolio with 15% risk and you add purchase and sale weights outputs obtained from the “estimateFrontier” functions to set up a trade blotter:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = Portfolio('InitPort', pwgt0);
p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');
p = setAssetMoments(p, m, C);
p = setDefaultConstraints(p);
[pwgt, pbuy, psell] = estimateFrontierByRisk(p, 0.15);

Blotter = dataset([{100*[pwgt0, pwgt, pbuy, psell]}, ...
     {'Initial','Weight', 'Purchases','Sales'}],'obsnames',p.AssetList);

display(Blotter)
```

```
Blotter =

                         Initial    Weight    Purchases    Sales 
    Bonds                30         20.299         0       9.7007
    Large-Cap Equities   30         41.366    11.366            0
    Small-Cap Equities   20         10.716         0       9.2838
    Emerging Equities    10         27.619    17.619            0
```

If you have prices for each asset (in this example, they can be ETFs), add them to your blotter and then use the tools of the `dataset` object to obtain shares and shares to be traded. For an example, see “Asset Allocation Case Study” on page 4-172.

When to Use Portfolio Objects Over Optimization Toolbox

While you can use Optimization Toolbox to solve portfolio optimization problems, Financial Toolbox has the `Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` objects that you can use as well. Which tool you use depends on the problem case:

- **Always** use a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object when the problem can most easily be written and implemented using one of these objects. This case includes problems that can be solved only with the internal solvers of the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object. The Optimization Toolbox solvers cannot directly handle these problems. For details, see "Always Use Portfolio, PortfolioCVaR, or PortfolioMAD Object" on page 4-130.
- **Prefer** to use a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object when the problem can be modeled and implemented using both the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object and the Optimization Toolbox problem-based framework. The advantage of using a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object instead of the Optimization Toolbox is that the internal tools of these objects simplify the analysis. For details, see "Preferred Use of Portfolio, PortfolioCVaR, or PortfolioMAD Object" on page 4-131.
- **Opt** to use Optimization Toolbox for problems that cannot be solved with the internal solvers of the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object. Some of the problems that the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object cannot solve can be addressed using the Optimization Toolbox problem-based framework. Problems that cannot be directly solved with either framework require either some restructuring of the model or an implementation of a specialized solver. For details, see "Use Optimization Toolbox" on page 4-132.

The following table summarizes the objective functions, constraints, and variables that apply in each case for solving a portfolio problem.

Case for Solving Portfolio Problem	Objective Function	Constraints	Integer (Binary) Variables
"Always" case with Financial Toolbox	• Return — Gross portfolio returns or net portfolio returns • Risk — Variance, CVaR, or MAD • Sharpe ratio (only for mean-variance problems using `Portfolio` object) • Continuous convex functions (only using the `Portfolio` object)	• Return — Gross portfolio returns or net portfolio returns • Risk — Variance, CVaR, or MAD (risk constraints are only supported when the objective is the return) • Linear equalities • Linear inequalities • Tracking error (only for mean-variance problems using `Portfolio` object. Not supported with custom objectives using `estimateCustomObjectivePortfolio`. Tracking error is only supported when the objective is the return, variance, or Sharpe ratio.) • Turnover	• Bounds on the number of assets • Conditional (semicontinuous) bounds (for example, if asset *i* is selected, then $x_i \geq lb_i$, otherwise $x_i = 0$)

Case for Solving Portfolio Problem	Objective Function	Constraints	Integer (Binary) Variables
"Preferred" case with Financial Toolbox	• Return — Gross portfolio returns or net portfolio returns • Risk — Variance, CVaR, or MAD • Sharpe ratio (only for mean-variance problems using `Portfolio` object) • Continuous functions (only using the `Portfolio` object)	• Return — Gross portfolio returns or net portfolio returns • Risk — Variance, CVaR, or MAD (risk constraints are only supported when the objective is the return) • Linear equalities • Linear inequalities • Tracking error (only for mean-variance problems using `Portfolio` object. Not supported with custom objectives using `estimateCustomObjectivePortfolio`. Tracking error is only supported when the objective is the return, variance, or Sharpe ratio.))	None
Optimization Toolbox	Any other nonlinear function not mentioned in “Always Use Portfolio, PortfolioCVaR, or PortfolioMAD Object” on page 4-130 and “Preferred Use of Portfolio, PortfolioCVaR, or PortfolioMAD Object” on page 4-131	Any other nonlinear function not mentioned in “Always Use Portfolio, PortfolioCVaR, or PortfolioMAD Object” on page 4-130 and “Preferred Use of Portfolio, PortfolioCVaR, or PortfolioMAD Object” on page 4-131	None

Always Use Portfolio, PortfolioCVaR, or PortfolioMAD Object

The two general cases for always using the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object are:

- Problems with *both* supported nonlinear constraints *and* conditional bounds or bounds in the number of assets.

  These problems include:

  - Minimum risk problems subject to constraints for return, linear equality, linear inequality, turnover, and tracking error where the supported risk measures are variance, conditional value-at-risk (CVaR), and mean-absolute-deviation (MAD)
  - Maximum return problems subject to constraints for linear equality, liner inequality, turnover, risk, and tracking error where the supported risk measures are variance, CVaR, and MAD

    Tracking error is supported only for mean-variance problems using the `Portfolio` object. For more information on the supported constraints for a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object, see “Portfolio Set for Optimization Using Portfolio Objects” on page 4-8.
  - Custom objective minimization or maximization. The custom objective function (using `estimateCustomObjectivePortfolio`) must be continuous and convex subject to constraints for return, linear equality, linear inequality, and turnover.

  Tracking error is supported using the `Portfolio` object only when the objective is the return, variance or Sharpe ratio. Sharpe ratio is supported only using the `Portfolio` object.

  For more information on the supported constraints and nonlinear risk functions for `Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` objects, see “Portfolio Set for Optimization Using Portfolio Objects” on page 4-8 and “Portfolio Optimization Theory” on page 4-3. The integer (binary) variables can come from either of the following sources: bounds on the number of assets that can be selected in the portfolio or the use of conditional (semicontinuous) bounds for the assets. For example, if asset *i* is selected, then $x_i \geq \texttt{lb}_i$, otherwise $x_i = 0$. These problems cannot be solved using the Optimization Toolbox solvers. However, you can implement your own mixed-integer solver. For more information, see “Mixed-Integer Quadratic Programming Portfolio Optimization: Problem-Based”.
- Problems with turnover constraints and sell or buy costs

  Although the continuous version of these problems can be solved by the Optimization Toolbox solvers, the variable space must be manipulated to rewrite the nonsmooth constraints into equivalent smooth constraints. Given that rewriting the problem requires optimization knowledge, it is recommended to use the `Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` objects instead.

Preferred Use of Portfolio, PortfolioCVaR, or PortfolioMAD Object

The general case for preferred use of the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object is:

- Continuous problems with minimum risk, maximum return, and maximum Sharpe ratio that are subject to linear equality, liner inequality, turnover, and tracking error constraints.

  Sharpe ratio is supported only for mean-variance problems using the `Portfolio` object. For more information on the supported constraints for a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object, see “Portfolio Set for Optimization Using Portfolio Objects” on page 4-8.
- Custom objective minimization or maximization. The custom objective function (using `estimateCustomObjectivePortfolio`) must be continuous and convex subject to constraints for return, linear equality, linear inequality, and turnover.

Tracking error is supported using the `Portfolio` object only when the objective is the return, variance or Sharpe ratio. Sharpe ratio is supported only using the `Portfolio` object.

The supported risk measures are variance, CVaR, and MAD. For more information on the supported constraints for these risk measures, see “Portfolio Set for Optimization Using Portfolio Objects” on page 4-8, “Portfolio Set for Optimization Using PortfolioCVaR Object” on page 5-8, and “Portfolio Set for Optimization Using PortfolioMAD Object” on page 6-7. For all other risk measures and constraints and if tracking error is in the objective, use the Optimization Toolbox.

The advantage of the `Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object framework over the problem-based framework for the type of problems in the "preferred" case is that common portfolio optimization workflows are leveraged. For example, the `Portfolio`, `PortfolioCVaR`, and `PortfolioMAD` object framework supports the following workflows:

- Estimating and plotting the efficient frontier
- Exchanging the return and risk proxies from the objective function to a constraint
- Solving the maximum Sharpe ratio problem
- Adding bounds on the number of assets selected
- Adding semicontinuous bounds
- Simplifying the use of turnover constraints and sell or buy costs

Use Optimization Toolbox

The two general cases to use Optimization Toolbox is:

- Problems that have nonlinear constraints other than the constraints for risk or tracking error

Comparison of Methods for Covariance Estimation

Mean-variance portfolio optimization is a common technique in portfolio allocation. It usually requires an estimate of the covariance matrix to compute the portfolio weights. Many methods can be used for covariance estimation. The traditional covariance estimate is computed using `cov`. However, in practice the standard covariance estimate is noisy. Since the optimal solution of the portfolio weights is very sensitive to the mean and covariance estimates, noise in the covariance matrix increases the portfolio weights estimation error leading to large turnover and transaction costs. Here are some methods that mitigate the estimation error:

- `robustcov` computes a covariance estimate from a data sample. This function reduces the noise in the estimator by identifying the outliers in the sample and removing them from the final covariance estimate.
- `covarianceShrinkage` computes a covariance estimate from a data sample. This function reduces the noise in the estimator generated from using a finite sample. Shrinkage estimators are used to reduce the mean squared error (MSE) of an estimate. MSE consists of two parts, the bias and the noise. Shrinkage methods reduce the noise in the estimator by pulling the standard covariance estimate towards a target matrix. Thus, the shrinkage estimator results in a biased estimate, but with a lower variance than that of the standard covariance estimate. The method implemented in `covarianceShrinkage` considers a multiple of the identity as the target matrix.

  In covariance shrinkage, the intensity parameter determines how much the standard covariance estimate is pulled towards the target matrix. Because computing the optimal intensity parameter depends on the sample size, `covarianceDenoising` runs slower when the sample size significantly increases.
- `covarianceDenoising` computes a covariance estimate from a data sample or from an initial covariance estimate (usually the standard covariance estimate from `cov`). The `covarianceDenoising` function reduces the noise in the estimator generated from using a finite sample. Unlike `covarianceShrinkage`, the `covarianceDenoising` function differentiates between the noise and the signal in the data to pull only the eigenvalues associated with noise towards a target value. This technique results in an estimate that decreases noise while increasing the signal.

  The computation of the `covarianceDenoising` estimate depends on the number of assets (variables). If the number of assets is too small, there is not enough information to identify between the noisy and meaningful factors. On the other hand, if the number of assets is too large, the underlying optimization problem used to identify the noisy eigenvalues grows, and it takes longer to compute the estimate.

The following table summarizes the information needed to compute the different covariance estimates.

Function	Number of Assets	Sample Size	Sample
`cov` (MATLAB)	Any	Any	Required
`robustcov` (Statistics and Machine Learning Toolbox)	Any	≥ 2 × `numAssets`	Required
`covarianceShrinkage` (Financial Toolbox)	Any (≥ 3 recommended)	Any (≤ 25,000 recommended)	Required

Function	Number of Assets	Sample Size	Sample
`covarianceDenoising` (Financial Toolbox)	Any (≥ 10 recommended)	Any	Not required

Another useful tool for covariance estimation is `nearcorr`. Use `nearcorr` to compute the nearest correlation matrix by minimizing the Frobenius distance to an initial estimate. This is particularly useful to get a positive definite covariance matrix when the number of observations is less than the number of assets.

Troubleshooting Portfolio Optimization Results

Portfolio Object Destroyed When Modifying

If a `Portfolio` object is destroyed when modifying, remember to pass an existing object into the `Portfolio` object if you want to modify it, otherwise it creates a new object. See “Creating the Portfolio Object” on page 4-24 for details.

Optimization Fails with “Bad Pivot” Message

If the optimization fails with a "bad pivot" message from `lcprog`, try a larger value for `tolpiv` which is a tolerance for pivot selection in the `lcprog` algorithm (try `1.0e-7`, for example) or try the `interior-point-convex` version of `quadprog`. For details, see “Choosing and Controlling the Solver for Mean-Variance Portfolio Optimization” on page 4-110, the help header for `lcprog`, and `quadprog`.

Speed of Optimization

Although it is difficult to characterize when one algorithm is faster than the other, the default solver, `lcprog` is faster for smaller problems and the `quadprog` solver is faster for larger problems. If one solver seems to take too much time, try the other solver. To change solvers, use `setSolver`.

Matrix Incompatibility and "Non-Conformable" Errors

If you get matrix incompatibility or "non-conformable" errors, the representation of data in the tools follows a specific set of basic rules described in “Conventions for Representation of Data” on page 4-22.

Missing Data Estimation Fails

If asset return data has missing or `NaN` values, the `estimateAssetMoments` function with the `'missingdata'` flag set to `true` may fail with either too many iterations or a singular covariance. To correct this problem, consider this:

- If you have asset return data with no missing or `NaN` values, you can compute a covariance matrix that may be singular without difficulties. If you have missing or `NaN` values in your data, the supported missing data feature requires that your covariance matrix must be positive-definite, that is, nonsingular.
- `estimateAssetMoments` uses default settings for the missing data estimation procedure that might not be appropriate for all problems.

In either case, you might want to estimate the moments of asset returns separately with either the ECM estimation functions such as `ecmnmle` or with your own functions.

mv_optim_transform Errors

If you obtain optimization errors such as:

```
Error using mv_optim_transform (line 233)
Portfolio set appears to be either empty or unbounded. Check constraints.
```

```
Error in Portfolio/estimateFrontier (line 63)
    [A, b, f0, f, H, g, lb] = mv_optim_transform(obj);
```

or

```
Error using mv_optim_transform (line 238)
Cannot obtain finite lower bounds for specified portfolio set.

Error in Portfolio/estimateFrontier (line 63)
    [A, b, f0, f, H, g, lb] = mv_optim_transform(obj);
```

Since the portfolio optimization tools require a bounded portfolio set, these errors (and similar errors) can occur if your portfolio set is either empty and, if nonempty, unbounded. Specifically, the portfolio optimization algorithm requires that your portfolio set have at least a finite lower bound. The best way to deal with these problems is to use the validation functions in “Validate the Portfolio Problem for Portfolio Object” on page 4-90. Specifically, use `estimateBounds` to examine your portfolio set, and use `checkFeasibility` to ensure that your initial portfolio is either feasible and, if infeasible, that you have sufficient turnover to get from your initial portfolio to the portfolio set.

Tip To correct this problem, try solving your problem with larger values for turnover or tracking-error and gradually reduce to the value that you want.

solveContinuousCustomObjProb or solveMICustomObjProb Errors

These errors can occur if the portfolio set is empty or unbounded. If the portfolio set is empty, the error states that the problem is infeasible. The best way to deal with these problems is to use the validation functions in “Validate the Portfolio Problem for Portfolio Object” on page 4-90. Specifically, use `estimateBounds` to examine your portfolio set, and use `checkFeasibility` to ensure that your initial portfolio is either feasible or, if infeasible, that you have sufficient turnover to get from your initial portfolio to the portfolio set.

Efficient Portfolios Do Not Make Sense

If you obtain efficient portfolios that do not seem to make sense, this can happen if you forget to set specific constraints or you set incorrect constraints. For example, if you allow portfolio weights to fall between `0` and `1` and do not set a budget constraint, you can get portfolios that are 100% invested in every asset. Although it may be hard to detect, the best thing to do is to review the constraints you have set with display of the object. If you get portfolios with 100% invested in each asset, you can review the display of your object and quickly see that no budget constraint is set. Also, you can use `estimateBounds` and `checkFeasibility` to determine if the bounds for your portfolio set make sense and to determine if the portfolios you obtained are feasible relative to an independent formulation of your portfolio set.

Efficient Frontiers Do Not Make Sense

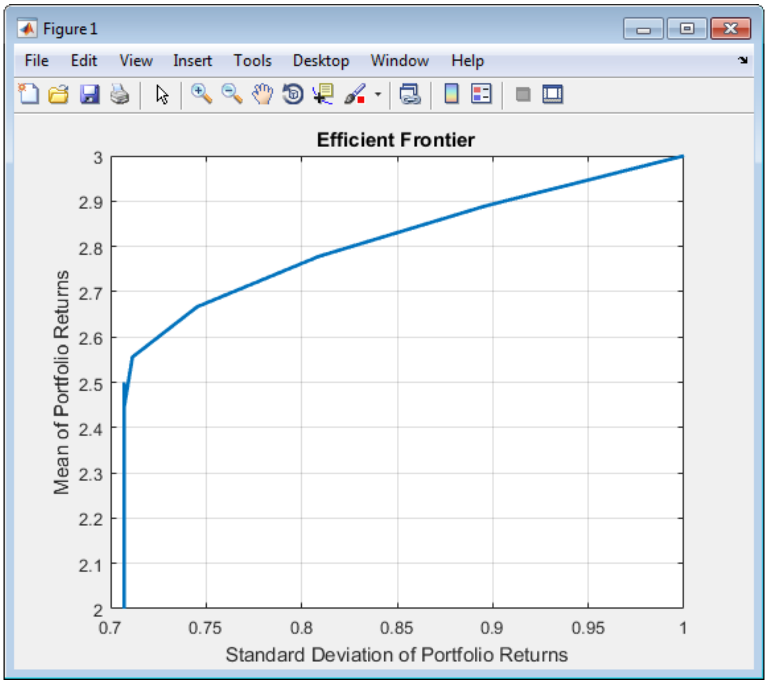
If you obtain efficient frontiers that do not seem to make sense, this can happen for some cases of mean and covariance of asset returns. It is possible for some mean-variance portfolio optimization problems to have difficulties at the endpoints of the efficient frontier. It is rare for standard portfolio problems, but this can occur. For example, this can occur when using unusual combinations of turnover constraints and transaction costs. Usually, the workaround of setting the hidden property `enforcePareto` produces a single portfolio for the entire efficient frontier, where any other solutions are not Pareto optimal (which is what efficient portfolios must be).

An example of a portfolio optimization problem that has difficulties at the endpoints of the efficient frontier is this standard mean-variance portfolio problem (long-only with a budget constraint) with the following mean and covariance of asset returns:

```
m = [ 1; 2; 3 ];
C = [ 1 1 0; 1 1 0; 0 0 1 ];

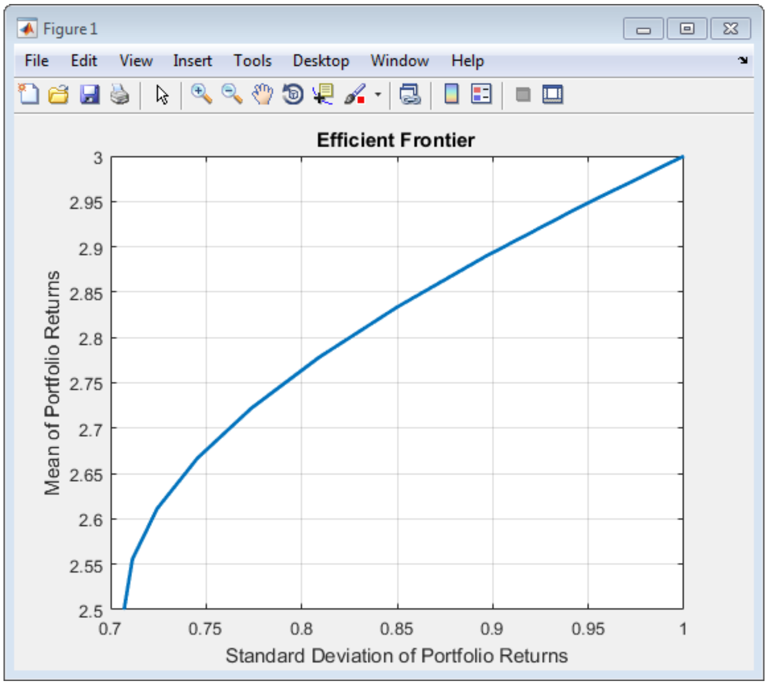
p = Portfolio;
p = Portfolio(p, 'assetmean', m, 'assetcovar', C);
p = Portfolio(p, 'lowerbudget', 1, 'upperbudget', 1);
p = Portfolio(p, 'lowerbound', 0);

plotFrontier(p)
```



To work around this problem, set the hidden Portfolio object property for `enforcePareto`. This property instructs the optimizer to perform extra steps to ensure a Pareto-optimal solution. This slows down the solver, but guarantees a Pareto-optimal solution.

```
p.enforcePareto = true;
plotFrontier(p)
```



Troubleshooting estimateCustomObjectivePortfolio

When using `estimateCustomObjectivePortfolio`, nonconvex functions are not supported for problems with cardinality constraints or conditional bounds. Specifically, the following error displays when using `estimateCustomObjectivePortfolio` with a `Portfolio` object that includes `'Conditional'` `BoundType` (semicontinuous) constraints using `setBounds` or `MinNumAssets` and `MaxNumAssets` (cardinality) constraints using `setMinMaxNumAssets`.

```
Error using solveMICustomObjProb
Objective function must be convex in problems with cardinality constraints and/or conditional bounds.

Error in Portfolio/estimateCustomObjectivePortfolio (line 88)
    [pwgt,exitflag] = solveMICustomObjProb(obj,prob,fun,flags);
```

Note This error applies only to quadratic functions. This error is not detected in nonlinear functions. Therefore, if you are using a nonlinear function, you must validate your input.

For more information, see “Role of Convexity in Portfolio Problems” on page 4-148.

Troubleshooting for Setting 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints

When configuring a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object to include `'Conditional'` `BoundType` (semicontinuous) constraints using `setBounds` or `MinNumAssets` and `MaxNumAssets` (cardinality) constraints using `setMinMaxNumAssets`, the values of the inputs that you supply can result in warning messages.

Conditional Bounds with LowerBound Defined as Empty or Zero

When using `setBounds` with the `BoundType` set to `'Conditional'` and the `LowerBound` input argument is empty (`[ ]`) or `0`, the `Conditional` bound is not effective and is equivalent to a `Simple` bound.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;
    0.00022983 0.00049937 0.00019247;
    0.00420395 0.00019247 0.00764097 ];
p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
p = setBounds(p, 0, 0.5, 'BoundType', 'Conditional');
p = setMinMaxNumAssets(p, 3, 3);
estimateFrontier(p, 10)
```

```
Warning: Conditional bounds with 'LowerBound' as zero are equivalent to simple bounds.
Consider either using strictly positive 'LowerBound' or 'simple' as the 'BoundType'
instead.
> In internal.finance.PortfolioMixedInteger/checkBoundType (line 46)
  In Portfolio/checkarguments (line 204)
  In Portfolio/setBounds (line 80)
Warning: The solution may have less than 'MinNumAssets' assets with nonzero weight. To
enforce 'MinNumAssets' requirement, set strictly positive lower conditional bounds.
> In internal.finance.PortfolioMixedInteger/hasIntegerConstraints (line 44)
  In Portfolio/estimateFrontier (line 51)

ans =

    0.4608    0.5000
```

In all the 10 optimal allocations, there are allocations (the first and last ones) that only have two assets, which is in conflict with the `MinNumAssets` constraint that three assets should be allocated. Also there are two warnings, which actually explain what happens. In this case, the `'Conditional'` bound constraints are defined as `xi = 0` or `0 <= xi <= 0.5`, which are internally modeled as 0*vi*<=xi<=0.5*vi*, where *vi* is `0` or `1`, where `0` indicates not allocated, and `1` indicates allocated. Here, *vi*=`1`, which still allows the asset to have a weight of `0`. In other words, setting `LowerBound` as `0` or empty, doesn't clearly define the minimum allocation for an allocated asset. Therefore, a `0` weighted asset is also considered as an allocated asset. To fix this warning, follow the instructions in the warning message, and set a `LowerBound` value that is strictly positive.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;

```

Length of 'BoundType' Must Be Conformable with NumAssets

The `setBounds` optional name-value argument for `'BoundType'` must be defined for all assets in a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object. By default, the `'BoundType'` is `'Simple'` and applies to all assets. Using `setBounds`, you can choose to define a `'BoundType'` for each asset. In this case, the number of `'BoundType'` specifications must match the number of assets (`NumAssets`) in the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object. The following example demonstrates the error when the number of `'BoundType'` specifications do not match the number of assets in the `Portfolio` object.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;
    0.00022983 0.00049937 0.00019247;
    0.00420395 0.00019247 0.00764097 ];
p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
p = setBounds(p, 0.1, 0.5, 'BoundType',["simple"; "conditional"])
```

```
Cannot create bound constraints.

Caused by:
    Error using internal.finance.PortfolioMixedInteger/checkBoundType (line 28)
    Length of 'BoundType' must be conformable with 'NumAssets'=3.
```

To correct this, modify the `BoundType` to include three specifications because the `Portfolio` object has three assets.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;
    0.00022983 0.00049937 0.00019247;
    0.00420395 0.00019247 0.00764097 ];

p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
p = setBounds(p, 0.1, 0.5, 'BoundType',["simple"; "conditional";"conditional"])
p.BoundType
```

```

Redundant Constraints from 'BoundType', 'MinNumAssets', 'MaxNumAssets' Constraints

When none of the constraints from `'BoundType'`, `'MinNumAssets'`, or `'MaxNumAssets'` are active, the redundant constraints from `'BoundType'`, `'MinNumAssets'`, `'MaxNumAssets'` warning occurs. This happens when you explicitly use `setBounds` and `setMinMaxNumAssets` but with values that are inactive. That is, the `'Conditional'` `BoundType` has a `LowerBound = [ ]` or `0`, `'MinNumAssets'` is `0`, or `'MaxNumAssets'` is the same value as `NumAssets`. In other words, if any of these three are active, the warning will not show up when using the `estimate` functions or `plotFrontier`. The following two examples show the rationale.

The first example is when the `BoundType` is explicitly set as `'Conditional'` but the `LowerBound` is `0`, and no `'MinNumAssets'` and `'MaxNumAssets'` constraints are defined using `setMinMaxNumAssets`.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;
    0.00022983 0.00049937 0.00019247;
    0.00420395 0.00019247 0.00764097 ];
p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
p = setBounds(p, 0, 0.5, 'BoundType', 'Conditional');
estimateFrontier(p, 10)
```

```
Warning: Redundant constraints from 'BoundType', 'MinNumAssets', 'MaxNumAssets'.
> In internal.finance.PortfolioMixedInteger/hasIntegerConstraints (line 24)
  In Portfolio/estimateFrontier (line 51)

ans =

  Columns 1 through 8

    0.5000    0.3555    0.3011    0.3299    0.3586    0.3873    0.4160    0.4448
    0.5000    0.5000    0.4653    0.3987    0.3321    0.2655    0.1989    0.1323
         0    0.1445    0.2335    0.2714    0.3093    0.3471    0.3850    0.4229

  Columns 9 through 10

    0.4735    0.5000
    0.0657         0
    0.4608    0.5000
```

The second example is when you explicitly set the three constraints, but all with inactive values. In this example, the `BoundType` is `'Conditional'` and the `LowerBound` is `0`, thus specifying ineffective `'Conditional'` `BoundType` constraints, and the `'MinNumAssets'` and `'MaxNumAssets'` values are `0` and `3`, respectively. The `setMinMaxNumAssets` function specifies ineffective `'MinNumAssets'` and `'MaxNumAssets'` constraints.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;
    0.00022983 0.00049937 0.00019247;
    0.00420395 0.00019247 0.00764097 ];
p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
p = setBounds(p, 0, 0.5, 'BoundType', 'Conditional');
p = setMinMaxNumAssets(p, 0, 3);

Infeasible Portfolio Problem with 'BoundType', 'MinNumAssets', 'MaxNumAssets'

The `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object performs validations of all the constraints that you set before solving any specific optimization problems. The `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object first considers all constraints other than `'Conditional'` `BoundType`, `'MinNumAssets'`, and `'MaxNumAssets'` and issues an error message if they are not compatible. Then the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object adds the three constraints to check if they are compatible with the already checked constraints. This separation is natural because `'Conditional'` `BoundType`, `'MinNumAssets'`, and `'MaxNumAssets'` require additional binary variables in the mathematical formulation that leads to a MINLP, while other constraints only need continuous variables. You can follow the error messages to check when the infeasible problem occurs and take actions to fix the constraints.

One possible scenario is when the `BoundType` is `'Conditional'` and Groups are defined for the `Portfolio` object. In this case, the Group definitions are themselves in conflict. Consequently, the `'Conditional'` bound constraint cannot be applied when running `estimateFrontierLimits`.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;
    0.00022983 0.00049937 0.00019247;
    0.00420395 0.00019247 0.00764097 ];

p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
p = setBounds(p, 0.1, 0.5, 'BoundType','Conditional');
p = setGroups(p, [1,1,0], 0.3, 0.5);
p = addGroups(p, [0,1,0], 0.6, 0.7);
pwgt = estimateFrontierLimits(p)
```

```
Error using Portfolio/buildMixedIntegerProblem (line 31)
Infeasible portfolio problem prior to considering 'BoundType', 'MinNumAssets',
'MaxNumAssets'. Verify if constraints from groups, bounds, group ratios, inequality,
equality, etc. are compatible.

Error in Portfolio/estimateFrontierLimits>int_frontierLimits (line 93)
ProbStruct = buildMixedIntegerProblem(obj);

Error in Portfolio/estimateFrontierLimits (line 73)
    pwgt = int_frontierLimits(obj, minsolution, maxsolution);
```

To correct this error, change the `LowerGroup` in the `addGroups` function to also be `0.3` to match the `GroupMatrix` input from `setGroups`.

```
AssetMean = [ 0.0101110; 0.0043532; 0.0137058 ];
AssetCovar = [ 0.00324625 0.00022983 0.00420395;

    0.00420395 0.00019247 0.00764097 ];

p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
p = setBounds(p, 0.1, 0.5, 'BoundType','Conditional');
p = setGroups(p, [1,1,0], 0.3, 0.5);
p = addGroups(p, [0,1,0], 0.3, 0.7);
pwgt = estimateFrontierLimits(p)
```

```
pwgt =

         0    0.2000
    0.5000    0.3000
    0.5000    0.5000
```

A second possible scenario is when the `BoundType` is `'Conditional'` and the `setEquality` function is used with the `bEquality` parameter set to `0.04`. This sets an equality constraint to have *x*1 + *x*3 = `0.04`. At the same time, `setBounds` also set the semicontinuous constraints to have *xi* = `0` or `0.1` <= *xi* <= `2.5`, which lead to *x*1 + *x*3 = `0` or `0.1` <= *x*1 + *x*3 <= `5`. The semicontinuous constraints are not compatible with the equality constraint because there is no way to get x1 + x3 to equal 0.04. Therefore, the error message is displayed.

```
AssetMean = [ 0.05; 0.1; 0.12; 0.18 ];
AssetCovar = [ 0.0064   0.00408  0.00192      0;
               0.00408  0.0289   0.0204   0.0119;
               0.00192  0.0204   0.0576   0.0336;
               0        0.0119   0.0336   0.1225 ];

p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar, 'Budget', 1);
A = [ 1 0 1 0 ];
b = 0.04;
p = setEquality(p, A, b);
p = setBounds(p, 0.1, 2.5, 'BoundType','Conditional');
p = setMinMaxNumAssets(p, 2, 2);
pwgt = estimateFrontierLimits(p)
```

```
Error using Portfolio/buildMixedIntegerProblem (line 109)
Infeasible portfolio problem when considering 'BoundType', 'MinNumAssets',
'MaxNumAssets'. Verify if these are compatible with constraints from groups, bounds,

         0    0.6000
```

Unbounded Portfolio Problem

This error occurs when you are using a Portfolio, PortfolioCVaR, or PortfolioMAD object and there is no UpperBound defined in setBounds and you are using setMinMaxNumAssets. In this case, this is formulated as a mixed integer programming problem and an UpperBound is required to enforce MinNumAssets and MaxNumAssets constraints.

The optimizer first attempts to estimate the upper bound of each asset, based on all the specified constraints. If the UpperBound cannot be found, an error message occurs which instructs you to set an explicit UpperBound. In most cases, as long as you set some upper bounds to the problem using any set function, the optimizer can successfully find a good estimation.

```
AssetMean = [ 0.05; 0.1; 0.12; 0.18 ];
AssetCovar = [ 0.0064   0.00408  0.00192      0;
               0.00408  0.0289   0.0204   0.0119;
               0.00192  0.0204   0.0576   0.0336;
               0        0.0119   0.0336   0.1225 ];

p = Portfolio('AssetMean', AssetMean, 'AssetCovar', AssetCovar);
p = setBounds(p, 0.1, 'BoundType','Conditional');
p = setGroups(p, [1,1,1,0], 0.3, 0.5);
p = setMinMaxNumAssets(p, 3, 3);
pwgt = estimateFrontierLimits(p)
```

```
Error using Portfolio/buildMixedIntegerProblem (line 42)

         0    0.9000
```

Total Number of Portfolio Weights with a Value > 0 Are Greater Than MaxNumAssets Specified

When using a `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object, the optimal allocation `w` may contain some very small values that leads to `sum(w>0)` larger than `MaxNumAssets`, even though the `MaxNumAssets` constraint is specified using `setMinMaxNumAssets`. For example, in the following code when `setMinMaxNumAssets` is used to set `MaxNumAssets` to `15`, the `sum(w>0)` indicates that there are `19` assets. A close examination of the weights shows that the weights are extremely small and are actually 0.

```
T = readtable('dowPortfolio.xlsx');
symbol = T.Properties.VariableNames(3:end);
assetReturn = tick2ret(T{:,3:end});
p = Portfolio('AssetList', symbol, 'budget', 1);
p = setMinMaxNumAssets(p, 10, 15);
p = estimateAssetMoments(p,assetReturn);
p = setBounds(p,0.01,0.5,'BoundType','Conditional','NumAssets',30);
p = setTrackingError(p,0.05,ones(1, p.NumAssets)/p.NumAssets);
w = estimateFrontierLimits(p,'min'); % minimum risk portfolio

sum(w>0)   % Number of assets that are allocated in the optimal portfolio
w(w<eps)   % Check the weights of the very small weighted assets
```

```
ans =

    19

ans =

```

```
         0
         0
         0
```

This situation only happens when the `OuterApproximation` algorithm is used with `setSolverMINLP` to solve a MINLP portfolio optimization problem. The `OuterApproximation` internally fixes the latest solved integer variables and runs an NLP with `quadprog` or `fmincon`, which introduces numerical issues and leads to weights that are very close to 0.

If you do not want to deal with very small values, you can use `setSolverMINLP` to select a different algorithm. In this example, the `'TrustRegionCP'` algorithm is specified.

```
T = readtable('dowPortfolio.xlsx');
symbol = T.Properties.VariableNames(3:end);
assetReturn = tick2ret(T{:,3:end});
p = Portfolio('AssetList', symbol, 'budget', 1);
p = setMinMaxNumAssets(p, 10, 15);
p = estimateAssetMoments(p,assetReturn);
p = setBounds(p,0.01,0.5,'BoundType','Conditional','NumAssets',30);
p = setTrackingError(p,0.05,ones(1, p.NumAssets)/p.NumAssets);
p = setSolverMINLP(p,'TrustRegionCP');
w = estimateFrontierLimits(p,'min'); % minimum risk portfolio

sum(w>0)   % Number of assets that are allocated in the optimal portfolio
w(w<eps)   % The weights of the very small weighted assets are strictly zeros
```

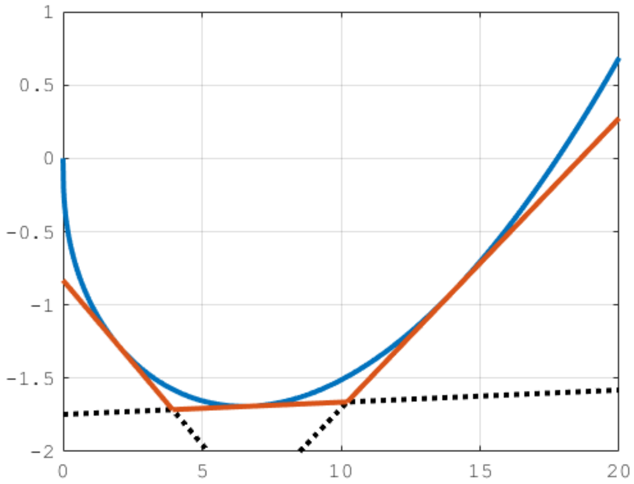
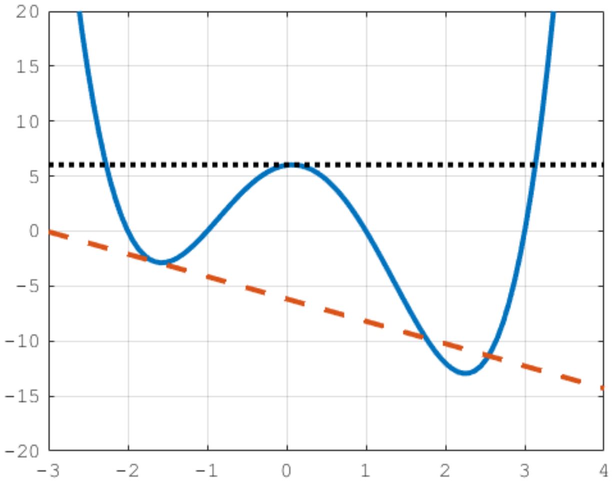
Role of Convexity in Portfolio Problems

When using a `Portfolio` object and the `estimateCustomObjectivePortfolio` function with the Financial Toolbox solvers, the solvers return a local minimum, which is not guaranteed to be a global minimum. A local minimum of a function is a point where the function value is smaller than the points around it, but the value is larger than a distant point. A global minimum is the point where the function value is smaller than at all other points. Convex functions play an important role in optimization because they guarantee that all local minima are global minima. In other words, any solution found by the solver is guaranteed to be a global minimum.

Another important feature of convex functions is that all tangents of the function lie underneath the function. This feature is particularly useful in problems with cardinality constraints or conditional bounds. For more information on cardinality constraints and conditional bounds, see “Working with 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints Using Portfolio Objects” on page 4-78 and `setMinMaxNumAssets`. The Financial Toolbox internal solvers for portfolio problems with binary variables use an iterative method that approximates the nonlinear functions (for example, variance) with a collection of linear functions. The linear functions used to approximate the original function are the tangents of the function at different points. Because the tangents for convex functions always lie underneath the function, the Financial Toolbox solvers guarantee that the approximation does not remove any minimum from the problem.



Using Financial Toolbox solvers for portfolio problems with nonconvex functions and cardinality constraints or conditional bounds might result in suboptimal solutions. The reason is that the tangent lines used to approximate the nonconvex functions might cut off different minima as demonstrated in the following figure:



Even though the red dashed tangent line cuts off only a small piece of the graph, that small piece already contains an important point, the global minima. In the worst case scenario, the Financial Toolbox solvers compute the tangent line at a point that removes all minima of the function, like the black dotted line does. Therefore, it is important to be aware of the type of function passed to a Financial Toolbox solver.

All the above applies to minimization problems. Conversely, maximization problems with cardinality constraints or conditional bounds can be solved by the Financial Toolbox solvers only if the functions are concave.

Examples of Convex Functions

Here are some examples of common convex functions used in finance. You can use these convex functions in minimization problems when using a `Portfolio` object with the `estimateCustomObjectivePortfolio` function:

- Variance:

  $$x^T \Sigma x$$
- Tracking error:

  $$(x - x_0)^T \Sigma (x - x_0)$$
- Herfindahl-Hirschman index:

  $$x^T x$$
- Any linear function
- Any positive combination of convex functions:

  $$x^T \Sigma x + \lambda({}^{x}\Sigma(x - x_0),\ \lambda \geq 0$$

  $$x^T \Sigma x + \lambda_1 x^T x + \lambda_2({}^{x}\Sigma(x - x_0),\ \lambda_1, \lambda_2 \geq 0$$

Note If the portfolio problem has cardinality constraints or conditional bounds specified using `setMinMaxNumAssets` or `setBounds`, the objective function must also be convex.

Examples of Concave Functions

Here are some examples of common concave functions used in finance. You can use concave functions in maximization problems when using a `Portfolio` object with the `estimateCustomObjectivePortfolio` function.

- Risk penalized return:

  $$\mu^T x - \lambda x^T \Sigma x,\ \lambda \geq 0$$
- Any linear function
- Any positive combination of concave functions

Examples of Nonconvex Functions

Here are some examples of common nonconvex functions used in finance. You can use nonconvex functions in minimization or maximization problems when using a `Portfolio` object *without cardinality constraints or conditional bounds* with the `estimateCustomObjectivePortfolio` function.

- Sharpe ratio:

  $$\frac{\mu^T x - r_f}{\sqrt{x^T \Sigma x}}$$
- Information ratio:

  $$\frac{\mu^T (x - x_0)}{\sqrt{(x - x_0)^T \Sigma (x - x_0)}}$$
- Diversification ratio:

  $$\frac{\sigma^T x}{\sqrt{x^T \Sigma x}}$$
- Risk budgeting deviation:

  $$\sum_i \left(\frac{x_i (\Sigma x)_i}{x^T \Sigma x} - b_i \right)^2$$
- The following function is a special case:

  $$x^T \Sigma x - \lambda \sum_i \ln x_i$$

  This function is commonly used to construct risk parity portfolios. Although this function is convex, problems with cardinality constraints or conditional bounds make this function ill-defined. This happens because $\ln x_i$ is not defined when $x_i = 0$. Since adding cardinality constraints or conditional bounds imply that some assets have a weight of 0, the function becomes ill-defined at the points of interest.

Note If the portfolio problem has cardinality constraints or conditional bounds specified using `setMinMaxNumAssets` or `setBounds`, the objective function cannot be nonconvex.

Portfolio Optimization Examples Using Financial Toolbox™

Follow a sequence of examples that highlight features of the `Portfolio` object. Specifically, the examples use the `Portfolio` object to show how to set up mean-variance portfolio optimization problems that focus on the two-fund theorem, the impact of transaction costs and turnover constraints, how to obtain portfolios that maximize the Sharpe ratio, and how to set up two popular hedge-fund strategies — dollar-neutral and 130-30 portfolios.

Set up the Data

Every example works with moments for monthly total returns of a universe of 30 "blue-chip" stocks. Although derived from real data, these data are for illustrative purposes and are not meant to be representative of specific assets or of market performance. The data are contained in the file `BlueChipStockMoments.mat` with a list of asset identifiers in the variable `AssetList`, a mean and covariance of asset returns in the variables `AssetMean` and `AssetCovar`, and the mean and variance of cash and market returns in the variables `CashMean`, `CashVar`, `MarketMean`, and `MarketVar`. Since most of the analysis requires the use of the standard deviation of asset returns as the proxy for risk, cash, and market variances are converted into standard deviations.

```
load BlueChipStockMoments

mret = MarketMean;
mrsk = sqrt(MarketVar);
cret = CashMean;
crsk = sqrt(CashVar);
```

Create a Portfolio Object

First create a "standard" `Portfolio` object with `Portfolio` to incorporate the list of assets, the risk-free rate, and the moments of asset returns into the object.

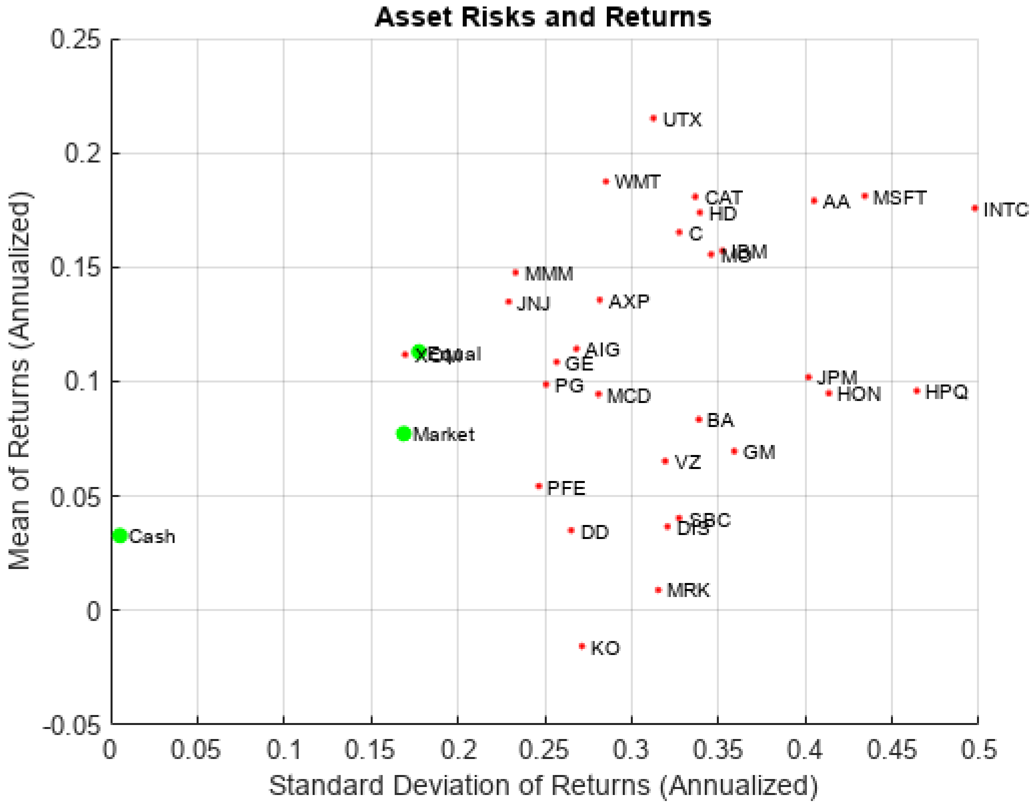
```
p = Portfolio('AssetList',AssetList,'RiskFreeRate',CashMean);
p = setAssetMoments(p,AssetMean,AssetCovar);
```

To provide a basis for comparison, set up an equal-weight portfolio and make it the initial portfolio in the `Portfolio` object. Keep in mind that the hedged portfolios to be constructed later will require a different initial portfolio. Once the initial portfolio is created, the `estimatePortMoments` function estimates the mean and standard deviation of equal-weight portfolio returns.

```
p = setInitPort(p,1/p.NumAssets);
[ersk,eret] = estimatePortMoments(p,p.InitPort);
```

A specialized "helper" function `portfolioexamples_plot` makes it possible to plot all results to be developed here. The first plot shows the distribution of individual assets according to their means and standard deviations of returns. In addition, the equal-weight, market, and cash portfolios are plotted on the same plot. Note that the `portfolioexamples_plot` function converts monthly total returns into annualized total returns.

```
clf;
portfolioexamples_plot('Asset Risks and Returns', ...
    {'scatter', mrsk, mret, {'Market'}}, ...
    {'scatter', crsk, cret, {'Cash'}}, ...
    {'scatter', ersk, eret, {'Equal'}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



Set up a Portfolio Optimization Problem

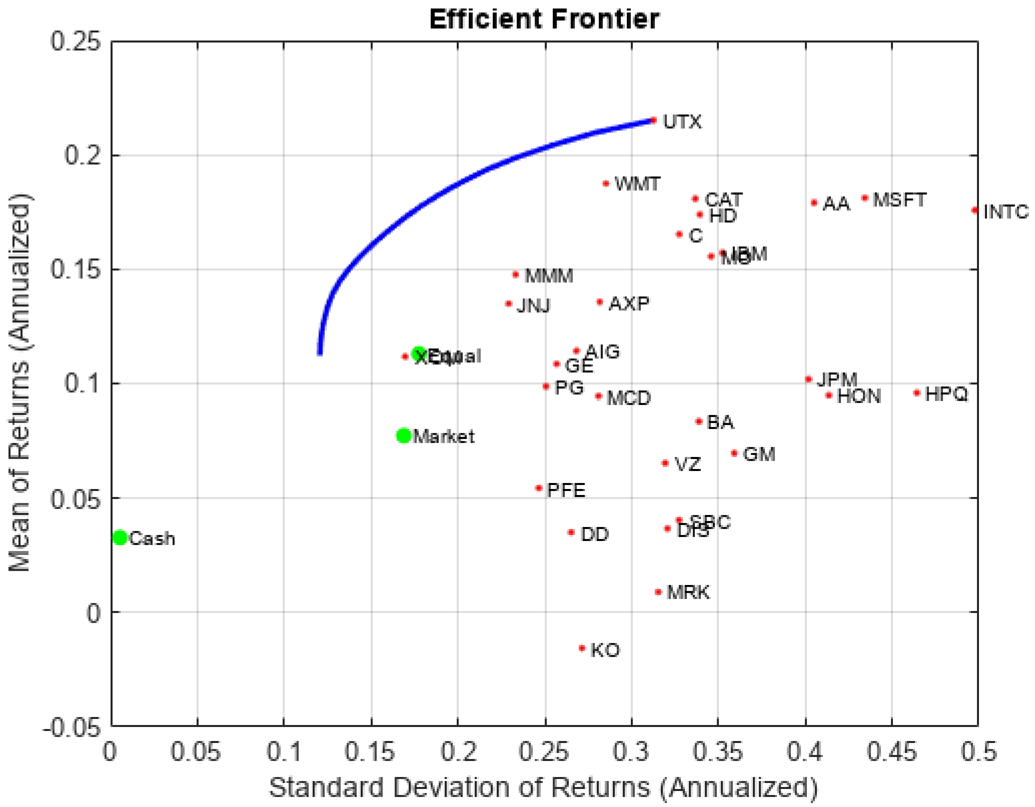
Set up a "standard" or default mean-variance portfolio optimization problem with the `setDefaultConstraints` function that requires fully-invested long-only portfolios (non-negative weights that must sum to 1). Given this initial problem, estimate the efficient frontier with the functions `estimateFrontier` and `estimatePortMoments`, where `estimateFrontier` estimates efficient portfolios and `estimatePortMoments` estimates risks and returns for portfolios. The next figure overlays the efficient frontier on the previous plot.

```
p = setDefaultConstraints(p);

pwgt = estimateFrontier(p,20);
[prsk,pret] = estimatePortMoments(p,pwgt);

% Plot the efficient frontier.

clf;
portfolioexamples_plot('Efficient Frontier', ...
    {'line', prsk, pret}, ...
    {'scatter', [mrsk, crsk, ersk], [mret, cret, eret], {'Market', 'Cash', 'Equal'}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



Illustrate the Tangent Line to the Efficient Frontier

Tobin's mutual fund theorem (Tobin 1958 on page 4-170) says that the portfolio allocation problem is viewed as a decision to allocate between a riskless asset and a risky portfolio. In the mean-variance framework, cash serves as a proxy for a riskless asset and an efficient portfolio on the efficient frontier serves as the risky portfolio such that any allocation between cash and this portfolio dominates all other portfolios on the efficient frontier. This portfolio is called a *tangency portfolio* because it is located at the point on the efficient frontier where a tangent line that originates at the riskless asset touches the efficient frontier.

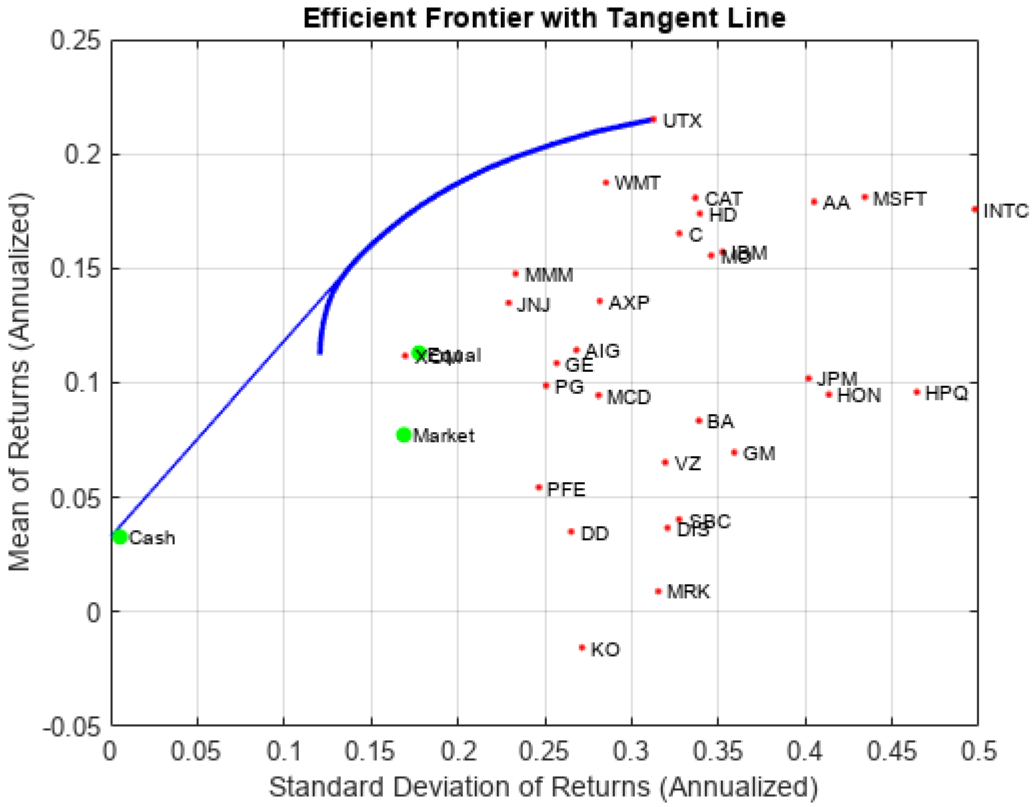
Given that the `Portfolio` object already has the risk-free rate, obtain the tangent line by creating a copy of the `Portfolio` object with a budget constraint that permits allocation between 0% and 100% in cash. Since the `Portfolio` object is a value object, it is easy to create a copy by assigning the output of either `Portfolio` or the "set" functions to a new instance of the `Portfolio` object. The plot shows the efficient frontier with Tobin's allocations that form the tangent line to the efficient frontier.

```
q = setBudget(p, 0, 1);

qwgt = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);

% Plot efficient frontier with tangent line (0 to 1 cash).

clf;
portfolioexamples_plot('Efficient Frontier with Tangent Line', ...
    {'line', prsk, pret}, ...
    {'line', qrsk, qret, [], [], 1}, ...
    {'scatter', [mrsk, crsk, ersk], [mret, cret, eret], {'Market', 'Cash', 'Equal'}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



Note that cash actually has a small risk so that the tangent line does not pass through the cash asset.

Obtain Range of Risks and Returns

To obtain efficient portfolios with target values of either risk or return, it is necessary to obtain the range of risks and returns among all portfolios on the efficient frontier. This is accomplished with the `estimateFrontierLimits` function.

```
[rsk,ret] = estimatePortMoments(p,estimateFrontierLimits(p));
```

```
display(rsk)
```

```
rsk = 2×1

    0.0348
    0.0903
```

```
display(ret)
```

```
ret = 2×1

    0.0094
    0.0179
```

The range of monthly portfolio returns is between 0.9% and 1.8% and the range for portfolio risks is between 3.5% and 9.0%. In annualized terms, the range of portfolio returns is 11.2% to 21.5% and the range of portfolio risks is 12.1% to 31.3%.

Find a Portfolio with a Targeted Return and Targeted Risk

Given the range of risks and returns, it is possible to locate specific portfolios on the efficient frontier that have target values for return and risk using the functions `estimateFrontierByReturn` and `estimateFrontierByRisk`.

```
TargetReturn = 0.20;            % Input target annualized return and risk here.
TargetRisk = 0.15;

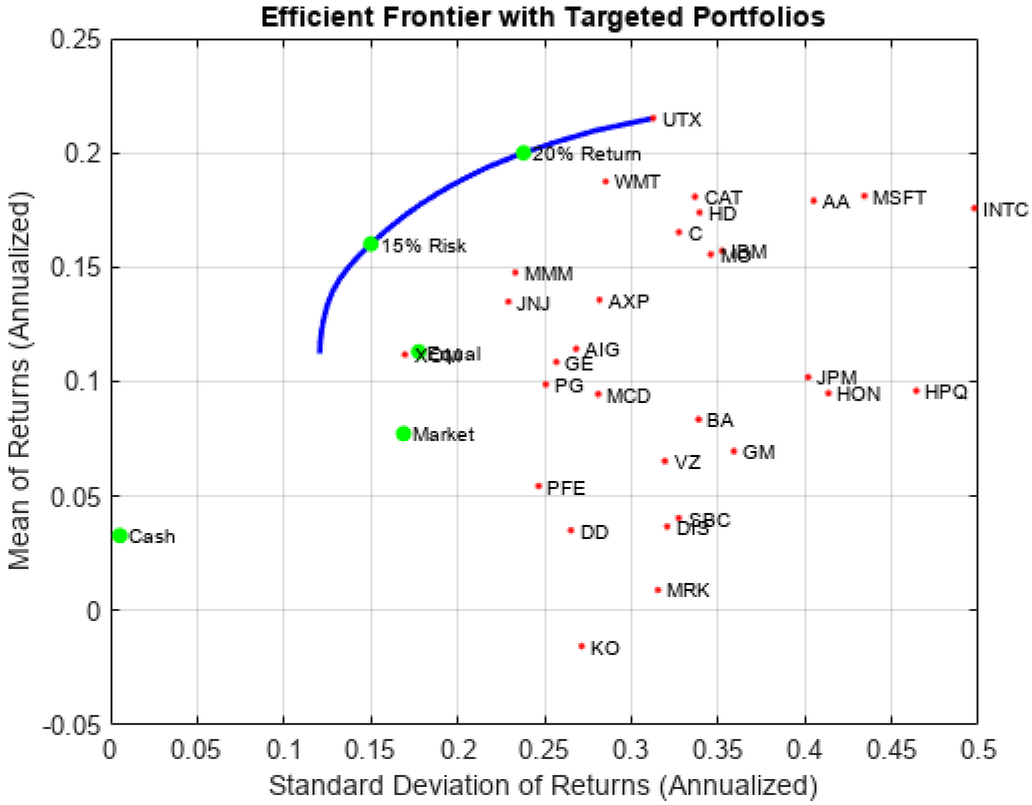
% Obtain portfolios with targeted return and risk.

awgt = estimateFrontierByReturn(p,TargetReturn/12);
[arsk,aret] = estimatePortMoments(p,awgt);

bwgt = estimateFrontierByRisk(p,TargetRisk/sqrt(12));
[brsk,bret] = estimatePortMoments(p,bwgt);

% Plot efficient frontier with targeted portfolios.

clf;
portfolioexamples_plot('Efficient Frontier with Targeted Portfolios', ...
    {'line', prsk, pret}, ...
    {'scatter', [mrsk, crsk, ersk], [mret, cret, eret], {'Market', 'Cash', 'Equal'}}, ...
    {'scatter', arsk, aret, {sprintf('%g%% Return',100*TargetReturn)}}, ...
    {'scatter', brsk, bret, {sprintf('%g%% Risk',100*TargetRisk)}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



To see what these targeted portfolios look like, use the `dataset` object to set up "blotters" that contain the portfolio weights and asset names (which are obtained from the `Portfolio` object).

```
aBlotter = dataset({100*awgt(awgt > 0),'Weight'}, 'obsnames', p.AssetList(awgt > 0));

displayPortfolio(sprintf('Portfolio with %g%% Target Return', 100*TargetReturn), aBlotter, false
```

```

Transactions Costs

The `Portfolio` object makes it possible to account for transaction costs as part of the optimization problem. Although individual costs can be set for each asset, use the scalar expansion features of the `Portfolio` object's functions to set up uniform transaction costs across all assets and compare efficient frontiers with gross versus net portfolio returns.

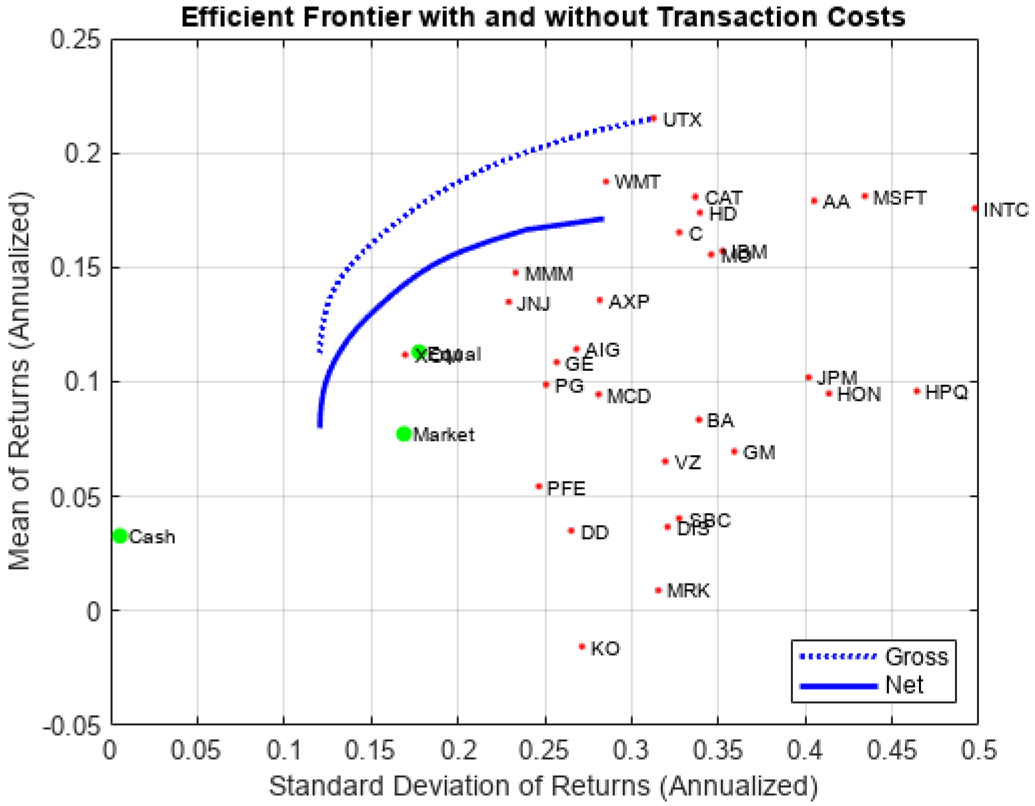
```
BuyCost = 0.0020;
SellCost = 0.0020;

q = setCosts(p,BuyCost,SellCost);

qwgt = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);

% Plot efficient frontiers with gross and net returns.

clf;
portfolioexamples_plot('Efficient Frontier with and without Transaction Costs', ...
    {'line', prsk, pret, {'Gross'}, ':b'}, ...
    {'line', qrsk, qret, {'Net'}}, ...
    {'scatter', [mrsk, crsk, ersk], [mret, cret, eret], {'Market', 'Cash', 'Equal'}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



Turnover Constraint

In addition to transaction costs, the `Portfolio` object can handle turnover constraints. The following example demonstrates that a turnover constraint produces an efficient frontier in the neighborhood of an initial portfolio that may restrict trading. Moreover, the introduction of a turnover constraint often implies that multiple trades may be necessary to shift from an initial portfolio to an unconstrained efficient frontier. Consequently, the turnover constraint introduces a form of time diversification that can spread trades out over multiple time periods. In this example, note that the sum of purchases and sales from the `estimateFrontier` function confirms that the turnover constraint is satisfied.

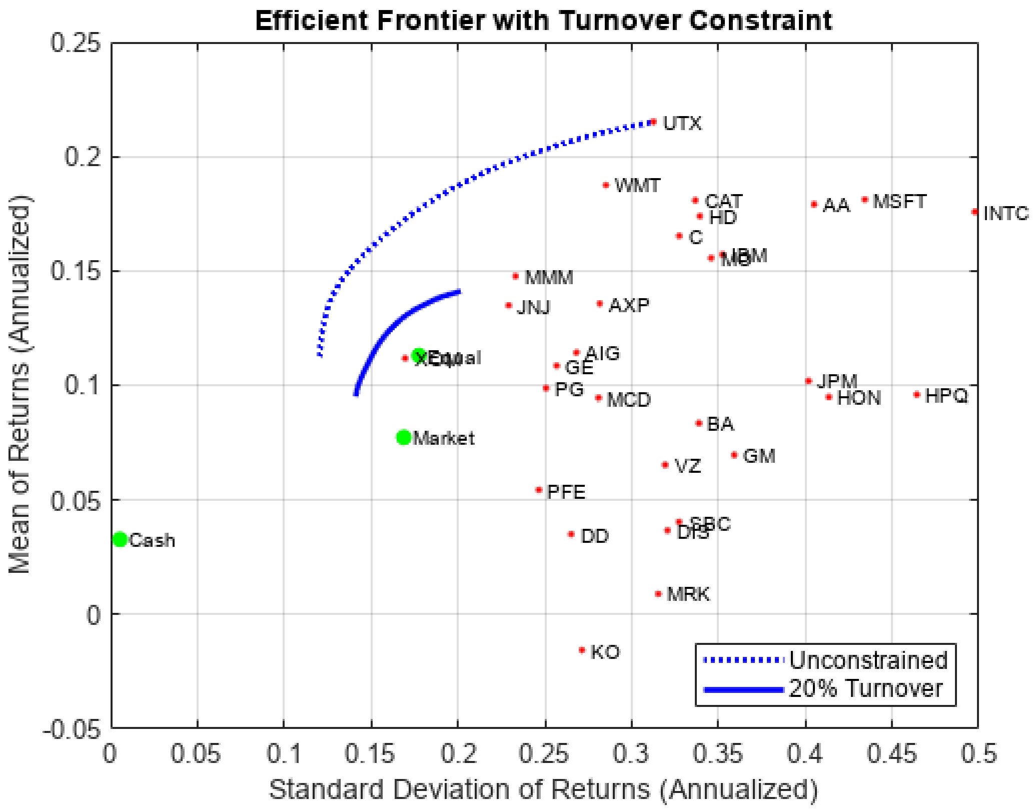
```
BuyCost = 0.0020;
SellCost = 0.0020;
Turnover = 0.2;

q = setCosts(p, BuyCost,SellCost);
q = setTurnover(q,Turnover);

[qwgt,qbuy,qsell] = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);

% Plot efficient frontier with turnover constraint.

clf;
portfolioexamples_plot('Efficient Frontier with Turnover Constraint', ...
    {'line', prsk, pret, {'Unconstrained'}, ':b'}, ...
    {'line', qrsk, qret, {sprintf('%g%% Turnover', 100*Turnover)}}, ...
    {'scatter', [mrsk, crsk, ersk], [mret, cret, eret], {'Market', 'Cash', 'Equal'}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



```

Sum of Sales by Portfolio along Efficient Frontier (Max. Turnover 20%)
20.0000 20.0000 20.0000 20.0000 20.0000 20.0000 20.0000 20.0000 20.0000 20.0000 20.0000 20.0000
```

Tracking-Error Constraint

The Portfolio object can handle tracking-error constraints, where tracking-error is the relative risk of a portfolio compared with a tracking portfolio. In this example, a sub-collection of nine assets forms an equally-weighted tracking portfolio. The goal is to find efficient portfolios with tracking errors that are within 5% of this tracking portfolio.

```
ii = [15, 16, 20, 21, 23, 25, 27, 29, 30];    % Indexes of assets to include in the tracking por

TrackingError = 0.05/sqrt(12);
TrackingPort = zeros(30, 1);
TrackingPort(ii) = 1;
TrackingPort = (1/sum(TrackingPort))*TrackingPort;

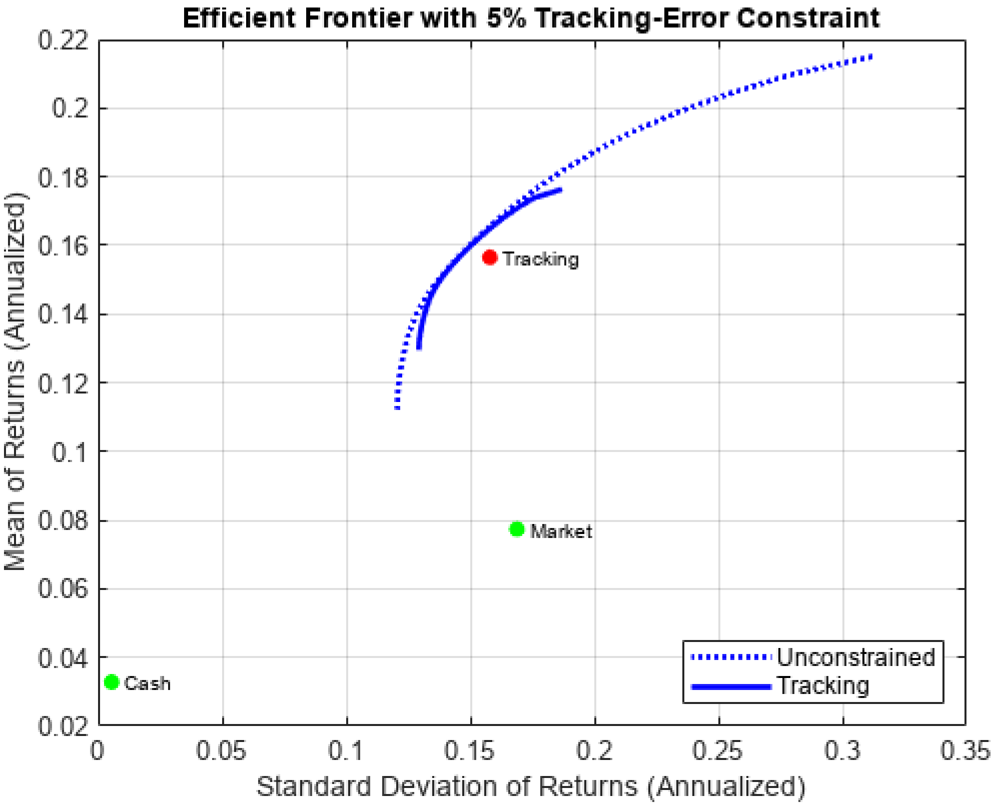
q = setTrackingError(p,TrackingError,TrackingPort);

qwgt = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);
```

```
[trsk,tret] = estimatePortMoments(q,TrackingPort);

% Plot the efficient frontier with tracking-error constraint.

clf;
portfolioexamples_plot('Efficient Frontier with 5% Tracking-Error Constraint', ...
    {'line', prsk, pret, {'Unconstrained'}, ':b'}, ...
    {'line', qrsk, qret, {'Tracking'}}, ...
    {'scatter', [mrsk, crsk], [mret, cret], {'Market', 'Cash'}}, ...
    {'scatter', trsk, tret, {'Tracking'}, 'r'});
```



Combined Turnover and Tracking-Error Constraints

This example illustrates the interactions that can occur with combined constraints. In this case, both a turnover constraint relative to an initial equal-weight portfolio and a tracking-error constraint relative to a tracking portfolio must be satisfied. The turnover constraint has a maximum of 30% turnover and the tracking-error constraint has a maximum of 5% tracking error. Note that the turnover to get from the initial portfolio to the tracking portfolio is 70% so that an upper bound of 30% turnover means that the efficient frontier will lie somewhere between the initial portfolio and the tracking portfolio.

```
Turnover = 0.3;
InitPort = (1/q.NumAssets)*ones(q.NumAssets, 1);

ii = [15, 16, 20, 21, 23, 25, 27, 29, 30];    % Indexes of assets to include in tracking portfol
```

```
TrackingError = 0.05/sqrt(12);
TrackingPort = zeros(30, 1);
TrackingPort(ii) = 1;
TrackingPort = (1/sum(TrackingPort))*TrackingPort;

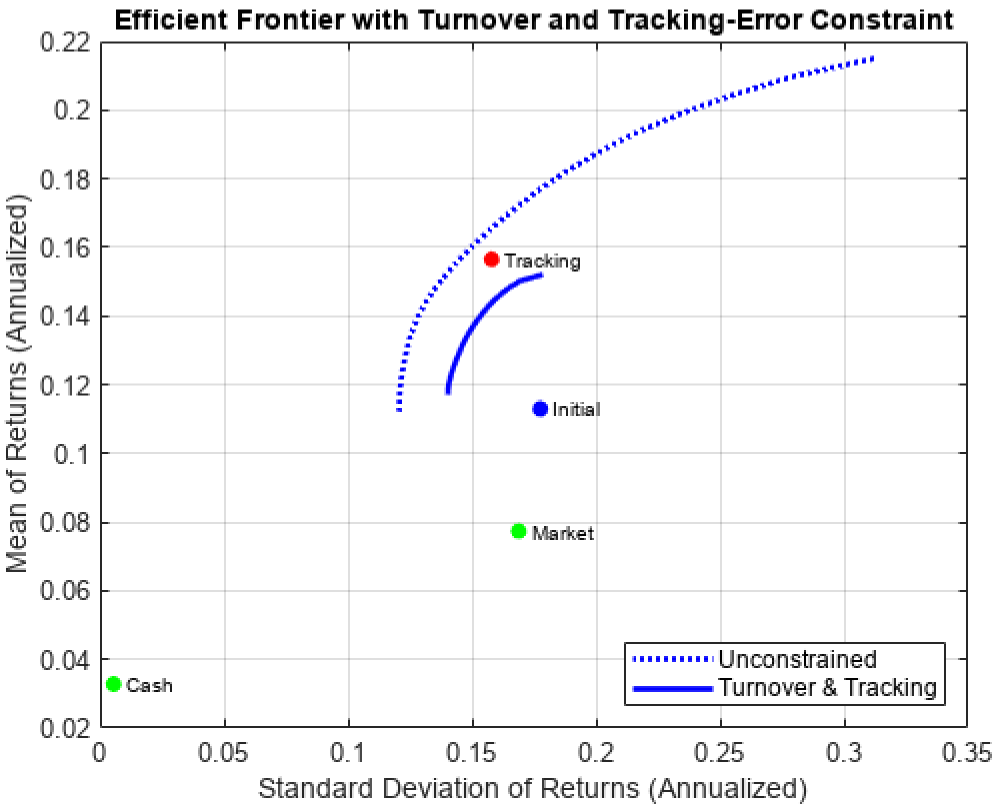
q = setTurnover(q,Turnover,InitPort);

qwgt = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);

[trsk,tret] = estimatePortMoments(q,TrackingPort);
[ersk,eret] = estimatePortMoments(q,InitPort);

% Plot the efficient frontier with combined turnover and tracking-error constraint.

clf;
portfolioexamples_plot('Efficient Frontier with Turnover and Tracking-Error Constraint', ...
    {'line', prsk, pret, {'Unconstrained'}, ':b'}, ...
    {'line', qrsk, qret, {'Turnover & Tracking'}}, ...
    {'scatter', [mrsk, crsk], [mret, cret], {'Market', 'Cash'}}, ...
    {'scatter', trsk, tret, {'Tracking'}, 'r'}, ...
    {'scatter', ersk, eret, {'Initial'}, 'b'});
```



Maximize the Sharpe Ratio

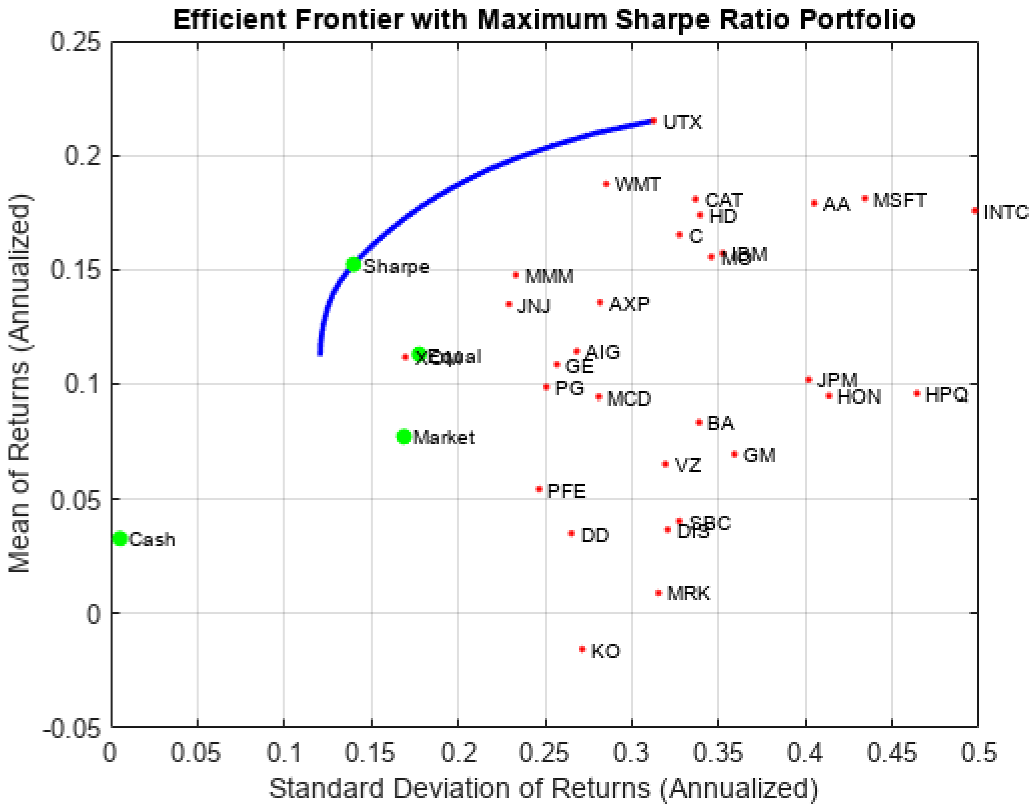
The Sharpe ratio (Sharpe 1966 on page 4-170) is a measure of return-to-risk that plays an important role in portfolio analysis. Specifically, a portfolio that maximizes the Sharpe ratio is also the tangency portfolio on the efficient frontier from the mutual fund theorem. The maximum Sharpe ratio portfolio is located on the efficient frontier with the function `estimateMaxSharpeRatio` and the `dataset` object is used to list the assets in this portfolio.

```
p = setInitPort(p, 0);

swgt = estimateMaxSharpeRatio(p);
[srsk,sret] = estimatePortMoments(p,swgt);

% Plot the efficient frontier with portfolio that attains maximum Sharpe ratio.

clf;
portfolioexamples_plot('Efficient Frontier with Maximum Sharpe Ratio Portfolio', ...
    {'line', prsk, pret}, ...
    {'scatter', srsk, sret, {'Sharpe'}}, ...
    {'scatter', [mrsk, crsk, ersk], [mret, cret, eret], {'Market', 'Cash', 'Equal'}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



```
% Set up a dataset object that contains the portfolio that maximizes the Sharpe ratio.

Blotter = dataset({100*swgt(swgt > 0),'Weight'}, 'obsnames', AssetList(swgt > 0));

displayPortfolio('Portfolio with Maximum Sharpe Ratio', Blotter, false);
```

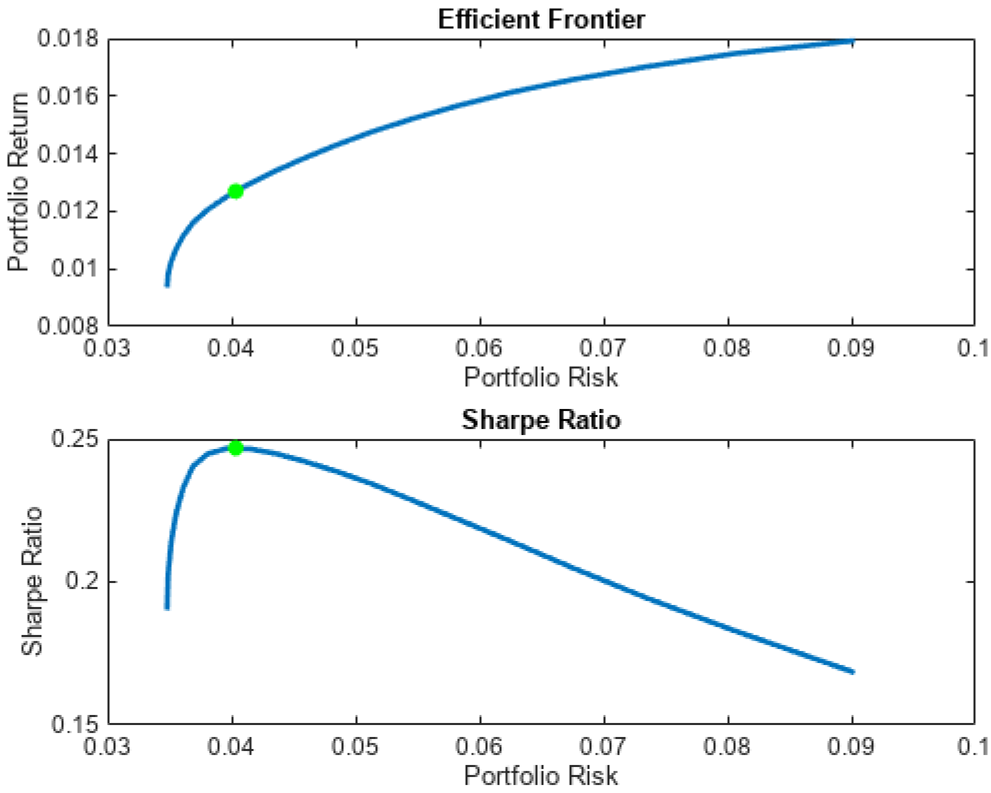
Confirm that Maximum Sharpe Ratio is a Maximum

The following plot demonstrates that this portfolio (which is located at the dot on the plots) indeed maximizes the Sharpe ratio among all portfolios on the efficient frontier.

```
psratio = (pret - p.RiskFreeRate) ./ prsk;
ssratio = (sret - p.RiskFreeRate) / srsk;

clf;
subplot(2,1,1);
plot(prsk, pret, 'LineWidth', 2);
hold on
scatter(srsk, sret, 'g', 'filled');
title('\bfEfficient Frontier');
xlabel('Portfolio Risk');
ylabel('Portfolio Return');
hold off

subplot(2,1,2);
plot(prsk, psratio, 'LineWidth', 2);
hold on
scatter(srsk, ssratio, 'g', 'filled');
title('\bfSharpe Ratio');
xlabel('Portfolio Risk');
ylabel('Sharpe Ratio');
hold off
```



Illustrate that Sharpe is the Tangent Portfolio

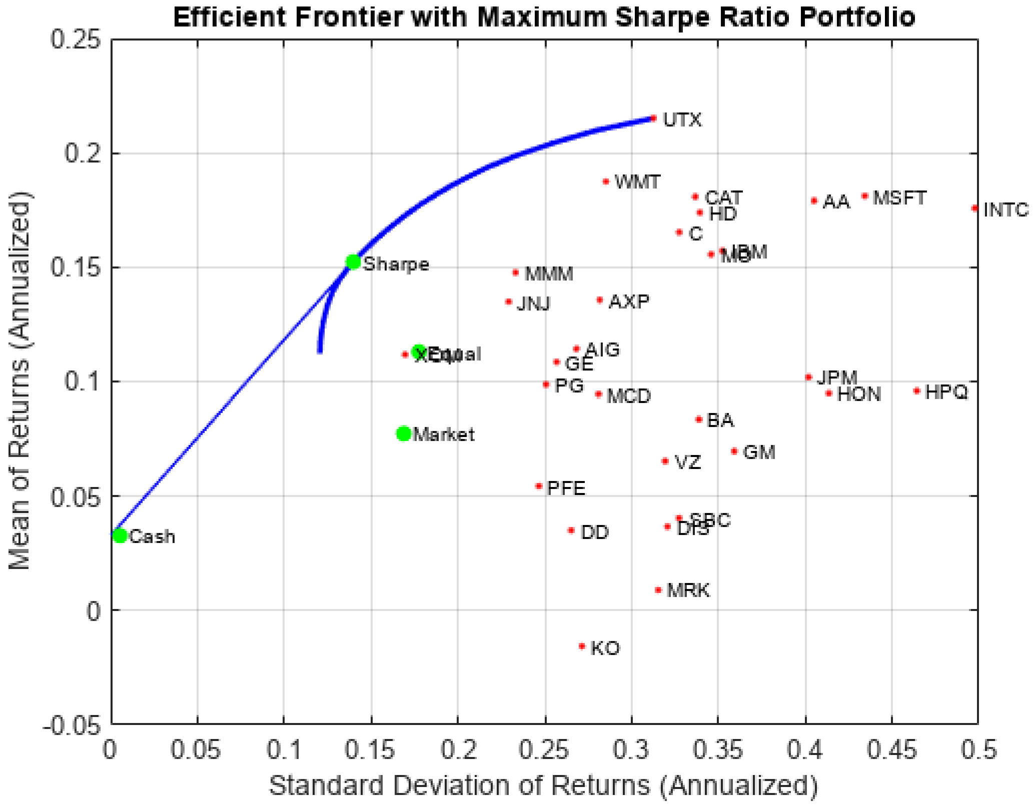
The next plot demonstrates that the portfolio that maximizes the Sharpe ratio is also a tangency portfolio (in this case, the budget constraint is opened up to permit between 0% and 100% in cash).

```
q = setBudget(p, 0, 1);

qwgt = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);

% Plot showing that the Sharpe ratio portfolio is the tangency portfolio.

clf;
portfolioexamples_plot('Efficient Frontier with Maximum Sharpe Ratio Portfolio', ...
    {'line', prsk, pret}, ...
    {'line', qrsk, qret, [], [], 1}, ...
    {'scatter', srsk, sret, {'Sharpe'}}, ...
    {'scatter', [mrsk, crsk, ersk], [mret, cret, eret], {'Market', 'Cash', 'Equal'}}, ...
    {'scatter', sqrt(diag(p.AssetCovar)), p.AssetMean, p.AssetList, '.r'});
```



Dollar-Neutral Hedge-Fund Structure

To illustrate how to use the portfolio optimization tools in hedge fund management, two popular strategies with dollar-neutral and 130-30 portfolios are examined. The dollar-neutral strategy invests equally in long and short positions such that the net portfolio position is `0`. Such a portfolio is said to be "dollar-neutral."

To set up a dollar-neutral portfolio, start with the "standard" portfolio problem and set the maximum exposure in long and short positions in the variable `Exposure`. The bounds for individual asset weights are plus or minus `Exposure`. Since the net position must be dollar-neutral, the budget constraint is `0` and the initial portfolio must be `0`. Finally, the one-way turnover constraints provide the necessary long and short restrictions to prevent "double-counting" of long and short positions. The blotter shows the portfolio weights for the dollar-neutral portfolio that maximizes the Sharpe ratio. The long and short positions are obtained from the buy and sell trades relative to the initial portfolio.

```
Exposure = 1;

q = setBounds(p, -Exposure, Exposure);
q = setBudget(q, 0, 0);
q = setOneWayTurnover(q, Exposure, Exposure, 0);

[qwgt,qlong,qshort] = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);

[qswgt,qslong,qsshort] = estimateMaxSharpeRatio(q);
```

```
[qsrsk,qsret] = estimatePortMoments(q,qswgt);

% Plot the efficient frontier for a dollar-neutral fund structure with tangency portfolio.

clf;
portfolioexamples_plot('Efficient Frontier with Dollar-Neutral Portfolio', ...

130/30 Fund Structure

Finally, the turnover constraints are used to set up a 130-30 portfolio structure, which is a structure with a net long position but permits leverage with long and short positions up to a maximum amount of leverage. In the case of a 130-30 portfolio, the leverage is 30%.

To set up a 130-30 portfolio, start with the "standard" portfolio problem and set the maximum value for leverage in the variable `Leverage`. The bounds for individual asset weights range between `-Leverage` and `1 + Leverage`. Since the net position must be long, the budget constraint is `1` and, once again, the initial portfolio is `0`. Finally, the one-way turnover constraints provide the necessary long and short restrictions to prevent "double-counting" of long and short positions. The blotter shows the portfolio weights for the 130-30 portfolio that maximizes the Sharpe ratio. The long and short positions are obtained from the buy and sell trades relative to the initial portfolio.

```
Leverage = 0.3;

q = setBounds(p, -Leverage, 1 + Leverage);
q = setBudget(q, 1, 1);
q = setOneWayTurnover(q, 1 + Leverage, Leverage);

[qwgt,qbuy,qsell] = estimateFrontier(q,20);
[qrsk,qret] = estimatePortMoments(q,qwgt);

[qswgt,qslong,qsshort] = estimateMaxSharpeRatio(q);
[qsrsk,qsret] = estimatePortMoments(q,qswgt);

Asset Allocation Case Study

This example shows how to set up a basic asset allocation problem that uses mean-variance portfolio optimization with a `Portfolio` object to estimate efficient portfolios.

Step 1. Defining the portfolio problem.

Suppose that you want to manage an asset allocation fund with four asset classes: bonds, large-cap equities, small-cap equities, and emerging equities. The fund is long-only with no borrowing or leverage, should have no more than 85% of the portfolio in equities, and no more than 35% of the portfolio in emerging equities. The cost to trade the first three assets is 10 basis points annualized and the cost to trade emerging equities is four times higher. Finally, you want to ensure that average turnover is no more than 15%. To solve this problem, you will set up a basic mean-variance portfolio optimization problem and then slowly introduce the various constraints on the problem to get to a solution.

To set up the portfolio optimization problem, start with basic definitions of known quantities associated with the structure of this problem. Each asset class is assumed to have a tradeable asset with a real-time price. Such assets can be, for example, exchange-traded funds (ETFs). The initial portfolio with holdings in each asset that has a total of $7.5 million along with an additional cash position of $60,000. These basic quantities and the costs to trade are set up in the following variables with asset names in the cell array `Asset`, current prices in the vector `Price`, current portfolio holdings in the vector `Holding`, and transaction costs in the vector `UnitCost`.

To analyze this portfolio, you can set up a blotter in a `table` object to help track prices, holdings, weights, and so forth. In particular, you can compute the initial portfolio weights and maintain them in a new blotter field called `InitPort`.

```
Asset = { 'Bonds', 'Large-Cap Equities', 'Small-Cap Equities', 'Emerging Equities' };
Price = [ 52.4; 122.7; 35.2; 46.9 ];
Holding = [ 42938; 24449; 42612; 15991 ];
UnitCost = [ 0.001; 0.001; 0.001; 0.004 ];

Blotter = table('RowNames', Asset);
Blotter.Price = Price;
Blotter.InitHolding = Holding;
Wealth = sum(Blotter.Price .* Blotter.InitHolding);
Blotter.InitPort = (1/Wealth)*(Blotter.Price .* Blotter.InitHolding);
Blotter.UnitCost = UnitCost;
Blotter
```

```
Blotter=4×4 table
                          Price    InitHolding    InitPort    UnitCost
                          _____    ___________    ________    ________

    Bonds                  52.4       42938          0.3        0.001 
    Large-Cap Equities    122.7       24449          0.4        0.001 
    Small-Cap Equities     35.2       42612          0.2        0.001 
    Emerging Equities      46.9       15991          0.1        0.004 
```

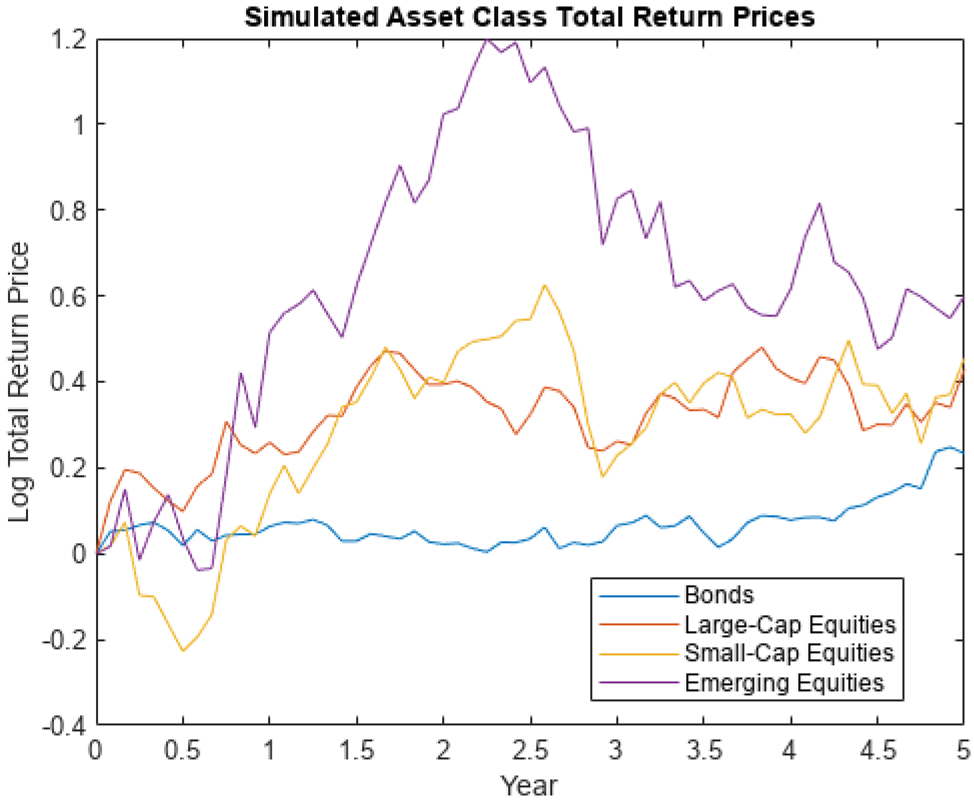
Step 2. Simulating asset prices.

Since this is a hypothetical example, to simulate asset prices from a given mean and covariance of annual asset total returns for the asset classes, the `portsim` function is used to create asset returns with the desired mean and covariance. Specifically, `portsim` is used to simulate five years of monthly total returns and then plotted to show the log of the simulated total return prices

The mean and covariance of annual asset total returns are maintained in the variables `AssetMean` and `AssetCovar`. The simulated asset total return prices (which are compounded total returns) are maintained in the variable `Y`. All initial asset total return prices are normalized to `1` in this example.

```
AssetMean = [ 0.05; 0.1; 0.12; 0.18 ];
AssetCovar = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

X = portsim(AssetMean'/12, AssetCovar/12, 60); % Monthly total returns for 5 years (60 months)
[Y, T] = ret2tick(X, [], 1/12);                % form total return prices.
plot(T, log(Y));
title('\bfSimulated Asset Class Total Return Prices');
xlabel('Year');
ylabel('Log Total Return Price');
legend(Asset,'Location','best');
```



Step 3. Setting up the Portfolio object.

To explore portfolios on the efficient frontier, set up a `Portfolio` object using these specifications:

- Portfolio weights are nonnegative and sum to `1`.

- Equity allocation is no more than 85% of the portfolio.
- Emerging equity is no more than 35% of the portfolio.

These specifications are incorporated into the Portfolio object p in the following sequence of using functions that starts with using the Portfolio object.

1. The specification of the initial portfolio from Blotter gives the number of assets in your universe so you do not need to specify the NumAssets property directly. Next, set up default constraints (long-only with a budget constraint). In addition, set up the group constraint that imposes an upper bound on equities in the portfolio (equities are identified in the group matrix with 1's) and the upper bound constraint on emerging equities. Although you could have set the upper bound on emerging equities using the setBounds function, notice how the addGroups function is used to set up this constraint.
2. To have a fully specified mean-variance portfolio optimization problem, you must specify the mean and covariance of asset returns. Since starting with these moments in the variables AssetMean and AssetCovar, you can use the setAssetMoments function to enter these variables into your Portfolio object (remember that you are assuming that your raw data are monthly returns which is why you divide your annual input moments by 12 to get monthly returns).
3. Use the total return prices with the estimateAssetMoments function with a specification that your data in Y are prices, and not returns, to estimate asset return moments for your Portfolio object.
4. Although the returns in your Portfolio object are in units of monthly returns, and since subsequent costs are annualized, it is convenient to specify them as annualized total returns with this direct transformation of the AssetMean and AssetCovar properties of your Portfolio object p.
5. Display the Portfolio object p.

```
p = Portfolio('Name', 'Asset Allocation Portfolio', ...
'AssetList', Asset, 'InitPort', Blotter.InitPort);

p = setDefaultConstraints(p);
p = setGroups(p, [ 0, 1, 1, 1 ], [], 0.85);
p = addGroups(p, [ 0, 0, 0, 1 ], [], 0.35);

p = setAssetMoments(p, AssetMean/12, AssetCovar/12);
p = estimateAssetMoments(p, Y, 'DataFormat', 'Prices');

p.AssetMean = 12*p.AssetMean;
p.AssetCovar = 12*p.AssetCovar;

display(p)
```

```
p =
  Portfolio with properties:

          BuyCost: []
         SellCost: []
     RiskFreeRate: []
        AssetMean: [4x1 double]
       AssetCovar: [4x4 double]
    TrackingError: []
     TrackingPort: []
         Turnover: []
```

```
      BuyTurnover: []
     SellTurnover: []
             Name: 'Asset Allocation Portfolio'
        NumAssets: 4
        AssetList: {'Bonds'  'Large-Cap Equities'  'Small-Cap Equities'  'Emerging Equities'}
         InitPort: [4x1 double]
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []
       LowerBound: [4x1 double]
       UpperBound: []
      LowerBudget: 1
      UpperBudget: 1
      GroupMatrix: [2x4 double]
       LowerGroup: []
       UpperGroup: [2x1 double]
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
     MinNumAssets: []
     MaxNumAssets: []
        BoundType: [4x1 categorical]
```

Step 4. Validate the portfolio problem.

An important step in portfolio optimization is to validate that the portfolio problem is feasible and the main test is to ensure that the set of portfolios is nonempty and bounded. Use the `estimateBounds` function to determine the bounds for the portfolio set. In this case, since both `lb` and `ub` are finite, the set is bounded.

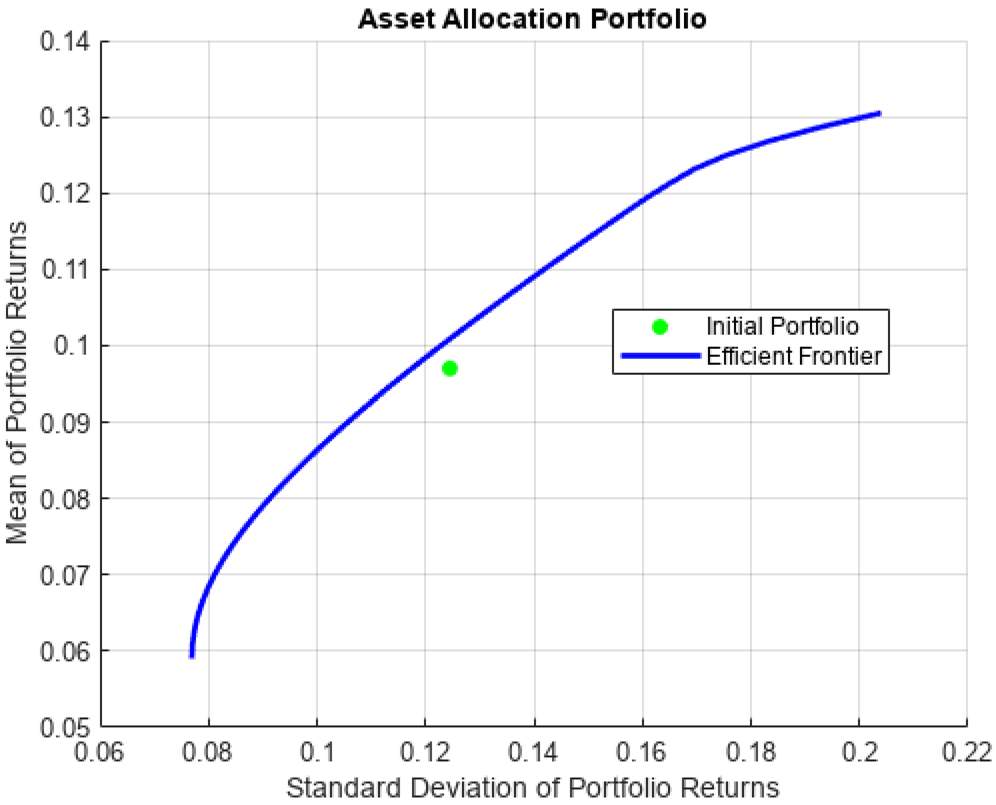
```
[lb, ub] = estimateBounds(p);
display([lb, ub])
```

```
    0.1500    1.0000
         0    0.8500
         0    0.8500
         0    0.3500
```

Step 5. Plotting the efficient frontier.

Given the constructed `Portfolio` object, use the `plotFrontier` function to view the efficient frontier. Instead of using the default of 10 portfolios along the frontier, you can display the frontier with 40 portfolios. Notice gross efficient portfolio returns fall between approximately 6% and 16% per years.

```
plotFrontier(p, 40)
```



Step 6. Evaluating gross vs. net portfolio returns.

The `Portfolio` object `p` does not include transaction costs so that the portfolio optimization problem specified in `p` uses gross portfolio return as the return proxy. To handle net returns, create a second `Portfolio` object `q` that includes transaction costs.

```
q = setCosts(p, UnitCost, UnitCost);
display(q)
```

```
q = 
  Portfolio with properties:

          BuyCost: [4x1 double]
         SellCost: [4x1 double]
     RiskFreeRate: []
        AssetMean: [4x1 double]
       AssetCovar: [4x4 double]
    TrackingError: []
     TrackingPort: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
             Name: 'Asset Allocation Portfolio'
        NumAssets: 4
        AssetList: {'Bonds'  'Large-Cap Equities'  'Small-Cap Equities'  'Emerging Equities'}
         InitPort: [4x1 double]
      AInequality: []
      bInequality: []
```

```
        AEquality: []
        bEquality: []
       LowerBound: [4x1 double]
       UpperBound: []
      LowerBudget: 1
      UpperBudget: 1
      GroupMatrix: [2x4 double]
       LowerGroup: []
       UpperGroup: [2x1 double]
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
     MinNumAssets: []
     MaxNumAssets: []
        BoundType: [4x1 categorical]
```

Step 7. Analyzing descriptive properties of the Portfolio structures.

To be more concrete about the ranges of efficient portfolio returns and risks, use the `estimateFrontierLimits` function to obtain portfolios at the endpoints of the efficient frontier. Given these portfolios, compute their moments using the `estimatePortMoments` function. The following code generates a table that lists the risk and return of the initial portfolio as well as the gross and net moments of portfolio returns for the portfolios at the endpoints of the efficient frontier:

```
[prsk0, pret0] = estimatePortMoments(p, p.InitPort);

pret = estimatePortReturn(p, p.estimateFrontierLimits);
qret = estimatePortReturn(q, q.estimateFrontierLimits);

displayReturns(pret0, pret, qret)
```

```
Annualized Portfolio Returns ...
                                    Gross       Net
Initial Portfolio Return             9.70 %    9.70 %
Minimum Efficient Portfolio Return   5.90 %    5.77 %
Maximum Efficient Portfolio Return  13.05 %   12.86 %
```

The results show that the cost to trade ranges from 14 to 19 basis points to get from the current portfolio to the efficient portfolios at the endpoints of the efficient frontier (these costs are the difference between gross and net portfolio returns.) In addition, notice that the maximum efficient portfolio return (13%) is less than the maximum asset return (18%) due to the constraints on equity allocations.

Step 8. Obtaining a Portfolio at the specified return level on the efficient frontier.

A common approach to select efficient portfolios is to pick a portfolio that has a desired fraction of the range of expected portfolio returns. To obtain the portfolio that is 30% of the range from the minimum to maximum return on the efficient frontier, obtain the range of net returns in `qret` using the `Portfolio` object `q` and interpolate to obtain a 30% level with the `interp1` function to obtain a portfolio `qwgt`.

```
Level = 0.3;

qret = estimatePortReturn(q, q.estimateFrontierLimits);
qwgt = estimateFrontierByReturn(q, interp1([0, 1], qret, Level));
```

```
[qrsk, qret] = estimatePortMoments(q, qwgt);

displayReturnLevel(Level, qret, qrsk);
```

```
Portfolio at 30% return level on efficient frontier ...
    Return       Risk
      7.90       9.09
```

```
display(qwgt)
```

```
qwgt = 4×1

    0.6252
    0.1856
    0.0695
    0.1198
```

The target portfolio that is 30% of the range from minimum to maximum net returns has a return of 7.9% and a risk of 9.1%.

Step 9. Obtaining a Portfolio at the specified risk levels on the efficient frontier.

Although you could accept this result, suppose that you want to target values for portfolio risk. Specifically, suppose that you have a conservative target risk of 10%, a moderate target risk of 15%, and an aggressive target risk of 20% and you want to obtain portfolios that satisfy each risk target. Use the `estimateFrontierByRisk` function to obtain targeted risks specified in the variable `TargetRisk`. The resultant three efficient portfolios are obtained in `qwgt`.

```
TargetRisk = [ 0.10; 0.15; 0.20 ];
qwgt = estimateFrontierByRisk(q, TargetRisk);
display(qwgt)
```

```
qwgt = 4×3

    0.5407    0.2020    0.1500
    0.2332    0.4000    0.0318
    0.0788    0.1280    0.4682
    0.1474    0.2700    0.3500
```

Use the `estimatePortRisk` function to compute the portfolio risks for the three portfolios to confirm that the target risks have been attained:

```
display(estimatePortRisk(q, qwgt))
```

```
    0.1000
    0.1500
    0.2000
```

Suppose that you want to shift from the current portfolio to the moderate portfolio. You can estimate the purchases and sales to get to this portfolio:

```
[qwgt, qbuy, qsell] = estimateFrontierByRisk(q, 0.15);
```

If you average the purchases and sales for this portfolio, you can see that the average turnover is 17%, which is greater than the target of 15%:

```
disp(sum(qbuy + qsell)/2)
```

```
    0.1700
```

Since you also want to ensure that average turnover is no more than 15%, you can add the average turnover constraint to the `Portfolio` object using `setTurnover`:

```
q = setTurnover(q, 0.15);
[qwgt, qbuy, qsell] = estimateFrontierByRisk(q, 0.15);
```

You can enter the estimated efficient portfolio with purchases and sales into the `Blotter`:

```
qbuy(abs(qbuy) < 1.0e-5) = 0;
qsell(abs(qsell) < 1.0e-5) = 0;  % Zero out near 0 trade weights.

Blotter.Port = qwgt;
Blotter.Buy = qbuy;
Blotter.Sell = qsell;

display(Blotter)
```

```
Blotter=4×7 table
                          Price    InitHolding    InitPort    UnitCost     Port      Buy       Se
                          _____    ___________    ________    ________    _______    ____    ____

    Bonds                  52.4       42938         0.3        0.001      0.18787       0     0.1
    Large-Cap Equities    122.7       24449         0.4        0.001          0.4       0
    Small-Cap Equities     35.2       42612         0.2        0.001      0.16213       0    0.03
    Emerging Equities      46.9       15991         0.1        0.004         0.25    0.15
```

The `Buy` and `Sell` elements of the `Blotter` are changes in portfolio weights that must be converted into changes in portfolio holdings to determine the trades. Since you are working with net portfolio returns, you must first compute the cost to trade from your initial portfolio to the new portfolio. This is accomplished as follows:

```
TotalCost = Wealth * sum(Blotter.UnitCost .* (Blotter.Buy + Blotter.Sell))
```

```
TotalCost = 5.6248e+03
```

The cost to trade is $5,625, so that, in general, you would have to adjust your initial wealth accordingly before setting up your new portfolio weights. However, to keep the analysis simple, note that you have sufficient cash ($60,0000) set aside to pay the trading costs and that you will not touch the cash position to build up any positions in your portfolio. Thus, you can populate your blotter with the new portfolio holdings and the trades to get to the new portfolio without making any changes in your total invested wealth. First, compute the portfolio holding:

```
Blotter.Holding = Wealth * (Blotter.Port ./ Blotter.Price);
```

Compute number of shares to `Buy` and `Sell` in your `Blotter`:

```
Blotter.BuyShare = Wealth * (Blotter.Buy ./ Blotter.Price);
Blotter.SellShare = Wealth * (Blotter.Sell ./ Blotter.Price);
```

Notice how you used an *ad hoc* truncation rule to obtain unit numbers of shares to buy and sell. Clean up the `Blotter` by removing the unit costs and the buy and sell portfolio weights:

```
Blotter.Buy = [];
Blotter.Sell = [];
Blotter.UnitCost = [];
```

Step 10. Displaying the final results.

The final result is a blotter that contains proposed trades to get from your current portfolio to a moderate-risk portfolio. To make the trade, you would need to sell 16,049 shares of your bond asset and 8,069 shares of your small-cap equity asset and would need to purchase 23,986 shares of your emerging equities asset.

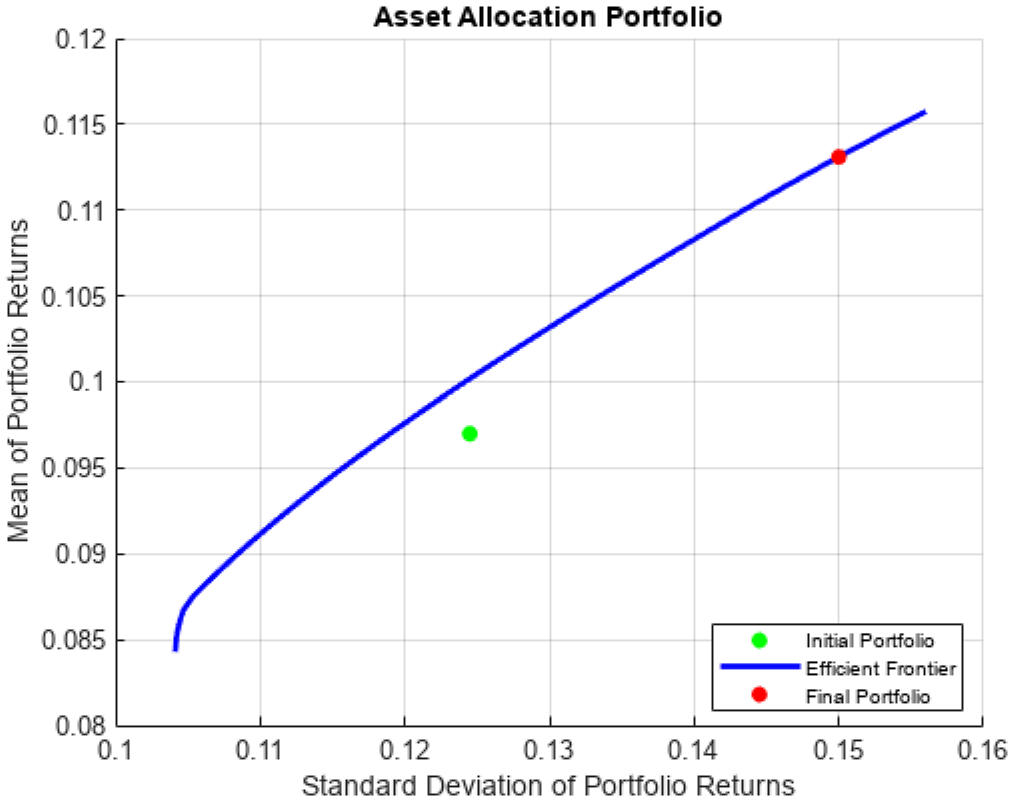
```
display(Blotter)
```

```
Blotter=4×7 table
                          Price    InitHolding    InitPort     Port      Holding    BuyShare    S
                          _____    ___________    ________    _______    _______    ________    _

    Bonds                  52.4       42938          0.3      0.18787     26889            0
    Large-Cap Equities    122.7       24449          0.4          0.4     24449            0
    Small-Cap Equities     35.2       42612          0.2      0.16213     34543            0
    Emerging Equities      46.9       15991          0.1         0.25     39977        23986
```

The final plot uses the `plotFrontier` function to display the efficient frontier and the initial portfolio for the fully specified portfolio optimization problem. It also adds the location of the moderate-risk or final portfolio on the efficient frontier.

```
plotFrontier(q, 40);
hold on
scatter(estimatePortRisk(q, qwgt), estimatePortReturn(q, qwgt), 'filled', 'r');
h = legend('Initial Portfolio', 'Efficient Frontier', 'Final Portfolio', 'location', 'best');
set(h, 'Fontsize', 8);
hold off
```



Local Functions

```
function displayReturns(pret0, pret, qret)
fprintf('Annualized Portfolio Returns ...\n');
fprintf('                                   %6s    %6s\n','Gross','Net');
fprintf('Initial Portfolio Return           %6.2f %%  %6.2f %%\n',100*pret0,100*pret0);
fprintf('Minimum Efficient Portfolio Return %6.2f %%  %6.2f %%\n',100*pret(1),100*qret(1));
fprintf('Maximum Efficient Portfolio Return %6.2f %%  %6.2f %%\n',100*pret(2),100*qret(2));
end

function displayReturnLevel(Level, qret, qrsk)
fprintf('Portfolio at %g%% return level on efficient frontier ...\n',100*Level);
fprintf('%10s %10s\n','Return','Risk');
fprintf('%10.2f %10.2f\n',100*qret,100*qrsk);
end
```

Portfolio Optimization with Semicontinuous and Cardinality Constraints

This example shows how to use a Portfolio object to directly handle semicontinuous and cardinality constraints when performing portfolio optimization. Portfolio optimization finds the asset allocation that maximizes the return or minimizes the risk, subject to a set of investment constraints. The Portfolio class in Financial Toolbox™ is designed and implemented based on the Markowitz Mean-Variance Optimization framework. The Mean-Variance Optimization framework handles problems where the return is the expected portfolio return, and the risk is the variance of portfolio returns. Using the Portfolio class, you can minimize the risk on the efficient frontier (EF), maximize the return on the EF, maximize the return for a given risk, and minimize the risk for a given return. You can also use PortfolioCVaR or PortfolioMAD classes in Financial Toolbox™ to specify semicontinuous and cardinality constraints. Such optimization problems integrate with constraints such as group, linear inequality, turnover, and tracking error constraints. These constraints are formulated as nonlinear programming (NLP) problems with continuous variables represented as the asset weights x_i.

Semicontinuous and cardinality constraints are two other common categories of portfolio constraints that are formulated mathematically by adding the binary variables v_i.

- A *semicontinuous constraint* confines the allocation of an asset. For example, you can use this constraint to confine the allocated weight of an allocated asset to between 5% and 50%. By using this constraint, you can avoid very small or large positions to minimize the churns and operational costs. To mathematically formulate this type of constraint, a binary variable v_i is needed, where v_i is 0 or 1. The value 0 indicates that asset *i* is not allocated and the value 1 indicates that asset *i* is allocated. The mathematical form is $\mathrm{lb} * v_i \le x_i \le \mathrm{ub} * v_i$, where v_i is 0 or 1. Specify this type of constraint as a 'Conditional' BoundType in the Portfolio class using the setBounds function.
- A *cardinality constraint* limits the number of assets in the optimal allocation, For example, for a portfolio with a universe of 100 assets, you can specify an optimal portfolio allocation between 20 and 40 assets. This capability helps limit the number of positions, and thus reduce operational costs. To mathematically formulate this type of constraint, binary variables represented as v_i are needed, where v_i is 0 or 1. The value 0 indicates that asset *i* is not allocated and the value 1 indicates that asset *i* is allocated. The mathematical form is $\mathrm{MinNumAssets} \le \sum_1^{\mathrm{NumAssets}} v_i \le \mathrm{MaxNumAssets}$, where v_i is 0 or 1. Specify this type of constraint by setting the 'MinNumAssets' and 'MaxNumAssets'constraints in the Portfolio class using the setMinMaxNumAssets function.

For more information on semicontinuous and cardinality constraints, see “Algorithms” on page 15-1399.

When semicontinuous and cardinality constraints are used for portfolio optimization, this leads to mixed integer nonlinear programming problems (MINLP). The Portfolio class allows you to configure these two constraints, specifically, semicontinuous constraints using setBounds with 'Conditional' BoundType, and cardinality constraints using setMinMaxNumAssets. The Portfolio class automatically formulates the mathematical problems and validates the specified constraints. The Portfolio class also provides built-in MINLP solvers and flexible solver options for you to tune the solver performance using the setSolverMINLP function.

This example demonstrates a `Portfolio` object with semicontinuous and cardinality constraints and uses the `BlueChipStockMoments` dataset, which has a universe of 30 assets.

```
load BlueChipStockMoments
numAssets = numel(AssetList)
```

```
numAssets = 30
```

Limit the Minimum Weight for Each Allocated Asset

Create a fully invested portfolio with only long positions: $x_i \geq 0$ and $\text{sum}(x_i) = 1$. These are configured with `setDefaultConstraints`.

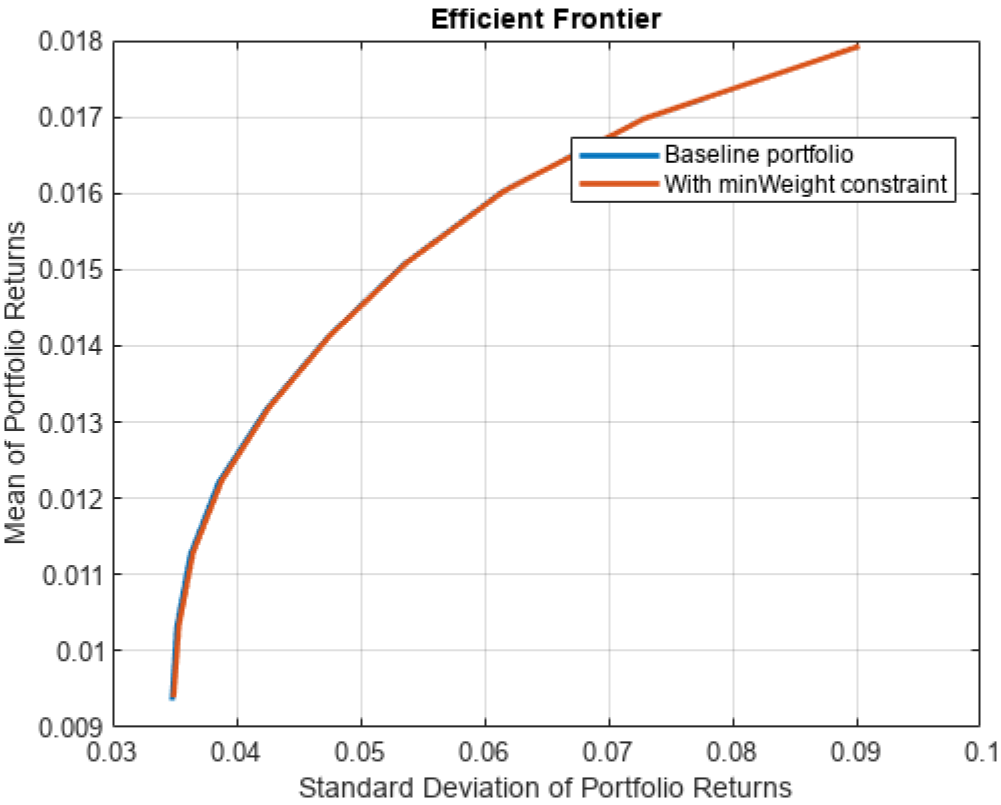
```
p = Portfolio('AssetList', AssetList,'AssetCovar', AssetCovar, 'AssetMean', AssetMean);
p = setDefaultConstraints(p);
```

Suppose that you want to avoid very small positions to minimize the churn and operational costs. Add another constraint to confine the allocated positions to be no less than 5%, by setting the constraints $x_i = 0$ or $x_i \geq 0.05$ using `setBounds` with a `'Conditional'` `BoundType`.

```
pWithMinWeight = setBounds(p, 0.05, 'BoundType', 'Conditional');
```

Plot the efficient frontiers for both `Portfolio` objects.

```
wgt = estimateFrontier(p);
wgtWithMinWeight = estimateFrontier(pWithMinWeight);
figure(1);
plotFrontier(p, wgt); hold on;
plotFrontier(pWithMinWeight, wgtWithMinWeight); hold off;
legend('Baseline portfolio', 'With minWeight constraint', 'location', 'best');
```



The figure shows that the two `Portfolio` objects have almost identical efficient frontiers. However, the one with the minimum weight requirement is more practical, since it prevents the close-to-zero positions.

Check the optimal weights for the portfolio with default constraints to see how many assets are below the 5% limit for each optimal allocation.

```
toler = eps;
sum(wgt>toler & wgt<0.05)
```

```
ans = 1×10

     5     7     5     4     2     3     4     2     0     0
```

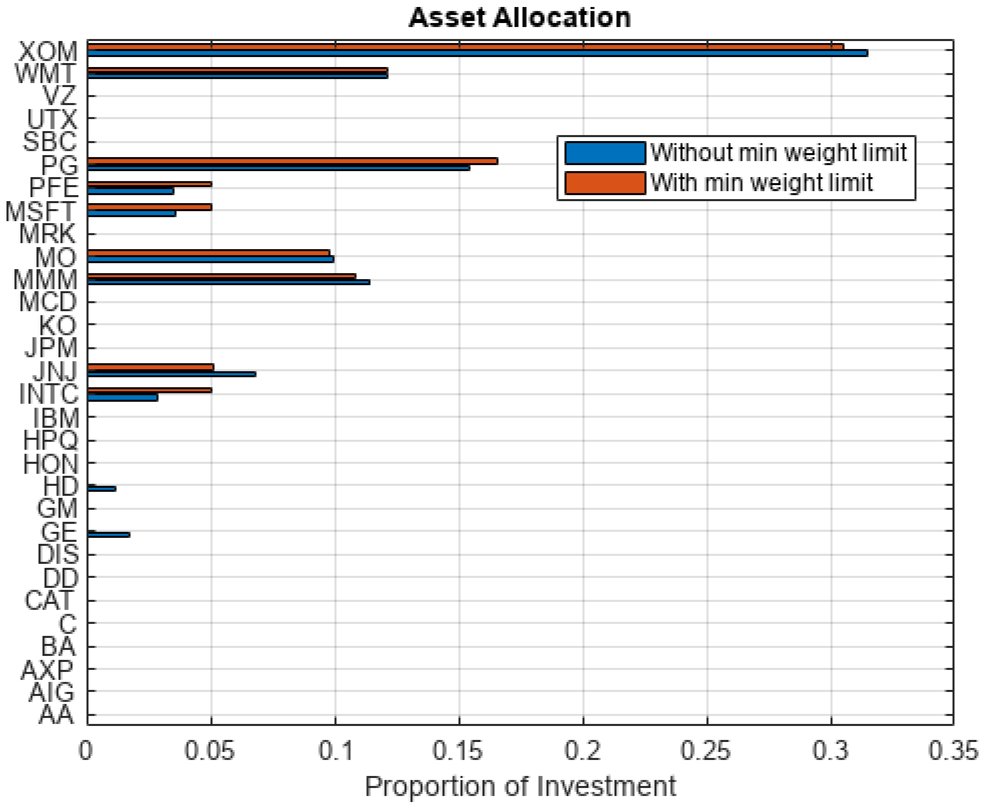
Use `estimateFrontierByReturn` to investigate the portfolio compositions for a target return on the frontier for both cases.

```
targetRetn = 0.011;
pwgt = estimateFrontierByReturn(p, targetRetn);
pwgtWithMinWeight = estimateFrontierByReturn(pWithMinWeight, targetRetn);
```

Plot the composition of the two `Portfolio` objects for the universe of 30 assets.

```
figure(2);
barh([pwgt, pwgtWithMinWeight]);
grid on
xlabel('Proportion of Investment')
```

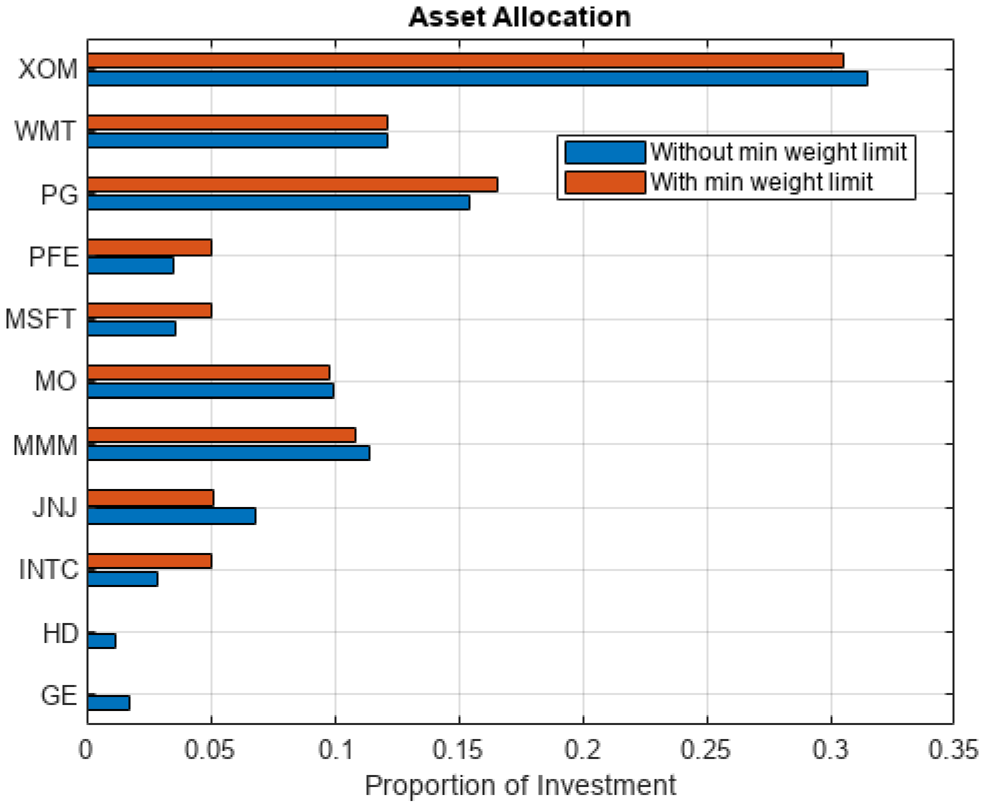
```
yticks(1:p.NumAssets);
yticklabels(p.AssetList);
title('Asset Allocation');
legend('Without min weight limit', 'With min weight limit', 'location', 'best');
```



Show only the allocated assets.

```
idx = (pwgt>toler) | (pwgtWithMinWeight>toler);

barh([pwgt(idx), pwgtWithMinWeight(idx)]);
grid on
xlabel('Proportion of Investment')
yticks(1:sum(idx));
yticklabels(p.AssetList(idx));
title('Asset Allocation');
legend('Without min weight limit', 'With min weight limit', 'location', 'best');
```

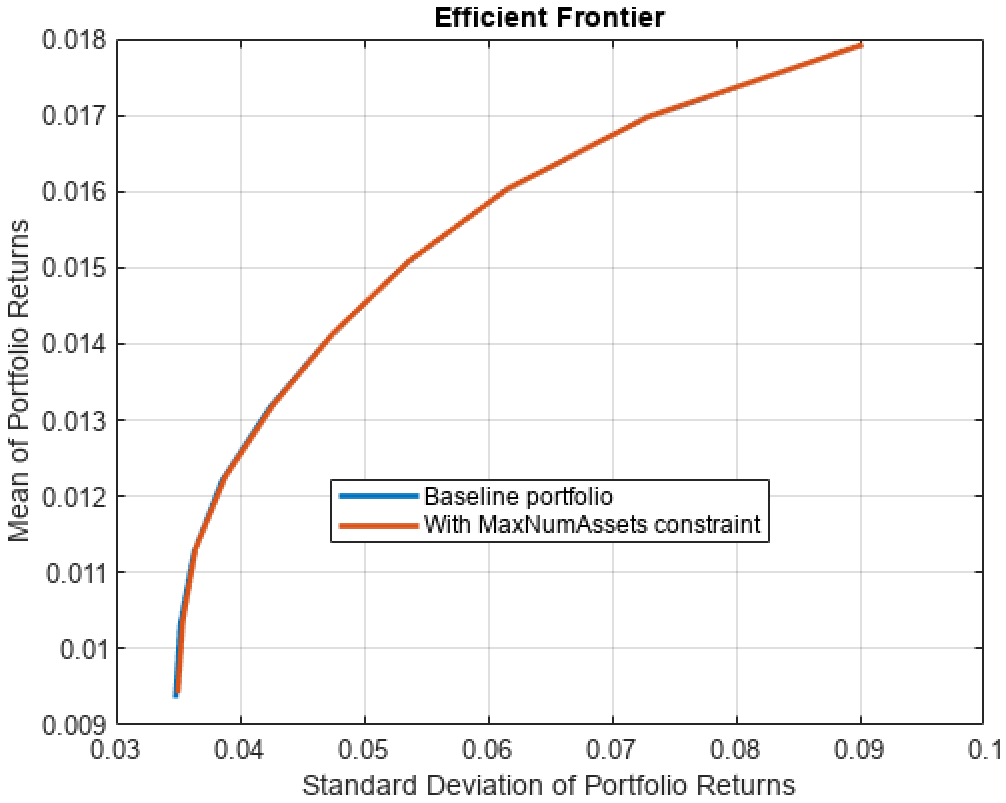


Limit the Maximum Number of Assets to Allocate

Use `setMinMaxNumAssets` to set the maximum number of allocated assets for the `Portfolio` object. Suppose that you want no more than eight assets invested in the optimal portfolio. To do this with a `Portfolio` object, use `setMinMaxNumAssets`.

```
pWithMaxNumAssets = setMinMaxNumAssets(p, [], 8);

wgt = estimateFrontier(p);
wgtWithMaxNumAssets = estimateFrontier(pWithMaxNumAssets);
plotFrontier(p, wgt); hold on;
plotFrontier(pWithMaxNumAssets, wgtWithMaxNumAssets); hold off;
legend('Baseline portfolio', 'With MaxNumAssets constraint', 'location', 'best');
```



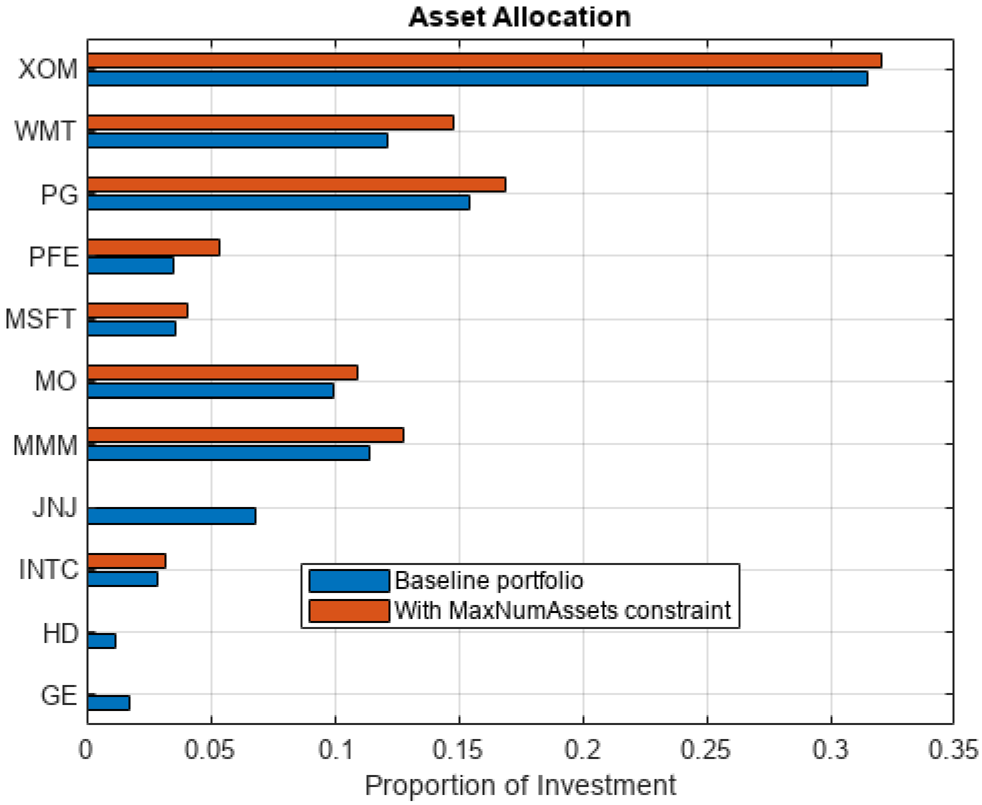
Use `estimateFrontierByReturn` to find the allocation that minimizes the risk on the frontier for the given target return.

```
pwgtWithMaxNum = estimateFrontierByReturn(pWithMaxNumAssets, targetRetn);
```

Plot the composition of the two `Portfolio` objects for the universe of 30 assets.

```
idx = (pwgt>toler) | (pwgtWithMaxNum>toler);

barh([pwgt(idx), pwgtWithMaxNum(idx)]);
grid on
xlabel('Proportion of Investment')
yticks(1:sum(idx));
yticklabels(p.AssetList(idx));
title('Asset Allocation');
legend('Baseline portfolio', 'With MaxNumAssets constraint', 'location', 'best');
```



```
sum(abs(pwgt)>toler)
```

```
ans = 11
```

Count the total number of allocated assets to verify that only eight assets at most are allocated.

```
sum(abs(pwgtWithMaxNum)>toler)
```

```
ans = 8
```

Limit the Minimum and Maximum Number of Assets to Allocate

Suppose that you want to set both the lower and upper bounds for the number of assets to allocate in a portfolio, given the universe of assets. Use `setBounds` to specify the allowed number of assets to allocate as from 5 through 10, and the allocated weight as no less than 5%.

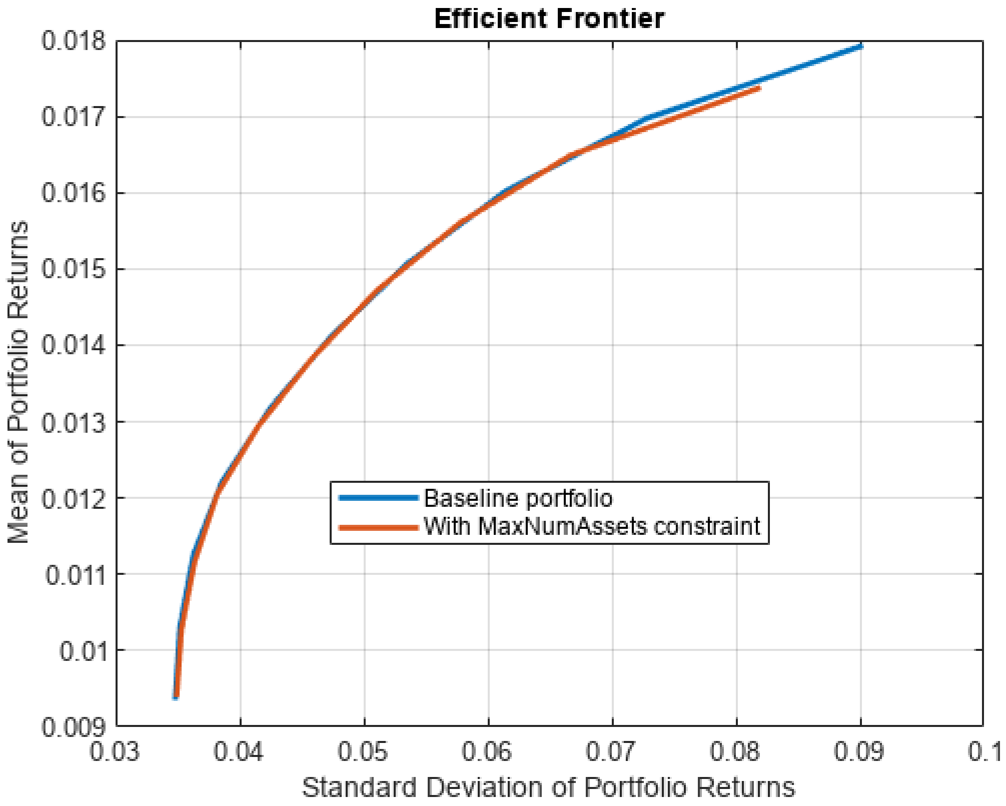
```
p1 = setMinMaxNumAssets(p, 5, 10);
p1 = setBounds(p1, 0.05, 'BoundType', 'conditional');
```

If an asset is allocated, it is necessary to clearly define the minimum weight requirement for that asset. This is done using `setBounds` with a `'Conditional'` `BoundType`. Otherwise, the optimizer cannot evaluate which assets are allocated and cannot formulate the `MinNumAssets` constraint. For more details, see “Conditional Bounds with LowerBound Defined as Empty or Zero” on page 4-140.

Plot the efficient frontier to compare this portfolio to the baseline portfolio, which has only default constraints.

```
wgt = estimateFrontier(p);
wgt1 = estimateFrontier(p1);
```

```
plotFrontier(p, wgt); hold on;
plotFrontier(p1, wgt1); hold off;
legend('Baseline portfolio', 'With MaxNumAssets constraint', 'location', 'best');
```



Asset Allocation for an Equal-Weighted Portfolio

Create an equal-weighted portfolio using both `setBounds` and `setMinMaxNumAssets` functions.

```
numAssetsAllocated = 8;
weight= 1/numAssetsAllocated;
p2 = setBounds(p, weight, weight, 'BoundType', 'conditional');
p2 = setMinMaxNumAssets(p2, numAssetsAllocated, numAssetsAllocated);
```

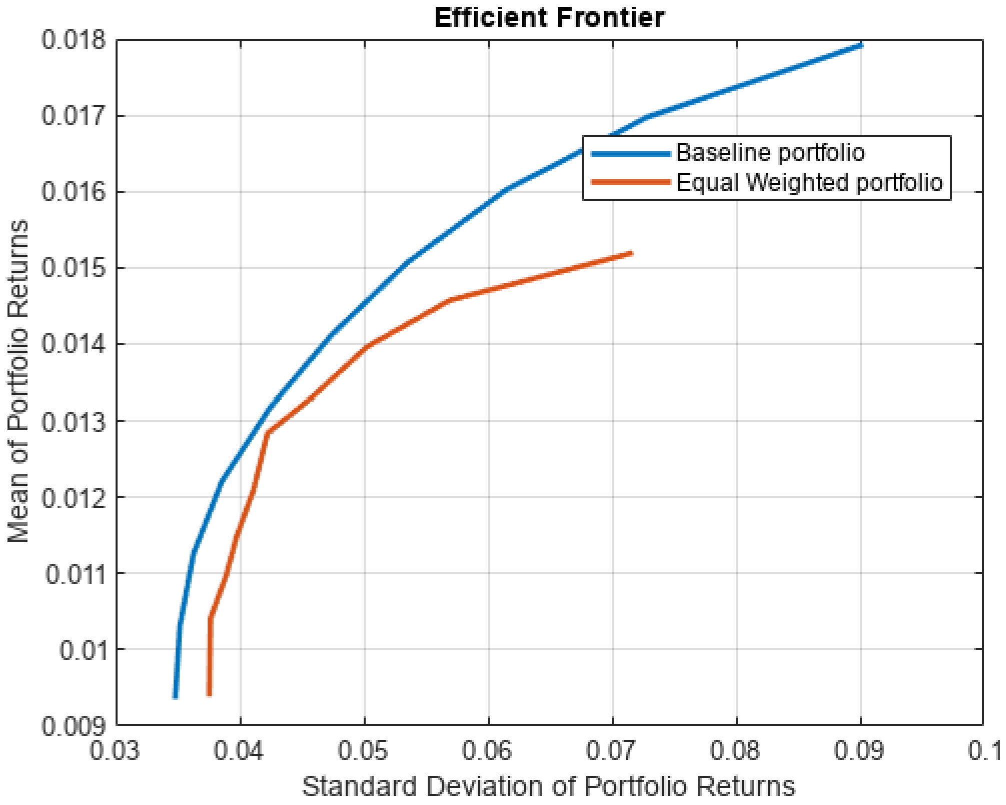
When any one, or any combination of `'Conditional'` `BoundType`, `MinNumAssets`, or `MaxNumAssets` are active, the optimization problem is formulated as a mixed integer nonlinear programming (MINLP) problem. The `Portfolio` class automatically constructs the MINLP problem based on the specified constraints.

When working with a `Portfolio` object, you can select one of three solvers using the `setSolverMINLP` function. In this example, instead of using default MINLP solver options, customize the solver options to help with a convergence issue. Use a large number (`50`) for `'MaxIterationsInactiveCut'` with `setSolverMINLP`, instead of the default value of `30` for '`MaxIterationsInactiveCut'`. The value `50` works well in finding the efficient frontier of optimal asset allocation.

```
p2 = setSolverMINLP(p2, 'OuterApproximation', 'MaxIterationsInactiveCut', 50);
```

Plot the efficient frontiers for the baseline and equal-weighted portfolios.

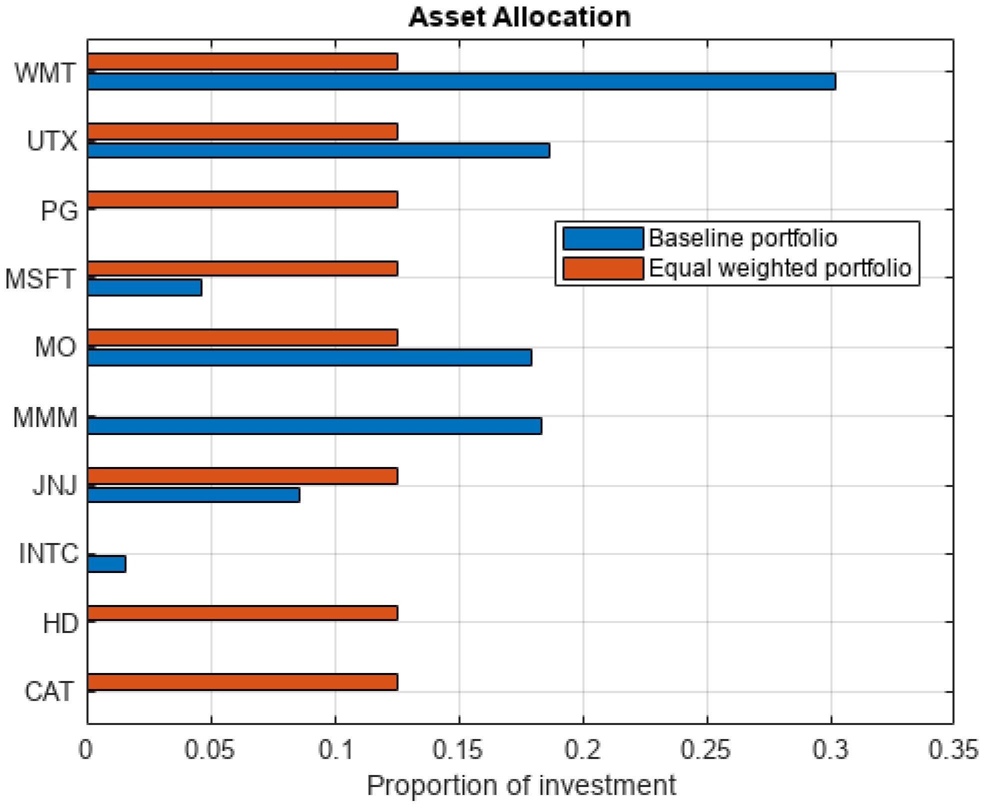
```
wgt = estimateFrontier(p);
wgt2 = estimateFrontier(p2);
plotFrontier(p, wgt); hold on;
plotFrontier(p2, wgt2); hold off;
legend('Baseline portfolio', 'Equal Weighted portfolio', 'location', 'best');
```



Use `estimateFrontierByRisk` to optimize for a specific risk level, in this case `.05`, to determine what allocation maximizes the portfolio return.

```
targetRisk = 0.05;
pwgt = estimateFrontierByRisk(p, targetRisk);
pwgt2 = estimateFrontierByRisk(p2, targetRisk);

idx = (pwgt>toler) | (pwgt2>toler);
barh([pwgt(idx), pwgt2(idx)]);
grid on
xlabel('Proportion of investment')
yticks(1:sum(idx));
yticklabels(p.AssetList(idx));
title('Asset Allocation');
legend('Baseline portfolio', 'Equal weighted portfolio', 'location', 'best');
```



Use 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints with Other Constraints

You can define other constraints for a Portfolio object using the set functions. These other constraints for a Portfolio object, such as group, linear inequality, turnover, and tracking error can be used together with the 'Conditional' BoundType, 'MinNumAssets', and 'MaxNumAssets' constraints. For example, specify a tracking error constraint using setTrackingError.

```
ii = [15, 16, 20, 21, 23, 25, 27, 29, 30];    % indexes of assets to include in tracking portfoli
trackingPort(ii) = 1/numel(ii);
q = setTrackingError(p, 0.5, trackingPort);
```

Then use setMinMaxNumAssets to add a constraint to limit maximum number of assets to invest.

```
q = setMinMaxNumAssets(q, [], 8);
```

On top of these previously specified constraints, use setBounds to add a constraint to limit the weight for the allocated assets. You can use constraints with mixed BoundType values, where 'Simple' means lb ≤ x_i ≤ ub and 'Conditional' means x_i = 0 or lb ≤ x_i ≤ ub.

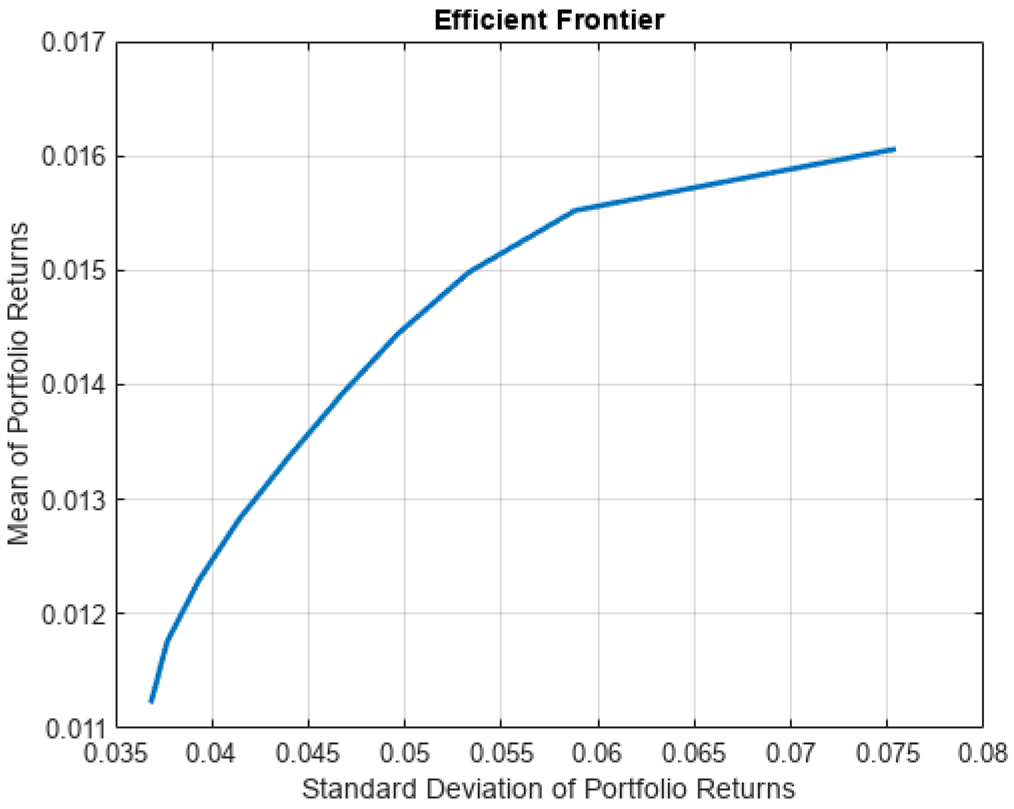
Allow the assets in trackingPort to have the BoundType value 'Conditional' in the optimum allocation.

```
lb = zeros(q.NumAssets, 1);
ub = zeros(q.NumAssets, 1)*0.5;
lb(ii) = 0.1;
ub(ii) = 0.3;
```

```
boundType = repmat("simple",q.NumAssets,1);
boundType(ii) = "conditional";
q = setBounds(q, lb, ub, 'BoundType',boundType);
```

Plot the efficient frontier:

```
plotFrontier(q);
```



Use `estimateFrontierByReturn` to find the allocation that minimizes the risk for a given return at `0.125`.

```
targetRetn = 0.0125;
pwgt = estimateFrontierByReturn(q, targetRetn);
```

Show the allocation of assets by weight.

```
idx = abs(pwgt)>eps;
assetnames = q.AssetList';
Asset = assetnames(idx);
Weight = pwgt(idx);
resultAlloc = table(Asset, Weight)
```

```
resultAlloc=7×2 table
      Asset       Weight
    _________    _______

    {'JNJ' }         0.1
    {'MMM' }     0.19503
    {'MO'  }     0.1485
    {'MSFT'}        0.1
    {'PG'  }        0.1
    {'WMT' }     0.2212
    {'XOM' }    0.13527
```

Portfolio Optimization Against a Benchmark

This example shows how to perform portfolio optimization using the `Portfolio` object in Financial Toolbox™.

This example, in particular, demonstrates optimizing a portfolio to maximize the information ratio relative to a market benchmark. Specifically, financial data contained in a `table` is read into MATLAB® and visualizations (at both daily and annual levels) are performed. A `Portfolio` object is created with the market data using an active daily return for each asset. Using functions supporting a `Portfolio` object, the efficient frontier is calculated directly and a customized optimization problem is solved to find the asset allocation with the maximized information ratio.

The solution is an optimization of a portfolio of stocks that maximizes the information ratio relative to the DJI market benchmark.

Import Historical Data Using MATLAB®

Import historical prices for the asset universe and the Dow Jones Industrial Average (DJI) market benchmark. The data is imported into a `table` from a Microsoft® Excel® spreadsheet using the MATLAB® `readtable` function.

```
data = readtable('dowPortfolio.xlsx');
head(data, 10)
```

```
       Dates        DJI      AA       AIG      AXP      BA       C        CAT      DD       DIS
    ___________    _____    _____    _____    _____    _____    _____    _____    _____    _____

    03-Jan-2006    10847    28.72    68.41    51.53    68.63    45.26    55.86    40.68    24.18

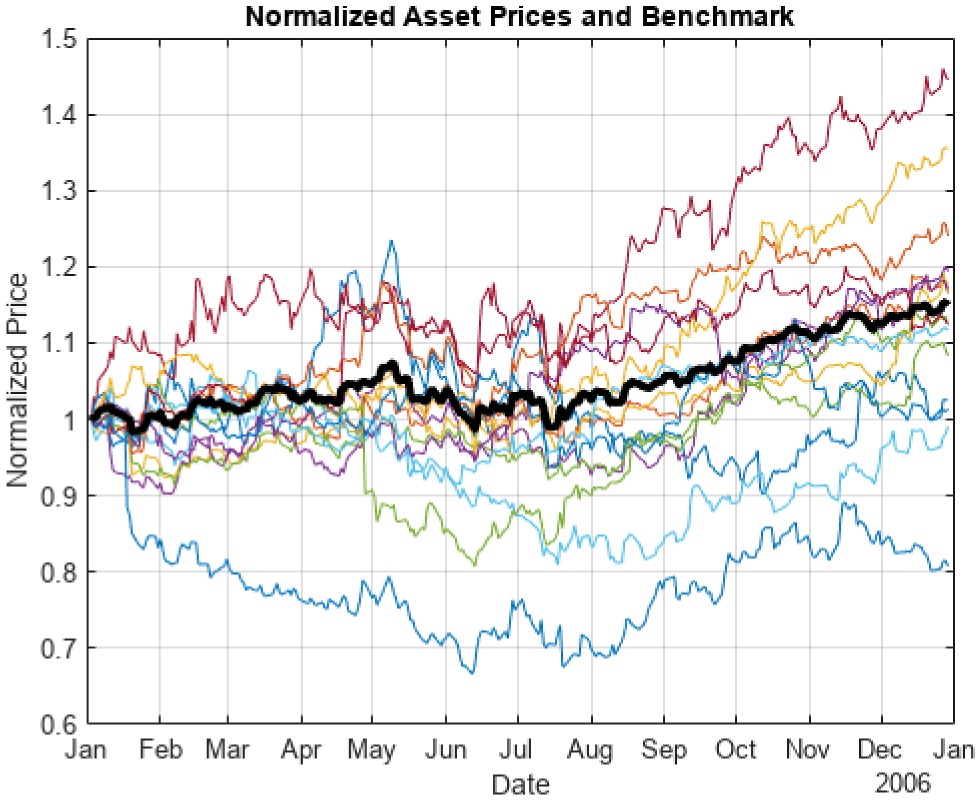
    10-Jan-2006    11012    28.44    69.18    52.88    67.33    44.57    59.25     40.2    25.09
    11-Jan-2006    11043    28.05     69.6    52.59     68.3    44.98    59.28    38.87    25.33
    12-Jan-2006    10962    27.68    69.04     52.6     67.9    45.02    60.13    38.02    25.41
    13-Jan-2006    10960     27.81     68.84      52.5      67.7     44.92     60.24     37.86     25.47
    17-Jan-2006    10896     27.97     67.84     52.03     66.93     44.47     60.85     37.75     25.15
```

Separate the asset names, asset prices, and DJI benchmark prices from the table. The visualization shows the evolution of all the asset prices normalized to start at unity, that is accumulative returns.

```
benchPrice = data.DJI;
assetNames = data.Properties.VariableNames(3:2:end); % using half of the assets for display
assetPrice = data(:,assetNames).Variables;

assetP = assetPrice./assetPrice(1, :);
benchmarkP = benchPrice / benchPrice(1);

figure;
plot(data.Dates,assetP);
hold on;
plot(data.Dates,benchmarkP,'LineWidth',3,'Color','k');
hold off;
xlabel('Date');
ylabel('Normalized Price');
title('Normalized Asset Prices and Benchmark');
grid on;
```



The bold line indicates the DJIA market benchmark.

Compute Returns and Risk-Adjusted Returns

Calculate the return series from the price series and compute the asset moments (historical returns and standard deviations). The visualization shows a scatter plot of the risk-return characteristics of all the assets and the DJI market benchmark.

```
benchReturn = tick2ret(benchPrice);
assetReturn = tick2ret(assetPrice);

benchRetn = mean(benchReturn);
benchRisk =  std(benchReturn);
assetRetn = mean(assetReturn);
assetRisk =  std(assetReturn);
```

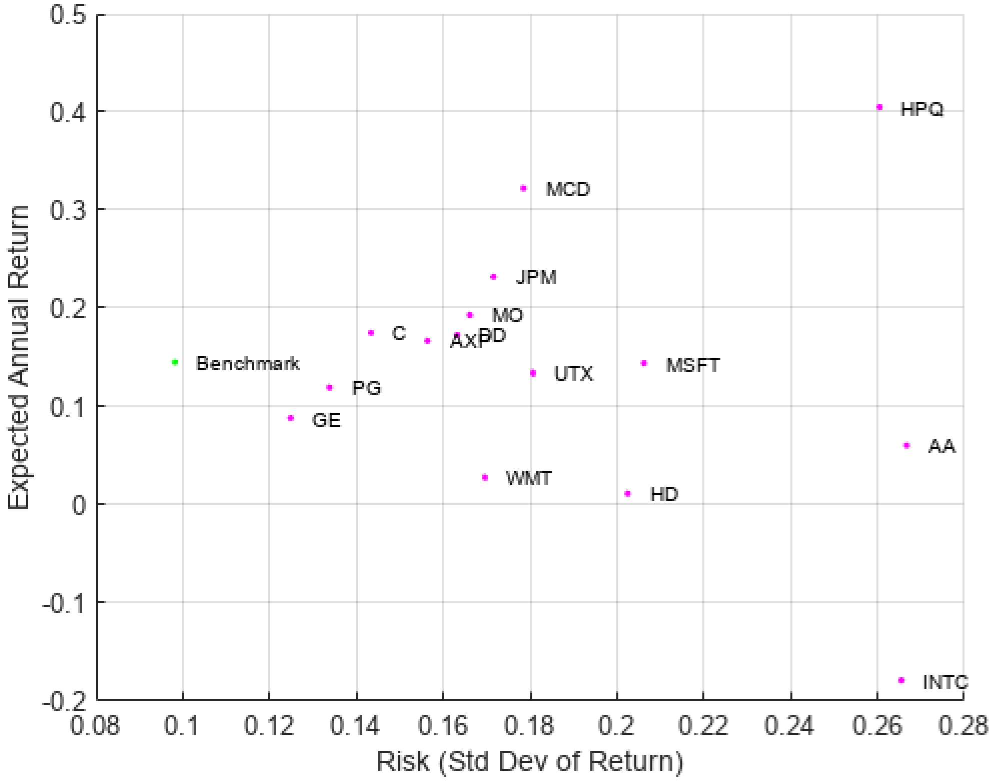
Calculate historical statistics and plot the annual risk-return. Note that the plot is at the annual level, therefore scaling is performed on the daily returns.

```
scale = 252;

assetRiskR = sqrt(scale) * assetRisk;
benchRiskR = sqrt(scale) * benchRisk;
assetReturnR = scale * assetRetn;
benchReturnR = scale * benchRetn;

figure;
scatter(assetRiskR, assetReturnR, 6, 'm', 'Filled');
hold on
scatter(benchRiskR, benchReturnR, 6, 'g', 'Filled');
for k = 1:length(assetNames)
    text(assetRiskR(k) + 0.005, assetReturnR(k), assetNames{k}, 'FontSize', 8);
end
text(benchRiskR + 0.005, benchReturnR, 'Benchmark', 'Fontsize', 8);
hold off;

xlabel('Risk (Std Dev of Return)');
ylabel('Expected Annual Return');
grid on;
```



Set Up a Portfolio Optimization

Set up a portfolio optimization problem by populating the object using `Portfolio`. Because the goal is to optimize portfolio allocation against a benchmark, the active return of each asset is computed and used in the `Portfolio` object. In this example, the expected returns and covariances of the assets in the portfolio are set to their historical values.

```
p = Portfolio('AssetList',assetNames);
```

Set up default portfolio constraints (all weights sum to 1, no shorting, and 100% investment in risky assets).

```
p = setDefaultConstraints(p);
```

Add asset returns and covariance to the `Portfolio` object.

```
activReturn = assetReturn - benchReturn;
pAct = estimateAssetMoments(p,activReturn,'missingdata',false)
```

```
pAct = 
  Portfolio with properties:

Compute the Efficient Frontier Using the Portfolio Object

Compute the mean-variance efficient frontier of 20 optimal portfolios. Visualize the frontier over the risk-return characteristics of the individual assets. Furthermore, calculate and visualize the information ratio for each portfolio along the frontier.

```
pwgtAct = estimateFrontier(pAct, 20); % Estimate the weights.
[portRiskAct, portRetnAct] = estimatePortMoments(pAct, pwgtAct); % Get the risk and return.

% Extract the asset moments and names.
[assetActRetnDaily, assetActCovarDaily] = getAssetMoments(pAct);
assetActRiskDaily = sqrt(diag(assetActCovarDaily));
assetNames = pAct.AssetList;

% Rescale.
assetActRiskAnnual = sqrt(scale) * assetActRiskDaily;
portRiskAnnual  = sqrt(scale) *  portRiskAct;
assetActRetnAnnual = scale * assetActRetnDaily;
portRetnAnnual = scale *  portRetnAct;

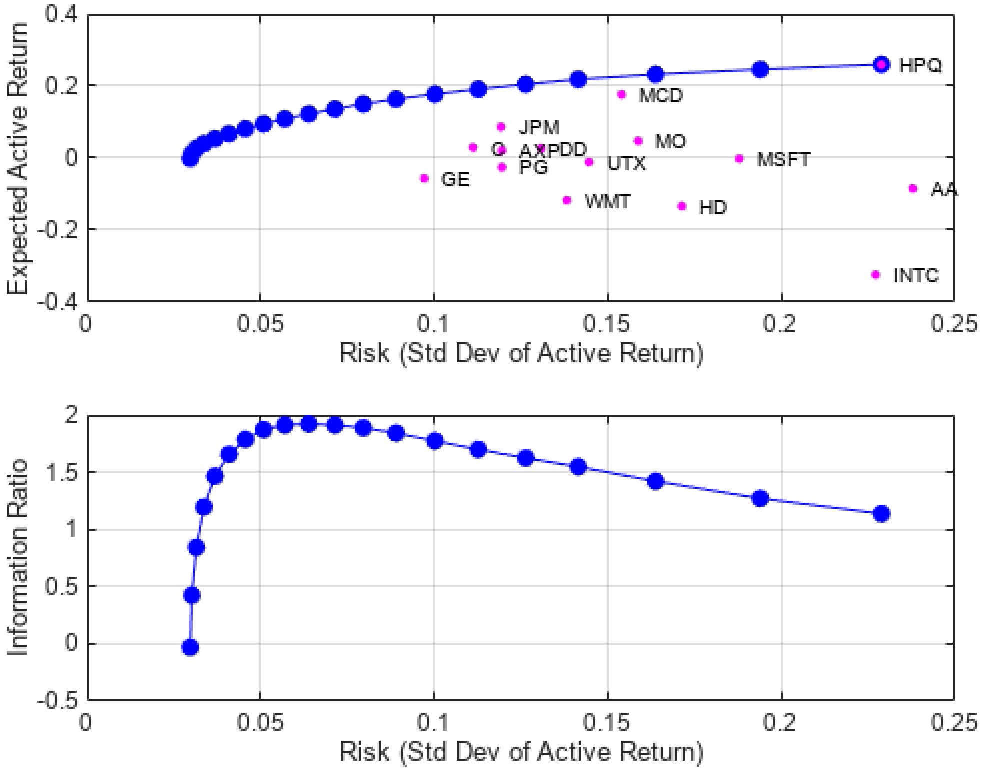
figure;
subplot(2,1,1);
plot(portRiskAnnual, portRetnAnnual, 'bo-', 'MarkerFaceColor', 'b');
hold on;

scatter(assetActRiskAnnual, assetActRetnAnnual, 12, 'm', 'Filled');
hold on;
for k = 1:length(assetNames)
    text(assetActRiskAnnual(k) + 0.005, assetActRetnAnnual(k), assetNames{k}, 'FontSize', 8);
end
```

```
hold off;

xlabel('Risk (Std Dev of Active Return)');
ylabel('Expected Active Return');
grid on;

subplot(2,1,2);
plot(portRiskAnnual, portRetnAnnual./portRiskAnnual, 'bo-', 'MarkerFaceColor', 'b');
xlabel('Risk (Std Dev of Active Return)');
ylabel('Information Ratio');
grid on;
```



Perform Information Ratio Maximization

Find the portfolio along the frontier with the maximum information ratio. The information ratio is the ratio of relative return to relative risk (also known as the "tracking error"). Whereas the Sharpe ratio looks at returns relative to a riskless asset, the information ratio is based on returns relative to a risky benchmark, in this case the DJI benchmark. You can compute the information ratio using `estimateCustomObjectivePortfolio`.

```
infoRatio = @(x) (pAct.AssetMean'*x)/sqrt(x'*pAct.AssetCovar*x);
optWts = estimateCustomObjectivePortfolio(pAct,infoRatio,...
    ObjectiveSense="maximize");
```

Get the information ratio, risk, and return for the optimal portfolio.

```
optInfoRatio = infoRatio(optWts);
[optPortRisk,optPortRetn] = estimatePortMoments(pAct,optWts)
```

```
optPortRisk = 0.0040

optPortRetn = 4.8166e-04
```

Plot the Optimal Portfolio

Verify that the portfolio found is indeed the maximum information-ratio portfolio.

```
% Rescale.
optPortRiskAnnual = sqrt(scale) * optPortRisk;
optPortReturnAnnual = scale * optPortRetn;

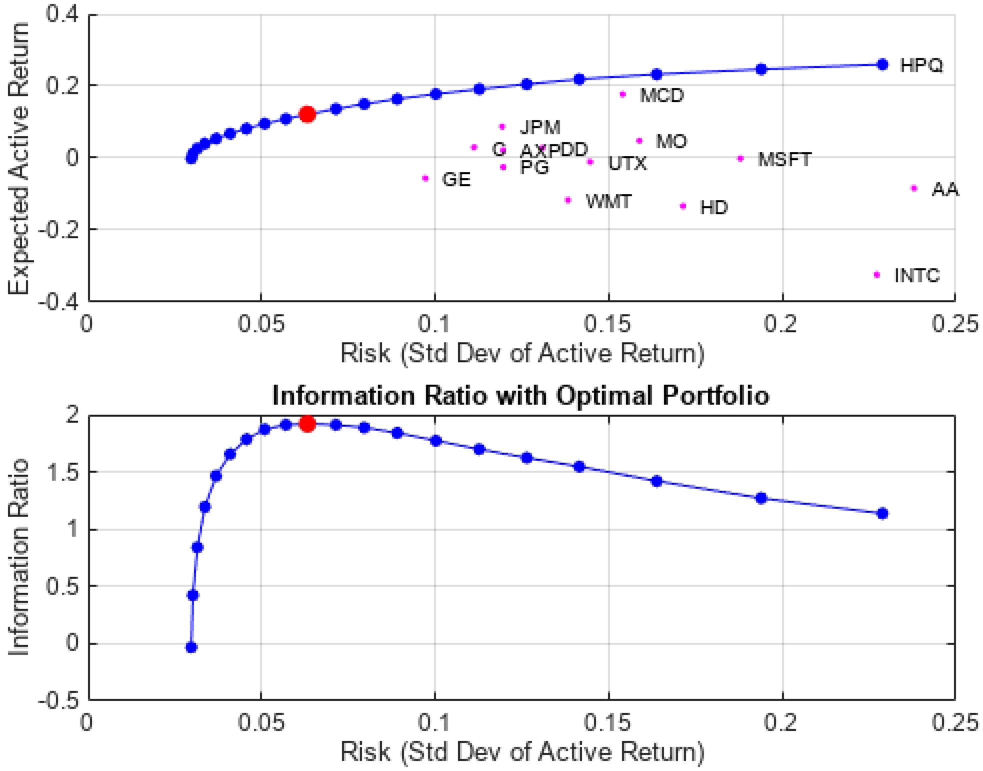
figure;
subplot(2,1,1);

scatter(assetActRiskAnnual, assetActRetnAnnual, 6, 'm', 'Filled');
hold on
for k = 1:length(assetNames)
    text(assetActRiskAnnual(k) + 0.005,assetActRetnAnnual(k),assetNames{k},'FontSize',8);
end
plot(portRiskAnnual,portRetnAnnual,'bo-','MarkerSize',4,'MarkerFaceColor','b');
plot(optPortRiskAnnual,optPortReturnAnnual,'ro-','MarkerFaceColor','r');
hold off;

xlabel('Risk (Std Dev of Active Return)');
ylabel('Expected Active Return');
grid on;

subplot(2,1,2);
plot(portRiskAnnual,portRetnAnnual./portRiskAnnual,'bo-','MarkerSize',4,'MarkerFaceColor','b');
hold on
plot(optPortRiskAnnual,optPortReturnAnnual./optPortRiskAnnual,'ro-','MarkerFaceColor','r');
hold off;

xlabel('Risk (Std Dev of Active Return)');
ylabel('Information Ratio');
title('Information Ratio with Optimal Portfolio');
grid on;
```



Display the Portfolio Optimization Solution

Display the portfolio optimization solution.

```
assetIndx = optWts > .001;
results = table(assetNames(assetIndx)', optWts(assetIndx)*100, 'VariableNames',{'Asset', 'Weight
disp('Maximum Information Ratio Portfolio:')

Portfolio Analysis with Turnover Constraints

This example shows how to analyze the characteristics of a portfolio of equities, and then compare them with the efficient frontier. This example seeks to answer the question of how much closer can you get to the efficient frontier by only risking a certain percentage of a portfolio to avoid transaction costs.

Import Data for the Portfolio Holdings

Load information on the current portfolio holdings from a Microsoft® Excel® spreadsheet into a table using the MATLAB® `readtable` function.

```
AssetHoldingData = readtable('portfolio.xls');
% Create a normalized current holdings vector that shows the respective
% investments as a percentage of total capital:
W = AssetHoldingData.Value/sum(AssetHoldingData.Value);
```

Import Market Data for Share Prices

Import the market data from a data source supported by Datafeed Toolbox™ that constitutes three years of closing prices for the stocks listed in the portfolio.

```
load SharePrices
```

Create a `Portfolio` Object

The `Portfolio` class enables you to use the imported data to create a `Portfolio` object. The `estimateAssetMoments` function for the `Portfolio` object enables you to set up a portfolio given only a historical price or returns series. The `estimateAssetMoments` function estimates mean and covariance of asset returns from data even if there is missing data.

```
P = Portfolio('Name', 'Sample Turnover Constraint Portfolio');
P = estimateAssetMoments(P,data,'DataFormat','Prices');

% You can assign text names to each asset in the portfolio.
P = setAssetList(P,AssetHoldingData.Symbol);

% Provide the current holdings.
P = setInitPort(P,W);
```

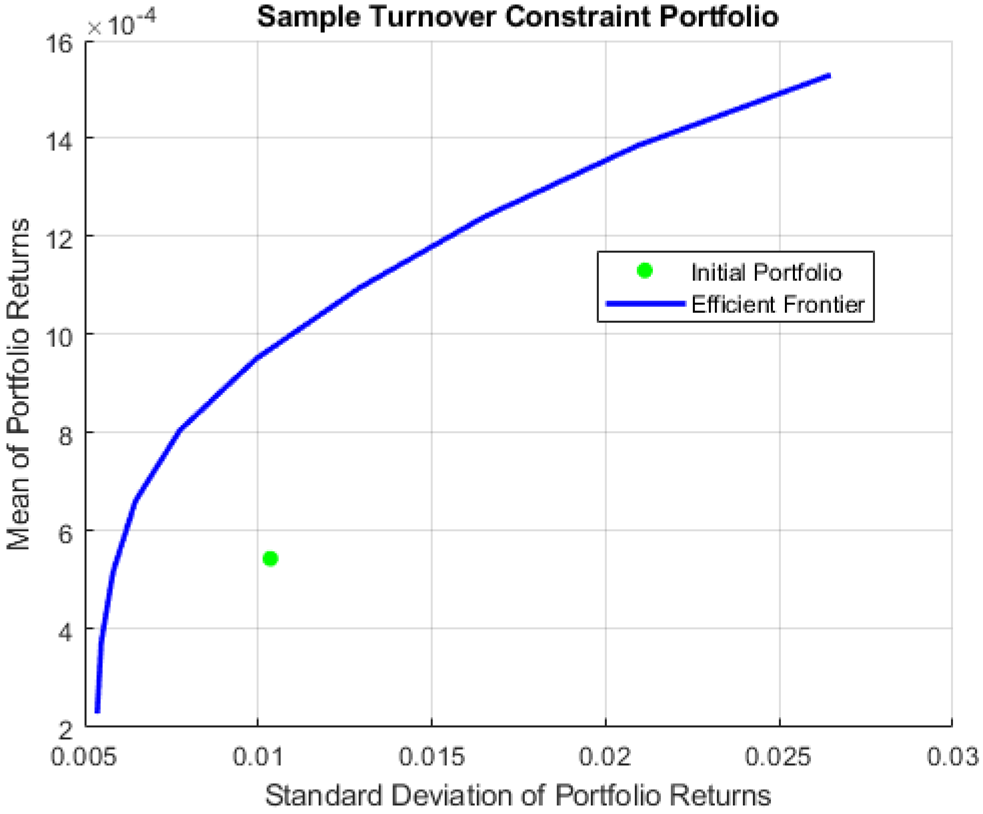
Perform Portfolio Optimization with No Turnover Constraint

The `Portfolio` object can optimize the holdings given any number of constraints. This example demonstrates using a simple, default constraint, that is, long positions only and 100% invested in assets.

```
P = setDefaultConstraints(P);
```

Visualize this efficient frontier with the `plotFrontier` function.

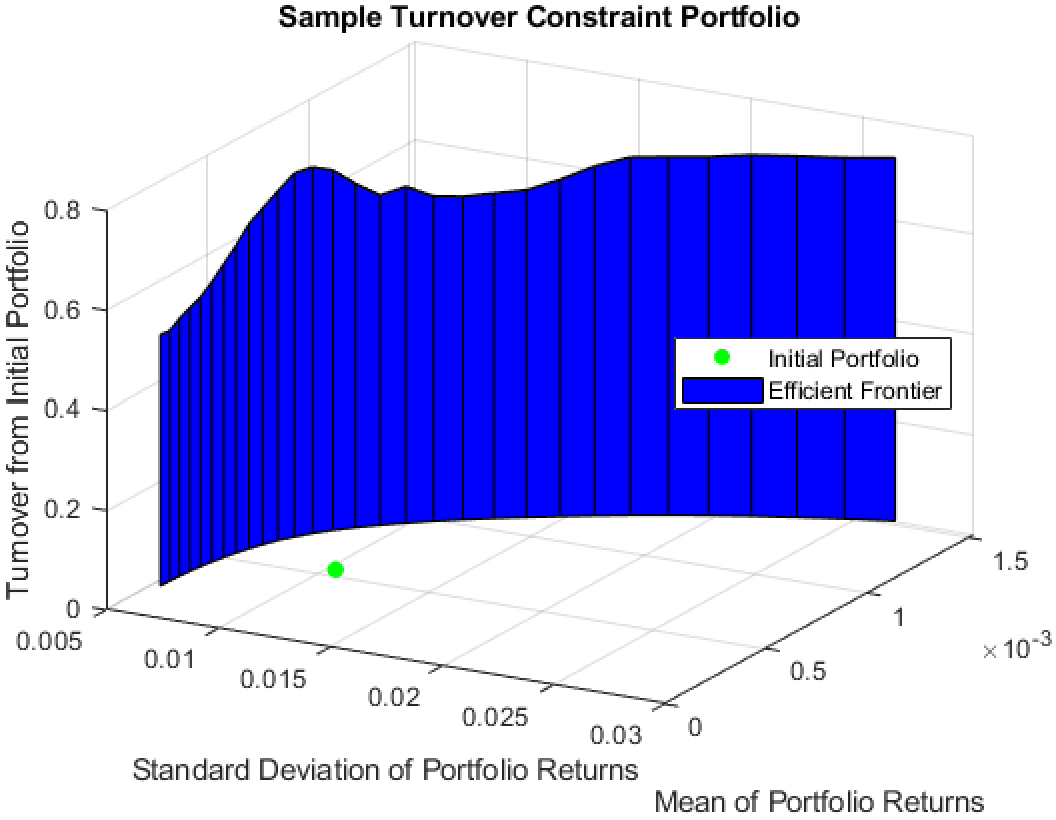
```
plotFrontier(P)
```



Visualize the Transaction Costs and Turnover

Due to transaction costs, it can be expensive to shift holdings from the current portfolio to a portfolio along this efficient frontier. The following custom plot shows that you must turn over between 50% and 75% of the holdings to get to this frontier.

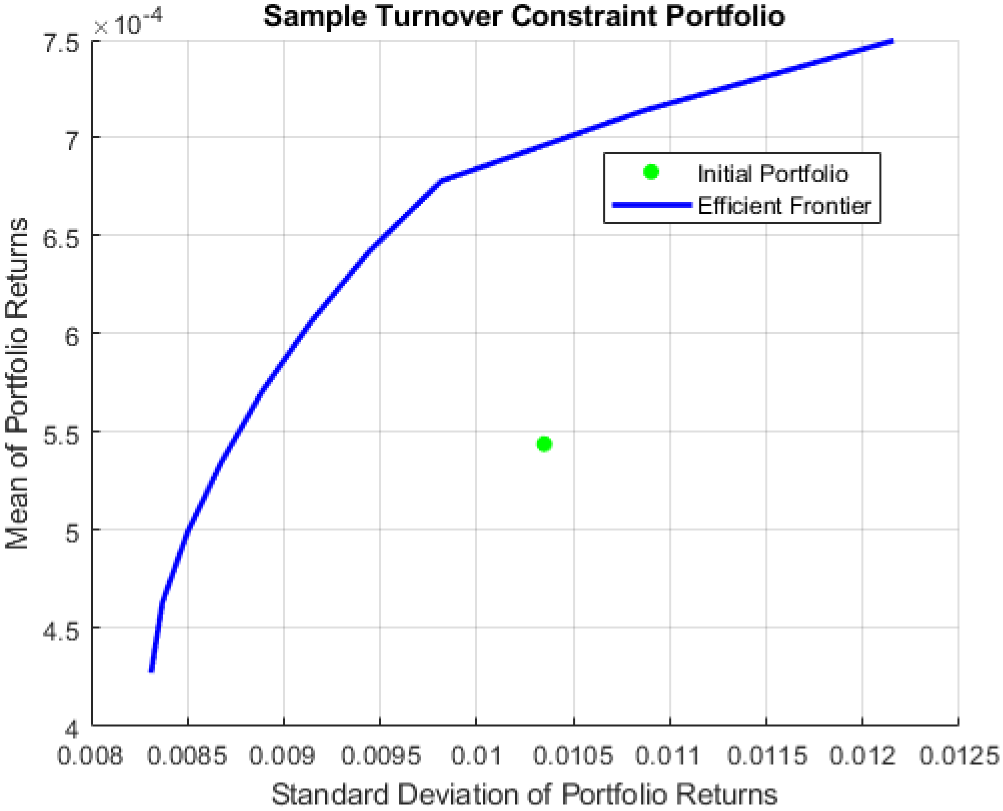
```
TurnoverPlot(P)
```



Perform Portfolio Optimization with a Turnover Constraint

How close can you get to this efficient frontier by only trading some of the portfolio? Assume that you want to trade only a certain percentage of the portfolio to avoid too much turnover in your holdings. This requirement imposes some nonlinear constraints on the problem and gives a problem with multiple local minima. Even so, the `Portfolio` object solves the problem, and you specify the turnover constraint using the `setTurnover` function.

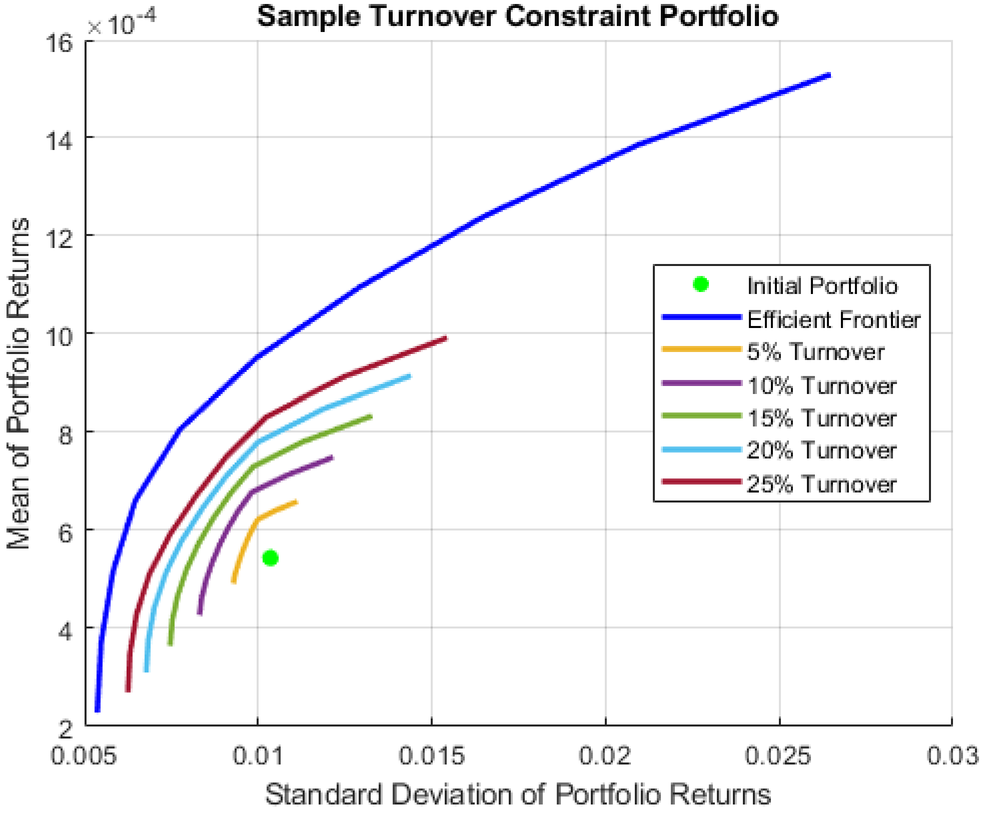
```
P10 = setTurnover(P,0.10);
plotFrontier(P10)
```



Visualize the Efficient Frontier at Different Turnover Thresholds

This efficient frontier is much closer to the initial portfolio than the starting efficient frontier without turnover constraints. To visualize this difference, use the custom function `TurnoverConstraintPlot` to visualize multiple constrained efficient frontiers at different turnover thresholds.

```
turnovers = 0.05:0.05:0.25;
TurnoverConstraintPlot(P,turnovers)
```



The `Portfolio` object is a powerful and efficient tool for performing various portfolio analysis tasks. In addition to turnover constraints, you can also optimize a `Portfolio` object for transaction costs for buying and selling portfolio assets using the `setCosts` function.

Leverage in Portfolio Optimization with a Risk-Free Asset

This example shows how to use the `setBudget` function for the `Portfolio` class to define the limits on the `sum(AssetWeight_i)` in risky assets.

If the `sum(AssetWeight_i)` is less than `1`, the extra cash is invested in a risk-free asset. If the `sum(AssetWeight_i)` is larger than `1`, meaning that total risky asset investment is larger than initial available cash, the risk-free asset is shorted (borrowed) to fund the extra investment in a risky asset. The cost associated with borrowing a risk-free asset is automatically captured in the mean-variance optimization model for the `Portfolio` class. Therefore, you can use the `setBudget` function directly to control the level of leverage of cash for the portfolio.

Portfolio Without Leverage

Consider the following example that does not leverage a risk-free asset.

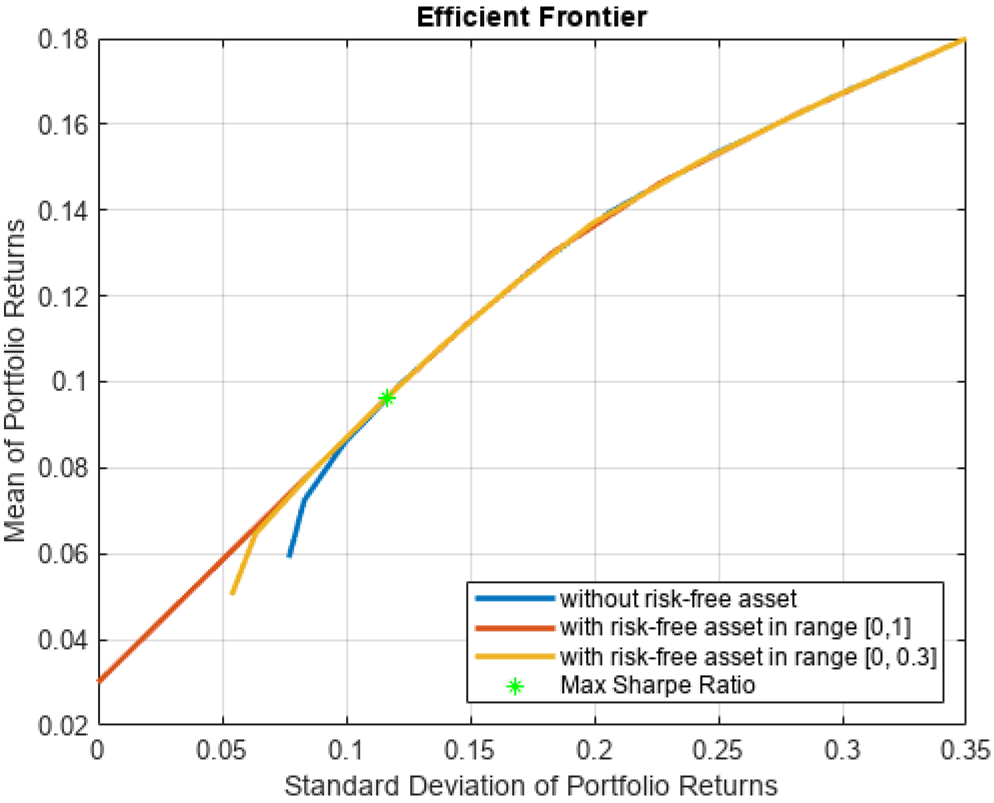
```
assetsMean = [ 0.05; 0.1; 0.12; 0.18; ];
assetCovar = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225];
riskFreeRate = 0.03;

% create a portfolio and define risk-free rate.
p = Portfolio('RiskFreeRate', riskFreeRate, 'assetmean', assetsMean, 'assetcovar', assetCovar, 'T
```

Create multiple portfolios with different budgets on risky assets to control the limits for investing in a risk-free asset.

```
p = setBudget(p, 1, 1);     % allow 0% risk free asset allocation, meaning fully invested in risk
p1 = setBudget(p, 0, 1);    % allow 0% to 100% risk free asset allocation
p2 = setBudget(p, 0.7, 1);  % allow 0% to 30% risk free asset allocation
[risk, retn] = estimatePortMoments(p, estimateMaxSharpeRatio(p));

figure;
plotFrontier(p); hold on;
plotFrontier(p1);hold on;
plotFrontier(p2); hold on;
plot(risk, retn, 'g*'); hold off;
legend('without risk-free asset', ...
    'with risk-free asset in range [0,1]', ...
    'with risk-free asset in range [0, 0.3]', ...
    'Max Sharpe Ratio', 'location','southeast');
```



In the efficient frontiers in the above figure, the lower-left part of the red efficient frontier line for the portfolio with a risk-free asset is in range `[0,1]` and is actually the capital allocation line (CAL). The slope of this line is the maximum Sharpe ratio of the portfolio, which demonstrates how return is best awarded by taking extra risk. The upper right of the red efficient frontier line is the same as a fully invested portfolio (blue line). Once the portfolio crosses the Sharpe ratio point, the portfolio is fully invested and there is no more cash available to allow high risk-awarded returns following the straight CAL. However, if borrowing of a risk-free asset is allowed, you can effectively use the funds from the borrowing of a risk-free asset to invest in more risky assets, as demonstrated in the "Portfolio with Leverage" section.

Portfolio with Leverage

To fund investments in risky assets, consider using leverage by borrowing a risk-free asset. The `Portfolio` class enables you to use leverage in asset allocation when a risk-free asset is available in the portfolio.

First, check if the `RiskFreeRate` property for the `Portfolio` object is nonzero.

```
p
```

```
p = 
  Portfolio with properties:

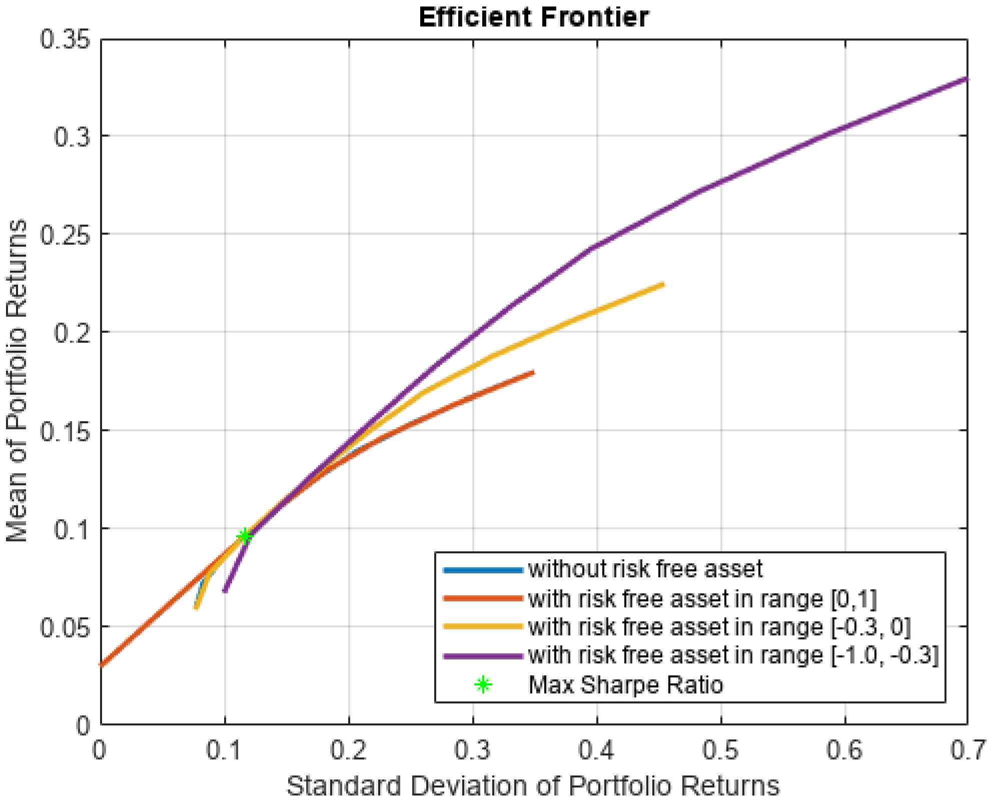
          BuyCost: []
         SellCost: []
     RiskFreeRate: 0.0300
        AssetMean: [4x1 double]
```

```
       AssetCovar: [4x4 double]
    TrackingError: []
     TrackingPort: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
             Name: []
        NumAssets: 4
        AssetList: []
         InitPort: []
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []
       LowerBound: [4x1 double]
       UpperBound: []
      LowerBudget: 1
      UpperBudget: 1
      GroupMatrix: []
       LowerGroup: []
       UpperGroup: []
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
     MinNumAssets: []
     MaxNumAssets: []
        BoundType: []
```

In this `Portfolio` object, the lower and upper budgets are both `1`. Limits must be set on the total investment in risky assets. Borrowing a risk-free asset funds the extra investment in risky assets. Use `setBudget` to set the lower and upper bounds to set the limits of the borrowed risk-free assets.

```
p = setBudget(p, 1, 1);      % allow 0% risk free asset allocation, meaning fully invested in ris
p3 = setBudget(p, 1, 1.3);   % allow 0% risk free asset allocation, and allow borrowing of risk
p4 = setBudget(p, 1.3, 2);   % allow 0% risk free asset allocation, and allow borrowing of risk
[risk, retn] = estimatePortMoments(p, estimateMaxSharpeRatio(p));

figure
plotFrontier(p); hold on;
plotFrontier(p1);hold on;
plotFrontier(p3); hold on;
plotFrontier(p4); hold on;
plot(risk, retn, 'g*'); hold off;
legend('without risk free asset',  ...
    'with risk free asset in range [0,1]', ...
    'with risk free asset in range [-0.3, 0]', ...
    'with risk free asset in range [-1.0, -0.3]',...
    'Max Sharpe Ratio', 'location','southeast');
```



In this figure, the upper-right parts of both the orange and purple efficient frontiers extend from the CAL (lower-left red line), because of the leverage of a risk-free asset. The same levels of risk-awarded returns are obtained. Once the portfolio exhausts the maximum allowed leverage, the efficient frontier starts to fall below the CAL again, resulting in portfolios with lower Sharpe ratios.

Black-Litterman Portfolio Optimization Using Financial Toolbox™

This example shows the workflow to implement the Black-Litterman model with the `Portfolio` class in Financial Toolbox™. The Black-Litterman model is an asset allocation approach that allows investment analysts to incorporate subjective views (based on investment analyst estimates) into market equilibrium returns. By blending analyst views and equilibrium returns instead of relying only on historical asset returns, the Black-Litterman model provides a systematic way to estimate the mean and covariance of asset returns.

	Mean-Variance Optimization	Black-Litterman Approach
Asset Mean	Mean of historical asset returns	Blended asset returns estimated from analyst views and equilibrium returns
Asset Covariance	Covariance of historical asset returns	Covariance of historical asset returns + Estimation uncertainty of the blended asset returns

In the Black-Litterman model, the blended expected return is $\bar{\mu} = \left[P^T\Omega^{-1}P + C^{-1}\right]^{-1}\left[P^T\Omega^{-1}q + C^{-1}\pi\right]$ and the estimation uncertainty is $\mathrm{cov}(\mu) = \left[P^T\Omega^{-1}P + C^{-1}\right]^{-1}$. To use the Black-Litterman model, you must prepare the inputs: P, q , Ω , π, and C. The inputs for P, q , and Ω are view-related and defined by the investment analyst. π is the equilibrium return and C is the uncertainty in prior belief. This example guides you to define these inputs and use the resulting blended returns in a portfolio optimization. For more information on the concept and derivation of the Black-Litterman model, see the Appendix section Black-Litterman Model under a Bayesian Framework on page 4-221.

Define the Universe of Assets

The `dowPortfolio.xlsx` data set includes 30 assets and one benchmark. Seven assets from this data set comprise the investment universe in this example. The risk-free rate is assumed to be zero.

```
T = readtable('dowPortfolio.xlsx');
```

Define the asset universe and extract the asset returns from the price data.

```
assetNames = ["AA", "AIG", "WMT", "MSFT", "BA", "GE", "IBM"];
benchmarkName = "DJI";
head(T(:,["Dates" benchmarkName assetNames]))
```

```
       Dates        DJI       AA       AIG      WMT      MSFT      BA       GE       IBM

    12-Jan-2006    10962    27.68    69.04    44.43    26.48     67.9    33.25    81.61
```

```
retnsT = tick2ret(T(:, 2:end));
assetRetns = retnsT(:, assetNames);
benchRetn = retnsT(:, "DJI");
numAssets = size(assetRetns, 2);
```

Specify Views of the Market

The views represent the subjective views of the investment analyst regarding future market changes, expressed as $\boldsymbol{q} = \boldsymbol{P} * \mu + \varepsilon, \;\; \varepsilon \sim N(0, \Omega), \; \Omega = \mathrm{diag}(\omega_1, \omega_2, \ldots \omega_v)$, where v is total number of views. For more information, see the Appendix section Assumptions and Views on page 4-221. With v views and k assets, P is a v-by-k matrix, $\boldsymbol{q}$ is a v-by-1 vector, and Ω is a v-by-v diagonal matrix (representing the independent uncertainty in the views). The views do not necessarily need to be independent among themselves and the structure of Ω can be chosen to account for investment analyst uncertainties in the views [4 on page 4-222]. The smaller the ω_i in Ω, the smaller the variance in the distribution of the ith view, and the stronger or more certain the investor's ith view. This example assumes three independent views.

1. AIG is going to have 5% annual return with uncertainty 1e-3. This is a weak absolute view due to its high uncertainty.
2. WMT is going to have 3% annual return with uncertainty 1e-3. This is a weak absolute view due to its high uncertainty.
3. MSFT is going to outperform IBM by 5% annual return with uncertainty 1e-5. This is a strong relative view due to its low uncertainty.

```
v = 3;  % total 3 views
P = zeros(v, numAssets);
q = zeros(v, 1);
Omega = zeros(v);

% View 1
P(1, assetNames=="AIG") = 1;
q(1) = 0.05;
Omega(1, 1) = 1e-3;

% View 2
P(2, assetNames=="WMT") = 1;
q(2) = 0.03;
Omega(2, 2) = 1e-3;

% View 3
P(3, assetNames=="MSFT") = 1;
P(3, assetNames=="IBM") = -1;
q(3) = 0.05;
Omega(3, 3) = 1e-5;
```

Visualize the three views in table form.

```
viewTable = array2table([P q diag(Omega)], 'VariableNames', [assetNames "View_Return" "View_Unce
```

```
viewTable=3×9 table
    AA    AIG    WMT    MSFT    BA    GE    IBM    View_Return    View_Uncertainty
    __    ___    ___    ____    __    __    ___    ___________    ________________

    0      1      0      0      0     0      0        0.05              0.001     
    0      0      1      0      0     0      0        0.03              0.001     
    0      0      0      1      0     0     -1        0.05              1e-05     
```

Because the returns from `dowPortfolio.xlsx` data set are daily returns and the views are on the annual returns, you must convert views to be on daily returns.

```
bizyear2bizday = 1/252;
q = q*bizyear2bizday;
Omega = Omega*bizyear2bizday;
```

Estimate the Covariance from the Historical Asset Returns

Σ is the covariance of the historical asset returns.

```
Sigma = cov(assetRetns.Variables);
```

Define the Uncertainty *C*

The Black-Litterman model makes the assumption that the structure of C is proportional to the covariance Σ. Therefore, $C = \tau\Sigma$, where τ is a small constant. A smaller τ indicates a higher confidence in the prior belief of μ. The work of He and Litterman uses a value of 0.025. Other authors suggest using $1/n$ where n is the number of data points used to generate the covariance matrix [3 on page 4-222]. This example uses $1/n$.

```
tau = 1/size(assetRetns.Variables, 1);
C = tau*Sigma;
```

Market Implied Equilibrium Return

In the absence of any views, the equilibrium returns are likely equal to the implied returns from the equilibrium portfolio holding. In practice, the applicable equilibrium portfolio holding can be any optimal portfolio that the investment analyst would use in the absence of additional views on the market, such as the portfolio benchmark, an index, or even the current portfolio [2 on page 4-222]. In this example, you use linear regression to find a market portfolio that tracks the returns of the DJI benchmark. Then, you use the market portfolio as the equilibrium portfolio and the equilibrium returns are implied from the market portfolio. The `findMarketPortfolioAndImpliedReturn` function, defined in Local Functions on page 4-220, implements the equilibrium returns. This function takes historical asset returns and benchmark returns as inputs and outputs the market portfolio and the corresponding implied returns.

```
[wtsMarket, PI] = findMarketPortfolioAndImpliedReturn(assetRetns.Variables, benchRetn.Variables)
```

Compute the Estimated Mean Return and Covariance

Use the P, q , Ω , π , and C inputs to compute the blended asset return and variance using the Black-Litterman model.

You can compute $\bar{\mu}$ and $\mathrm{cov}(\mu)$ directly by using this matrix operation:

$$\bar{\mu} = \left[P^T\Omega^{-1}P + C^{-1}\right]^{-1}\left[P^T\Omega^{-1}q + C^{-1}\pi\right], \mathrm{cov}(\mu) = \left[P^T\Omega^{-1}P + C^{-1}\right]^{-1}$$

```
mu_bl = (P'*(Omega\P) + inv(C)) \ ( C\PI + P'*(Omega\q));
cov_mu = inv(P'*(Omega\P) + inv(C));
```

Comparing the blended expected return from Black-Litterman model to the prior belief of expected return π, you find that the expected return from Black-Litterman model is indeed a mixture of both prior belief and investor views. For example, as shown in the table below, the prior belief assumes similar returns for MSFT and IBM, but in the blended expected return, MSFT has a higher return than IBM by more than 4%. This difference is due to the imposed strong view that MSFT outperforms IBM by 5%.

```
table(assetNames', PI*252, mu_bl*252, 'VariableNames', ["Asset_Name", ...
    "Prior_Belief_of_Expected_Return", "Black_Litterman_Blended_Expected_Return"])
```

```

      "IBM"                   0.14816                                0.12877                
```

Portfolio Optimization and Results

The `Portfolio` object in Financial Toolbox™ implements the Markowitz mean variance portfolio optimization framework. Using a `Portfolio` object, you can find the efficient portfolio for a given risk or return level, and you can also maximize the Sharpe ratio.

Use `estimateMaxSharpeRatio` with the `Portfolio` object to find allocations with the maximum Sharpe ratio for the following portfolios:

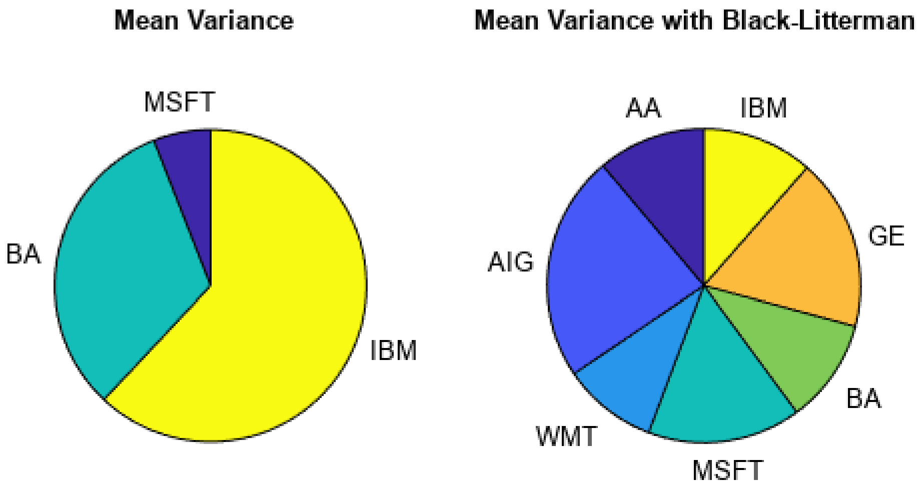
- Portfolio with asset mean and covariance from historical asset returns
- Portfolio with blended asset return and covariance from the Black-Litterman model

```
port = Portfolio('NumAssets', numAssets, 'lb', 0, 'budget', 1, 'Name', 'Mean Variance');
port = setAssetMoments(port, mean(assetRetns.Variables), Sigma);
wts = estimateMaxSharpeRatio(port);

portBL = Portfolio('NumAssets', numAssets, 'lb', 0, 'budget', 1, 'Name', 'Mean Variance with Blac
portBL = setAssetMoments(portBL, mu_bl, Sigma + cov_mu);
wtsBL = estimateMaxSharpeRatio(portBL);

ax1 = subplot(1,2,1);
idx = wts>0.001;
pie(ax1, wts(idx), assetNames(idx));
title(ax1, port.Name ,'Position', [-0.05, 1.6, 0]);

ax2 = subplot(1,2,2);
idx_BL = wtsBL>0.001;
pie(ax2, wtsBL(idx_BL), assetNames(idx_BL));
title(ax2, portBL.Name ,'Position', [-0.05, 1.6, 0]);
```



```
table(assetNames', wts, wtsBL, 'VariableNames', ["AssetName", "Mean_Variance", ...
     "Mean_Variance_with_Black_Litterman"])
```

```

     "GE"         7.7553e-15                    0.1772              
     "IBM"           0.61993                   0.11439              
```

When you use the values for the blended asset return and the covariance from the Black-Litterman model in a mean-variance optimization, the optimal allocations reflect the views of the investment analyst directly. The allocation from the Black-Litterman model is more diversified, as the pie chart shows. Also, the weights among the assets in the Black-Litterman model agree with the investment analyst views. For example, when you compare the Black-Litterman result with the plain mean-variance optimization result, you can see that the Black-Litterman result is more heavily invested in MSFT than in IBM. This is because the investment analyst has a strong view that MSFT will outperform IBM.

Local Functions

```
function [wtsMarket, PI] = findMarketPortfolioAndImpliedReturn(assetRetn, benchRetn)
% Find the market portfolio that tracks the benchmark and its corresponding implied expected retu
```

The implied return is calculated by reverse optimization. The risk-free rate is assumed to be zero. The general formulation of a portfolio optimization is given by the Markowitz optimization problem: $\underset{\omega}{\operatorname{argmax}}\ \omega^T\mu - \frac{\delta}{2}\omega^T\Sigma\omega$. Here ω is an N-element vector of asset weights, μ is an N-element vector of expected asset returns, Σ is the N-by-N covariance matrix of asset returns, and δ is a positive risk aversion parameter. Given δ , in the absence of constraints, a closed form solution to this problem is $\omega = \frac{1}{\delta}\Sigma^{-1}\mu$. Therefore, with a market portfolio, the implied expected return is $\pi = \delta\Sigma\omega_{mkt}$.

To compute an implied expected return, you need $\Sigma,\ \ \omega_{mkt},\ \ \delta$.

1) Find Σ.

Σ is calculated from historical asset returns.

```
Sigma = cov(assetRetn);
```

2) Find the market portfolio.

To find the market portfolio, regress against the DJI. The imposed constraints are fully invested and long only: $\sum_{i=1}^{n}\omega_i = 1, 0 \le \omega_i,\ \ \forall i \in \{1, . . . , n\}$

```
numAssets = size(assetRetn,2);
LB = zeros(1,numAssets);
Aeq = ones(1,numAssets);
Beq = 1;
opts = optimoptions('lsqlin','Algorithm','interior-point', 'Display',"off");
wtsMarket = lsqlin(assetRetn, benchRetn, [], [], Aeq, Beq, LB, [], [], opts);
```

3) Find δ.

Multiply both sides of $\pi = \delta\Sigma\omega_{mkt}$ with ω_{mkt}^T to output $\delta = \frac{SharpeRatio}{\sigma_m}$. Here, the Benchmark is assumed to be maximizing the Sharpe ratio and the corresponding value is used as market Sharpe ratio. Alternatively, you can calibrate an annualized Sharpe ratio to be 0.5, which leads to `shpr`=0.5/`sqrt`(252) [1 on page 4-222]. σ_m is the standard deviation of the market portfolio.

```
shpr = mean(benchRetn)/std(benchRetn);
delta = shpr/sqrt(wtsMarket'*Sigma*wtsMarket);
```

4) Compute the implied expected return.

Assuming that the market portfolio maximizes the Sharpe ratio, the implied return, without the effects from constraints, is computed directly as $\pi = \delta\Sigma\omega$.

```
PI = delta*Sigma*wtsMarket;
end
```

Appendix: Black-Litterman Model Under a Bayesian Framework

Assumptions and Views

Assume that the investment universe is composed of k assets and the vector of asset returns $\boldsymbol{r}$ is modeled as a random variable, following a multivariate normal distribution $\boldsymbol{r} \sim N(\mu, \Sigma)$. Σ is the covariance from historical asset returns. The unknown model parameter is the expected return μ. From the perspective of Bayesian statistics, the Black-Litterman model attempts to estimate μ by combining the investment analyst views (or "observations of the future") and some prior knowledge about μ.

In addition, assume the prior knowledge that μ is a normally distributed random variable $\mu \sim N(\pi, \boldsymbol{C})$ [1, 2 on page 4-222]. In the absence of any views (observations), the prior mean π is likely to be the equilibrium returns, implied from the equilibrium portfolio holding. In practice, the applicable equilibrium portfolio holding is not necessarily the equilibrium portfolio, but rather a target optimal portfolio that the investment analyst would use in the absence of additional views on the market, such as the portfolio benchmark, an index, or even the current portfolio. C represents the uncertainty in the prior and the Black-Litterman model makes the assumption that the structure of C is $\tau\Sigma$. τ is a small constant, and many authors use different values. A detailed discussion about τ can be found in [3 on page 4-222].

Observations are necessary to perform a statistical inference on μ. In the Black-Litterman model, the observations are views about future asset returns expressed at the portfolio level. A view is the expected return of a portfolio composed of the universe of k assets. Usually, the portfolio return has uncertainty, so an error term is added to catch the departure. Assume that there is a total of v views. For a view i, $\boldsymbol{p}_i$ is a row vector with dimension 1 x k, and q_i is a scalar [2 on page 4-222].

$$q_i = E[\boldsymbol{p}_i * \boldsymbol{r} \mid \mu] + \varepsilon_i\ ,\ \ i = 1, 2, \ldots, v$$

You can stack the v views vertically, and Ω is the covariance of the uncertainties from all views. Assume that the uncertainties are independent.

$$\boldsymbol{q}\ =\ E[\boldsymbol{P} * \boldsymbol{r} \mid \mu] +\ \varepsilon,\ \ \varepsilon \sim N(0,\ \Omega),\ \ \Omega = \text{diag}(\omega_1, \omega_2, \ldots \omega_v).$$

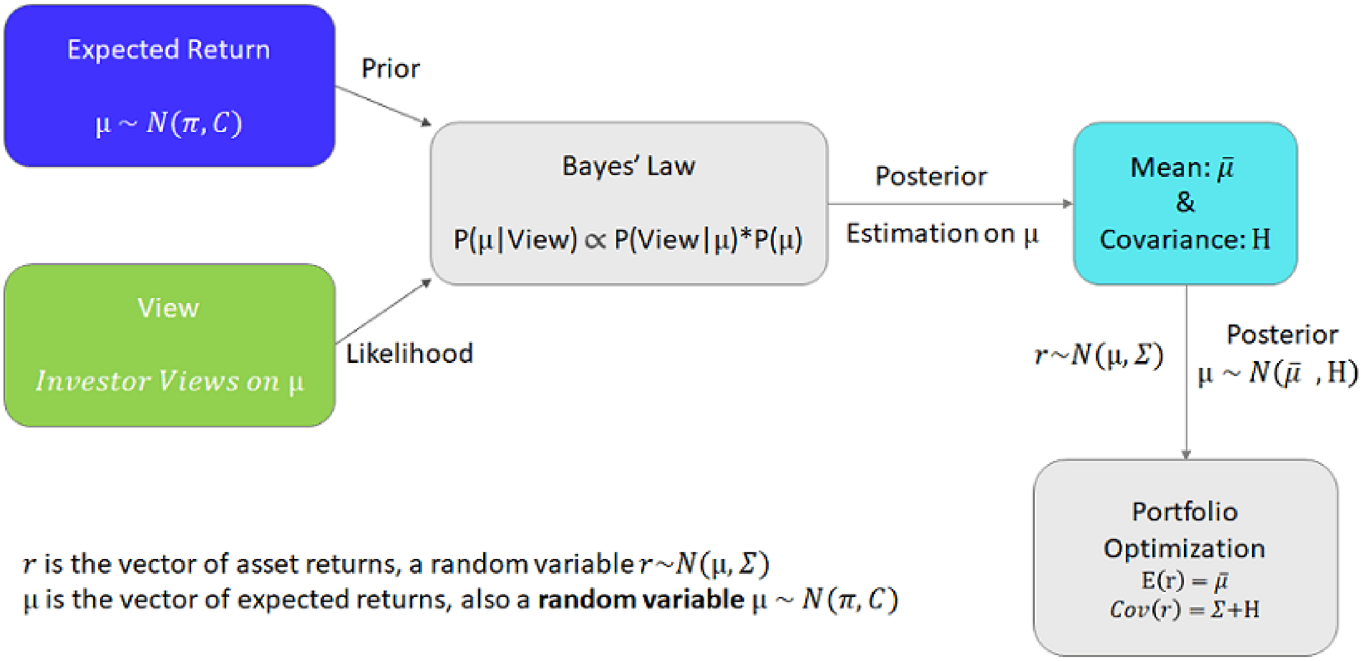
Note that Ω does not necessarily need to be a diagonal matrix. The investment analyst can choose the structure of Ω to account for their uncertainties in the views [4 on page 4-222].

Under the previous assumption $\boldsymbol{r} \sim N(\mu, \Sigma)$, it follows that

$$\boldsymbol{q}\ = \boldsymbol{P} * \mu\ +\ \varepsilon,\ \ \varepsilon \sim N(0,\ \Omega),\ \Omega = \text{diag}(\omega_1, \omega_2, \ldots \omega_v).$$

The Bayesian Definition of the Black-Litterman Model

Based on Bayesian statistics, it is known that: posterior $\propto$ likelihood $*$ prior.



r is the vector of asset returns, a random variable $r \sim N(\mu, \Sigma)$
μ is the vector of expected returns, also a **random variable** $\mu \sim N(\pi, C)$

Figure 1. Black-Litterman Model

In the context of the Black-Litterman model, posterior ∝ likelihood * prior is expressed as $f(\mu|q) \propto f(q|\mu)*f(\mu)$, where each Bayesian term is defined as follows [2 on page 4-222]:

- The *likelihood* is how likely it is for the views to happen given μ and is expressed as $f(q|\mu) \propto \exp\left[-\frac{1}{2}(P\mu - q)'\Omega^{-1}(P\mu - q)\right]$.
- The *prior* assumes the prior knowledge that $\mu \sim N(\pi, C)$ and is expressed as $f(\mu) \propto \exp\left[-\frac{1}{2}(\mu - \pi)'C^{-1}(\mu - \pi)\right]$.
- The *posterior* is the distribution of μ given views and is expressed as $f(\mu|q) \propto \exp\left[-\frac{1}{2}(P\mu - q)'\Omega^{-1}(P\mu - q) - \frac{1}{2}(\mu - \pi)'C^{-1}(\mu - \pi)\right]$.

As previously stated, the posterior distribution of μ is also a normal distribution. By completing the squares, you can derive the posterior mean and covariance as $\bar{\mu} = \left[P^T\Omega^{-1}P + C^{-1}\right]^{-1}\left[P^T\Omega^{-1}q + C^{-1}\pi\right]$, $\mathrm{cov}(\mu) = \left[P^T\Omega^{-1}P + C^{-1}\right]^{-1}$.

Finally, by combining the Bayesian posterior distribution of μ and the model of asset returns $\boldsymbol{r} \sim N(\mu, \Sigma)$, you then have the posterior prediction of asset returns as $\boldsymbol{r} \sim N(\bar{\mu},\ \Sigma + \mathrm{cov}(\mu))$.

Portfolio Optimization Using Factor Models

This example shows two approaches for using a factor model to optimize asset allocation under a mean-variance framework. Multifactor models are often used in risk modeling, portfolio management, and portfolio performance attribution. A multifactor model reduces the dimension of the investment universe and is responsible for describing most of the randomness of the market [1 on page 4-229]. The factors can be statistical, macroeconomic, and fundamental. In the first approach in this example, you build statistical factors from asset returns and optimize the allocation directly against the factors. In the second approach you use the given factor information to compute the covariance matrix of the asset returns and then use the `Portfolio` class to optimize the asset allocation.

Load Data

Load a simulated data set, which includes asset returns total $p = 100$ assets and 2000 daily observations.

```
load('asset_return_100_simulated.mat');
[nObservation, p] = size(stockReturns)
```

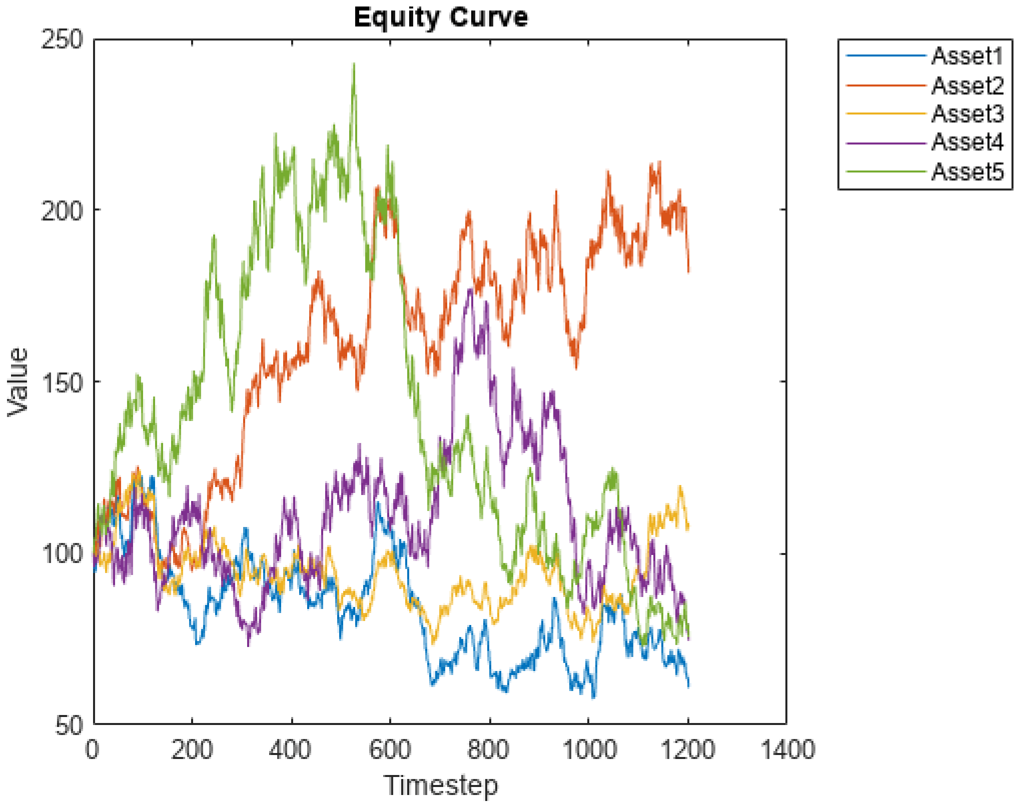
```
nObservation = 2000
```

```
p = 100
```

```
splitPoint = ceil(nObservation*0.6);
training = 1:splitPoint;
test = splitPoint+1:nObservation;
trainingNum = numel(training);
```

Visualize the equity curve for each stock. For this example, plot the first five stocks.

```
plot(ret2tick(stockReturns{training,1:5}, 'method', 'simple')*100); hold off;
xlabel('Timestep');
ylabel('Value');
title('Equity Curve');
legend(stockReturns.Properties.VariableNames(1:5), 'Location',"bestoutside",'Interpreter', 'none
```



Optimize the Asset Allocation Directly Against Factors with a Problem-Based Definition Framework

For the factors, you can use statistical factors extracted from the asset return series. In this example, you use principal component analysis (PCA) to extract statistical factors [1 on page 4-229]. You can then use this factor model to solve the portfolio optimization problem.

With a factor model, p asset returns can be expressed as a linear combination of k factor returns, $r_a = \mu_a + F\, r_f + \varepsilon_a$, where $k << p$. In the mean-variance framework, portfolio risk is

$$\mathrm{Var}(R_p) = \mathrm{Var}\left(r_a{}^T w_a\right) = \mathrm{Var}\left(\left(\mu_a + F\, r_f + \varepsilon_a\right)^T w_a\right) = w_a^T\left(F \Sigma_f F^T + D\right) w_a = w_f^T\, \Sigma_f\, w_f + w_a^T\, D\, w_a, \text{ with}$$
$$w_f = F^T w_a,$$

where:

R_p is the portfolio return (a scalar).

r_a is the asset return.

μ_a is the mean of asset return.

F is the factor loading, with the dimensions *p-by-k*.

r_f is the factor return.

ε_a is the idiosyncratic return related to each asset.

w_a is the asset weight.

w_f is the factor weight.

Σ_f is the covariance of factor returns.

D is the variance of idiosyncratic returns.

The parameters r_a, w_a, μ_a, ε_a are p-by-1 column vectors, $r_f$and w_f are k-by-1 column vectors, Σ_a is a p-by-p matrix, Σ_k is a k-by-k matrix, and D is a p-by-p diagonal matrix.

Therefore, the mean-variance optimization problem is formulated as

$$\max \mu_a^T w_a\,, \;\; s.t.\, F^T w_a = w_f,\, w_f^T \Sigma_f w_f + w_a^T D\, w_a \le t_{\text{risk}}, 0 \le w \le 1,\, e^T w_a = 1.$$

In the p dimensional space formed by p asset returns, PCA finds the most important k directions that capture the most important variations in the given returns of p assets. Usually, k is less than p. Therefore, by using PCA you can decompose the p asset returns into the k factors, which greatly reduces the dimension of the problem. The k principal directions are interpreted as factor loadings and the scores from the decomposition are interpreted as factor returns. For more information, see `pca` (Statistics and Machine Learning Toolbox™). In this example, use k = `10` as the number of principal components. Alternatively, you can also find the k value by defining a threshold for the total variance represented as the top k principal components. Usually 95% is an acceptable threshold.

```
k = 10;
[factorLoading,factorRetn,latent,tsq,explained,mu] = pca(stockReturns{training,:}, 'NumComponents
disp(size(factorLoading))
```

```
   100    10
```

```
disp(size(factorRetn))
```

```
        1200           10
```

In the output p-by-k `factorLoading`, each column is a principal component. The asset return vector at each timestep is decomposed to these k dimensional spaces, where $k << p$. The output `factorRetn` is a *trainingNum*-by-k dimension.

Alternatively, you can also use the `covarianceDenoising` function to estimate a covariance matrix (`denoisedCov`) using denoising to reduce the noise and enhance the signal of the empirical covariance matrix. [1 on page 4-229] The goal of denoising is to separate the eigenvalues associated with signal from the ones associated with noise and shrink the eigenvalues associated with noise to enhance the signal. Thus, `covarianceDenoising` is a reasonable tool to identify the number of factors.

```
[denoisedCov,numFactorsDenoising] = covarianceDenoising(stockReturns{training,:});
```

The number of factors (`numFactorsDenoising`) is `6`.

```
disp(numFactorsDenoising)
```

```
     6
```

Estimate the factor covariance matrix with factor returns (`factorRetn`) obtained using the `pca` function.

```
covarFactor = cov(factorRetn);
```

You can reconstruct the p asset returns for each observation using each k factor returns by following $r_a = \mu_a + F\, r_f + \varepsilon_a$.

Reconstruct the total 1200 observations for the training set.

```
reconReturn = factorRetn*factorLoading' + mu;
unexplainedRetn = stockReturns{training,:} - reconReturn;
```

There are unexplained asset returns ε_a because the remaining (p - k) principal components are dropped. You can attribute the unexplained asset returns to the asset-specific risks represented as D.

```
unexplainedCovar = diag(cov(unexplainedRetn));
D = diag(unexplainedCovar);
```

You can use a problem-based definition framework from Optimization Toolbox™ to construct the variables, objective, and constraints for the problem: max $\mu_a^T\, w_a\, ,\ s.t.\ F^T w_a = w_f$, $w_f^T\, \Sigma_f\, w_f + w_a^T\, D\, w_a \le t_{\text{risk}}, e^T w_a = 1, 0 \le w \le 1$. The problem-based definition framework enables you to define variables and express objective and constraints symbolically. You can add other constraints or use a different objective based on your specific problem. For more information, see “First Choose Problem-Based or Solver-Based Approach”.

```
targetRisk = 0.007;  % Standard deviation of portfolio return
tRisk = targetRisk*targetRisk;  % Variance of portfolio return
meanStockRetn = mean(stockReturns{training,:});

optimProb = optimproblem('Description','Portfolio with factor covariance matrix','ObjectiveSense
wgtAsset = optimvar('asset_weight', p, 1, 'Type', 'continuous', 'LowerBound', 0, 'UpperBound', 1
wgtFactor = optimvar('factor_weight', k, 1, 'Type', 'continuous');

optimProb.Objective = sum(meanStockRetn'.*wgtAsset);

optimProb.Constraints.asset_factor_weight = factorLoading'*wgtAsset - wgtFactor == 0;
optimProb.Constraints.risk = wgtFactor'*covarFactor*wgtFactor + wgtAsset'*D*wgtAsset <= tRisk;
optimProb.Constraints.budget = sum(wgtAsset) == 1;

x0.asset_weight = ones(p, 1)/p;
x0.factor_weight = zeros(k, 1);
opt = optimoptions("fmincon", "Algorithm","sqp", "Display", "off", ...
    'ConstraintTolerance', 1.0e-8, 'OptimalityTolerance', 1.0e-8, 'StepTolerance', 1.0e-8);
x = solve(optimProb,x0, "Options",opt);
assetWgt1 = x.asset_weight;
```

In this example, you are maximizing the portfolio return for a target risk. This is a nonlinear programming problem with a quadratic constraint and you use `fmincon` to solve this problem.

Check for asset allocations that are over 5% to determine which assets have large investment weights.

```
percentage = 0.05;
AssetName = stockReturns.Properties.VariableNames(assetWgt1>=percentage)';
Weight = assetWgt1(assetWgt1>=percentage);
T1 = table(AssetName, Weight)
```

```
T1=7×2 table
     AssetName      Weight 
    ___________    ________

    {'Asset9' }    0.080054
    {'Asset32'}     0.22355
    {'Asset47'}     0.11369
    {'Asset57'}    0.088321
    {'Asset61'}    0.068846
    {'Asset75'}    0.063648
    {'Asset94'}     0.22163
```

Optimize Asset Allocation Using `Portfolio` Class with Factor Information

If you already have the factor loading and factor covariance matrix from some other analysis or third-party provider, you can use this information to compute the asset covariance matrix and then directly run a mean-variance optimization using the `Portfolio` class. Recall that portfolio risk is $\mathrm{Var}\left(R_p\right) = \mathrm{Var}\left(\left(\mu_a + F\, r_f + \varepsilon_a\right)^T w_a\right) = w_a^T\left(F\Sigma_f F^T + D\right) w_a$, so you can obtain the covariance of the asset returns by $\Sigma_a = F\Sigma_f F^T + D$.

Use `estimateFrontierByRisk` in the `Portfolio` class to solve the optimization problem: $\max \mu_a^T\, w_a\,,\ s.t.\ w_a^T\ \Sigma_a\, w_a \le t_{\mathrm{risk}}, 0 \le w_a \le 1,\ e^T w_a = 1$. The `Portfolio` class supports has a variety of built-in constraints that you can use to describe your portfolio problem and estimate the risk and returns on the efficient frontier. For more information, see “Portfolio Set for Optimization Using Portfolio Objects” on page 4-8.

```
covarAsset = factorLoading*covarFactor*factorLoading'+D;
port = Portfolio("AssetMean", meanStockRetn, 'AssetCovar', covarAsset, 'LowerBound', 0, 'UpperBou
    'Budget', 1);
assetWgt2 = estimateFrontierByRisk(port, targetRisk);

AssetName = stockReturns.Properties.VariableNames(assetWgt2>=percentage)';
Weight = assetWgt2(assetWgt2>=percentage);
T2 = table(AssetName, Weight)
```

```
T2=7×2 table
     AssetName      Weight 
    ___________    ________

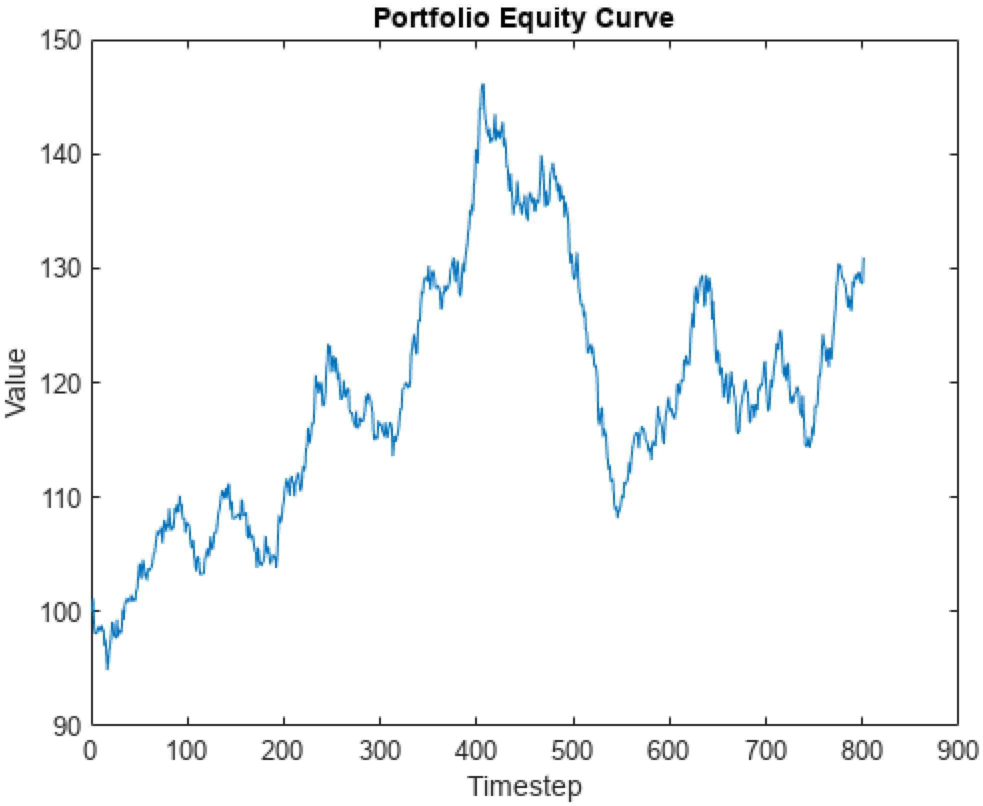
    {'Asset9' }    0.080061
    {'Asset32'}     0.22355
    {'Asset47'}     0.11369
    {'Asset57'}    0.088314
    {'Asset61'}    0.068847
    {'Asset75'}    0.063644
    {'Asset94'}     0.22163
```

Portfolio Optimization Results

Tables `T1` and `T2` show an identical allocation for the asset allocations that are over 5%. Therefore, in this example, both approaches to portfolio optimization with a factor model obtain asset weights that are identical.

Visualize the performance of the optimized allocation over the testing period.

```
retn = stockReturns{test, :}*assetWgt1;
plot(ret2tick(retn, 'method', 'simple')*100); hold off;
xlabel('Timestep');
ylabel('Value');
title('Portfolio Equity Curve');
```



This example demonstrates how to derive statistical factors from asset returns using PCA and then use these factors to perform a factor-based portfolio optimization. This example also shows how to use these statistical factors with the `Portfolio` class. In practice, you can adapt this example to incorporate some measurable market factors, such as industrial factors or ETF returns from various sectors, to describe the randomness in the market [1 on page 4-229]. You can define custom constraints on the weights of factors or assets with high flexibility using the problem-based definition framework from Optimization Toolbox™. Alternatively, you can work directly with the `Portfolio` class to run a portfolio optimization with various built-in constraints.

Backtest Investment Strategies Using Financial Toolbox™

Perform backtesting of portfolio strategies using a backtesting framework. Backtesting is a useful tool to compare how investment strategies perform over historical or simulated market data. This example develops five different investment strategies and then compares their performance after running over a one-year period of historical stock data. The backtesting framework is implemented in two Financial Toolbox™ classes: `backtestStrategy` and `backtestEngine`.

Load Data

Load one year of adjusted price data for 30 stocks. The backtesting frameworks require adjusted asset prices, meaning prices adjusted for dividends, splits, or other events. The prices must be stored in a MATLAB® `timetable` with each column holding a time series of asset prices for an investable asset.

For this example, use one year of asset price data from the component stocks of the Dow Jones Industrial Average.

```
% Read a table of daily adjusted close prices for 2006 DJIA stocks.
T = readtable('dowPortfolio.xlsx');

% For readability, use only 15 of the 30 DJI component stocks.
assetSymbols = ["AA","CAT","DIS","GM","HPQ","JNJ","MCD","MMM","MO","MRK","MSFT","PFE","PG","T","X

% Prune the table to hold only the dates and selected stocks.
timeColumn = "Dates";
T = T(:,[timeColumn assetSymbols]);

% Convert to the table to a timetable.
pricesTT = table2timetable(T,'RowTimes','Dates');

% View the structure of the prices timetable.
head(pricesTT)
```

```
       Dates        AA       CAT      DIS       GM      HPQ      JNJ      MCD      MMM      MO
    ___________    _____    _____    _____    _____    _____    _____    _____    _____    _____

Define the Strategies

Investment strategies capture the logic used to make asset allocation decisions while a backtest is running. As the backtest runs, each strategy is periodically given the opportunity to update its portfolio allocation based on the trailing market conditions, which it does by setting a vector of asset weights. The asset weights represent the percentage of available capital invested into each asset, with each element in the weights vector corresponding to the respective column in the asset `pricesTT` timetable. If the sum of the weights vector is `1`, then the portfolio is fully invested.

In this example, there are five backtest strategies. The backtest strategies assign asset weights using the following criteria:

- Equal-weighted

$$\omega\mathrm{EW} = (\omega_1, \omega_2, \ldots, \omega_N), \omega_i = \frac{1}{N}$$

- Maximization of Sharpe ratio

$\omega\mathrm{SR} \ = \ \underset{\omega}{\operatorname{argmax}}\left\{\frac{r'\omega}{\sqrt{\omega' Q\omega}} \,|\, \omega \geq 0, \sum_1^N \omega_i = 1, 0 \leq \omega \leq 0.1\right\}$, where r is a vector of expected returns and Q is the covariance matrix of asset returns.

- Inverse variance

$\omega\mathrm{IV} = \ (\omega_1, \omega_2, \ldots, \omega_N), \omega_i = \frac{\left(\sigma_{\mathrm{ii}}^{-1}\right)}{\sum_{i\,=\,1}^{N} \sigma_{\mathrm{ii}}^{-1}}$, where σ_{ii} are diagonal elements of the asset return covariance matrix.

- Markowitz portfolio optimization (maximizing return and minimizing risk with fixed risk-aversion coefficient)

$R_{\mathrm{Mkwtz}} = \max_{\omega}\left\{r'\omega \ - \lambda\omega' Q\omega \mid \omega \geq 0, \sum_1^N \omega_i = 1, 0 \leq \omega \leq 0.1\right\}$, where λ is the risk-aversion coefficient.

- Robust optimization with uncertainty in expected returns
- The robust portfolio optimization strategy, in contrast to the deterministic Markowitz formulation, takes into consideration the uncertainty expected returns of the assets and their variances and covariances. Instead of modeling unknown values (for example, expected returns) as one point, typically represented by the mean value calculated from the past, unknowns are specified as a set of values that contain the most likely possible realizations, $r = \{r \,|\, r \in S(r_0)\}$.

In this case, the expected return is defined not by the deterministic vector r_0 but by the region $S(r_0)$ around the vector r_0.

Taking this into consideration, there are several ways to reformulate the portfolio optimization problem. One of the most frequently used methods is to formulate the problem as a problem of finding the maximum and minimum:

$$R_{\mathrm{robust}} = \max_{\omega} \min_{r \in S(r_0)}\left\{r'\omega \ - \lambda\omega' Q\omega \mid \omega \geq 0, \sum_1^N \omega_i = 1, 0 \leq \omega \leq 0.1\right\}$$

In this example, the region of uncertainty $S(r_0)$ is specified as an ellipsoid:

$$S(r_0) = \{r \mid (r - r_0)' \Sigma_r^{-1} (r - r_0) \le \kappa^2\}$$

Here, κ - is the uncertainty aversion coefficient that defines how wide the uncertainty region is, and Σ_r is the matrix of estimation errors in expected returns r.

With the addition of the ellipsoid uncertainty to the Markowitz model, the robust optimization problem is reformulated as:

$$R_{\text{robust}} = \max_{\omega} \left\{ r'\omega \ - \lambda\omega' Q\omega - \text{kz} \mid \omega \ge 0,\ z \ge 0,\ \omega'\Sigma_r\omega - z^2 \le 0,\ \sum_1^N \omega_i = 1, 0 \le \omega \le 0.1 \right\}$$

Implement the Strategy Rebalance Functions

The core logic of each strategy is implemented in a rebalance function. A rebalance function is a user-defined MATLAB® function that specifies how a strategy allocates capital in a portfolio. The rebalance function is an input argument to `backtestStrategy`. The rebalance function must implement the following fixed signature:

```
function new_weights = allocationFunctionName(current_weights,
pricesTimetable)
```

This fixed signature is the API that the backtest framework uses when rebalancing a portfolio. As the backtest runs, the backtesting engine calls the rebalance function of each strategy, passing in these inputs:

- `current_weights` — Current portfolio weights before rebalancing
- `pricesTimetable` — MATLAB® timetable object containing the rolling window of asset prices.

The `backtestStrategy` rebalance function uses this information to compute the desired new portfolio weights, which are returned to the backtesting engine in the function output `new_weights`. See the Local Functions on page 4-240 sections for the rebalance function for each of the five strategies.

Compute Initial Strategy Weights

Use the strategy rebalance functions to compute the initial weights for each strategy. Setting the initial weights is important because otherwise the strategies begin the backtest with 100% in cash, earning the risk-free rate, until the first rebalance date.

This example uses the first 40 days of the data set (about 2 months) to initialize the strategies. The backtest is then run over the remaining data (about 10 months).

```
warmupPeriod = 40;
```

The initial weights are calculated by calling the `backtestStrategy` rebalance function in the same way that the backtesting engine will call it. To do so, pass in a vector of current weights (all zeros, that is 100% cash) as well as a window of price data that the strategies will use to set the desired weights (the warm-up data partition). Using the rebalance functions to compute the initial weights in this way is not required. The initial weights are a vector of the initial portfolio weights and can be set to any appropriate value. The rebalance functions in this example approximate the state the strategies would be in had they been already running at the start of the backtest.

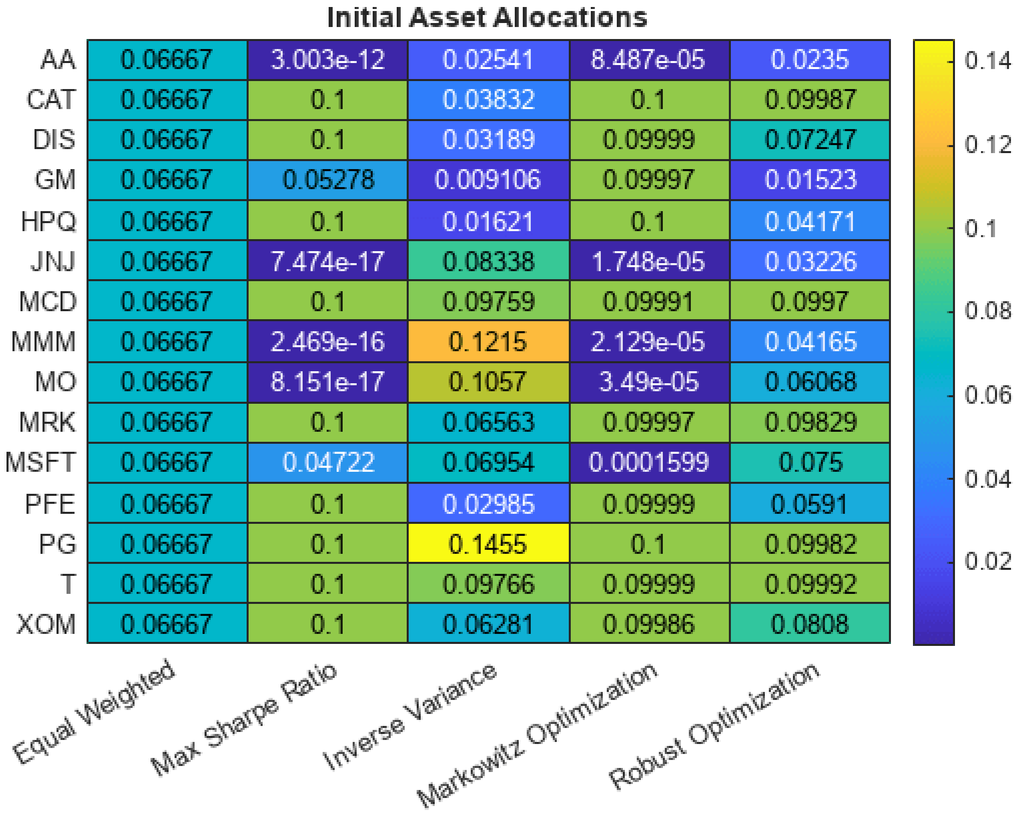
```
% No current weights (100% cash position).
current_weights = zeros(1,numAssets);
```

```
% Warm-up partition of data set timetable.
warmupTT = pricesTT(1:warmupPeriod,:);

% Compute the initial portfolio weights for each strategy.
equalWeight_initial     = equalWeightFcn(current_weights,warmupTT);
maxSharpeRatio_initial  = maxSharpeRatioFcn(current_weights,warmupTT);
inverseVariance_initial = inverseVarianceFcn(current_weights,warmupTT);
markowitz_initial       = markowitzFcn(current_weights,warmupTT);
robustOptim_initial     = robustOptimFcn(current_weights,warmupTT);
```

Visualize the initial weight allocations from the strategies.

```
strategyNames = {'Equal Weighted', 'Max Sharpe Ratio', 'Inverse Variance', 'Markowitz Optimizati
assetSymbols = pricesTT.Properties.VariableNames;
initialWeights = [equalWeight_initial(:), maxSharpeRatio_initial(:), inverseVariance_initial(:),
heatmap(strategyNames, assetSymbols, initialWeights, 'title','Initial Asset Allocations','Colorma
```



Create Backtest Strategies

To use the strategies in the backtesting framework, you must build `backtestStrategy` objects, one for each strategy. The `backtestStrategy` function takes as input the strategy name and rebalancing function for each strategy. Additionally, the `backtestStrategy` can take a variety of name-value pair arguments to specify various options. For more information on creating backtest strategies, see `backtestStrategy`.

Set the rebalance frequency and lookback window size are set in terms of number of time steps (that is, rows of the `pricesTT` timetable). Since the data is daily price data, specify the rebalance frequency and rolling lookback window in days.

```
% Rebalance approximately every 1 month (252 / 12 = 21).
rebalFreq = 21;

% Set the rolling lookback window to be at least 40 days and at most 126
% days (about 6 months).
lookback  = [40 126];

% Use a fixed transaction cost (buy and sell costs are both 0.5% of amount
% traded).
transactionsFixed = 0.005;

% Customize the transaction costs using a function. See the
% variableTransactionCosts function below for an example.
transactionsVariable = @variableTransactionCosts;

% The first two strategies use fixed transaction costs. The equal-weighted
% strategy does not require a lookback window of trailing data, as its
% allocation is fixed.
strat1 = backtestStrategy('Equal Weighted', @equalWeightFcn, ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', 0, ...
    'TransactionCosts', transactionsFixed, ...
    'InitialWeights', equalWeight_initial);

strat2 = backtestStrategy('Max Sharpe Ratio', @maxSharpeRatioFcn, ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', transactionsFixed, ...
    'InitialWeights', maxSharpeRatio_initial);

% Use variable transaction costs for the remaining strategies.
strat3 = backtestStrategy('Inverse Variance', @inverseVarianceFcn, ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', @variableTransactionCosts, ...
    'InitialWeights', inverseVariance_initial);

strat4 = backtestStrategy('Markowitz Optimization', @markowitzFcn, ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', transactionsFixed, ...
    'InitialWeights', markowitz_initial);

strat5 = backtestStrategy('Robust Optimization', @robustOptimFcn, ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', transactionsFixed, ...
    'InitialWeights', robustOptim_initial);

% Aggregate the strategy objects into an array.
strategies = [strat1, strat2, strat3, strat4, strat5];
```

Backtest the Strategies

Use the following the workflow to backtest the strategies with a `backtestEngine`.

Define Backtesting Engine

The `backtestEngine` function takes as input an array of `backtestStrategy` objects. Additionally, when using `backtestEngine`, you can set several options, such as the risk-free rate and the initial portfolio value. When the risk-free rate is specified in annualized terms, the `backtestEngine` uses `Basis` property to set the day count convention. For more information on creating backtesting engines, see `backtestEngine`.

```
% Risk-free rate is 1% annualized
annualRiskFreeRate = 0.01;

% Create the backtesting engine object
backtester = backtestEngine(strategies, 'RiskFreeRate', annualRiskFreeRate)
```

```
backtester = 
  backtestEngine with properties:

               Strategies: [1x5 backtestStrategy]
             RiskFreeRate: 0.0100
           CashBorrowRate: 0
          RatesConvention: "Annualized"
                    Basis: 0
    InitialPortfolioValue: 10000
           DateAdjustment: "Previous"
                NumAssets: []
                  Returns: []
                Positions: []
                 Turnover: []
                  BuyCost: []
                 SellCost: []
                     Fees: []
```

Run Backtest

Use `runBacktest` to run the backtest using the test data partition. Use the `runBacktest` name-value pair argument `'Start'`to avoid look-ahead bias (that is, "seeing the future"). Begin the backtest at the end of the "warm-up" period. Running the backtest populates the empty fields of the `backtestEngine` object with the day-by-day backtest results.

```
backtester = runBacktest(backtester, pricesTT, 'Start', warmupPeriod)
```

```
backtester = 
  backtestEngine with properties:

               Strategies: [1x5 backtestStrategy]
             RiskFreeRate: 0.0100
           CashBorrowRate: 0
          RatesConvention: "Annualized"
                    Basis: 0
    InitialPortfolioValue: 10000
           DateAdjustment: "Previous"
                NumAssets: 15
                  Returns: [211x5 timetable]
                Positions: [1x1 struct]
                 Turnover: [211x5 timetable]
                  BuyCost: [211x5 timetable]
                 SellCost: [211x5 timetable]
                     Fees: [1x1 struct]
```

Examine Backtest Results

Use the `summary` function to generate a table of strategy performance results for the backtest.

```
summaryByStrategies = summary(backtester)
```

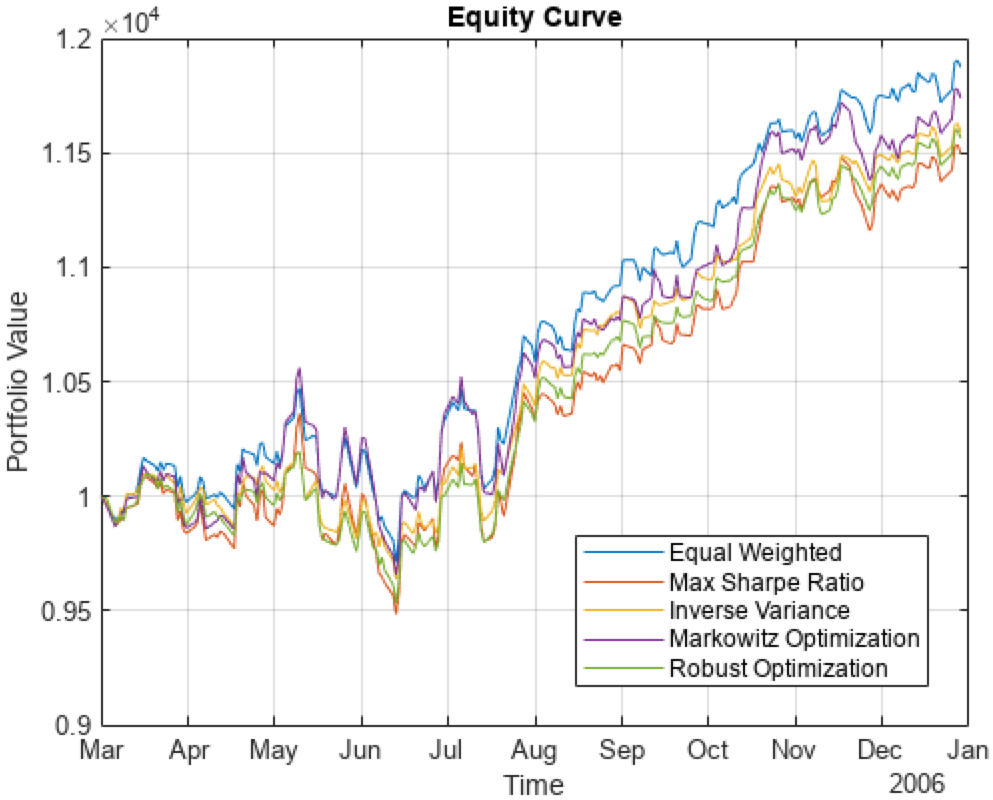
```
summaryByStrategies=9×5 table
                       Equal_Weighted    Max_Sharpe_Ratio    Inverse_Variance    Markowitz_Optimi
                       ______________    ________________    ________________    ________________

    TotalReturn             0.18745             0.14991             0.15906                 0.17404
    SharpeRatio             0.12559            0.092456             0.12179                 0.10339
    Volatility            0.0063474           0.0070186           0.0055626               0.0072466
    AverageTurnover      0.00087623           0.0065762           0.0028666               0.0058268
    MaxTurnover            0.031251               0.239             0.09114                 0.21873
    AverageReturn        0.00083462          0.00068672           0.0007152              0.00078682
    MaxDrawdown            0.072392            0.084768            0.054344                0.085544
    AverageBuyCost         0.047298              0.3449             0.15228                  0.3155
    AverageSellCost        0.047298              0.3449             0.22842                  0.3155
```

The detailed backtest results, including the daily returns, asset positions, turnover, and fees are stored in properties of the `backtestEngine` object.

Use `equityCurve` to plot the equity curve for the five different investment strategies.

```
equityCurve(backtester)
```



Transposing the summary table to make plots of certain metrics can be useful.

```
% Transpose the summary table to plot the metrics.
summaryByMetrics = rows2vars(summaryByStrategies);
summaryByMetrics.Properties.VariableNames{1} = 'Strategy'
```

```
summaryByMetrics=5×10 table
             Strategy                 TotalReturn    SharpeRatio    Volatility    AverageTurnover
    __________________________        ___________    ___________    __________    _______________

    {'Equal_Weighted'         }         0.18745        0.12559      0.0063474       0.00087623

Backtest Investment Strategies with Trading Signals

This example shows how to perform backtesting of portfolio strategies that incorporate investment signals in their trading strategy. The term *signals* includes any information that a strategy author needs to make with respect to trading decisions outside of the price history of the assets. Such information can include technical indicators, the outputs of machine learning models, sentiment data, macroeconomic data, and so on. This example uses three simple investment strategies based on derivative signal data:

- Moving average crossovers
- Moving average convergence/divergence
- Relative strength index

In this example you can run a backtest using these strategies over one year of stock data. You then analyze the results to compare the performance of each strategy.

Even though technical indicators are not typically used as standalone trading strategies, this example uses these strategies to demonstrate how to build investment strategies based on signal data when you use the `backtestEngine` object in MATLAB®.

Load Data

Load the adjusted price data for 15 stocks for the year 2006. This example uses a small set of investable assets for readability.

Read a table of daily adjusted close prices for 2006 DJIA stocks.

```
T = readtable('dowPortfolio.xlsx');
```

For readability, use only 15 of the 30 DJI component stocks.

```
symbols = ["AA","CAT","DIS","GM","HPQ","JNJ","MCD","MMM","MO","MRK","MSFT","PFE","PG","T","XOM"]
```

Prune the table to hold only the dates and selected stocks.

```
timeColumn = "Dates";
T = T(:,[timeColumn symbols]);
```

Convert the data to a timetable.

```
pricesTT = table2timetable(T,'RowTimes','Dates');
```

View the structure of the prices timetable.

```
head(pricesTT)
```

```
       Dates         AA       CAT      DIS      GM       HPQ      JNJ      MCD      MMM      MO

Build Signal Table

In addition to the historical adjusted asset prices, the backtesting framework allows you to optionally specify *signal* data when running a backtest. Specify the signal data in a similar way as the prices by using a MATLAB® `timetable`. The "time" dimension of the *signal* timetable must match that of the *prices* timetable — that is, the rows of each table must have matching datetime values for the `Time` column.

This example builds a signal timetable to support each of the three investment strategies:

- Simple moving average crossover (SMA) strategy
- Moving Average Convergence / Divergence (MACD) strategy
- Relative Strength Index (RSI) strategy

Each strategy has a timetable of signals that are precomputed. Before you run the backtest, you merge the three separate signal timetables into a single aggregate signal timetable to use for the backtest.

SMA: Simple Moving Average Crossover

The SMA indicator uses 5-day and 20-day simple moving averages to make buy and sell decisions. When the 5-day SMA crosses the 20-day SMA (moving upwards), then the stock is bought. When the 5-day SMA crosses below the 20-day SMA, the stock is sold.

```
% Create SMA timetables using the movavg function.
sma5  = movavg(pricesTT,'simple',5);
sma20 = movavg(pricesTT,'simple',20);
```

Create the SMA indicator signal timetable.

```
smaSignalNameEnding = '_SMA5over20';

smaSignal = timetable;
for i = 1:numel(symbols)
    symi = symbols(i);
    % Build a timetable for each symbol, then aggregate them together.
    smaSignali = timetable(pricesTT.Dates,...
        double(sma5.(symi) > sma20.(symi)),...
        'VariableNames',{sprintf('%s%s',symi,smaSignalNameEnding)});
    % Use the synchronize function to merge the timetables together.
    smaSignal = synchronize(smaSignal,smaSignali);
end
```

The SMA signal timetable contains an indicator with a value of `1` when the 5-day moving average is above the 20-day moving average for each asset, and a `0` otherwise. The column names for each stock indicator are [*stock symbol*]`SMA5over20`. The `backtestStrategy` object makes trading decisions based on these crossover events.

View the structure of the SMA signal timetable.

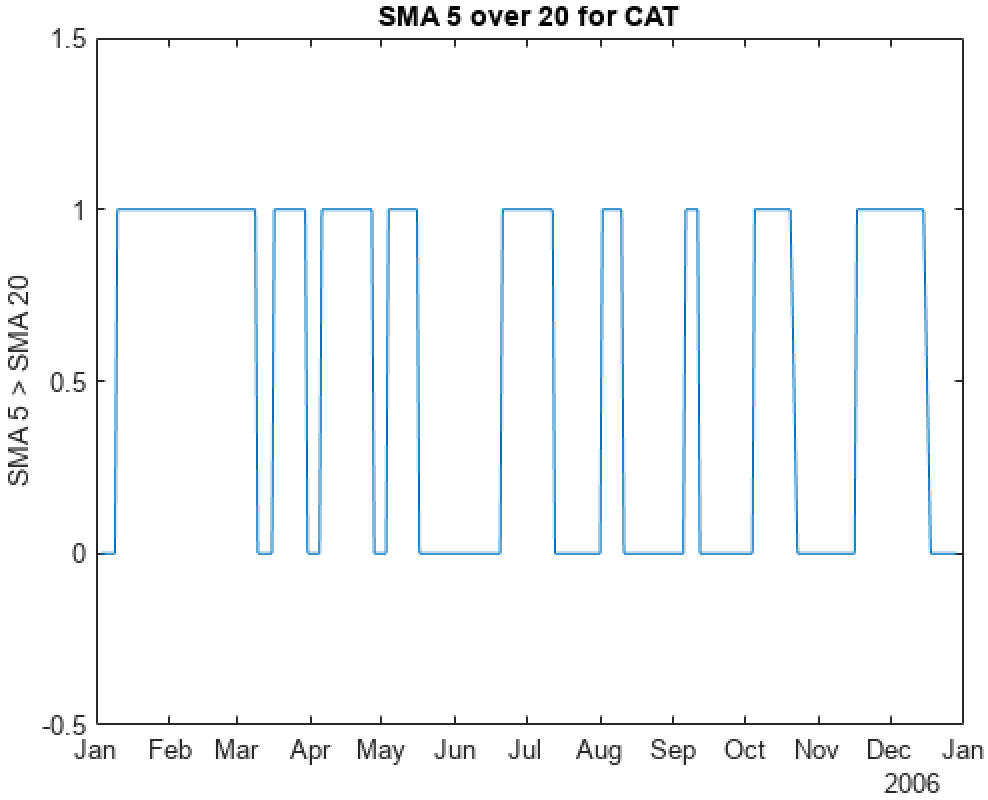
```
head(smaSignal)
```

```
       Time        AA_SMA5over20    CAT_SMA5over20    DIS_SMA5over20    GM_SMA5over20    HPQ_SMA5
    ___________    _____________    ______________    ______________    _____________    ________

    03-Jan-2006          0                0                 0                 0                0
    04-Jan-2006          0                0                 0                 0                0
    05-Jan-2006          0                0                 0                 0                0
    06-Jan-2006          0                0                 0                 0                0
    09-Jan-2006          0                0                 0                 0                0
    10-Jan-2006          1                1                 1                 1                1
    11-Jan-2006          0                1                 1                 1                1
    12-Jan-2006          0                1                 1                 1                1
```

Plot the signal for a single asset to preview the trading frequency.

```
plot(smaSignal.Time,smaSignal.CAT_SMA5over20);
ylim([-0.5, 1.5]);
ylabel('SMA 5 > SMA 20');
title(sprintf('SMA 5 over 20 for CAT'));
```



MACD: Moving Average Convergence/Divergence

You can use the MACD metric in a variety of ways. Often, MACD is compared to its own exponential moving average, but for this example, MACD serves as a trigger for a buy signal when the MACD rises above 0. A position is sold when the MACD falls back below 0.

```
% Create a timetable of the MACD metric using the MACD function.
macdTT = macd(pricesTT);
```

Create the MACD indicator signal timetable.

```
macdSignalNameEnding = '_MACD';

macdSignal = timetable;
for i = 1:numel(symbols)
    symi = symbols(i);
    % Build a timetable for each symbol, then aggregate the symbols together.
    macdSignali = timetable(pricesTT.Dates,...
        double(macdTT.(symi) > 0),...
        'VariableNames',{sprintf('%s%s',symi,macdSignalNameEnding)});
    macdSignal = synchronize(macdSignal,macdSignali);
end
```

The MACD signal table contains a column for each asset with the name [*stock symbol*]MACD. Each signal has a value of 1 when the MACD of the stock is above 0. The signal has a value of 0 when the MACD of the stock falls below 0.

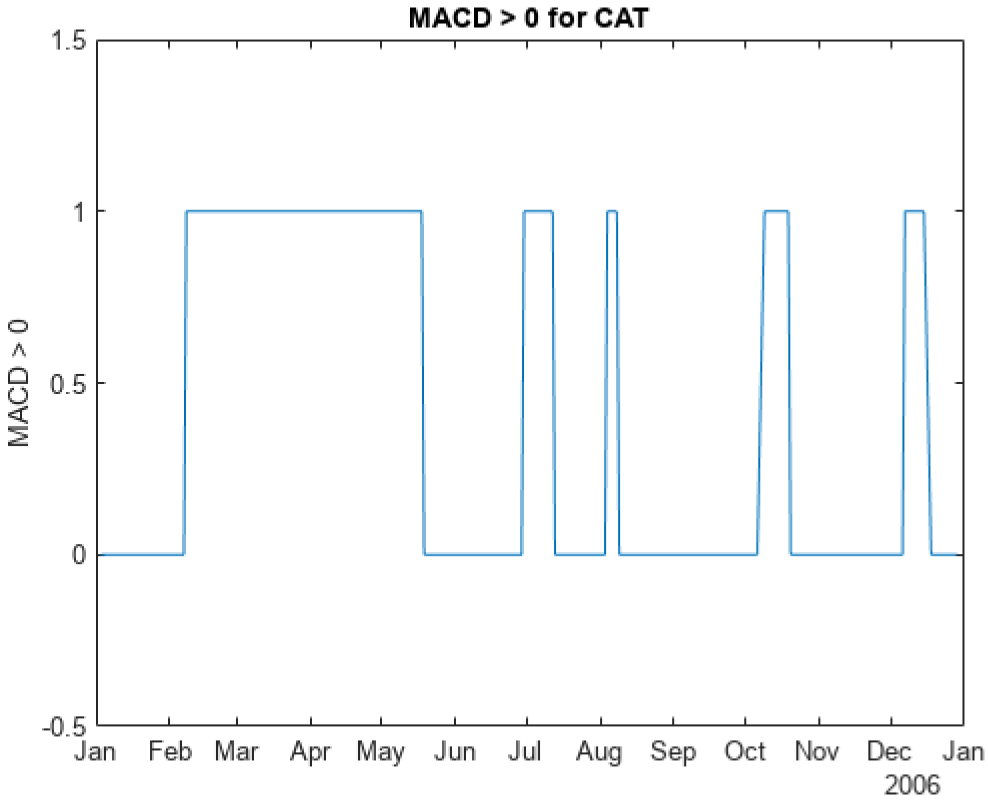
```
head(macdSignal)
```

```
       Time        AA_MACD    CAT_MACD    DIS_MACD    GM_MACD    HPQ_MACD    JNJ_MACD    MCD_MACD
    ___________    _______    ________    ________    _______    ________    ________    ________

    03-Jan-2006       0           0           0          0           0           0           0
    04-Jan-2006       0           0           0          0           0           0           0
    05-Jan-2006       0           0           0          0           0           0           0
    06-Jan-2006       0           0           0          0           0           0           0
    09-Jan-2006       0           0           0          0           0           0           0
    10-Jan-2006       0           0           0          0           0           0           0
    11-Jan-2006       0           0           0          0           0           0           0
    12-Jan-2006       0           0           0          0           0           0           0
```

Similar to the SMA, plot the signal for a single asset to preview the trading frequency.

```
plot(macdSignal.Time,macdSignal.CAT_MACD)
ylim([-0.5, 1.5]);
ylabel('MACD > 0');
title(sprintf('MACD > 0 for CAT'));
```



RSI: Relative Strength Index

The RSI is a metric to capture momentum. A common heuristic is to buy when the RSI falls below `30` and to sell when the RSI rises above `70`.

```
rsiSignalNameEnding = '_RSI';

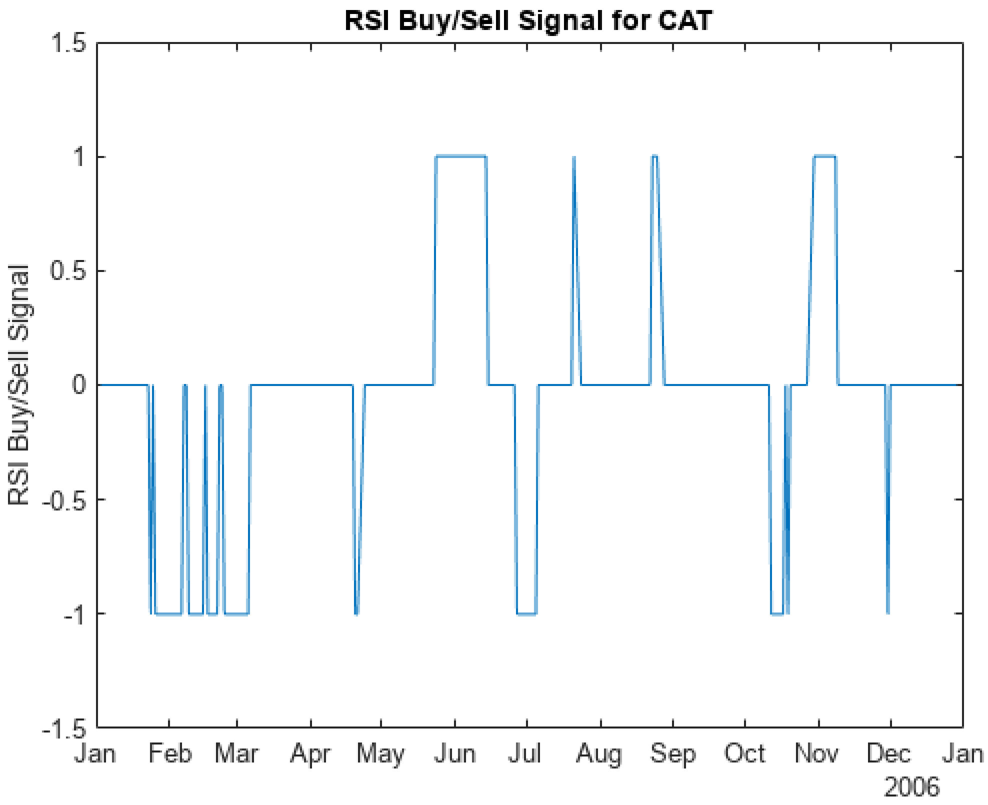
rsiSignal = timetable;
for i = 1:numel(symbols)
```

```
    symi = symbols(i);
    rsiValues = rsindex(pricesTT.(symi));
    rsiBuySell = zeros(size(rsiValues));
    rsiBuySell(rsiValues < 30) = 1;
    rsiBuySell(rsiValues > 70) = -1;
    % Build a timetable for each symbol, then aggregate the symbols together.
    rsiSignali = timetable(pricesTT.Dates,...
        rsiBuySell,...
        'VariableNames',{sprintf('%s%s',symi,rsiSignalNameEnding)});
    rsiSignal = synchronize(rsiSignal,rsiSignali);
end
```

The RSI signal takes a value of 1 (indicating a buy signal) when the RSI value for the stock falls below 30. The signal takes a value of -1 (indicating a sell signal) when the RSI for the stock rises above 70. Otherwise, the signal takes a value of 0, indicating no action.

Plot the signal for a single asset to preview the trading frequency.

```
plot(rsiSignal.Time,rsiSignal.CAT_RSI)
ylim([-1.5, 1.5]);
ylabel('RSI Buy/Sell Signal');
title(sprintf('RSI Buy/Sell Signal for CAT'));
```



Build the Strategies

Build the strategies for the backtestStrategy object using the rebalance functions defined in the Local Functions on page 4-254 section. Each strategy uses the rebalance function to make trading decisions based on the appropriate signals.

The signals require sufficient trailing data to compute the trading signals (for example, computing the SMA20 for day *X* requires prices from the 20 days prior to day *X*). All of the trailing data is captured in the precomputed trading signals. So the actual strategies need only a 2-day lookback window to make trading decisions to evaluate when the signals cross trading thresholds.

All strategies pay 25 basis points transaction costs on buys and sells.

The initial weights are computed based on the signal values after 20 trading days. The backtest begins after this 20 day initialization period.

```
tradingCosts = 0.0025;

% Use the crossoverRebalanceFunction for both the SMA
% strategy as well as the MACD strategy.  This is because they both trade
% on their respective signals in the same way (buy when signal goes from
% 0->1, sell when signal goes from 1->0).  Build an anonymous
% function for the rebalance functions of the strategies that calls the
% shared crossoverRebalanceFcn() with the appropriate signal name string
% for each strategy.

% Each anonymous function takes the current weights (w), prices (p),
% and signal (s) data from the backtest engine and passes it to the
% crossoverRebalanceFcn function with the signal name string.
smaInitWeights = computeInitialWeights(smaSignal(20,:));
smaRebalanceFcn = @(w,p,s) crossoverRebalanceFcn(w,p,s,smaSignalNameEnding);
smaStrategy = backtestStrategy('SMA',smaRebalanceFcn,...
    'TransactionCosts',tradingCosts,...
    'LookbackWindow',2,...
    'InitialWeights',smaInitWeights);

macdInitWeights = computeInitialWeights(macdSignal(20,:));
macdRebalanceFcn = @(w,p,s) crossoverRebalanceFcn(w,p,s,macdSignalNameEnding);
macdStrategy = backtestStrategy('MACD',macdRebalanceFcn,...
    'TransactionCosts',tradingCosts,...
    'LookbackWindow',2,...
    'InitialWeights',macdInitWeights);

% The RSI strategy uses its signal differently, buying on a 0->1
% transition and selling on a 0->-1 transition.  This logic is captured in
% the rsiRebalanceFcn function defined in the Local Functions section.
rsiInitWeights = computeInitialWeights(rsiSignal(20,:));
rsiStrategy = backtestStrategy('RSI',@rsiRebalanceFcn,...
    'TransactionCosts',tradingCosts,...
    'LookbackWindow',2,...
    'InitialWeights',rsiInitWeights);
```

Set Up Backtest

As a benchmark, this example also runs a simple equal-weighted strategy to determine if the trading signals are providing valuable insights into future returns of the assets. The benchmark strategy is rebalanced every four weeks.

```
% The equal weight strategy requires no history, so set LookbackWindow to 0.
benchmarkStrategy = backtestStrategy('Benchmark',@equalWeightFcn,...
    'TransactionCosts',tradingCosts,...
    'RebalanceFrequency',20,...
    'LookbackWindow',0);
```

Aggregate each of the individual signal timetables into a single backtest signal timetable.

```
% Combine the three signal timetables.
signalTT = timetable;
signalTT = synchronize(signalTT, smaSignal);
signalTT = synchronize(signalTT, macdSignal);
signalTT = synchronize(signalTT, rsiSignal);
```

Use `backtestEngine` to create the backtesting engine and then use `runBacktest` to run the backtest. The risk-free rate earned on uninvested cash is 1% annualized.

```
% Put the benchmark strategy and three signal strategies into an array.
strategies = [benchmarkStrategy smaStrategy macdStrategy rsiStrategy];
% Create the backtesting engine.
bt = backtestEngine(strategies,'RiskFreeRate',0.01)
```

```
bt = 
  backtestEngine with properties:

               Strategies: [1x4 backtestStrategy]
             RiskFreeRate: 0.0100
           CashBorrowRate: 0
          RatesConvention: "Annualized"
                    Basis: 0
    InitialPortfolioValue: 10000
           DateAdjustment: "Previous"
                NumAssets: []
                  Returns: []
                Positions: []
                 Turnover: []
                  BuyCost: []
                 SellCost: []
                     Fees: []
```

Backtest Strategies

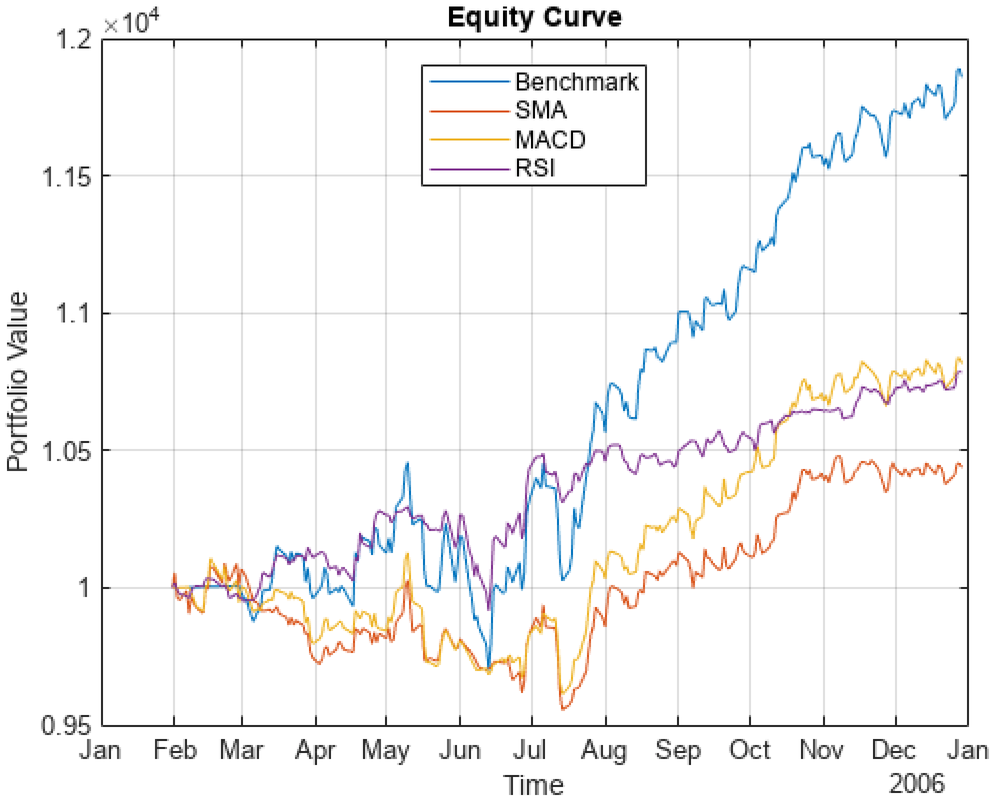
```
% Start with the end of the initial weights calculation warm-up period.
startIdx = 20;

% Run the backtest.
bt = runBacktest(bt,pricesTT,signalTT,'Start',startIdx);
```

Examine Backtest Results

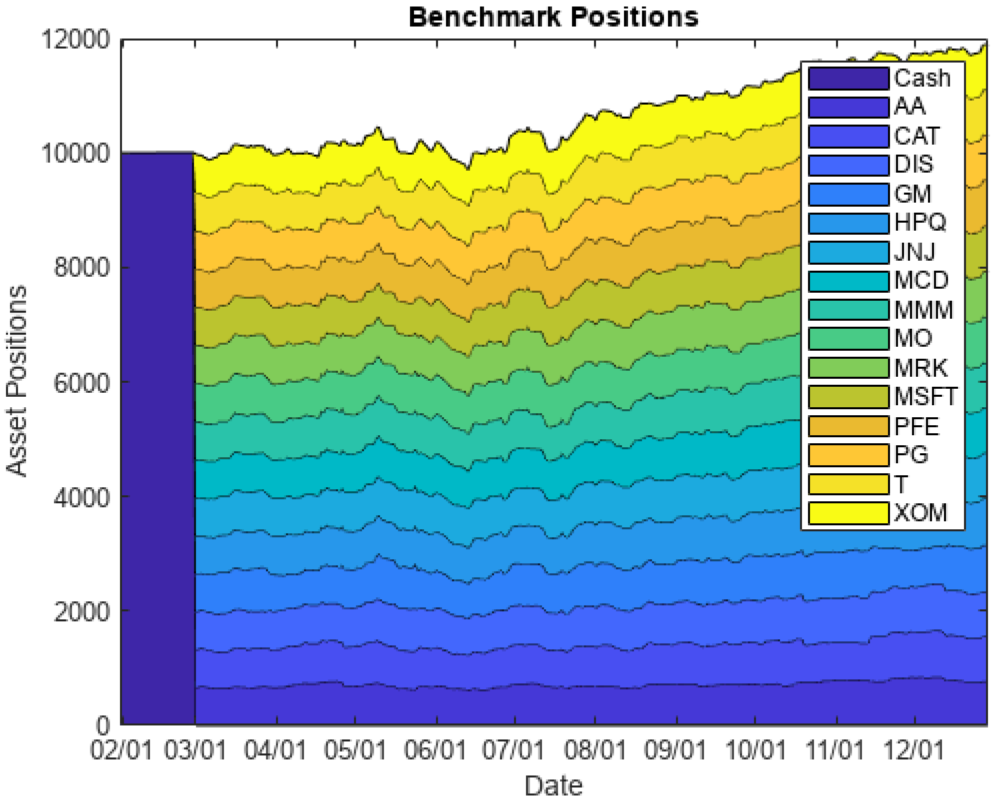
Use `equityCurve` to plot the strategy equity curves to visualize their performance over the backtest.

```
equityCurve(bt)
```



As mentioned previously, these strategies are not typically used as standalone trading signals. In fact, these three strategies perform worse than the simple benchmark strategy for the 2006 timeframe. You can visualize how the strategy allocations change over time using an area chart of the daily asset positions. To do so, use the `assetAreaPlot` helper function, defined in the Local Functions on page 4-254 section.

```
strategyName = Equal Weighted ;
assetAreaPlot(bt,strategyName)
```



Conclusion

The broad equity market had a very bullish 6 months in the second half of 2006 and all three of these strategies failed to fully capture that growth by leaving too much capital in cash. While none of these strategies performed well on their own, this example demonstrates how you can build signal-based trading strategies and backtest them to assess their performance.

Local Functions

The initial weight calculation function as well as the strategy rebalancing functions follow.

```
function initial_weights = computeInitialWeights(signals)
% Compute initial weights based on most recent signal.

nAssets = size(signals,2);
final_signal = signals{end,:};
buys = final_signal == 1;
initial_weights = zeros(1,nAssets);
initial_weights(buys) = 1 / nAssets;

end

function new_weights = crossoverRebalanceFcn(current_weights, pricesTT, signalTT, signalNameEndi
% Signal crossover rebalance function.

% Build cell array of signal names that correspond to the crossover signals.
symbols = pricesTT.Properties.VariableNames;
```

```
signalNames = cellfun(@(s) sprintf('%s%s',s,signalNameEnding), symbols, 'UniformOutput', false);

% Pull out the relevant signal data for the strategy.
crossoverSignals = signalTT(:,signalNames);

% Start with our current weights.
new_weights = current_weights;

% Sell any existing long position where the signal has turned to 0.
idx = crossoverSignals{end,:} == 0;
new_weights(idx) = 0;

% Find the new crossovers (signal changed from 0 to 1).
idx = crossoverSignals{end,:} == 1 & crossoverSignals{end-1,:} == 0;

% Bet sizing, split available capital across all remaining assets, and then
% invest only in the new positive crossover assets.  This leaves some
% proportional amount of capital uninvested for future investments into the
% zero-weight assets.
availableCapital = 1 - sum(new_weights);
uninvestedAssets = sum(new_weights == 0);
new_weights(idx) = availableCapital / uninvestedAssets;

end

function new_weights = rsiRebalanceFcn(current_weights, pricesTT, signalTT)
% Buy and sell on 1 and -1 rebalance function.

signalNameEnding = '_RSI';

% Build cell array of signal names that correspond to the crossover signals.
symbols = pricesTT.Properties.VariableNames;
signalNames = cellfun(@(s) sprintf('%s%s',s,signalNameEnding), symbols, 'UniformOutput', false);

% Pull out the relevant signal data for the strategy.
buySellSignals = signalTT(:,signalNames);

% Start with the current weights.
new_weights = current_weights;

% Sell any existing long position where the signal has turned to -1.
idx = buySellSignals{end,:} == -1;
new_weights(idx) = 0;

% Find the new buys (signal is 1 and weights are currently 0).
idx = new_weights == 0 & buySellSignals{end,:} == 1;

% Bet sizing, split available capital across all remaining assets, and then
% invest only in the new positive crossover assets.  This leaves some
% proportional amount of capital uninvested for future investments into the
% zero-weight assets.
availableCapital = 1 - sum(new_weights);
uninvestedAssets = sum(new_weights == 0);
new_weights(idx) = availableCapital / uninvestedAssets;

end
```

```
function new_weights = equalWeightFcn(current_weights,~)
% Equal-weighted portfolio allocation.

nAssets = numel(current_weights);
new_weights = ones(1,nAssets);
new_weights = new_weights / sum(new_weights);

end

function assetAreaPlot(backtester,strategyName)
% Plot the asset allocation as an area plot.

t = backtester.Positions.(strategyName).Time;
positions = backtester.Positions.(strategyName).Variables;
h = area(t,positions);
title(sprintf('%s Positions',strrep(strategyName,'_',' ')));
xlabel('Date');
ylabel('Asset Positions');
datetick('x','mm/dd','keepticks');
xlim([t(1) t(end)])
oldylim = ylim;
ylim([0 oldylim(2)]);
cm = parula(numel(h));
for i = 1:numel(h)
    set(h(i),'FaceColor',cm(i,:));
end
legend(backtester.Positions.(strategyName).Properties.VariableNames)

end
```

Portfolio Optimization Using Social Performance Measure

Use a `Portfolio` object to minimize the variance, maximize return, and maximize the average percentage of women on a company's board. The same workflow can be applied with other Environmental, Social and Governance (ESG) criteria, such as an ESG score, a climate, or a temperature score.

The goal of this example is to find portfolios that are effcient in the sense that they minimize the variance, maximize return, and maximize the average percentage of women on the board of directors. To find the average percentage of women on a company's board (`WoB`) for a given portfolio, this example uses a weighted sum of the percentages of `WoB` for each individual asset, where the weights are given by the amount invested in each asset for the portfolio. By defining the average percentage of `WoB` this way, the `WoB` function is linear with respect to the weights.

Load Portfolio Data

```
load CAPMuniverse
% Assume that the percentage of women on the board of directors per
% company are as follows
WoB = [0.2857; 0.5; 0.3; 0.2857; 0.3077; 0.2727; ...
    0.4167; 0.2143; 0.3; 0.4167; 0.3077];
table(WoB,'VariableNames',{'WoB'},'RowNames',Assets(1:11))
```

```
ans=11×1 table
               WoB  
             ______

    AAPL     0.2857
    AMZN        0.5
    CSCO        0.3
    DELL     0.2857
    EBAY     0.3077
    GOOG     0.2727
    HPQ      0.4167
    IBM      0.2143
    INTC        0.3
    MSFT     0.4167
    ORCL     0.3077
```

Create `Portfolio` Object

Create a standard `Portfolio` object and incorporate the list of assets and estimate the moments of the assets' returns from the data. Use `setDefaultConstraints` to set the default mean-variance portfolio constraints. These constraints require fully invested, long-only portfolios where the nonnegative weights must sum to `1`.

```
% Create portfolio with default constraints
p = Portfolio('AssetList',Assets(1:11));
p = estimateAssetMoments(p, Data(:,1:11));
p = setDefaultConstraints(p);
```

Set Group Constraints

Use getGroups to include group contraints. The first group constraint ensures that the weights invested in mixed retail (Amazon and eBay) are at least 15%. The second group constraint ensures that the weights invested in computer companies (Apple, Dell and HP) are between 25% and 50%.

```
% Group constraints
G = [0 1 0 0 1 0 0 0 0 0 0;
     1 0 0 1 0 0 1 0 0 0 0];
LowG = [0.15; 0.25];
UpG = [Inf; 0.5];
p = setGroups(p, G, LowG, UpG);
```

Find the minimum and maximum percentage of WoB that a portfolio can attain given these extra group constraints. This is done using the estimateCustomObjectivePortfolio function with the average percentage of women on a company's board as the objective function.

```
% Set average WoB as the objective
objFun = @(x) WoB'*x;
```

Find the portfolio with the minimum average percentage of WoB with the group constraints using estimateCustomObjectivePortfolio with the function handle objFun.

```
% Minimum percetage of women on the board
wgt_minWoB = estimateCustomObjectivePortfolio(p,objFun);
minWoB = objFun(wgt_minWoB)
```

```
minWoB = 0.2462
```

Find the portfolio with the maximum average percentage of WoB with the group constraints using estimateCustomObjectivePortfolio with the name-value argument ObjectiveSense set to maximize.

```
% Maximum percentage of women on the board
wgt_maxWoB = estimateCustomObjectivePortfolio(p,objFun,...
    ObjectiveSense="maximize");
maxWoB = objFun(wgt_maxWoB)
```

```
maxWoB = 0.4792
```

Compute and Plot the Efficient Surface

Define a grid of WoB percentages such that minWoB = targetWoB(1) ≤ ... ≤ targetWoB(N) = maxWoB.

```
N = 20; % Size of grid
targetWoB = linspace(minWoB,maxWoB,N);
```

Use setInequality to set the percentage of WoB as a constraint. The coefficients of the linear constraint should be the WoB percentages associated to each asset, and the right-hand side should be the target portfolio WoB. The convention of the inequality is ≤. Since the goal is to maximize portfolio WoB, then the target WoB should be a lower bound for the portfolio WoB. Therefore, the signs of the coefficients and the right-hand side of the added inequality should be flipped.

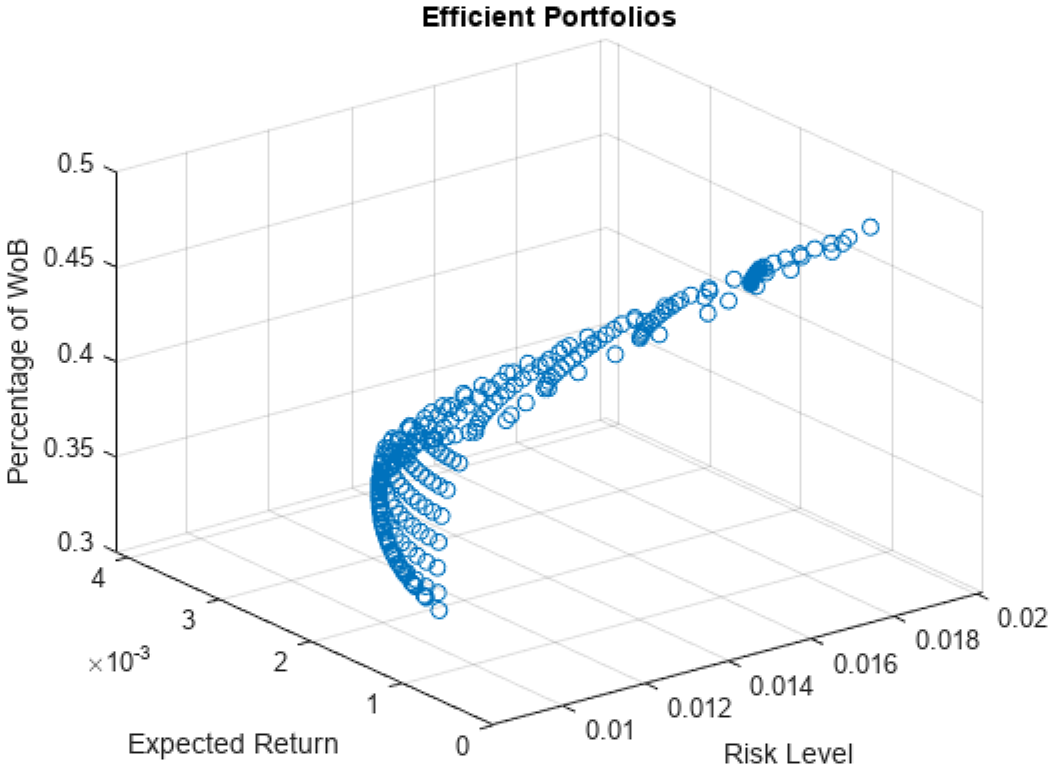
```
Ain = -WoB';
bin = -minWoB; % Start with the smallest WoB
p = setInequality(p,Ain,bin);
```

For each target WoB, targetWoB(i), find the efficient mean-variance frontier using estimateFrontier. At each iteration, the right-hand side of the WoB portfolio constraint should be changed to ensure that the returned portfolios achieve at least the target WoB. This method returns the weights of the portfolios on the mean-variance efficient frontier that have a WoB of at least targetWoB(i). Using the weights obtained for each target WoB, compute the portfolios' expected return, risk, and percentage of WoB.

```
% Get efficient surface values
prsk = cell(N,1);
pret = cell(N,1);
pWoB = cell(N,1);
for i = 1:N
    p.bInequality = -targetWoB(i);
    pwgt = estimateFrontier(p,N);
    [prsk{i},pret{i}] = estimatePortMoments(p,pwgt);
    pWoB{i} = pwgt'*WoB;
end
```

Plot the efficient portfolios.

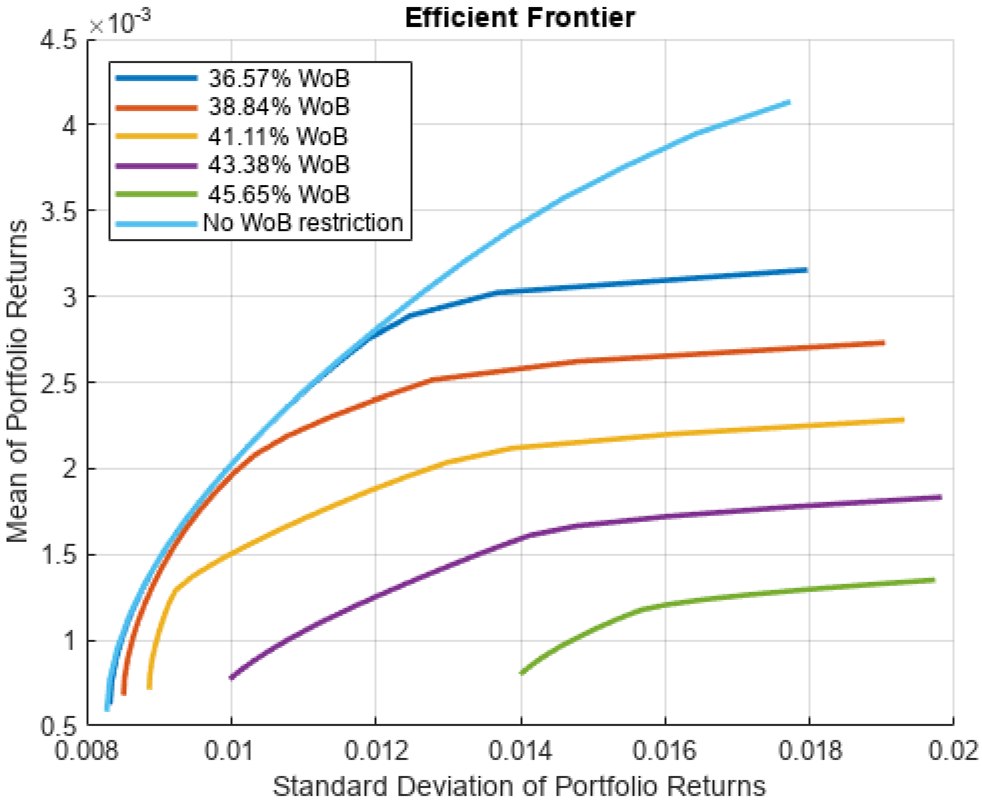
```
% Plot efficient surface
scatter3(cell2mat(prsk),cell2mat(pret),cell2mat(pWoB))
title('Efficient Portfolios')
xlabel('Risk Level')
ylabel('Expected Return')
zlabel('Percentage of WoB')
```



To visualize the tradeoff between a portfolio's average percentage of `WoB` and the traditional mean-variance efficient frontier, a set of contour plots are computed for some target `WoB` percentages using the `plotContours` function in Local Functions on page 4-262.

```
nC = 5; % Number of contour plots
minContour = max(pWoB{1}); % WoB values lower than this return
                           % overlapped contours.

% Plot contours
plotContours(p,minContour,maxWoB,nC,N)
```



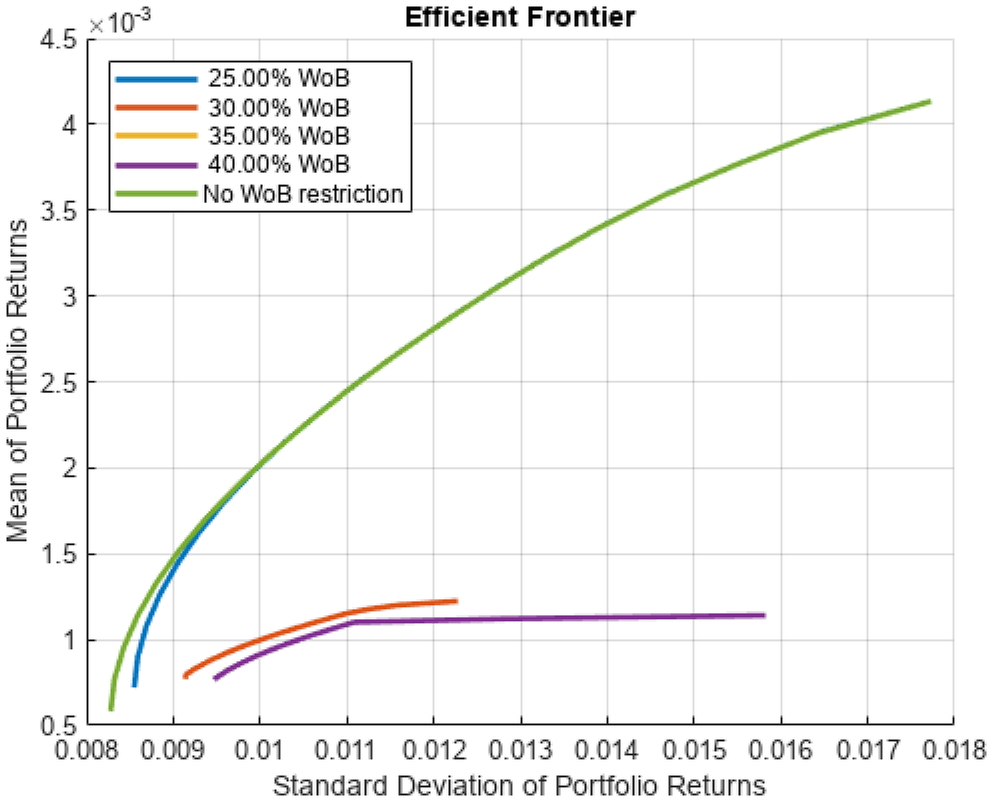
Exclusion Examples

Instead of requiring a specific level for the portfolio's average percentage of `WoB`, the goal is to find the traditional mean-variance efficient frontiers while excluding assets that have a percentage of WoB lower than a given threshold. You can plot the exclusion using the `plotExclusionExample` function in Local Functions on page 4-262.

```
% Remove the average percetage of WoB constraint
p.AInequality = []; p.bInequality = [];

% Set of thresholds for excluding assets
thresholdWoB = 0.25:0.05:0.40;

% Plot exclusion example
plotExclusionExample(p,WoB,thresholdWoB,N)
```



The differences between this approach and the one presented in the previous section are quite evident. Requiring all the assets to have a `WoB` percentage of at least 35% gives an efficient frontier that can achieve a return of at most around $1.2(10)^{-3}$. On the other hand, requiring only that the portfolio's average percentage of `WoB` is 36.57% gives the possibility to reach a return of around $3.2(10)^{-3}$, almost 2.5 times the return obtained when excluding assets. To better show the diffences between these two approaches, compute the maximum return achieved for a given standard deviation for the two ways of including the percentage of `WoB` requirements to the portfolio.

Approach 1

In the first approach, exclude all assets with a `WoB` percentage lower than 33% and find the portfolio of maximum return that has a standard deviation of at most `0.012`.

```
% Select assets to exclude
ub = zeros(p.NumAssets,1);
ub(WoB >= 0.33) = 1;
p.UpperBound = ub;
% Estimate the return for a risk level of 0.012
pwgt_exclude = estimateFrontierByRisk(p,0.012);
ret_exclude = estimatePortReturn(p,pwgt_exclude)
```

```
ret_exclude = 0.0011
```

```
% Return constraints to the original portfolio
p.UpperBound = [];
```

Approach 2

For the second approach, ensure that the average `WoB` percentage is of at least 33% and find the portfolio of maximum return that has a standard deviation of at most `0.012`.

```
% Include WoB constraint into the portfolio
p = addInequality(p,-WoB',-0.33);
% Estimate the return for a risk level of 0.012
pwgt_avgWoB = estimateFrontierByRisk(p,0.012);
ret_avgWoB = estimatePortReturn(p,pwgt_avgWoB)
```

```
ret_avgWoB = 0.0028
```

```
% Return constraints to the original portfolio
p.AInequality = []; p.bInequality = [];
```

Compute the increase in return between these two approaches.

```
ret_increase = (ret_avgWoB-ret_exclude)/ret_exclude
```

```
ret_increase = 1.5202
```

This `ret_increase` value shows that the return from the approach that only bounds the portfolio's average WoB percentage instead of excluding certain assets has a return 152% higher (for the same risk level). Hence, when tackling problems with more than two objectives, excluding assets that do not meet a certain criteria might not be the best option. Instead, a weighted sum of the criteria of interest might show better results.

Local Functions

```
function [] = plotContours(p,minWoB,maxWoB,nContour,nPort)

% Set of WoB levels for contour plot
contourWoB = linspace(minWoB,maxWoB,nContour+1);

% Compute and plot efficient frontier for each value in contourWoB
figure;
hold on
labels = strings(nContour+1,1);
for i = 1:nContour
    p.bInequality = -contourWoB(i);
    plotFrontier(p,nPort);
    labels(i) = sprintf("%6.2f%% WoB",contourWoB(i)*100);
end
% Plot the "original" mean-variance frontier, i.e., the frontier
% without WoB requierements
p.AInequality = []; p.bInequality = [];
plotFrontier(p,nPort);
labels(i+1) = "No WoB restriction";
legend(labels,'Location','northwest')
hold off

end

function [] = plotExclusionExample(p,WoB,thresholdWoB, ...
    nPort)

% Compute and plot efficient frontier excluding assets that are below
% the WoB threshold
nT = length(thresholdWoB);
figure;
hold on
labels = strings(nT+1,1);
for i=1:nT
    ub = zeros(p.NumAssets,1);
    % Only select assets above WoB threshold
    ub(WoB >= thresholdWoB(i)) = 1;
    p.UpperBound = ub;
    plotFrontier(p,nPort);
    labels(i) = sprintf("%6.2f%% WoB",thresholdWoB(i)*100);
end
% Plot the "original" mean-variance frontier, i.e., the frontier
% without the WoB threshold
p.UpperBound = [];
plotFrontier(p,nPort);
labels(i+1) = "No WoB restriction";
legend(labels,'Location','northwest')
hold off

end
```

Diversify ESG Portfolios

This example shows how to include qualitative factors for environmental, social, and corporate governance (ESG) in the portfolio selection process. The example extends the traditional mean-variance portfolio using a Portfolio object to include the ESG metric. First, the estimateFrontier function computes the mean-variance efficient frontier for different ESG levels. Then, the example illustrates how to combine the ESG performance measure with portfolio diversification techniques. Specifically, it introduces hybrid models that use the Herfindahl-Hirshman (HH) index and the most diversified portfolio (MDP) approach using the estimateCustomObjectivePortfolio function. Finally, the backtestEngine framework compares the returns and behavior of the different ESG strategies.

Define Mean-Variance Portfolio

Load the table with the asset returns and a vector with ESG scores for the assets. Both the asset returns and their ESG scores are simulated values and do not represent the performance of any real securities. Hower, you can apply the code and workflow in this example to any data set with prices and returns and ESG information.

```
% Load data
load('asset_return_100_simulated.mat') % Returns table
load('ESG_s26.mat')                    % ESG scores
```

Transform the returns table into a prices timetable.

```
% Transform returns to prices
assetPrices = ret2tick(stockReturns);
% Transform prices table to timetable
nRows = size(stockReturns,1);
day = datetime("today");
Time = (day-nRows):day;
assetPrices = table2timetable(assetPrices,"RowTimes",Time);
```

Define a Portfolio object with default constraints where the weights must be nonnegative and sum to 1.

```
% Create a mean-variance Portfolio object with default constraints
p = Portfolio;
p = estimateAssetMoments(p,stockReturns);
p = setDefaultConstraints(p);
```

Compute the Mean-Variance Efficient Frontier for Different ESG Levels

Obtain contour plots of the ESG-mean-variance efficient surface. You obtain the efficient surface from the Pareto optima of the multiobjective problem that includes all the performance metrics: average ESG score, average return, and return variance.

First, obtain feasible values of the ESG metric by finding the minimum and maximum ESG levels. To do this step, use the estimateCustomObjectivePortfolio function assigning the average ESG score as the objective function. The average ESG score of a portfolio is the weighted sum of the individual asset ESG scores, where the weights are given by the amount invested in each asset.

```
% Define objective function: average ESG score
ESGscore = @(x) ESGnumeric'*x;
```

```
% Find the minimum ESG score
solMin = estimateCustomObjectivePortfolio(p,ESGscore);
minESG = ESGscore(solMin)
```

```
minESG = 0.0187
```

```
% Find the maximum ESG score
solMax = estimateCustomObjectivePortfolio(p,ESGscore, ...
    ObjectiveSense="maximize");
maxESG = ESGscore(solMax)
```

```
maxESG = 0.9735
```

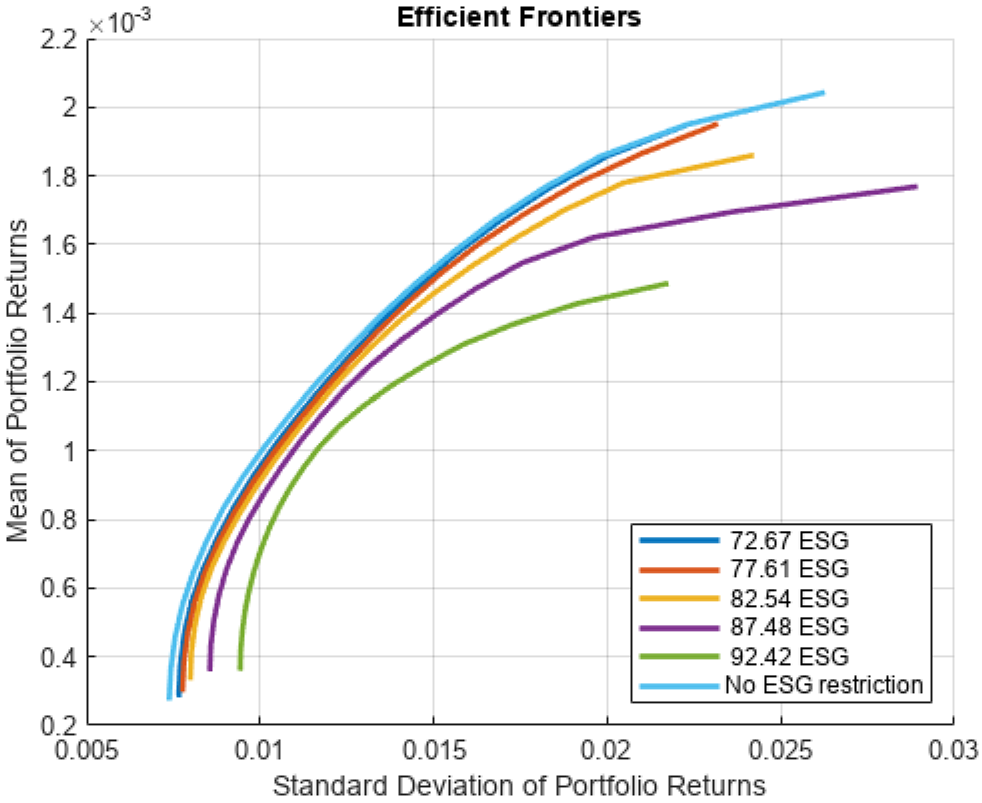
To compute the contours of the efficient surface, you add the average ESG score as a constraint using the `setInequality` function. The coefficients of the linear constraint are the ESG scores associated with each asset and the right-hand side is the target ESG score for the desired contour. Notice that the convention of the inequalities in the `Portfolio` object is ≤. Because the goal is to maximize the average ESG score, the target ESG value for the contour should be a lower bound. Therefore, you need to flip the signs of the coefficients and the right-hand side of the added inequality. The function that computes and plots the contours is in the Local Functions on page 4-276 section.

```
N = 20; % Number of efficient portfolios per ESG value

% Add ESG score as a constraint to the Portfolio object
Ain = -ESGnumeric';
bin = -minESG; % Start with the smallest ESG score
p = setInequality(p,Ain,bin);

% Esimate lower value for contour plots
pwgt = estimateFrontier(p,N);
pESG = pwgt'*ESGnumeric;
minContour = max(pESG); % All ESG scores lower than this have
                        % overlapped contours.

% Plot contours
nC = 5; % Number of contour plots
plotESGContours(p,ESGnumeric,minContour,maxESG,nC,N);
```



Diversification Techniques

In this example, the two diversification measures are the equally weighted (EW) portfolio and the most diversified portfolio (MDP).

You obtain the EW portfolio using the Herfindahl-Hirschman (HH) index as the diversification measure

$$\mathrm{HH}(x) = \sum_{i=1}^{n} x_i^2$$

An equally weighted portfolio minimizes this index. Therefore, the portfolios that you obtain from using this index as a penalty have weights that satisfy the portfolio constraints and are more evenly weighted.

The diversification measure for the most diversified portfolio (MDP) is

$$\mathrm{MDP}(x) = -\sum_{i=1}^{n} \sigma_i x_i$$

where σ_i represents the standard deviation of asset i. Using this measure as a penalty function maximizes the diversification ratio [1 on page 4-276].

$$\varphi(x) = \frac{x^T \sigma}{\sqrt{x^T \Sigma x}}$$

If the portfolio is fully invested in one asset, or if all assets are perfectly correlated, the diversification ratio $\varphi(x)$ is equal to 1. For all other cases, $\varphi(x) > 1$. Therefore, if $\varphi(x) \approx 1$, there is no diversification, so the goal is to maximize $\varphi(x)$. Unlike the HH index, the goal of MDP is not to obtain a portfolio whose weights are evenly distributed among all assets, but to obtain a portfolio whose selected (nonzero) assets have the same correlation to the portfolio as a whole.

Diversification for Fixed ESG Level

You can extend the traditional minimum variance portfolio problem subject to an expected return to inlcude the ESG metric by setting an ESG constraint for the problem. The purpose of the ESG constraint is to force the portfolio to achieve an ESG score greater than a certain target. Then, add a penalty term to the objective function to guide the problem toward more or less diversified portfolios. How diversified a portfolio is depends on your choice of the penalty parameter.

Choose an ESG level of `0.85` and an expected return of `0.001`.

```
% Minimum ESG and return levels
ESG0 = 0.85;
ret0 = 1e-3;
```

Currently, the portfolio problem assumes that the weights must be nonnegative and sum to 1. Add the requirement that the return of the portfolio is at least `ret0` and the ESG score is at least `ESG0`. The feasible set is represented as X, which is

$$X = \left\{ x \;\middle|\; x \geq 0,\ \sum_{i=1}^{n} x_i = 1,\ \mu^T x \geq ret_0,\ \mathrm{ESG}(x) \geq ESG_0 \right\}$$

Add the ESG constraint using the `setInequality` function.

```
% Add ESG constraint
Ain = -ESGnumeric';
bin = -ESG0; % Set target ESG score
p = setInequality(p,Ain,bin);
```

To add the return constraint, pass the name-value argument `TargetReturn=ret0` to the `estimateCustomObjectivePortfolio` function for each of the different custom objective portfolios of interest.

The portfolio that minimizes the variance with the HH penalty is

$$\min_{x \in X} \; x^T \Sigma x + \lambda_{\mathrm{HH}} x^T x$$

```
% HH penalty parameter
lambdaHH = 0.001 ;
% Variance + Herfindahl-Hirschman (HH) index
var_HH = @(x) x'*p.AssetCovar*x + lambdaHH*(x'*x);
% Solution that accounts for risk and HH diversification
wHHMix = estimateCustomObjectivePortfolio(p,var_HH,TargetReturn=ret0);
```

The portfolio that minimizes the variance with the MDP penalty is

$$\min_{x \in X} \; x^T \Sigma x - \lambda_{\mathrm{MDP}}\, \sigma^T x$$

```
% MDP penalty parameter
lambdaMDP = 0.01 ;
```

```
% Variance + Most Diversified Portfolio (MDP)
sigma = sqrt(diag(p.AssetCovar));
var_MDP = @(x) x'*p.AssetCovar*x - lambdaMDP*(sigma'*x);
% Solution that accounts for risk and MDP diversification
wMDPMix = estimateCustomObjectivePortfolio(p,var_MDP,TargetReturn=ret0);
```

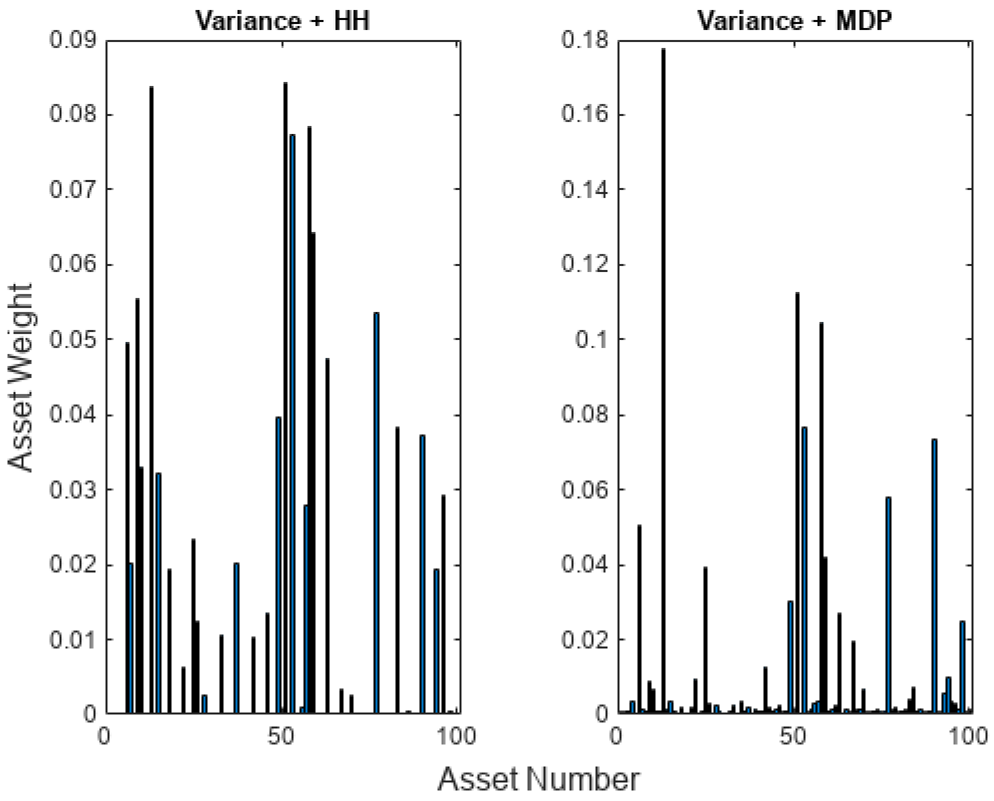
Plot the asset allocation from the penalized strategies.

```
% Plot asset allocation
figure
t = tiledlayout(1,2);

% HH penalized method
nexttile
bar(wHHMix');
title('Variance + HH')

% MDP penalized method
nexttile
bar(wMDPMix')
title('Variance + MDP')

% General labels
ylabel(t,'Asset Weight')
xlabel(t,'Asset Number')
```



The strategies that include the penalty function in the objective give weights that are between the minimum variance portfolio weights and the weights from the respective maximum diversification technique. In fact, for the problem with the HH penalty, choosing $\lambda_{\mathrm{HH}} = 0$ returns the minimum variance solution, and as $\lambda_{\mathrm{HH}} \to \infty$, the solution approaches the one that maximizes HH diversification. For the problem with the MDP penalty, choosing $\lambda_{\mathrm{MDP}} = 0$ also returns the minimum variance solution, and there exists a value $\widehat{\lambda}_{\mathrm{MDP}}$ such that the MDP problem and the penalized version are equivalent. Consequently, values of $\lambda_{\mathrm{MDP}} \in \left[0, \widehat{\lambda}_{\mathrm{MDP}}\right]$ return asset weights that range from the minimum variance behavior to the MDP behavior.

Diversification by "Tilting"

The strategies in Diversification for Fixed ESG Level on page 4-268 explicitly set a target ESG average score. However, a different set of strategies controls the ESG score in a less direct way. The method in these strategies uses ESG *tilting*. With tilting, you discretize the ESG score into `'high'` and `'low'` levels and the objective function penalizes each level differently. In other words, you use the diversification measure to tilt the portfolio toward higher or lower ESG values. Therefore, instead of explicitly requiring that the portfolios maintain a target ESG average score, you select assets, with respect to their ESG score, implicitly through the choice of penalty parameters.

Start by labeling the assets with an ESG score less than or equal to `0.5` as `'low'` and assets with an ESG score greater than `0.5` as `'high'`, and then remove the ESG constraint.

```
% Label ESG data
ESGlabel = discretize(ESGnumeric,[0 0.5 1], ...
    "categorical",{'low','high'});
% Create table with ESG scores and labels
ESG = table(ESGnumeric,ESGlabel);
% Remove ESG constraint
p = setInequality(p,[],[]);
```

The tilted version of the portfolio with the HH index is

$$\begin{aligned} &\min \;\; x^T \Sigma x + \lambda_{\mathrm{HH}}^{\mathrm{high}} \sum_{i \in H} x_i^2 + \lambda_{\mathrm{HH}}^{\mathrm{low}} \sum_{i \in L} x_i^2 \\ &\text{s.t.} \;\; \sum_{i=1}^{n} x_i = 1,\; \mu^T x \geq ret_0,\; x \geq 0 \end{aligned}$$

The feasible region does not bound the average ESG level of the portfolio. Instead, you implicitly control the ESG score by applying different penalization terms to assets with a `'high'` ESG score ($i \in H$) and assets with a `'low'` ESG score ($i \in L$). To achieve a portfolio with a high average ESG score, the penalty terms must satisfy that $0 \leq \lambda_{\mathrm{HH}}^{\mathrm{high}} \leq \lambda_{\mathrm{HH}}^{\mathrm{low}}$.

```
% HH penalty parameters
% Penalty parameter for assets with 'low' ESG score
lambdaLowHH =  0.01 ;
% Penalty parameter for assets with 'high' ESG score
lambdaHighHH =  0.001 ;
% Lambda for HH 'tilted' penalty
lambdaTiltHH = (ESG.ESGlabel=='low').*lambdaLowHH + (ESG.ESGlabel=='high').*lambdaHighHH;

% Variance + Herfindahl-Hirschman (HH) index
tilt_HH = @(x) x'*p.AssetCovar*x + lambdaTiltHH'*(x.^2);
% Solution that minimizes variance + HH term
wTiltHH = estimateCustomObjectivePortfolio(p,tilt_HH,TargetReturn=ret0);
```

Similarly, the tilted version of the portfolio with the MDP penalty term is given by

$$\begin{aligned}&\min\ \ x^T\Sigma x - \lambda_{\mathrm{MDP}}^{\mathrm{high}} \sum_{i\,\in\,H} \sigma_i x_i - \lambda_{\mathrm{MDP}}^{\mathrm{low}} \sum_{i\,\in\,L} \sigma_i x_i \\ &\mathrm{s.t.}\ \ \sum_{i\,=\,1}^{n} x_i = 1,\ \mu^T x \geq ret_0,\ x \geq 0\end{aligned}$$

In this case, to achieve a portfolio with a high average ESG score, the penalty terms must satisfy that $0 \leq \lambda_{\mathrm{MDP}}^{\mathrm{low}} \leq \lambda_{\mathrm{MDP}}^{\mathrm{high}}$.

```
% MDP penalty parameters
% Penalty parameter for assets with 'low' ESG score
lambdaLowMDP = 0.001 ;
% Penalty parameter for assets with 'high' ESG score
lambdaHighMDP = 0.01 ;
% Lambda for MDP 'tilted' penalty
lambdaTiltMDP = (ESG.ESGlabel=='low').*lambdaLowMDP + (ESG.ESGlabel=='high').*lambdaHighMDP;

% Variance + MDP index
tilt_MDP = @(x) x'*p.AssetCovar*x - lambdaTiltMDP'*(sigma.*x);
% Solution that minimizes variance + HH term
wTiltMDP = estimateCustomObjectivePortfolio(p,tilt_MDP,TargetReturn=ret0);
```

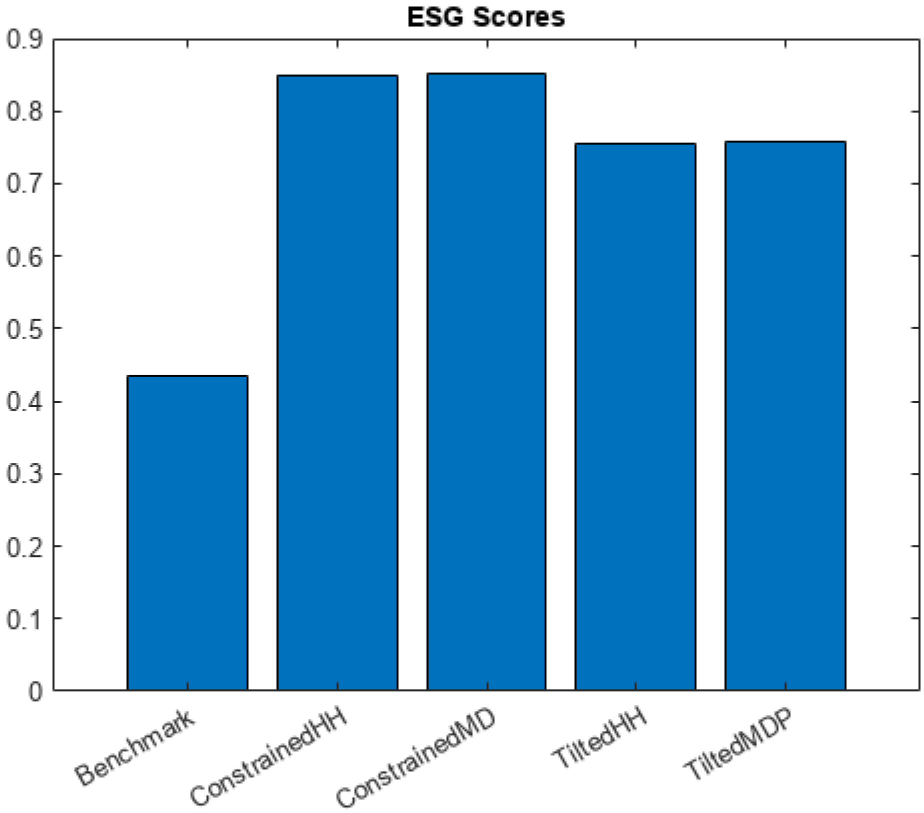
Compare ESG Scores

Compare the ESG scores using tilting and a target ESG constraint. For the comparison to be more meaningful, compute the minimum variance portfolio without ESG constraints or penalty terms, and use the ESG score of the minimum variance portfolio as benchmark.

```
% Compute the minimum variance portfolio without ESG constraints
p = setInequality(p,[],[]);
wBmk = estimateFrontierByReturn(p,ret0);

% Compute ESG scores for the different strategies
Benchmark = ESGnumeric'*wBmk;
ConstrainedHH = ESGnumeric'*wHHMix;
ConstrainedMD = ESGnumeric'*wMDPMix;
TiltedHH = ESGnumeric'*wTiltHH;
TiltedMDP = ESGnumeric'*wTiltMDP;

% Create table
strategiesESG = table(Benchmark,ConstrainedHH,ConstrainedMD,TiltedHH,TiltedMDP);
figure;
bar(categorical(strategiesESG.Properties.VariableNames),strategiesESG.Variables)
title('ESG Scores')
```



As expected, the ESG scores of the penalized strategies are better than the ESG scores of the minimum variance portfolio without constraint and penalty terms. However, the tilted strategies achieve lower ESG scores than the ones that include the target ESG score as a constraint. This comparison shows the flexibility of the tilted strategy. If the ESG target score is not an essential requirement, then you can consider a tilting strategy.

Backtest Using Strategies

To show the performance through time for the two strategies (Diversification for Fixed ESG Level on page 4-268 and Diversification by "Tilting" on page 4-270), use the `backtestEngine` framework. Use `backtestStrategy` to compare the strategies with a prespecified target ESG score with the strategies that use ESG tilting.

```
% Store info to pass to ESG constrained strategies
Ain = -ESGnumeric';
bin = -ESG0; % Set target ESG score
conStruct.p = setInequality(p,-ESGnumeric',-ESG0);
conStruct.ret0 = ret0;
conStruct.lambdaHH = 0.01 ;
conStruct.lambdaMDP = 0.05 ;

% Store info to pass to ESG tilting strategies
tiltStruct.p = setInequality(p,[],[]);
tiltStruct.ret0 = ret0;
% HH tilting penalty parameters
% Penalty parameter for assets with 'low' ESG score
HHlambdaLow = 0.1;
% Penalty parameter for assets with 'high' ESG score
HHlambdaHigh = 0.01;
% Combined penalty terms for HH
tiltStruct.lambdaHH = (ESG.ESGlabel=='low').*HHlambdaLow + ...
    (ESG.ESGlabel=='high').*HHlambdaHigh;
% MDP tilting penalty parameters
% Penalty parameter for assets with 'low' ESG score
MDPlambdaLow = 0.005;
% Penalty parameter for assets with 'high' ESG score
MDPlambdaHigh = 0.05;
% Combined penalty terms for MDP
tiltStruct.lambdaMDP = (ESG.ESGlabel=='low').*MDPlambdaLow + ...
    (ESG.ESGlabel=='high').*MDPlambdaHigh;
```

Define the investment strategies that you want to use to make the asset allocation decisions at each investment period. For this example, four investment strategies are defined as input to `backtestStrategy`. The first two strategies require a minimum ESG score and the last two use the ESG tilting method.

```
% Define backtesting parameters
warmupPeriod = 84;       % Warmup period
rebalFreq = 42;          % Rebalance frequency
lookback  = [42 126];     % Lookback window
transactionCost = 0.001; % Transaction cost for trade
% Constrained variance + HH strategy
strat1 = backtestStrategy('MixedHH', @(w,P) MixHH(w,P,conStruct), ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', transactionCost, ...
    'InitialWeights', wHHMix);
% Constrained variance + MDP
strat2 = backtestStrategy('MixedMDP', @(w,P) MixMDP(w,P,conStruct), ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', transactionCost, ...
    'InitialWeights', wMDPMix);
% HH tilted strategy
strat3 = backtestStrategy('TiltedHH', @(w,P) tiltedHH(w,P,tiltStruct), ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', transactionCost, ...
    'InitialWeights', wTiltHH);
% MDP tilted strategy
strat4 = backtestStrategy('TiltedMDP', @(w,P) tiltedMDP(w,P,tiltStruct), ...
    'RebalanceFrequency', rebalFreq, ...
    'LookbackWindow', lookback, ...
    'TransactionCosts', transactionCost, ...
    'InitialWeights', wTiltMDP);
% All strategies
strategies = [strat1,strat2,strat3,strat4];
```

Run the backtest using `runBacktest` and generate a `summary` for each strategy's performance results.

```
% Create the backtesting engine object
backtester = backtestEngine(strategies);
% Run backtest
backtester = runBacktest(backtester,assetPrices,...
    'Start',warmupPeriod);

% Summary
summary(backtester)
```

```

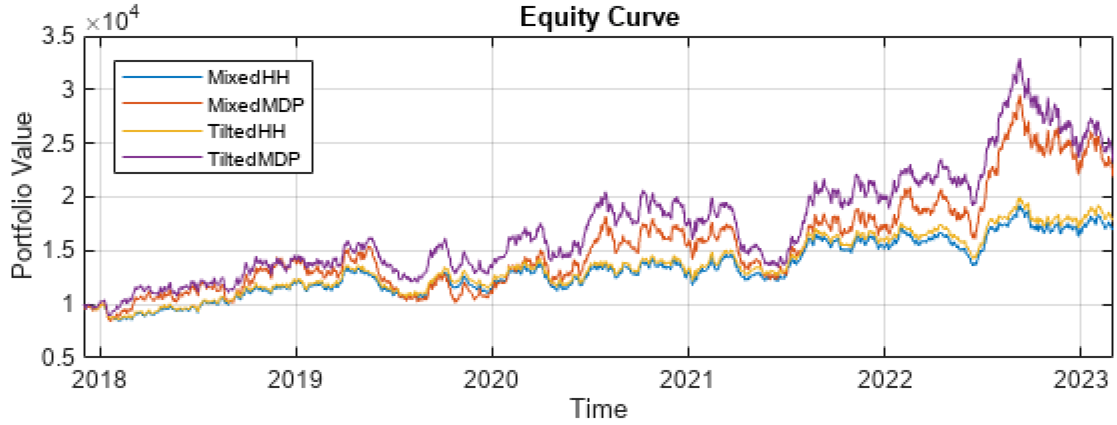
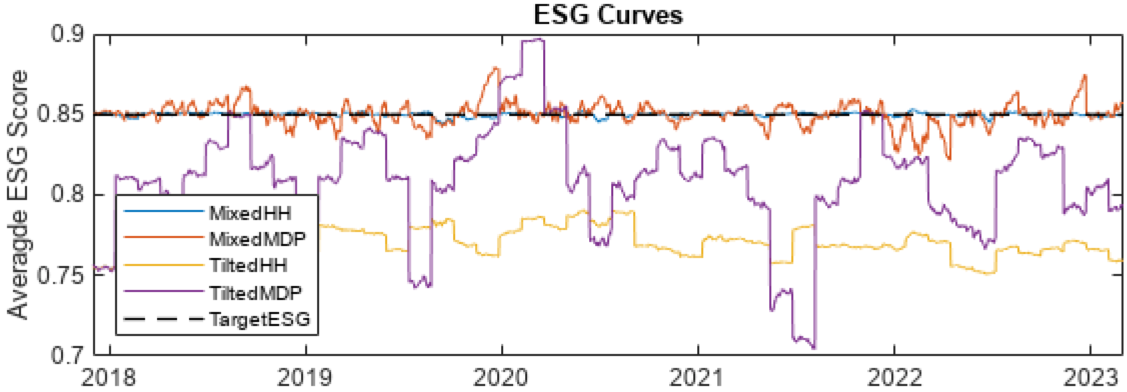
To visualize their performance over the entire investment period, plot the daily results of the strategies using `equityCurve`.

```
% Plot daily stocks and ESG strategy behavior
figure
t = tiledlayout(2,1,'Padding','none');

% Equity curves
nexttile(t)
equityCurve(backtester);

% Table and plot of the average ESG score for the mixed and tilted
% strategies throughout the investment period
nexttile(t)
TAvgESG = averageESGTimetable(backtester,ESGnumeric,ESG0);
```





In the Equity Curve plot, the tilted MDP strategy is the one that performs the best by the end of the investment period, followed by the mixed MDP strategy with the ESG constraint. The performance of the mixed and tilted strategies depend on the choice of the penalty parameters. Both ESG methods, the constrained and the tilted methods, require defining two parameters for each strategy. The ESG constrained method requires you to provide a target ESG score and a penalty parameter for the diversification term. The ESG tilting requires one penalty parameter value for the assets with `'high'` ESG scores and a different one for `'low'` ESG scores. In addition, the ESG tilting requires a third parameter to determine the cutoff point between `'high'` and `'low'` ESG assets. Given the dependency of the penalized strategies on the value of their parameters, the performance of those strategies vary widely. However, this example shows that it is possible to find values of the parameters so that the resulting strategies obtain good returns while improving on the average ESG score.

The ESG Curves plot shows the average ESG evolution computed throughout the investment period for the penalized investment strategies, both for the ESG constrained method and the ESG tilting method. You can see that, unlike the choice of the ESG target for the ESG constraint, the selection of the tilting penalty parameters has an effect on the ESG score of the optimal portfolios that is less explicit. Therefore, the average ESG score varies more with the tilting strategies than with the constrained strategies, as expected.

Although not shown in this example, the traditional minimum variance portfolio strategy, subject to the same expected return and ESG levels, results in higher average turnover and transaction costs than any of the strategies covered in the example. Another advanvange of adding a diversification measure to the formulation of the problem is to reduce the average turnover and transaction costs.

Risk Budgeting Portfolio

This example shows how to use `riskBudgetingPortfolio` to create a risk budgeting portfolio and `portfolioRiskContribution` to compute the risk contribution of the assets in the portfolio.

Risk budgeting is a portfolio allocation strategy that focuses on the allocation of risk to define the weights of a portfolio. The risk budgeting portfolio is constructed by ensuring that the risk contribution of each asset to the portfolio overall risk matches a target risk budget.

A common risk budgeting porfolio is the risk parity or equal risk contribution portfolio. For risk parity portfolios, the goal is to ensure that all assets contribute equally to the portfolio risk, that is, the target risk budget is the same for all assets. Key advantages of the risk budgeting portfolio are stability and diversification of weights:

- **Stability of the allocations**: The weights of the risk parity portfolio are more robust to changes in the returns covariance than the weights of the mean-variance portfolio.
- **Diversification of the portfolio weights**: The risk parity portfolio keeps the portfolio from concentrating in just a few number of assets.

This example follows the example in Section 3.1.1 of Bruder and Roncalli.[1 on page 4-284]

Define the Asset Returns Covariance

Define the covariance matrix of the asset returns (`Sigma`). `Sigma` must be a positive semidefinite matrix.

```
% Define the returns covariance matrix.
sigma = [0.2; 0.21; 0.1];      % Assets risk
rho = 0.8;                     % Assets correlation
C = @(rho) [  1  rho  rho;
            rho    1  rho;
            rho  rho    1 ];    % Uniform correlation
Sigma = corr2cov(sigma,C(rho)); % Covariance
% Check that Sigma is positive semidefinite. All
% eigenvalues should be nonnegative (>= 0).
eig(Sigma)
```

```
ans = 3×1

    0.0026
    0.0084
    0.0831
```

Create Risk Budgeting Portfolio

Use `riskBudgetingPortfolio` with the covariance matrix (`Sigma`) and a vector of risk budgets (`budget`) to compute the long-only fully invested risk budgeting portfolio. When you omot the target risk budget, the function computes the risk parity portfolio.

```
% Define a risk budget.
budget = [0.5; 0.25; 0.25];
wRB = riskBudgetingPortfolio(Sigma,budget)
```

```
wRB = 3×1
```

```
    0.3912
    0.1964
    0.4124
```

Compute Risk Contribution for Each Asset

Use `portfolioRiskContribution` to check that the risk contribution of the portfolio obtained in `wRB` matches the target risk budget. By default, `portfolioRiskContribution` computes the relative risk contribution of a given portfolio (`wRB`) with respect to the provided covariance matrix (`Sigma`).

```
prc = portfolioRiskContribution(wRB,Sigma)
```

```
prc = 3×1

    0.5000
    0.2500
    0.2500
```

As expected, the risk contribution of each asset matches the target risk budget (`budget`). You can also use `portfolioRiskContribution` to compute the absolute risk contribution of each asset.

```
mrc = portfolioRiskContribution(wRB,Sigma,RiskContributionType="absolute")
```

```
mrc = 3×1

    0.0751
    0.0376
    0.0376
```

Compare Risk Budgeting Portfolios with Mean-Variance

While the allocation strategy of the risk budgeting portfolio focuses only on the risk, the allocation strategy of the mean-variance portfolio also makes use of the assets' return information.

```
% Define the returns mean.
mu = [0.08; 0.08; 0.05];
```

Initialize a `Portfolio` object with default constraints using `Sigma` and `mu`.

```
% Define the mean-variance portfolio.
p = Portfolio(AssetMean=mu,AssetCovar=Sigma);
p = setDefaultConstraints(p);
```

Compute the portfolio on the efficient frontier with a target volatility equal to the risk attained by the risk budgeting portfolio previously computed as `wRB`.

```
% Define the target volatility.
targetRisk = sqrt(wRB'*Sigma*wRB);
wMV = estimateFrontierByRisk(p,targetRisk)
```

```
wMV = 3×1

    0.3846
    0.2030
    0.4124
```

Assume that the correlation between the assets is `0.7` instead of `0.8`. Use the new covariance matrix (`Sigma7`) to compute the same mean-variance and risk budgeting portfolios.

```
% Update the covariance matrix.
Sigma7 = corr2cov(sigma,C(0.7));
% Compute the mean-variance portfolio.
p = Portfolio(AssetMean=mu,AssetCovar=Sigma7);
p = setDefaultConstraints(p);
wMV_rho7 = estimateFrontierByRisk(p,targetRisk)
```

```
wMV_rho7 = 3×1

    0.3841
    0.2600
    0.3559
```

```
% Compute the risk budgeting portfolio.
wRB_rho7 = riskBudgetingPortfolio(Sigma7,budget)
```

```
wRB_rho7 = 3×1

    0.3844
    0.1986
    0.4170
```

What if the correlation is `0.9` instead of `0.8` (`Sigma9`) and the risk of the second asset is `0.18` instead of `0.21`?

```
% Update the covariance matrix.
sigma2 = sigma;
sigma2(2) = 0.18;
Sigma9 = corr2cov(sigma2,C(0.9));
% Compute the mean-variance portfolio.
p = Portfolio(AssetMean=mu,AssetCovar=Sigma9);
p = setDefaultConstraints(p);
wMV_rho9 = estimateFrontierByRisk(p,targetRisk)
```

```
wMV_rho9 = 3×1

         0
    0.6612
    0.3388
```

```
% Compute the risk budgeting portfolio.
wRB_rho9 = riskBudgetingPortfolio(Sigma9,budget)
```

```
wRB_rho9 = 3×1

    0.3852
    0.2196
    0.3952
```

What if the original covariance (`Sigma`) is correct, but the mean of the first asset is `0.09` instead of `0.08`?

```
% Update the returns vector.
mu1 = mu;
mu1(1) = 0.09;
% Compute the mean-variance portfolio.
p = Portfolio(AssetMean=mu1,AssetCovar=Sigma);
p = setDefaultConstraints(p);
wMV_mu1 = estimateFrontierByRisk(p,targetRisk)
```

```
wMV_mu1 = 3×1

    0.5664
         0
    0.4336
```

```
% Compute the risk budgeting portfolio.
wRB_mu1 = riskBudgetingPortfolio(Sigma,budget)
```

```
wRB_mu1 = 3×1

    0.3912
    0.1964
    0.4124
```

The weights of the risk budgeting portolio are more stable than those of the mean-variance portfolio. When the change is in the expected returns, the risk budgeting portfolio remains the same as in the original problem. The risk budgeting portfolio accounts only for changes to the covariance matrix and a change in the vector of expected returns does not affect the weights allocation.

```
% Display a table of weights for the risk budgeting portfolios.
RBtable = table(wRB,wRB_rho7,wRB_rho9,wRB_mu1)
```

```
RBtable=3×4 table
      wRB      wRB_rho7    wRB_rho9    wRB_mu1
    _______    ________    ________    _______

    0.39123    0.38444     0.38521     0.39123
    0.19638    0.19857     0.21957     0.19638
    0.41239    0.41699     0.39522     0.41239
```

```
% Display a table of weights for the mean-variance portfolios.
MVtable = table(wMV,wMV_rho7,wMV_rho9,wMV_mu1)
```

```
MVtable=3×4 table
      wMV      wMV_rho7    wMV_rho9    wMV_mu1
    _______    ________    ________    _______

    0.38462    0.38411           0     0.56638
    0.20301    0.26003      0.6612           0
    0.41237    0.35586      0.3388     0.43362
```

The results on these tables show that the risk budgeting portfolio is more robust to changes in the parameters. The weights in the third and fourth column of the mean-variance portfolio table change so drastically that the portfolios stop investing in some assets altogether when the parameters change. The mean-variance portfolio tends to concentrate weights in a few number of assets, which decreases portfolio diversification.

Backtest Using Risk-Based Equity Indexation

This example shows how to use backtesting with a risk parity or equal risk contribution strategy rebalanced approximately every month as a risk-based indexation. In this example, you use the backtesting engine (`backtestEngine`) to create the risk parity strategy, that all assets in the portfolio contribute equally to the risk of the portfolio at each rebalancing period.

To highlight advantages, the example compares the proposed risk-based indexation against a capitalization-weighted indexation. In contrast to a risk parity strategy, the assets of capitalization-weighted portfolios are weighted with respect to the market portfolio. One disadvatage of capitalization-weighted indexation is that it is a trend-following strategy that leads to bubble-risk exposure as the best performers represent a larger proportion of the market. Also, capitalization-weighted indexation can sometimes lead to weights concentratng in a sector. A risk-based indexation is an alternative investment strategy to avoid these issues of capitalization-weighted indexation.

Define Assets

```
% Read the table of daily adjusted close prices for 2006 DJIA stocks.
T = readtable('dowPortfolio.xlsx');
% Convert the table to a timetable.
pricesTT = table2timetable(T);
% Define the number of assets (not counting the market index).
nAssets = size(pricesTT,2)-1;
```

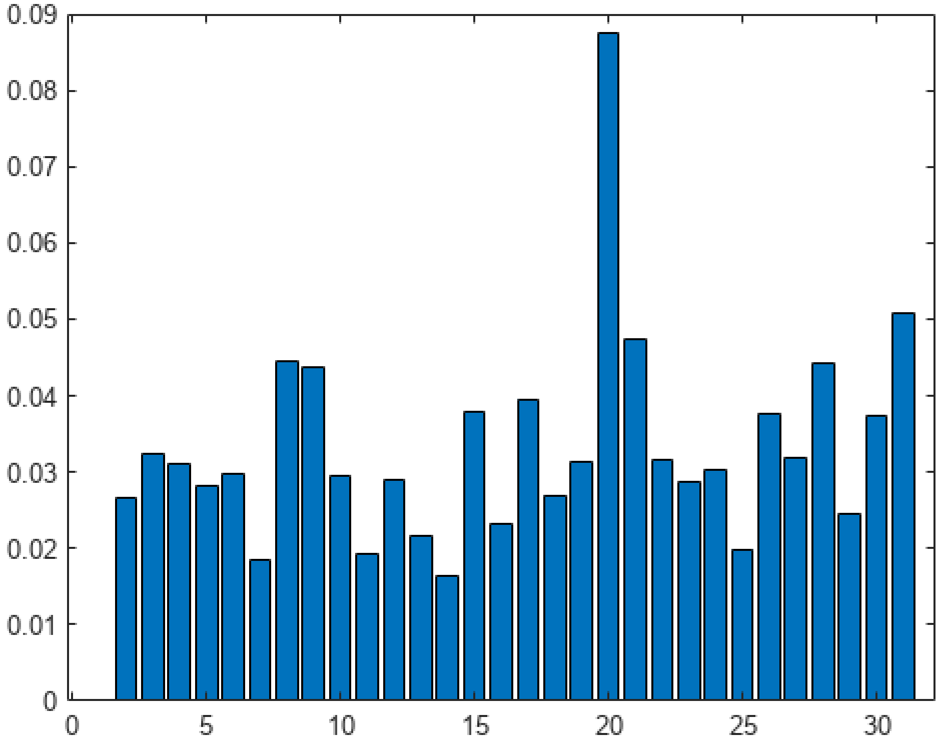
Define Risk Parity Strategy

To obtain the long-only fully invested risk parity portfolio, use the `riskBudgetingPortfolio` function. When you pass a returns covariance matrix to `riskBudgetingPortfolio`, the function computes the associated risk parity portfolio. To compute the initial weights for the risk parity strategy, `riskBudgetingPortfolio` uses the covariance matrix estimated with information from the first two months.

```
% Set backtesting warm-up period to two 21-day months.
warmupPeriod = 21*2;
% Set warm-up partition of timetable.
% Invest only in assets. First column of pricesTT is the market index.
warmupTT = pricesTT(1:warmupPeriod,2:end);
% Estimate the covariance matrix.
assetReturns = tick2ret(warmupTT);
assetCov = cov(assetReturns{:,:});
% Compute the initial risk parity portfolio.
initialRiskParity = [0; riskBudgetingPortfolio(assetCov)];
```

Visualize initial risk parity portfolio weights.

```
% Plot a bar chart.
bar(initialRiskParity)
```



Create the risk parity backtesting strategy using a `backtestStrategy` object. Set the risk parity strategy to rebalance every month.

```
% Rebalance frequency
rebalFreq = 21; % Every month
```

To gather enough data, set the lookback window to at least 2 months. To remove old data from the covariance estimation, set the lookback window to no more than 6 months.

```
% Lookback window
lookback = [42 126];
```

Use a fixed transaction cost equal to 0.5% of the amount traded.

```
% Fixed transaction cost
transactionCost = 0.005;
```

Define the risk parity allocation strategy using the `riskParityFcn` rebalancing function that is defined in Local Functions on page 4-289. Notice that the `riskBudgetingPortfolio` function is at the core of `riskParityFcn`.

```
% Risk parity allocation strategy
stratRP = backtestStrategy('Risk Parity', @riskParityFcn, ...
    RebalanceFrequency=rebalFreq, ...
    LookbackWindow=lookback, ...
    TransactionCosts=transactionCost, ...
    InitialWeights=initialRiskParity);
```

Define Benchmark Strategy

Next, compare the risk parity strategy against the portfolio that follows the Dow Jones Industrial Average (DJI) market index. To obtain the market-following portfolio, invest all assets to the first entry of the weights vector because the first column of the prices timetable (`pricesTT`) represents the market index.

```
% Compute the initial market portfolio.
initialMkt = [1;zeros(nAssets,1)];
```

Define the benchmark strategy using the `mktFcn` rebalancing function that is defined in Local Functions on page 4-289.

```
% Market index allocation strategy
stratBmk = backtestStrategy('Market Index', @mktFcn, ...
    RebalanceFrequency=rebalFreq, ...
    LookbackWindow=lookback, ...
    TransactionCosts=transactionCost, ...
    InitialWeights=initialMkt);
```

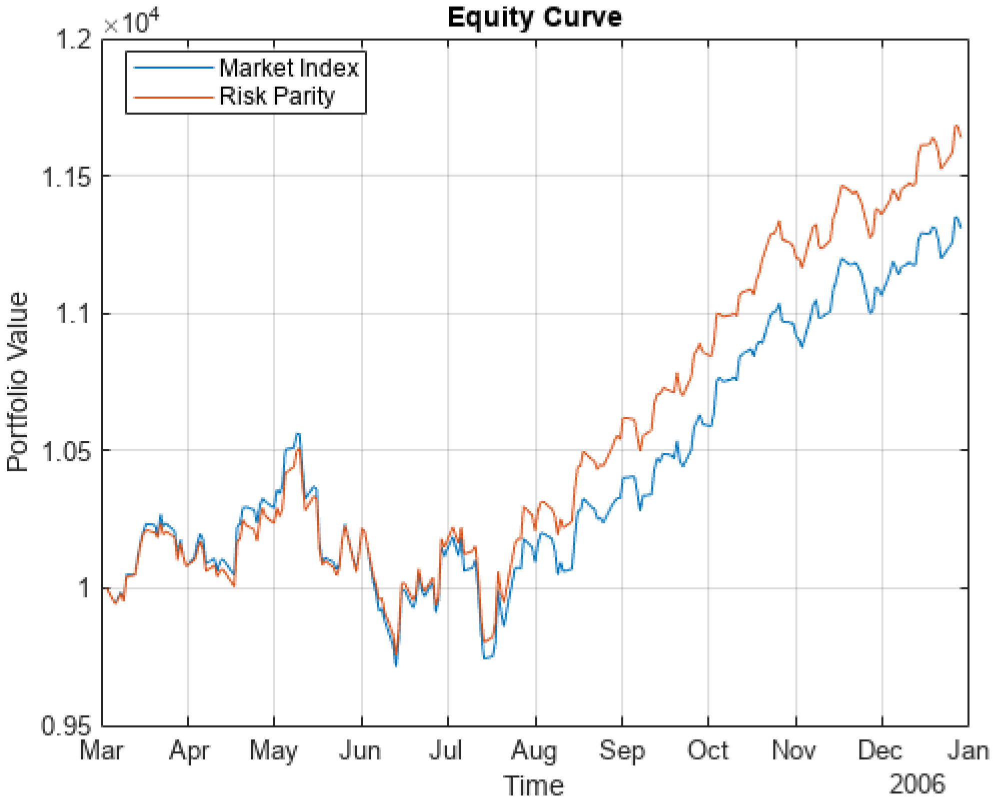
Run Backtest

Run the backtest using a `backtestEngine` object and `runBacktest`.

```
% Define strategies for backtest engine.
strategies = [stratBmk stratRP];
% Define a backtest engine.
backtester = backtestEngine(strategies);
% Run the backtest.
backtester = runBacktest(backtester,pricesTT,Start=warmupPeriod);
```

Use `equityCurve` to plot the equity curve.

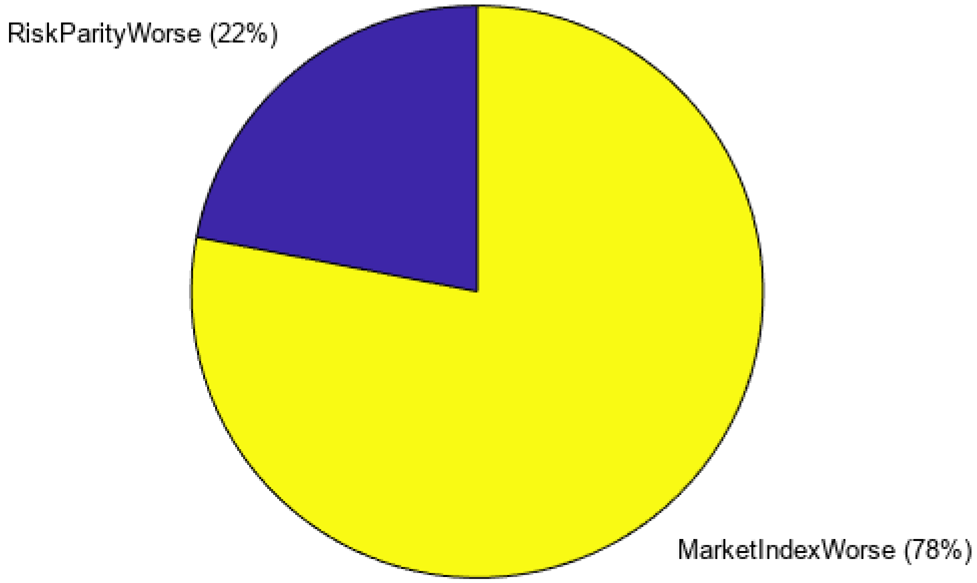
```
% Plot equity curve.
equityCurve(backtester)
```



The risk parity strategy outperforms the market index by the end of the investment period. To understand why, you can look at which strategy performs better in the event of meaningful losses.

```
% Get returns timetable.
returnsTT = backtester.Returns;
% Determine levels of losses to consider.
cutoff = 0.004 ;

% Obtain scenarios with losses below cutoff.
idxLoss = returnsTT.Market_Index <= -cutoff | ...
    returnsTT.Risk_Parity <= -cutoff;
% Indices when risk parity outperforms the market
idxLossMarketWorse = ...
    returnsTT.Market_Index(idxLoss) <= returnsTT.Risk_Parity(idxLoss);
catLoss = categorical(idxLossMarketWorse, ...
    [0 1], {'RiskParityWorse','MarketIndexWorse'});
% Plot pie chart.
pie(catLoss)
```



The plot shows that in 78% of the scenarios with *meaningful losses*, the market index loses more than the risk parity strategy. In this example, the reason the risk parity strategy outperforms the market index is because the risk parity strategy is more resilient to larger losses.

Local Functions

```
function new_weights = riskParityFcn(~,pricesTT)
% Risk parity rebalance function

% Invest only in assets. First column of pricesTT is the market index.
assetReturns = tick2ret(pricesTT(:,2:end));
assetCov = cov(assetReturns{:,:});

% Do not invest in the market index.
new_weights = [0; riskBudgetingPortfolio(assetCov)];

end

function new_weights = mktFcn(~,pricesTT)
% Market index rebalance function

% Invest only in the market index.
new_weights = zeros(size(pricesTT,2),1);
new_weights(1) = 1;

end
```

```
% The API of the rebalance functions (riskParityFcn and mktFcn) require
% a first input with the current weights. They are
% redundant for these two strategies and can be ignored.
```

Create Hierarchical Risk Parity Portfolio

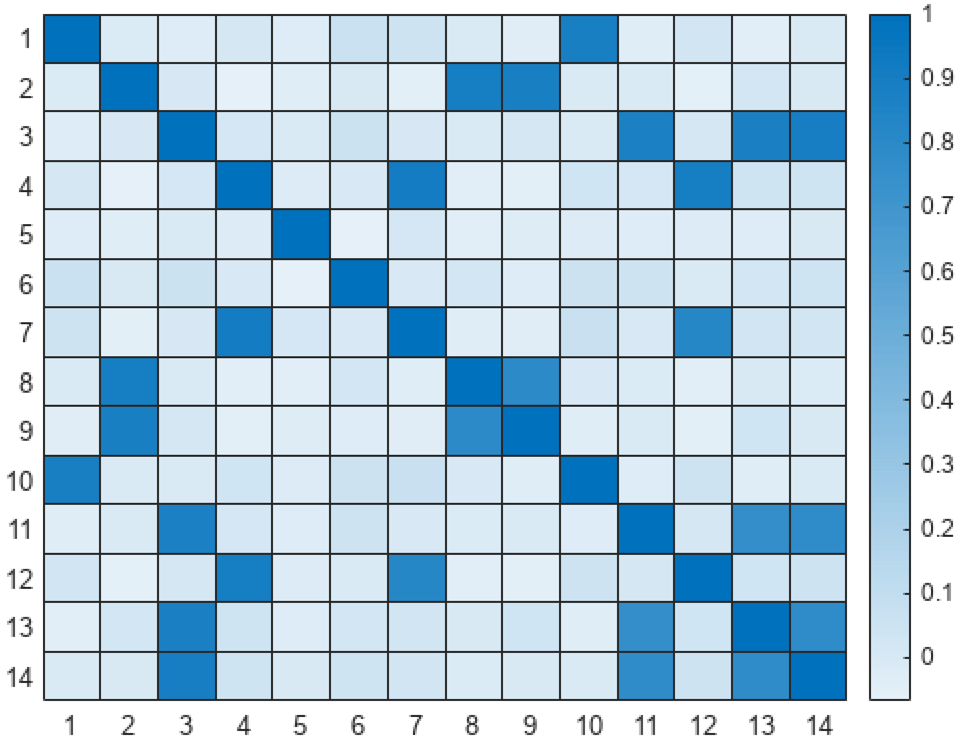
This example shows how to compute a hierarchical risk parity (HRP) portfolio. You can use HRP as a technique for portfolio diversification where the assets are divided and weighted according to a hierarchical tree structure. The weights of the assets within a cluster and between clusters can be assigned in many ways. A few ideas of the ways to allocate the weights are:

- Compute an inverse variance portfolio within each cluster. Then, allocate weights to each cluster using a value proportional to the inverse of the variance of the cluster's portfolio.
- Compute a risk parity portfolio within each cluster. Then, use a risk parity allocation strategy to assign each cluster's weights. The risk parity between clusters uses the covariance matrix between the cluster's portfolios. This example focuses on this allocation strategy.
- Use a bisection approach like the one described in Lopez de Prado [1 on page 4-296]. For more information, see the example Asset Allocation - Hierarchical Risk Parity.

Begin by loading the data and looking at the correlation between the assets returns.

```
% Load data
assetRetn = readmatrix("./retns_assets.txt");
[nSample,nAssets] = size(assetRetn);

% Compute covariance and correlation matrices
Sigma = cov(assetRetn);
C = corrcov(Sigma);
heatmap(C);
```



Hierachical Clustering

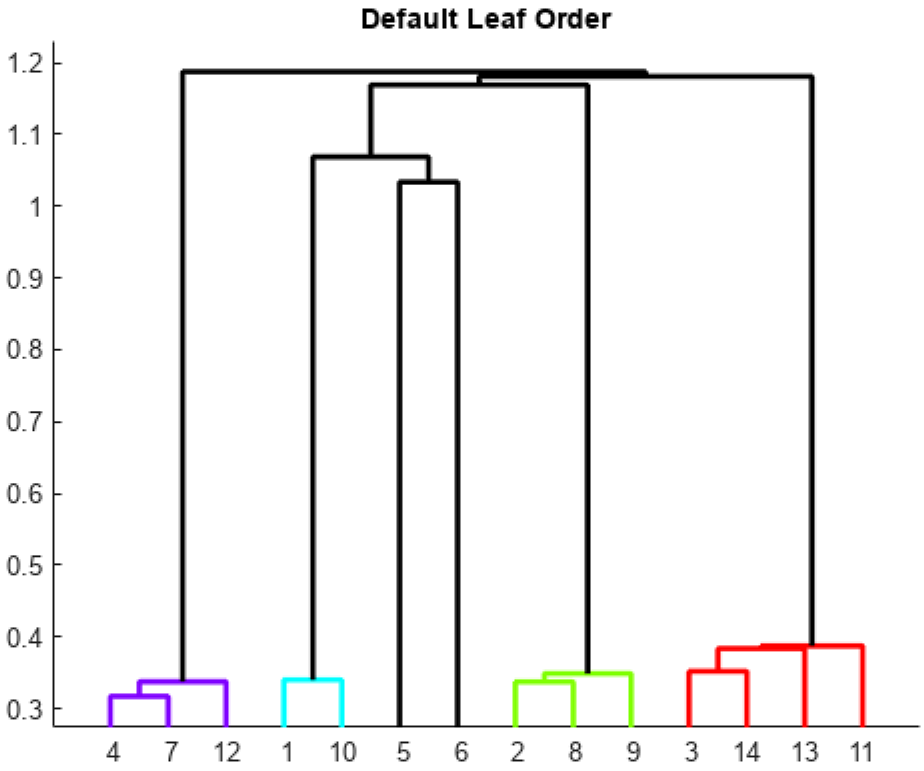
Hierarchical clustering is a common clustering technique in machine learning. In the context of asset allocation, a hierarchical clustering algorithm is applied to find the distance or similarity between each pair of assets and group them into a multilevel binary hierarchical tree.

Begin by deffining a measure of likeness or distance between the assets. The more correlated two assets are, the closer they should be.

```
% Compute the correlation distance matrix
distCorr = ((1-C)/2).^0.5;
```

Use the `linkage` function to compute the matrix that encodes the hierarchical tree of the assets in the universe. Them use the `dendrogram` function to visualize the hierarchical structure.

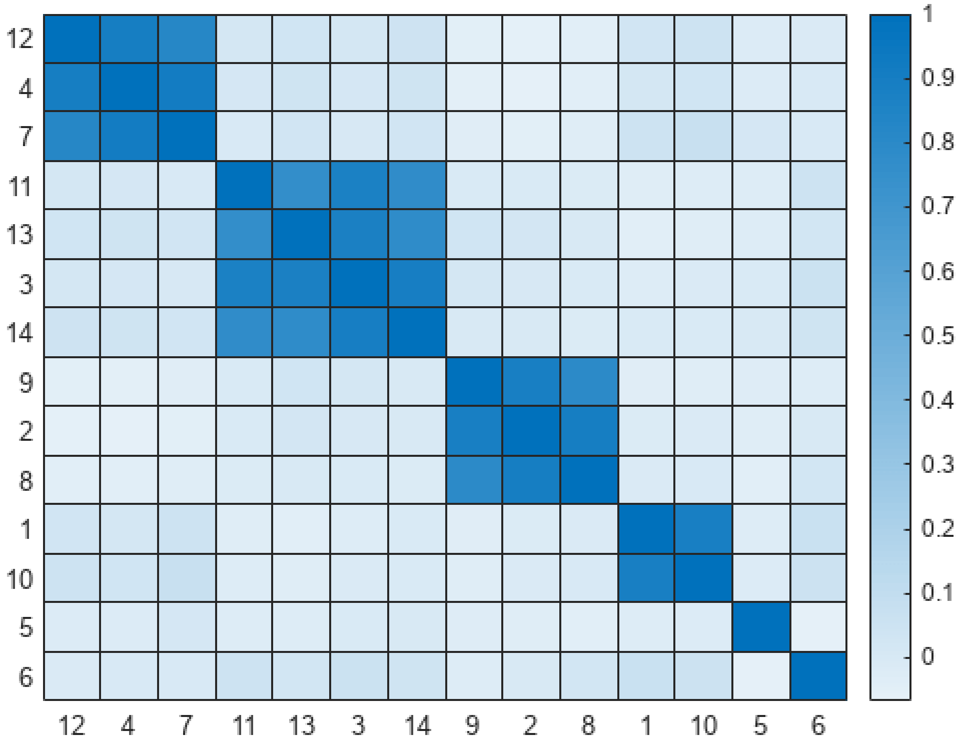
```
% Compute the linkage
link = linkage(distCorr);
figure;
h = dendrogram(link, ColorThreshold='default');
set(h, LineWidth=2);
title('Default Leaf Order');
```



The covariance or correlation matrix can be rearranged to be very close to a block diagonal matrix using the information obtained from the hierarchical tree. Each block in the diagonal shows the assets that are closely related.

```
% Sort assets for quasi-diagonalization
nLeafNodes = size(link,1) + 1;
```

```
rootNodeId = 2*nLeafNodes - 1;
sortedIdx = getLeafNodesInGroup(rootNodeId,link);
heatmap(C(sortedIdx,sortedIdx), XData=sortedIdx, YData=sortedIdx);
```



The plot shows that there are 6 blocks of assets that are closer together. You can divide the assets into 6 clusters using the `cluster` function.

```
% Get clusters
T = cluster(link, MaxClust=6);
```

Hierarchical Risk Parity Algorithm

Given a clustering of the assets, the HRP algorithm presented in this example follows these steps:

1. Build a risk parity portfolio within each cluster. The `hrpPortfolio` function in Local Functions on page 4-296 computes the HRP portfolio by receiving a vector with the cluster assignment and a covariance matrix Σ. Then, a risk parity portfolio is computed within each cluster by using `riskBudgetingPortfolio`. The `riskBudgetingPortfolio` function receives a reduced covariance matrix that only inlcudes the information of the assets within the cluster and it returns the weights of the assets in the cluster

$$w^j = \texttt{riskBudgetingPortfolio}(\Sigma^j),$$

where Σ^j is a matrix whose entries inlcude the covariance information only for the assets in the jth cluster.

2. Compute each cluster's weight usign the covariance between each cluster's portfolio. Now, the `riskBudgetingPortfolio` function receives a matrix (Γ) that represents the covariance between the cluster's portfolios (w^j).

$\Gamma_{\text{ij}} = W^T \Sigma W,$

where $W_{\text{ij}} = w_i^j$ if asset i is in cluster j, otherwise $W_{\text{ij}} = 0$. In other words $W = \left(w^1 | \ldots | w^K\right)$, for K clusters and $\gamma =$`riskBudgetingPortfolio(`Γ`).`

3. The final asset allocation is given by the cluster's risk parity portfolio (w^j) multiplied by each cluster's weight (γ_j)

$w = W\gamma.$

```
% Compute HRP portfolio
wHRP = hrpPortfolio(T,Sigma)
```

```
wHRP = 14×1

    0.0854
    0.0584
    0.0423
    0.0567
    0.1867
    0.1648
    0.0521
    0.0540
    0.0539
    0.0755
       ⋮
```

Compare HRP and Mean-Variance Portfolios

Define a long-only, fully-invested mean-variance `Portfolio` object. Then, compute the associated minimum variance portfolio.

```
% Define Portfolio object
p = Portfolio(AssetMean=mean(assetRetn), AssetCovar=Sigma);
p = setDefaultConstraints(p); % long-only, fully-invested portfolio
% Min variance portfolio
wMV = estimateFrontierLimits(p,'min');
```

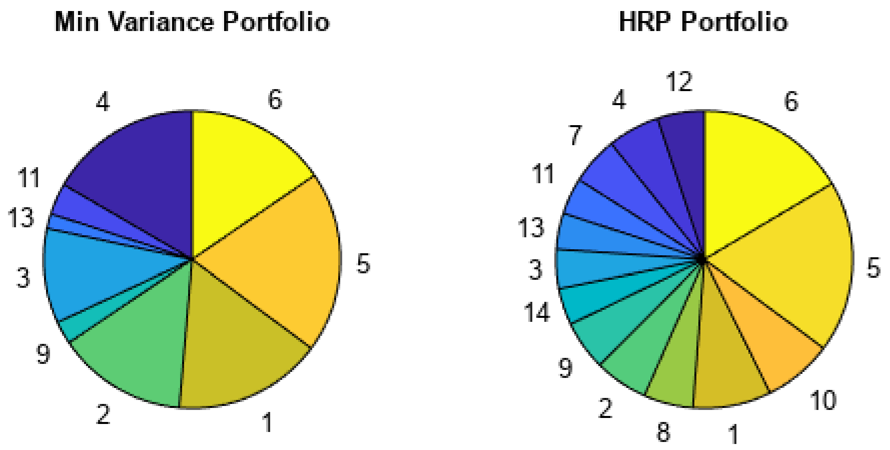
Visualize the resulting allocations from these two strategies.

```
% Create pie chart labels to improve plot reading
labels = 1:nAssets;
labels = string(labels);

% Sort assets following quasi-diagonalization order
labels = labels(sortedIdx);
wMV = wMV(sortedIdx);
wHRP = wHRP(sortedIdx);

% Plot pie charts
```

```
tiledlayout(1,2);
% Min variance portfolio
nexttile
pie(wMV(wMV>=1e-8),labels(wMV>=1e-8))
title('Min Variance Portfolio',Position=[0,1.5]);
% HRP portfolio
nexttile
pie(wHRP,labels)
title('HRP Portfolio',Position=[0,1.5]);
```



You can see that the HRP portfolio is a much more diversified portfolio as compared to the portfolio obtained using the traditional mean-variance approach. In addition, you can see the following:

- The assets that were not correlated with others, assets 5 and 6, represent a much larger area of the pie. In fact, the sum of the areas of assets that are in the same cluster (for example, assets 1 and 10 or assets 11, 13, 3 and 14) are close to the individual areas of assets 5 and 6. This shows that the weights are divided somewhat evenly between clusters and that each cluster's weight is divided somewhat evenly among the assets within the cluster. This is consistent with the HRP theory.
- The risk parity portfolio of fully correlated assets with the same variance is an equally weighted portfolio. The same happens for assets that are completely uncorrelated. Since all the assets in the universe have a similar variance, and assets between clusters are almost uncorrelated, the weights allocated to each cluster are almost even. And, since the assets within a cluster are meant to be highly correlated, the weights of the assets within a culster are evenly distibuted.

Backtest Strategies Using Deep Learning

Construct trading strategies using a deep learning model and then backtest the strategies using the Financial Toolbox™ backtesting framework. The example uses Deep Learning Toolbox™ to train a predictive model from a set of time series and demonstrates the steps necessary to convert the model output into trading signals. It builds a variety of trading strategies that backtest the signal data over a 5-year period.

This example illustrates the following workflow:

1. Load price data for a set of energy commodities on page 4-298.
2. Clean and trim data on page 4-299.
3. Use the historical data to train a long short-term memory (LSTM) network to predict the change in energy prices over the next trading day on page 4-300.
4. Use the LSTM network to build a timetable of trading signal data for the backtest engine on page 4-305.
5. Construct trading strategies that allocate capital based on the trading signals on page 4-306.
6. Backtest the strategies using the backtesting framework on page 4-306.
7. Examine the backtest results on page 4-307.

The focus of this example is on the workflow from data, to a trained model, to trading strategies, and finally to a backtest of the strategies. The deep learning model, its output, the subsequent trading signals, and the strategies are fictional. The intent is only to show the steps for developing and deploying this type of model.

Load Data

Load the historical price data. This data set contains daily spot prices for 12 different energy products ranging from 1986 to 2021 and consists of the following time series:

- WTI — West Texas Intermediate light crude oil
- Brent — Brent light crude oil
- NaturalGas — Henry Hub natural gas
- Propane — Mon Belvieu propane
- Kerosene — US Gulf Coast kerosene-type jet fuel
- HeatingOil — New York Harbor no. 2 heating oil
- GulfRegular — US Gulf Coast conventional gasoline
- LARegular — Los Angeles reformulated RBOB regular gasoline
- NYRegular — New York Harbor conventional gasoline
- GulfDiesel — US Gulf Coast ultra-low sulfur no. 2 diesel
- LADiesel — Los Angeles ultra-low sulfur CARB diesel
- NYDiesel — New York Harbor ultra-low sulfur no. 2 diesel

The source of this data is the US Energy Information Administration (Nov 2021).

```
priceData = load('energyPrices.mat','energyPrices');
priceData = priceData.energyPrices;
tail(priceData)
```

```

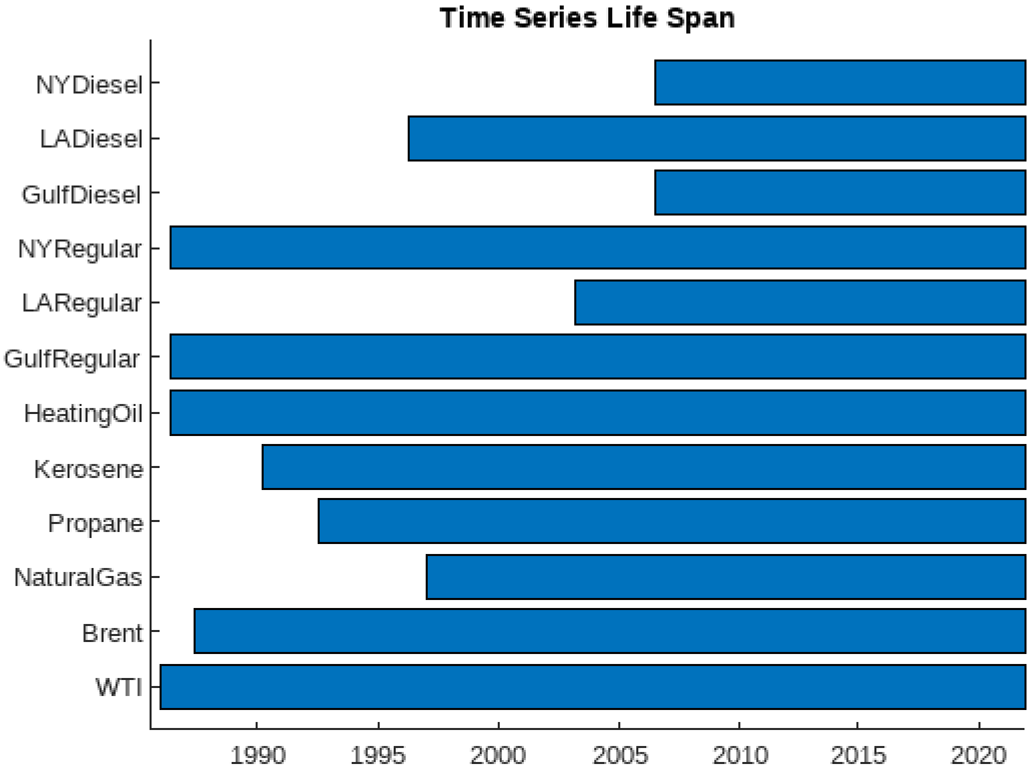
```

Clean and Trim Data

The price datasets do not all start at the same time. Some datasets start later than others and have fewer data points. The following plot shows the time span for each price series.

```
seriesLifespanPlot(priceData)
```



To avoid large spans of missing data, remove the series with shorter histories.

```
priceData = removevars(priceData,["NYDiesel","GulfDiesel","LARegular"]);
```

The remaining table variables contain sporadic missing elements (NaNs) due to holidays or other reasons. Missing data is handled in a variety of ways depending on the dataset. In some cases, it may be appropriate to interpolate or use the `fillmissing` function. In this example, you can remove the remaining NaN prices.

```
priceData = rmmissing(priceData);
```

Then, convert the price data to a return series using the `tick2ret` function. The final dataset consists of nine price series with daily data from 1997 through 2021.

```
returnData = tick2ret(priceData)
```

```
returnData=6167×9 timetable

Prepare Data for Training LSTM Model

Prepare and partition the dataset in order to train the LSTM model. The model uses a 30-day rolling window of trailing feature data and predicts the next day price changes for four of the assets: Brent crude oil, natural gas, propane, and kerosene.

```
% Model is trained using a 30-day rolling window to predict 1 day in the
% future.
historySize = 30;
futureSize = 1;

% Model predicts returns for oil, natural gas, propane, and kerosene.
outputVarName = ["Brent" "NaturalGas", "Propane" "Kerosene"];
numOutputs = numel(outputVarName);

% start_idx and end_idx are the index positions in the returnData
% timetable corresponding to the first and last date for making a prediction.
start_idx = historySize + 1;
end_idx   = height(returnData) - futureSize + 1;
numSamples = end_idx - start_idx + 1;

% The date_vector variable stores the dates for making predictions.
date_vector = returnData.Time(start_idx-1:end_idx-1);
```

Convert the `returnData` timetable to a `numSamples`-by-`1` cell array. Each cell contains a `numFeatures`-by-`seqLength` matrix. The response variable is a `numSamples`-by-`numResponses` matrix.

```
network_features  = cell(numSamples,1);
network_responses = zeros(numSamples,numOutputs);

for j = 1:numSamples
    network_features{j} = (returnData(j:j+historySize-1,:).Variables)';
    network_responses(j,:) = ...
        (returnData(j+historySize:j+historySize+futureSize-1,outputVarName).Variables)';
end
```

Split the `network_features` and the `network_responses` into three parts: training, validation, and backtesting. Select the backtesting set as a set of sequential data points. The remainder of the data is randomly split into a training and a validation set. Use the validation set to prevent overfitting while training the model. The backtesting set is not used in the training process, but it is reserved for the final strategy backtest.

```
% Specify rows to use in the backtest (31-Dec-2015 to 2-Nov-2021).
backtest_start_idx = find(date_vector < datetime(2016,1,1),1,'last');
backtest_indices = backtest_start_idx:size(network_responses,1);

% Specify data reserved for the backtest.
Xbacktest = network_features(backtest_indices);
Tbacktest = network_responses(backtest_indices,:);

% Remove the backtest data.
network_features = network_features(1:backtest_indices(1)-1);
network_responses = network_responses(1:backtest_indices(1)-1,:);

% Partition the remaining data into training and validation sets.
rng('default');
cv_partition = cvpartition(size(network_features,1),'HoldOut',0.2);

% Training set
Xtraining = network_features(~cv_partition.test,:);
Ttraining = network_responses(~cv_partition.test,:);

% Validation set
Xvalidation = network_features(cv_partition.test,:);
Tvalidation = network_responses(cv_partition.test,:);
```

Define LSTM Network Architecture

Specify the network architecture as a series of layers. For more information on LSTM networks, see “Long Short-Term Memory Neural Networks” (Deep Learning Toolbox). The Deep Network Designer (Deep Learning Toolbox) is a powerful tool for designing deep learning models.

```
numFeatures = width(returnData);
numHiddenUnits_LSTM = 10;

layers_LSTM = [ ...
    sequenceInputLayer(numFeatures)
    lstmLayer(numHiddenUnits_LSTM)
    layerNormalizationLayer
    lstmLayer(numHiddenUnits_LSTM)
    layerNormalizationLayer
    lstmLayer(numHiddenUnits_LSTM,'OutputMode','last')
    layerNormalizationLayer
    fullyConnectedLayer(numOutputs)
    regressionLayer];
```

Specify Training Options for LSTM Model

Next, you specify training options using the `trainingOptions` (Deep Learning Toolbox) function. Many training options are available and their use varies depending on your use case. Use the Experiment Manager (Deep Learning Toolbox) to explore different network architectures and sets of network hyperparamters.

```
max_epochs = 500;
mini_batch_size = 128;
learning_rate = 1e-4;

options_LSTM = trainingOptions('adam', ...
    'Plots','training-progress', ...
    'Verbose',0, ...
    'MaxEpochs',max_epochs, ...
    'MiniBatchSize',mini_batch_size, ...
    'Shuffle','every-epoch', ...
    'ValidationData',{Xvalidation,Tvalidation}, ...
    'ValidationFrequency',50, ...
    'ValidationPatience',10, ...
    'InitialLearnRate',learning_rate, ...
    'GradientThreshold',1);
```

Train LSTM Model

Train the LSTM network. Use the `trainNetwork` (Deep Learning Toolbox) function to train the network until the network meets a stopping criteria. This process can take several minutes depending on the computer running the example. For more information on increasing the network training performance, see “Scale Up Deep Learning in Parallel, on GPUs, and in the Cloud” (Deep Learning Toolbox).

To avoid waiting for the network training, load the pretrained network by setting the `doTrain` flag to `false`. To train the network using `trainNetwork` (Deep Learning Toolbox), set the `doTrain` flag to `true`.

```
doTrain = false;

if doTrain
    % Train the LSTM network.
    net_LSTM = trainNetwork(Xtraining,Ttraining,layers_LSTM,options_LSTM);
else
    % Load the pretrained network.
    load lstmBacktestNetwork
end
```

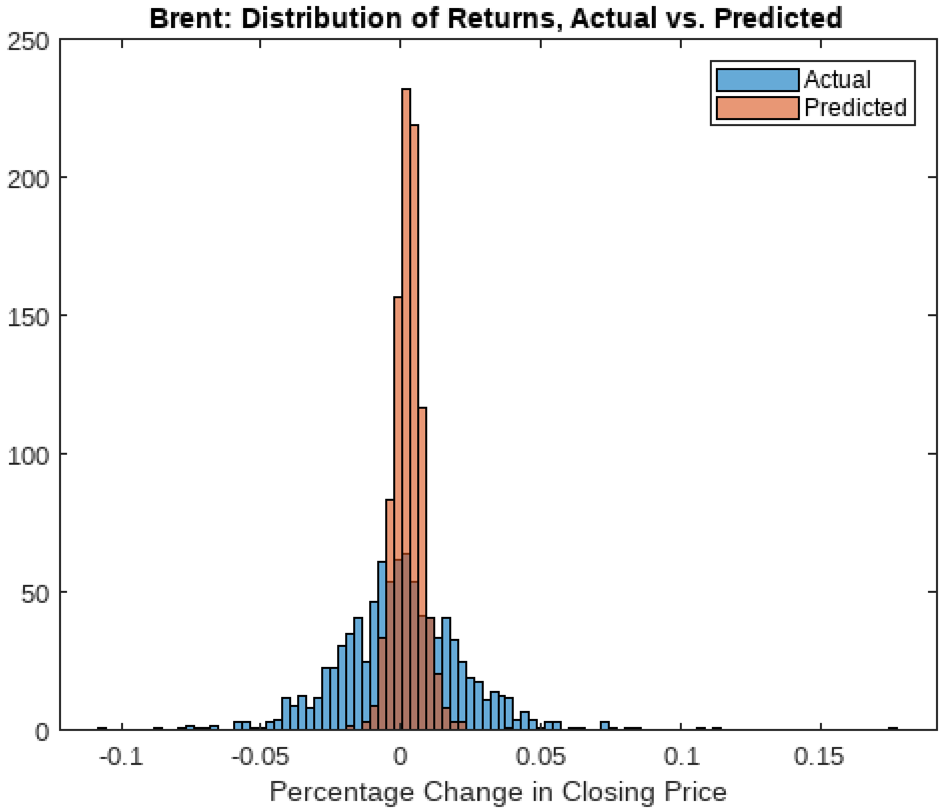
Visualize Training Results

Visualize the results of the trained model by comparing the predicted values against the actual values from the validation set.

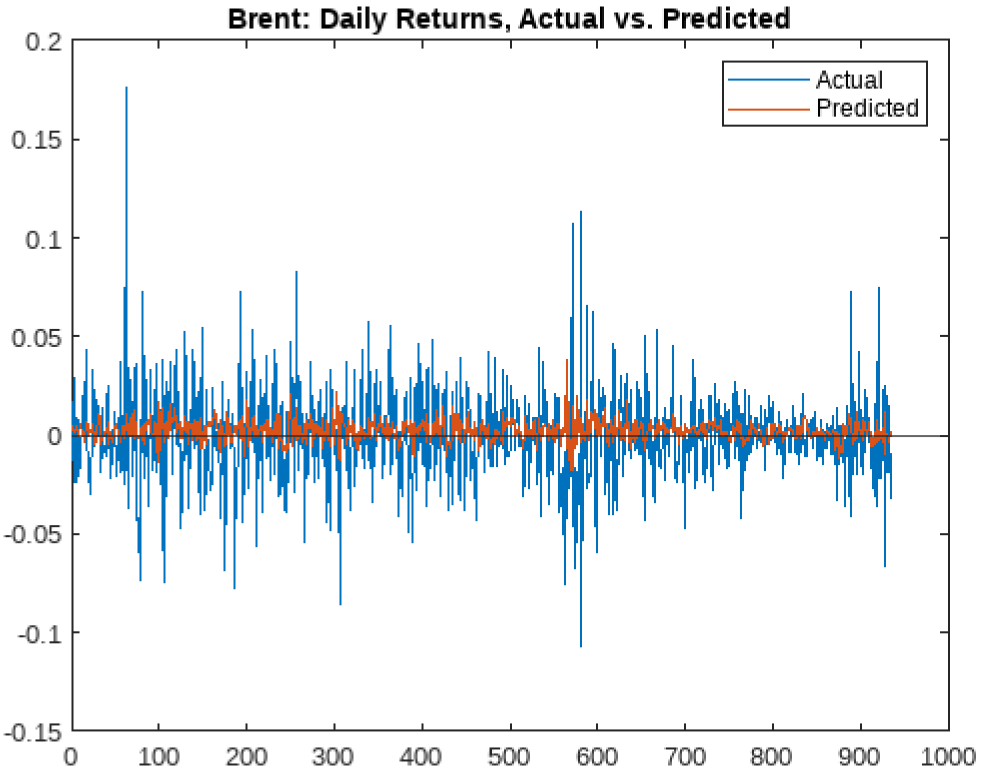
```
% Compare the actual returns to model predicted returns.
actual    = Tvalidation;
predicted = predict(net_LSTM,Xvalidation,'MiniBatchSize',mini_batch_size);

% Overlay histogram of actual vs. predicted returns for the validation set.
output_idx = Oil ▾;
figure;

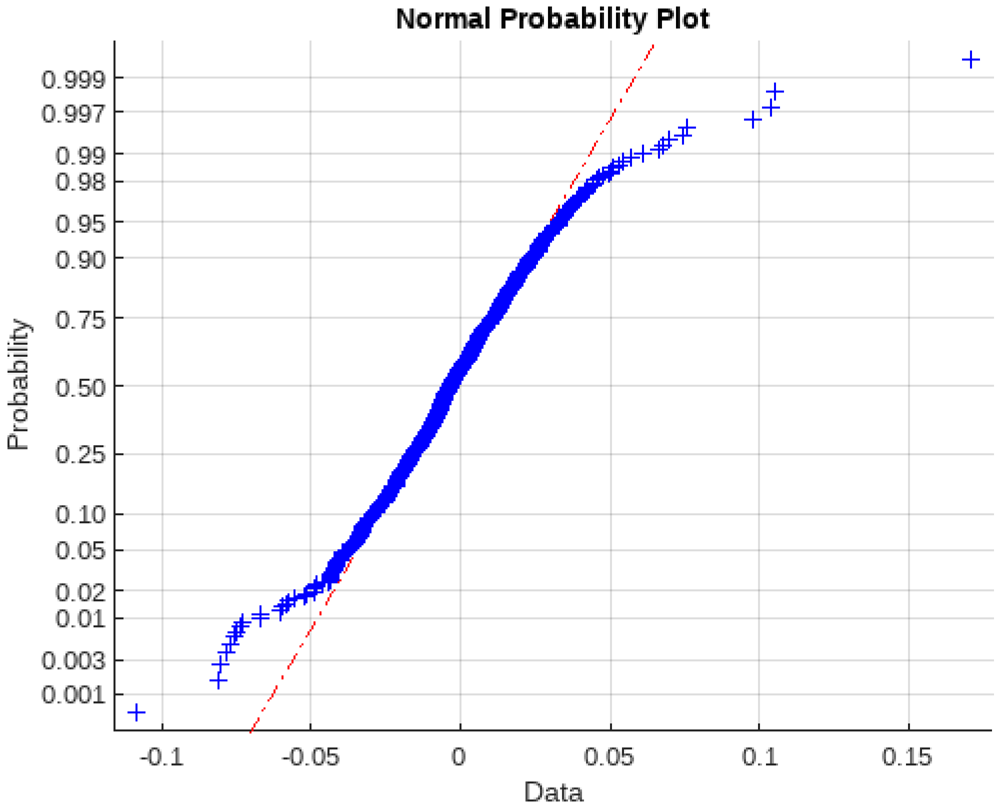
[~,edges] = histcounts(actual(:,output_idx),100);
histogram(actual(:,output_idx),edges);
hold on
histogram(predicted(:,output_idx),edges)
hold off
xlabel('Percentage Change in Closing Price')
legend('Actual','Predicted')
title(sprintf('%s: Distribution of Returns, Actual vs. Predicted', outputVarName(output_idx)))
```



```
% Display the predicted vs. actual daily returns for the validation set.
figure
plot(actual(:,output_idx))
hold on
plot(predicted(:,output_idx))
yline(0)
legend({'Actual','Predicted'})
title(sprintf('%s: Daily Returns, Actual vs. Predicted', outputVarName(output_idx)))
```



```
% Examine the residuals.
residuals = actual(:,output_idx) - predicted(:,output_idx);
figure;
normplot(residuals);
```



The actual data has fatter tails than the trained model predictions. The model predictions are not accurate, but the goal of this example is to show the workflow from loading data, to model development, to backtesting. A more sophisticated model with a larger and more varied set of training data is likely to have more predictive power.

Prepare Backtest Data

Use the predictions from the LSTM model to build the backtest strategies. You can post-process the model output in a number of ways to create trading signals. However, for this example, take the model regression output and convert it to a timetable.

Use `predict` (Deep Learning Toolbox) with the trained network to generate model predictions over the backtest period.

```
backtestPred_LSTM = predict(net_LSTM,Xbacktest,'MiniBatchSize',mini_batch_size);
```

Convert the predictions to a trading signal timetable.

```
backtestSignalTT = timetable(date_vector(backtest_indices),backtestPred_LSTM);
```

Construct the prices timetable corresponding to the backtest time span. The backtest trades in and out of the four energy commodities. The prices timetable has the closing price for the day on which the prediction is made.

```
backtestPriceTT = priceData(date_vector(backtest_indices),outputVarName);
```

Set the risk-free rate to be 1% annualized. The backtest engine also supports setting the risk-free rate to a timetable containing the historical daily rates.

```
risk_free_rate = 0.01;
```

Create Backtest Strategies

Use `backtestStrategy` to create four trading strategies based on the signal indicators. The following trading strategies are intended as examples to show how to convert the trading signals into actionable asset allocation strategies that you can then backtest:

- Long Only — Invest all capital across the assets with positive predicted return, proportional to their signal strength (predicted return).
- Long Short — Invest capital across the assets, both long and short positions, proportional to their signal strength.
- Best Bet — Invest all capital into the single asset with the highest predicted return.
- Equal Weight — Rebalance each day to equal-weighted allocation.

```
% Specify 10 basis points as the trading cost.
tradingCosts = 0.001;

% Invest in long positions proportionally to their predicted return.
LongStrategy = backtestStrategy('LongOnly',@LongOnlyRebalanceFcn, ...
    'TransactionCosts',tradingCosts, ...
    'LookbackWindow',1);

% Invest in both long and short positions proportionally to their predicted returns.
LongShortStrategy = backtestStrategy('LongShort',@LongShortRebalanceFcn, ...
    'TransactionCosts',tradingCosts, ...
    'LookbackWindow',1);

% Invest 100% of capital into single asset with highest predicted returns.
BestBetStrategy = backtestStrategy('BestBet',@BestBetRebalanceFcn, ...
    'TransactionCosts',tradingCosts, ...
    'LookbackWindow',1);

% For comparison, invest in an equal-weighted (buy low and sell high) strategy.
equalWeightFcn = @(current_weights,prices,signal) ones(size(current_weights)) / numel(current_we
EqualWeightStrategy = backtestStrategy('EqualWeight',equalWeightFcn, ...
    'TransactionCosts',tradingCosts, ...
    'LookbackWindow',0);
```

Put the `strategies` into an array and then use `backtestEngine` to create the backtesting engine.

```
strategies = [LongStrategy LongShortStrategy BestBetStrategy EqualWeightStrategy];

bt = backtestEngine(strategies,'RiskFreeRate',risk_free_rate);
```

Run Backtest

Use `runBacktest` to backtest the strategies over the backtest range.

```
bt = runBacktest(bt,backtestPriceTT,backtestSignalTT)
```

```
bt = 
  backtestEngine with properties:
```

```
              Strategies: [1×4 backtestStrategy]
            RiskFreeRate: 0.0100
          CashBorrowRate: 0
         RatesConvention: "Annualized"
                   Basis: 0
   InitialPortfolioValue: 10000
          DateAdjustment: "Previous"

```

Examine Backtest Results

Use the `summary` and `equityCurve` functions to summarize and plot the backtest results. This model and its derivative trading strategies are not expected to be profitable in a realistic trading scenario. However, this example illustrates a workflow that should be useful for practitioners with more comprehensive data sets and more sophisticated models and strategies.

Backtest with Brinson Attribution to Evaluate Portfolio Performance

This example shows how to compute Brinson attribution using the output of the MATLAB® backtest framework. The backtest framework allows you to build custom trading strategies and then backtest them against historical or simulated market data. The example uses the Brinson attribution function (`brinsonAttribution`) to explain a portfolio's performance versus a benchmark.

Load Data

Brinson attribution requires that a category is assigned to each asset. Load the `dowPortfolio.xlsx` data set, then assign each of the 30 stocks to a category.

```
% Read a table of daily adjusted close prices for 2006 DJIA stocks.
pricesTT = readtimetable('dowPortfolio.xlsx');

% Remove the index from the dataset.
pricesTT= removevars(pricesTT,'DJI');
num_assets = width(pricesTT);

% Set the sectors for each stock.
asset_categories = categorical(["Materials";"Financials";"Financials"; ...
    "Industrials";"Financials";"Industrials";"Materials"; ...
    "Communication Services";"Industrials";"Consumer Discretionary"; ...
    "Consumer Discretionary";"Industrials";"Information Technology"; ...
    "Information Technology";"Information Technology";"Health Care"; ...
    "Financials";"Consumer Staples";"Consumer Discretionary"; ...
    "Industrials";"Consumer Staples";"Health Care"; ...
    "Information Technology";"Health Care";"Consumer Staples"; ...
    "Communication Services";"Industrials";"Communication Services"; ...
    "Consumer Staples";"Energy"]);

% Display the stock categories.
Symbol = pricesTT.Properties.VariableNames(:);
table(Symbol,asset_categories)
```

```
ans=30×2 table
     Symbol         asset_categories

```

Define and Create Backtest Strategies

Multiperiod Brinson attribution expects fixed, regular time periods. In this case, the backtest strategy rebalance schedules will match the Brinson periods. You can set the rebalance dates to be monthly starting from January first.

```
% Rebalance on the first trading day of each month.
rebalance_schedule = datetime(2006,1,1):calmonths(1):datetime(2006,12,1);
for idx = 1:numel(rebalance_schedule)
    priceIdx = find(rebalance_schedule(idx) <= pricesTT.Dates,1,'first');
    rebalance_schedule(idx) = pricesTT.Dates(priceIdx);
end
```

The risk budgeting strategy needs historical data in order to set initial weights. You can use the first month of price data as a warm-up period to set the initial weights. The backtest begins at the end of the warm-up period.

```
% Use first month as warm-up period for the risk budgeting strategy.
start_date = rebalance_schedule(2);

% Get the first month of prices to initialize the risk budgeting strategy.
initial_prices = pricesTT(pricesTT.Dates <= start_date,:);
```

Brinson attribution measures portfolio manager performance against some benchmark. For this example, use a simple equal-weighted strategy as the benchmark. This example examines the performance of the following two strategies relative to this benchmark:

- Equal Category — This strategy allocates resources equally *per category*, and then allocates equal weights for stocks within each category.
- Risk Budgeting — This strategy sets weights for stocks with the goal of minimizing each asset's risk contribution.

Create a `backtestStrategy` object for the benchmark and the two candidate strategies. Define each of these strategies to use the same rebalance schedule and assign the appropriate initial weights.

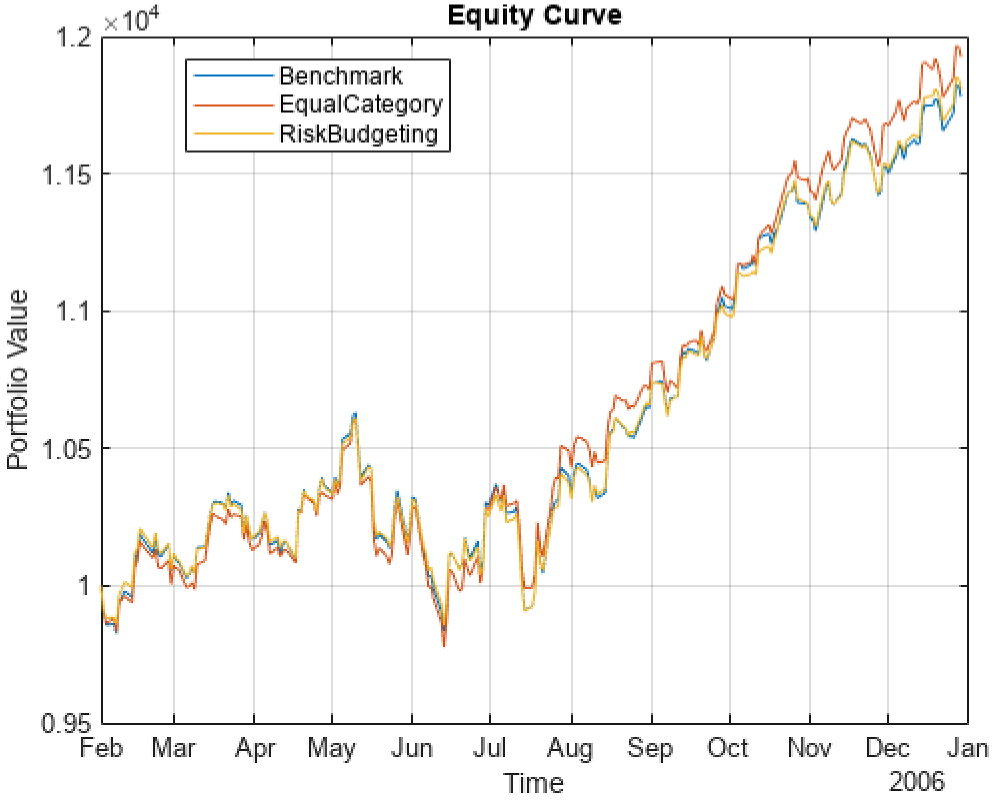
```
% Define the Benchmark strategy.
benchmark = backtestStrategy('Benchmark',@equalWeightRebalanceFcn, ...
    'RebalanceFrequency',rebalance_schedule, ...
    'InitialWeights',computeEqualWeights(num_assets), ...
    'UserData',struct());

% Define the equal category strategy.
equalCategory = backtestStrategy('EqualCategory',@equalCategoryRebalanceFcn, ...
    'RebalanceFrequency',rebalance_schedule, ...
    'InitialWeights',computeEqualCategory(asset_categories), ...
    'UserData',struct('Categories',asset_categories));

% Define the risk budgeting strategy.
riskBudgeting = backtestStrategy('RiskBudgeting',@riskBudgetingRebalanceFcn, ...
    'RebalanceFrequency',rebalance_schedule, ...
    'InitialWeights',computeRiskBudgeting(initial_prices));
```

Use backtestEngine to create a backtestEngine object for the strategies and then use runBacktest to run the backtest. Display the equity curve using equityCurve and then use summary to display the backtest summary table. Both the equal category and risk budgeting strategies outperform the benchmark.

```
strategies = [benchmark,equalCategory,riskBudgeting];
bt = backtestEngine(strategies);
bt = runBacktest(bt,pricesTT,'Start',start_date);
equityCurve(bt)
```



```
summary(bt)
```

```
ans=9×3 table

```

Prepare Backtest Results for Brinson Attribution

Set the strategy name of the benchmark.

```
benchmark_name = 'Benchmark';
```

Define Brinson periods by the rebalance dates and the backtest end date.

```
period_dates = [rebalance_schedule(2:end), pricesTT.Dates(end)];
```

Compute Brinson Attribution for Backtested Investment Strategy

Select whether to analyze the equal category or risk budgeting strategy. Then, use the `backtest2brinson` function in Local Functions on page 4-317 to compute `asset_table` that is formatted for use with the `brinsonAttribution` function. For more information on the format of the `asset_table`, see the description for the `AssetTable` input argument in the `brinsonAttribution` function.

```
% Select strategy to analyze
strategy_name = EqualCategory ▾;

asset_table = backtest2brinson(bt,strategy_name,benchmark_name,pricesTT,asset_categories,period_
head(asset_table)
```

```
    Period     Name       Return              Category              PortfolioWeight    BenchmarkWeight

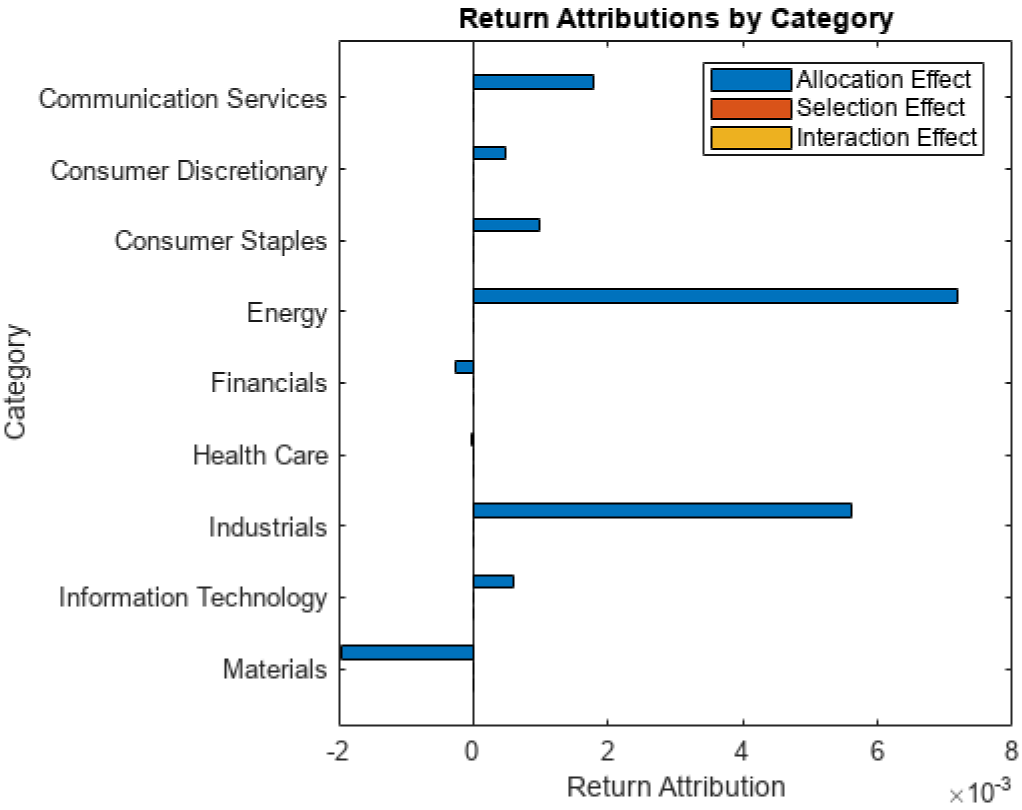
ans=11×1 table
                                      Brinson Attribution Summary
                                      ___________________________

    Total Number of Assets                          30
    Number of Assets in Portfolio                   30
    Number of Assets in Benchmark                   30
    Number of Periods                               11
    Number of Categories                             9
    Portfolio Return                           0.19249
    Benchmark Return                           0.17811
    Active Return                             0.014376
    Allocation Effect                         0.014376
    Selection Effect                        8.5567e-18
    Interaction Effect                     -1.1701e-19
```

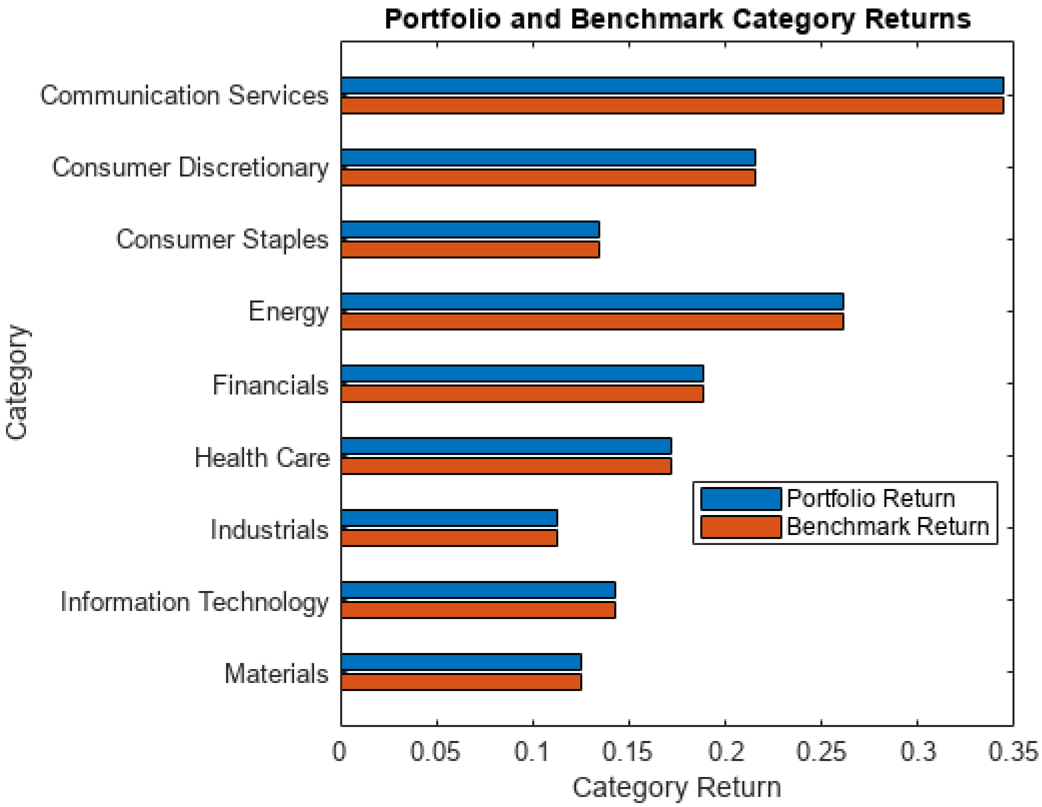
Generate the attribution chart using `attributionsChart` with the `brinson` object. The attributions chart creates a horizontal bar chart of portfolio performance attributions by category, aggregated over all time periods.

```
attributionsChart(brinson)
```



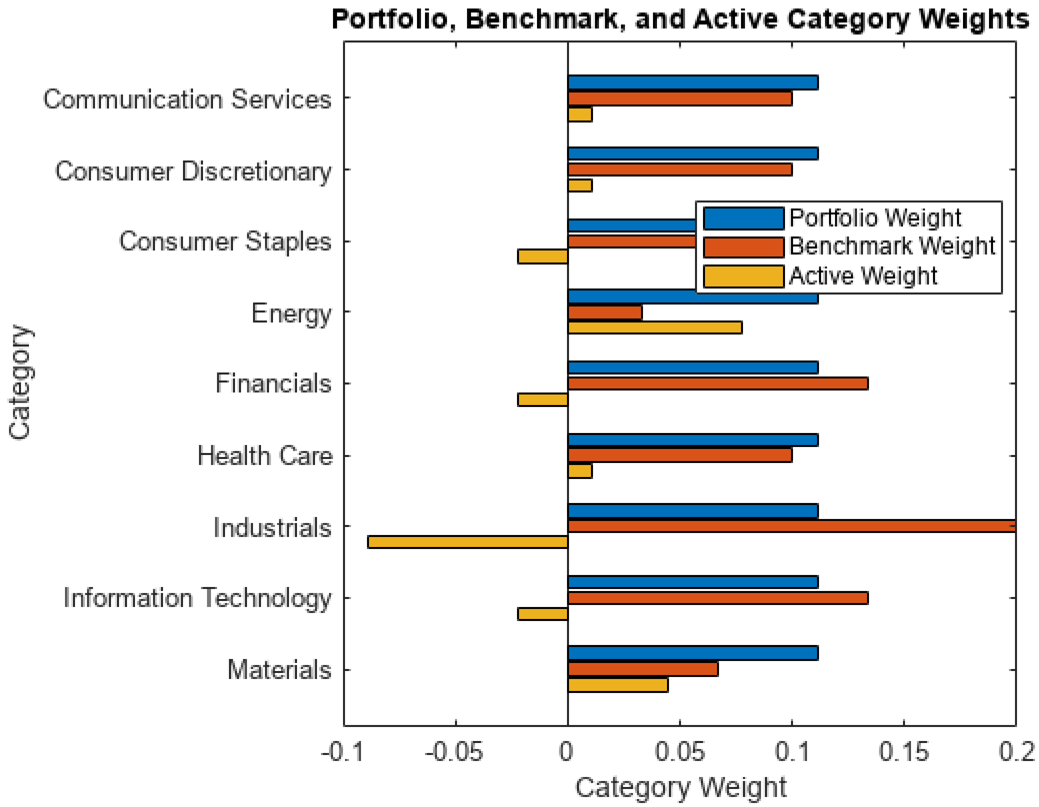
Generate a category returns chart using `categoryReturnsChart` with the `brinson` object. The category returns chart creates a horizontal bar chart of portfolio and benchmark category returns, aggregated over all time periods.

```
categoryReturnsChart(brinson)
```



Generate a category weights chart using `categoryWeightsChart` with the `brinson` object. Te category weights chart creates a horizontal bar chart of portfolio, benchmark, and active weights by category, averaged over all time periods.

```
categoryWeightsChart(brinson)
```



The equal category strategy, despite having different category weights from the benchmark, has the same equal-weighted asset selection process *within each category*. Therefore, the equal category strategy has no selection or interaction effect (relative to the benchmark). Meanwhile, the risk budgeting strategy disregards the asset categories when setting portfolio weights, so it has selection and interaction effects.

Local Functions

Both the equal asset weight and equal category weight rebalance functions compute a fixed weight that is assigned at each rebalance date. In order to avoid calculating the weights each time, the weights are calculated once and then the result is saved in the `UserData` struct for the `backtestStrategy` object. For more information on the `UserData` struct, see the “rebalanceFcn” on page 15-0 input argument for `backtestStrategy`.

```
function [new_weights,user_data] = equalWeightRebalanceFcn(~,pricesTT,user_data)
% Equal asset weight rebalance function

if ~isfield(user_data,'FixedAllocation')
    % If this is the first call to the rebalance function, calculate the
    % desired fixed allocation and save it.
    user_data.FixedAllocation = computeEqualWeights(width(pricesTT));
end
new_weights = user_data.FixedAllocation;

end
```

```
function weights = computeEqualWeights(num_assets)
% Equal asset weight portfolio allocation

weights = ones(1,num_assets) / num_assets;

end

function [new_weights,user_data] = equalCategoryRebalanceFcn(~, ~, user_data)
% Equal category weight rebalance function

if ~isfield(user_data,'FixedAllocation')
    % If this is the first call to the rebalance function, calculate the
    % desired fixed allocation and save it.
    user_data.FixedAllocation = computeEqualCategory(user_data.Categories);
end
new_weights = user_data.FixedAllocation;

end

function weights = computeEqualCategory(asset_categories)
% Equal category weight portfolio allocation

weights = zeros(1,numel(asset_categories));
unique_categories = unique(asset_categories);
category_weight = 1 / numel(unique_categories);

for i = 1:numel(unique_categories)
    category_mask = asset_categories == unique_categories(i);
    weights(category_mask) = category_weight / sum(category_mask);
end

end

function new_weights = riskBudgetingRebalanceFcn(~,pricesTT)
% Risk budgeting rebalance function

new_weights = computeRiskBudgeting(pricesTT);

end

function new_weights = computeRiskBudgeting(pricesTT)
% Risk budgeting portfolio allocation

asset_returns = tick2ret(pricesTT);
asset_cov = cov(asset_returns{:,:});
new_weights = riskBudgetingPortfolio(asset_cov);

end

function asset_table = backtest2brinson(bt,strategy_name,benchmark_name,pricesTT,asset_categories
% Build Brinson attribution input asset table based on the results of the
% completed backtest.
% Compute asset returns per period
asset_returns = tick2ret(pricesTT(period_dates,:));

Analyze Performance Attribution Using Brinson Model

This example shows how to prepare data, create a brinsonAttribution object, and then analyze the performance attribution with respect to category (sector) weights and returns. In this example, you use the categoryAttribution, categoryReturns, categoryWeights, totalAttribution, and summary functions for the analysis. Also, you can generate plots for the results, using categoryReturnsChart, categoryWeightsChart, and attributionsChart.

Prepare Data

Load the stock price data into a table.

```
T = readtable('dowPortfolio.xlsx');
MonthIdx = [1;20;39;62;81;103;125;145;168;188;210;231;251];
MonthlyPrices = T(MonthIdx,3:end);
```

Compute the monthly returns using tick2ret.

```
MonthlyReturns = tick2ret(MonthlyPrices.Variables)';
[NumAssets,NumPeriods] = size(MonthlyReturns);
```

Define the asset categories (sectors) using categorical.

```
Category = categorical(["Materials";"Financials";"Financials"; ...
    "Industrials";"Financials";"Industrials";"Materials"; ...
    "Communication Services";"Industrials";"Consumer Discretionary"; ...
    "Consumer Discretionary";"Industrials";"Information Technology"; ...
    "Information Technology";"Information Technology";"Health Care"; ...
    "Financials";"Consumer Staples";"Consumer Discretionary"; ...
    "Industrials";"Consumer Staples";"Health Care"; ...
    "Information Technology";"Health Care";"Consumer Staples"; ...
    "Communication Services";"Industrials";"Communication Services"; ...
    "Consumer Staples";"Energy"]);
Category = repmat(Category,1,NumPeriods);
```

Define Benchmark and Portfolio Weights

Define the benchmark weight and the portfolio weights, by quarter, for each of the stock assets.

```
BenchmarkWeight = 1./length(MonthlyReturns).*ones(NumAssets, NumPeriods);

PortfolioWeightQ1 = [0;0;0.022;0.033;0;0.044;0.022;0.011;0.065;0.033; ...
    0.055;0.072;0;0.04;0;0.05;0.08;0.042;0.03;0.043;0.055;0.036;0.111; ...
    0.036;0;0.03;0;0.05;0;0.04]*ones(1,3);

PortfolioWeightQ2 = [0;0;0.022;0.033;0;0.044;0.022;0.011;0.049;0.033; ...
    0.055;0.074;0;0.04;0;0.05;0.08;0.042;0.03;0.02;0.055;0.036;0.148; ...
    0.036;0;0.03;0;0.05;0;0.04]*ones(1,3);

PortfolioWeightQ3 = [0;0;0.022;0.033;0;0.042;0.022;0.01;0.049;0.033; ...
    0.05;0.07;0;0.04;0;0.05;0.08;0.042;0.03;0.02;0.055;0.036;0.16; ...
    0.036;0;0.03;0;0.05;0;0.04]*ones(1,3);

PortfolioWeightQ4 = [0;0;0.022;0.033;0;0.042;0.02;0.01;0.039;0.033; ...
    0.05;0.07;0;0.04;0;0.05;0.08;0.042;0.03;0.02;0.055;0.036;0.198; ...
    0.036;0;0.03;0;0.03;0;0.034]*ones(1,3);
```

```
PortfolioWeight = [PortfolioWeightQ1 PortfolioWeightQ2 ...
    PortfolioWeightQ3 PortfolioWeightQ4];

Period = (1:NumPeriods).*ones(NumAssets,1);

Name = repmat(string(MonthlyPrices.Properties.VariableNames(:)),1,NumPeriods);
```

Create AssetTable Input

Use `table` to create the `AssetTable` input to use when creating a `brinsonAttribution` object.

```
AssetTable = table(Period(:), Name(:), ...
MonthlyReturns(:), Category(:), ...
PortfolioWeight(:), BenchmarkWeight(:), ...
VariableNames=["Period", "Name","Return","Category",...
"PortfolioWeight","BenchmarkWeight"])
```

```
AssetTable=360×6 table
    Period     Name        Return              Category            PortfolioWeight    BenchmarkWei

    ______    ______    ___________    ______________________    _______________    _____________

```

Create brinsonAttribution Object

Use `brinsonAttribution` to create a `brinsonAttribution` object.

```
BrinsonPAobj = brinsonAttribution(AssetTable)
```

```
BrinsonPAobj = 
  brinsonAttribution with properties:

                NumAssets: 30
       NumPortfolioAssets: 22
       NumBenchmarkAssets: 30
               NumPeriods: 12
            NumCategories: 9
                AssetName: [30x1 string]
              AssetReturn: [30x12 double]
            AssetCategory: [30x12 categorical]
     PortfolioAssetWeight: [30x12 double]
```

```
      BenchmarkAssetWeight: [30x12 double]
   PortfolioCategoryReturn: [9x12 double]
   BenchmarkCategoryReturn: [9x12 double]
   PortfolioCategoryWeight: [9x12 double]
   BenchmarkCategoryWeight: [9x12 double]
           PortfolioReturn: 0.2234
           BenchmarkReturn: 0.2046
              ActiveReturn: 0.0188
```

Compute Category Weights

Use the `brinsonAttribution` object and `categoryWeights` to compute the average and periodic category weights for the portfolio and the benchmark, as well as, the corresponding active weights.

```
[AverageCategoryWeights,PeriodicCategoryWeights] = categoryWeights(BrinsonPAobj)
```

```
AverageCategoryWeights=9×4 table
           Category           AveragePortfolioWeight    AverageBenchmarkWeight    AverageActiveWe

Diversify Portfolios Using Custom Objective

This example shows three techniques of asset diversification in a portfolio using the `estimateCustomObjectivePortfolio` function with a `Portfolio` object. The purpose of asset diversification is to balance the exposure of the portfolio to any given asset to reduce volatility over a period of time. Given the sensitivity of the minimum variance portfolio to the estimation of the covariance matrix, some practitioners have added diversification techniques to the portfolio selection with the hope of minimizing risk measures other than the variance measures such as turnover, maximum drawdown, and so on.

This example applies these common diversification techniques:

- Equally weighted (EW) portfolio on page 4-331
- Equal risk contribution (ERC) on page 4-334
- Most diversified portfolio (MDP) on page 4-332

Additionally, this example demonstrates penalty methods that you can use to achieve different degrees of diversification. In those methods, you add a penalty term to the `estimateCustomObjectivePortfolio` function to balance the level of variance reduction and the diversification of the portfolio.

Retrieve Market Data and Define Mean-Variance Portfolio

Begin by loading and computing the expected returns and their covariance matrix.

```
% Load data
load('port5.mat');
% Store returns and covariance
mu = mean_return;
Sigma = Correlation .* (stdDev_return * stdDev_return');
```

Define a mean-variance portfolio using a `Portfolio` object with default constraints to create a fully invested, long-only portfolio.

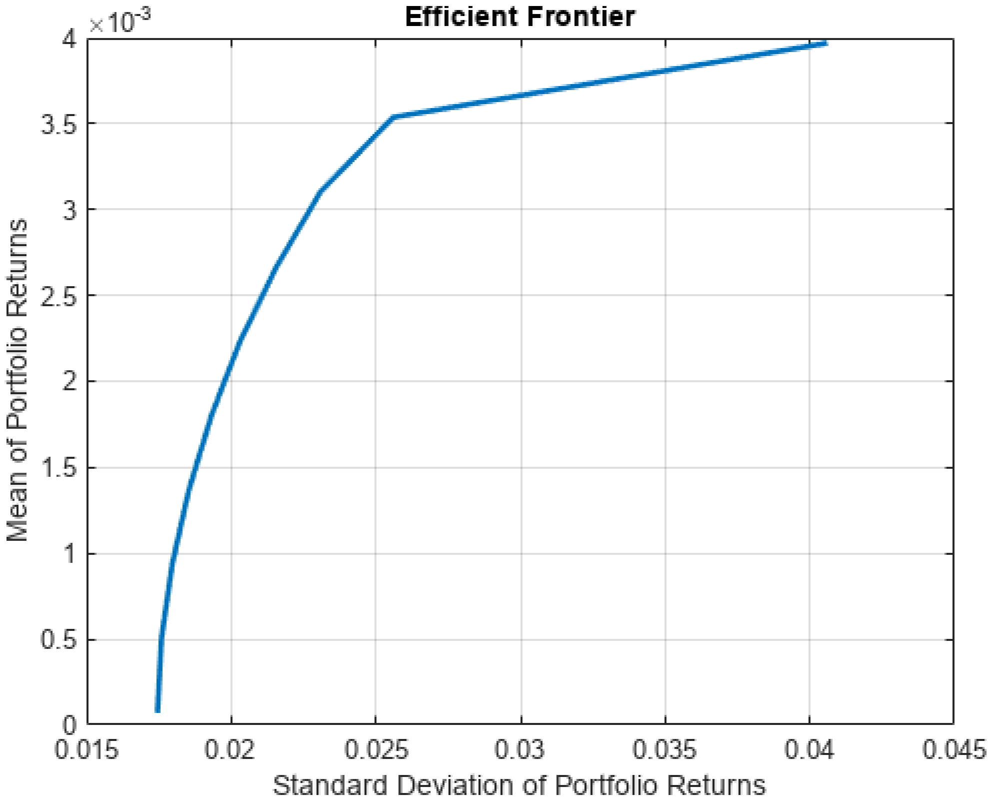
```
% Create a mean-variance Portfolio object with default constraints
p = Portfolio('AssetMean',mu,'AssetCovar',Sigma);
p = setDefaultConstraints(p);
```

One of the many features of the `Portfolio` object is that it can obtain the efficient frontier of the portfolio problem. The efficient frontier is computed by solving a series of optimization problems for which the return level of the portfolio, μ_0, is modified to obtain different points on the efficient frontier. These problems are defined as

$$\begin{aligned} \min \;\; & x^T \Sigma x \\ \text{st.} \;\; & \sum_{i=1}^{n} x_i = 1 \\ & x^T \mu \geq \mu_0 \\ & x \geq 0 \end{aligned}$$

The advantage of using the `Portfolio` object to compute the efficient frontier is that you can obtain without having to manually formulate and solve the multiple optimization problems shown above.

```
plotFrontier(p);
```



The Portfolio object can also compute the weights associated with the minimum variance portfolio, which is defined by the following problem.

$$\begin{aligned} &\min \ x^T \Sigma x \\ &\text{st.} \ \sum_{i=1}^{n} x_i = 1 \\ &\quad x \geq 0 \end{aligned}$$

The minimum variance weights is the benchmark against which all the weights of the diversification strategies are compared.

```
wMinVar = estimateFrontierLimits(p,'min');
```

To learn more about the problems that you can solve with the Portfolio object, see “When to Use Portfolio Objects Over Optimization Toolbox” on page 4-128.

Specify Diversification Techniques

This section presents the three diversification methods. Each of the three diversification methods is associated with a diversification measure and that diversification measure defines a penalty term to achieve different diversification levels. The diversification, obtained by adding the penalty term to the objective function, ranges from the behavior achieved by the minimum variance portfolio to the behavior of the EW, ECR, and MDP, respectively.

The default portfolio has only one equality constraint and a lower bound for the assets weights. The weights must be nonnegative and they must sum to 1. The feasible set is represented as$X$:

$$X = \left\{ x \;\middle|\; x \geq 0,\ \sum_{i=1}^{n} x_i = 1 \right\}$$

Equally Weighted Portfolio

One of the diversification measures is the Herfindahl-Hirschman (HH) index defined as:

$$\mathrm{HH}(x) = \sum_{i=1}^{n} x_i^2$$

This index is minimized when the portfolio is equally weighted. The portfolios obtained from using this index as a penalty have weights that satisfy the portfolio constraints and that are more evenly weighted.

The portfolio that minimizes the HH index is $\min_{x \in X}\ x^T x$. Since the constraints in X are the default constraints, the solution of this problem is the equally weighted (EW) portfolio. If X had extra constraints, the solution would be the portfolio that satisfies all the constraints and, at the same time, keeps the weights as equal as possible. Use the function handle HHObjFun for the Herfindahl-Hirschman (HH) index with the estimateCustomObjectivePortfolio function.

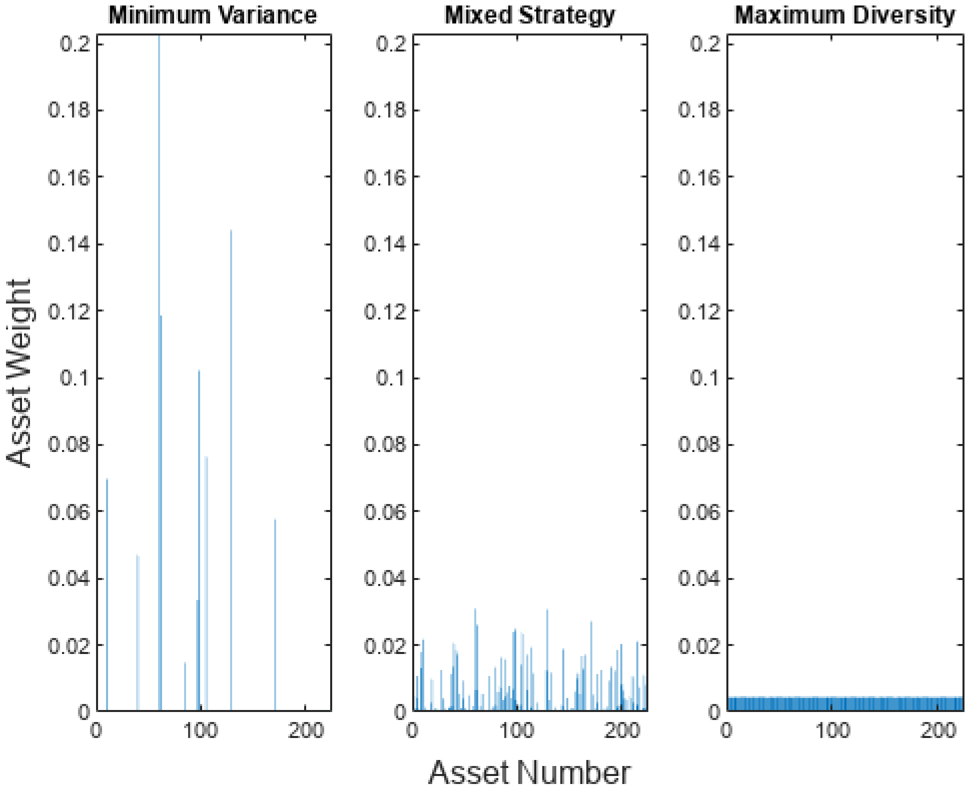
```
% Maximize the HH diversification (by minimizing the HH index)
HHObjFun = @(x) x'*x;
% Solution that minimizes the HH index
wHH = estimateCustomObjectivePortfolio(p,HHObjFun);
```

The portfolio that minimizes the variance with the HH penalty is $\min_{x \in X}\ x^T \Sigma x + \lambda_{\mathrm{HH}} x^T x$. Use the function handle HHMixObjFun for the HH penalty with the estimateCustomObjectivePortfolio function.

```
% HH penalty parameter
lambdaHH = 1e-2;
% Variance + Herfindahl-Hirschman (HH) index
HHMixObjFun = @(x) x'*p.AssetCovar*x + lambdaHH*(x'*x);
% Solution that accounts for risk and HH diversification
wHHMix = estimateCustomObjectivePortfolio(p,HHMixObjFun);
```

Plot the weights distribution for the minimum variance portfolio, the equal weight portfolio, and the penalized strategy.

```
% Plot different strategies
plotAssetAllocationChanges(wMinVar,wHHMix,wHH)
```



This plot shows how the penalized strategy returns weights that are between the minimum variance portfolio and the EW portfolio. In fact, choosing $\lambda_{\mathrm{HH}} = 0$ returns the minimum variance solution, and as $\lambda_{\mathrm{HH}} \rightarrow \infty$, the solution approaches the EW portfolio.

Most Diversified Portfolio

The diversification index associated to the most diversified portfolio (MDP) is defined as

$$\mathrm{MDP}(x) = -\sum_{i=1}^{n} \sigma_i x_i$$

where σ_i represents the standard deviation of asset i.

The MDP is the portfolio that maximizes the diversification ratio:

$$\varphi(x) = \frac{x^T \sigma}{\sqrt{x^T \Sigma x}}$$

The diversification ratio $\varphi(x)$ is equal to 1 if the portfolio is fully invested in one asset or if all assets are perfectly correlated. For all other cases, $\varphi(x) > 1$. If $\varphi(x) \approx 1$, there is no diversification, so the goal is to find the portolio that maximizes $\varphi(x)$:

$$\max_{x \in X} \frac{\sigma^T x}{\sqrt{x^T \Sigma x}}$$

Unlike the HH index, the MDP goal is not to obtain a portfolio whose weights are evenly distributed among all assets, but to obtain a portfolio whose selected (nonzero) assets have the same correlation to the portfolio as a whole. Use the function handle `MDPObjFun` for the most diversified portfolio (MDP) with the `estimateCustomObjectivePortfolio` function.

```
% Maximize the diversification ratio
sigma = sqrt(diag(p.AssetCovar));
MDPObjFun = @(x) (sigma'*x)/sqrt(x'*p.AssetCovar*x);
% Solution of MDP
wMDP = estimateCustomObjectivePortfolio(p,MDPObjFun, ...
    ObjectiveSense="maximize");
```

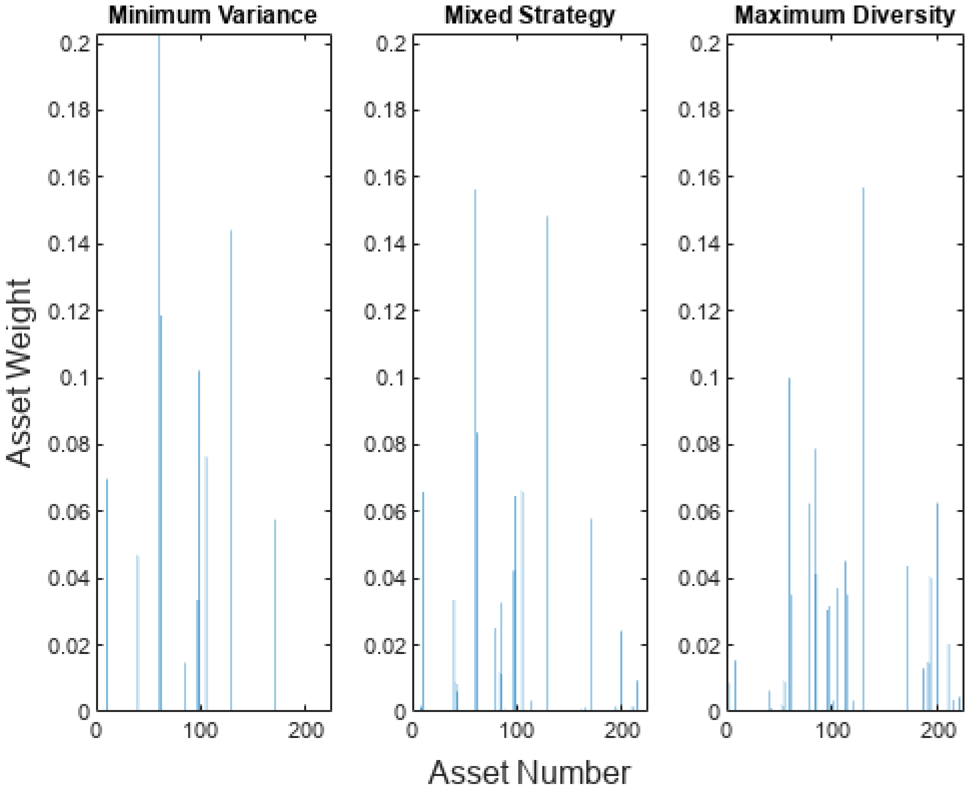
The following code shows that there exists a value $\widehat{\lambda}_{\text{MDP}} > 0$ such that the MDP problem and the problem with its penalized version are equivalent.The portfolio that minimizes the variance with the MDP penalty is $\min_{x \in X} \ x^T \Sigma x - \lambda_{\text{MDP}} \, \sigma^T x$.

Define an MDP penalty parameter and solve for MDP using the function handle `MDPMixObjFun` for the MDP penalty with the `estimateCustomObjectivePortfolio` function.

```
% MDP penalty parameter
lambdaMDP = 1e-2;
% Variance + Most Diversified Portfolio (MDP)
MDPMixObjFun = @(x) x'*p.AssetCovar*x - lambdaMDP*(sigma'*x);
% Solution that accounts for risk and MDP diversification
wMDPMix = estimateCustomObjectivePortfolio(p,MDPMixObjFun);
```

Plot the weights distribution for the minimum variance portfolio, the MDP, and the penalized strategy.

```
% Plot different strategies
plotAssetAllocationChanges(wMinVar,wMDPMix,wMDP)
```



In this plot, the penalized strategy weights are between the minimum variance portfolio and the MDP. This result is the same as with the HH penalty, where choosing $\lambda_{\text{MDP}} = 0$ returns the minimum variance solution and values of $\lambda_{\text{MDP}} \in \left[0, \widehat{\lambda}_{\text{MDP}}\right]$ return asset weights that range from the minimum variance behavior to the MDP behavior.

Equal Risk Contribution Portfolio

The diversification index associated with the equal risk contribution (ERC) portfolio is defined as

$$\text{ERC}(x) = -\sum_{i=1}^{n} \ln(x_i)$$

This index is related to a convex reformulation shown by Maillard [1 on page 4-339] that computes the ERC portfolio. The authors show that you can obtain the ERC portfolio by solving the following optimization problem

$$\min_{y \geq 0} y^T \Sigma y$$
$$\text{st.} \quad \sum_{i=1}^{n} \ln(y_i) \geq c$$

and by defining x, the ERC portfolio with default constraints, as $x = \frac{y}{\Sigma_i y_i}$, where $c > 0$ can be any constant. You implement this procedure in the riskBudgetingPortfolio on page 4-339 function.

The purpose of the ERC portfolio is to select the assets weights in such a way that the risk contribution of each asset to the portfolio volatility is the same for all assets.

```
% ERC portfolio
wERC = riskBudgetingPortfolio(p.AssetCovar);
```

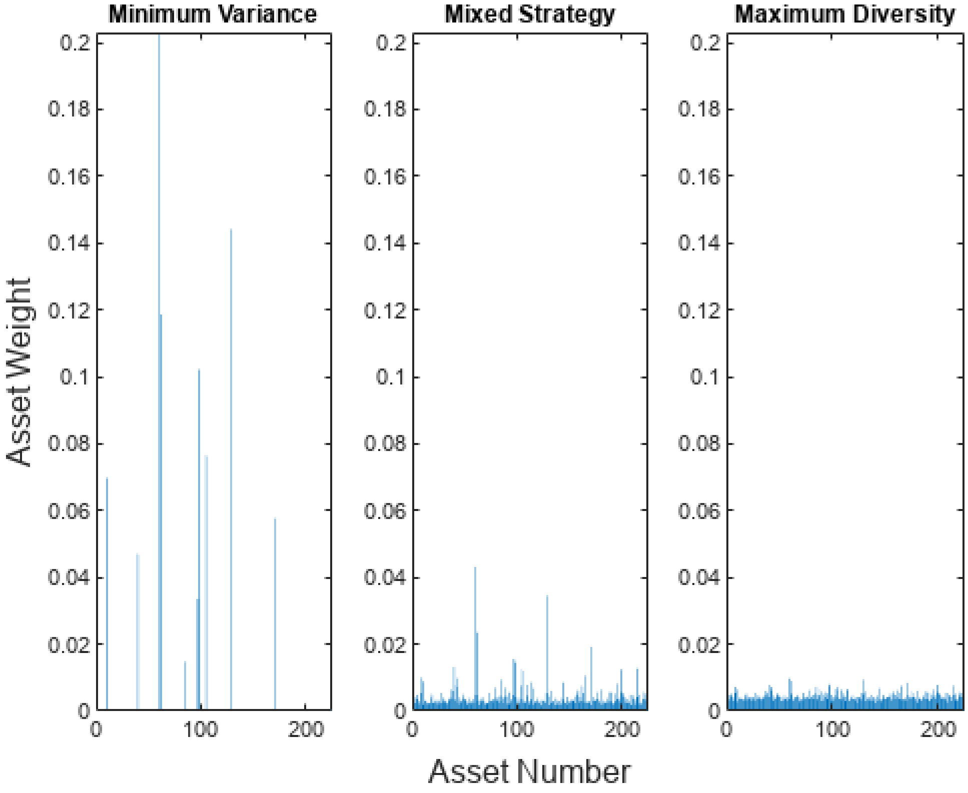
The portfolio that minimizes the variance with the ERC penalty is $\min_{x \in X} \; x^T \Sigma x - \lambda_{\mathrm{ERC}} \sum_{i=1}^{n} \ln(x_i)$.

Similar to the case for the MDP penalized formulation, there exists a $\hat{\lambda}_{\mathrm{ERC}}$ such that the ERC problem and its penalized version are equivalent. Use the function handle `ERCMixObjFun` for the ERC penalty with the `estimateCustomObjectivePortfolio` function.

```
% ERC penalty parameter
lambdaERC = 3e-6; % lambdaERC is so small because the log of a number
                  % close to zero (the portfolio weights) is large
% Variance + Equal Risk Contribution (ERC)
ERCMixObjFun = @(x) x'*p.AssetCovar*x - lambdaERC*sum(log(x));
% Solution that accounts for risk and ERC diversification
wERCMix = estimateCustomObjectivePortfolio(p,ERCMixObjFun);
```

Plot the weights distribution for the minimum variance portfolio, the ERC, and the penalized strategy.

```
% Plot different strategies
plotAssetAllocationChanges(wMinVar,wERCMix,wERC)
```



Comparable to the two diversification measures above, here the penalized strategy weights are between the minimum variance portfolio and the ERC portfolio. Choosing $\lambda_{\text{ERC}} = 0$ returns the minimum variance solution and the values of $\lambda_{\text{ERC}} \in \left[0, \widehat{\lambda}_{\text{ERC}}\right]$ return asset weights that range from the minimum variance behavior to the ERC portfolio behavior.

Compare Diversification Strategies

Compute the number of assets that are selected in each portfolio. Assume that an asset is selected if the weight associated to that asset is above a certain threshold.

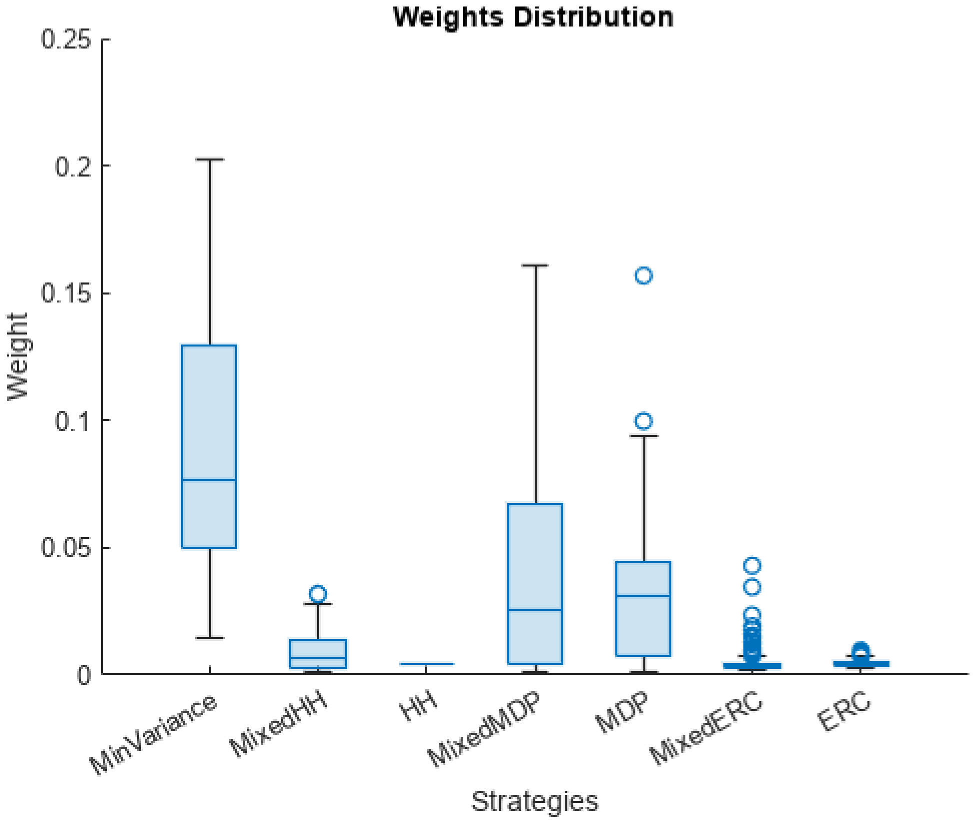
```
% Build a weights table
varNames = {'MinVariance','MixedHH','HH','MixedMDP','MDP', ...
    'MixedERC','ERC'};
weightsTable = table(wMinVar,wHHMix,wHH,wMDPMix,wMDP, ...
    wERCMix,wERC,'VariableNames',varNames);
% Number of assets with nonzero weights
cutOff = 1e-3; % Weights below cut-off point are considered zero.
[reweightedTable,TnonZero] = tableWithNonZeroWeights(weightsTable, ...
    cutOff,varNames);
display(TnonZero)
```

```
TnonZero=1×7 table
                       MinVariance    MixedHH    HH     MixedMDP    MDP    MixedERC    ERC
                       ___________    _______    ___    ________    ___    ________    ___

    Nonzero weights        11           104      225       23       28       225       225
```

As discussed above, the HH penalty goal is to obtain more evenly weighted portfolios. The portfolio that maximizes the HH diversity (and corresponds to the EW portfolio when only the default constraints are selected) has the largest number of assets selected and the weights of these assets are closer together. You can see this latter quality in the following `boxchart`. Also, the strategy that adds the HH index as a penalty function to the objective has a larger number of assets than the minimum variance portfolio but less than the portfolio that maximizes HH diversity. The ERC portfolio also selects all the assets because all weigths need to be nonzero to have some risk contribution.

```
% Boxchart of portfolio weights
figure;
matBoxPlot = reweightedTable.Variables;
matBoxPlot(matBoxPlot == 0) = NaN;
boxchart(matBoxPlot)
xticklabels(varNames)
title('Weights Distribution')
xlabel('Strategies')
ylabel('Weight')
```

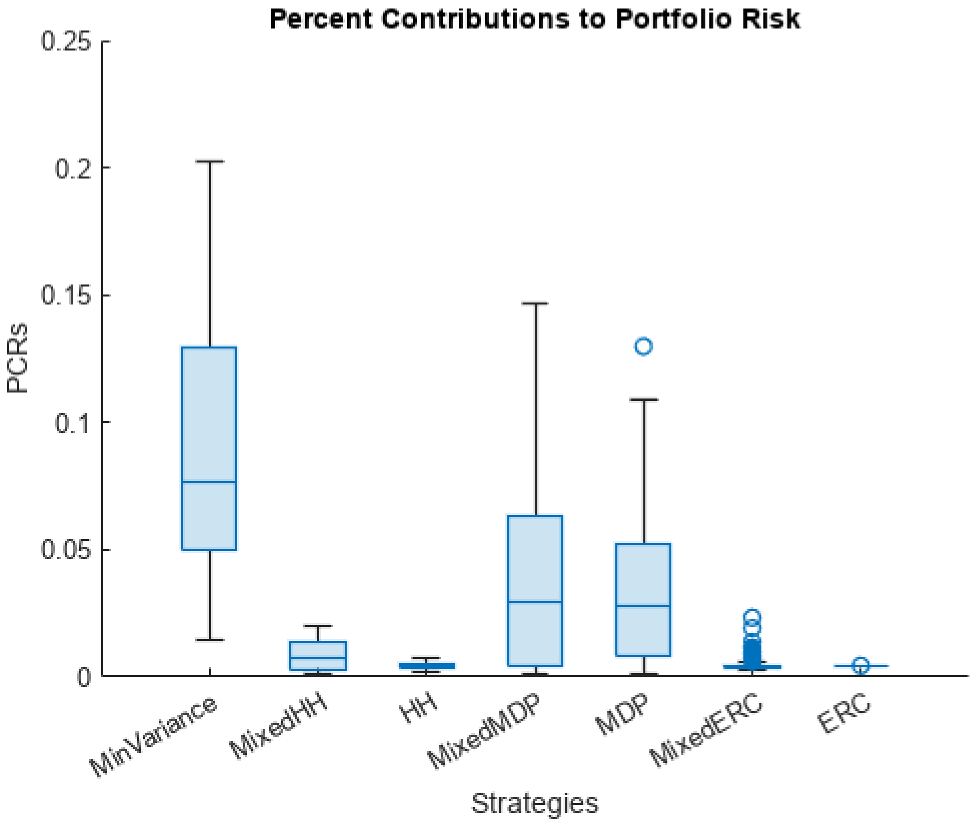


This `boxchart` shows the spread of the assets' positive weights for the different portfolios. As previously discussed, the weights of the portfolio that maximize the HH diversity are all the same. If the portfolio had other types of constraints, the weights would not all be the same, but they would have the lowest variance. The ERC portfolio weights also have a small variance. In fact, you can observe as the number of assets increases as the variance of the ERC portfolio weights becomes smaller.

The weights variability of the MDP is smaller than the variability of the minimum variance weights. However, it is not necessarily true that the MDP's weights will have less variability than the minimum variance weights because the goal of the MDP is not to obtain equally weighted assets, but to distribute the correlation of each asset with its portfolio evenly.

```
% Compute and plot the risk contribution of each individual
% asset to the portfolio
riskContribution = portfolioRiskContribution(p.AssetCovar, ...
    weightsTable.Variables);
% Remove small contributions
riskContribution(riskContribution < 1e-3) = NaN;

% Compare percent contribution to portofolio risk
boxchart(riskContribution)
xticklabels(varNames)
title('Percent Contributions to Portfolio Risk')
xlabel('Strategies')
ylabel('PCRs')
```

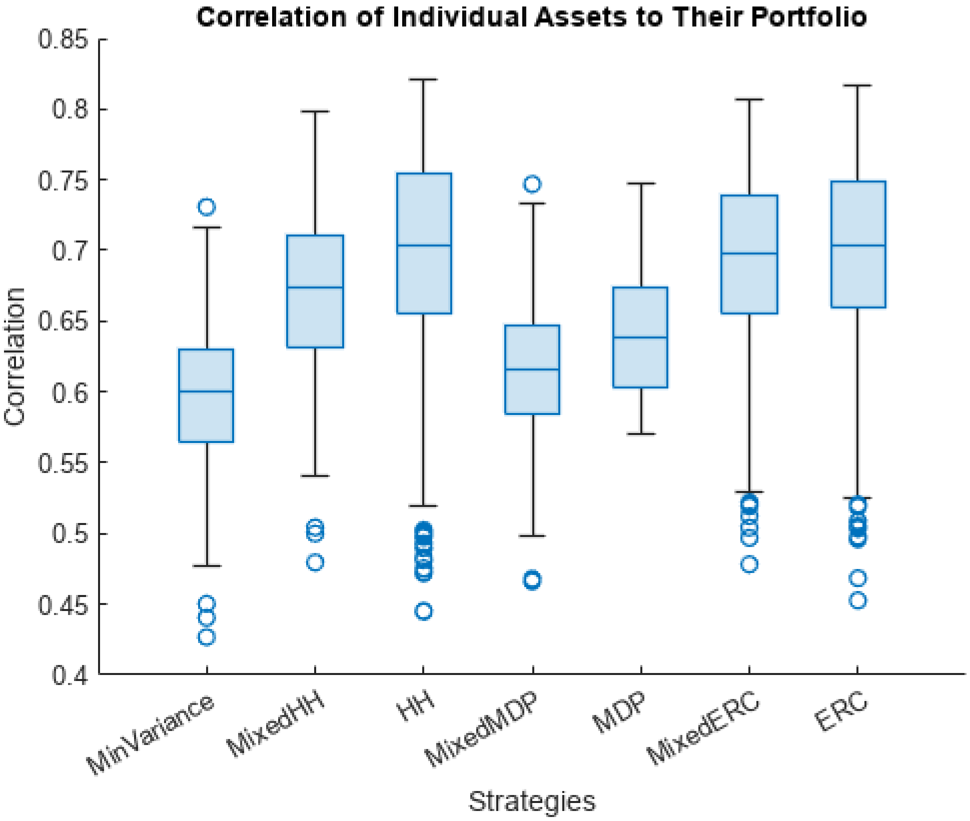


This `boxchart` shows the percent risk contribution of each asset to the total portfolio risk. The percent risk contribution is computed as

$$(\mathrm{PRC})_i = \frac{x_i(\Sigma x)_i}{x^T \Sigma x}$$

As expected, all the ERC portfolio assets have the same risk contribution to the portfolio. As discussed after the weights distribution plot, if the problem had other types of constraints, the risk contribution of the ERC portfolio would not be the same for all assets, but they would have the lowest variance. Also, the behavior shown in this picture is similar to the behavior shown by the weights distribution.

```
% Compute and plot the correlation of each individual asset to its
% portfolio
corrAsset2Port = correlationInfo(p.AssetCovar, ...
    weightsTable.Variables);
% Boxchart of assets to portfolio correlations
figure
boxchart(corrAsset2Port)
xticklabels(varNames)
title('Correlation of Individual Assets to Their Portfolio')
xlabel('Strategies')
ylabel('Correlation')
```



This `boxchart` shows the distribution of the correlations of each asset with its respective portfolio. The correlation of asset *i* to its portfolio is computed with the following formula:

$$\rho_{\mathrm{iP}} = \frac{(\Sigma x)_i}{\sigma_i \sqrt{x^T \Sigma x}}$$

The MDP is the portfolio whose correlations are closer together and this is followed by the strategy that uses the MDP penalty term. In fact, if the portfolio problem allowed negative weights, then all the assets of the MDP would have the same correlation to its portfolio. Also, both the HH (EW) and ERC portfolios have almost the same correlation variability.

Solve Problem for Minimum Variance Portfolio with Tracking Error Penalty

This example shows how to compute a portfolio that minimizes the tracking error subject to a benchmark portfolio. This example uses `estimateCustomObjectivePortfolio` to solve a problem for a minimum variance `Portfolio` with a tracking error penalty. The example also shows how to add the tracking error as a "soft constraint" to any portfolio optimization problem. The tracking error measures the standard deviation of the divergence between a portfolio's return and that of a benchmark.

Define the mean and covariance of the assets returns.

```
% Define assets mean.
mu = [ 0.05; 0.1; 0.12; 0.18 ];
% Define assets covariance.
Sigma = [ 0.0064 0.00408 0.00192 0;
        0.00408 0.0289 0.0204 0.0119;
        0.00192 0.0204 0.0576 0.0336;
        0 0.0119 0.0336 0.1225 ];
```

Simulate a timeseries of assets returns with mean `mu` and covariance `Sigma`. From this point onward, assume that the true mean and covariance are not known and they can only be estimated from the timetable data.

```
% Find all business days of the last two years.
tEnd = datetime('today');
bdates = busdays(tEnd-calyears(2),tEnd);
% Create a simulated timetable.
rng('default')
nScen = size(bdates,1);
assetsTT = array2timetable(mvnrnd(mu,Sigma,nScen),RowTimes=bdates);
```

Define a long-only, fully invested portfolio problem using `Portfolio`.

```
% Define a Portfolio object.
p = Portfolio;
p = estimateAssetMoments(p,assetsTT);
% Specify constraints for a long-only, fully invested portfolio.
p = setDefaultConstraints(p);
```

Assume that there is a market index that follows the maximum Sharpe ratio portfolio. Use `estimateMaxSharpeRatio` to create the benchmark portfolio.

```
% Create the benchmark portfolio.
bmkPort = estimateMaxSharpeRatio(p);
% Create the benchmark returns timetable.
marketTT = timetable(assetsTT.Time,assetsTT.Variables*bmkPort, ...
    VariableNames={'Benchmark'});
```

Minimize Tracking Error

You can use two methods to obtain the tracking error. The first method uses the variance of the excess return of the portfolio with respect to the benchmark. This method assumes that the benchmark prices or returns are given, but does not require knowledge of the weights of the assets associated to the benchmark. The second method requires you to decompose the benchmark into the different weights for each asset.

Tracking Error Using Benchmark Returns

To compute the tracking error, you first need to compute the excess return of each asset with respect to the benchmark.

```
% Compute the excess return.
excessReturn = assetsTT.Variables-marketTT.Variables;
```

Then, you can compute the excess returns covariance matrix $\Sigma_{\widehat{R}}$.

```
excessRetSigma = cov(excessReturn);
```

Compute the tracking error as the variance of the excess return of the portfolio

$$x^T \Sigma_{\widehat{R}} x\,.$$

For this example, you want to find the portfolio that minimizes the tracking error to the benchmark with, at most, half of the assets in the universe. Furthermore, if an asset is selected in the portfolio, at least 10% must be invested in that asset. This problem is as follows:

$$\begin{aligned} &\min_x \; x^T \Sigma_{\widehat{R}} x \\ &s.t.\; \sum_i x_i = 1, \\ &\quad \sum_i \#(x_i \neq 0) \leq 2, \\ &\quad x = 0 \text{ or } x \geq 0.1 \end{aligned}$$

To solve this problem, first add the constraints to the `Portfolio` object using the `setBudget`, `setMinMaxNumAssets`, and `setBounds` functions.

```
% Specify that the budget sums to one constraint.
p = setBudget(p,1,1);
% Specify the maximum number of assets as 15.
p = setMinMaxNumAssets(p,[],2);
% Specify the conditional bounds.
p = setBounds(p,0.1,[],BoundType="conditional");
```

Define a function handle for the objective function $x^T \Sigma_{\widehat{R}} x$.

```
% Define the objective function.
TEsquared1 = @(x) x'*excessRetSigma*x;
```

Use `estimateCustomObjectivePortfolio` to compute the solution to the problem.

```
% Solve the porfolio problem.
wMinTE1 = estimateCustomObjectivePortfolio(p,TEsquared1)
```

```
wMinTE1 = 4×1

    0.8392
         0
         0
    0.1608
```

Tracking Error Using Benchmark Weights

You can also define the tracking error as

$$(x - x_0)^T \Sigma (x - x_0).$$

In this formulation, Σ is the covariance matrix of the assets returns (not the excess returns) and this example assumes that the weight vector of the benchmark portfolio is known. Using the same constraints as the Tracking Error Using the Benchmark Returns on page 4-343 method, the problem is as follows:

$$\begin{aligned} &\min_x \ (x - x_0)^T \Sigma (x - x_0) \\ &s.t. \sum_i x_i = 1, \\ &\quad \sum_i \#(x_i \neq 0) \leq 2, \\ &\quad x = 0 \text{ or } x \geq 0.01 \end{aligned}$$

Since the constraints are the same, you need only to define a new objective function.

```
% Define the objective function.
TESquared2 = @(x) (x-bmkPort)'*p.AssetCovar*(x-bmkPort);
```

Use `estimateCustomObjectivePortfolio` to compute the solution to the problem.

```
% Solve the porfolio problem.
wMinTE2 = estimateCustomObjectivePortfolio(p,TESquared2)
```

```
wMinTE2 = 4×1

    0.8392
         0
         0
    0.1608
```

The difference in the allocation for the different methods is negligible within a numerical accuracy. This means that the solution to both problems is the same.

```
norm(wMinTE1-wMinTE2,"inf")
```

```
ans = 0
```

Add Tracking Error Constraints

When you have a portfolio problem with cardinality constraints or conditional bounds and you use an objective function that is different than the return or variance for a mixed-integer problem, this portfolio problem does not support tracking error constraints. One option for including a tracking error constraint with a mixed-integer problem is to add the tracking error as a penalty to the objective function. In this case, the tracking error becomes a soft constraint and the strength of the constraint is controlled with the penalty parameter $\lambda \geq 0$. The larger λ is, the stronger the tracking error constraint becomes, and conversely, the smaller λ is, the weaker the tracking error constraint becomes.

Assume that you are interested in obtaining the portfolio closest to the equally weighted portfolio (EWP) such that the tracking error is smaller than 5.3%. Minimizing the Herfindahl-Hirschman (HH) index, given by x^Tx, returns the portfolio closest to the EWP that satisfies the necessary constraints. Assuming that the portfolio must satisfy the same constraints as in Minimizing Tracking Error on page 4-342, the problem is as follows:

$$\begin{aligned}
&\min_x \; x^T x + \lambda (x - x_0)^T \Sigma (x - x_0)\\
&s.t. \sum_i x_i = 1,\\
&\qquad \sum_i \#(x_i \neq 0) \leq 2,\\
&\qquad x = 0 \text{ or } x \geq 0.01
\end{aligned}$$

Define the penalized objective function. In this case, you can use the minimum tracking error portfolio as the benchmark portfolio.

```
% Define the objective function.
lambda = 100 ;
penalizedObjFun = @(x) x'*x + ...
    lambda*(x-bmkPort)'*p.AssetCovar*(x-bmkPort);
```

Use `estimateCustomObjectivePortfolio` to solve problem.

```
% Solve the penalized problem.
wEWPwithTE = estimateCustomObjectivePortfolio(p,penalizedObjFun)
```

```
wEWPwithTE = 4×1

    0.6312
    0.3688
         0
         0
```

Check if the tracking error satisfies the constraint. If it does not, make λ larger.

```
% Check if tracking error is smaller than 5.3%.
sqrt(TESquared2(wEWPwithTE)) <= 0.053
```

```
ans = logical
   1
```

Compare the different portfolio allocations.

```
% Compare the weights of the different portfolios.
pwgt = table(wEWPwithTE,wMinTE1,bmkPort, ...
    VariableNames={'EWPwithTE','MinTE','Benchmark'})
```

```
pwgt=4×3 table
    EWPwithTE     MinTE      Benchmark
    _________    _______    _________

     0.63115     0.83924     0.64539
     0.36885           0     0.14658
```

```
         0           0    0.088365
         0     0.16076     0.11967
```

When you compare the weights of the portfolio that minimizes the HH index with the tracking error penalty against the weights of the portfolio that minimizes the tracking error, you can see:

- As $\lambda \to 0$, the weights of the penalized problem become exactly 0.5 in two assets. This happens because a portfolio with 0.5 weights in two assets is the one that is closest to the EW portfolio and satisfies the constraints.
- As $\lambda \to \infty$, the weights of the penalized problem come closer to the weights of the minimum tracking error problem. This result happens because the penalized term in the objective overcomes the HH index.

Selecting different values of $\lambda \geq 0$ modifies the strength of the tracking error constraint.

Solve Problem for Minimum Tracking Error with Net Return Constraint

This example shows how to use `estimateCustomObjectivePortfolio` to solve a portfolio problem for minimum tracking error with a net return constraint using a custom objective.

Create `Portfolio` Object

Create a `Portfolio` object.

```
% Create a Portfolio object
load('SixStocks.mat')
p = Portfolio(AssetMean=AssetMean,AssetCovar=AssetCovar);
```

Define Problem

The portfolio problem for a minimum tracking error problem with a net return constraint is defined as

$$\min_{x}\ (x-x_0)^T\Sigma(x-x_0)$$
$$s.t.\, \mu^T x - c_B^T \max(0, x-x_0) - c_S^T \max(0, x_0 - x) \geq \mu_0$$
$$\sum_i x_i = 1$$
$$x \geq 0$$

Define Problem Parameters

Define the problem parameters for the `Portfolio` object.

```
% Initial portfolio
initPort = 1/p.NumAssets*ones(p.NumAssets,1);
% Buy cost
buyCost = 0.001*ones(p.NumAssets,1);
% Sell cost
sellCost = 0.002*ones(p.NumAssets,1);
% Net return target
ret0 = 0.03;
```

Solve Portfolio Problem

Use `estimateCustomObjectivePortfolio` to solve this portfolio problem for a minimum tracking error with a net return constraint. When using the `estimateCustomObjectivePortfolio` function with a `Portfolio` object, you add return constraints by using the `estimateCustomObjectivePortfolio` name-value argument `TargetReturn` with a return target value.

```
% Long-only, fully invested portfolio
p = setDefaultConstraints(p);
% Set the buy and sell costs
p = setCosts(p,buyCost,sellCost,initPort);

% Set the objective
fun = @(x) (x-initPort)'*p.AssetCovar*(x-initPort);
```

```
% Solve the portfolio problem
wFinTbx = estimateCustomObjectivePortfolio(p,fun,TargetReturn=ret0)

wFinTbx = 6×1

    0.1633
    0.0648
    0.1950
    0.2618
    0.0625
    0.2525
```

Solve Robust Portfolio Maximum Return Problem with Ellipsoidal Uncertainty

This example shows a robust formulation of portfolio optimization with uncertainty in the assets returns. It uses `estimateCustomObjectivePortfolio` to solve a robust `Portfolio` problem for a maximum return problem with an ellipsoidal uncertainty. Robust portfolio optimization, in contrast to the deterministic Markowitz mean-variance formulation, considers the uncertainty in the parameters of the problem: the assets' expected returns and their covariance matrix. In the traditional mean-variance model, the mean and covariance are assumed to take the point-values of the historical mean and covariance. However, in robust optimization, the mean and covariance are in a set that contains the most likely realizations, and the problem is optimized with respect to the worst possible outcome in that set.

Define Problem

If the vector of expected returns r has no uncertainty, the portfolio optimization problem that maximizes the returns is

$$R_{\text{port}} = \max_{x \in X} r^T x,$$

where

- $x \in \mathbb{R}^n$ is the vector of portfolio weights.
- X is the set of feasible allocations represented by a set of constraints.

Robust optimization assumes that the estimates of the expected returns are unreliable, but live in a set that contains the most likely realizations. The set of possible realizations of the expected returns is the *uncertainty set* and is given by

$$\{r \mid r \in \mathrm{S}(r_0)\},$$

where

- $\mathrm{S}(r_0)$ is a region around the vector r_0.

A common robust formulation of the portfolio problem is the one that tries to maximize the expected return of the portfolio in the worst case scenario of the uncertainty set. This is represented with the following "max-min" problem

$$R_{\text{port}} = \max_{x \in X} \min_{r \in \mathrm{S}(r_0)} r^T x .$$

In this example, assume that the uncertainty set follows the common ellipsoidal uncertainty given by

$$\mathrm{S}(r_0) = \left\{ r \mid (r - r_0)^T \Sigma_r^{-1} (r - r_0) \le \kappa^2 \right\},$$

where

- κ is the uncertainty aversion parameter that defines the width of the uncertainty.
- Σ_r is the covariance matrix of estimation errors in the expected returns r.

Goldfarb and Iyengar [1 on page 4-353] show that the robust maximization return problem with ellipsoidal uncertainty in the return is formulated as

$$\max_{x \in X} \; r_0^T x - \kappa\sqrt{x^T \Sigma_r x}\,.$$

Build Matrix of Estimated Errors in Expected Returns

Assume that the covariance matrix of estimation errors Σ_r is a diagonal matrix whose entries are proportional to the assets variance.

Load the data.

```
% Read the table of daily adjusted close prices for 2006 DJI stocks.
T = readtable('dowPortfolio.xlsx');
% Convert the table to a timetable.
pricesTT = table2timetable(T);
% Remove the DJI stock from the table.
pricesTT = pricesTT(:,2:end);
```

Build the covariance matrix of estimation errors in the expected returns.

```
% Compute the returns from the prices.
returnsTT = tick2ret(pricesTT);
% Compute the assets covariance matrix.
Sigma = cov(returnsTT.Variables);
% Compute the covariance matrix of estimation errors in the expected returns.
SigmaR = diag(diag(Sigma));
```

Solve Robust Problem

Define a `Portfolio` object.

```
% Define a traditional mean-variance portfolio.
p = Portfolio;
p = estimateAssetMoments(p,returnsTT,MissingData=true,GetAssetList=true);
```

Add constraints to the `Portfolio` object. The portfolio is a fully invested, long-short portfolio with bounds `[-0.2,0.2]`.

```
% Specify a fully invested constraint.
p = setBudget(p,1,1);
% Specify the long-short bounds.
p = setBounds(p,-0.2,0.2);
```

Define the objective function with $\kappa = 0.5$ as the ellipsoidal uncertainty parameter.

```
% Objective function handle
kappa = 0.5;
robustObjective = @(x) p.AssetMean'*x - kappa*sqrt(x'*SigmaR*x);
```

Solve the robust maximum return problem using `estimateCustomObjectivePortfolio`.

```
wRobustMaxRet = estimateCustomObjectivePortfolio(p,robustObjective,ObjectiveSense="maximize");
```

Compare Mean-Variance and Robust Portfolio Strategies

Compare the performance of the traditional maximum return portfolio against its robust counterpart using backtesting.

Define the warmup period to compute the initial portfolios for the different strategies using the data in that period.

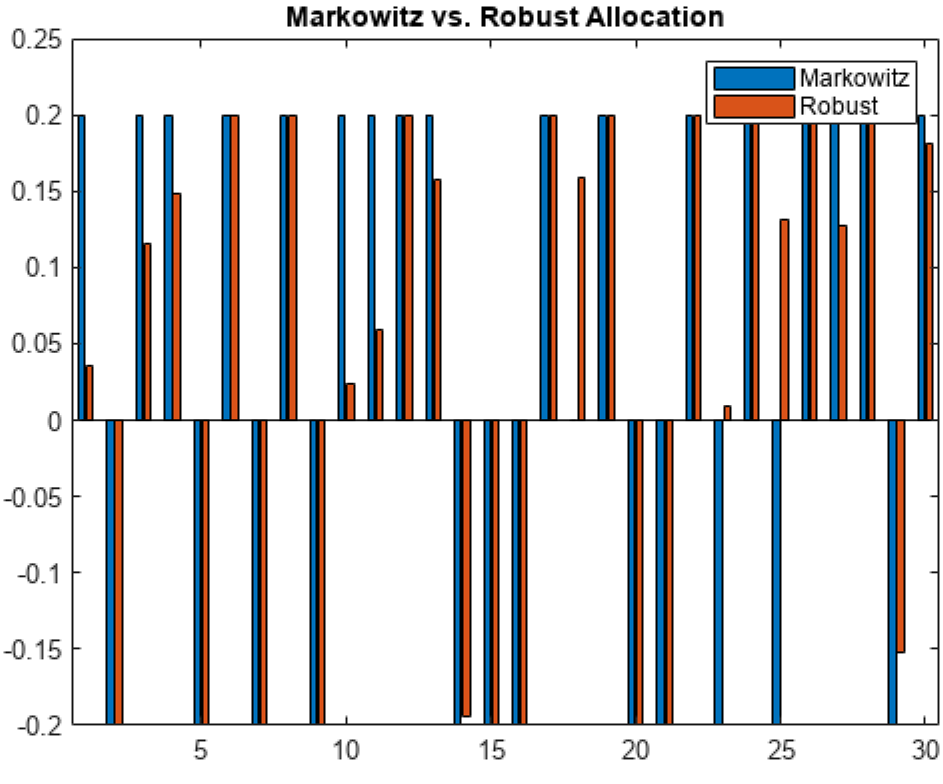
```
% Set backtesting warmup period to two 21-day months.
warmupPeriod = 21*2;
% Set a warmup partition of the timetable.
warmupTT = pricesTT(1:warmupPeriod,:);
```

Compute the initial portfolios using the rebalancing functions (`markowitzFcn` and `robustFcn`) that are defined in Local Functions on page 4-354.

```
% Define the initial Markowitz portfolio.
initialMarkowitz = markowitzFcn(zeros(p.NumAssets,1),warmupTT,p);
% Define the initial robust portfolio.
initialRP = robustFcn(zeros(p.NumAssets,1),warmupTT,p,kappa);
```

Plot both types of portfolios to compare the initial behavior.

```
% Plot the intial portfolios.
bar([initialMarkowitz initialRP])
legend('Markowitz','Robust')
title('Markowitz vs. Robust Allocation')
```



Out of 30 assets in the Markowitz allocation, 29 are at the extremes of the feasible bounds. On the other hand, only 17 assets in the robust allocation are at their extremes. The number of assets at the extremes of the feasible bounds shows the sensitivity of the traditional maximum return allocation strategy to the parameters of the problem. The Markowitz strategy invests everything possible in the assets with the highest returns. This result means that the Markowitz strategy shorts the assets with the lowest returns to be able to allocate more to the assets with the largest returns. On the other hand, the robust strategy does not have the same extreme behavior.

Define Backtesting Parameters

Set the backtesting strategies to rebalance every month.

```
% Define the monthly rebalance frequency.
rebalFreq = 21;
```

To gather enough data, set the `backtestStrategy` lookback window for the backtesting to at least 2 months. To remove old data from the parameter estimation, set the lookback window to no more than 6 months.

```
% Define the lookback window.
lookback = [42 126];
```

Use a fixed transaction cost equal to 0.5% of the amount traded.

```
% Define a fixed transaction cost.
transactionCost = 0.005;
```

Define the allocation strategies using `backtestStrategy`.

```
% Define a traditional mean-variance strategy.
stratMarkowitz = backtestStrategy('Markowitz', @(w,TT) markowitzFcn(w,TT,p), ...
    RebalanceFrequency=rebalFreq, ...
    LookbackWindow=lookback, ...
    TransactionCosts=transactionCost, ...
    InitialWeights=initialMarkowitz);

% Define a robust strategy.
stratRobust = backtestStrategy('Robust', @(w,TT) robustFcn(w,TT,p,kappa), ...
    RebalanceFrequency=rebalFreq, ...
    LookbackWindow=lookback, ...
    TransactionCosts=transactionCost, ...
    InitialWeights=initialRP);
```

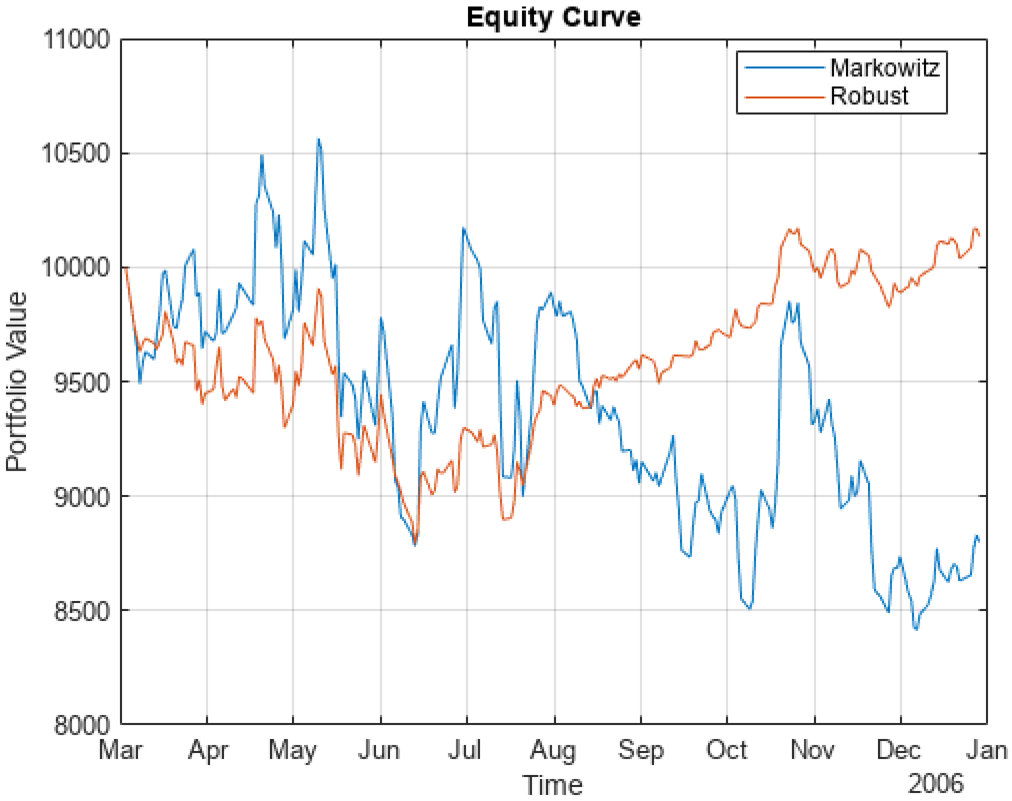
Run Backtest

Create a `backtestEngine` object and then run the backtest using `runBacktest`.

```
% Define strategies for backtest engine
strategies = [stratMarkowitz stratRobust];
% Define a backtest engine
backtester = backtestEngine(strategies);
% Run the backtest
backtester = runBacktest(backtester,pricesTT,Start=warmupPeriod);
```

Use `equityCurve` to plot the equity curve.

```
equityCurve(backtester)
```



Use `summary` to generate a table of performance results for both strategies.

```
summary(backtester)
```

```
ans=9×2 table
                          Markowitz       Robust
                         ___________    __________

    TotalReturn             -0.12004      0.013641
    SharpeRatio             -0.02926      0.011774
    Volatility              0.016383     0.0088013
    AverageTurnover         0.047756      0.021642
    MaxTurnover               1.8849        1.0392
    AverageReturn        -0.00047822    0.00010338
    MaxDrawdown              0.20332       0.12068
    AverageBuyCost             2.276         1.036
    AverageSellCost            2.276         1.036
```

As expected, the robust strategy has lower volatility than the traditional mean-variance strategy. This characteristic is observed in all the performance indicators that measure variability: volatility, turnover, and maximum drawdown. This result is the expected outcome of robust strategies. Although it is not always the case, in this particular example, the robust strategy also outperforms the traditional mean-variance allocation.

Risk Parity or Budgeting with Constraints

This example shows how to solve risk parity or budgeting problems with constraints using `estimateCustomObjectivePortfolio`.

Risk parity is a portfolio allocation strategy that focuses on the allocation of risk to define the weights of a portfolio. You construct the risk parity portfolio, or equal risk contribution portfolio, by ensuring that all assets in a portfolio have the same risk contribution to the overall portfolio risk. The generalization of this problem is the risk budgeting portfolio in which you set the risk contribution of each asset to the overall portfolio risk. In other words, instead of all assets contributing equally to the risk of the portfolio, the assets' risk contribution must match a target risk budget.

In “Risk Budgeting Portfolio” on page 4-280, the example describes some advantages of risk parity or budgeting portfolios. It shows how to use `riskBudgetingPortfolio` to solve long-only, fully invested risk parity or budgeting problems. When the only constraints of the risk budgeting problem enforce nonnegative weights that sum to 1, the risk budgeting problem is a feasibility problem. In other words, the solution to the problem is the one that exactly matches the target risk budget and it is unique. Therefore, there is no need for an objective function. The `riskBudgetingPortfolio` function is optimized to solve this specific type of problems.

When you add more constraints to the risk parity problem, you must find the weight allocation that satisfies the extra constraints while trying to match the target risk budget as much as possible. The next section explains how.

Define Problem

Start by defining the problem data.

```
% Assets variance
vol = [0.1;0.15;0.2;0.3];
% Assets correlation
rho = [1.00  0.50  0.50  0.50;
       0.50  1.00  0.50  0.50;
       0.50  0.50  1.00  0.75;
       0.50  0.50  0.75  1.00];
% Assets covariance matrix
Sigma = corr2cov(vol,rho);
% Risk budget
budget = [0.3;0.3;0.195;0.205];
```

Obtain the long-only, fully invested risk budgeting portfolio to use as benchmark.

```
% Long-only fully invested risk budgeting portfolio
w_simple = riskBudgetingPortfolio(Sigma,budget);
% Compute the risk contribution of the weight allocation
RC_simple = portfolioRiskContribution(w_simple,Sigma);
% Table with weights and risk contributions
T_simple = table(w_simple,RC_simple,budget, ...
    VariableNames={'RB Portfolio','RB Contribution','Budget'})
```

```
T_simple=4×3 table
    RB Portfolio    RB Contribution    Budget
    ____________    _______________    ______

      0.45053             0.3            0.3
    0.30035              0.3           0.3
    0.14668            0.195         0.195
    0.10244            0.205         0.205
```

As desired, the risk contribution of the risk budgeting portfolio matches the `budget`.

Add Constraints to Risk Parity or Budgeting Portfolio

When you add constraints, other than the long-only, fully invested constraints, to the risk parity formulation, you must find the portfolio allocation that satisfies all the constraints and minimizes the deviation from the target risk budget.

The percent risk contribution of asset i is defined as

$$\mathrm{RC}_i(w) = \frac{w_i(\Sigma w)_i}{w^T\Sigma w},$$

and the goal is to find the portfolio that minimizes the deviation of $\mathrm{RC}_i(w)$ to b_i, the target risk budget of asset i. For risk parity problems, $b_i = \frac{1}{n}$, where n is the number of assets.

A common way to measure deviation is to use a norm. In this example, use the 2-norm. The risk parity or budgeting problem with constraints results in

$$\begin{aligned} &\min_w \sum_i \left(\frac{w_i(\Sigma w)_i}{w^T\Sigma w} - b_i\right)^2 \\ &s.t.\ \ w \in \Omega \end{aligned}$$

where Ω represents the feasible set that is defined by the desired constraints. The objective function is the sum of squares of the deviation of the risk contributions from the target. Notice that the objective function is nonconvex.

Next, introduce the constraint $x_i \le 0.3$, which means that no more than 30% of the capital can be invested in each asset.

```
% Define the Portfolio object
p = Portfolio(AssetCovar=Sigma);
% Set bound constraints
p = setBounds(p,0,0.3);
% Set budget constraint
p = setBudget(p,1,1);
```

Create a function handle for the nonconvex objective

$$\sum_i \left(\frac{w_i(\Sigma w)_i}{w^T\Sigma w} - b_i\right)^2.$$

```
% Define objective function
objFun = @(w) sum(((w.*(Sigma*w))/(w'*Sigma*w) - budget).^2);
```

Solve the problem using `estimateCustomObjectivePortfolio` and `riskBudgetingPortfolio`.

```
% Risk budgeting portfolio with extra constraints
w_extra = estimateCustomObjectivePortfolio(p,objFun);
% Risk contribution
```

```
RC_extra = portfolioRiskContribution(w_extra,Sigma);
% Table with weights and risk contributions
T_extra = table(w_extra,RC_extra,budget, ...
    VariableNames={'RB Portfolio','RB Contribution','Budget'})
```

```
T_extra=4×3 table
    RB Portfolio    RB Contribution    Budget
    ____________    _______________    ______

        0.3             0.15505          0.3 
        0.3             0.24998          0.3 
     0.2465             0.30862        0.195 
     0.1535             0.28635        0.205 
```

Now that you have added additional constraints, the risk contribution of the resulting portfolio does not match the budget. Yet, the solution to the problem is minimizing the deviation of the risk contribution to the target risk budget. Because the risk budgeting portfolio without the extra constraints assigns weights larger than 30% to the first and second assets, the solution to the problem that minimizes the deviation assigns as much as possible to the first and second assets and distributes the rest to the other assets.

As explained in “Role of Convexity in Portfolio Problems” on page 4-148, because the objective function is nonconvex, this formulation cannot be solved by the `Portfolio` object solvers if you add cardinality constraints or conditional bounds to the problem.

Compare Risk Parity and Mean-Variance Portfolios

You can examine the difference in the allocation between the traditional minimum variance portfolio and the risk parity portfolio.

First compute the minimum variance portfolio. The traditional mean-variance framework requires the assets mean return to be defined before you compute any of the portfolios on the efficient frontier.

```
% Define assets mean
p.AssetMean = [0.1; 0.1; 0.15; 0.2];
% Minimum variance portfolio
wMinVar = estimateFrontierLimits(p,'min');
```

To compute the risk parity portfolio, make sure all assets contribute equally to the risk. Set $b_i = \frac{1}{n}$ and update the objective function.

```
% Update budget
budget = 1/p.NumAssets*ones(p.NumAssets,1);
% Update objective
objFun = @(w) sum(((w.*(Sigma*w))/(w'*Sigma*w) - budget).^2);
```

Solve the risk parity problem using `estimateCustomObjectivePortfolio`.

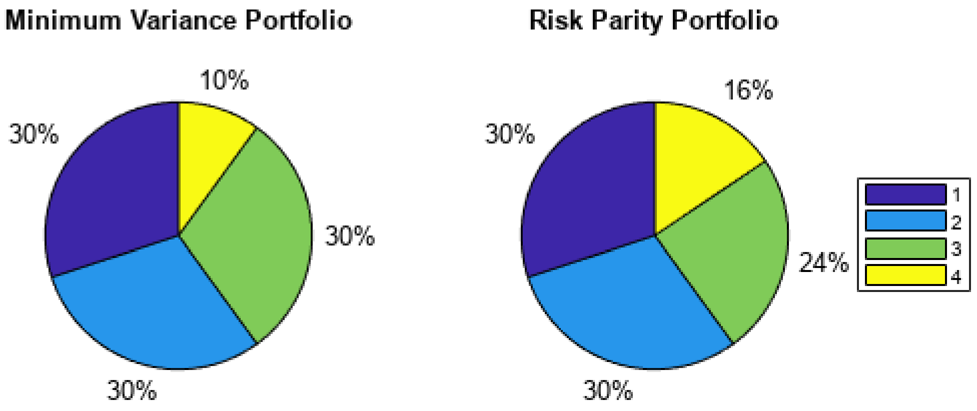
```
% Risk parity portfolio with extra constraints
wRP = estimateCustomObjectivePortfolio(p,objFun);
```

Compare the weight allocation concentrations.

```
% Plot pie charts
tiledlayout(1,2);
% Minimum variance portfolio
```

```
nexttile
pie(wMinVar)
title('Minimum Variance Portfolio',Position=[0,1.5]);
% Risk parity portfolio
nexttile
pie(wRP)
title('Risk Parity Portfolio',Position=[0,1.5]);

% Add legend
lgd = legend({'1','2','3','4'});
lgd.Layout.Tile = 'east';
```



The portfolio allocation of the minimum variance portfolio sets all assets with the smallest risk to their maximum (30%). On the other hand, the risk parity allocation sets only the first two assets to 30% and the last two are more balanced. This result is a simple example of how the risk parity allocation helps to diversify a portfolio.

Single Period Goal-Based Wealth Management

This example shows a method for goal-based wealth management (GBWM). In GBWM, risk is not necessarily measured using the standard deviation, the value-at-risk, or any other common risk measure. Instead, risk is understood as the likelihood of not attaining an investor's goal. You choose a weight allocation that is on the traditional mean-variance efficient frontier and that also maximizes the probability of exceeding a wealth goal at the end of the investment horizon. In other words, you choose the portfolio on the efficient frontier that minimizes the risk of not attaining the investor's goal.

A common issue after computing the mean-variance efficient frontier is how to choose a single portfolio to invest in. This portfolio could be the maximum Sharpe ratio portfolio, which selects the weights that achieve the highest return given the amount of risk taken. However, choosing this portfolio does not take the investor's preferences into account. Another way strategy is to gauge the risk preference of the investor and select a portfolio that achieves a risk no larger than the investor's preferred risk. However, it is difficult to quantify the risk aversion of an investor. In this example, you use the probability of achieving a wealth goal to help choose a portfolio on the efficient frontier.

Load Data

Load the data and then annualize the asset returns and the variance-covariance matrix.

```
% Load data
load BlueChipStockMoments.mat
AssetMean = 12*AssetMean;
AssetCovar = 12*AssetCovar;
```

Plot Efficient Frontier

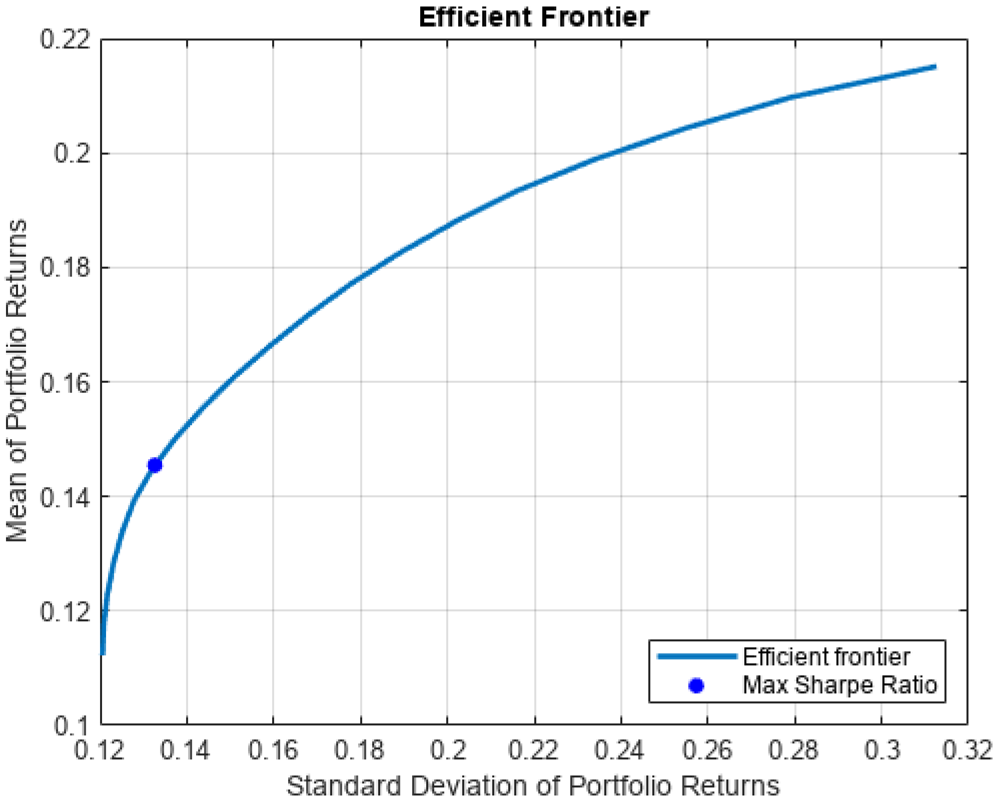
Use `Portfolio` to create a `Portfolio` object and `estimateMaxSharpeRatio` to compute the maximum Sharpe ratio. Then, use `plotFrontier` to plot the efficient frontier for long-only, fully-invested portfolios and mark the maximum Sharpe ratio portfolio.

```
% Create Portfolio object
p = Portfolio(AssetList=AssetList,AssetMean=AssetMean,...
    AssetCovar=AssetCovar);

% Add long-only, fully-invested constraints
p = setDefaultConstraints(p);

% Compute maximum Sharpe ratio portfolio
wSR = estimateMaxSharpeRatio(p);

% Plot efficient frontier
numPorts = 20;
figure;
[pret,prisk] = plotFrontier(p,20);
hold on
plot(estimatePortRisk(p,wSR),estimatePortReturn(p,wSR),'b.',...
    'MarkerSize',20);
legend('Efficient frontier','Max Sharpe Ratio',...
    'Location','southeast')
hold off
```



Choose Single Portfolio Using GBWM

GBWM provides a way to choose a single portfolio on the efficient frontier that allows you to incorporate the investor's preference in a straightforward way. In this case, the investor's goal is to reach a target wealth G from their initial wealth W_0 at the end of the investment period T. Therefore, you can formulate the problem as choosing the portfolio that maximizes the probability of having a wealth at time T that surpasses the goal G, while making sure that the chosen weights are on the efficient frontier.

$$\max_{w,\mu,\sigma} \; P(W_T \geq G)$$

$$s.t. \;\; {\mu_0}^T w = \mu$$

$$w^T \Sigma_0 w = \sigma^2$$

$$\sum_{i=1}^{n} w_i = 1$$

$$0 \leq w \leq 1$$

```
% Define investor's preferences
W0 = 100;
G = 200;
T = 10;
```

For this example, assume that the wealth evolves following a Brownian motion [1 on page 4-365]

$$W_T = W_0 \exp\left\{\left(\mu - \frac{\sigma^2}{2}\right)T + \sigma\sqrt{T}Z\right\},$$

where Z is a standard normal random variable.

The approach in this example also assumes that the returns follow a stationary distribution. In other words, the approach assumes that the returns have the same expectation and covariance throughout the investment period. The term “single-period” refers to the fact that the optimal allocation is computed *only once* at the beginning of the investment horizon assuming that the allocations will remain constant. This is a “set-it-and-forget-it” strategy. Although you can recompute the allocation weights at each reinvestment period by updating the time horizon and initial wealth, a single-period problem does not consider possible allocation changes in the middle of the investment horizon. In contrast, the optimal solution for a "multi-period" approach takes into account possible changes to the weights at intermediate investment periods. Thus, instead of just selecting the initial portfolio weights, multi-period problems compute the optimal strategy that should be followed given the changes in wealth at each of the reinvestment periods. The “Dynamic Portfolio Allocation in Goal-Based Wealth Management for Multiple Time Periods” on page 4-366 example shows a multi-period version of the problem in this example.

Define Objective Function and Solve Problem

Find the portfolio that maximizes the probability of achieving the investor's goal given the prior assumptions. Maximizing $P(W_T \geq G)$ is equivalent to minimizing $P(W_T \leq G)$, so the objective function is rewritten as

$$\max_{w,\mu,\sigma} P(W_T \geq G) = \min_{w,\mu,\sigma} P(W_T \leq G) = \min_{w,\mu,\sigma} \Phi\left(\frac{1}{\sigma\sqrt{T}}\left[\ln\left(\frac{G}{W_0}\right) - \left(\mu - \frac{\sigma^2}{2}\right)T\right]\right).$$

Since the relationship of μ and σ to the weights w is represented by equality constraints in the problem, you can substitute these values in the objective function and remove the equality constraints that show the relationship between these three variables.

$$\max_{w,\mu,\sigma} P(W_T \geq G) = \min_{w} \Phi\left(\frac{1}{\sqrt{T\left(w^T\Sigma_0 w\right)}}\left[\ln\left(\frac{G}{W_0}\right) - \left(\mu_0^T w - \frac{w^T\Sigma_0 w}{2}\right)T\right]\right)$$

Define the objective function handle using the definition above and then use `estimateCustomObjectivePortfolio` to solve the problem.

```
% Define objective function
probability = @(w) normcdf(1/sqrt(T*(w'*p.AssetCovar*w)) * ...
    (log(G/W0) - (p.AssetMean'*w - (w'*p.AssetCovar*w)/2)*T));

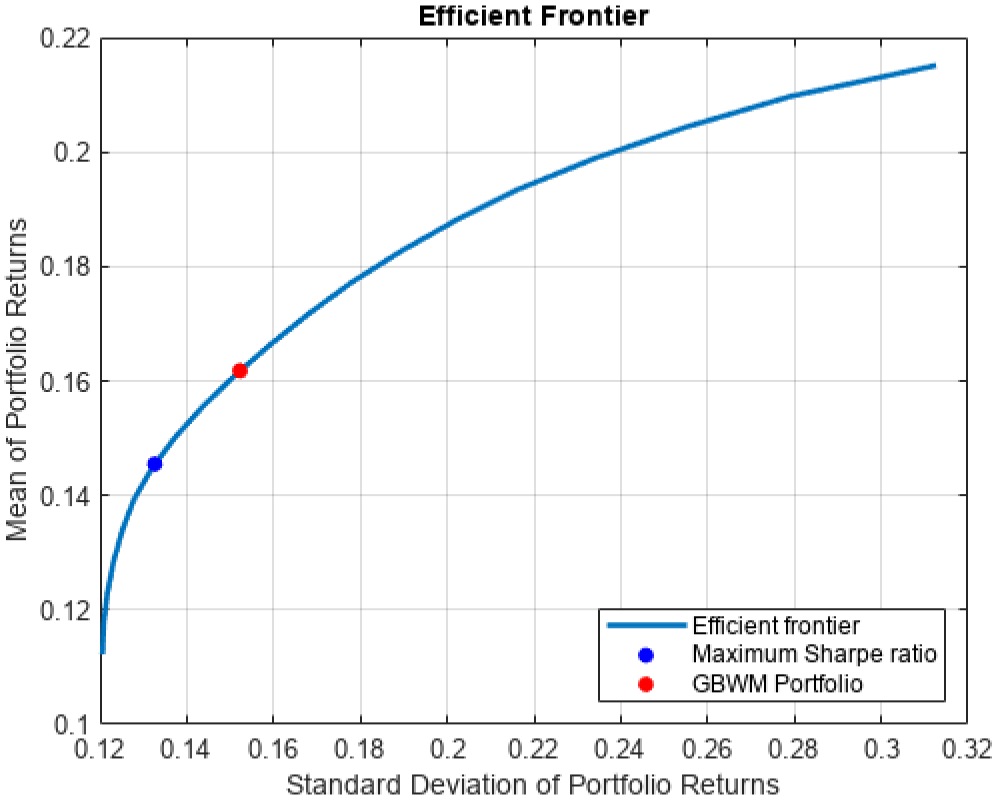
% Solve problem
wGBWM = estimateCustomObjectivePortfolio(p,probability);
```

Plot Efficient Frontier

Use `plotFrontier` to plot the efficient frontier, the maximum Sharpe ratio portfolio, and the portfolio that maximizes the probability of achieving the goal (called the GBWM portfolio).

```
% Plot efficient frontier
figure;
plotFrontier(p,pret,prisk);
hold on
```

```
plot(estimatePortRisk(p,wSR),estimatePortReturn(p,wSR),'b.', ...
    'MarkerSize',20);
plot(estimatePortRisk(p,wGBWM),estimatePortReturn(p,wGBWM),'r.', ...
    'MarkerSize',20);
legend('Efficient frontier','Maximum Sharpe ratio', ...
    'GBWM Portfolio','Location','southeast')
hold off
```



The GBWM portfolio is riskier than the maximum Sharpe ratio portfolio. This extra risk is necessary to maximize the probability of attaining the investor's wealth goal G by time T.

Compare GBWM Portfolio to Maximum Sharpe Ratio Portfolio

Compare the probabilities of acheiving the wealth goal G by the end of the investment period T for the maximum Sharpe ratio portfolio against the GBWM portfolio.

```
Tprobabilities = table(1-probability(wSR),1-probability(wGBWM),...
    RowNames={'P(W_T >= G)'},VariableNames={'SR','GBWM'})
```

```
Tprobabilities=1×2 table
                    SR         GBWM  
                 _______    _______

    P(W_T >= G)  0.94592    0.95347
```

The probability of successfully meeting the investor's wealth goal does not change much between the maximum Sharpe ratio portfolio and the GBWM portfolio. Using this information, an investor can understand the trade-off between acheiving their wealth goal G by time T compared to choosing a less risky portfolio. For example, an investor might choose a minimum variance portfolio that has a much lower probability of acheiving their wealth goal G by time T. Find the minimum variance (MV) portfolio, and compare the probability of achieving the wealth goal using this portfolio with the other two approaches.

```
wMV = estimateFrontierLimits(p,'min');
Tprobabilities.MV = 1-probability(wMV)
```

```
Tprobabilities=1×3 table
                     SR        GBWM        MV  
                   _______    _______    ______

    P(W_T >= G)    0.94592    0.95347    0.8252
```

Dynamic Portfolio Allocation in Goal-Based Wealth Management for Multiple Time Periods

This example shows a dynamic programming strategy to maximize the probability of obtaining an investor's wealth goal at the end of the investment horizon. This dynamic programming strategy is known in the literature as a goal-based wealth management (GBWM) strategy. In GBWM, risk is not necessarily measured using the standard deviation, the value-at-risk, or any other common risk metric. Instead, risk is understood as the likelihood of not attaining an investor's goal. This alternative concept of risk implies that, sometimes, in order to increase the probability of attaining an investor’s goal, the optimal portfolio’s traditional risk (that is, standard deviation) must increase if the portfolio is underfunded. In other words, for the investor’s view of risk to *decrease*, the traditional view of risk must *increase* if the portfolio’s wealth is too low.

The objective of the investment strategy is to determine a dynamic portfolio allocation such that the portfolios chosen at each rebalancing period are on the traditional mean-variance efficient frontier and these portfolios maximize the probability of achieving the wealth goal G at the time horizon T. This objective is represented as

$$\max_{\{A(0), A(1), \ldots, A(T-1)\}} \mathbb{P}(W(T) \geq G),$$

where $W(T)$ is the terminal portfolio wealth and $A(t)$ are the possible actions and allocations at time $t = 0, 1, \ldots, T - 1$.

The dynamic portfolio problem consists of the following parts:

- Time periods — Portfolio rebalancing periods
- Actions — Portfolio weights rebalancing
- States — Wealth levels
- Value function — Probability of achieving the goal at the end of the investment period
- Policy or strategy — Optimal actions at each state and time period

This example follows the GBWM strategy of Das [1 on page 4-377]. For an example of GBWM for a single time period, see the “Single Period Goal-Based Wealth Management” on page 4-361 example.

Inputs for Investment Wealth Goals

Specify the initial wealth.

```
W0 = 100;
```

Specify the target wealth at the end of the investment horizon.

```
G = 200;
```

Define the time horizon.

```
T = 10;
```

Load the asset information.

```
load BlueChipStockMoments.mat
```

Rebalancing Period Actions for Efficient Portfolios

The action at each rebalancing period is to choose the weights of the investment portfolio for the next time period. In this example assume that the possible portfolio weights are assosicated with the portfolios on the efficient frontier. This example also assumes that the choice of possible portfolios is fixed throughout the full investment period. However, weights are not required to be on the efficient frontier. The only requirement is that the set of actions (portfolio choices) remains fixed throughout the investment period.

To simplify the computations, define a finite subset of the efficient portfolios for possible actions. Start by creating a `Portfolio` object with the asset information from `BlueChipStockMoments.mat`.

```
p = Portfolio(AssetList=AssetList,AssetMean=AssetMean,...
    AssetCovar=AssetCovar);
```

Annualize the asset returns and the variance-covariance matrix.

```
p.AssetMean  = 12*p.AssetMean;
p.AssetCovar = 12*p.AssetCovar;
```

Use `setBounds` to add constraints to the portfolio problem. Here, assets do not represent more than 10% of the portfolio wealth and shorting is not allowed.

```
p = setBounds(p,0,0.1);
```

Use `setBudget` to specify that the porfolio must be fully invested.

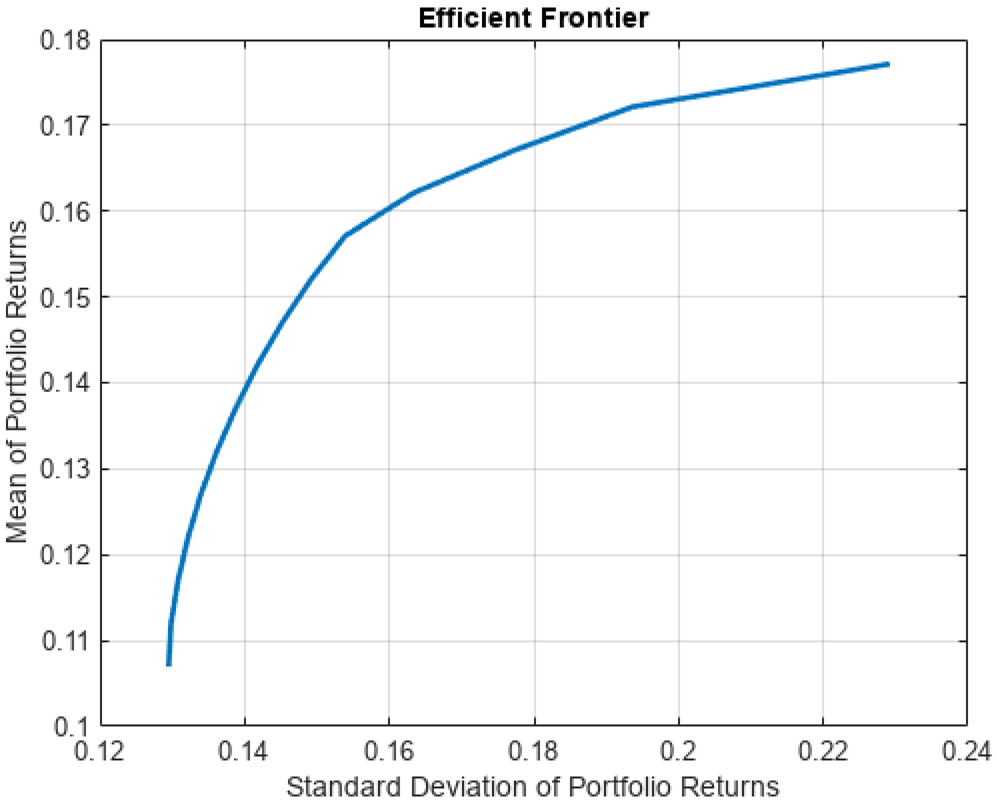
```
p = setBudget(p,1,1);
```

Compute the the weights of `15` portfolios on the efficient frontier using `estimateFrontier`. These portfolios represent the possible actions at each rebalancing period.

```
nPortfolios = 15;
pwgt = estimateFrontier(p,nPortfolios);
```

Plot the efficient frontier using `plotFrontier`.

```
[prsk,pret] = plotFrontier(p,pwgt);
```



States for Wealth Nodes

The states are defined as the wealth values at time t. To simplify the problem, discretize the wealth values to generate a wealth grid, W_i, for $i \in \{1, \ldots, i_{\max}\}.W_1$ corresponds to the smallest possible wealth $W_{\min}$ and $W_{i_{\max}}$ corresponds to the largest possible wealth $W_{\max}$. To determine $W_{\min}$ and $W_{\max}$, assume that the evolution of wealth follows a geometric Browninan motion

$$W(t) = W(0)e^{\left(\mu - \sigma^2/2\right)t + \sigma\sqrt{t}Z},$$

where Z is a standard normal random variable. GBWM does not require that the wealth evolution follow a Brownian motion. However, the technique in this example requires the evolution model to be Markovian. Therefore, this example assumes that the probability of being at a certain state at time $t + 1$ only depends on the state at time t and the action taken.

This example also assumes that Z realistically takes values between -3 and 3. When $Z = -3$, $W_{\min}$ corresponds to the smallest value obtained in the trajectory of the Brownian motion setting, μ is the smallest possible portfolio return $\mu_{\min}$, and σ is the largest possible portfolio risk $\sigma_{\max}$. Likewise, when $Z = 3$, $W_{\max}$ corresponds to the largest value in the trajectory, μ is the largest possible portfolio return $\mu_{\max}$, and σ is the largest possible portfolio risk $\sigma_{\max}$. For $W_{\max}$, use $\sigma_{\max}$ because the term in the exponential is increasing for all $\sigma \leq 3/\sqrt{t}$; if $\sigma_{\max} > 3/\sqrt{t}$, use $\sigma = 3/\sqrt{t}$ instead.

Define $\mu_{\min}$, $\mu_{\max}$, $\sigma_{\min}$, and $\sigma_{\max}$.

```
% Define return limits.
mu_min = pret(1);
```

```
mu_max = pret(end);

% Define volatility limits.
sigma_min = prsk(1);
sigma_max = prsk(end);
```

The smallest realistic value of W is

$$\widehat{W}_{\min} = \min_{\tau \in \{0, 1, \ldots, T\}} \left\{ W(0) e^{\left(\mu_{\min} - \frac{\sigma_{\max}^2}{2}\right)\tau - 3\sigma_{\max}\sqrt{\tau}} \right\}.$$

```
% Define the minimum possible wealth.
timeVec = 0:T;
WMinVec = W0*exp((mu_min-(sigma_max^2)/2)*timeVec- ...
    3*sigma_max*sqrt(timeVec));
WHatMin = min(WMinVec);
```

The largest realistic value of W is

$$\widehat{W}_{\max} = \max_{\tau \in \{0, 1, \ldots, T\}} \left\{ W(0) e^{\left(\mu_{\max} - \frac{\sigma_{\max}^2}{2}\right)\tau + 3\sigma_{\max}\sqrt{\tau}} \right\}.$$

```
% Define the maximum possible wealth.
WMaxVec = W0*exp((mu_max-(sigma_max^2)/2)*timeVec+ ...
    3*sigma_max*sqrt(timeVec));
WHatMax = max(WMaxVec);
```

Now, you can fill in the grid points between $\widehat{W}_{\min}$ and $\widehat{W}_{\max}$. When you set $Z = 1$and $t = 1$ and ignore the drift term $\left(\mu - \sigma^2/2\right)t$, note that σ is proportional to the logarithm of the wealth. Thus, you can work in logarithmic space and add a grid point every $\sigma_{\min}/\rho_{\text{grid}}$ units. ρ_{grid} is an exogenous parameter that determines the density of the grid. As ρ_{grid} grows, the number of wealth nodes increases.

```
% Transform to the logarithmic space.
lWHatMin = log(WHatMin);
lWHatMax = log(WHatMax);
% Define the grid in the logarithmic space.
rho = 3;
lWGrid = (lWHatMin:sigma_min/rho:lWHatMax)';
```

To guarantee that there exists a point in the wealth grid that matches $W(0)$, shift the logarithmic grid downwards by the smallest shift such that one of those values matches the logarithm of the initial portfolio value.

```
% Compute the shift for wealth grid.
lW0 = log(W0);
difference = lWGrid-lW0;
minDownShift = min(difference(difference>=0));
% Define the wealth nodes.
WGrid = exp(lWGrid - minDownShift);
nWealthNodes = size(WGrid,1); % Number of wealth nodes
```

Value Function and Optimal Strategy

The problem in this example is a multi-period optimization problem. The goal is to find the action at each rebalancing period that maximizes the probability that the wealth exceeds the target goal at the end of the investment period. To solve this problem, use the Bellman equation, which in this case is given by

$$V(W_i(t)) = \max_{\pi}\left[\sum_j V\big(W_j(t+1)\big)p\big(W_j(t+1)\,\big|\,W_i(t),\pi\big)\right].$$

The value function $V(W_i(t))$ represents the probability of exceeding the wealth goal G at time T, given that at time t, the wealth level is W_i. Simultaneously, $p\big(W_j(t+1)\,|\,W_i(t),\pi\big)$ represents the probability of moving to wealth node j at time $t+1$, given that at time t, you are at wealth node i and you chose portfolio π as the rebalancing action.

Compute Transition Probabilities

Since this example assumes that the wealth goal follows a geometric Brownian motion, the transition probabilities of being in wealth node W_j at time $t+1$, given that you are at wealth node W_i at time t, are time-homogeneous. Thus, the transition probability for a given portfolio choice π is defined as

$$p\big(W_j(t+1)\,|\,W_i(t),\pi\big) = \mathbb{P}\big(W_j \leq W(t+1) < W_{j+1}\,|\,W(t) = W_i,\pi\big) = \widetilde{p}\big(W_{j+1}\,|\,W_i,\pi\big) - \widetilde{p}\big(W_j\,|\,W_i,\pi\big),\ \ \forall\, t, \in \{0,\ldots,T\}$$

where

$$\widetilde{p}(W_k\,|\,W_i,\pi) = \Phi\left(\frac{1}{\sigma_\pi}\left(\ln\left(\frac{W_k}{W_i}\right) - \left(\mu_\pi - \frac{{\sigma_\pi}^2}{2}\right)\right)\right),$$

Φ is the cumulative distribution function of the standard normal random variable, and μ_π and σ_π are the return and risk of portfolio π. If $j = 1$,

$$p(W_1(t+1)\,|\,W_i(t),\pi) = \widetilde{p}(W_2\,|\,W_i,\pi),\ \ \forall\, t \in \{0,\ldots,T\},$$

and if $j = i_{\max}$,

$$p\big(W_{i_{\max}}(t+1)\,|\,W_i(t),\pi\big) = 1 - \widetilde{p}\big(W_{i_{\max}}\,|\,W_i,\pi\big),\ \ \forall\, t \in \{0,\ldots,T\}.$$

Note that this example computes transition probabilities differently from the transition probabilities as described by Das [1 on page 4-377], to keep a consistent mapping between $W(t)$ and a unique wealth node index.

```
% Compute the transition probabilities for different portfolios:
% pTransition(i,j,k) = p(Wj|Wi,mu_k)
pTransition = zeros(nWealthNodes,nWealthNodes,nPortfolios);
for k = 1:nPortfolios
    % Get the return and variance of portfolio k.
    mu = pret(k);
    sigma = prsk(k);

    % Compute p tilde before the cdf.
    pTilde = 1/sigma*(log(WGrid'./WGrid) - (mu-(sigma^2)/2));
    % Auxiliary matrices for edge cases (j = 1 and j = i_max)
    pTildeAuxUB = [pTilde(:,2:end) inf(nWealthNodes,1)];
    pTildeAuxLB = [-inf(nWealthNodes,1) pTilde(:,2:end)];

    % Compute the transition probabilities for portfolio k.
    pTransition(:,:,k) = normcdf(pTildeAuxUB)-normcdf(pTildeAuxLB);
end
```

Maximize Probability of Achieving Investor's Goal

Since the value function is the probability of achieving the wealth investment goal G at the final time step, you know that the value function at $t = T$ is given by

$$V(W_i(t)) = \begin{cases} 0 \text{ if } W_i(T) < G \\ 1 \text{ if } W_i(T) \geq G \end{cases}.$$

```
% Intialize the matrix that stores the value function at different
% wealth nodes and time periods.
V = zeros(nWealthNodes,T+1);
% Define the Value function at t = T.
V(:,end) = (WGrid >= G);
```

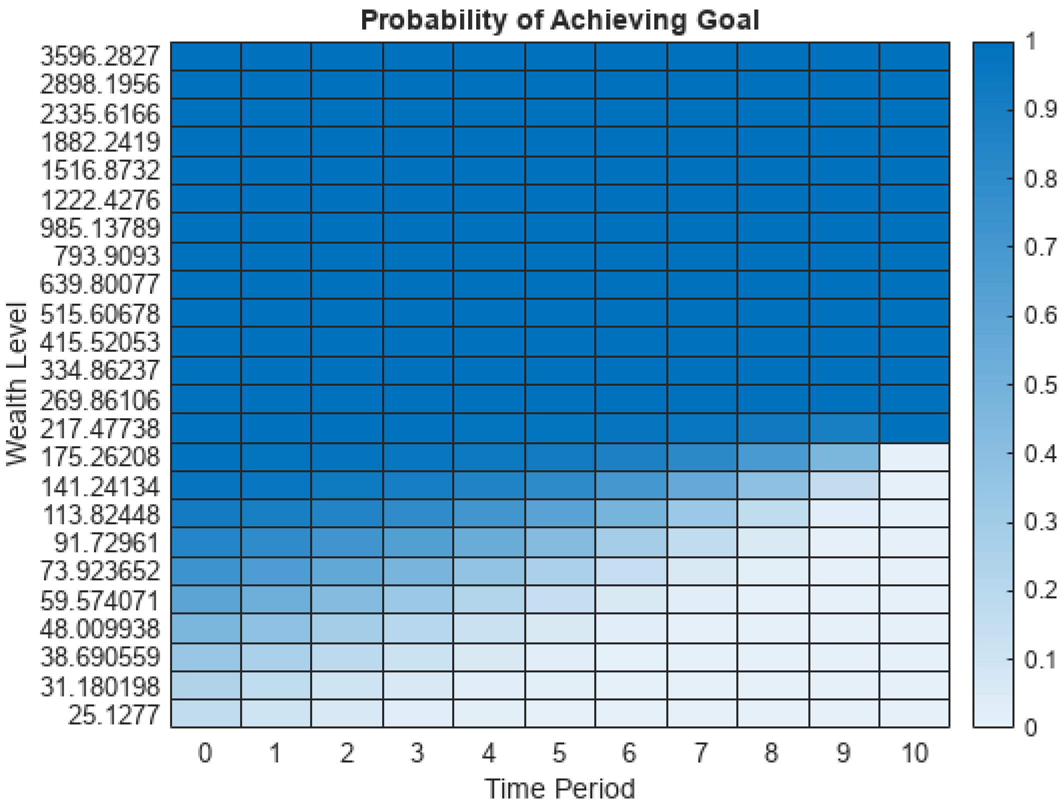
To compute the value of $V(W_i(t))$ for $t < T$, you need to go backwards in time. You start at $t = T - 1$ to determine the portfolio that achieves the maximum in the Bellman equation and $V(W_i(T-1))$. Then continue with $t = T - 2$, then $t = T - 3$, until you reach $t = 0$. The value of $V(W(0))$ is the optimal probability of attaining the wealth goal G from the initial wealth $W(0)$.

```
% Compute the optimal value function and portfolio at different
% wealth nodes and time periods.
portIdx = zeros(nWealthNodes,T);
for t = T:-1:1
    pTilde = zeros(nWealthNodes,nPortfolios);
    for k = 1:nPortfolios
        % sum_j ( V(Wj(t+1)) * p(Wj|Wi,mu_k) )
        pTilde(:,k) = pTransition(:,:,k)*V(:,t+1);
    end
    % Choose the portfolios that achieve the best probabilities.
    [V(:,t),portIdx(:,t)] = max(pTilde,[],2);
end
```

Note that `V(i,t)` is $V(W_i(t-1))$, which denotes the optimal probability of achieving the wealth goal from wealth node W_i at time period $t - 1$. On the other hand, `portIdx(i,t)` defines the optimal portfolio to be chosen at time period $t - 1$ if you are at wealth node W_i. The value of t is shifted down for `V(i,t)` and `portIdx(i,t)`, given that array indices start at `1` and t starts at `0`.

Use `heatmap` to plot the value function.

```
% Plot a heatmap of the value function.
figure;
heatmap(0:T,flip(WGrid(1:5:end)),flip(V(1:5:end,:)))
xlabel("Time Period")
ylabel("Wealth Level")
title("Probability of Achieving Goal")
```



The figure shows how the probability of achieving the goal becomes larger as the initial wealth grows. Also, this figure demonstrates that as time passes, the current wealth must be higher than in the previous periods to get the same probability of achieving the goal.

Use `heatmap` to plot the optimal portfolio.

```
% Plot a heatmap of optimal portfolio.
figure;
heatmap(0:T-1,flip(WGrid(1:5:end)),flip(portIdx(1:5:end,:)))
xlabel("Time Period")
ylabel("Wealth Level")
title("Portfolio Aggressiveness")
```

This figure shows that the higher the wealth, the lower the number of the optimal portfolio. Since the number of the portfolio is directly related to the aggressiveness of the strategy, you can see that the wealthier the portfolio, the less risk is needed to achieve the final wealth goal. When the portfolio has less money, then the optimal portfolio is the one with a larger expected return, even at the cost of increasing the volatility. Also, note that the closer the time period is to the end of the investment horizon, the choice of the optimal portfolio becomes polarized, where the portfolio is either extremely aggressive or extremely conservative.

Implement Optimal Strategy

The following describes the workflow to implement the optimal strategy:

1. At $t = 0$, choose the optimal strategy shown in `portIdx(i,j)` such that i is the index asociated with the wealth node that satisfies $W_i \leq W(0) < W_{i+1}$ and $j = t + 1$. Also, let $A^*(0) =$ `portIdx(i,j)`.
2. Rebalance the portfolio to match the weights in `pwgt(:,`$A^*(0)$`)`. Then, define $\pi^*(0) =$`pwgt(:,` $A^*(0)$`)`.
3. Either using historical data for time period $t = 0$ or simulating one step of a Brownian motion, obtain $W(1)$, given that you started at $W(0)$, and chose portfolio $\pi^*(0)$.
4. Repeat steps 1 through 3 for $t = 1, \ldots, T - 1$.

```
% Simulate one path following the optimal strategy.
rng('default')
[Z,WPath,portPath,VPath] = DynamicPortSim(W0,WGrid,pret,prsk, ...
    portIdx,V);
```

Present a table with the results of the simulation.

```
simulation = table((0:T)',Z,WPath,portPath,VPath,'VariableNames', ...
    {'t','Z','Wealth','OptPort','ProbOfSuccess'})
```

```
simulation=11×5 table
    t        Z         Wealth    OptPort    ProbOfSuccess
    __    ________    ______    _______    _____________

     0     0.53767       100       12          0.87953
     1      1.8339    126.69       11          0.92018
     2     -2.2588    194.27       11          0.98474
     3     0.86217    158.68       11           0.9323
     4     0.31877    209.52       11          0.98044
     5     -1.3077    254.46       10          0.99184
     6    -0.43359    241.04       10          0.98366
     7     0.34262    260.14        8          0.99024
     8      3.5784    311.62        5          0.99927
     9      2.7694    566.28        1                1
    10         NaN     894.5      NaN                1
```

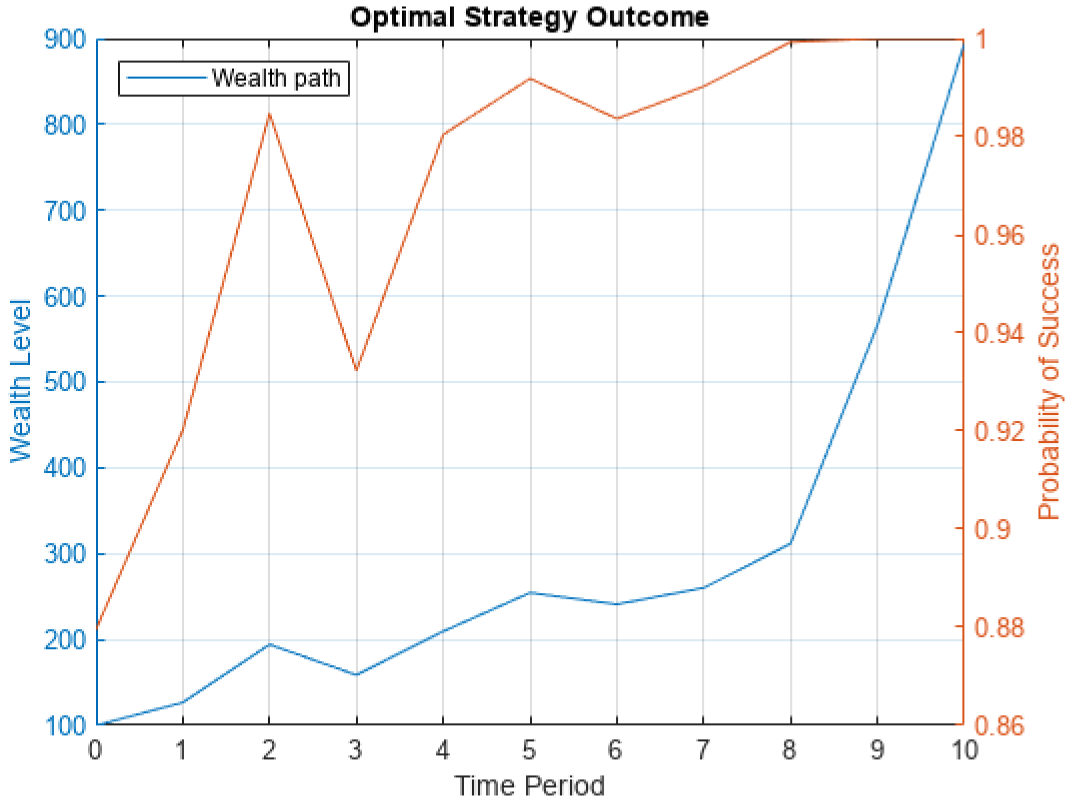
Note that as the probability of attaining the wealth goal (the value function) increases, the aggressiveness (number) of the optimal portfolio decreases. Now, you can plot the path of the wealth against the probability of achieving the wealth goal at the end of the investment period.

```
figure;

% Plot the wealth path.
yyaxis left
plot(0:T,WPath)
hold on
yline(G,'--k');
ylabel("Wealth Level");

% Plot the value function path.
yyaxis right
plot(0:T,VPath)
ylabel("Probability of Success");

% Specify the title, labels, and legends for the plot.
title("Optimal Strategy Outcome")
xlabel("Time Period");
legend("Wealth path","Wealth goal",Location="nw");
grid on
hold off
```

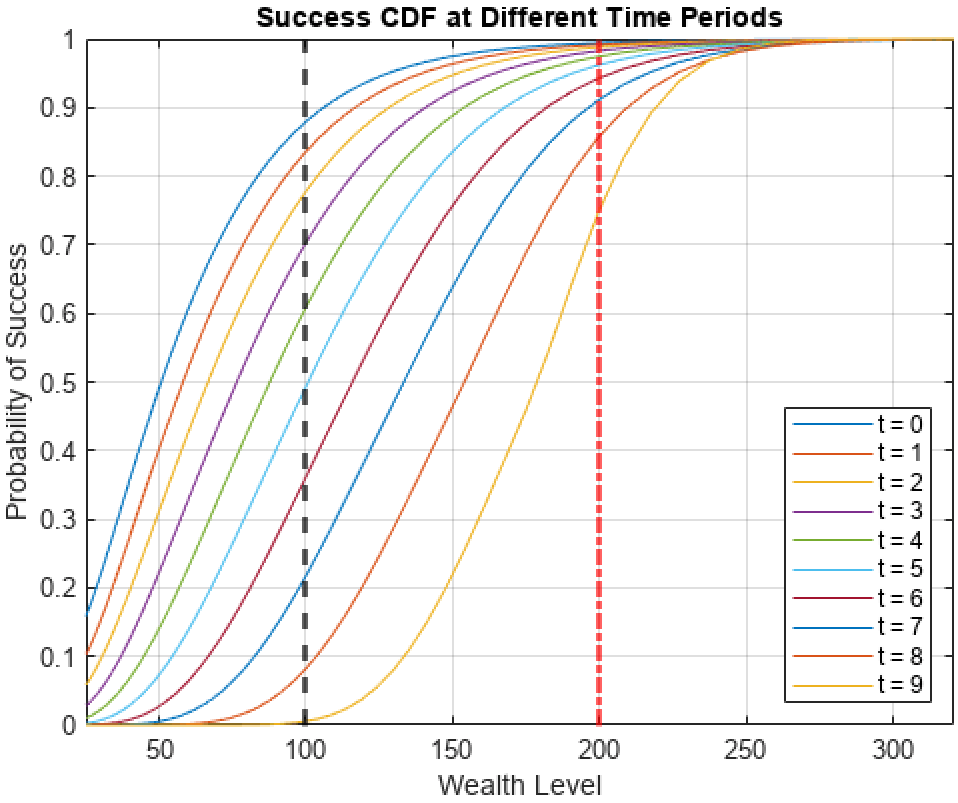


At $t = 4$, the wealth goal has been achieved. However, because of the uncertainty in the problem, the probability of success is not yet 1. Furthermore, trying different paths (random seeds) shows how even a monotonic increase in the wealth does not translate to a monotonic increase in the probability of success. This behavior occurs because the wealth increase at later time periods should be higher than at earlier time periods to have the same increase in the probability of success.

Plot the cumulative distribution function (CDF) of attaining the goal wealth at different time periods.

```
% Plot the cumulative distribution function (CDF) of success at
% different time periods.
figure
nWN = 60;
plot(WGrid(1:nWN),V(1:nWN,1:end-1))
xline(W0,'--k','LineWidth',2); % Initial wealth
xline(G,'-.r','LineWidth',2); % Goal wealth
xlim(WGrid([1,nWN]))

% Specify the title, labels, and legends.
title('Success CDF at Different Time Periods')
xlabel('Wealth Level')
ylabel('Probability of Success')
legend("t = "+num2str((0:T-1)'),Location="se")
grid on
```



This figure shows how as the time period approaches the investment horizon, the CDF shifts to the right and becomes steeper. This shift demonstrates that changes in the wealth level have a higher impact toward the end of the investment horizon. For example, an increase of 100 to 110 wealth points at *t* = 0 only increases the probability of success by 3%, while the same wealth increase at *t* = 4 increases the probability of success by 7%.

Local Functions

```
function [Z,WPath,portPath,VPath] = DynamicPortSim(W0,WGrid,...
    pret,prsk,portIdx,V)
% Define time periods.
T = size(V,2)-1;

% Define standard normal random variables for the Brownian motion.
Z = randn(T,1);
Z = [Z;nan]; % No randomness at the final time period

% Find the wealth node index of the initial wealth.
tol = 1e-8; % Account for numerical inaccuracies
difference = WGrid-W0;
% Assign to wealth node j such that W_j <= W(0) < W_{j+1}
WNodeIdx = find(difference<=tol,1,'last');

% Run the simulation.
WPath = [W0; zeros(T,1)];
portPath = [portIdx(WNodeIdx,1); zeros(T,1)];
VPath = [V(WNodeIdx,1); zeros(T,1)];
```

```
for t = 1:T
    % Get the return and variance of optimal portfolio at time t.
    mu = pret(portIdx(WNodeIdx,t));
    sigma = prsk(portIdx(WNodeIdx,t));

    % Compute the wealth at time t+1 following the Browninan motion.
    WPath(t+1) = WPath(t)*exp(mu-(sigma^2)/2+sigma*Z(t));

    % Compute the wealth node index corresponding to the current wealth.
    difference = WGrid-WPath(t+1);
    % Assign to wealth node j such that W_j <= W(t+1) < W_{j+1}
    WNodeIdx = find(difference <= tol,1,'last');

    % Store the optimum strategy and value function.
    if t<T
        portPath(t+1) = portIdx(WNodeIdx,t+1);
    else
        portPath(t+1) = nan;
    end
    VPath(t+1) = V(WNodeIdx,t+1);
end
end
```

Compare Performance of Covariance Denoising with Factor Modeling Using Backtesting

This example uses backtesting to compare the performance of two investment strategies that use factor information to compute the portfolio weights. The first investment strategy uses `covarianceDenoising` to estimate both the covariance matrix and the number of factors to use in the second investment strategy. The second investment strategy uses a principal component analysis (PCA) factor model to estimate the covariance matrix with the number of factors obtained with `covarianceDenoising`. The PCA factor model follows the process in “Portfolio Optimization Using Factor Models” on page 4-224.

Load Data

Load a simulated data set that includes asset returns for a total n = 100 assets and 2000 daily observations.

```
load('asset_return_100_simulated.mat');
[numObservations,numAssets] = size(stockReturns)
```

```
numObservations = 2000
```

```
numAssets = 100
```

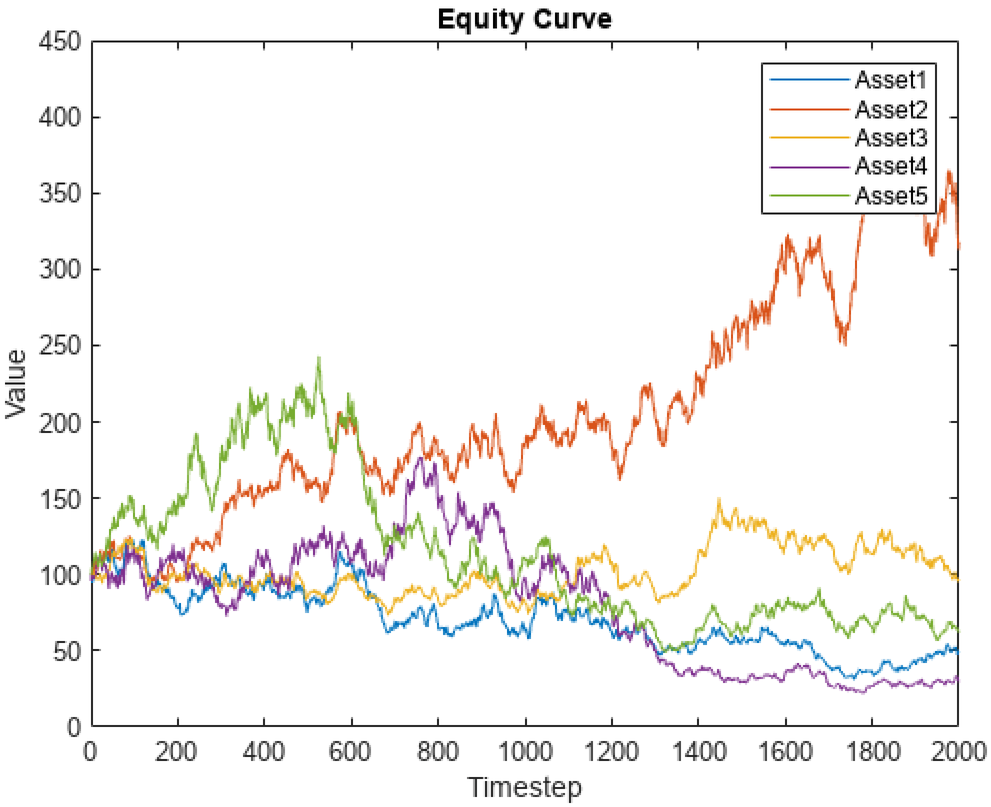
Create a timetable of asset prices from the asset returns.

```
% Convert the returns to prices
pricesT = ret2tick(stockReturns,'StartPrice',100);

% Create timetable
rowTimes = datetime("today"):datetime("today")+numObservations;
pricesTT = table2timetable(pricesT,'RowTimes',rowTimes);
```

Visualize the equity curve for each stock. For this example, plot the first five stocks.

```
figure;
plot(0:2000,pricesTT{:,1:5})
xlabel('Timestep');
ylabel('Value');
title('Equity Curve');
legend(pricesTT.Properties.VariableNames(1:5));
```



Optimize Asset Allocation Using Covariance Denoising

Covariance denoising is a technique that you can use to reduce the noise and enhance the signal in a covariance matrix. First, the eigenvalues that are associated with noise are separated from the eigenvalues associated with signal. Then, the eigenvalues associated with noise are shrunk towards a target value. This technique helps improve the stability of the covariance matrix over time as well as its condition number.

The function `covarianceDenoising` computes the denoised estimate of the covariance matrix and returns as a second output the number of eigenvalues identified with signal. You use this number in the Optimize the Asset Allocation Using Factor Modeling on page 4-380 section to determine the number of factors that the factor model allocation uses.

This example uses the first 42 days (approximately 2 months) of the data set to select the initial portfolio allocations.

```
% Warm-up period
warmupPeriod = 42;

% No current weights (100% cash position)
w0 = zeros(1,numAssets);

% Warm-up partition of prices timetable
warmupTT = pricesTT(1:warmupPeriod,:);
```

Compute the maximum return portfolio subject to a target risk of `0.008` using the denoised covariance estimate.

```
% Compute weights with denoised strategy
wDenoised_initial = denoising(w0,warmupTT);
```

Check for asset allocations that are over 5% to identify assets with large investment weights.

```
percentage = 0.05;
AssetName = pricesTT.Properties.VariableNames(...
    wDenoised_initial>=percentage)';
Weight = wDenoised_initial(wDenoised_initial>=percentage);
T1 = table(AssetName,Weight)
```

```
T1=5×2 table
     AssetName      Weight 
    ___________    ________

    {'Asset6' }    0.066014
    {'Asset47'}     0.10991
    {'Asset50'}     0.24654
    {'Asset75'}     0.11752
    {'Asset94'}     0.31708
```

Optimize Asset Allocation Using Factor Modeling

For factor modeling, you can use statistical factors extracted from the asset return series. In this example, PCA is used to extract these factors [1 on page 4-384]. You can then use this factor model to solve the portfolio optimization problem.

With a factor model, n asset returns can be expressed as a linear combination of k factor returns, $r_a = \mu_a + F\, r_f + \varepsilon_a$, where $k \ll p$. In the mean-variance framework, portfolio risk is

$$\mathrm{Var}\left(R_p\right) = \mathrm{Var}\left({r_a}^T w_a\right) = \mathrm{Var}\left(\left(\mu_a + F\, r_f + \varepsilon_a\right)^T w_a\right) = w_a^T\left(F\Sigma_f F^T + D\right) w_a,$$

where:

- R_p is the portfolio return (a scalar).
- r_a is the asset returns.
- μ_a is the mean of asset returns.
- F is the factor loading, with dimension $n \times k$.
- r_f is the factor return.
- ε_a is the idiosyncratic return related to each asset.
- w_a is the asset weight.
- Σ_f is the covariance of factor returns.
- D is the variance of idiosyncratic returns.

The parameters r_a, w_a, μ_a and ε_a are $n \times 1$ column vectors, $r_f$and w_f are $k \times 1$ column vectors, and Σ_k and D are a $k \times k$ and a $n \times n$ matrices, respectively.

Therefore, the mean-variance optimization problem is formulated as

$$\begin{aligned}
&\max_{w_a} \ \mu_a^T w_a \\
&s.t. \ w_a^T\left(F\Sigma_f F^T + D\right)w_a \le \tau, \\
&\qquad \sum_{a \in A} w_a = 1, \\
&\qquad 0 \le w_a \le 1 .
\end{aligned}$$

In the dimensional space formed by n asset returns, PCA finds the k directions that capture the most important variations in the returns. Usually, k is less than n. Therefore, by using PCA, you can decompose the n asset returns into k directions that are interpreted as factor loadings. The scores from the decomposition are interpreted as the factor returns. For more information, see `pca` (Statistics and Machine Learning Toolbox™). In this example, the factor model uses k =`nFactors`, where `covarianceDenoising` determines the `numFactors`.

Compute the maximum return portfolio subject to a target risk of 0.008 using the factor model covariance estimate. For details on how to obtain the weights allocation using factor modeling, see “Portfolio Optimization Using Factor Models” on page 4-224.

```
% Compute weights with denoised strategy
userData.numFactors = [];
[wFactorModel_initial,userData] = factorModeling(w0,warmupTT, ...
    userData);
```

Check for asset allocations that are over 5% to show assets with large investment weights.

```
percentage = 0.05;
AssetName = pricesTT.Properties.VariableNames( ...
    wFactorModel_initial>=percentage)';
Weight = wFactorModel_initial(wFactorModel_initial>=percentage);
T2 = table(AssetName,Weight)
```

```
T2=6×2 table
     AssetName       Weight 
    ___________    ________

    {'Asset6' }    0.075366
    {'Asset35'}    0.069395
    {'Asset47'}     0.10676
    {'Asset50'}     0.21628
    {'Asset75'}     0.12423
    {'Asset94'}      0.3068
```

The assets with large investment weights are almost the same for both investment strategies. `Asset35` is the only asset that appears in one table, namely in the factor model strategy, and not the other. Even the weights of the assets are similar.

Backtesting

Use `backtestStrategy` to create strategy objects for the two investment strategies. Compare the denoising strategy (`strat1`) against the factor model strategy (`strat2`) using backtesting.

```
% Rebalance approximately every month
rebalFreq = 21;
```

```
% Set the rolling lookback window to be at least 2 months and at
% most 6 months
lookback  = [42 126];

% Use a fixed transaction cost (buy and sell costs are both 0.5%
% of amount traded)
transactionsFixed = 0.005;

% Strategies
strat1 = backtestStrategy('Factor Modeling', @factorModeling, ...
    UserData=userData, ...
    RebalanceFrequency=rebalFreq, ...
    LookbackWindow=lookback, ...
    TransactionCosts=transactionsFixed, ...
    InitialWeights=wFactorModel_initial);

strat2 = backtestStrategy('Denoising', @denoising, ...
    RebalanceFrequency=rebalFreq, ...
    LookbackWindow=lookback, ...
    TransactionCosts=transactionsFixed, ...
    InitialWeights=wDenoised_initial);

% Aggregate the strategy objects into an array
strategies = [strat1, strat2];
```

Create a `backtestEngine` object for the strategies, run the backtest using `runBacktest`, and generate a report using `summary`.

```
% Create the backtesting engine object
backtester = backtestEngine(strategies);

% Run backtest
backtester = runBacktest(backtester,pricesTT,'Start',warmupPeriod);

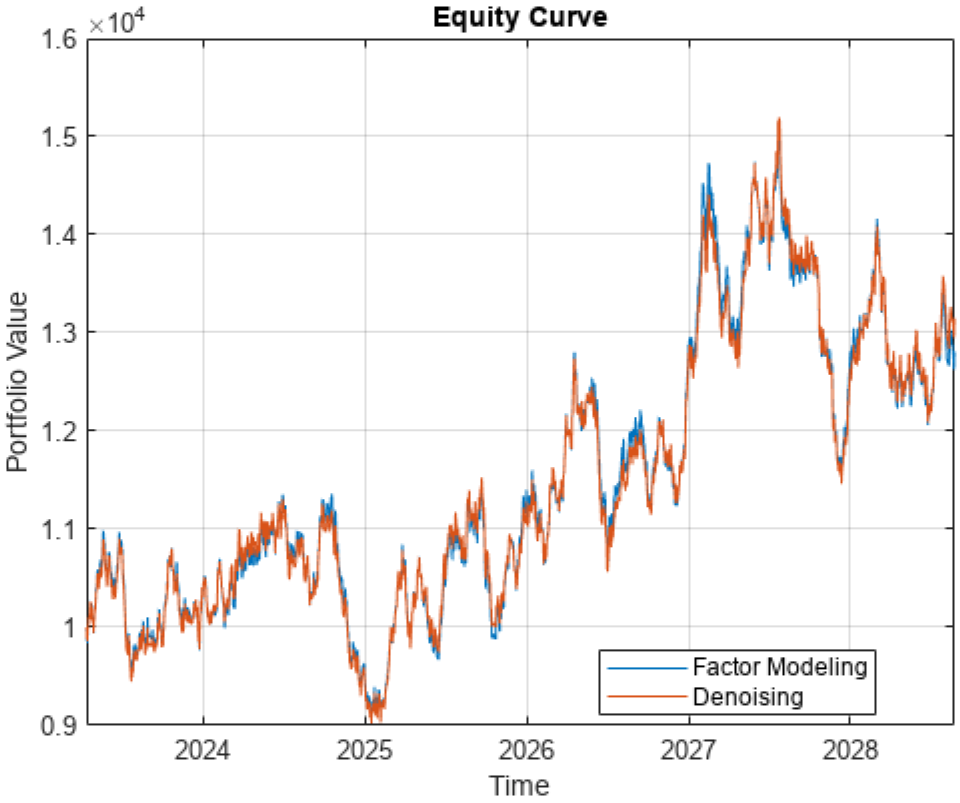
% Generate summary table of strategies performance
summary(backtester)
```

```
ans=9×2 table
                       Factor_Modeling    Denoising 
                       _______________    __________

    TotalReturn              0.28079         0.31501
    SharpeRatio             0.018583        0.020462
    Volatility             0.0089592       0.0086696
    AverageTurnover         0.014646        0.013843
    MaxTurnover              0.56184         0.58224
    AverageReturn         0.00016644      0.00017736
    MaxDrawdown              0.23384         0.24536
    AverageBuyCost           0.84446         0.79536
    AverageSellCost          0.84446         0.79536
```

Use `equityCurve` to plot the equity curve to compare the performance of both strategies.

```
equityCurve(backtester)
```



The performance of both strategies is similar, although not identical. This similarity is because the factor model strategy uses the number of factors identified by `covarianceDenoising` to select the number of principal components. Factor model strategies are usually not implemented this way, but rather the number of factors is a fixed parameter that is chosen *a priori*.

In this example, the number of factors that is most frequently identified is `1`.

```
% Count the number of different factors
categoricalNumFactors = ...
    categorical(backtester.Strategies(1).UserData.numFactors);
[N,uniqueFactors] = histcounts(categoricalNumFactors);
factorFrequency = table(uniqueFactors',N', ...
    'VariableNames',{'NumFactors','Frequency'})
```

```
factorFrequency=3×2 table
    NumFactors    Frequency
    __________    _________

      {'1' }         81    
      {'2' }         12    
      {'17'}          1    
```

Therefore, you can run the factor modeling strategy using `1` as the number of factors instead of using `covarianceDenoising` to identify the number of factors at each rebalancing period.

Deep Reinforcement Learning for Optimal Trade Execution

This example shows how to use the Reinforcement Learning Toolbox™ and Deep Learning Toolbox™ to design agents for optimal trade execution.

Introduction

Optimal trade execution seeks to minimize trading costs when selling or buying a set number of stock shares over a certain time horizon within the trading day. Optimization is necessary because executing trades too quickly results in suboptimal prices due to market impact, while executing trades too slowly results in exposure to the risk of adverse price changes or the inability to execute all trades within the time horizon. This optimization affects nearly all trading strategies and portfolio management practices, since minimizing trading costs is directly linked to profitability that is related to buying or selling decisions. Also, brokers compete to provide better trade order execution, and many jurisdictions legally require brokers to provide the best execution for their clients. Early studies by Bertsimas and Lo [1 on page 4-419] and Almgren and Chriss [2 on page 4-419] derived analytical solutions for the optimal trade execution problem by assuming a model for the underlying prices. Later, Nevmyvaka et al. [3 on page 4-419] demonstrated that the use of reinforcement learning (RL) for optimal execution did not require making assumptions about the market micro-structure. More recent studies use deep reinforcement learning,which combines reinforcement learning (RL) with deep learning, for optimal trade execution (Ning *et al*. [4 on page 4-419], Lin and Beling [5 on page 4-419,6 on page 4-419]). This approach overcomes the limitations of Q-learning as noted by Nevmyvaka et al. [3 on page 4-419].

This example uses deep reinforcement learning to design and train two deep Q-network (DQN) agents for optimal trade execution. One DQN agent is for sell trades and the other agent is for buy trades.

Data

This example uses the intraday trading data on Intel Corporation stock (INTC) provided by LOBSTER [7 on page 4-420] and included with Financial Toolbox™. While the reinforcement learning for optimal execution literature typically uses trading data over one year or more to train and test RL agents [3 on page 4-419,4 on page 4-419,5 on page 4-419,6 on page 4-419], in this proof-of-concept example you use a shorter data set, which you can expand for further study. The intraday trading data on the Intel stock (`INTC_2012-06-21_34200000_57600000_orderbook_5.csv`) contains limit order book data over 6.5 hours, including bid and ask prices as well as corresponding shares for 5 levels. This data is sampled at 5 second intervals to create 390 one minute trading horizons, such that each trading horizon contains 12 steps at five second intervals. Out of these 390 horizons, you use 293 horizons (about 75 percent) to train the agents and the remaining 97 horizons (about 25 percent) to test the agents.

Baseline Trade Execution Algorithm

An agent's performance must be compared with a baseline trade execution algorithm. For this example, the baseline trade execution algorithm is the time-weighted average price (TWAP) policy. Under this policy, the total trading shares are divided equally over the trading horizon, so that the same number of shares are traded at each time step. In contrast, the original paper by Nevmyvaka *et al*. [3 on page 4-419] used a "submit and leave" policy as the baseline, where a limit order is placed at a fixed price for the entire trading shares for the entire horizon, and any remaining unfilled shares are traded with a market order at the last step. However, the TWAP baseline was adopted in later studies [4 on page 4-419,5 on page 4-419,6 on page 4-419], since it has become more popular in recent years with increasing use of algorithmic trading, and it is also a highly effective strategy that is thought to be optimal when the price movement follows a Brownian motion [4 on page 4-419,5 on page 4-419,6 on page 4-419].

Agents

Different types of agents are used in the reinforcement learning for optimal execution studies, including Q-learning [3 on page 4-419], DQN [4 on page 4-419,5 on page 4-419], and PPO [6 on page 4-419] agents. In this example, you design and train DQN agents using the Reinforcement Learning Designer (Reinforcement Learning Toolbox) after creating separate training environments for sell trades and buy trades. These DQN agents only have a critic without an actor, and they use the default setting of `UseDoubleDQN` set to `true`, while the `DiscountFactor` is set to `1` due to the short trading horizon [4 on page 4-419,5 on page 4-419,6 on page 4-419]. In addition, the critic network of these agents include a long short-term memory (LSTM) network because the trading data is sequential in time, and LSTM networks are effective in designing agents for optimal execution [6 on page 4-419]. For more information on setting options for DQN agents, see `rlDQNAgentOptions` (Reinforcement Learning Toolbox).

Observation Space

The observation space defines which information (or feature) to provide to the agents at each step. The agents use this observation to decide the next action, based on the policy learned and reinforced by the rewards received after taking the previous actions. Designing a good observation space for the agents is an area of active research in optimal execution studies. You can experiment with different observation spaces, using variables such as the bid-ask spread, the bid or ask volume, price trends, or even the entire limit order book prices and shares [6 on page 4-419]. This example uses the following observation variables:

- Remaining shares to be traded by the agent in the current trading horizon
- Remaining time intervals (steps) left in the current trading horizon
- Cumulative implementation shortfall (IS) of agent until the previous step
- Current limit order book price divergence from arrival price

The first two observation variables (remaining shares to be traded and remaining time in horizon) are called "private" variables by Nevmyvaka *et al*. [3 on page 4-419], as they only apply to the specific situation of the trading agents, and they do not apply to other market participants. As the agent trained by Nevmyvaka *et al*. [3 on page 4-419] using only "private" variables was able to outperform the "submit and leave" baseline policy, the "private" variables are also used in the subsequent studies [4 on page 4-419,5 on page 4-419,6 on page 4-419].

The third variable, cumulative IS, is a measure of trading cost that the agents seek to minimize. As the name "shortfall" indicates, a lower implementation shortfall implies better trade execution. Technically, Implementation Shortfall should include the opportunity cost of failing to execute all shares within the trading horizon. In this example, as with many of the previously mentioned studies, the Implementation Shortfall is computed under the ending inventory constraint:

- For a sell trade, the constraint is to have zero ending inventory, assuming successful liquidation of all shares.
- For a buy trade, the constraint is to have full ending inventory, assuming successful purchase of all shares.

Under this ending inventory constraint, Implementation Shortfall is computed as follows:

- For a sell trade:
  $\text{Implementation Shortfall} = \text{Arrival Price} \times \text{Traded Volume} - \text{Executed Price} \times \text{Traded Volume}$
- For a buy trade:
  $\text{Implementation Shortfall} = \text{Executed Price} \times \text{Traded Volume} - \text{Arrival Price} \times \text{Traded Volume}$

The arrival price is the first bid or ask price observed at the beginning of the trade horizon. If Implementation Shortfall is positive, it implies that the average executed price was worse than the arrival price, while a negative Implementation Shortfall implies that the average executed price was better than the arrival price. The cumulative Implementation Shortfall from the beginning of the trade horizon until the previous step reflects the trading cost incurred by the agent in the past, and it serves as the third observation variable.

The last observation variable is the current price divergence from arrival price. This variable reflects the current market condition and it is measured as the difference between the arrival price and the average price of the first two levels of the current limit order book (LOB).

- For a sell trade:
  $\text{Price Divergence} = \text{Average Bid Prices of First 2 Levels of Current LOB} - \text{Arrival Price}$
- For a buy trade:
  $\text{Price Divergence} = \text{Arrival Price} - \text{Average Ask Prices of First 2 Levels of Current LOB}$

A positive price divergence implies more favorable current trading conditions than the arrival price, and a negative divergence less favorable conditions.

Action Space

The action space is defined as the possible number of shares traded at each step. For a TWAP policy, the only possible action at each step is to trade a constant number of shares computed as the total trading shares divided by the number of steps in the horizon. Meanwhile, the agents in this example choose from 39 possible actions that are mostly evenly spaced, ranging from trading 0 shares to trading twice the number of shares as the corresponding TWAP trade.

For both TWAP trades and agent trades, you enforce ending inventory constraints so that if the target ending inventory is not met by the last step of the horizon, the action for the last step is to:

- Sell any remaining shares in the inventory for a Sell trade.
- Buy any missing shares in the inventory for a Buy trade.

Also, you place limits on the agent actions to take advantage of price divergence and to prevent selling more than the available shares in the inventory or buying more than the target number of shares.

Reward

The reward is another important aspect of agent design, as agents learn their policies at each step using the rewards received after taking the previous actions. Research on reward design shows wide variations in optimal execution, and you can experiment with different rewards. Since the agent performance is measured against the baseline using Implementation Shortfall, many studies use Implementation Shortfalls directly in the rewards, while others use related quantities. Some studies use the proceeds from the trade as the reward [3 on page 4-419], while others also impose a penalty for trading many shares too quickly [4 on page 4-419]. Another study uses an elaborately shaped reward algorithm that is designed to use the TWAP policy most of the time, while encouraging the agent to deviate from the TWAP policy only when it is advantageous to do so [5 on page 4-419]. If there is enough data, the reward may be given sparsely, only at the end of each horizon rather than at each step [6 on page 4-419]. In this example, the data size is small, so you give the reward at each step and design it so that the reward at each step approximates the expected reward at the end of the horizon.

Specifically, you use a reward that compares the Implementation Shortfall of the TWAP baseline against that of the agent at each step, while also taking into account the penalty for the approximate Implementation Shortfall of the remaining unexecuted shares based on the current limit order book. The reward is also scaled based on the current time relative to the end of the horizon.

$$\text{Reward}(t) = \left[\left(\text{IS}_{\text{TWAP}}(0,t) + \text{IS}_{\text{TWAP, Penalty}}(t,T)\right) - \left(\text{IS}_{\text{Agent}}(0,t) + \text{IS}_{\text{Agent, Penalty}}(t,T)\right)\right] \times \frac{t}{T}$$

$\text{Reward}(t)$ is the reward at time step t

$\text{IS}_{\text{TWAP}}(0,t)$ is the Implementation Shortfall of TWAP from the beginning of the horizon until time step t

$\text{IS}_{\text{TWAP, Penalty}}(t,T)$ is the approximate Implementation Shortfall of TWAP from time step t to the end of the horizon at time step T

$\text{IS}_{\text{Agent}}(0,t)$ is the Implementation Shortfall of the agent from the beginning of horizon until time step t

$\text{IS}_{\text{Agent, Penalty}}(t,T)$ is the approximate Implementation Shortfall of the agent from time step t to the end of the horizon at time step T

Since the agent performance is ultimately measured against the baseline using Implementation Shortfall at the end of the horizon at time step T, and the approximate reward becomes more accurate as t approaches T, $\text{Reward}(t)$ has a scaling factor $\frac{t}{T}$ so that its magnitude increases as t approaches T. At time step T, the reward becomes $\text{Reward}(T)$.

$$\text{Reward}(T) = \text{IS}_{\text{TWAP}}(0,T) - \text{IS}_{\text{Agent}}(0,T)$$

Performance Analysis

You measure agent performance against the TWAP baseline using Implementation Shortfall (IS), by computing the following for all horizons:

- IS total outperformance of agent over TWAP — Sum of $\text{IS}_{\text{TWAP}}(0,T) - \text{IS}_{\text{Agent}}(0,T)$
- IS total-gain-to-loss ratio (TGLR) — Ratio of total positive over total negative $\text{IS}_{\text{TWAP}}(0,T) - \text{IS}_{\text{Agent}}(0,T)$ magnitudes
- IS gain-to-loss ratio (GLR) — Ratio of mean positive over mean negative $\text{IS}_{\text{TWAP}}(0,T) - \text{IS}_{\text{Agent}}(0,T)$ magnitudes

Workflow Organization

The workflow in this example is:

- **Load and Prepare Data** on page 4-390
- - LOBSTER Message Data — Contains time stamps

- - LOBSTER Limit Order Book Data — Contains bid and ask prices and corresponding shares
- **Optimal Execution for Sell Trades** on page 4-391
- - TWAP Baseline
- - Train the DQN Agent
- - Test the DQN Agent
- - Summary of Selling Results
- **Optimal Execution for Buy Trades** on page 4-415
- **Local Functions** on page 4-420
- - `executeTWAPTrades` — Executes TWAP Baseline trades and computes IS
- - `RL_OptimalExecution_LOB_ResetFcn` — Reset function for training and testing environments
- - `RL_OptimalExecution_LOB_StepFcn` — Step function for training and testing environments
- - `tradeLOB` — Executes trades on current limit order book
- - `endingInventoryIS` — Computes IS with ending inventory constraints
- - `ISTGLR` — Computes total-gain-to-loss ratio and gain-to-loss ratio for IS

Load and Prepare Message Data

Extract the LOBSTER data files from the ZIP file included with Financial Toolbox™. The expanded files include two CSV files of data and the text file `LOBSTER_SampleFiles_ReadMe.txt`.

```
unzip("LOBSTER_SampleFile_INTC_2012-06-21_5.zip");
```

The limit order book file contains the bid and ask prices and corresponding shares for five levels, while the message file contains the description of the limit order book data including time stamps.

```
LOBFileName = 'INTC_2012-06-21_34200000_57600000_orderbook_5.csv'; % Limit Order Book Data file
MSGFileName = 'INTC_2012-06-21_34200000_57600000_message_5.csv'; % Message file (description of
```

Load the message file and define the time at the start and end of trading hours as seconds after midnight.

```
TradeMessage = readmatrix(MSGFileName);
StartTradingSec   = 9.5*60*60;  % Starting time 9:30 in seconds after midnight
EndTradingSec     = 16*60*60;   % Ending time 16:00 in seconds after midnight
```

Define the trading interval as five seconds and pick message index values corresponding to the five-second intervals.

```
TradingIntervalSec = 5; % Trading interval length in seconds
IntervalBoundSec = (StartTradingSec:TradingIntervalSec:EndTradingSec)';
MessageSampleIdx = zeros(size(IntervalBoundSec));
k1 = 1;
for k2 = 1:size(TradeMessage,1)
    if TradeMessage(k2,1) >= IntervalBoundSec(k1)
        MessageSampleIdx(k1) = k2;
        k1 = k1+1;
    end
end
MessageSampleIdx(end) = length(TradeMessage);
```

Load and Prepare Limit Order Book Data

Load the limit order book data and define the number of levels in the limit order book.

```
LOB = readmatrix(LOBFileName);
NumLevels = 5;
```

Since LOBSTER stores prices in units of 10,000 dollars, convert the prices in the limit order book data into dollars by dividing by 10000.

```
LOB(:,1:2:(4*NumLevels)) = LOB(:,1:2:(4*NumLevels))./10000;
```

Using the message index values obtained previously, sample the limit order book at 5 second intervals.

```
SampledBook = LOB(MessageSampleIdx(2:end),1:NumLevels*4);
```

Define a one minute (60 seconds) trading horizon and compute the total number of intervals over 6.5 hours of trading data.

```
TradingHorizon = 1*60;
TotalNumIntervals = length(MessageSampleIdx(2:end));
TotalNumHorizons = 6.5*60*60/TradingHorizon;
```

The number of intervals per horizon is computed by dividing the total number of intervals by the total number of horizons.

```
NumIntervalsPerHorizon = round(TotalNumIntervals/TotalNumHorizons);
```

Allocate 75 percent of data for training and 25 percent for testing.

```
NumTrainingHorizons = round(TotalNumHorizons*0.75);
NumTestingHorizons = TotalNumHorizons - NumTrainingHorizons;
NumTrainingSteps = NumTrainingHorizons*NumIntervalsPerHorizon;
NumTestingSteps = NumTestingHorizons*NumIntervalsPerHorizon;
TrainingLOB = SampledBook(1:NumTrainingSteps,:);
TestingLOB = SampledBook(NumTrainingSteps+1:end,:);
```

Optimal Execution for Sell Trades

These sections compose the workflow for designing a DQN agent for the optimal execution of sell trades:

1. Define Settings for Sell Trades on page 4-392
2. TWAP Baseline Analysis on Training Data on page 4-392
3. Set Up RL Training Environment for Sell Trades on page 4-393
4. Validate Training Environment Reset and Step Functions for Sell Trades on page 4-394
5. Create and Train Agent for Sell Trades on page 4-396
6. Compute IS Using Trained Agent and Training Data for Sell Trades on page 4-401
7. Plot Training Results for Sell Trades on page 4-402
8. Display Summary of Training Results for Sell Trades on page 4-406
9. TWAP Baseline Analysis on Testing Data on page 4-407
10. Set Up RL Testing Environment for Sell Trades on page 4-408

11 Validate Testing Environment Reset and Step Functions for Sell Trades on page 4-409
12 Compute IS Using Trained Agent and Testing Data for Sell Trades on page 4-410
13 Plot Testing Results for Sell Trades on page 4-411
14 Display Summary of Training and Testing Results for Sell Trades on page 4-414

Define Settings for Sell Trades

To indicate sell trades, set the `BuyTrade` logical flag to `false`.

```
BuyTrade = false;
```

Define the total number of shares to sell over the horizon.

```
TotalTradingShares_Sell = 2738;
```

TWAP Baseline Analysis on Training Data

Execute TWAP trades and compute Implementation Shortfall (IS) using the `executeTWAPTrades` function, which uses the `tradeLOB` function to execute the trades and the `endingInventoryIS` function to compute IS. These functions are in the Local Functions on page 4-420 section.

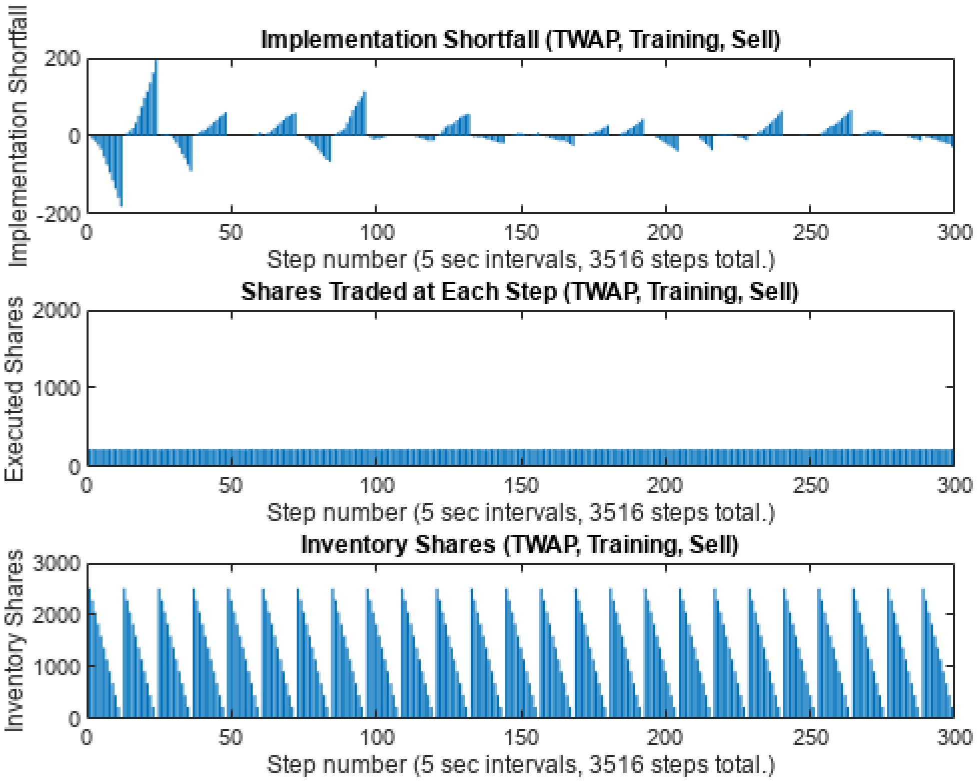
```
[IS_TWAP_Horizon_Train_Sell,IS_TWAP_Step_Train_Sell, ...
    InventoryShares_Step_TWAP_Train_Sell,TradingShares_Step_TWAP_Train_Sell] = ...
    executeTWAPTrades(TrainingLOB,NumLevels,TotalTradingShares_Sell, ...
    NumIntervalsPerHorizon,NumTrainingHorizons,BuyTrade);
```

Plot the implementation shortfall, executed shares, and inventory shares for the TWAP baseline for each step using the training data.

```
figure
subplot(3,1,1)
bar(1:NumTrainingSteps, IS_TWAP_Step_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Implementation Shortfall")
title("Implementation Shortfall (TWAP, Training, Sell)")
xlim([0 300])

subplot(3,1,2)
bar(1:NumTrainingSteps, TradingShares_Step_TWAP_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Executed Shares")
title("Shares Traded at Each Step (TWAP, Training, Sell)")
xlim([0 300])
ylim([0 2000])

subplot(3,1,3)
bar(1:NumTrainingSteps, InventoryShares_Step_TWAP_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Inventory Shares")
title("Inventory Shares (TWAP, Training, Sell)")
xlim([0 300])
```



The TWAP executed shares in the middle panel have a flat profile, since the same number of shares are traded at each step. Also, the inventory shares in the bottom panel have a nearly perfect triangular sawtooth pattern, with the number of inventory shares declining linearly at each horizon as the shares are sold. The IS in the top panel sometimes declines to negative values (implying better executions than arrival price) for some horizons, while it increases to positive values (implying worse executions than arrival price) for other horizons.

Set Up RL Training Environment for Sell Trades

The RL environment requires observation and action information, reset function, and a step function.

Define the observation information for the four observation variables.

```
ObservationDimension = [1 4];
ObservationInfo_Train_Sell = rlNumericSpec(ObservationDimension);
ObservationInfo_Train_Sell.Name = 'Observation Data';
ObservationInfo_Train_Sell.Description = 'RemainingSharesToTrade, RemainingIntervals, IS_Agent, 
ObservationInfo_Train_Sell.LowerLimit = -inf;
ObservationInfo_Train_Sell.UpperLimit = inf;
```

Define the environment constants for the training data and the reset function. The function definition for `RL_OptimalExecution_LOB_ResetFcn` is in the Local Functions on page 4-420 section.

```
EnvConstants_Train_Sell.SampledBook = TrainingLOB;
EnvConstants_Train_Sell.BuyTrade = BuyTrade;
EnvConstants_Train_Sell.TotalTradingShares = TotalTradingShares_Sell;
EnvConstants_Train_Sell.NumIntervalsPerHorizon = NumIntervalsPerHorizon;
EnvConstants_Train_Sell.NumHorizons = NumTrainingHorizons;
EnvConstants_Train_Sell.NumSteps = NumTrainingSteps;
EnvConstants_Train_Sell.NumLevels = NumLevels;
EnvConstants_Train_Sell.IS_TWAP = IS_TWAP_Step_Train_Sell;

ResetFunction_Sell = @() RL_OptimalExecution_LOB_ResetFcn(EnvConstants_Train_Sell);
```

Define the action information as the number of shares to be traded at each step, ranging from zero shares to twice the number of shares as in TWAP.

```
NumActions = 39;
LowerActionRange = linspace(0,TradingShares_Step_TWAP_Train_Sell(1), round(NumActions/2));
ActionRange = round([LowerActionRange(1:end-1) ...
    linspace(TradingShares_Step_TWAP_Train_Sell(1), ...
    TradingShares_Step_TWAP_Train_Sell(1)*2,round(NumActions/2))]);

ActionInfo_Sell = rlFiniteSetSpec(ActionRange);
ActionInfo_Sell.Name = 'Trading Action (Number of Shares)';
ActionInfo_Sell.Description = 'Number of Shares to be Traded at Each Time Step';
```

Define the step function, which computes the rewards and updates the observations at each step. The function definition for `RL_OptimalExecution_LOB_StepFcn` is in the Local Functions on page 4-420 section.

```
StepFunction_Train_Sell = @(Action,LoggedSignals) ...
    RL_OptimalExecution_LOB_StepFcn(Action,LoggedSignals,EnvConstants_Train_Sell);
```

Create the environment using the custom function handles defined in this section.

```
RL_OptimalExecution_Training_Environment_Sell = rlFunctionEnv(ObservationInfo_Train_Sell,ActionIn
```

```
Reset!
Reset!

RL_OptimalExecution_Training_Environment_Sell = 
  rlFunctionEnv with properties:

         StepFcn: @(Action,LoggedSignals)RL_OptimalExecution_LOB_StepFcn(Action,LoggedSignals,En
        ResetFcn: @()RL_OptimalExecution_LOB_ResetFcn(EnvConstants_Train_Sell)
    LoggedSignals: [1×1 struct]
```

Validate Training Environment Reset and Step Functions for Sell Trades

Before using the created environment, the best practice is to validate the reset and step functions for the environment. Call the reset and step functions to see if they produce reasonable results without errors.

Validate the reset function and the initial observation.

```
InitialObservation = reset(RL_OptimalExecution_Training_Environment_Sell);
```

```
Reset!
```

```
InitialObservation
```

```
InitialObservation = 1×4
```

```
        2738          12           0           0
```

Validate the step function by monitoring the logged signals and rewards while calling the step functions multiple times. Here, you can see the time interval index increasing at each step and the current inventory shares changing as the trades are executed at each step.

```
[~,Reward1,~,LoggedSignals1] = step(RL_OptimalExecution_Training_Environment_Sell,TradingShares_S
LoggedSignals1
```

```
LoggedSignals1 = struct with fields:
               IntervalIdx: 1
                HorizonIdx: 1
    CurrentInventoryShares: 2624
              ArrivalPrice: 27.4600
            ExecutedShares: 114
            ExecutedPrices: 27.4600
     HorizonExecutedShares: [60×1 double]
     HorizonExecutedPrices: [60×1 double]
                  IS_Agent: [3516×1 double]
                    Reward: [3516×1 double]
    NumIntervalsPerHorizon: 12
               NumHorizons: 293
                 NumLevels: 5
```

```
Reward1
```

```
Reward1 = 0
```

```
[~,Reward2,~,LoggedSignals2] = step(RL_OptimalExecution_Training_Environment_Sell,10);
LoggedSignals2
```

```
LoggedSignals2 = struct with fields:
               IntervalIdx: 2
                HorizonIdx: 1
    CurrentInventoryShares: 2614
              ArrivalPrice: 27.4600
            ExecutedShares: 10
            ExecutedPrices: 27.4900
     HorizonExecutedShares: [60×1 double]
     HorizonExecutedPrices: [60×1 double]
                  IS_Agent: [3516×1 double]
                    Reward: [3516×1 double]
    NumIntervalsPerHorizon: 12
               NumHorizons: 293
                 NumLevels: 5
```

```
Reward2
```

```
Reward2 = 0.6150
```

```
[~,Reward3,~,LoggedSignals3] = step(RL_OptimalExecution_Training_Environment_Sell,35);
LoggedSignals3
```

```
LoggedSignals3 = struct with fields:
               IntervalIdx: 3
                HorizonIdx: 1
```

```
    CurrentInventoryShares: 2579
              ArrivalPrice: 27.4600
            ExecutedShares: 35
            ExecutedPrices: 27.4900
     HorizonExecutedShares: [60×1 double]
     HorizonExecutedPrices: [60×1 double]
                  IS_Agent: [3516×1 double]
                    Reward: [3516×1 double]
    NumIntervalsPerHorizon: 12
               NumHorizons: 293
                 NumLevels: 5
```

```
Reward3
```

```
Reward3 = 0.8925
```

Call the reset function again to restore the environment back to the initial state.

```
reset(RL_OptimalExecution_Training_Environment_Sell);
```

```
Reset!
```

Create and Train Agent for Sell Trades

Open Reinforcement Learning Designer (Reinforcement Learning Toolbox).

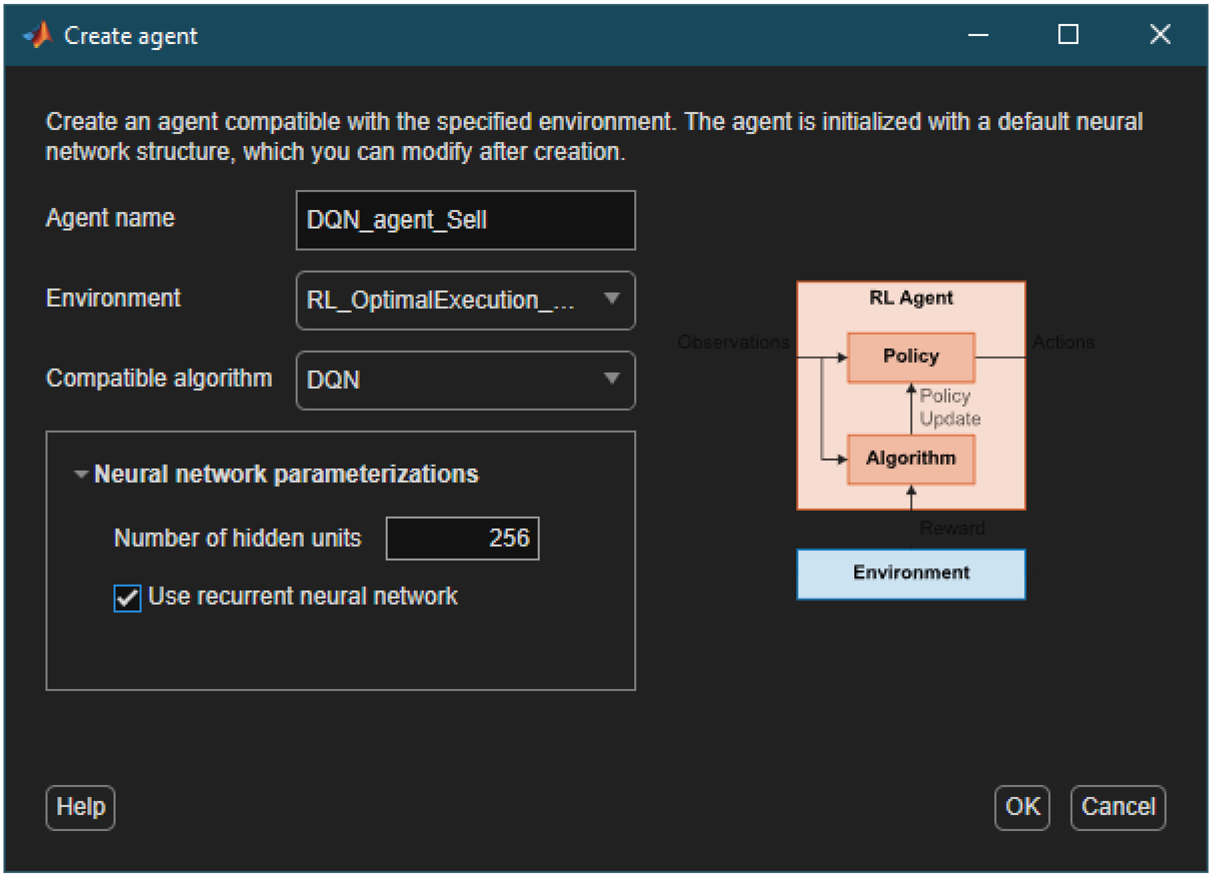
Use the toolstrip above to configure and train your reinforcement learning problem.

Create a new DQN agent by selecting **New > Agent**, then selecting `DQN` from the **Compatible algorithm** menu. Enable LSTM by selecting **Use recurrent neural network**.



Create an agent compatible with the specified environment. The agent is initialized with a default neural network structure, which you can modify after creation.

Agent name: DQN_agent_Sell

Environment: RL_OptimalExecution_...

Compatible algorithm: DQN

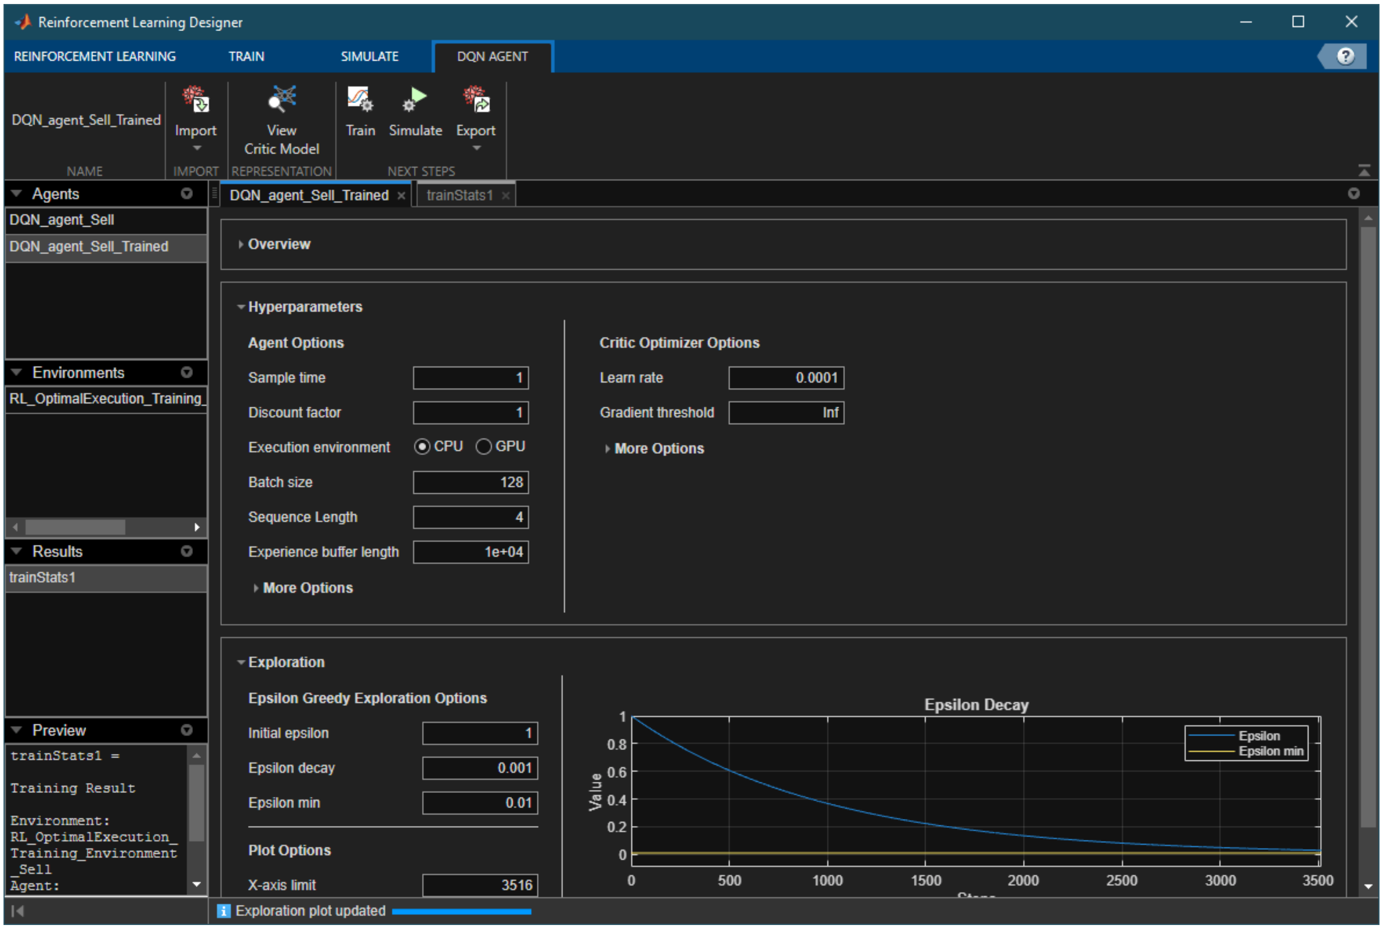
Neural network parameterizations

Number of hidden units: 256

☑ Use recurrent neural network

Set the agent hyperparameters and exploration parameters in the **DQN Agent** tab. Use the default options, except for the following:

- **Discount factor** — 1
- **Learn rate** — `0.0001`
- **Batch size** — 128
- **Sequence length** — 4
- **Initial epsilon** — 1
- **Epsilon decay** — `0.001`



```

Plot Training Results for Sell Trades

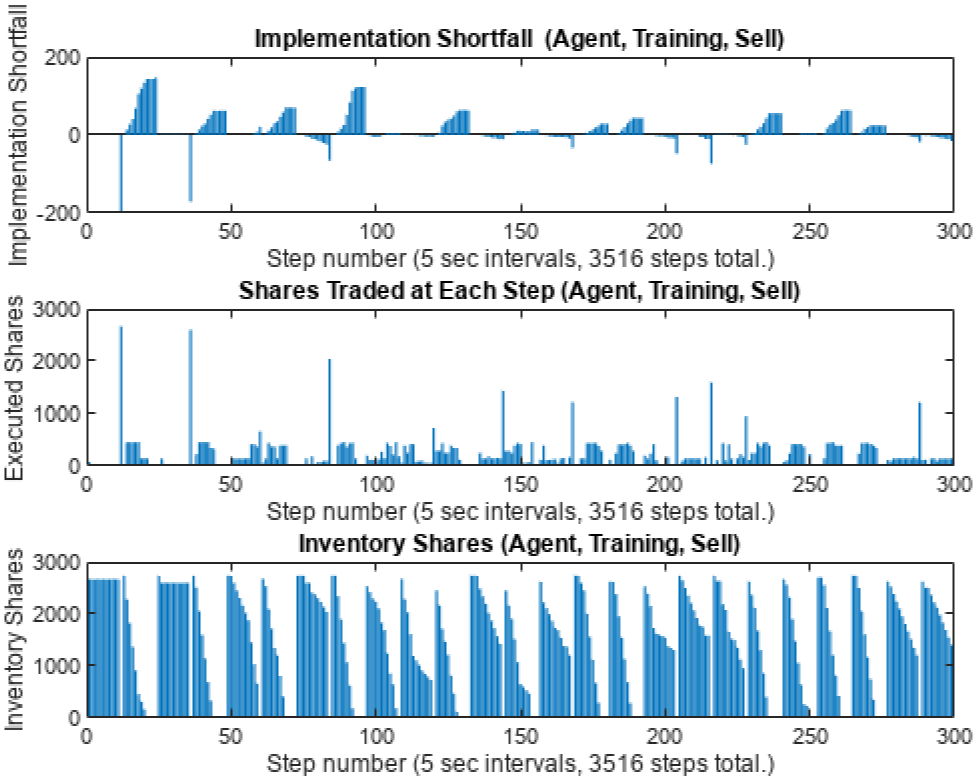
Plot Implementation Shortfall (IS), executed shares, and inventory shares for the agent for each step using training data.

```
figure
subplot(3,1,1)
bar(1:NumTrainingSteps, IS_Agent_Step_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Implementation Shortfall")
title("Implementation Shortfall  (Agent, Training, Sell)")
xlim([0 300])
ylim([-200 200])

subplot(3,1,2)
bar(1:NumTrainingSteps, SimExecutedShares_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
```

```
ylabel("Executed Shares")
title("Shares Traded at Each Step (Agent, Training, Sell)")
xlim([0 300])

subplot(3,1,3)
bar(1:NumTrainingSteps, SimInventory_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Inventory Shares")
title("Inventory Shares (Agent, Training, Sell)")
xlim([0 300])
```



Unlike the previous TWAP baseline plot, where the executed shares in the middle panel have a flat profile, here you can see that the agent actively changes the number of executed shares at each step. Also, the inventory shares in the bottom panel decline in a non-linear manner.

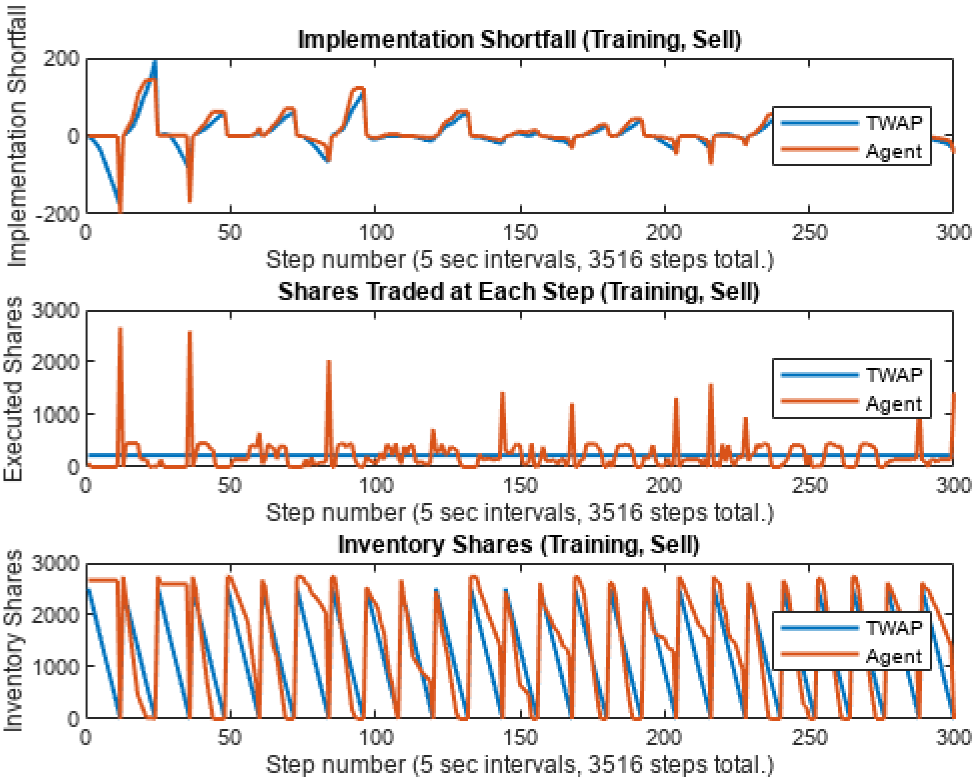
To directly compare the results from the agent with the TWAP baseline, you can plot both results on the same chart. Generate plots to compare implementation shortfall, executed shares, and inventory shares between the TWAP baseline and the agent for each step using the training data.

```
figure
subplot(3,1,1)
plot(1:NumTrainingSteps, [IS_TWAP_Step_Train_Sell IS_Agent_Step_Train_Sell], linewidth=1.5)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Implementation Shortfall")
title("Implementation Shortfall (Training, Sell)")
```

```
legend(["TWAP" "Agent"], location="east")
xlim([0 300])

subplot(3,1,2)
plot(1:NumTrainingSteps, [TradingShares_Step_TWAP_Train_Sell ...
    SimExecutedShares_Train_Sell], linewidth=1.5)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Executed Shares")
title("Shares Traded at Each Step (Training, Sell)")
legend(["TWAP" "Agent"], location="east")
xlim([0 300])

subplot(3,1,3)
plot(1:NumTrainingSteps, [InventoryShares_Step_TWAP_Train_Sell ...
    SimInventory_Train_Sell], linewidth=1.5)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
ylabel("Inventory Shares")
title("Inventory Shares (Training, Sell)")
legend(["TWAP" "Agent"], location="east")
xlim([0 300])
```



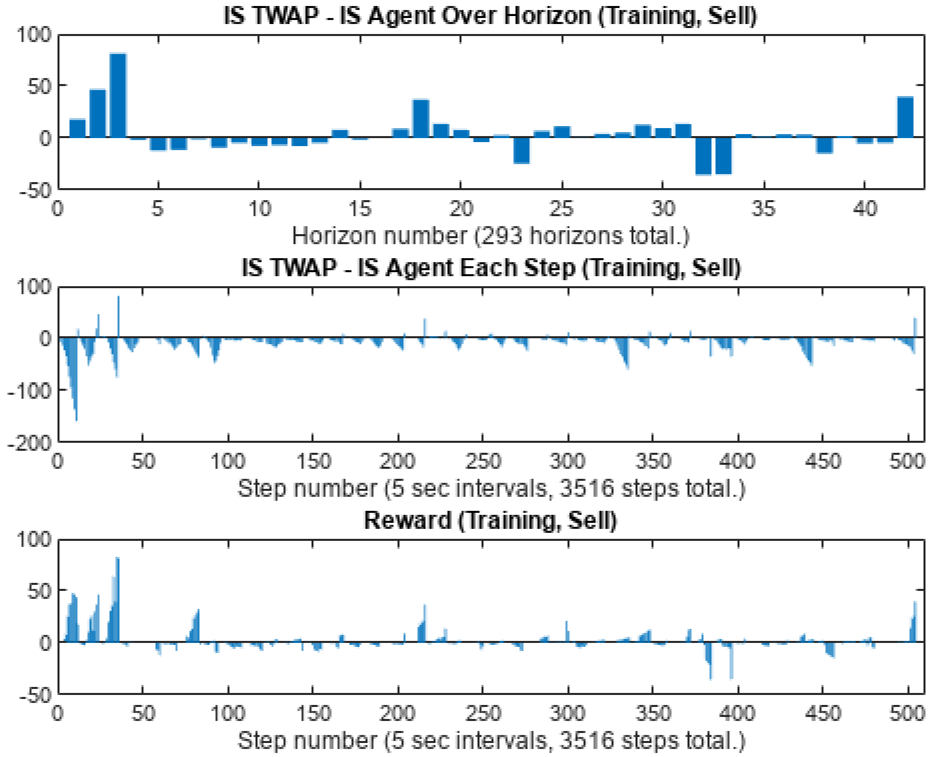
You can see the differences between the TWAP baseline (blue) and the agent (red) in their IS, executed shares, and inventory shares. Also, the agent tends to behave differently when the IS trends negative as compared to positive.

- For example, in the first horizon (step numbers 1 to 12) and the third horizon (step numbers 25 to 36), the IS trends negative (more favorable prices than the arrival price) and the agent initially trades fewer shares than TWAP, until there are large spikes in the executed shares at the ends of the horizons to meet the ending inventory constraint. Also, the inventories initially declines more slowly than TWAP, until the abrupt declines to zero at the end of the horizon. This coincided with negative pulls in the agent's IS at the end of the first and the third horizons that go even lower than the IS of TWAP.
- On the other hand, in the second horizon (step numbers 13 to 24), the IS trends positive (less favorable prices than the arrival price), and the agent initially trades more shares than TWAP to liquidate the inventory faster than TWAP. This has a limiting effect on the agent's IS at the end of the horizon, which is also lower than the IS of TWAP.

You can see similar behaviors in other horizons, although they do not always lead to an outperformance of the agent over TWAP.

Also, you can plot the differences in IS between TWAP and the agent, and then compare them with the rewards.

```
figure
subplot(3,1,1)
bar(1:NumTrainingHorizons, IS_TWAP_Horizon_Train_Sell - IS_Agent_Horizon_Train_Sell)
xlabel(strcat("Horizon number (", num2str(NumTrainingHorizons), " horizons total.)"))
title("IS TWAP - IS Agent Over Horizon (Training, Sell)")
xlim([0 43])
subplot(3,1,2)
bar(1:NumTrainingSteps, IS_TWAP_Step_Train_Sell - IS_Agent_Step_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
title("IS TWAP - IS Agent Each Step (Training, Sell)")
xlim([0 510])
subplot(3,1,3)
bar(1:NumTrainingSteps, SimReward_Train_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTrainingSteps), " steps total.)"))
title("Reward (Training, Sell)")
xlim([0 510])
```



The top panel ($\mathrm{IS}_{\mathrm{TWAP}}(0, T) - \mathrm{IS}_{\mathrm{Agent}}(0, T)$) shows the final performance of the agent for the training data as the differences in IS between TWAP and the agent at the ends of the horizons at times T. For example, in the top panel, you can see the outperformance of the agent (positive IS difference) in the first three horizons, while the agent underperforms in some of the other horizons. The middle panel ($\mathrm{IS}_{\mathrm{TWAP}}(0, t) - \mathrm{IS}_{\mathrm{Agent}}(0, t)$) shows the differences in IS for all time steps t, including the ones before the ends of the horizons. The middle panel does not appear to track the top panel values very well in some steps (except for the very last steps in the horizons, which are the top panel values when $t = T$), as there are frequent trend reversals between negative and positive values at the last steps of the horizons. Therefore, the simple difference in IS between TWAP and the agent at each step ($\mathrm{IS}_{\mathrm{TWAP}}(0, t) - \mathrm{IS}_{\mathrm{Agent}}(0, t)$) shown in the middle panel may not be a good reward function. On the other hand, the bottom panel, which plots the rewards used by the agent in this example at each step, appears to track the top panel values more closely than the middle panel at most steps.

Display Summary of Training Results for Sell Trades

Display the total Implementation Shortfall outperformance of the agent over TWAP for the training data.

```
sum(IS_TWAP_Horizon_Train_Sell - IS_Agent_Horizon_Train_Sell)
```

```
ans = 164.4700
```

Display total-gain-to-loss ratio (TGLR) for the training data.

```
ISTGLR(IS_TWAP_Horizon_Train_Sell - IS_Agent_Horizon_Train_Sell)
```

```
ans = 1.2327
```

TWAP Baseline Analysis on Testing Data

Using the same trained agent as the Compute IS Using Trained Agent and Training Data for Sell Trades on page 4-401 section, you can perform the same analysis on the testing data that you kept separate from the training data.

First, execute the TWAP trades and compute IS for the testing data.

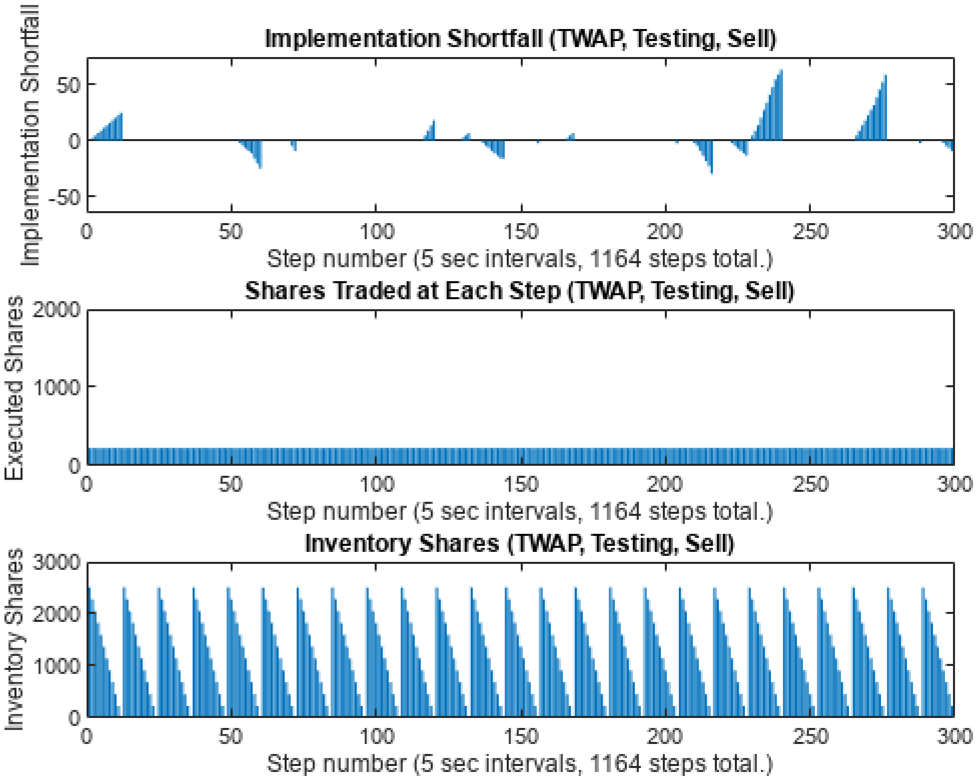
```
[IS_TWAP_Horizon_Test_Sell,IS_TWAP_Step_Test_Sell, ...
    InventoryShares_Step_TWAP_Test_Sell,TradingShares_Step_TWAP_Test_Sell] = ...
    executeTWAPTrades(TestingLOB,NumLevels,TotalTradingShares_Sell,...
    NumIntervalsPerHorizon,NumTestingHorizons,BuyTrade);
```

Plot the implementation shortfall, executed shares, and inventory shares for the TWAP baseline for each step using testing data.

```
figure
subplot(3,1,1)
bar(1:NumTestingSteps, IS_TWAP_Step_Test_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTestingSteps), " steps total.)"))
ylabel("Implementation Shortfall")
title("Implementation Shortfall (TWAP, Testing, Sell)")
xlim([0 300])
ylim([-65 75])

subplot(3,1,2)
bar(1:NumTestingSteps, TradingShares_Step_TWAP_Test_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTestingSteps), " steps total.)"))
ylabel("Executed Shares")
title("Shares Traded at Each Step (TWAP, Testing, Sell)")
xlim([0 300])
ylim([0 2000])

subplot(3,1,3)
bar(1:NumTestingSteps, InventoryShares_Step_TWAP_Test_Sell)
xlabel(strcat("Step number (", num2str(TradingIntervalSec), ...
    " sec intervals, ", num2str(NumTestingSteps), " steps total.)"))
ylabel("Inventory Shares")
title("Inventory Shares (TWAP, Testing, Sell)")
xlim([0 300])
```



Set Up RL Testing Environment for Sell Trades

Next, define the reset function for the testing environment.

```
EnvConstants_Test_Sell.SampledBook = TestingLOB;
EnvConstants_Test_Sell.BuyTrade = BuyTrade;
EnvConstants_Test_Sell.TotalTradingShares = TotalTradingShares_Sell;
EnvConstants_Test_Sell.NumIntervalsPerHorizon = NumIntervalsPerHorizon;
EnvConstants_Test_Sell.NumHorizons = NumTestingHorizons;
EnvConstants_Test_Sell.NumSteps = NumTestingSteps;
EnvConstants_Test_Sell.NumLevels = NumLevels;
EnvConstants_Test_Sell.IS_TWAP = IS_TWAP_Step_Test_Sell;

ResetFunction_Test_Sell = @() RL_OptimalExecution_LOB_ResetFcn(EnvConstants_Test_Sell);
```

Define the step function for the testing environment.

```
StepFunction_Test_Sell = @(Action,LoggedSignals) ...
    RL_OptimalExecution_LOB_StepFcn(Action,LoggedSignals,EnvConstants_Test_Sell);
```

Create the testing environment using the reset and step function handles.

```
RL_OptimalExecution_Testing_Environment_Sell = ...
    rlFunctionEnv(ObservationInfo_Train_Sell,ActionInfo_Sell, ...
    StepFunction_Test_Sell,ResetFunction_Test_Sell)
```

```
Reset!
Reset!
```

```
RL_OptimalExecution_Testing_Environment_Sell = 
  rlFunctionEnv with properties:

         StepFcn: @(Action,LoggedSignals)RL_OptimalExecution_LOB_StepFcn(Action,LoggedSignals,En
        ResetFcn: @()RL_OptimalExecution_LOB_ResetFcn(EnvConstants_Test_Sell)
    LoggedSignals: [1×1 struct]
```

Validate Testing Environment Reset and Step Functions for Sell Trades

Now, validate the testing environment using reset and step function handles.

```
InitialObservation = reset(RL_OptimalExecution_Testing_Environment_Sell);
```

```
Reset!
```

```

Optimal Execution for Buy Trades

You can use a shortened version of the previous procedure (Optimal Execution for Sell Trades on page 4-391) to support the workflow for designing a DQN agent for optimal execution of buy trades. To repeat the same workflow for buy trades, first set the `BuyTrade` logical flag to `true` and define the total number of shares to buy over the horizon.

```
BuyTrade = true;
TotalTradingShares_Buy = 2551;
```

Execute TWAP trades and compute the Implementation Shortfall (IS).

```
[IS_TWAP_Horizon_Train_Buy,IS_TWAP_Step_Train_Buy, ...
    InventoryShares_Step_TWAP_Train_Buy,TradingShares_Step_TWAP_Train_Buy] = ...
    executeTWAPTrades(TrainingLOB,NumLevels,TotalTradingShares_Buy, ...
    NumIntervalsPerHorizon,NumTrainingHorizons,BuyTrade);
```

Set up the RL training environment for buy trades.

```
ObservationDimension = [1 4];
ObservationInfo_Train_Buy = rlNumericSpec(ObservationDimension);
ObservationInfo_Train_Buy.Name = 'Observation Data';
ObservationInfo_Train_Buy.Description = ['RemainingSharesToTrade, ...' ...
    'RemainingIntervals, IS_Agent, PriceDivergence'];
ObservationInfo_Train_Buy.LowerLimit = -inf;
ObservationInfo_Train_Buy.UpperLimit = inf;
```

```
EnvConstants_Train_Buy.SampledBook = TrainingLOB;
EnvConstants_Train_Buy.BuyTrade = BuyTrade;
EnvConstants_Train_Buy.TotalTradingShares = TotalTradingShares_Buy;
EnvConstants_Train_Buy.NumIntervalsPerHorizon = NumIntervalsPerHorizon;
EnvConstants_Train_Buy.NumHorizons = NumTrainingHorizons;
EnvConstants_Train_Buy.NumSteps = NumTrainingSteps;
EnvConstants_Train_Buy.NumLevels = NumLevels;
EnvConstants_Train_Buy.IS_TWAP = IS_TWAP_Step_Train_Buy;
ResetFunction_Buy = @() RL_OptimalExecution_LOB_ResetFcn(EnvConstants_Train_Buy);

NumActions = 39;
LowerActionRange = linspace(0,TradingShares_Step_TWAP_Train_Buy(1), round(NumActions/2));
ActionRange = round([LowerActionRange(1:end-1) ...
    linspace(TradingShares_Step_TWAP_Train_Buy(1), ...
    TradingShares_Step_TWAP_Train_Buy(1)*2,round(NumActions/2))]);
NumActions = length(ActionRange);

ActionInfo_Buy = rlFiniteSetSpec(ActionRange);
ActionInfo_Buy.Name = 'Trading Action (Number of Shares)';
ActionInfo_Buy.Description = 'Number of Shares to be Traded at Each Time Step';

StepFunction_Train_Buy = @(Action,LoggedSignals) ...
    RL_OptimalExecution_LOB_StepFcn(Action,LoggedSignals,EnvConstants_Train_Buy);

RL_OptimalExecution_Training_Environment_Buy = rlFunctionEnv( ...
    ObservationInfo_Train_Buy,ActionInfo_Buy,StepFunction_Train_Buy,ResetFunction_Buy)
```

```
Reset!
Reset!

RL_OptimalExecution_Training_Environment_Buy = 
  rlFunctionEnv with properties:

           StepFcn: @(Action,LoggedSignals)RL_OptimalExecution_LOB_StepFcn(Action,LoggedSignals,En
          ResetFcn: @()RL_OptimalExecution_LOB_ResetFcn(EnvConstants_Train_Buy)
    LoggedSignals: [1×1 struct]
```

Use Reinforcement Learning Designer (Reinforcement Learning Toolbox) to create and train the agent for the buy trades. You use the same procedure (Optimal Execution for Sell Trades on page 4-391) as with the sell trades, except that the imported training environment is for buy trades (`RL_OptimalExecution_Training_Environment_Buy`). Once the training is complete, export the trained agent to the workspace. Since training can take a long time, this example uses a pretrained agent (`DQN_agent_Buy_Trained.mat`).

```
load DQN_agent_Buy_Trained.mat
```

Compute IS using the trained agent and training data for buy trades.

```
rng('default');
reset(RL_OptimalExecution_Training_Environment_Buy);
```

```
Reset!
```

```

Portfolio Optimization Theory

In this section...

Portfolio Optimization Problems

Portfolio optimization problems involve identifying portfolios that satisfy three criteria:

- Minimize a proxy for risk.
- Match or exceed a proxy for return.
- Satisfy basic feasibility requirements.

Portfolios are points from a feasible set of assets that constitute an asset universe. A portfolio specifies either holdings or weights in each individual asset in the asset universe. The convention is to specify portfolios in terms of weights, although the portfolio optimization tools work with holdings as well.

The set of feasible portfolios is necessarily a nonempty, closed, and bounded set. The proxy for risk is a function that characterizes either the variability or losses associated with portfolio choices. The proxy for return is a function that characterizes either the gross or net benefits associated with portfolio choices. The terms “risk” and “risk proxy” and “return” and “return proxy” are interchangeable. The fundamental insight of Markowitz (see “Portfolio Optimization” on page A-5) is that the goal of the portfolio choice problem is to seek minimum risk for a given level of return and to seek maximum return for a given level of risk. Portfolios satisfying these criteria are efficient portfolios and the graph of the risks and returns of these portfolios forms a curve called the efficient frontier.

Portfolio Problem Specification

To specify a portfolio optimization problem, you need the following:

- Proxy for portfolio return (μ)
- Proxy for portfolio risk (σ)
- Set of feasible portfolios (X), called a portfolio set

Financial Toolbox has three objects to solve specific types of portfolio optimization problems:

- The `Portfolio` object supports mean-variance portfolio optimization (see Markowitz [46], [47] at “Portfolio Optimization” on page A-5). This object has either gross or net portfolio returns as the return proxy, the variance of portfolio returns as the risk proxy, and a portfolio set that is any combination of the specified constraints to form a portfolio set.
- The `PortfolioCVaR` object implements what is known as conditional value-at-risk portfolio optimization (see Rockafellar and Uryasev [48], [49] at “Portfolio Optimization” on page A-5), which is generally referred to as CVaR portfolio optimization. CVaR portfolio optimization works

with the same return proxies and portfolio sets as mean-variance portfolio optimization but uses conditional value-at-risk of portfolio returns as the risk proxy.

- The `PortfolioMAD` object implements what is known as mean-absolute deviation portfolio optimization (see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5), which is referred to as MAD portfolio optimization. MAD portfolio optimization works with the same return proxies and portfolio sets as mean-variance portfolio optimization but uses mean-absolute deviation portfolio returns as the risk proxy.

Return Proxy

The proxy for portfolio return is a function $\mu: X \rightarrow R$ on a portfolio set $X \subset R^n$ that characterizes the rewards associated with portfolio choices. Usually, the proxy for portfolio return has two general forms, gross and net portfolio returns. Both portfolio return forms separate the risk-free rate r_0 so that the portfolio $x \in X$ contains only risky assets.

Regardless of the underlying distribution of asset returns, a collection of S asset returns $y_1,...,y_S$ has a mean of asset returns

$$m = \frac{1}{S}\sum_{s=1}^{S} y_s,$$

and (sample) covariance of asset returns

$$C = \frac{1}{S-1}\sum_{s=1}^{S} (y_s - m)(y_s - m)^T .$$

These moments (or alternative estimators that characterize these moments) are used directly in mean-variance portfolio optimization to form proxies for portfolio risk and return.

Gross Portfolio Returns

The gross portfolio return for a portfolio $x \in X$ is

$$\mu(x) = r_0 + (m - r_0 1)^T x,$$

where:

r_0 is the risk-free rate (scalar).

m is the mean of asset returns (n vector).

If the portfolio weights sum to `1`, the risk-free rate is irrelevant. The properties in the `Portfolio` object to specify gross portfolio returns are:

- `RiskFreeRate` for r_0
- `AssetMean` for m

Net Portfolio Returns

The net portfolio return for a portfolio $x \in X$ is

$$\mu(x) = r_0 + (m - r_0 1)^T x - b^T \max\left\{0, x - x_0\right\} - s^T \max\left\{0, x_0 - x\right\},$$

where:

r_0 is the risk-free rate (scalar).

m is the mean of asset returns (n vector).

b is the proportional cost to purchase assets (n vector).

s is the proportional cost to sell assets (n vector).

You can incorporate fixed transaction costs in this model also. Though in this case, it is necessary to incorporate prices into such costs. The properties in the `Portfolio` object to specify net portfolio returns are:

- `RiskFreeRate` for r_0
- `AssetMean` for m
- `InitPort` for x_0
- `BuyCost` for b
- `SellCost` for s

Risk Proxy

The proxy for portfolio risk is a function $\sigma\colon X \to R$ on a portfolio set $X \subset R^n$ that characterizes the risks associated with portfolio choices.

Variance

The variance of portfolio returns for a portfolio $x \in X$ is

$$Variance(x) = x^T C x$$

where C is the covariance of asset returns (`n`-by-`n` positive-semidefinite matrix). Covariance is a measure of the degree to which returns on two assets move in tandem. A positive covariance means that asset returns move together; a negative covariance means they vary inversely.

The property in the `Portfolio` object to specify the variance of portfolio returns is `AssetCovar` for C.

Although the risk proxy in mean-variance portfolio optimization is the variance of portfolio returns, the square root, which is the standard deviation of portfolio returns, is often reported and displayed. Moreover, this quantity is often called the “risk” of the portfolio. For details, see Markowitz (“Portfolio Optimization” on page A-5).

Conditional Value-at-Risk

The conditional value-at-risk for a portfolio $x \in X$, which is also known as expected shortfall, is defined as

$$CVaR_\alpha(x) = \frac{1}{1-\alpha} \int_{f(x,y) \geq VaR_\alpha(x)} f(x,y)p(y)dy,$$

where:

α is the probability level such that $0 < \alpha < 1$.

f(x,y) is the loss function for a portfolio *x* and asset return *y*.

p(y) is the probability density function for asset return *y*.

VaR_α is the value-at-risk of portfolio *x* at probability level α.

The value-at-risk is defined as

$$VaR_\alpha(x) = \min\{\gamma\colon \Pr[f(x, Y) \le \gamma] \ge \alpha\}\ .$$

An alternative formulation for CVaR has the form:

$$CVaR_\alpha(x) = VaR_\alpha(x) + \frac{1}{1-\alpha}\int_{R^n} \max\{0, (f(x, y) - VaR_\alpha(x))\}p(y)dy$$

The choice for the probability level α is typically 0.9 or 0.95. Choosing α implies that the value-at-risk $VaR_\alpha(x)$ for portfolio *x* is the portfolio return such that the probability of portfolio returns falling below this level is $(1 - \alpha)$. Given $VaR_\alpha(x)$ for a portfolio *x*, the conditional value-at-risk of the portfolio is the expected loss of portfolio returns above the value-at-risk return.

Note Value-at-risk is a positive value for losses so that the probability level α indicates the probability that portfolio returns are below the negative of the value-at-risk.

To describe the probability distribution of returns, the `PortfolioCVaR` object takes a finite sample of return scenarios y_s, with $s = 1,...,S$. Each y_s is an *n* vector that contains the returns for each of the *n* assets under the scenario *s*. This sample of *S* scenarios is stored as a scenario matrix of size *S*-by-*n*. Then, the risk proxy for CVaR portfolio optimization, for a given portfolio $x \in X$ and $\alpha \in (0, 1)$, is computed as

$$CVaR_\alpha(x) = VaR_\alpha(x) + \frac{1}{(1-\alpha)S}\sum_{s=1}^{S} \max\left\{0, \ -y_s^T x - VaR_\alpha(x)\right\}$$

The value-at-risk, $VaR_\alpha(x)$, is estimated whenever the CVaR is estimated. The loss function is $f(x, y_s) = \ -y_s^T x$, which is the portfolio loss under scenario *s*.

Under this definition, VaR and CVaR are sample estimators for VaR and CVaR based on the given scenarios. Better scenario samples yield more reliable estimates of VaR and CVaR.

For more information, see Rockafellar and Uryasev [48], [49], and Cornuejols and Tütüncü, [51], at “Portfolio Optimization” on page A-5.

Mean Absolute-Deviation

The mean-absolute deviation (MAD) for a portfolio $x \in X$ is defined as

$$MAD(x) = \frac{1}{S}\sum_{s=1}^{S} \left|(y_s - m)^T x\right|$$

where:

y_s are asset returns with scenarios $s = 1,...S$ (S collection of n vectors).

f(x,y) is the loss function for a portfolio x and asset return y.

m is the mean of asset returns (n vector).

such that

$$m = \frac{1}{S}\sum_{s=1}^{S} y_s$$

For more information, see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5.

Portfolio Set for Optimization Using PortfolioCVaR Object

The final element for a complete specification of a portfolio optimization problem is the set of feasible portfolios, which is called a portfolio set. A portfolio set $X \subset R^n$ is specified by construction as the intersection of sets formed by a collection of constraints on portfolio weights. A portfolio set necessarily and sufficiently must be a nonempty, closed, and bounded set.

When setting up your portfolio set, ensure that the portfolio set satisfies these conditions. The most basic or “default” portfolio set requires portfolio weights to be nonnegative (using the lower-bound constraint) and to sum to `1` (using the budget constraint). The most general portfolio set handled by the portfolio optimization tools can have any of these constraints and which are properties for the `PortfolioCVaR` object:

- Linear inequality constraints
- Linear equality constraints
- `'Simple'` Bound constraints
- `'Conditional'` Bond constraints
- Budget constraints
- Group constraints
- Group ratio constraints
- Average turnover constraints
- One-way turnover constraints
- Cardinality constraints

Linear Inequality Constraints

Linear inequality constraints are general linear constraints that model relationships among portfolio weights that satisfy a system of inequalities. Linear inequality constraints take the form

$$A_I x \leq b_I$$

where:

x is the portfolio (n vector).

A_I is the linear inequality constraint matrix (n_I-by-n matrix).

b_I is the linear inequality constraint vector (n_I vector).

n is the number of assets in the universe and n_I is the number of constraints.

`PortfolioCVaR` object properties to specify linear inequality constraints are:

- `AInequality` for A_I
- `bInequality` for b_I
- `NumAssets` for n

The default is to ignore these constraints.

Linear Equality Constraints

Linear equality constraints are general linear constraints that model relationships among portfolio weights that satisfy a system of equalities. Linear equality constraints take the form

$$A_E x = b_E$$

where:

x is the portfolio (n vector).

A_E is the linear equality constraint matrix (n_E-by-n matrix).

b_E is the linear equality constraint vector (n_E vector).

n is the number of assets in the universe and n_E is the number of constraints.

`PortfolioCVaR` object properties to specify linear equality constraints are:

- `AEquality` for A_E
- `bEquality` for b_E
- `NumAssets` for n

The default is to ignore these constraints.

'Simple' Bound Constraints

`'Simple'` Bound constraints are specialized linear constraints that confine portfolio weights to fall either above or below specific bounds. Since every portfolio set must be bounded, it is often a good practice, albeit not necessary, to set explicit bounds for the portfolio problem. To obtain explicit bounds for a given portfolio set, use the `estimateBounds` function. Bound constraints take the form

$$l_B \le x \le u_B$$

where:

x is the portfolio (n vector).

l_B is the lower-bound constraint (n vector).

u_B is the upper-bound constraint (n vector).

n is the number of assets in the universe.

`PortfolioCVaR` object properties to specify bound constraints are:

- `LowerBound` for l_B
- `UpperBound` for u_B
- `NumAssets` for n

The default is to ignore these constraints.

The default portfolio optimization problem (see “Default Portfolio Problem” on page 5-15) has l_B = `0` with u_B set implicitly through a budget constraint.

'Conditional' Bound Constraints

`'Conditional'` Bound constraints, also called semicontinuous constraints, are mixed-integer linear constraints that confine portfolio weights to fall either above or below specific bounds *if* the asset is selected; otherwise, the value of the asset is zero. Use `setBounds` to specify bound constraints with a `'Conditional'` `BoundType`. To mathematically formulate this type of constraints, a binary variable v_i is needed. $v_i = 0$ indicates that asset i is not selected and v_i indicates that the asset was selected. Thus

$$l_i v_i \leq x_i \leq u_i v_i$$

where

x is the portfolio (n vector).

l is the conditional lower-bound constraint (n vector).

u is the conditional upper-bound constraint (n vector).

n is the number of assets in the universe.

`PortfolioCVaR` object properties to specify the bound constraint are:

- `LowerBound` for l_B
- `UpperBound` for u_B
- `NumAssets` for n

The default is to ignore this constraint.

Budget Constraints

Budget constraints are specialized linear constraints that confine the sum of portfolio weights to fall either above or below specific bounds. The constraints take the form

$$l_S \leq 1^T x \leq u_S$$

where:

x is the portfolio (n vector).

`1` is the vector of ones (n vector).

l_S is the lower-bound budget constraint (scalar).

u_S is the upper-bound budget constraint (scalar).

n is the number of assets in the universe.

`PortfolioCVaR` object properties to specify budget constraints are:

- `LowerBudget` for l_S
- `UpperBudget` for u_S
- `NumAssets` for n

The default is to ignore this constraint.

The default portfolio optimization problem (see “Default Portfolio Problem” on page 5-15) has $l_S = u_S = 1$, which means that the portfolio weights sum to 1. If the portfolio optimization problem includes possible movements in and out of cash, the budget constraint specifies how far portfolios can go into cash. For example, if $l_S = 0$ and $u_S = 1$, then the portfolio can have 0–100% invested in cash. If cash is to be a portfolio choice, set RiskFreeRate (r_0) to a suitable value (see “Portfolio Problem Specification” on page 5-3 and “Working with a Riskless Asset” on page 5-45).

Group Constraints

Group constraints are specialized linear constraints that enforce “membership” among groups of assets. The constraints take the form

$$l_G \leq Gx \leq u_G$$

where:

x is the portfolio (n vector).

l_G is the lower-bound group constraint (n_G vector).

u_G is the upper-bound group constraint (n_G vector).

G is the matrix of group membership indexes (n_G-by-n matrix).

Each row of G identifies which assets belong to a group associated with that row. Each row contains either 0s or 1s with 1 indicating that an asset is part of the group or 0 indicating that the asset is not part of the group.

PortfolioCVaR object properties to specify group constraints are:

- GroupMatrix for G
- LowerGroup for l_G
- UpperGroup for u_G
- NumAssets for n

The default is to ignore these constraints.

Group Ratio Constraints

Group ratio constraints are specialized linear constraints that enforce relationships among groups of assets. The constraints take the form

$$l_{Ri}(G_B x)_i \leq (G_A x)_i \leq u_{Ri}(G_B x)_i$$

for $i = 1,..., n_R$ where:

x is the portfolio (n vector).

l_R is the vector of lower-bound group ratio constraints (n_R vector).

u_R is the vector matrix of upper-bound group ratio constraints (n_R vector).

G_A is the matrix of base group membership indexes (n_R-by-n matrix).

G_B is the matrix of comparison group membership indexes (n_R-by-n matrix).

n is the number of assets in the universe and n_R is the number of constraints.

Each row of G_A and G_B identifies which assets belong to a base and comparison group associated with that row.

Each row contains either `0`s or `1`s with `1` indicating that an asset is part of the group or `0` indicating that the asset is not part of the group.

`PortfolioCVaR` object properties to specify group ratio constraints are:

- `GroupA` for G_A
- `GroupB` for G_B
- `LowerRatio` for l_R
- `UpperRatio` for u_R
- `NumAssets` for n

The default is to ignore these constraints.

Average Turnover Constraints

Turnover constraint is a linear absolute value constraint that ensures estimated optimal portfolios differ from an initial portfolio by no more than a specified amount. Although portfolio turnover is defined in many ways, the turnover constraints implemented in Financial Toolbox computes portfolio turnover as the average of purchases and sales. Average turnover constraints take the form

$$\frac{1}{2}1^T\left|x - x_0\right| \le \tau$$

where:

x is the portfolio (n vector).

`1` is the vector of ones (n vector).

x_0 is the initial portfolio (n vector).

τ is the upper bound for turnover (scalar).

n is the number of assets in the universe.

`PortfolioCVaR` object properties to specify the average turnover constraint are:

- `Turnover` for τ
- `InitPort` for x_0
- `NumAssets` for n

The default is to ignore this constraint.

One-way Turnover Constraints

One-way turnover constraints ensure that estimated optimal portfolios differ from an initial portfolio by no more than specified amounts according to whether the differences are purchases or sales. The constraints take the forms

$$1^T \times \max\{0, x - x_0\} \leq \tau_B$$

$$1^T \times \max\{0, x_0 - x\} \leq \tau_S$$

where:

x is the portfolio (n vector)

`1` is the vector of ones (n vector).

x_0 is the Initial portfolio (n vector).

τ_B is the upper bound for turnover constraint on purchases (scalar).

τ_S is the upper bound for turnover constraint on sales (scalar).

To specify one-way turnover constraints, use the following properties in the `Portfolio`, `PortfolioCVaR`, or `PortfolioMAD` object:

- `BuyTurnover` for τ_B
- `SellTurnover` for τ_S
- `InitPort` for x_0

The default is to ignore this constraint.

Note The average turnover constraint (see “Average Turnover Constraints” on page 5-12) with τ is not a combination of the one-way turnover constraints with $\tau = \tau_B = \tau_S$.

Cardinality Constraints

Cardinality constraint limits the number of assets in the optimal allocation for an `PortfolioCVaR` object. Use `setMinMaxNumAssets` to specify the `'MinNumAssets'` and `'MaxNumAssets'` constraints. To mathematically formulate this type of constraints, a binary variable v_i is needed. $v_i = 0$ indicates that asset i is not selected and $v_i = 1$ indicates that the asset was selected. Thus

$$MinNumAssets \leq \sum_{i = 1}^{NumAssets} v_i \leq MaxNumAssets$$

The default is to ignore this constraint.

Default Portfolio Problem

The default portfolio optimization problem has a risk and return proxy associated with a given problem, and a portfolio set that specifies portfolio weights to be nonnegative and to sum to `1`. The lower bound combined with the budget constraint is sufficient to ensure that the portfolio set is nonempty, closed, and bounded. The default portfolio optimization problem characterizes a long-only investor who is fully invested in a collection of assets.

- For mean-variance portfolio optimization, it is sufficient to set up the default problem. After setting up the problem, data in the form of a mean and covariance of asset returns are then used to solve portfolio optimization problems.
- For conditional value-at-risk portfolio optimization, the default problem requires the additional specification of a probability level that must be set explicitly. Generally, “typical” values for this level are 0.90 or 0.95. After setting up the problem, data in the form of scenarios of asset returns are then used to solve portfolio optimization problems.
- For MAD portfolio optimization, it is sufficient to set up the default problem. After setting up the problem, data in the form of scenarios of asset returns are then used to solve portfolio optimization problems.

PortfolioCVaR Object Workflow

The `PortfolioCVaR` object workflow for creating and modeling a CVaR portfolio is:

1. Create a CVaR Portfolio.

   Create a `PortfolioCVaR` object for conditional value-at-risk (CVaR) portfolio optimization. For more information, see “Creating the PortfolioCVaR Object” on page 5-22.
2. Define asset returns and scenarios.

   Evaluate scenarios for portfolio asset returns, including assets with missing data and financial time series data. For more information, see “Asset Returns and Scenarios Using PortfolioCVaR Object” on page 5-36.
3. Specify the CVaR Portfolio Constraints.

   Define the constraints for portfolio assets such as linear equality and inequality, bound, budget, group, group ratio, turnover constraints, `'Conditional'` `BoundType`, and `MinNumAssets`, `MaxNumAssets` constraints. For more information, see “Working with CVaR Portfolio Constraints Using Defaults” on page 5-50 and “Working with 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints Using PortfolioCVaR Objects” on page 5-69.
4. Validate the CVaR Portfolio.

   Identify errors for the portfolio specification. For more information, see “Validate the CVaR Portfolio Problem” on page 5-78.
5. Estimate the efficient portfolios and frontiers.

   Analyze the efficient portfolios and efficient frontiers for a CVaR portfolio. For more information, see “Estimate Efficient Portfolios for Entire Frontier for PortfolioCVaR Object” on page 5-82 and “Estimate Efficient Frontiers for PortfolioCVaR Object” on page 5-102.
6. Postprocess the results.

   Use the efficient portfolios and efficient frontiers results to set up trades. For more information, see “Postprocessing Results to Set Up Tradable Portfolios” on page 5-110.

PortfolioCVaR Object

In this section...

PortfolioCVaR Object Properties and Functions

The `PortfolioCVaR` object implements conditional value-at-risk (CVaR) portfolio optimization. Every property and function of the `PortfolioCVaR` object is public, although some properties and functions are hidden. See `PortfolioCVaR` for the properties and functions of a `PortfolioCVaR` object. The `PortfolioCVaR` object is a value object where every instance of the object is a distinct version of the object. Since the `PortfolioCVaR` object is also a MATLAB object, it inherits the default functions associated with MATLAB objects.

Working with PortfolioCVaR Objects

The `PortfolioCVaR` object and its functions are an interface for conditional value-at-risk portfolio optimization. So, almost everything you do with the `PortfolioCVaR` object can be done using the functions. The basic workflow is:

1. Design your portfolio problem.
2. Use `PortfolioCVaR` to create the `PortfolioCVaR` object or use the various set functions to set up your portfolio problem.
3. Use estimate functions to solve your portfolio problem.

In addition, functions are available to help you view intermediate results and to diagnose your computations. Since MATLAB features are part of a `PortfolioCVaR` object, you can save and load objects from your workspace and create and manipulate arrays of objects. After settling on a problem, which, in the case of CVaR portfolio optimization, means that you have either scenarios, data, or moments for asset returns, a probability level, and a collection of constraints on your portfolios, use `PortfolioCVaR` to set the properties for the `PortfolioCVaR` object.

`PortfolioCVaR` lets you create an object from scratch or update an existing object. Since the `PortfolioCVaR` object is a value object, it is easy to create a basic object, then use functions to build upon the basic object to create new versions of the basic object. This is useful to compare a basic problem with alternatives derived from the basic problem. For details, see "Creating the PortfolioCVaR Object" on page 5-22.

Setting and Getting Properties

You can set properties of a PortfolioCVaR object using either the PortfolioCVaR object or various set functions.

Note Although you can also set properties directly, it is not recommended since error-checking is not performed when you set a property directly.

The PortfolioCVaR object supports setting properties with name-value pair arguments such that each argument name is a property and each value is the value to assign to that property. For example, to set the LowerBound, Budget, and ProbabilityLevel properties in an existing PortfolioCVaR object p, use the syntax:

```
p = PortfolioCVaR(p,'LowerBound', 0, 'Budget', 1, 'ProbabilityLevel', 0.95);
```

In addition to the PortfolioCVaR object, which lets you set individual properties one at a time, groups of properties are set in a PortfolioCVaR object with various “set” and “add” functions. For example, to set up an average turnover constraint, use the setTurnover function to specify the bound on portfolio turnover and the initial portfolio. To get individual properties from a PortfolioCVaR object, obtain properties directly or use an assortment of “get” functions that obtain groups of properties from a PortfolioCVaR object. The PortfolioCVaR object and set functions have several useful features:

- The PortfolioCVaR object and set functions try to determine the dimensions of your problem with either explicit or implicit inputs.
- The PortfolioCVaR object and set functions try to resolve ambiguities with default choices.
- The PortfolioCVaR object and set functions perform scalar expansion on arrays when possible.
- The CVaR functions try to diagnose and warn about problems.

Displaying PortfolioCVaR Objects

The PortfolioCVaR object uses the default display functions provided by MATLAB, where display and disp display a PortfolioCVaR object and its properties with or without the object variable name.

Saving and Loading PortfolioCVaR Objects

Save and load PortfolioCVaR objects using the MATLAB save and load commands.

Estimating Efficient Portfolios and Frontiers

Estimating efficient portfolios and efficient frontiers is the primary purpose of the CVaR portfolio optimization tools. An efficient portfolio are the portfolios that satisfy the criteria of minimum risk for a given level of return and maximum return for a given level of risk. A collection of “estimate” and “plot” functions provide ways to explore the efficient frontier. The “estimate” functions obtain either efficient portfolios or risk and return proxies to form efficient frontiers. At the portfolio level, a collection of functions estimates efficient portfolios on the efficient frontier with functions to obtain efficient portfolios:

- At the endpoints of the efficient frontier
- That attain targeted values for return proxies
- That attain targeted values for risk proxies
- Along the entire efficient frontier

These functions also provide purchases and sales needed to shift from an initial or current portfolio to each efficient portfolio. At the efficient frontier level, a collection of functions plot the efficient frontier and estimate either risk or return proxies for efficient portfolios on the efficient frontier. You can use the resultant efficient portfolios or risk and return proxies in subsequent analyses.

Arrays of PortfolioCVaR Objects

Although all functions associated with a `PortfolioCVaR` object are designed to work on a scalar `PortfolioCVaR` object, the array capabilities of MATLAB enables you to set up and work with arrays of `PortfolioCVaR` objects. The easiest way to do this is with the `repmat` function. For example, to create a 3-by-2 array of `PortfolioCVaR` objects:

```
p = repmat(PortfolioCVaR, 3, 2);
disp(p)
```

```
disp(p)
  3×2 PortfolioCVaR array with properties:

    BuyCost
    SellCost
    RiskFreeRate
    ProbabilityLevel
    Turnover
    BuyTurnover
    SellTurnover
    NumScenarios
    Name
    NumAssets
    AssetList
    InitPort
    AInequality
    bInequality
    AEquality
    bEquality
    LowerBound
    UpperBound
    LowerBudget
    UpperBudget
    GroupMatrix
    LowerGroup
    UpperGroup
    GroupA
    GroupB
    LowerRatio
    UpperRatio
    MinNumAssets
    MaxNumAssets
    BoundType
```

After setting up an array of `PortfolioCVaR` objects, you can work on individual `PortfolioCVaR` objects in the array by indexing. For example:

```
p(i,j) = PortfolioCVaR(p(i,j), ... );
```

This example calls PortfolioCVaR for the (i,j) element of a matrix of PortfolioCVaR objects in the variable p.

If you set up an array of PortfolioCVaR objects, you can access properties of a particular PortfolioCVaR object in the array by indexing so that you can set the lower and upper bounds lb and ub for the (i,j,k) element of a 3-D array of PortfolioCVaR objects with

```
p(i,j,k) = setBounds(p(i,j,k), lb, ub);
```

and, once set, you can access these bounds with

```
[lb, ub] = getBounds(p(i,j,k));
```

PortfolioCVaR object functions work on only one PortfolioCVaR object at a time.

Subclassing PortfolioCVaR Objects

You can subclass the PortfolioCVaR object to override existing functions or to add new properties or functions. To do so, create a derived class from the PortfolioCVaR class. This gives you all the properties and functions of the PortfolioCVaR class along with any new features that you choose to add to your subclassed object. The PortfolioCVaR class is derived from an abstract class called AbstractPortfolio. Because of this, you can also create a derived class from AbstractPortfolio that implements an entirely different form of portfolio optimization using properties and functions of the AbstractPortfolio class.

Conventions for Representation of Data

The CVaR portfolio optimization tools follow these conventions regarding the representation of different quantities associated with portfolio optimization:

- Asset returns or prices for scenarios are in matrix form with samples for a given asset going down the rows and assets going across the columns. In the case of prices, the earliest dates must be at the top of the matrix, with increasing dates going down.
- Portfolios are in vector or matrix form with weights for a given portfolio going down the rows and distinct portfolios going across the columns.
- Constraints on portfolios are formed in such a way that a portfolio is a column vector.
- Portfolio risks and returns are either scalars or column vectors (for multiple portfolio risks and returns).

Creating the PortfolioCVaR Object

In this section...

To create a fully specified CVaR portfolio optimization problem, instantiate the PortfolioCVaR object using PortfolioCVaR. For information on the workflow when using PortfolioCVaR objects, see "PortfolioCVaR Object Workflow" on page 5-16.

Syntax

Use PortfolioCVaR to create an instance of an object of the PortfolioCVaR class. You can use PortfolioCVaR object in several ways. To set up a portfolio optimization problem in a PortfolioCVaR object, the simplest syntax is:

```
p = PortfolioCVaR;
```

This syntax creates a PortfolioCVaR object, p, such that all object properties are empty.

The PortfolioCVaR object also accepts collections of argument name-value pair arguments for properties and their values. The PortfolioCVaR object accepts inputs for public properties with the general syntax:

```
    p = PortfolioCVaR('property1', value1, 'property2', value2, ... );
```

If a PortfolioCVaR object already exists, the syntax permits the first (and only the first argument) of PortfolioCVaR to be an existing object with subsequent argument name-value pair arguments for properties to be added or modified. For example, given an existing PortfolioCVaR object in p, the general syntax is:

```
p = PortfolioCVaR(p, 'property1', value1, 'property2', value2, ... );
```

Input argument names are not case-sensitive, but must be completely specified. In addition, several properties can be specified with alternative argument names (see "Shortcuts for Property Names" on page 5-26). The PortfolioCVaR object tries to detect problem dimensions from the inputs and, once set, subsequent inputs can undergo various scalar or matrix expansion operations that simplify the overall process to formulate a problem. In addition, a PortfolioCVaR object is a value object so that, given portfolio p, the following code creates two objects, p and q, that are distinct:

```
q = PortfolioCVaR(p, ...)
```

PortfolioCVaR Problem Sufficiency

A CVaR portfolio optimization problem is completely specified with the PortfolioCVaR object if the following three conditions are met:

- You must specify a collection of asset returns or prices known as scenarios such that all scenarios are finite asset returns or prices. These scenarios are meant to be samples from the underlying probability distribution of asset returns. This condition can be satisfied by the setScenarios function or with several canned scenario simulation functions.

- The set of feasible portfolios must be a nonempty compact set, where a compact set is closed and bounded. You can satisfy this condition using an extensive collection of properties that define different types of constraints to form a set of feasible portfolios. Since such sets must be bounded, either explicit or implicit constraints can be imposed and several tools, such as the `estimateBounds` function, provide ways to ensure that your problem is properly formulated.
- You must specify a probability level to locate the level of tail loss above which the conditional value-at-risk is to be minimized. This condition can be satisfied by the `setProbabilityLevel` function.

  Although the general sufficient conditions for CVaR portfolio optimization go beyond the first three conditions, the `PortfolioCVaR` object handles all these additional conditions.

PortfolioCVaR Function Examples

If you create a `PortfolioCVaR` object, `p`, with no input arguments, you can display it using `disp`:

```
p = PortfolioCVaR;
disp(p)
```

```
PortfolioCVaR with properties:

             BuyCost: []
            SellCost: []
        RiskFreeRate: []
    ProbabilityLevel: []
            Turnover: []
         BuyTurnover: []
        SellTurnover: []
        NumScenarios: []
                Name: []
           NumAssets: []
           AssetList: []
            InitPort: []
         AInequality: []
         bInequality: []
           AEquality: []
           bEquality: []
          LowerBound: []
          UpperBound: []
         LowerBudget: []
         UpperBudget: []
         GroupMatrix: []
          LowerGroup: []
          UpperGroup: []
              GroupA: []
              GroupB: []
          LowerRatio: []
          UpperRatio: []
        MinNumAssets: []
        MaxNumAssets: []
           BoundType: []
```

The approaches listed provide a way to set up a portfolio optimization problem with the `PortfolioCVaR` object. The custom set functions offer additional ways to set and modify collections of properties in the `PortfolioCVaR` object.

Using the PortfolioCVaR Function for a Single-Step Setup

You can use the PortfolioCVaR object to directly set up a “standard” portfolio optimization problem. Given scenarios of asset returns in the variable AssetScenarios, this problem is completely specified as follows:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR('Scenarios', AssetScenarios, ...
'LowerBound', 0, 'LowerBudget', 1, 'UpperBudget', 1, ...
'ProbabilityLevel', 0.95)
```

```
p = 

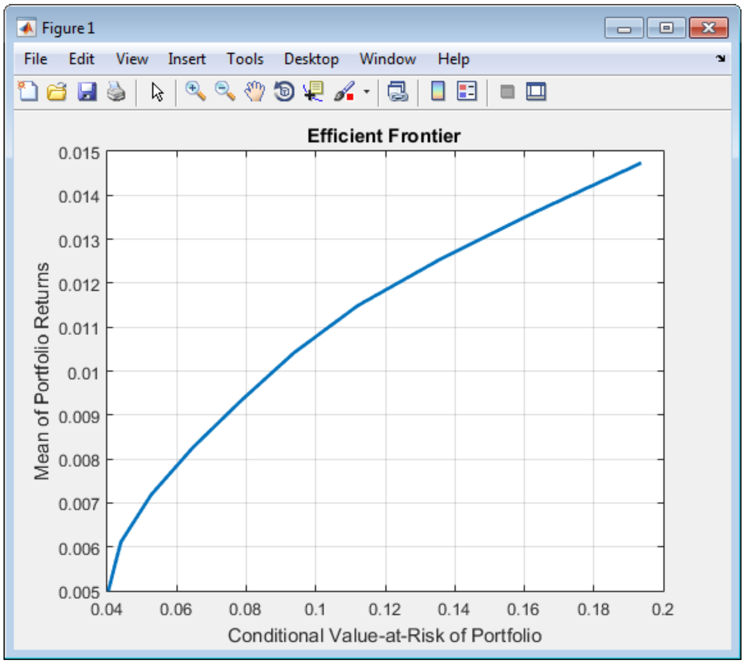
  PortfolioCVaR with properties:

             BuyCost: []
            SellCost: []
        RiskFreeRate: []
    ProbabilityLevel: 0.9500
            Turnover: []
         BuyTurnover: []
        SellTurnover: []
        NumScenarios: 20000
                Name: []
           NumAssets: 4
           AssetList: []
            InitPort: []
         AInequality: []
         bInequality: []
           AEquality: []
           bEquality: []
          LowerBound: [4×1 double]
          UpperBound: []
         LowerBudget: 1
         UpperBudget: 1
         GroupMatrix: []
          LowerGroup: []
          UpperGroup: []
              GroupA: []
              GroupB: []
          LowerRatio: []
          UpperRatio: []
        MinNumAssets: []
        MaxNumAssets: []
           BoundType: []
```

The LowerBound property value undergoes scalar expansion since AssetScenarios provides the dimensions of the problem.

You can use dot notation with the function plotFrontier.

```
p.plotFrontier
```



Using the PortfolioCVaR Function with a Sequence of Steps

An alternative way to accomplish the same task of setting up a “standard” CVaR portfolio optimization problem, given `AssetScenarios` variable is:

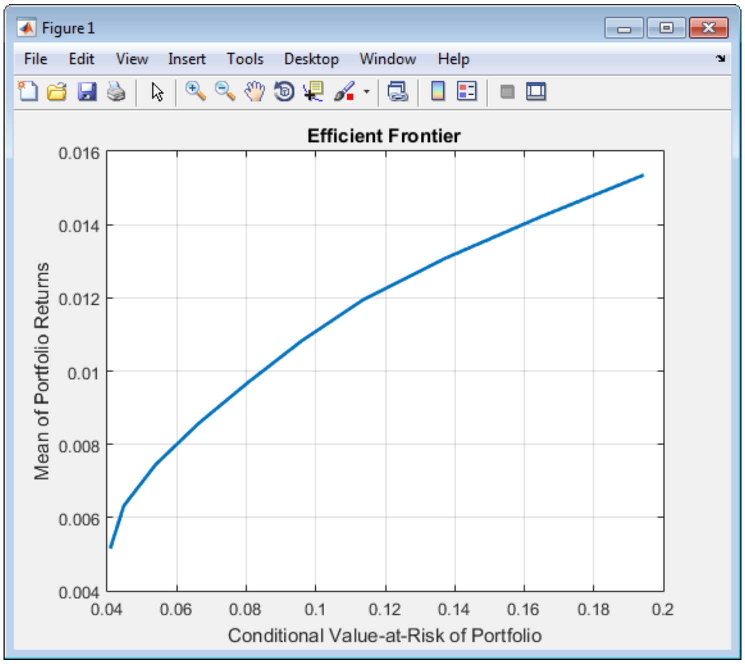
```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = PortfolioCVaR(p, 'LowerBound', 0);
p = PortfolioCVaR(p, 'LowerBudget', 1, 'UpperBudget', 1);
p = setProbabilityLevel(p, 0.95);

plotFrontier(p)
```



This way works because the calls to the are in this particular order. In this case, the call to initialize `AssetScenarios` provides the dimensions for the problem. If you were to do this step last, you would have to explicitly dimension the `LowerBound` property as follows:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = PortfolioCVaR(p, 'LowerBound', zeros(size(m)));
p = PortfolioCVaR(p, 'LowerBudget', 1, 'UpperBudget', 1);
p = setProbabilityLevel(p, 0.95);
p = setScenarios(p, AssetScenarios);
```

Note If you did not specify the size of `LowerBound` but, instead, input a scalar argument, the `PortfolioCVaR` object assumes that you are defining a single-asset problem and produces an error at the call to set asset scenarios with four assets.

Shortcuts for Property Names

The `PortfolioCVaR` object has shorter argument names that replace longer argument names associated with specific properties of the `PortfolioCVaR` object. For example, rather than enter `'ProbabilityLevel'`, the `PortfolioCVaR` object accepts the case-insensitive name `'plevel'` to set the `ProbabilityLevel` property in a `PortfolioCVaR` object. Every shorter argument name corresponds with a single property in the PortfolioCVaR object. The one exception is the alternative argument name 'budget', which signifies both the LowerBudget and UpperBudget properties. When 'budget' is used, then the LowerBudget and UpperBudget properties are set to the same value to form an equality budget constraint.

Shortcuts for Property Names

Shortcut Argument Name	Equivalent Argument / Property Name
ae	AEquality
ai	AInequality
assetnames or assets	AssetList
be	bEquality
bi	bInequality
budget	UpperBudget and LowerBudget
group	GroupMatrix
lb	LowerBound
n or num	NumAssets
level, problevel, or plevel	ProbabilityLevel
rfr	RiskFreeRate
scenario or assetscenarios	Scenarios
ub	UpperBound

For example, this call to the PortfolioCVaR object uses these shortcuts for properties:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR('scenario', AssetScenarios, 'lb', 0, 'budget', 1, 'plevel', 0.95);
plotFrontier(p)
```

Direct Setting of Portfolio Object Properties

Although not recommended, you can set properties directly using dot notation, however no error-checking is done on your inputs:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
```

```
p = setScenarios(p, AssetScenarios);
p.ProbabilityLevel = 0.95;

p.LowerBudget = 1;
p.UpperBudget = 1;
p.LowerBound = zeros(size(m));

plotFrontier(p)
```

Note Scenarios cannot be assigned directly using dot notation to a `PortfolioCVaR` object. Scenarios must always be set through either the `PortfolioCVaR` object, the `setScenarios` function, or any of the scenario simulation functions.

Common Operations on the PortfolioCVaR Object

In this section...

Naming a PortfolioCVaR Object

To name a `PortfolioCVaR` object, use the `Name` property. `Name` is informational and has no effect on any portfolio calculations. If the `Name` property is nonempty, `Name` is the title for the efficient frontier plot generated by `plotFrontier`. For example, if you set up an asset allocation fund, you could name the `PortfolioCVaR` object Asset Allocation Fund:

```
p = PortfolioCVaR('Name','Asset Allocation Fund');
disp(p.Name)
```

```
Asset Allocation Fund
```

Configuring the Assets in the Asset Universe

The fundamental quantity in the `PortfolioCVaR` object is the number of assets in the asset universe. This quantity is maintained in the `NumAssets` property. Although you can set this property directly, it is usually derived from other properties such as the number of assets in the scenarios or the initial portfolio. In some instances, the number of assets may need to be set directly. This example shows how to set up a `PortfolioCVaR` object that has four assets:

```
p = PortfolioCVaR('NumAssets', 4);
disp(p.NumAssets)
```

```
4
```

After setting the `NumAssets` property, you cannot modify it (unless no other properties are set that depend on `NumAssets`). The only way to change the number of assets in an existing `PortfolioCVaR` object with a known number of assets is to create a new `PortfolioCVaR` object.

Setting Up a List of Asset Identifiers

When working with portfolios, you must specify a universe of assets. Although you can perform a complete analysis without naming the assets in your universe, it is helpful to have an identifier associated with each asset as you create and work with portfolios. You can create a list of asset identifiers as a cell vector of character vectors in the property `AssetList`. You can set up the list using the next two methods.

Setting Up Asset Lists Using the PortfolioCVaR Function

Suppose that you have a `PortfolioCVaR` object, `p`, with assets with symbols `'AA''`, `'BA'`, `'CAT'`, `'DD'`, and `'ETR'`. You can create a list of these asset symbols in the object using the `PortfolioCVaR` object:

```
p = PortfolioCVaR('assetlist', { 'AA', 'BA', 'CAT', 'DD', 'ETR' });
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

Notice that the property `AssetList` is maintained as a cell array that contains character vectors, and that it is necessary to pass a cell array into the `PortfolioCVaR` object to set `AssetList`. In addition, notice that the property `NumAssets` is set to `5` based on the number of symbols used to create the asset list:

```
disp(p.NumAssets)
```

```
5
```

Setting Up Asset Lists Using the setAssetList Function

You can also specify a list of assets using the `setAssetList` function. Given the list of asset symbols `'AA'`, `'BA'`, `'CAT'`, `'DD'`, and`'ETR'`, you can use `setAssetList` with:

```
p = PortfolioCVaR;
p = setAssetList(p, { 'AA', 'BA', 'CAT', 'DD', 'ETR' });
disp(p.AssetList)
```

```
 'AA'    'BA'    'CAT'    'DD'    'ETR'
```

`setAssetList` also enables you to enter symbols directly as a comma-separated list without creating a cell array of character vectors. For example, given the list of assets symbols `'AA'`, `'BA'`, `'CAT'`, `'DD'`, and `'ETR'`, use `setAssetList`:

```
p = PortfolioCVaR;
p = setAssetList(p, 'AA', 'BA', 'CAT', 'DD', 'ETR');
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

`setAssetList` has many additional features to create lists of asset identifiers. If you use `setAssetList` with just a `PortfolioCVaR` object, it creates a default asset list according to the name specified in the hidden public property `defaultforAssetList` (which is `'Asset'` by default). The number of asset names created depends on the number of assets in the property `NumAssets`. If `NumAssets` is not set, then `NumAssets` is assumed to be `1`.

For example, if a `PortfolioCVaR` object `p` is created with `NumAssets = 5`, then this code fragment shows the default naming behavior:

```
p = PortfolioCVaR('numassets',5);
p = setAssetList(p);
disp(p.AssetList)
```

```
'Asset1'    'Asset2'    'Asset3'    'Asset4'    'Asset5'
```

Suppose that your assets are, for example, ETFs and you change the hidden property `defaultforAssetList` to `'ETF'`, you can then create a default list for ETFs:

```
p = PortfolioCVaR('numassets',5);
p.defaultforAssetList = 'ETF';
p = setAssetList(p);
disp(p.AssetList)
```

```
'ETF1'    'ETF2'    'ETF3'    'ETF4'    'ETF5'
```

Truncating and Padding Asset Lists

If the `NumAssets` property is already set and you pass in too many or too few identifiers, the `PortfolioCVaR` object, and the `setAssetList` function truncate or pad the list with numbered default asset names that use the name specified in the hidden public property `defaultforAssetList`. If the list is truncated or padded, a warning message indicates the discrepancy. For example, assume that you have a `PortfolioCVaR` object with five ETFs and you only know the first three CUSIPs `'921937835'`, `'922908769'`, and `'922042775'`. Use this syntax to create an asset list that pads the remaining asset identifiers with numbered `'UnknownCUSIP'` placeholders:

```
p = PortfolioCVaR('numassets',5);
p.defaultforAssetList = 'UnknownCUSIP';
p = setAssetList(p, '921937835', '922908769', '922042775');
disp(p.AssetList)
```

```
Warning: Input list of assets has 2 too few identifiers. Padding with numbered assets.
> In PortfolioCVaR.setAssetList at 118
    '921937835'    '922908769'    '922042775'    'UnknownCUSIP4'    'UnknownCUSIP5'
```

Alternatively, suppose that you have too many identifiers and need only the first four assets. This example illustrates truncation of the asset list using the `PortfolioCVaR` object:

```
p = PortfolioCVaR('numassets',4);
p = PortfolioCVaR(p, 'assetlist', { 'AGG', 'EEM', 'MDY', 'SPY', 'VEU' });
disp(p.AssetList)
```

```
Warning: AssetList has 1 too many identifiers. Using first 4 assets.
> In PortfolioCVaR.checkarguments at 399
  In PortfolioCVaR.PortfolioCVaR>PortfolioCVaR.PortfolioCVaR at 195
    'AGG'    'EEM'    'MDY'    'SPY'
```

The hidden public property `uppercaseAssetList` is a Boolean flag to specify whether to convert asset names to uppercase letters. The default value for `uppercaseAssetList` is `false`. This example shows how to use the `uppercaseAssetList` flag to force identifiers to be uppercase letters:

```
p = PortfolioCVaR;
p.uppercaseAssetList = true;
p = setAssetList(p, { 'aa', 'ba', 'cat', 'dd', 'etr' });
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

Setting Up an Initial or Current Portfolio

In many applications, creating a new optimal portfolio requires comparing the new portfolio with an initial or current portfolio to form lists of purchases and sales. The PortfolioCVaR object property InitPort lets you identify an initial or current portfolio. The initial portfolio also plays an essential role if you have either transaction costs or turnover constraints. The initial portfolio need not be feasible within the constraints of the problem. This can happen if the weights in a portfolio have shifted such that some constraints become violated. To check if your initial portfolio is feasible, use the checkFeasibility function described in “Validating CVaR Portfolios” on page 5-79. Suppose that you have an initial portfolio in x0, then use the PortfolioCVaR object to set up an initial portfolio:

```
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = PortfolioCVaR('InitPort', x0);
disp(p.InitPort)
```

```
    0.3000
    0.2000
    0.2000
         0
```

As with all array properties, you can set InitPort with scalar expansion. This is helpful to set up an equally weighted initial portfolio of, for example, 10 assets:

```
p = PortfolioCVaR('NumAssets', 10, 'InitPort', 1/10);
disp(p.InitPort)
```

```
  0.1000
  0.1000
  0.1000
  0.1000
  0.1000
  0.1000
  0.1000
  0.1000
  0.1000
  0.1000
```

To clear an initial portfolio from your PortfolioCVaR object, use either the PortfolioCVaR object or the setInitPort function with an empty input for the InitPort property. If transaction costs or turnover constraints are set, it is not possible to clear the InitPort property in this way. In this case, to clear InitPort, first clear the dependent properties and then clear theInitPort property.

The InitPort property can also be set with setInitPort which lets you specify the number of assets if you want to use scalar expansion. For example, given an initial portfolio in x0, use setInitPort to set the InitPort property:

```
p = PortfolioCVaR;
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = setInitPort(p, x0);
disp(p.InitPort)
```

```
  0.3000
  0.2000
  0.2000
       0
```

To create an equally weighted portfolio of four assets, use setInitPort:

```
p = PortfolioCVaR;
p = setInitPort(p, 1/4, 4);
disp(p.InitPort)
```

```
 0.2500
 0.2500
 0.2500
 0.2500
```

PortfolioCVaR object functions that work with either transaction costs or turnover constraints also depend on the InitPort property. So, the set functions for transaction costs or turnover constraints permit the assignment of a value for the InitPort property as part of their implementation. For details, see “Working with Average Turnover Constraints Using PortfolioCVaR Object” on page 5-72, “Working with One-Way Turnover Constraints Using PortfolioCVaR Object” on page 5-75, and “Working with Transaction Costs” on page 5-46. If either transaction costs or turnover constraints are used, then the InitPort property must have a nonempty value. Absent a specific value assigned through the PortfolioCVaR object or various set functions, the PortfolioCVaR object sets InitPort to 0 and warns if BuyCost, SellCost, or Turnover properties are set. This example shows what happens if you specify an average turnover constraint with an initial portfolio:

```
p = PortfolioCVaR('Turnover', 0.3, 'InitPort', [ 0.3; 0.2; 0.2; 0.0 ]);
disp(p.InitPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

In contrast, this example shows what happens if an average turnover constraint is specified without an initial portfolio:

```
p = PortfolioCVaR('Turnover', 0.3);
disp(p.InitPort)
```

```
Warning: InitPort and NumAssets are empty and either transaction costs or turnover constraints specified.
Will set NumAssets = 1 and InitPort = 0.

Asset Returns and Scenarios Using PortfolioCVaR Object

In this section...

How Stochastic Optimization Works

The CVaR of a portfolio is a conditional expectation. (For the definition of the CVaR function, see “Risk Proxy” on page 5-5.) Therefore, the CVaR portfolio optimization problem is a stochastic optimization problem. Given a sample of scenarios, the conditional expectation that defines the sample CVaR of the portfolio can be expressed as a finite sum, a weighted average of losses. The weights of the losses depend on their relative magnitude; for a confidence level α, only the worst (1 − α) x 100% losses get a positive weight. As a function of the portfolio weights, the CVaR of the portfolio is a convex function (see [48], [49] Rockafellar & Uryasev at “Portfolio Optimization” on page A-5). It is also a nonsmooth function, but its edges are less sharp as the sample size increases.

There are reformulations of the CVaR portfolio optimization problem (see [48], [49] at Rockafellar & Uryasev) that result in a linear programming problem, which can be solved either with standard linear programming techniques or with stochastic programming solvers. The `PortfolioCVaR` object, however, does not reformulate the problem in such a manner. The `PortfolioCVaR` object computes the CVaR as a nonlinear function. The convexity of the CVaR, as a function of the portfolio weights and the dull edges when the number of scenarios is large, make the CVaR portfolio optimization problem tractable, in practice, for certain nonlinear programming solvers, such as `fmincon` from Optimization Toolbox. The problem can also be solved using a cutting-plane method (see Kelley [45] at “Portfolio Optimization” on page A-5). For more information, see Algorithms section of `setSolver`. To learn more about the workflow when using `PortfolioCVaR` objects, see “PortfolioCVaR Object Workflow” on page 5-16.

What Are Scenarios?

Since conditional value-at-risk portfolio optimization works with scenarios of asset returns to perform the optimization, several ways exist to specify and simulate scenarios. In many applications with CVaR portfolio optimization, asset returns may have distinctly nonnormal probability distributions with either multiple modes, binning of returns, truncation of distributions, and so forth. In other applications, asset returns are modeled as the result of various simulation methods that might include Monte-Carlo simulation, quasi-random simulation, and so forth. Often, the underlying probability distribution for risk factors may be multivariate normal but the resultant transformations are sufficiently nonlinear to result in distinctively nonnormal asset returns.

For example, this occurs with bonds and derivatives. In the case of bonds with a nonzero probability of default, such scenarios would likely include asset returns that are −100% to indicate default and some values slightly greater than −100% to indicate recovery rates.

Although the PortfolioCVaR object has functions to simulate multivariate normal scenarios from either data or moments (simulateNormalScenariosByData and simulateNormalScenariosByMoments), the usual approach is to specify scenarios directly from your own simulation functions. These scenarios are entered directly as a matrix with a sample for all assets across each row of the matrix and with samples for an asset down each column of the matrix. The architecture of the CVaR portfolio optimization tools references the scenarios through a function handle so scenarios that have been set cannot be accessed directly as a property of the PortfolioCVaR object.

Setting Scenarios Using the PortfolioCVaR Function

Suppose that you have a matrix of scenarios in the AssetScenarios variable. The scenarios are set through the PortfolioCVaR object with:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR('Scenarios', AssetScenarios);

disp(p.NumAssets)
disp(p.NumScenarios)
```

```
4

20000
```

Notice that the PortfolioCVaR object determines and fixes the number of assets in NumAssets and the number of scenarios in NumScenarios based on the scenario’s matrix. You can change the number of scenarios by calling the PortfolioCVaR object with a different scenario matrix. However, once the NumAssets property has been set in the object, you cannot enter a scenario matrix with a different number of assets. The getScenarios function lets you recover scenarios from a PortfolioCVaR object. You can also obtain the mean and covariance of your scenarios using estimateScenarioMoments.

Although not recommended for the casual user, an alternative way exists to recover scenarios by working with the function handle that points to scenarios in the PortfolioCVaR object. To access some or all the scenarios from a PortfolioCVaR object, the hidden property localScenarioHandle is a function handle that points to a function to obtain scenarios that have already been set. To get scenarios directly from a PortfolioCVaR object p, use

```
scenarios = p.localScenarioHandle([], []);
```

and to obtain a subset of scenarios from rows startrow to endrow, use

```
scenarios = p.localScenarioHandle(startrow, endrow);
```

where 1 ≤ `startrow` ≤ `endrow` ≤ `numScenarios`.

Setting Scenarios Using the setScenarios Function

You can also set scenarios using `setScenarios`. For example, given the mean and covariance of asset returns in the variables `m` and `C`, the asset moment properties can be set:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);

disp(p.NumAssets)
disp(p.NumScenarios)
```

```
4

20000
```

Estimating the Mean and Covariance of Scenarios

The `estimateScenarioMoments` function obtains estimates for the mean and covariance of scenarios in a `PortfolioCVaR` object.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
[mean, covar] = estimateScenarioMoments(p)
```

```
mean =

    0.0043
    0.0085
    0.0098
    0.0153
```

```
covar =

    0.0005    0.0003    0.0002    0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0049    0.0029
    0.0000    0.0010    0.0029    0.0102
```

Simulating Normal Scenarios

As a convenience, the two functions (`simulateNormalScenariosByData` and `simulateNormalScenariosByMoments`) exist to simulate scenarios from data or moments under an assumption that they are distributed as multivariate normal random asset returns.

Simulating Normal Scenarios from Returns or Prices

Given either return or price data, use the function `simulateNormalScenariosByData` to simulate multivariate normal scenarios. Either returns or prices are stored as matrices with samples going down the rows and assets going across the columns. In addition, returns or prices can be stored in a `table` or `timetable` (see “Simulating Normal Scenarios from Time Series Data” on page 5-41). To illustrate using `simulateNormalScenariosByData`, generate random samples of 120 observations of asset returns for four assets from the mean and covariance of asset returns in the variables `m` and `C` with `portsim`. The default behavior of `portsim` creates simulated data with estimated mean and covariance identical to the input moments `m` and `C`. In addition to a return series created by `portsim` in the variable *X*, a price series is created in the variable *Y*:

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];

X = portsim(m', C, 120);
Y = ret2tick(X);
```

Note Portfolio optimization requires that you use total returns and not just price returns. So, “returns” should be total returns and “prices” should be total return prices.

Given asset returns and prices in variables *X* and *Y* from above, this sequence of examples demonstrates equivalent ways to simulate multivariate normal scenarios for the `PortfolioCVaR` object. Assume a `PortfolioCVaR` object created in `p` that uses the asset returns in *X* uses `simulateNormalScenariosByData`:

```
p = PortfolioCVaR;
p = simulateNormalScenariosByData(p, X, 20000);

[passetmean, passetcovar] = estimateScenarioMoments(p)

passetmean =

    0.0043
    0.0083
    0.0102
    0.1507

passetcovar =

    0.0053    0.0003    0.0002    0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0049    0.0028
    0.0000    0.0010    0.0028    0.0101
```

The moments that you obtain from this simulation will likely differ from the moments listed here because the scenarios are random samples from the estimated multivariate normal probability distribution of the input returns *X*.

The default behavior of `simulateNormalScenariosByData` is to work with asset returns. If, instead, you have asset prices as in the variable *Y*, `simulateNormalScenariosByData` accepts a name-value pair argument name `'DataFormat'` with a corresponding value set to `'prices'` to indicate that the input to the function is in the form of asset prices and not returns (the default value for the `'DataFormat'` argument is `'returns'`). This example simulates scenarios with the asset price data in *Y* for the `PortfolioCVaR` object `q`:

```
p = PortfolioCVaR;
p = simulateNormalScenariosByData(p, Y, 20000, 'dataformat', 'prices');

[passetmean, passetcovar] = estimateScenarioMoments(p)
```

```
passetmean =

    0.0043
    0.0084
    0.0094
    0.1490

passetcovar =

    0.0054    0.0004    0.0001   -0.0000
    0.0004    0.0024    0.0016    0.0009
    0.0001    0.0016    0.0048    0.0028
   -0.0000    0.0009    0.0028    0.0100
```

Simulating Normal Scenarios with Missing Data

Often when working with multiple assets, you have missing data indicated by `NaN` values in your return or price data. Although “Multivariate Normal Regression” on page 9-2 goes into detail about regression with missing data, the `simulateNormalScenariosByData` function has a name-value pair argument name `'MissingData'` that indicates with a Boolean value whether to use the missing data capabilities of Financial Toolbox. The default value for `'MissingData'` is `false` which removes all samples with `NaN` values. If, however, `'MissingData'` is set to `true`, `simulateNormalScenariosByData` uses the ECM algorithm to estimate asset moments. This example shows how this works on price data with missing values:

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];
```

```
X = portsim(m', C, 120);
Y = ret2tick(X);
Y(1:20,1) = NaN;
Y(1:12,4) = NaN;
```

Notice that the prices above in Y have missing values in the first and fourth series.

```
p = PortfolioCVaR;
p = simulateNormalScenariosByData(p, Y, 20000, 'dataformat', 'prices');

q = PortfolioCVaR;
q = simulateNormalScenariosByData(q, Y, 20000, 'dataformat', 'prices', 'missingdata', true);

[passetmean, passetcovar] = estimateScenarioMoments(p)
[qassetmean, qassetcovar] = estimateScenarioMoments(q)
```

```
passetmean =

    0.0020
    0.0074
    0.0078
    0.1476

passetcovar =

    0.0055    0.0003   -0.0001   -0.0003
    0.0003    0.0024    0.0019    0.0012
   -0.0001    0.0019    0.0050    0.0028
   -0.0003    0.0012    0.0028    0.0101

qassetmean =

    0.0024
    0.0085
    0.0106
    0.1482

qassetcovar =

    0.0071    0.0004   -0.0001   -0.0004
    0.0004    0.0032    0.0022    0.0012
   -0.0001    0.0022    0.0063    0.0034
   -0.0004    0.0012    0.0034    0.0127
```

The first PortfolioCVaR object, p, contains scenarios obtained from price data in Y where NaN values are discarded and the second PortfolioCVaR object, q, contains scenarios obtained from price data in Y that accommodate missing values. Each time you run this example, you get different estimates for the moments in p and q.

Simulating Normal Scenarios from Time Series Data

The simulateNormalScenariosByData function implicitly works with matrices of data or data in a table or timetable object using the same rules for whether the data are returns or prices. To illustrate, use array2timetable to create a timetable for 14 assets from CAPMuniverse and the use the timetable to simulate scenarios for PortfolioCVaR.

```
load CAPMuniverse
time = datetime(Dates,'ConvertFrom','datenum');
stockTT = array2timetable(Data,'RowTimes',time, 'VariableNames', Assets);
stockTT.Properties
% Notice that GOOG has missing data, because it was not listed before Aug 2004
head(stockTT, 5)
```

```
ans =
  TimetableProperties with properties:

             Description: ''
                UserData: []
          DimensionNames: {'Time'  'Variables'}
           VariableNames: {'AAPL'  'AMZN'  'CSCO'  'DELL'  'EBAY'  'GOOG'  'HPQ'  'IBM'  'INTC'
    VariableDescriptions: {}
           VariableUnits: {}
      VariableContinuity: []
                RowTimes: [1471×1 datetime]
               StartTime: 03-Jan-2000
              SampleRate: NaN
                TimeStep: NaN
        CustomProperties: No custom properties are set.
      Use addprop and rmprop to modify CustomProperties.

ans =

  5×14 timetable

    0.0003    0.0003    0.0004    0.0003    0.0003    0.0002    0.0003    0.0005    0.0004    0.0
    0.0006    0.0006    0.0008    0.0006    0.0006    0.0002    0.0005    0.0004    0.0011    0.0
    0.0004    0.0004    0.0005    0.0004    0.0005    0.0002    0.0003    0.0002    0.0005    0.0
    0.0005    0.0006    0.0008    0.0005    0.0007    0.0003    0.0005    0.0004    0.0007    0.0
    0.0006    0.0011    0.0008    0.0006    0.0011    0.0011    0.0006    0.0004    0.0007    0.0
    0.0002    0.0002    0.0002    0.0002    0.0002    0.0001    0.0002    0.0002    0.0002    0.0
   -0.0000   -0.0000   -0.0000   -0.0000   -0.0000   -0.0000   -0.0000    0.0000   -0.0000   -0.0
```

Use the name-value input `'DataFormat'` to handle return or price data and `'MissingData'` to ignore or use samples with missing values. In addition, `simulateNormalScenariosByData` extracts asset names or identifiers from a `table` or `timetable` if the argument `'GetAssetList'` is set to `true` (the default value is `false`). If the `'GetAssetList'` value is `true`, the identifiers are used to set the `AssetList` property of the `PortfolioCVaR` object. Thus, repeating the formation of the `PortfolioCVaR` object `p` from the previous example with the `'GetAssetList'` flag set to `true` extracts the column names from the timetable object:

```
p = simulateNormalScenariosByData(p, stockTT, 20000 ,'missingdata',true, 'GetAssetList', true);
disp(p.AssetList)
```

```
 'AAPL'    'AMZN'    'CSCO'    'DELL'    'EBAY'    'GOOG'    'HPQ'    'IBM'    'INTC'    'MSFT'
```

If you set the`'GetAssetList'` flag set to `true` and your input data is in a matrix, `simulateNormalScenariosByData` uses the default labeling scheme from `setAssetList` as described in “Setting Up a List of Asset Identifiers” on page 5-29.

Simulating Normal Scenarios with Mean and Covariance

Given the mean and covariance of asset returns, use the `simulateNormalScenariosByMoments` function to simulate multivariate normal scenarios. The mean can be either a row or column vector and the covariance matrix must be a symmetric positive-semidefinite matrix. Various rules for scalar expansion apply. To illustrate using `simulateNormalScenariosByMoments`, start with moments in `m` and `C` and generate 20,000 scenarios:

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];

p = PortfolioCVaR;
p = simulateNormalScenariosByMoments(p, m, C, 20000);
[passetmean, passetcovar] = estimateScenarioMoments(p)
```

```
passetmean =

    0.0049
    0.0083
    0.0101
    0.1503

passetcovar =

    0.0053    0.0003    0.0002   -0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0047    0.0028
   -0.0000    0.0010    0.0028    0.0101
```

simulateNormalScenariosByMoments performs scalar expansion on arguments for the moments of asset returns. If NumAssets has not already been set, a scalar argument is interpreted as a scalar with NumAssets set to 1. simulateNormalScenariosByMoments provides an additional optional argument to specify the number of assets so that scalar expansion works with the correct number of assets. In addition, if either a scalar or vector is input for the covariance of asset returns, a diagonal matrix is formed such that a scalar expands along the diagonal and a vector becomes the diagonal.

Working with a Riskless Asset

The PortfolioCVaR object has a separate RiskFreeRate property that stores the rate of return of a riskless asset. Thus, you can separate your universe into a riskless asset and a collection of risky assets. For example, assume that your riskless asset has a return in the scalar variable r0, then the property for the RiskFreeRate is set using the PortfolioCVaR object:

```
r0 = 0.01/12;

p = PortfolioCVaR;
p = PortfolioCVaR('RiskFreeRate', r0);
disp(p.RiskFreeRate)
```

```
8.3333e-04
```

Note If your portfolio problem has a budget constraint such that your portfolio weights must sum to 1, then the riskless asset is irrelevant.

Working with Transaction Costs

The difference between net and gross portfolio returns is transaction costs. The net portfolio return proxy has distinct proportional costs to purchase and to sell assets which are maintained in the PortfolioCVaR object properties BuyCost and SellCost. Transaction costs are in units of total return and, as such, are proportional to the price of an asset so that they enter the model for net portfolio returns in return form. For example, suppose that you have a stock currently priced $40 and your usual transaction costs are 5 cents per share. Then the transaction cost for the stock is 0.05/40 = 0.00125 (as defined in “Net Portfolio Returns” on page 5-4). Costs are entered as positive values and credits are entered as negative values.

Setting Transaction Costs Using the PortfolioCVaR Function

To set up transaction costs, you must specify an initial or current portfolio in the InitPort property. If the initial portfolio is not set when you set up the transaction cost properties, InitPort is 0. The properties for transaction costs can be set using the PortfolioCVaR object. For example, assume that purchase and sale transaction costs are in the variables bc and sc and an initial portfolio is in the variable x0, then transaction costs are set:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioCVaR('BuyCost', bc, 'SellCost', sc, 'InitPort', x0);
disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)
```

```
     5

    0.0013
    0.0013
    0.0013
    0.0013
    0.0013

    0.0013

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

Setting Transaction Costs Using the setCosts Function

You can also set the properties for transaction costs using setCosts. Assume that you have the same costs and initial portfolio as in the previous example. Given a PortfolioCVaR object p with an initial portfolio already set, use setCosts to set up transaction costs:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];

p = PortfolioCVaR('InitPort', x0);
p = setCosts(p, bc, sc);

disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)
```

```
    5

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

You can also set up the initial portfolio's `InitPort` value as an optional argument to `setCosts` so that the following is an equivalent way to set up transaction costs:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];

p = PortfolioCVaR;
p = setCosts(p, bc, sc, x0);

disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)
```

```
    5

    0.0013
    0.0013
    0.0013
    0.0013
    0.0013

    0.0013
    0.0070
    0.0013
    0.0013
    0.0024

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

Setting Transaction Costs with Scalar Expansion

Both the PortfolioCVaR object and setCosts function implement scalar expansion on the arguments for transaction costs and the initial portfolio. If the NumAssets property is already set in the PortfolioCVaR object, scalar arguments for these properties are expanded to have the same value across all dimensions. In addition, setCosts lets you specify NumAssets as an optional final argument. For example, assume that you have an initial portfolio x0 and you want to set common transaction costs on all assets in your universe. You can set these costs in any of these equivalent ways:

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioCVaR('InitPort', x0, 'BuyCost', 0.002, 'SellCost', 0.002);
```

or

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioCVaR('InitPort', x0);
p = setCosts(p, 0.002, 0.002);
```

or

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioCVaR;
p = setCosts(p, 0.002, 0.002, x0);
```

To clear costs from your PortfolioCVaR object, use either the PortfolioCVaR object or setCosts with empty inputs for the properties to be cleared. For example, you can clear sales costs from the PortfolioCVaR object p in the previous example:

```
p = PortfolioCVaR(p, 'SellCost', []);
```

Working with CVaR Portfolio Constraints Using Defaults

The final element for a complete specification of a portfolio optimization problem is the set of feasible portfolios, which is called a portfolio set. A portfolio set $X \subset R^n$ is specified by construction as the intersection of sets formed by a collection of constraints on portfolio weights. A portfolio set necessarily and sufficiently must be a nonempty, closed, and bounded set.

When setting up your portfolio set, ensure that the portfolio set satisfies these conditions. The most basic or “default” portfolio set requires portfolio weights to be nonnegative (using the lower-bound constraint) and to sum to 1 (using the budget constraint). For information on the workflow when using PortfolioCVaR objects, see “PortfolioCVaR Object Workflow” on page 5-16.

Setting Default Constraints for Portfolio Weights Using PortfolioCVaR Object

The “default” CVaR portfolio problem has two constraints on portfolio weights:

- Portfolio weights must be nonnegative.
- Portfolio weights must sum to 1.

Implicitly, these constraints imply that portfolio weights are no greater than 1, although this is a superfluous constraint to impose on the problem.

Setting Default Constraints Using the PortfolioCVaR Function

Given a portfolio optimization problem with NumAssets = 20 assets, use the PortfolioCVaR object to set up a default problem and explicitly set bounds and budget constraints:

```
p = PortfolioCVaR('NumAssets', 20, 'LowerBound', 0, 'Budget', 1);
disp(p)
```

```
  PortfolioCVaR with properties:

             BuyCost: []
            SellCost: []
        RiskFreeRate: []
    ProbabilityLevel: []
            Turnover: []
         BuyTurnover: []
        SellTurnover: []
        NumScenarios: []
                Name: []
           NumAssets: 20
           AssetList: []

          LowerBound: [20x1 double]
          UpperBound: []
         LowerBudget: 1
         UpperBudget: 1
         GroupMatrix: []
```

```
          LowerGroup: []
          UpperGroup: []
              GroupA: []
              GroupB: []
          LowerRatio: []
          UpperRatio: []
```

Setting Default Constraints Using the setDefaultConstraints Function

An alternative approach is to use the `setDefaultConstraints` function. If the number of assets is already known in a `PortfolioCVaR` object, use `setDefaultConstraints` with no arguments to set up the necessary bound and budget constraints. Suppose that you have 20 assets to set up the portfolio set for a default problem:

```
p = PortfolioCVaR('NumAssets', 20);
p = setDefaultConstraints(p);
disp(p)
```

```
   PortfolioCVaR with properties:

             BuyCost: []
            SellCost: []
        RiskFreeRate: []
    ProbabilityLevel: []
            Turnover: []
         BuyTurnover: []
        SellTurnover: []
        NumScenarios: []
                Name: []
           NumAssets: 20
           AssetList: []
            InitPort: []
         AInequality: []
         bInequality: []
           AEquality: []
           bEquality: []
          LowerBound: [20×1 double]
          UpperBound: []
         LowerBudget: 1
         UpperBudget: 1
         GroupMatrix: []
          LowerGroup: []
          UpperGroup: []
              GroupA: []
              GroupB: []
          LowerRatio: []
          UpperRatio: []
        MinNumAssets: []
        MaxNumAssets: []
           BoundType: [20×1 categorical]
```

If the number of assets is unknown, `setDefaultConstraints` accepts `NumAssets` as an optional argument to form a portfolio set for a default problem. Suppose that you have 20 assets:

```
p = PortfolioCVaR;
p = setDefaultConstraints(p, 20);
disp(p)
```

```
 PortfolioCVaR with properties:

            BuyCost: []
           SellCost: []
       RiskFreeRate: []
   ProbabilityLevel: []
           Turnover: []
        BuyTurnover: []
       SellTurnover: []
       NumScenarios: []
               Name: []
          NumAssets: 20
          AssetList: []
           InitPort: []
        AInequality: []
        bInequality: []
          AEquality: []
          bEquality: []
         LowerBound: [20×1 double]
         UpperBound: []
        LowerBudget: 1
        UpperBudget: 1
        GroupMatrix: []
         LowerGroup: []
         UpperGroup: []
             GroupA: []
             GroupB: []
         LowerRatio: []
         UpperRatio: []
       MinNumAssets: []
       MaxNumAssets: []
          BoundType: [20×1 categorical]
```

Working with 'Simple' Bound Constraints Using PortfolioCVaR Object

'Simple' bound constraints are optional linear constraints that maintain upper and lower bounds on portfolio weights (see “'Simple' Bound Constraints” on page 5-9). Although every portfolio set must be bounded, it is not necessary to specify a portfolio set with explicit bound constraints. For example, you can create a portfolio set with an implicit upper bound constraint or a portfolio set with average turnover constraints. The bound constraints have properties LowerBound for the lower-bound constraint and UpperBound for the upper-bound constraint. Set default values for these constraints using the setDefaultConstraints function (see “Setting Default Constraints for Portfolio Weights Using Portfolio Object” on page 4-57).

Setting 'Simple' Bounds Using the PortfolioCVaR Function

The properties for bound constraints are set through the PortfolioCVaR object. Suppose that you have a balanced fund with stocks that can range from 50% to 75% of your portfolio and bonds that can range from 25% to 50% of your portfolio. The bound constraints for a balanced fund are set with:

```
lb = [ 0.5; 0.25 ];
ub = [ 0.75; 0.5 ];
p = PortfolioCVaR('LowerBound', lb, 'UpperBound', ub, 'BoundType', 'Simple');
disp(p.NumAssets)
disp(p.LowerBound)
disp(p.UpperBound)
```

```
 2

 0.5000
 0.2500

 0.7500
 0.5000
```

To continue with this example, you must set up a budget constraint. For details, see “Working with Budget Constraints Using Portfolio Object” on page 4-64.

Setting 'Simple' Bounds Using the setBounds Function

You can also set the properties for bound constraints using setBounds. Suppose that you have a balanced fund with stocks that can range from 50% to 75% of your portfolio and bonds that can range from 25% to 50% of your portfolio. Given a PortfolioCVaR object p, use setBounds to set the bound constraints:

```
lb = [ 0.5; 0.25 ];
ub = [ 0.75; 0.5 ];
p = PortfolioCVaR;
p = setBounds(p, lb, ub,'BoundType', 'Simple');
disp(p.NumAssets)
disp(p.LowerBound)
disp(p.UpperBound)
```

```
  2

  0.5000
  0.2500

  0.7500
  0.5000
```

Setting 'Simple' Bounds Using the PortfolioCVaR Function or setBounds Function

Both the `PortfolioCVaR` object and `setBounds` function implement scalar expansion on either the `LowerBound` or `UpperBound` properties. If the `NumAssets` property is already set in the `PortfolioCVaR` object, scalar arguments for either property expand to have the same value across all dimensions. In addition, `setBounds` lets you specify `NumAssets` as an optional argument. Suppose that you have a universe of 500 assets and you want to set common bound constraints on all assets in your universe. Specifically, you are a long-only investor and want to hold no more than 5% of your portfolio in any single asset. You can set these bound constraints in any of these equivalent ways:

```
p = PortfolioCVaR('NumAssets', 500, 'LowerBound', 0, 'UpperBound', 0.05,'BoundType', 'Simple');
```

or

```
p = PortfolioCVaR('NumAssets', 500);
p = setBounds(p, 0, 0.05,'BoundType','Simple');
```

or

```
p = PortfolioCVaR;
p = setBounds(p, 0, 0.05,'NumAssets', 500,'BoundType','Simple');
```

To clear bound constraints from your `PortfolioCVaR` object, use either the `PortfolioCVaR` object or `setBounds` with empty inputs for the properties to be cleared. For example, to clear the upper-bound constraint from the `PortfolioCVaR` object `p` in the previous example:

```
p = PortfolioCVaR(p, 'UpperBound', []);
```

Working with Budget Constraints Using PortfolioCVaR Object

The budget constraint is an optional linear constraint that maintains upper and lower bounds on the sum of portfolio weights (see "Budget Constraints" on page 5-10). Budget constraints have properties `LowerBudget` for the lower budget constraint and `UpperBudget` for the upper budget constraint. If you set up a CVaR portfolio optimization problem that requires portfolios to be fully invested in your universe of assets, you can set `LowerBudget` to be equal to `UpperBudget`. These budget constraints can be set with default values equal to `1` using `setDefaultConstraints` (see "Setting Default Constraints Using the PortfolioCVaR Function" on page 5-50).

Setting Budget Constraints Using the PortfolioCVaR Function

The properties for the budget constraint can also be set using the `PortfolioCVaR` object. Suppose that you have an asset universe with many risky assets and a riskless asset and you want to ensure that your portfolio never holds more than 1% cash, that is, you want to ensure that you are 99–100% invested in risky assets. The budget constraint for this portfolio can be set with:

```
p = PortfolioCVaR('LowerBudget', 0.99, 'UpperBudget', 1);
disp(p.LowerBudget)
disp(p.UpperBudget)
```

```
 0.9900

1
```

Setting Budget Constraints Using the setBudget Function

You can also set the properties for a budget constraint using `setBudget`. Suppose that you have a fund that permits up to 10% leverage which means that your portfolio can be from 100% to 110% invested in risky assets. Given a `PortfolioCVaR` object `p`, use `setBudget` to set the budget constraints:

```
p = PortfolioCVaR;
p = setBudget(p, 1, 1.1);
disp(p.LowerBudget)
disp(p.UpperBudget)
```

```
 1

 1.1000
```

If you were to continue with this example, then set the `RiskFreeRate` property to the borrowing rate to finance possible leveraged positions. For details on the `RiskFreeRate` property, see "Working with a Riskless Asset" on page 5-45. To clear either bound for the budget constraint from your `PortfolioCVaR` object, use either the `PortfolioCVaR` object or `setBudget` with empty inputs for the properties to be cleared. For example, clear the upper-budget constraint from the `PortfolioCVaR` object `p` in the previous example with:

```
p = PortfolioCVaR(p, 'UpperBudget', []);
```

Working with Group Constraints Using PortfolioCVaR Object

Group constraints are optional linear constraints that group assets together and enforce bounds on the group weights (see “Group Constraints” on page 5-11). Although the constraints are implemented as general constraints, the usual convention is to form a group matrix that identifies membership of each asset within a specific group with Boolean indicators (either `true` or `false` or with `1` or `0`) for each element in the group matrix. Group constraints have properties `GroupMatrix` for the group membership matrix, `LowerGroup` for the lower-bound constraint on groups, and `UpperGroup` for the upper-bound constraint on groups.

Setting Group Constraints Using the PortfolioCVaR Function

The properties for group constraints are set through the `PortfolioCVaR` object. Suppose that you have a portfolio of five assets and want to ensure that the first three assets constitute no more than 30% of your portfolio, then you can set group constraints:

```
G = [ 1 1 1 0 0 ];
p = PortfolioCVaR('GroupMatrix', G, 'UpperGroup', 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

The group matrix `G` can also be a logical matrix so that the following code achieves the same result.

```
G = [ true true true false false ];
p = PortfolioCVaR('GroupMatrix', G, 'UpperGroup', 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

Setting Group Constraints Using the setGroups and addGroups Functions

You can also set the properties for group constraints using `setGroups`. Suppose that you have a portfolio of five assets and want to ensure that the first three assets constitute no more than 30% of your portfolio. Given a `PortfolioCVaR` object `p`, use `setGroups` to set the group constraints:

```
G = [ true true true false false ];
p = PortfolioCVaR;
p = setGroups(p, G, [], 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

In this example, you would set the `LowerGroup` property to be empty (`[]`).

Suppose that you want to add another group constraint to make odd-numbered assets constitute at least 20% of your portfolio. Set up an augmented group matrix and introduce infinite bounds for unconstrained group bounds or use the `addGroups` function to build up group constraints. For this example, create another group matrix for the second group constraint:

```
p = PortfolioCVaR;
G = [ true true true false false ];    % group matrix for first group constraint
p = setGroups(p, G, [], 0.3);
G = [ true false true false true ];    % group matrix for second group constraint
p = addGroups(p, G, 0.2);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.LowerGroup)
disp(p.UpperGroup)
```

```
 5

1     1     1     0     0
1     0     1     0     1

  -Inf
0.2000

0.3000
  Inf
```

`addGroups` determines which bounds are unbounded so you only need to focus on the constraints that you want to set.

The `PortfolioCVaR` object, `setGroups`, and `addGroups` implement scalar expansion on either the `LowerGroup` or `UpperGroup` properties based on the dimension of the group matrix in the property `GroupMatrix`. Suppose that you have a universe of 30 assets with 6 asset classes such that assets 1–5, assets 6–12, assets 13–18, assets 19–22, assets 23–27, and assets 28–30 constitute each of your asset classes and you want each asset class to fall from 0% to 25% of your portfolio. Let the following group matrix define your groups and scalar expansion define the common bounds on each group:

```
p = PortfolioCVaR;
G = blkdiag(true(1,5), true(1,7), true(1,6), true(1,4), true(1,5), true(1,3));
p = setGroups(p, G, 0, 0.25);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.LowerGroup)
disp(p.UpperGroup)
```

```

Working with Group Ratio Constraints Using PortfolioCVaR Object

Group ratio constraints are optional linear constraints that maintain bounds on proportional relationships among groups of assets (see “Group Ratio Constraints” on page 5-11). Although the constraints are implemented as general constraints, the usual convention is to specify a pair of group matrices that identify membership of each asset within specific groups with Boolean indicators (either `true` or `false` or with `1` or `0`) for each element in each of the group matrices. The goal is to ensure that the ratio of a base group compared to a comparison group fall within specified bounds. Group ratio constraints have properties:

- `GroupA` for the base membership matrix
- `GroupB` for the comparison membership matrix
- `LowerRatio` for the lower-bound constraint on the ratio of groups
- `UpperRatio` for the upper-bound constraint on the ratio of groups

Setting Group Ratio Constraints Using the PortfolioCVaR Function

The properties for group ratio constraints are set using `PortfolioCVaR` object. For example, assume that you want the ratio of financial to nonfinancial companies in your portfolios to never go above 50%. Suppose that you have six assets with three financial companies (assets 1–3) and three nonfinancial companies (assets 4–6). To set group ratio constraints:

```
GA = [ 1 1 1 0 0 0 ];    % financial companies
GB = [ 0 0 0 1 1 1 ];    % nonfinancial companies
p = PortfolioCVaR('GroupA', GA, 'GroupB', GB, 'UpperRatio', 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

Group matrices `GA` and `GB` in this example can be logical matrices with `true` and `false` elements that yield the same result:

```
GA = [ true true true false false false ];    % financial companies
GB = [ false false false true true true ];    % nonfinancial companies
p = PortfolioCVaR('GroupA', GA, 'GroupB', GB, 'UpperRatio', 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

Setting Group Ratio Constraints Using the setGroupRatio and addGroupRatio Functions

You can also set the properties for group ratio constraints using `setGroupRatio`. For example, assume that you want the ratio of financial to nonfinancial companies in your portfolios to never go above 50%. Suppose that you have six assets with three financial companies (assets 1–3) and three nonfinancial companies (assets 4–6). Given a `PortfolioCVaR` object `p`, use `setGroupRatio` to set the group constraints:

```
GA = [ true true true false false false ];   % financial companies
GB = [ false false false true true true ];   % nonfinancial companies
p = PortfolioCVaR;
p = setGroupRatio(p, GA, GB, [], 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

In this example, you would set the `LowerRatio` property to be empty (`[]`).

Suppose that you want to add another group ratio constraint to ensure that the weights in odd-numbered assets constitute at least 20% of the weights in nonfinancial assets your portfolio. You can set up augmented group ratio matrices and introduce infinite bounds for unconstrained group ratio bounds, or you can use the `addGroupRatio` function to build up group ratio constraints. For this example, create another group matrix for the second group constraint:

```
p = PortfolioCVaR;
GA = [ true true true false false false ];   % financial companies
GB = [ false false false true true true ];   % nonfinancial companies
p = setGroupRatio(p, GA, GB, [], 0.5);

GA = [ true false true false true false ];   % odd-numbered companies
GB = [ false false false true true true ];   % nonfinancial companies
p = addGroupRatio(p, GA, GB, 0.2);

disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.LowerRatio)
disp(p.UpperRatio)
```

```
 6

1     1     1     0     0     0
1     0     1     0     1     0

0     0     0     1     1     1
0     0     0     1     1     1

  -Inf
0.2000

0.5000
  Inf
```

Notice that `addGroupRatio` determines which bounds are unbounded so you only need to focus on the constraints you want to set.

The `PortfolioCVaR` object, `setGroupRatio`, and `addGroupRatio` implement scalar expansion on either the `LowerRatio` or `UpperRatio` properties based on the dimension of the group matrices in `GroupA` and `GroupB` properties.

Working with Linear Equality Constraints Using PortfolioCVaR Object

Linear equality constraints are optional linear constraints that impose systems of equalities on portfolio weights (see "Linear Equality Constraints" on page 5-9). Linear equality constraints have properties `AEquality`, for the equality constraint matrix, and `bEquality`, for the equality constraint vector.

Setting Linear Equality Constraints Using the PortfolioCVaR Function

The properties for linear equality constraints are set using the `PortfolioCVaR` object. Suppose that you have a portfolio of five assets and want to ensure that the first three assets are 50% of your portfolio. To set this constraint:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioCVaR('AEquality', A, 'bEquality', b);
disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)
```

```
5

1     1     1     0     0

0.5000
```

Setting Linear Equality Constraints Using the setEquality and addEquality Functions

You can also set the properties for linear equality constraints using `setEquality`. Suppose that you have a portfolio of five assets and want to ensure that the first three assets are 50% of your portfolio. Given a `PortfolioCVaR` object `p`, use `setEquality` to set the linear equality constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioCVaR;
p = setEquality(p, A, b);
disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)
```

```
5

1     1     1     0     0

0.5000
```

Suppose that you want to add another linear equality constraint to ensure that the last three assets also constitute 50% of your portfolio. You can set up an augmented system of linear equalities or use `addEquality` to build up linear equality constraints. For this example, create another system of equalities:

```
p = PortfolioCVaR;
A = [ 1 1 1 0 0 ];    % first equality constraint
```

```
b = 0.5;
p = setEquality(p, A, b);

A = [ 0 0 1 1 1 ];    % second equality constraint
b = 0.5;
p = addEquality(p, A, b);

disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)

5

1     1     1     0     0
0     0     1     1     1

0.5000
0.5000
```

The `PortfolioCVaR` object, `setEquality`, and `addEquality` implement scalar expansion on the `bEquality` property based on the dimension of the matrix in the `AEquality` property.

Working with Linear Inequality Constraints Using PortfolioCVaR Object

Linear inequality constraints are optional linear constraints that impose systems of inequalities on portfolio weights (see “Linear Inequality Constraints” on page 5-8). Linear inequality constraints have properties `AInequality` for the inequality constraint matrix, and `bInequality` for the inequality constraint vector.

Setting Linear Inequality Constraints Using the PortfolioCVaR Function

The properties for linear inequality constraints are set using the `PortfolioCVaR` object. Suppose that you have a portfolio of five assets and you want to ensure that the first three assets are no more than 50% of your portfolio. To set up these constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioCVaR('AInequality', A, 'bInequality', b);
disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0

0.5000
```

Setting Linear Inequality Constraints Using the setInequality and addInequality Functions

You can also set the properties for linear inequality constraints using `setInequality`. Suppose that you have a portfolio of five assets and you want to ensure that the first three assets constitute no more than 50% of your portfolio. Given a `PortfolioCVaR` object `p`, use `setInequality` to set the linear inequality constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioCVaR;
p = setInequality(p, A, b);
disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0

0.5000
```

Suppose that you want to add another linear inequality constraint to ensure that the last three assets constitute at least 50% of your portfolio. You can set up an augmented system of linear inequalities or use the `addInequality` function to build up linear inequality constraints. For this example, create another system of inequalities:

```
p = PortfolioCVaR;
A = [ 1 1 1 0 0 ];    % first inequality constraint
b = 0.5;
p = setInequality(p, A, b);

A = [ 0 0 -1 -1 -1 ];    % second inequality constraint
b = -0.5;
p = addInequality(p, A, b);

disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)

5

1     1     1     0     0
0     0    -1    -1    -1

0.5000
-0.5000
```

The `PortfolioCVaR` object, `setInequality`, and `addInequality` implement scalar expansion on the `bInequality` property based on the dimension of the matrix in the `AInequality` property.

Working with 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints Using PortfolioCVaR Objects

When any one, or any combination of `'Conditional'` `BoundType`, `MinNumAssets`, or `MaxNumAssets` constraints are active, the portfolio problem is formulated by adding `NumAssets` binary variables, where `0` indicates not invested, and `1` is invested. For example, to explain the `'Conditional'` `BoundType` and `MinNumAssets` and `MaxNumAssets` constraints, assume that your portfolio has a universe of 100 assets that you want to invest:

- `'Conditional'` `BoundType` (also known as semicontinuous constraints), set by `setBounds`, is often used in situations where you do not want to invest small values. A standard example is a portfolio optimization problem where many small allocations are not attractive because of transaction costs. Instead, you prefer fewer instruments in the portfolio with larger allocations. This situation can be handled using`'Conditional'` `BoundType` constraints for a `PortfolioCVaR` object.

  For example, the weight you invest in each asset is either `0` or between `[0.01, 0.5]`. Generally, a semicontinuous variable *x* is a continuous variable between bounds [`lb`, `ub`] that also can assume the value `0`, where `lb` > `0`, `lb` ≤ `ub`. Applying this to portfolio optimization requires that very small or large positions should be avoided, that is values that fall in (`0`, `lb`) or are more than `ub`.
- `MinNumAssets` and `MaxNumAssets` (also known as cardinality constraints), set by `setMinMaxNumAssets`, limit the number of assets in a `PortfolioCVaR` object. For example, if you have 100 assets in your portfolio and you want the number of assets allocated in the portfolio to be from 40 through 60. Using `MinNumAssets` and `MaxNumAssets` you can limit the number of assets in the optimized portfolio, which allows you to limit transaction and operational costs or to create an index tracking portfolio.

Setting 'Conditional' BoundType Constraints Using the setBounds Function

Use `setBounds` with a `'conditional'` `BoundType` to set *xi* = `0` or `0.02` <= *xi* <= `0.5` for all *i*=1,...`NumAssets`:

```
p = PortfolioCVaR;
p = setBounds(p, 0.02, 0.5,'BoundType', 'Conditional', 'NumAssets', 3)
```

```
p = 

  PortfolioCVaR with properties:

             BuyCost: []
            SellCost: []
        RiskFreeRate: []
    ProbabilityLevel: []
            Turnover: []
         BuyTurnover: []
        SellTurnover: []
        NumScenarios: []
                Name: []
           NumAssets: 3
           AssetList: []
            InitPort: []
         AInequality: []
         bInequality: []
           AEquality: []
           bEquality: []
          LowerBound: [3×1 double]
          UpperBound: [3×1 double]
         LowerBudget: []
         UpperBudget: []
         GroupMatrix: []
          LowerGroup: []
          UpperGroup: []

              GroupB: []
          LowerRatio: []
          UpperRatio: []
        MinNumAssets: []
        MaxNumAssets: []
           BoundType: [3×1 categorical]
```

Setting the Limits on the Number of Assets Invested Using the setMinMaxNumAssets Function

You can also set the MinNumAssets and MaxNumAssets properties to define a limit on the number of assets invested using setMinMaxNumAssets. For example, by setting MinNumAssets=MaxNumAssets=2, only two of the three assets are invested in the portfolio.

```
p = PortfolioCVaR;
p = setBounds(p, 0.02, 0.5,'BoundType', 'Conditional', 'NumAssets', 3)
p = setMinMaxNumAssets(p, 2, 2)
```

```
 p = 

  PortfolioCVaR with properties:

             BuyCost: []
            SellCost: []
        RiskFreeRate: []
    ProbabilityLevel: []
            Turnover: []
         BuyTurnover: []
        SellTurnover: []
        NumScenarios: []
                Name: []
           NumAssets: 3
           AssetList: []
            InitPort: []
         AInequality: []
         bInequality: []

          UpperBound: [3×1 double]
         LowerBudget: []
         UpperBudget: []
         GroupMatrix: []
          LowerGroup: []
          UpperGroup: []
```

```
             GroupA: []
             GroupB: []
         LowerRatio: []
         UpperRatio: []
       MinNumAssets: 2
       MaxNumAssets: 2
          BoundType: [3×1 categorical]
```

Working with Average Turnover Constraints Using PortfolioCVaR Object

The turnover constraint is an optional linear absolute value constraint (see “Average Turnover Constraints” on page 5-12) that enforces an upper bound on the average of purchases and sales. The turnover constraint can be set using the `PortfolioCVaR` object or the `setTurnover` function. The turnover constraint depends on an initial or current portfolio, which is assumed to be zero if not set when the turnover constraint is set. The turnover constraint has properties `Turnover`, for the upper bound on average turnover, and `InitPort`, for the portfolio against which turnover is computed.

Setting Average Turnover Constraints Using the PortfolioCVaR Function

The properties for the turnover constraints are set using the `PortfolioCVaR` object. Suppose that you have an initial portfolio of 10 assets in a variable `x0` and you want to ensure that average turnover is no more than 30%. To set this turnover constraint:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioCVaR('Turnover', 0.3, 'InitPort', x0);
disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```
10

0.3000

0.1000
0.1000
0.1500
0.1100
0.0800
0.1000
```

Note if the `NumAssets` or `InitPort` properties are not set before or when the turnover constraint is set, various rules are applied to assign default values to these properties (see “Setting Up an Initial or Current Portfolio” on page 5-33).

Setting Average Turnover Constraints Using the setTurnover Function

You can also set properties for portfolio turnover using `setTurnover` to specify both the upper bound for average turnover and an initial portfolio. Suppose that you have an initial portfolio of 10 assets in a variable `x0` and want to ensure that average turnover is no more than 30%. Given a `PortfolioCVaR` object `p`, use `setTurnover` to set the turnover constraint with and without the initial portfolio being set previously:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioCVaR('InitPort', x0);
p = setTurnover(p, 0.3);

disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```
10

```

or

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioCVaR;
p = setTurnover(p, 0.3, x0);
disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```

0.1000
0.1000
0.1500
0.1100
0.0800
0.1000
```

`setTurnover` implements scalar expansion on the argument for the initial portfolio. If the `NumAssets` property is already set in the `PortfolioCVaR` object, a scalar argument for `InitPort` expands to have the same value across all dimensions. In addition, `setTurnover` lets you specify `NumAssets` as an optional argument. To clear turnover from your `PortfolioCVaR` object, use the `PortfolioCVaR` object or `setTurnover` with empty inputs for the properties to be cleared.

Working with One-Way Turnover Constraints Using PortfolioCVaR Object

One-way turnover constraints are optional constraints (see “One-way Turnover Constraints” on page 5-13) that enforce upper bounds on net purchases or net sales. One-way turnover constraints can be set using the PortfolioCVaR object or the setOneWayTurnover function. One-way turnover constraints depend upon an initial or current portfolio, which is assumed to be zero if not set when the turnover constraints are set. One-way turnover constraints have properties BuyTurnover, for the upper bound on net purchases, SellTurnover, for the upper bound on net sales, and InitPort, for the portfolio against which turnover is computed.

Setting One-Way Turnover Constraints Using the PortfolioCVaR Function

The Properties for the one-way turnover constraints are set using the PortfolioCVaR object. Suppose that you have an initial portfolio with 10 assets in a variable x0 and you want to ensure that turnover on purchases is no more than 30% and turnover on sales is no more than 20% of the initial portfolio. To set these turnover constraints:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioCVaR('BuyTurnover', 0.3, 'SellTurnover', 0.2, 'InitPort', x0);
disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```
    10

    0.3000

    0.2000

    0.1200
    0.0900
    0.0800
    0.0700
    0.1000
    0.1000
    0.1500
    0.1100
    0.0800
    0.1000
```

If the NumAssets or InitPort properties are not set before or when the turnover constraint is set, various rules are applied to assign default values to these properties (see “Setting Up an Initial or Current Portfolio” on page 5-33).

Setting Turnover Constraints Using the setOneWayTurnover Function

You can also set properties for portfolio turnover using setOneWayTurnover to specify to the upper bounds for turnover on purchases (BuyTurnover) and sales (SellTurnover) and an initial portfolio. Suppose that you have an initial portfolio of 10 assets in a variable x0 and want to ensure that turnover on purchases is no more than 30% and that turnover on sales is no more than 20% of the initial portfolio. Given a PortfolioCVaR object p, use setOneWayTurnover to set the turnover constraints with and without the initial portfolio being set previously:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioCVaR('InitPort', x0);
p = setOneWayTurnover(p, 0.3, 0.2);

disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```

    0.1000
    0.1500
    0.1100
    0.0800
    0.1000
```

or

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioCVaR;
p = setOneWayTurnover(p, 0.3, 0.2, x0);
disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```
    10

    0.3000

    0.2000

    0.1200

Validate the CVaR Portfolio Problem

In this section...

Sometimes, you may want to validate either your inputs to, or outputs from, a portfolio optimization problem. Although most error checking that occurs during the problem setup phase catches most difficulties with a portfolio optimization problem, the processes to validate CVaR portfolio sets and portfolios are time consuming and are best done offline. So, the portfolio optimization tools have specialized functions to validate CVaR portfolio sets and portfolios. For information on the workflow when using `PortfolioCVaR` objects, see "PortfolioCVaR Object Workflow" on page 5-16.

Validating a CVaR Portfolio Set

Since it is necessary and sufficient that your CVaR portfolio set must be a nonempty, closed, and bounded set to have a valid portfolio optimization problem, the `estimateBounds` function lets you examine your portfolio set to determine if it is nonempty and, if nonempty, whether it is bounded. Suppose that you have the following CVaR portfolio set which is an empty set because the initial portfolio at `0` is too far from a portfolio that satisfies the budget and turnover constraint:

```
p = PortfolioCVaR('NumAssets', 3, 'Budget', 1);
p = setTurnover(p, 0.3, 0);
```

If a CVaR portfolio set is empty, `estimateBounds` returns `NaN` bounds and sets the `isbounded` flag to `[]`:

```
[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

   NaN
   NaN
   NaN

ub =

   NaN
   NaN
   NaN

isbounded =

     []
```

Suppose that you create an unbounded CVaR portfolio set as follows:

```
p = PortfolioCVaR('AInequality', [1 -1; 1 1 ], 'bInequality', 0);
[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

  -Inf
  -Inf
```

```
ub =

  1.0e-008 *

   -0.3712
       Inf

isbounded =

     0
```

In this case, `estimateBounds` returns (possibly infinite) bounds and sets the `isbounded` flag to `false`. The result shows which assets are unbounded so that you can apply bound constraints as necessary.

Finally, suppose that you created a CVaR portfolio set that is both nonempty and bounded. `estimateBounds` not only validates the set, but also obtains tighter bounds which are useful if you are concerned with the actual range of portfolio choices for individual assets in your portfolio set:

```
p = PortfolioCVaR;
p = setBudget(p, 1,1);
p = setBounds(p, [ -0.1; 0.2; 0.3; 0.2 ], [ 0.5; 0.3; 0.9; 0.8 ]);

[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

   -0.1000
    0.2000
    0.3000
    0.2000

ub =

    0.3000
    0.3000
    0.7000
    0.6000

isbounded =

     1
```

In this example, all but the second asset has tighter upper bounds than the input upper bound implies.

Validating CVaR Portfolios

Given a CVaR portfolio set specified in a `PortfolioCVaR` object, you often want to check if specific portfolios are feasible with respect to the portfolio set. This can occur with, for example, initial portfolios and with portfolios obtained from other procedures. The `checkFeasibility` function determines whether a collection of portfolios is feasible. Suppose that you perform the following portfolio optimization and want to determine if the resultant efficient portfolios are feasible relative to a modified problem.

First, set up a problem in the `PortfolioCVaR` object `p`, estimate efficient portfolios in `pwgt`, and then confirm that these portfolios are feasible relative to the initial problem:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

pwgt = estimateFrontier(p);

checkFeasibility(p, pwgt)
```

```
ans =

     1     1     1     1     1     1     1     1     1     1
```

Next, set up a different portfolio problem that starts with the initial problem with an additional a turnover constraint and an equally weighted initial portfolio:

```
q = setTurnover(p, 0.3, 0.25);
checkFeasibility(q, pwgt)
```

```
ans =

     0     0     0     1     1     0     0     0     0     0
```

In this case, only two of the 10 efficient portfolios from the initial problem are feasible relative to the new problem in `PortfolioCVaR` object `q`. Solving the second problem using `checkFeasibility` demonstrates that the efficient portfolio for `PortfolioCVaR` object `q` is feasible relative to the initial problem:

```
qwgt = estimateFrontier(q);
checkFeasibility(p, qwgt)
```

```
ans =

     1     1     1     1     1     1     1     1     1     1
```

Estimate Efficient Portfolios for Entire Frontier for PortfolioCVaR Object

There are two ways to look at a portfolio optimization problem that depends on what you are trying to do. One goal is to estimate efficient portfolios and the other is to estimate efficient frontiers. The “Obtaining Portfolios Along the Entire Efficient Frontier” on page 5-83 example focuses on the former goal and “Estimate Efficient Frontiers for PortfolioCVaR Object” on page 5-102 focuses on the latter goal. For information on the workflow when using PortfolioCVaR objects, see “PortfolioCVaR Object Workflow” on page 5-16.

Obtaining Portfolios Along the Entire Efficient Frontier

The most basic way to obtain optimal portfolios is to obtain points over the entire range of the efficient frontier.

Given a portfolio optimization problem in a `PortfolioCVaR` object, the `estimateFrontier` function computes efficient portfolios spaced evenly according to the return proxy from the minimum to maximum return efficient portfolios. The number of portfolios estimated is controlled by the hidden property `defaultNumPorts` which is set to `10`. A different value for the number of portfolios estimated is specified as an input argument to `estimateFrontier`. This example shows the default number of efficient portfolios over the entire range of the efficient frontier.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

pwgt = estimateFrontier(p);
disp(pwgt)
```

```
    0.8645    0.6960    0.5319    0.3649    0.1948    0.0215         0         0         0
    0.0602    0.1582    0.2551    0.3559    0.4660    0.5740    0.4573    0.3115    0.1599
    0.0326    0.0451    0.0503    0.0567    0.0577    0.0677    0.0501    0.0253    0.0077
    0.0428    0.1007    0.1627    0.2226    0.2815    0.3368    0.4926    0.6632    0.8325    1.0
```

If you want only four portfolios, you can use `estimateFrontier` with `NumPorts` specified as `4`.

```
pwgt = estimateFrontier(p, 4);
disp(pwgt)
```

```
    0.8645    0.3649         0         0
    0.0602    0.3559    0.4573         0
    0.0326    0.0567    0.0501         0
    0.0428    0.2226    0.4926    1.0000
```

Starting from the initial portfolio, `estimateFrontier` also returns purchases and sales to get from your initial portfolio to each efficient portfolio on the efficient frontier. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontier(p);

display(pwgt)
```

```
pwgt = 4×10
```

```
    0.8645    0.6960    0.5319    0.3649    0.1948    0.0215         0         0         0
    0.0602    0.1582    0.2551    0.3559    0.4660    0.5740    0.4573    0.3115    0.1599
    0.0326    0.0451    0.0503    0.0567    0.0577    0.0677    0.0501    0.0253    0.0077
    0.0428    0.1007    0.1627    0.2226    0.2815    0.3368    0.4926    0.6632    0.8325    1.0
```

```
display(pbuy)
```

```
pbuy = 4×10

    0.5645    0.3960    0.2319    0.0649         0         0         0         0         0
         0         0         0    0.0559    0.1660    0.2740    0.1573    0.0115         0
         0         0         0         0         0         0         0         0         0
         0    0.0007    0.0627    0.1226    0.1815    0.2368    0.3926    0.5632    0.7325    0.9
```

```
display(psell)
```

```
psell = 4×10

         0         0         0         0    0.1052    0.2785    0.3000    0.3000    0.3000    0.3
    0.2398    0.1418    0.0449         0         0         0         0         0    0.1401    0.3
    0.1674    0.1549    0.1497    0.1433    0.1423    0.1323    0.1499    0.1747    0.1923    0.2
    0.0572         0         0         0         0         0         0         0         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Endpoints of the Efficient Frontier

Often when using a PortfolioCVaR object, you might be interested in the endpoint portfolios for the efficient frontier. Suppose that you want to determine the range of returns from minimum to maximum to refine a search for a portfolio with a specific target return. Use the estimateFrontierLimits function to obtain the endpoint portfolios.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);
pwgt = estimateFrontierLimits(p);

disp(pwgt)
```

```
    0.8645         0
    0.0602         0
    0.0326         0
    0.0428    1.0000
```

The estimatePortMoments function shows the range of risks and returns for efficient portfolios: Note that the endpoints of the efficient frontier depend upon the Scenarios in the PortfolioCVaR object. If you change the Scenarios, you are likely to obtain different endpoints.

Starting from an initial portfolio, estimateFrontierLimits also returns purchases and sales to get from the initial portfolio to the endpoint portfolios on the efficient frontier. For example, given an initial portfolio in pwgt0, you can obtain purchases and sales:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierLimits(p);
```

```
display(pwgt)

pwgt = 4×2

    0.8671         0
    0.0521         0
    0.0419         0
    0.0388    1.0000
```

```
display(pbuy)

pbuy = 4×2

    0.5671         0
         0         0
         0         0
         0    0.9000
```

```
display(psell)

psell = 4×2

         0    0.3000
    0.2479    0.3000
    0.1581    0.2000
    0.0612         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Efficient Portfolios for Target Returns

To obtain efficient portfolios that have targeted portfolio returns, the `estimateFrontierByReturn` function accepts one or more target portfolio returns and obtains efficient portfolios with the specified returns. For example, assume that you have a universe of four assets where you want to obtain efficient portfolios with target portfolio returns of 7%, 10%, and 12%:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

pwgt = estimateFrontierByReturn(p, [0.07,  0.10, .12]);
display(pwgt)
```

```
pwgt =

    0.7526    0.3773    0.1306
    0.1047    0.3079    0.4348
    0.0662    0.1097    0.1426
    0.0765    0.2051    0.2920
```

Sometimes, you can request a return for which no efficient portfolio exists. Based on the previous example, suppose that you want a portfolio with a 4% return (which is the return of the first asset). A portfolio that is fully invested in the first asset, however, is inefficient. `estimateFrontierByReturn` warns if your target returns are outside the range of efficient portfolio returns and replaces it with the endpoint portfolio of the efficient frontier closest to your target return:

```
 pwgt = estimateFrontierByReturn(p, [0.04]);
```

```
Warning: One or more target return values are outside the feasible range [
0.066388, 0.178834 ].
    Will return portfolios associated with endpoints of the range for these values.
> In PortfolioCVaR.estimateFrontierByReturn at 93
```

The best way to avoid this situation is to bracket your target portfolio returns with `estimateFrontierLimits` and `estimatePortReturn` (see “Obtaining Endpoints of the Efficient Frontier” on page 5-86 and “Obtaining CVaR Portfolio Risks and Returns” on page 5-102).

```
pret = estimatePortReturn(p, p.estimateFrontierLimits);

display(pret)
```

```
pret =

    0.0664
    0.1788
```

This result indicates that efficient portfolios have returns that range from 6.5% to 17.8%. Note, your results for these examples may be different due to the random generation of scenarios.

If you have an initial portfolio, `estimateFrontierByReturn` also returns purchases and sales to get from your initial portfolio to the target portfolios on the efficient frontier. For example, given an initial portfolio in `pwgt0`, to obtain purchases and sales with target returns of 7%, 10%, and 12%:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierByReturn(p, [0.07,  0.10, .12]);

display(pwgt)
display(pbuy)
display(psell)
```

```
pwgt =

    0.7526    0.3773    0.1306
    0.1047    0.3079    0.4348
    0.0662    0.1097    0.1426
    0.0765    0.2051    0.2920

pbuy =

    0.4526    0.0773         0
         0    0.0079    0.1348
         0         0         0
         0    0.1051    0.1920

psell =

         0         0    0.1694
    0.1953         0         0
    0.1338    0.0903    0.0574
    0.0235         0         0
```

If you do not have an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Efficient Portfolios for Target Risks

To obtain efficient portfolios that have targeted portfolio risks, the `estimateFrontierByRisk` function accepts one or more target portfolio risks and obtains efficient portfolios with the specified risks. Suppose that you have a universe of four assets where you want to obtain efficient portfolios with target portfolio risks of 12%, 14%, and 16%.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.9);

pwgt = estimateFrontierByRisk(p, [0.12, 0.14, 0.16]);

display(pwgt)
```

```
pwgt =

    0.3594    0.2524    0.1543
    0.3164    0.3721    0.4248
    0.1044    0.1193    0.1298
    0.2199    0.2563    0.2910
```

Sometimes, you can request a risk for which no efficient portfolio exists. Based on the previous example, suppose that you want a portfolio with 6% risk (individual assets in this universe have risks ranging from 7% to 42.5%). It turns out that a portfolio with 6% risk cannot be formed with these four assets. `estimateFrontierByRisk` warns if your target risks are outside the range of efficient portfolio risks and replaces it with the endpoint of the efficient frontier closest to your target risk:

```
pwgt = estimateFrontierByRisk(p, 0.06)
```

```
Warning: One or more target risk values are outside the feasible range [
0.0735749, 0.436667 ].
    Will return portfolios associated with endpoints of the range for these values.
> In PortfolioCVaR.estimateFrontierByRisk at 80

pwgt =

    0.7899
    0.0856
    0.0545
    0.0700
```

The best way to avoid this situation is to bracket your target portfolio risks with `estimateFrontierLimits` and `estimatePortRisk` (see “Obtaining Endpoints of the Efficient Frontier” on page 5-86 and “Obtaining CVaR Portfolio Risks and Returns” on page 5-102).

```
prsk = estimatePortRisk(p, p.estimateFrontierLimits);

display(prsk)
```

```
prsk =
    0.0736
    0.4367
```

This result indicates that efficient portfolios have risks that range from 7% to 42.5%. Note, your results for these examples may be different due to the random generation of scenarios.

Starting with an initial portfolio, `estimateFrontierByRisk` also returns purchases and sales to get from your initial portfolio to the target portfolios on the efficient frontier. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales from the example with target risks of 12%, 14%, and 16%:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierByRisk(p, [0.12, 0.14, 0.16]);

display(pwgt)
display(pbuy)
display(psell)
```

```
pwgt =

    0.3594    0.2524    0.1543
    0.3164    0.3721    0.4248
    0.1044    0.1193    0.1298
    0.2199    0.2563    0.2910

pbuy =

    0.0594         0         0
    0.0164    0.0721    0.1248
         0         0         0
    0.1199    0.1563    0.1910

psell =

         0    0.0476    0.1457
         0         0         0
    0.0956    0.0807    0.0702
         0         0         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Choosing and Controlling the Solver for PortfolioCVaR Optimizations

When solving portfolio optimizations for a `PortfolioCVaR` object, you are solving nonlinear optimization problems with either nonlinear objective or nonlinear constraints. You can use `'TrustRegionCP'` (default), `'ExtendedCP'`, or `'cuttingplane'` solvers that implement Kelley’s cutting plane method (see Kelley [45] at “Portfolio Optimization” on page A-5). Alternatively, you can use `fmincon` and all variations of `fmincon` from Optimization Toolbox are supported. When using `fmincon` as the `solverType`, `'sqp'` is the default algorithm for `fmincon`.

Using 'TrustRegionCP', 'ExtendedCP', and 'cuttingplane' SolverTypes

The `'TrustRegionCP'`, `'ExtendedCP'`, and `'cuttingplane'` solvers have options to control the number iterations and stopping tolerances. Moreover, these solvers use `linprog` as the master solver, and all `linprog` options are supported using `optimoptions` structures. All these options are set using `setSolver`.

For example, you can use `setSolver` to increase the number of iterations for `'TrustRegionCP'`:

```
p = PortfolioCVaR;
p = setSolver(p, 'TrustRegionCP', 'MaxIterations', 2000);
display(p.solverType)
display(p.solverOptions)
```

```
trustregioncp
                MaxIterations: 2000
         AbsoluteGapTolerance: 1.0000e-07
         RelativeGapTolerance: 1.0000e-05

     MaxIterationsInactiveCut: 30
           ActiveCutTolerance: 1.0000e-07
                  ShrinkRatio: 0.7500
    TrustRegionStartIteration: 2
                   DeltaLimit: 1
```

To change the main solver algorithm to `'interior-point'`, with no display, use `setSolver` to modify `'MainSolverOptions'`:

```
p = PortfolioCVaR;
options = optimoptions('linprog','Algorithm','interior-point','Display','off');
p = setSolver(p,'TrustRegionCP','MainSolverOptions',options);
display(p.solverType)
display(p.solverOptions)
display(p.solverOptions.MainSolverOptions.Algorithm)
display(p.solverOptions.MainSolverOptions.Display)
```

```
trustregioncp
                MaxIterations: 1000
         AbsoluteGapTolerance: 1.0000e-07
         RelativeGapTolerance: 1.0000e-05
       NonlinearScalingFactor: 1000
       ObjectiveScalingFactor: 1000
          MaainSolverOptions: [1×1 optim.options.Linprog]
```

```
                      Display: 'off'
                CutGeneration: 'basic'
     MaxIterationsInactiveCut: 30
           ActiveCutTolerance: 1.0000e-07
                  ShrinkRatio: 0.7500
    TrustRegionStartIteration: 2
                   DeltaLimit: 1

interior-point
off
```

Using 'fmincon' SolverType

Unlike Optimization Toolbox which uses the `interior-point` algorithm as the default algorithm for `fmincon`, the portfolio optimization for a `PortfolioCVaR` object uses the `sqp` algorithm. For details about `fmincon` and constrained nonlinear optimization algorithms and options, see “Constrained Nonlinear Optimization Algorithms”.

To modify `fmincon` options for CVaR portfolio optimizations, use `setSolver` to set the hidden properties `solverType` and `solverOptions` to specify and control the solver. (Note that you can see the default options by creating a dummy `PortfolioCVaR` object, using `p = PortfolioCVaR` and then type `p.solverOptions`.) Since these solver properties are hidden, you cannot set them using the `PortfolioCVaR` object. The default for the `fmincon` solver is to use the `sqp` algorithm objective function, gradients turned on, and no displayed output, so you do not need to use `setSolver` to specify the `sqp` algorithm.

```
p = PortfolioCVaR;
p = setSolver(p, 'fmincon');
display(p.solverOptions)
```

```
fmincon options:

   Options used by current Algorithm ('sqp'):
   (Other available algorithms: 'active-set', 'interior-point', 'sqp-legacy', 'trust-region-refle

   Set properties:
                    Algorithm: 'sqp'
          ConstraintTolerance: 1.0000e-08
                      Display: 'off'
          OptimalityTolerance: 1.0000e-08
    SpecifyConstraintGradient: 1
     SpecifyObjectiveGradient: 1
                StepTolerance: 1.0000e-08

   Default properties:
               CheckGradients: 0
     FiniteDifferenceStepSize: 'sqrt(eps)'
         FiniteDifferenceType: 'forward'
       MaxFunctionEvaluations: '100*numberOfVariables'
                MaxIterations: 400
               ObjectiveLimit: -1.0000e+20
                    OutputFcn: []
                      PlotFcn: []
                 ScaleProblem: 0
                     TypicalX: 'ones(numberOfVariables,1)'
                  UseParallel: 0
```

If you want to specify additional options associated with the `fmincon` solver, `setSolver` accepts these options as name-value pair arguments. For example, if you want to use `fmincon` with the `'active-set'` algorithm and with no displayed output, use `setSolver` with:

```
p = PortfolioCVaR;
p = setSolver(p, 'fmincon','Algorithm','active-set','Display','off');
display(p.solverOptions.Algorithm)
display(p.solverOptions.Display)
```

```
active-set
off
```

Alternatively, `setSolver` accepts an `optimoptions` object from Optimization Toolbox as the second argument. For example, you can change the algorithm to `'trust-region-reflective'` with no displayed output as follows:

```
p = PortfolioCVaR;
options = optimoptions('fmincon','Algorithm','trust-region-reflective', 'Display', 'off');
p = setSolver(p, 'fmincon', options);
display(p.solverOptions.Algorithm)
display(p.solverOptions.Display)
```

```
trust-region-reflective
off
```

Using the Mixed Integer Nonlinear Programming (MINLP) Solver

The mixed integer nonlinear programming (MINLP) solver, configured using `setSolverMINLP`, enables you to specify associated solver options for portfolio optimization for a `PortfolioCVaR` object. The MINLP solver is used when any one, or any combination of `'Conditional'` `BoundType`, `MinNumAssets`, or `MaxNumAssets` constraints are active. In this case, the portfolio problem is formulated by adding `NumAssets` binary variables, where `0` indicates not invested, and `1` is invested. For more information on using `'Conditional'` `BoundType`, see `setBounds`. For more information on specifying `MinNumAssets` and `MaxNumAssets`, see `setMinMaxNumAssets`.

When using the `estimate` functions with a `PortfolioCVaR` object where `'Conditional'` `BoundType`, `MinNumAssets`, or `MaxNumAssets` constraints are active, the mixed integer nonlinear programming (MINLP) solver is automatically used.

Solver Guidelines for PortfolioCVaR Objects

The following table provides guidelines for using `setSolver` and `setSolverMINLP`.

PortfolioCVaR Problem	PortfolioCVaR Function	Type of Optimization Problem	Main Solver	Helper Solver
PortfolioCVaR without active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierByRisk`	Optimizing a portfolio for a certain risk level introduces a nonlinear constraint. Therefore, this problem has a linear objective with linear and nonlinear constraints.	`'TrustRegionCP'`, `'ExtendedCP'`, `'fmincon'`, or `'cuttingplane'` using `setSolver`	`'linprog'` using `setSolver`
PortfolioCVaR without active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierByReturn`	Nonlinear objective with linear constraints	`'TrustRegionCP'`, `'ExtendedCP'`, `'fmincon'`, or `'cuttingplane'` using `setSolver`	`'linprog'` using `setSolver`
PortfolioCVaR without active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierLimits`	Nonlinear or linear objective with linear constraints	For ‘`min`’: nonlinear objective, `'TrustRegionCP'`, `'ExtendedCP'`, `'fmincon'`, or `'cuttingplane'` using `setSolver` For ‘`max`’: linear objective, `'linprog'` using `setSolver`	Not applicable

PortfolioCVaR Problem	PortfolioCVaR Function	Type of Optimization Problem	Main Solver	Helper Solver
PortfolioCVaR with active 'Conditional' BoundType, MinNumAssets, and MaxNumAssets	estimateFrontierByRisk	The problem is formulated by introducing NumAssets binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see setSolverMINLP.	Mixed integer nonlinear programming solver (MINLP) using setSolverMINLP	'fmincon' is used when the estimate functions reduce the problem into NLP. This solver is configured through setSolver.
PortfolioCVaR with active 'Conditional' BoundType, MinNumAssets, and MaxNumAssets	estimateFrontierByReturn	The problem is formulated by introducing NumAssets binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see setSolverMINLP. Estimate Efficient Frontiers for PortfolioCVaR Object

Whereas "Estimate Efficient Portfolios for Entire Frontier for PortfolioCVaR Object" on page 5-82 focused on estimation of efficient portfolios, this section focuses on the estimation of efficient frontiers. For information on the workflow when using `PortfolioCVaR` objects, see "PortfolioCVaR Object Workflow" on page 5-16.

Obtaining CVaR Portfolio Risks and Returns

Given any portfolio and, in particular, efficient portfolios, the functions `estimatePortReturn` and `estimatePortRisk` provide estimates for the return (or return proxy), risk (or the risk proxy). Each function has the same input syntax but with different combinations of outputs. Suppose that you have this following portfolio optimization problem that gave you a collection of portfolios along the efficient frontier in `pwgt`:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = setInitPort(p, pwgt0);
pwgt = estimateFrontier(p);
```

Note Remember that the risk proxy for CVaR portfolio optimization is CVaR.

Given `pwgt0` and `pwgt`, use the portfolio risk and return estimation functions to obtain risks and returns for your initial portfolio and the portfolios on the efficient frontier:

```
prsk0 = estimatePortRisk(p, pwgt0);
pret0 = estimatePortReturn(p, pwgt0);
prsk = estimatePortRisk(p, pwgt);
pret = estimatePortReturn(p, pwgt);
```

You obtain these risks and returns:

```
display(prsk0)
display(pret0)
display(prsk)
display(pret)
```

```
prsk0 =

    0.0591

pret0 =

    0.0067

prsk =

    0.0414
    0.0453
    0.0553
    0.0689
    0.0843
    0.1006
    0.1193
    0.1426
    0.1689
    0.1969

pret =

    0.0050
    0.0060
    0.0070
    0.0080
    0.0089
    0.0099
    0.0109
    0.0119
    0.0129
    0.0139
```

Obtaining Portfolio Standard Deviation and VaR

The PortfolioCVaR object has functions to compute standard deviations of portfolio returns and the value-at-risk of portfolios with the functions estimatePortStd and estimatePortVaR. These functions work with any portfolios, not necessarily efficient portfolios. For example, the following example obtains five portfolios (pwgt) on the efficient frontier and also has an initial portfolio in pwgt0. Various portfolio statistics are computed that include the return, risk, standard deviation, and value-at-risk. The listed estimates are for the initial portfolio in the first row followed by estimates for each of the five efficient portfolios in subsequent rows.

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
```

```
p = PortfolioCVaR('initport', pwgt0);
p = simulateNormalScenariosByMoments(p, m, C, 20000);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.9);

pwgt = estimateFrontier(p, 5);

pret = estimatePortReturn(p, [pwgt0, pwgt]);
prsk = estimatePortRisk(p, [pwgt0, pwgt]);
pstd = estimatePortStd(p, [pwgt0, pwgt]);
pvar = estimatePortVaR(p, [pwgt0, pwgt]);

[pret, prsk, pstd, pvar]

ans =

    0.0207    0.0464    0.0381    0.0283
    0.1009    0.0214    0.0699   -0.0109
    0.1133    0.0217    0.0772   -0.0137
    0.1256    0.0226    0.0849   -0.0164
    0.1380    0.0240    0.0928   -0.0182
    0.1503    0.0262    0.1011   -0.0197
```

Plotting the Efficient Frontier for a PortfolioCVaR Object

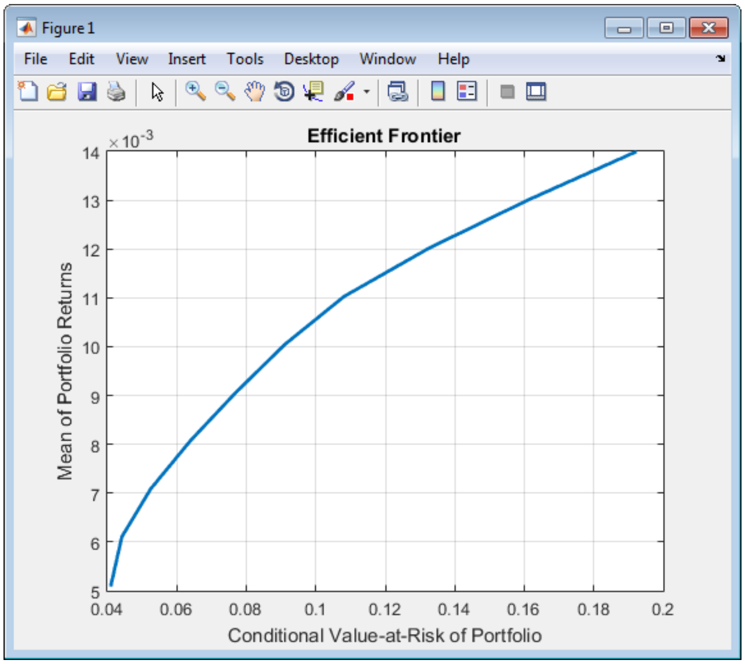
The plotFrontier function creates a plot of the efficient frontier for a given portfolio optimization problem. This function accepts several types of inputs and generates a plot with an optional possibility to output the estimates for portfolio risks and returns along the efficient frontier. plotFrontier has four different ways that it can be used. In addition to a plot of the efficient frontier, if you have an initial portfolio in the InitPort property, plotFrontier also displays the return versus risk of the initial portfolio on the same plot. If you have a well-posed portfolio optimization problem set up in a PortfolioCVaR object and you use plotFrontier, you get a plot of the efficient frontier with the default number of portfolios on the frontier (the default number is currently 10 and is maintained in the hidden property defaultNumPorts). This example illustrates a typical use of plotFrontier to create a new plot:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioCVaR;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

plotFrontier(p)
```

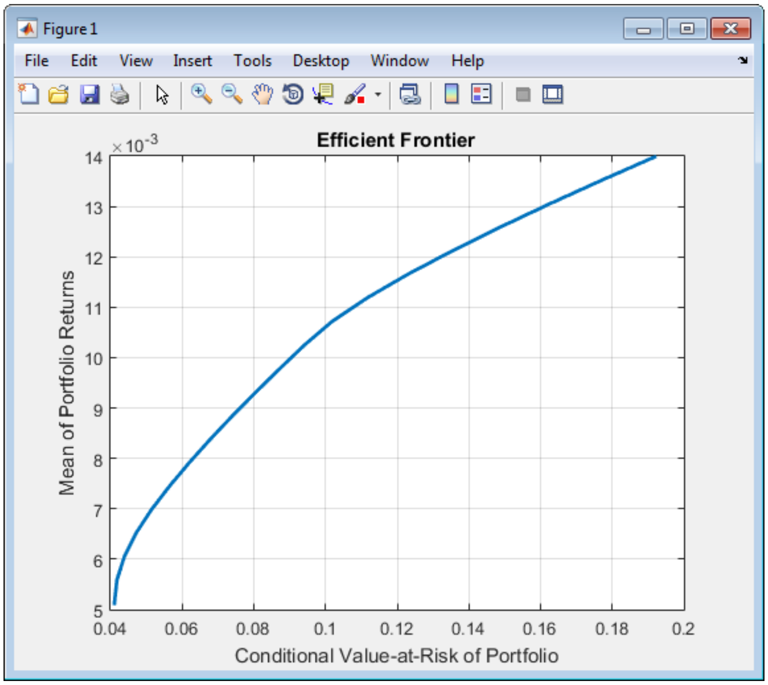


The Name property appears as the title of the efficient frontier plot if you set it in the PortfolioCVaR object. Without an explicit name, the title on the plot would be “Efficient Frontier.” If you want to obtain a specific number of portfolios along the efficient frontier, use plotFrontier with the number of portfolios that you want. Suppose that you have the PortfolioCVaR object from the previous example and you want to plot 20 portfolios along the efficient frontier and to obtain 20 risk and return values for each portfolio:

```
[prsk, pret] = plotFrontier(p, 20);
display([pret, prsk])
```

```
ans =

    0.0051    0.0406
    0.0056    0.0414
    0.0061    0.0437
    0.0066    0.0471
    0.0071    0.0515
    0.0076    0.0567
    0.0082    0.0624
    0.0087    0.0687
    0.0092    0.0753
    0.0097    0.0821
    0.0102    0.0891
    0.0107    0.0962
    0.0112    0.1044
    0.0117    0.1142
    0.0122    0.1251
    0.0127    0.1369
    0.0133    0.1496
    0.0138    0.1628
    0.0143    0.1766
    0.0148    0.1907
```



Plotting Existing Efficient Portfolios

If you already have efficient portfolios from any of the "estimateFrontier" functions (see “Estimate Efficient Portfolios for Entire Frontier for PortfolioCVaR Object” on page 5-82), pass them into `plotFrontier` directly to plot the efficient frontier:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

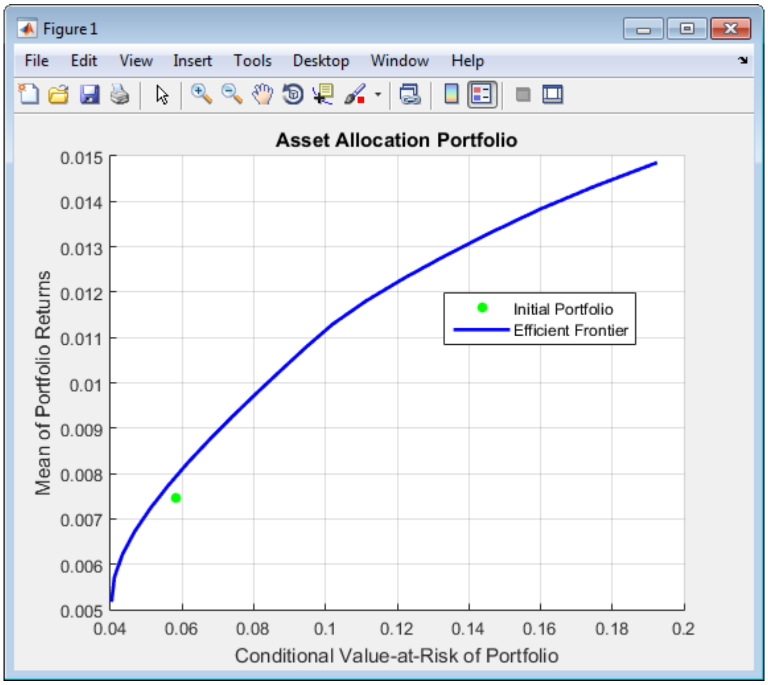
AssetScenarios = mvnrnd(m, C, 20000);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioCVaR('Name', 'Asset Allocation Portfolio', 'InitPort', pwgt0);

p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

pwgt = estimateFrontier(p, 20);
plotFrontier(p, pwgt)
```



Plotting Existing Efficient Portfolio Risks and Returns

If you already have efficient portfolio risks and returns, you can use the interface to `plotFrontier` to pass them into `plotFrontier` to obtain a plot of the efficient frontier:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];
```

```
AssetScenarios = mvnrnd(m, C, 20000);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioCVaR('Name', 'Asset Allocation Portfolio', 'InitPort', pwgt0);

p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.95);

pwgt = estimateFrontier(p);

pret= estimatePortReturn(p, pwgt);
prsk = estimatePortRisk(p, pwgt);

plotFrontier(p, prsk, pret)
```

Postprocessing Results to Set Up Tradable Portfolios

After obtaining efficient portfolios or estimates for expected portfolio risks and returns, use your results to set up trades to move toward an efficient portfolio. For information on the workflow when using `PortfolioCVaR` objects, see “PortfolioCVaR Object Workflow” on page 5-16.

Setting Up Tradable Portfolios

Suppose that you set up a portfolio optimization problem and obtained portfolios on the efficient frontier. Use the `dataset` object from Statistics and Machine Learning Toolbox to form a blotter that lists your portfolios with the names for each asset. For example, suppose that you want to obtain five portfolios along the efficient frontier. You can set up a blotter with weights multiplied by 100 to view the allocations for each portfolio:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioCVaR;
p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');
p = setInitPort(p, pwgt0);
p = simulateNormalScenariosByMoments(p, m, C, 20000);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.9);

pwgt = estimateFrontier(p, 5);

pnames = cell(1,5);
for i = 1:5
pnames{i} = sprintf('Port%d',i);
end

Blotter = dataset([{100*pwgt},pnames],'obsnames',p.AssetList);
display(Blotter)
```

```
Blotter = 

                          Port1     Port2     Port3     Port4     Port5     
    Bonds                  78.84    43.688    8.3448         0    1.2501e-12
    Large-Cap Equities    9.3338    29.131    48.467    23.602    9.4219e-13
    Small-Cap Equities    4.8843    8.1284    12.419    16.357     8.281e-14
    Emerging Equities     6.9419    19.053    30.769    60.041           100
```

Note Your results may differ from this result due to the simulation of scenarios.

This result indicates that you would invest primarily in bonds at the minimum-risk/minimum-return end of the efficient frontier (`Port1`), and that you would invest completely in emerging equity at the maximum-risk/maximum-return end of the efficient frontier (`Port5`). You can also select a particular efficient portfolio, for example, suppose that you want a portfolio with 15% risk and you add purchase and sale weights outputs obtained from the “estimateFrontier” functions to set up a trade blotter:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioCVaR;
p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');

p = setInitPort(p, pwgt0);
```

```
p = simulateNormalScenariosByMoments(p, m, C, 20000);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.9);

[pwgt, pbuy, psell] = estimateFrontierByRisk(p, 0.15);

Blotter = dataset([{100*[pwgt0, pwgt, pbuy, psell]}, ...
{'Initial','Weight', 'Purchases','Sales'}],'obsnames',p.AssetList);
display(Blotter)
```

```
Blotter = 

                          Initial    Weight    Purchases    Sales 
    Bonds                 30         15.036         0       14.964
    Large-Cap Equities    30         45.357    15.357            0
    Small-Cap Equities    20         12.102         0       7.8982
    Emerging Equities     10         27.505    17.505            0
```

If you have prices for each asset (in this example, they can be ETFs), add them to your blotter and then use the tools of the `dataset` object to obtain shares and shares to be traded.

Working with Other Portfolio Objects

The PortfolioCVaR object is for CVaR portfolio optimization. The Portfolio object is for mean-variance portfolio optimization. Sometimes, you might want to examine portfolio optimization problems according to different combinations of return and risk proxies. A common example is that you want to do a CVaR portfolio optimization and then want to work primarily with moments of portfolio returns. Suppose that you set up a CVaR portfolio optimization problem with:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioCVaR;
p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');
p = setInitPort(p, pwgt0);
p = simulateNormalScenariosByMoments(p, m, C, 20000);
p = setDefaultConstraints(p);
p = setProbabilityLevel(p, 0.9);
```

To work with the same problem in a mean-variance framework, you can use the scenarios from the PortfolioCVaR object to set up a Portfolio object so that p contains a CVaR optimization problem and q contains a mean-variance optimization problem based on the same data.

```
q = Portfolio('AssetList', p.AssetList);
q = estimateAssetMoments(q, p.getScenarios);
q = setDefaultConstraints(q);

pwgt = estimateFrontier(p);
qwgt = estimateFrontier(q);
```

Since each object has a different risk proxy, it is not possible to compare results side by side. To obtain means and standard deviations of portfolio returns, you can use the functions associated with each object to obtain:

```
pret = estimatePortReturn(p, pwgt);
pstd = estimatePortStd(p, pwgt);
qret = estimatePortReturn(q, qwgt);
qstd = estimatePortStd(q, qwgt);

[pret, qret]
[pstd, qstd]

ans =

    0.0665    0.0585
    0.0787    0.0716
    0.0910    0.0848
    0.1033    0.0979
    0.1155    0.1111
    0.1278    0.1243
    0.1401    0.1374
    0.1523    0.1506
    0.1646    0.1637
    0.1769    0.1769

ans =
    0.0797    0.0774
    0.0912    0.0835
    0.1095    0.0995
    0.1317    0.1217
    0.1563    0.1472
    0.1823    0.1746
    0.2135    0.2059
    0.2534    0.2472
    0.2985    0.2951
    0.3499    0.3499
```

To produce comparable results, you can use the returns or risks from one portfolio optimization as target returns or risks for the other portfolio optimization.

```
qwgt = estimateFrontierByReturn(q, pret);
qret = estimatePortReturn(q, qwgt);
qstd = estimatePortStd(q, qwgt);

[pret, qret]
[pstd, qstd]
```

```
ans =

    0.0665    0.0665
    0.0787    0.0787
    0.0910    0.0910
    0.1033    0.1033
    0.1155    0.1155
    0.1278    0.1278
    0.1401    0.1401
    0.1523    0.1523
    0.1646    0.1646
    0.1769    0.1769

ans =

    0.0797    0.0797
    0.0912    0.0912
    0.1095    0.1095
    0.1317    0.1317
    0.1563    0.1563
    0.1823    0.1823
    0.2135    0.2135
    0.2534    0.2534
    0.2985    0.2985
    0.3499    0.3499
```

Now it is possible to compare standard deviations of portfolio returns from either type of portfolio optimization.

Troubleshooting CVaR Portfolio Optimization Results

PortfolioCVaR Object Destroyed When Modifying

If a `PortfolioCVaR` object is destroyed when modifying, remember to pass an existing object into the `PortfolioCVaR` object if you want to modify it, otherwise it creates a new object. See “Creating the PortfolioCVaR Object” on page 5-22 for details.

Matrix Incompatibility and "Non-Conformable" Errors

If you get matrix incompatibility or "non-conformable" errors, the representation of data in the tools follows a specific set of basic rules described in “Conventions for Representation of Data” on page 5-20.

CVaR Portfolio Optimization Warns About “Max Iterations”

If the `'cuttingplane'` solver displays the following warning:

```
Warning: Max iterations reached. Consider modifying the solver options, or using fmincon.
> In @PortfolioCVaR\private\cvar_cuttingplane_solver at 255
  In @PortfolioCVaR\private\cvar_optim_min_risk at 85
  In PortfolioCVaR.estimateFrontier at 69
```

this warning indicates that some of the reported efficient portfolios may not be accurate enough.

This warning is usually related to portfolios in the lower-left end of the efficient frontier. The cutting plane solver may have gotten very close to the solution, but there may be too many portfolios with very similar risks and returns in that neighborhood, and the solver runs out of iterations before reaching the desired accuracy.

To correct this problem, you can use `setSolver` to make any of these changes:

- Increase the maximum number of iterations (`'MaxIter'`).
- Relax the stopping tolerances (`'AbsTol'` and/or `'RelTol'`).
- Use a different main solver algorithm (`'MainSolverOptions'`).
- Alternatively, you can try the `'fmincon'` solver.

When the default maximum number of iterations of the `'cuttingplane'` solver is reached, the solver usually needs many more iterations to reach the accuracy required by the default stopping tolerances. You may want to combine increasing the number of iterations (e.g., multiply by 5) with relaxing the stopping tolerances (for example, multiply by 10 or 100). Since the CVaR is a stochastic optimization problem, the accuracy of the solution is relative to the scenario sample, so a looser stopping tolerance may be acceptable. Keep in mind that the solution time may increase significantly when you increase the number of iterations. For example, doubling the number of iterations more than doubles the solution time. Sometimes using a different main solver (for example, switching to `'interior-point'` if you are using the default `'simplex'`) can get the `'cuttingplane'` solver to converge without changing the maximum number of iterations.

Alternatively, the `'fmincon'` solver may be faster than the `'cuttingplane'` solver for problems where cutting plane reaches the maximum number of iterations.

CVaR Portfolio Optimization Errors with “Could Not Solve” Message

If the `'cuttingplane'` solver generates the following error:

```
Error using cvar_cuttingplane_solver (line 251)
Could not solve the problem. Consider modifying the solver options, or using fmincon.

Error in cvar_optim_by_return (line 100)
        [x,~,~,exitflag] = cvar_cuttingplane_solver(...

Error in PortfolioCVaR/estimateFrontier (line 80)
    pwgt = cvar_optim_by_return(obj, r(2:end-1), obj.NumAssets, ...
```

this error means that the master solver failed to solve one of the master problems. The error may be due to numerical instability or other problem-specific situation.

To correct this problem, you can use `setSolver` to make any of these changes:

- Modify the main solver options (`'MainSolverOptions'`), for example, change the algorithm (`'Algorithm'`) or the termination tolerance (`'TolFun'`).
- Alternatively, you can try the `'fmincon'` solver.

Missing Data Estimation Fails

If asset return data has missing or `NaN` values, the `simulateNormalScenariosByData` function with the `'missingdata'` flag set to `true` may fail with either too many iterations or a singular covariance. To correct this problem, consider this:

- If you have asset return data with no missing or `NaN` values, you can compute a covariance matrix that may be singular without difficulties. If you have missing or `NaN` values in your data, the supported missing data feature requires that your covariance matrix must be positive-definite, that is, nonsingular.
- `simulateNormalScenariosByData` uses default settings for the missing data estimation procedure that might not be appropriate for all problems.

In either case, you might want to estimate the moments of asset returns separately with either the ECM estimation functions such as `ecmnmle` or with your own functions.

cvar_optim_transform Errors

If you obtain optimization errors such as:

```
Error using cvar_optim_transform (line 276)
Portfolio set appears to be either empty or unbounded. Check constraints.

Error in PortfolioCVaR/estimateFrontier (line 64)
    [AI, bI, AE, bE, lB, uB, f0, f, x0] = cvar_optim_transform(obj);
```

or

```
Error using cvar_optim_transform (line 281)
Cannot obtain finite lower bounds for specified portfolio set.

Error in PortfolioCVaR/estimateFrontier (line 64)
    [AI, bI, AE, bE, lB, uB, f0, f, x0] = cvar_optim_transform(obj);
```

Since the portfolio optimization tools require a bounded portfolio set, these errors (and similar errors) can occur if your portfolio set is either empty and, if nonempty, unbounded. Specifically, the portfolio optimization algorithm requires that your portfolio set have at least a finite lower bound.

The best way to deal with these problems is to use the validation functions in "Validate the CVaR Portfolio Problem" on page 5-78. Specifically, use `estimateBounds` to examine your portfolio set, and use `checkFeasibility` to ensure that your initial portfolio is either feasible and, if infeasible, that you have sufficient turnover to get from your initial portfolio to the portfolio set.

Tip To correct this problem, try solving your problem with larger values for turnover and gradually reduce to the value that you want.

Efficient Portfolios Do Not Make Sense

If you obtain efficient portfolios that, do not seem to make sense, this can happen if you forget to set specific constraints or you set incorrect constraints. For example, if you allow portfolio weights to fall between `0` and `1` and do not set a budget constraint, you can get portfolios that are 100% invested in every asset. Although it may be hard to detect, the best thing to do is to review the constraints you have set with display of the `PortfolioCVaR` object. If you get portfolios with 100% invested in each asset, you can review the display of your object and quickly see that no budget constraint is set. Also, you can use `estimateBounds` and `checkFeasibility` to determine if the bounds for your portfolio set make sense and to determine if the portfolios you obtained are feasible relative to an independent formulation of your portfolio set.

Hedging Using CVaR Portfolio Optimization

This example shows how to model two hedging strategies using CVaR portfolio optimization with a PortfolioCVaR object. First, you simulate the price movements of a stock by using a gbm object with simByEuler. Then you use CVaR portfolio optimization to estimate the efficient frontier of the portfolios for the returns at the horizon date. Finally, you compare the CVaR portfolio to a mean-variance portfolio to demonstrate the differences between these two types of risk measures.

Monte Carlo Simulation of Asset Scenarios

Scenarios are required to define and evaluate the CVaR portfolio. These scenarios can be generated in multiple ways, as well as obtained from historical observations. This example uses a Monte Carlo simulation of a geometric Brownian motion to generate the scenarios. The Monte Carlo simulation produces trials of a stock price after one year. These stock prices provide the returns of five different investment strategies that define the assets in the CVaR portfolio. This scenario generation strategy can be further generalized to simulations with more stocks, instruments, and strategies.

Define a stock profile.

```
% Price at time 0
Price_0 = 200;

% Drift (annualized)
Drift = 0.08;

% Volatility (annualized)
Vol = 0.4;

% Valuation date
Valuation = datetime(2012,1,1);

% Investment horizon date
Horizon = datetime(2013,1,1);

% Risk-free rate
RiskFreeRate = 0.03;
```

Simulate the price movements of the stock from the valuation date to the horizon date using a gbm object with simByEuler.

```
% Number of trials for the Monte Carlo simulation
NTRIALS = 100000;

% Length (in years) of the simulation
T = date2time(Valuation, Horizon, 1, 1);

% Number of periods per trial (approximately 100 periods per year)
NPERIODS = round(100*T);

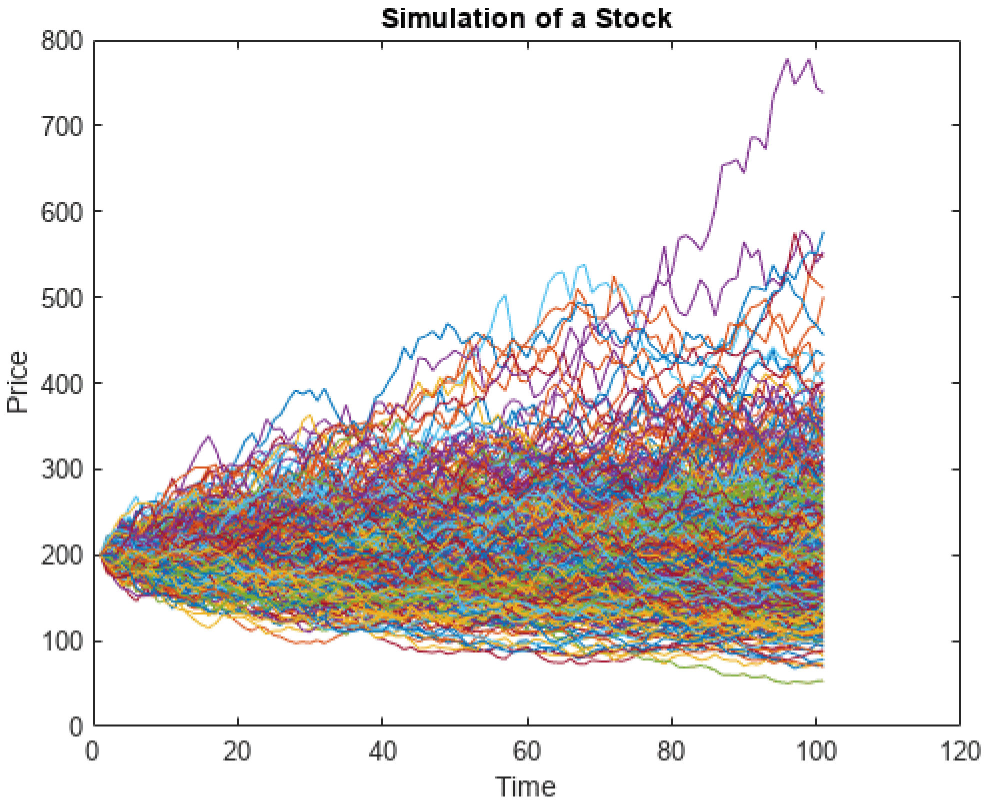
% Length (in years) of each time step per period
dt = T/NPERIODS;

% Instantiate the gbm object
StockGBM = gbm(Drift, Vol, 'StartState', Price_0);
```

```
% Run the simulation
Paths = StockGBM.simByEuler(NPERIODS, 'NTRIALS', NTRIALS, ...
    'DeltaTime', dt, 'Antithetic', true);
```

Plot the simulation of the stock. For efficiency, plot only some scenarios.

```
plot(squeeze(Paths(:,:,1:500)));
title('Simulation of a Stock');
xlabel('Time');
ylabel('Price');
```



Calculate the prices of different put options using a Black-Scholes model with the `blsprice` function.

```
% Put option with strike at 50% of current underlying price
Strike50 = 0.50*Price_0;
[~, Put50] = blsprice(Price_0, Strike50, RiskFreeRate, T, Vol);

% Put option with strike at 75% of current underlying price
Strike75 = 0.75*Price_0;
[~, Put75] = blsprice(Price_0, Strike75, RiskFreeRate, T, Vol);

% Put option with strike at 90% of current underlying price
Strike90 = 0.90*Price_0;
[~, Put90] = blsprice(Price_0, Strike90, RiskFreeRate, T, Vol);

% Put option with strike at 95% of current underlying price
Strike95 = 0.95*Price_0; % Same as strike
[~, Put95] = blsprice(Price_0, Strike95, RiskFreeRate, T, Vol);
```

The goal is to find the efficient portfolio frontier for the returns at the horizon date. Hence, obtain the scenarios from the trials of the Monte Carlo simulation at the end of the simulation period.

```
Price_T = squeeze(Paths(end, 1, :));
```

Generate the scenario matrix using five strategies. The first strategy is a stock-only strategy; the rest of the strategies are the stock hedged with put options at different strike price levels. To compute the returns from the prices obtained by the Monte Carlo simulation for the stock-only strategy, divide the change in the stock price `(Price_T - Price_0)` by the initial price `Price_0`. To compute the returns of the stock with different put options, first compute the "observed price" at the horizon date, that is, the stock price with the acquired put option taken into account. If the stock price at the horizon date is less than the strike price, the observed price is the strike price. Otherwise, the observed price is the true stock price. This observed price is represented by the formula

$$\text{Observed price} = \max\{\text{Price}_T, \text{ Strike}\}.$$

You can then compute the "initial cost" of the stock with the put option, which is given by the initial stock price `Price_0` plus the price of the put option. Finally, to compute the return of the put option strategies, divide the observed price minus the initial cost by the initial cost.

```
AssetScenarios = zeros(NTRIALS, 5);

% Strategy 1: Stock only
AssetScenarios(:, 1) = (Price_T - Price_0) ./ Price_0;

% Strategy 2: Put option cover at 50%
AssetScenarios(:, 2) = (max(Price_T, Strike50) - (Price_0 + Put50)) ./ ...
    (Price_0 + Put50);

% Strategy 2: Put option cover at 75%
AssetScenarios(:, 3) = (max(Price_T, Strike75) - (Price_0 + Put75)) ./ ...
    (Price_0 + Put75);

% Strategy 2: Put option cover at 90%
AssetScenarios(:, 4) = (max(Price_T, Strike90) - (Price_0 + Put90)) ./ ...
    (Price_0 + Put90);

% Strategy 2: Put option cover at 95%
AssetScenarios(:, 5) = (max(Price_T, Strike95) - (Price_0 + Put95)) ./ ...
    (Price_0 + Put95);
```

The portfolio weights associated with each of the five assets previously defined represent the percentage of the total weatlh to invest in each strategy. For example, consider a portfolio with the weights `[0.5 0 0.5 0]`. The weights indicate that the best allocation is to invest 50% in the stock-only strategy and the remaining 50% in a put option at 75%.

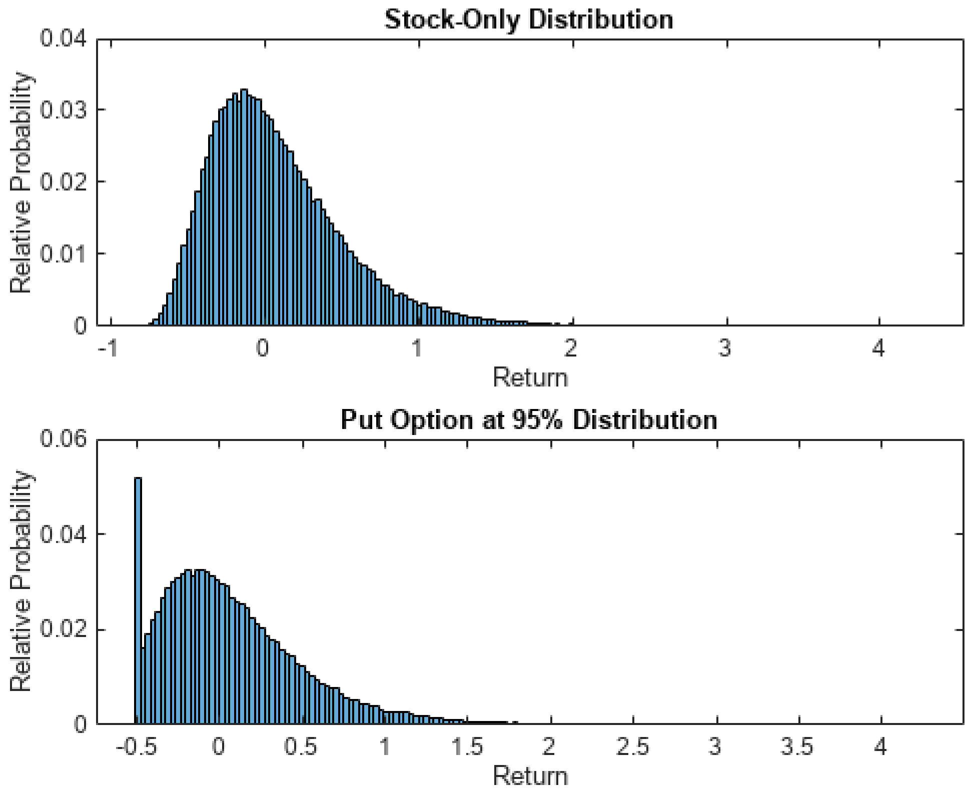
Plot the distribution of the returns for the stock-only strategy and the put option at the 95% strategy. Notice that the returns are not normally distributed. For a mean-variance portfolio, a lack of symmetry in the plotted returns usually indicates poor mean-variance portfolio performance since variance, as a risk measure, is not sensitive to skewed distributions.

```
% Create histogram
figure;

% Stock only
subplot(2,1,1);
```

```
histogram(AssetScenarios(:,1),'Normalization','probability')
title('Stock-Only Distribution')
xlabel('Return')
ylabel('Relative Probability')

% Put option cover
subplot(2,1,2);
histogram(AssetScenarios(:,2),'Normalization','probability')
title('Put Option at 95% Distribution')
xlabel('Return')
ylabel('Relative Probability')
```



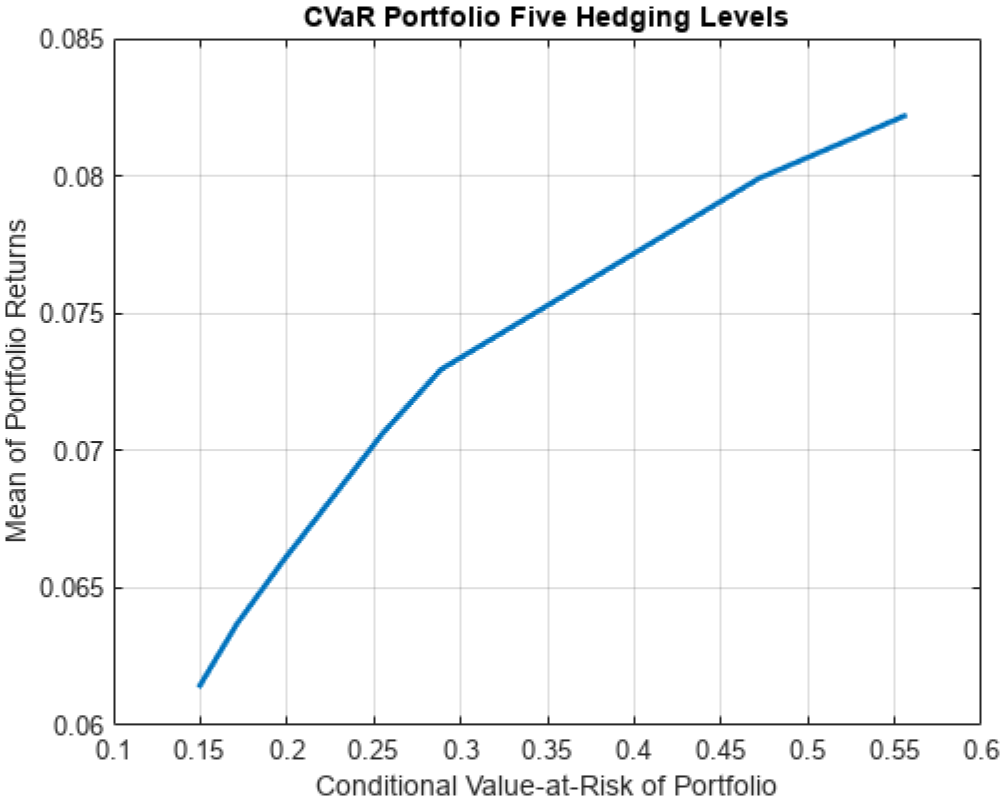
CVaR Efficient Frontier

Create a `PortfolioCVaR` object using the `AssetScenarios` from the simulation.

```
p = PortfolioCVaR('Name','CVaR Portfolio Five Hedging Levels',...
    'AssetList',{'Stock','Hedge50','Hedge75','Hedge90','Hedge95'},...
    'Scenarios', AssetScenarios, 'LowerBound', 0, ...
    'Budget', 1, 'ProbabilityLevel', 0.95);

% Estimate the efficient frontier to obtain portfolio weights
pwgt = estimateFrontier(p);

% Plot the efficient frontier
figure;
plotFrontier(p, pwgt);
```



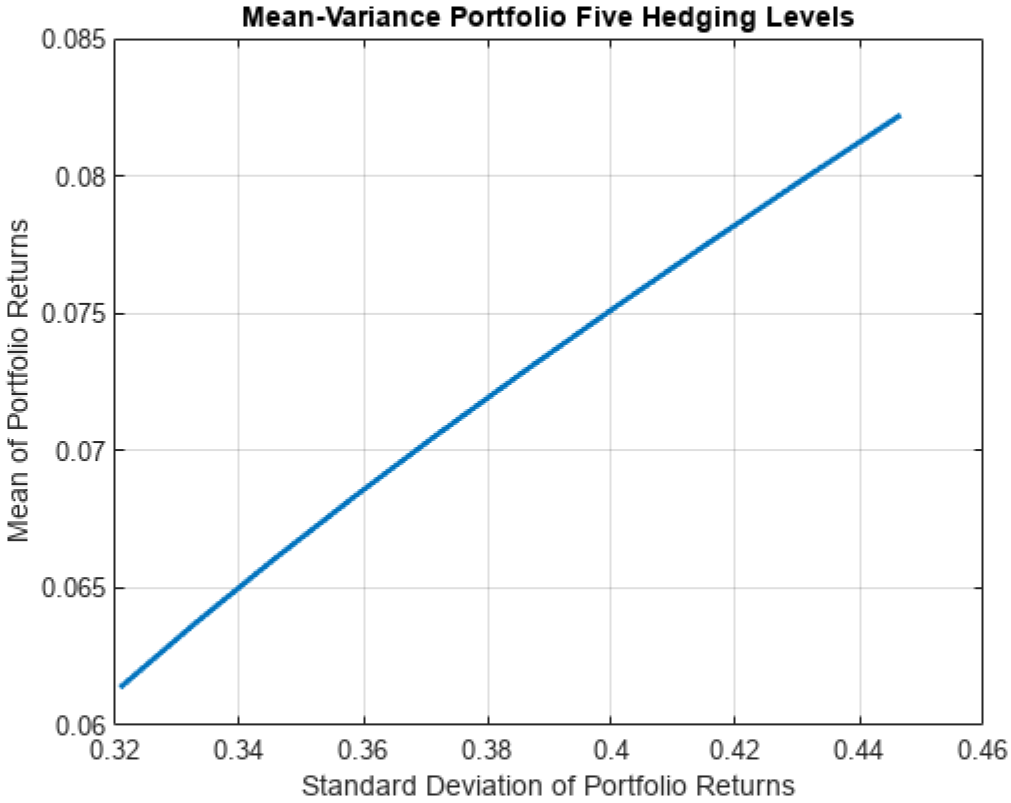
CVaR and Mean-Variance Efficient Frontier Comparison

Create the `Portfolio` object. Use `AssetScenarios` from the simulation to estimate the assets moments. Notice that, unlike for the `PortfolioCVaR` object, only an estimate of the assets moments is required to fully specify a mean-variance portfolio.

```
pmv = Portfolio('Name','Mean-Variance Portfolio Five Hedging Levels',...
   'AssetList',{'Stock','Hedge50','Hedge75','Hedge90','Hedge95'});
pmv = estimateAssetMoments(pmv, AssetScenarios);
pmv = setDefaultConstraints(pmv);

% Estimate the efficient frontier to obtain portfolio weights
pwgtmv = estimateFrontier(pmv);

% Plot the efficient frontier
figure;
plotFrontier(pmv, pwgtmv);
```



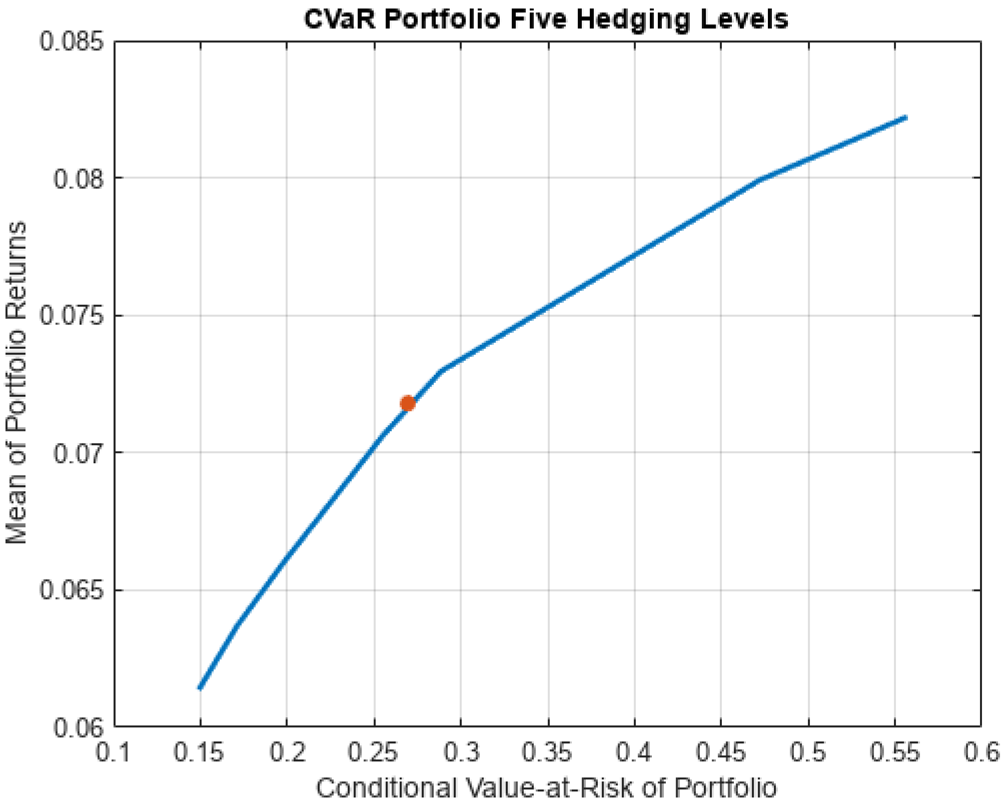
Select a target return. In this case, the target return is the midpoint return on the CVaR portfolio efficient frontier.

```
% Achievable levels of return
pretlimits = estimatePortReturn(p, estimateFrontierLimits(p));
TargetRet = mean(pretlimits); % Target half way up the frontier
```

Plot the efficient CVaR portfolio for the return `TargetRet` on the CVaR efficient frontier.

```
% Obtain risk level at target return
pwgtTarget = estimateFrontierByReturn(p,TargetRet); % CVaR efficient portfolio
priskTarget = estimatePortRisk(p,pwgtTarget);

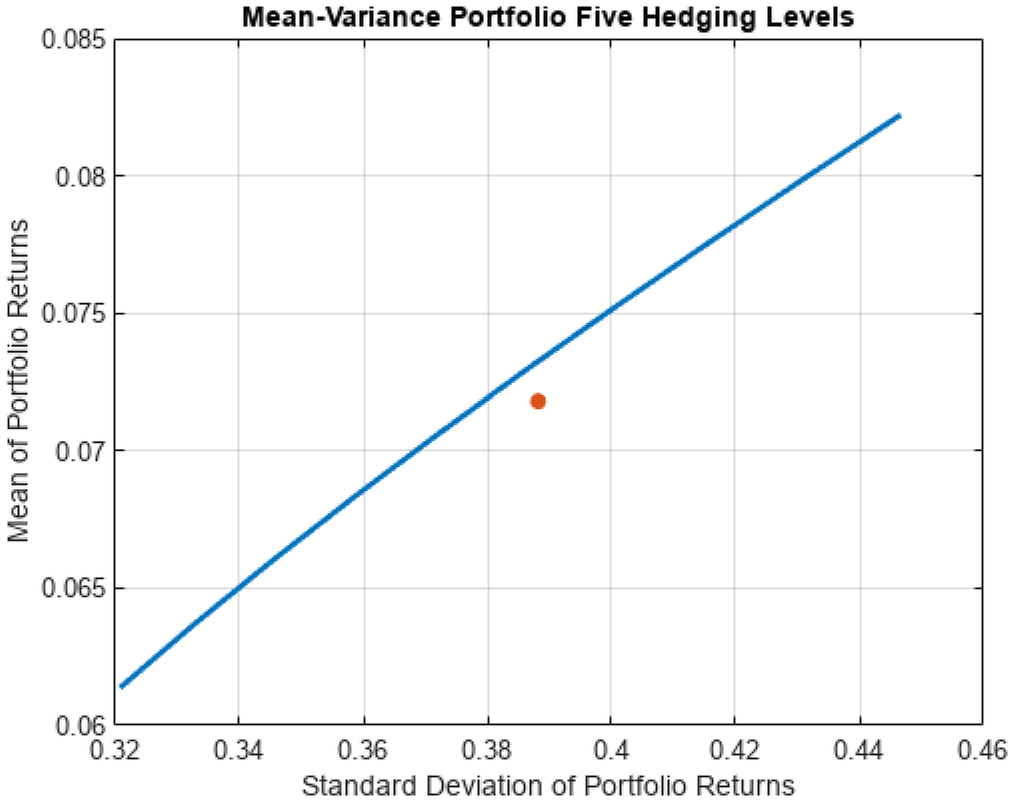
% Plot point onto CVaR efficient frontier
figure;
plotFrontier(p,pwgt);
hold on
scatter(priskTarget,TargetRet,[],'filled');
hold off
```



Plot the efficient CVaR portfolio for the return `TargetRet` on the mean-variance efficient frontier. Notice that the efficient CVaR portfolio is below the mean-variance efficient frontier.

```
% Obtain the variance for the efficient CVaR portfolio
pmvretTarget = estimatePortReturn(pmv,pwgtTarget); % Should be TargetRet
pmvriskTarget = estimatePortRisk(pmv,pwgtTarget);  % Risk proxy is variance

% Plot efficient CVaR portfolio onto mean-variance frontier
figure;
plotFrontier(pmv,pwgtmv);
hold on
scatter(pmvriskTarget,pmvretTarget,[],'filled');
hold off
```

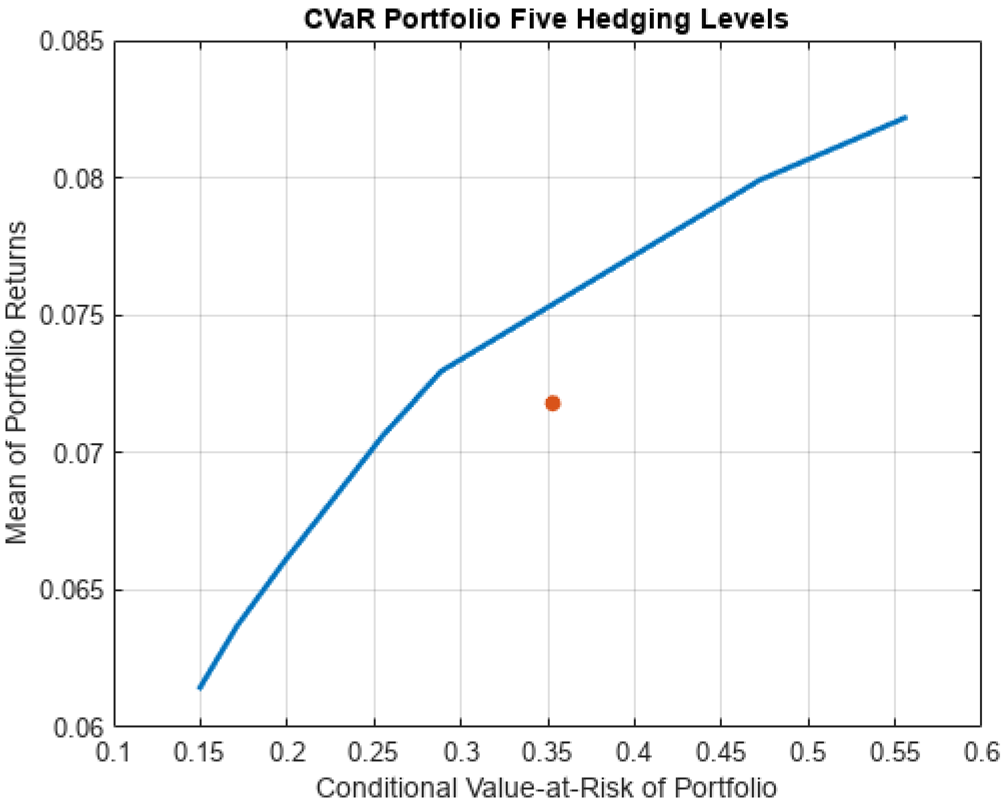


Plot the efficient mean-variance portfolio for the return `TargetRet` on the CVaR efficient frontier. Notice that the efficient mean-variance portfolio is below the CVaR efficient frontier.

```
% Obtain the mean-variance efficient portfolio at target return
pwgtmvTarget = estimateFrontierByReturn(pmv,TargetRet);

% Obtain the CVaR risk for the mean-variance efficient portfolio
pretTargetCVaR = estimatePortReturn(p,pwgtmvTarget); % Should be TargetRet
priskTargetCVaR = estimatePortRisk(p,pwgtmvTarget);  % Risk proxy is CVaR

% Plot mean-variance efficient portfolio onto the CVaR frontier
figure;
plotFrontier(p,pwgt);
hold on
scatter(priskTargetCVaR,pretTargetCVaR,[],'filled');
hold off
```



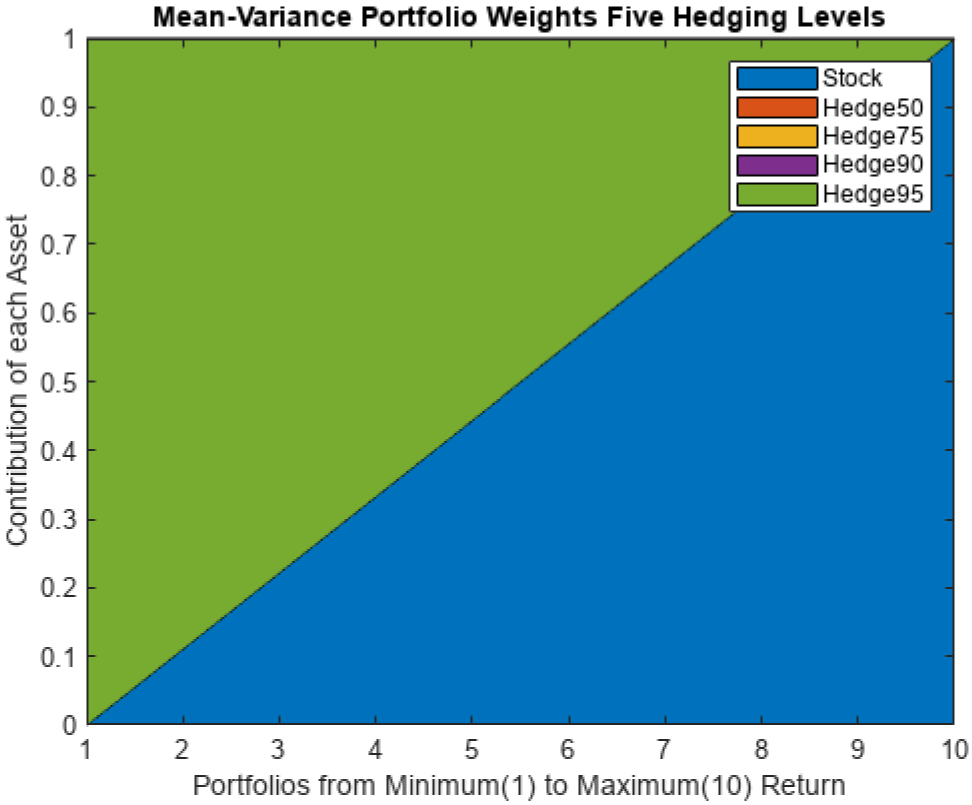
Since mean-variance and CVaR are two different risk measures, this example illustrates that the efficient portfolio for one type of risk measure is not efficient for the other.

CVaR and Mean-Variance Portfolio Weights Comparison

Examine the portfolio weights of the porfolios that make up each efficient frontier to obtain a more detailed comparison between the mean-variance and CVaR efficient frontiers.

Plot the weights associated with the mean-variance portfolio efficient frontier.

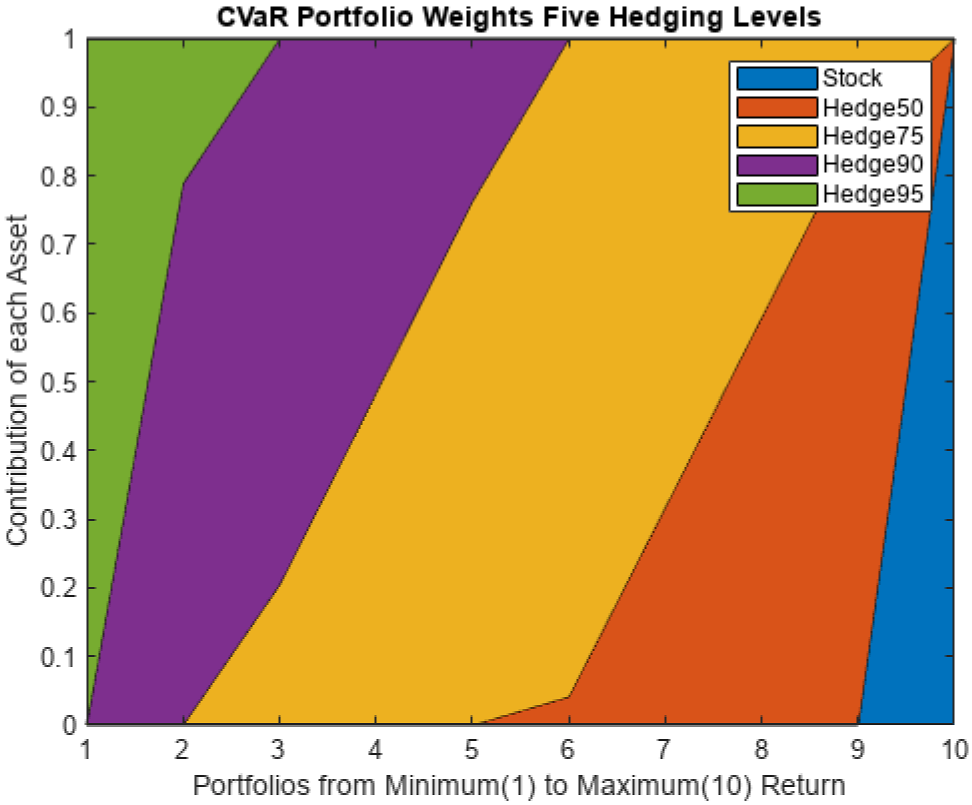
```
% Plot the mean-variance portfolio weights
figure;
area(pwgtmv');
legend(pmv.AssetList);
axis([1 10 0 1])
title('Mean-Variance Portfolio Weights Five Hedging Levels');
xlabel('Portfolios from Minimum(1) to Maximum(10) Return');
ylabel('Contribution of each Asset');
```



The weights associated with the mean-variance portfolios on the efficient frontier use only two strategies, `'Stock'` and `'Hedge95'`. This behavior is an effect of the correlations among the five assets in the portfolio. Because the correlations between the assests are close to 1, the standard deviation of the portfolio is almost a linear combination of the standard deviation of the assets. Hence, because assets with larger returns are associated with assets with larger variance, a linear combination of only the assets with the smallest and largest returns is observed in the efficient frontier.

Plot the weights associated with the CVaR portfolio efficient frontier.

```
% Plot the CVaR portfolio weights
figure;
area(pwgt');
legend(p.AssetList);
axis([1 10 0 1])
title('CVaR Portfolio Weights Five Hedging Levels');
xlabel('Portfolios from Minimum(1) to Maximum(10) Return');
ylabel('Contribution of each Asset');
```



For both types of portfolios, mean-variance and CVaR, the portfolio with the maximum expected return is the one that allocates all the weight to the stock-only strategy. This makes sense because no put options are acquired, which translates into larger returns. Also, the portfolio with minimum variance is the same for both risk measures. This portfolio is the one that allocates everything to `'Hedge95'` because that strategy limits the possible losses the most. The real differences between the two types of porfolios are observed for the return levels between the minimum and maximum. There, in contrast to the efficient portfolios obtained using variance as the measure of risk, the weights of the CVaR portfolios range among all five possible strategies.

Compute Maximum Reward-to-Risk Ratio for CVaR Portfolio

Create a `PortfolioCVaR` object and incorporate a list of assets from `CAPMUniverse.mat`. Use `simulateNormalScenariosByData` to simulate the scenarios for each of the assets. These portfolio constraints require fully invested long-only portfolios (nonnegative weights that must sum to 1).

```
rng(1) % Set the seed for reproducibility.
load CAPMuniverse

p = PortfolioCVaR('AssetList',Assets(1:12));
p = simulateNormalScenariosByData(p, Data(:,1:12), 20000 ,'missingdata',true);
p = setProbabilityLevel(p, 0.95);
p = setDefaultConstraints(p);
disp(p)
```

```
  PortfolioCVaR with properties:

```

To obtain the portfolio that maximizes the reward-to-risk ratio (which is equivalent to the Sharpe ratio for mean-variance portfolios), search on the efficient frontier iteratively for the porfolio that minimizes the negative of the reward-to-risk ratio:

$$-\frac{\text{portfolio return} - \text{risk free rate}}{\text{portfolio CVaR}}.$$

To do so, use the `sratio` function, defined in the Local Functions on page 5-132 section, to return the negative reward-to-risk ratio for a target return. Then, pass this function to `fminbnd`. `fminbnd` iterates through the possible return values and evaluates their associated reward-to-risk ratio. `fminbnd` returns the optimal return for which the maximum reward-to-risk ratio is achieved (or that minimizes the negative of the reward-to-risk ratio).

```
% Obtain the minimum and maximum returns of the portfolio.
pwgtLimits = estimateFrontierLimits(p);
retLimits = estimatePortReturn(p,pwgtLimits);
minret = retLimits(1);
maxret = retLimits(2);

% Search on the frontier iteratively. Find the return that minimizes the
% negative of the reward-to-risk ratio.
fhandle = @(ret) iterative_local_obj(ret,p);
options = optimset('Display', 'off', 'TolX', 1.0e-8);
optret = fminbnd(fhandle, minret, maxret, options);

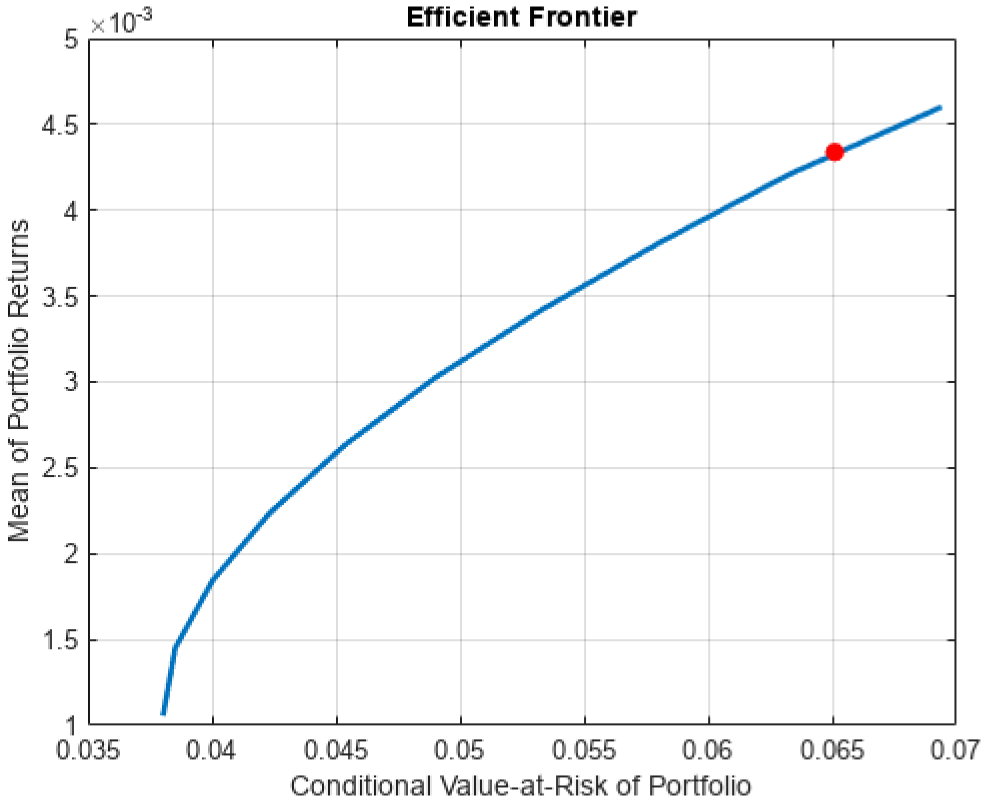
% Obtain the portfolio weights associated with the return that achieves
% the maximum reward-to-risk ratio.
pwgt = estimateFrontierByReturn(p,optret)
```

```
pwgt = 12×1

    0.0885
         0
         0
         0
         0
    0.9115
         0
         0
         0
         0
      ⋮
```

Use `plotFrontier` to plot the efficient frontier and `estimatePortRisk` to estimate the maximum reward-to-risk ratio portfolio.

```
plotFrontier(p);
hold on
% Compute the risk level for the maximum reward-to-risk ratio portfolio.
optrsk = estimatePortRisk(p,pwgt);
scatter(optrsk,optret,50,'red','filled')
hold off
```



Local Functions

This local function that computes the negative of the reward-to-risk ratio for a target return level.

```
function sratio = iterative_local_obj(ret, obj)
% Set the objective function to the negative of the reward-to-risk ratio.

risk = estimatePortRisk(obj,estimateFrontierByReturn(obj,ret));

if ~isempty(obj.RiskFreeRate)
    sratio = -(ret - obj.RiskFreeRate)/risk;
else
    sratio = -ret/risk;
end

end
```

Portfolio Optimization Theory

In this section...

Portfolio Optimization Problems

Portfolio optimization problems involve identifying portfolios that satisfy three criteria:

- Minimize a proxy for risk.
- Match or exceed a proxy for return.
- Satisfy basic feasibility requirements.

Portfolios are points from a feasible set of assets that constitute an asset universe. A portfolio specifies either holdings or weights in each individual asset in the asset universe. The convention is to specify portfolios in terms of weights, although the portfolio optimization tools work with holdings as well.

The set of feasible portfolios is necessarily a nonempty, closed, and bounded set. The proxy for risk is a function that characterizes either the variability or losses associated with portfolio choices. The proxy for return is a function that characterizes either the gross or net benefits associated with portfolio choices. The terms “risk” and “risk proxy” and “return” and “return proxy” are interchangeable. The fundamental insight of Markowitz (see “Portfolio Optimization” on page A-5) is that the goal of the portfolio choice problem is to seek minimum risk for a given level of return and to seek maximum return for a given level of risk. Portfolios satisfying these criteria are efficient portfolios and the graph of the risks and returns of these portfolios forms a curve called the efficient frontier.

Portfolio Problem Specification

To specify a portfolio optimization problem, you need the following:

- Proxy for portfolio return (μ)
- Proxy for portfolio risk (Σ)
- Set of feasible portfolios (X), called a portfolio set

Financial Toolbox has three objects to solve specific types of portfolio optimization problems:

- The `Portfolio` object supports mean-variance portfolio optimization (see Markowitz [46], [47] at “Portfolio Optimization” on page A-5). This object has either gross or net portfolio returns as the return proxy, the variance of portfolio returns as the risk proxy, and a portfolio set that is any combination of the specified constraints to form a portfolio set.
- The `PortfolioCVaR` object implements what is known as conditional value-at-risk portfolio optimization (see Rockafellar and Uryasev [48], [49] at “Portfolio Optimization” on page A-5), which is generally referred to as CVaR portfolio optimization. CVaR portfolio optimization works

with the same return proxies and portfolio sets as mean-variance portfolio optimization but uses conditional value-at-risk of portfolio returns as the risk proxy.

- The `PortfolioMAD` object implements what is known as mean-absolute deviation portfolio optimization (see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5), which is generally referred to as MAD portfolio optimization. MAD portfolio optimization works with the same return proxies and portfolio sets as mean-variance portfolio optimization but uses mean-absolute deviation portfolio returns as the risk proxy.

Return Proxy

The proxy for portfolio return is a function $\mu : X \rightarrow R$ on a portfolio set $X \subset R^n$ that characterizes the rewards associated with portfolio choices. Usually, the proxy for portfolio return has two general forms, gross and net portfolio returns. Both portfolio return forms separate the risk-free rate r_0 so that the portfolio $x \in X$ contains only risky assets.

Regardless of the underlying distribution of asset returns, a collection of S asset returns $y_1,...,y_S$ has a mean of asset returns

$$m = \frac{1}{S}\sum_{s=1}^{S} y_s,$$

and (sample) covariance of asset returns

$$C = \frac{1}{S-1}\sum_{s=1}^{S} (y_s - m)(y_s - m)^T .$$

These moments (or alternative estimators that characterize these moments) are used directly in mean-variance portfolio optimization to form proxies for portfolio risk and return.

Gross Portfolio Returns

The gross portfolio return for a portfolio $x \in X$ is

$$\mu(x) = r_0 + (m - r_0 1)^T x,$$

where:

r_0 is the risk-free rate (scalar).

m is the mean of asset returns (n vector).

If the portfolio weights sum to `1`, the risk-free rate is irrelevant. The properties in the `Portfolio` object to specify gross portfolio returns are:

- `RiskFreeRate` for r_0
- `AssetMean` for m

Net Portfolio Returns

The net portfolio return for a portfolio $x \in X$ is

$$\mu(x) = r_0 + (m - r_0 1)^T x - b^T \max\left\{0, x - x_0\right\} - s^T \max\left\{0, x_0 - x\right\},$$

where:

r_0 is the risk-free rate (scalar).

m is the mean of asset returns (n vector).

b is the proportional cost to purchase assets (n vector).

s is the proportional cost to sell assets (n vector).

You can incorporate fixed transaction costs in this model also. Though in this case, it is necessary to incorporate prices into such costs. The properties in the `Portfolio` object to specify net portfolio returns are:

- `RiskFreeRate` for r_0
- `AssetMean` for m
- `InitPort` for x_0
- `BuyCost` for b
- `SellCost` for s

Risk Proxy

The proxy for portfolio risk is a function $\sigma{:}X \rightarrow R$ on a portfolio set $X \subset R^n$ that characterizes the risks associated with portfolio choices.

Variance

The variance of portfolio returns for a portfolio $x \in X$ is

$$Variance(x) = x^T Cx$$

where C is the covariance of asset returns (`n`-by-`n` positive-semidefinite matrix).

The property in the `Portfolio` object to specify the variance of portfolio returns is `AssetCovar` for C.

Although the risk proxy in mean-variance portfolio optimization is the variance of portfolio returns, the square root, which is the standard deviation of portfolio returns, is often reported and displayed. Moreover, this quantity is often called the “risk” of the portfolio. For details, see Markowitz [46], [47] at (“Portfolio Optimization” on page A-5).

Conditional Value-at-Risk

The conditional value-at-risk for a portfolio $x \in X$, which is also known as expected shortfall, is defined as

$$CVaR_\alpha(x) = \frac{1}{1-\alpha} \int_{f(x,\,y) \geq VaR_\alpha(x)} f(x,y)p(y)dy,$$

where:

α is the probability level such that $0 < \alpha < 1$.

f(x,y) is the loss function for a portfolio *x* and asset return *y*.

p(y) is the probability density function for asset return *y*.

VaR_α is the value-at-risk of portfolio *x* at probability level α.

The value-at-risk is defined as

$$VaR_\alpha(x) = \min\{\gamma : \Pr[f(x, Y) \le \gamma] \ge \alpha\}\ .$$

An alternative formulation for CVaR has the form:

$$CVaR_\alpha(x) = VaR_\alpha(x) + \frac{1}{1-\alpha}\int_{R^n} \max\{0, (f(x, y) - VaR_\alpha(x))\} p(y) dy$$

The choice for the probability level α is typically 0.9 or 0.95. Choosing α implies that the value-at-risk $VaR_\alpha(x)$ for portfolio *x* is the portfolio return such that the probability of portfolio returns falling below this level is (1 –α). Given $VaR_\alpha(x)$ for a portfolio *x*, the conditional value-at-risk of the portfolio is the expected loss of portfolio returns above the value-at-risk return.

Note Value-at-risk is a positive value for losses so that the probability level α indicates the probability that portfolio returns are below the negative of the value-at-risk.

To describe the probability distribution of returns, the `PortfolioCVaR` object takes a finite sample of return scenarios y_s, with $s = 1,\ldots,S$. Each y_s is an *n* vector that contains the returns for each of the *n* assets under the scenario *s*. This sample of *S* scenarios is stored as a scenario matrix of size *S*-by-*n*. Then, the risk proxy for CVaR portfolio optimization, for a given portfolio $x \in X$ and $\alpha \in (0, 1)$, is computed as

$$CVaR_\alpha(x) = VaR_\alpha(x) + \frac{1}{(1-\alpha)S}\sum_{s=1}^{S} \max\left\{0,\ -y_s^T x - VaR_\alpha(x)\right\}$$

The value-at-risk, $VaR_\alpha(x)$, is estimated whenever the CVaR is estimated. The loss function is $f(x, y_s) = -y_s^T x$, which is the portfolio loss under scenario *s*.

Under this definition, VaR and CVaR are sample estimators for VaR and CVaR based on the given scenarios. Better scenario samples yield more reliable estimates of VaR and CVaR.

For more information, see Rockafellar and Uryasev [48], [49], and Cornuejols and Tütüncü, [51], at “Portfolio Optimization” on page A-5.

Mean Absolute-Deviation

The mean-absolute deviation (MAD) for a portfolio $x \in X$ is defined as

$$MAD(x) = \frac{1}{S}\sum_{s=1}^{S} \left|(y_s - m)^T x\right|$$

where:

y_s are asset returns with scenarios $s = 1,\ldots S$ (*S* collection of *n* vectors).

f(x,y) is the loss function for a portfolio *x* and asset return *y*.

m is the mean of asset returns (*n* vector).

such that

$$m = \frac{1}{S}\sum_{s=1}^{S} y_s$$

For more information, see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5.

Portfolio Set for Optimization Using PortfolioMAD Object

The final element for a complete specification of a portfolio optimization problem is the set of feasible portfolios, which is called a portfolio set. A portfolio set $X \subset R^n$ is specified by construction as the intersection of sets formed by a collection of constraints on portfolio weights. A portfolio set necessarily and sufficiently must be a nonempty, closed, and bounded set.

When setting up your portfolio set, ensure that the portfolio set satisfies these conditions. The most basic or “default” portfolio set requires portfolio weights to be nonnegative (using the lower-bound constraint) and to sum to `1` (using the budget constraint). The most general portfolio set handled by the portfolio optimization tools can have any of these constraints and which are properties for the `PortfolioMAD` object:

- Linear inequality constraints
- Linear equality constraints
- `'Simple'` Bound constraints
- `'Conditional'` Bond constraints
- Budget constraints
- Group constraints
- Group ratio constraints
- Average turnover constraints
- One-way turnover constraints
- Cardinality constraints

Linear Inequality Constraints

Linear inequality constraints are general linear constraints that model relationships among portfolio weights that satisfy a system of inequalities. Linear inequality constraints take the form

$$A_I x \leq b_I$$

where:

x is the portfolio (n vector).

A_I is the linear inequality constraint matrix (n_I-by-n matrix).

b_I is the linear inequality constraint vector (n_I vector).

n is the number of assets in the universe and n_I is the number of constraints.

`PortfolioMAD` object properties to specify linear inequality constraints are:

- `AInequality` for A_I
- `bInequality` for b_I
- `NumAssets` for n

The default is to ignore these constraints.

Linear Equality Constraints

Linear equality constraints are general linear constraints that model relationships among portfolio weights that satisfy a system of equalities. Linear equality constraints take the form

$$A_E x = b_E$$

where:

x is the portfolio (n vector).

A_E is the linear equality constraint matrix (n_E-by-n matrix).

b_E is the linear equality constraint vector (n_E vector).

n is the number of assets in the universe and n_E is the number of constraints.

`PortfolioMAD` object properties to specify linear equality constraints are:

- `AEquality` for A_E
- `bEquality` for b_E
- `NumAssets` for n

The default is to ignore these constraints.

'Simple' Bound Constraints

`'Simple'` Bound constraints are specialized linear constraints that confine portfolio weights to fall either above or below specific bounds. Since every portfolio set must be bounded, it is often a good practice, albeit not necessary, to set explicit bounds for the portfolio problem. To obtain explicit bounds for a given portfolio set, use the `estimateBounds` function. Bound constraints take the form

$$l_B \leq x \leq u_B$$

where:

x is the portfolio (n vector).

l_B is the lower-bound constraint (n vector).

u_B is the upper-bound constraint (n vector).

n is the number of assets in the universe.

`PortfolioMAD` object properties to specify bound constraints are:

- `LowerBound` for l_B
- `UpperBound` for u_B
- `NumAssets` for n

The default is to ignore these constraints.

The default portfolio optimization problem (see “Default Portfolio Problem” on page 6-14) has l_B = `0` with u_B set implicitly through a budget constraint.

'Conditional' Bound Constraints

`'Conditional'` Bound constraints, also called semicontinuous constraints, are mixed-integer linear constraints that confine portfolio weights to fall either above or below specific bounds *if* the asset is selected; otherwise, the value of the asset is zero. Use `setBounds` to specify bound constraints with a `'Conditional'` `BoundType`. To mathematically formulate this type of constraints, a binary variable v_i is needed. $v_i = 0$ indicates that asset i is not selected and v_i indicates that the asset was selected. Thus

$$l_i v_i \leq x_i \leq u_i v_i$$

where

x is the portfolio (n vector).

l is the conditional lower-bound constraint (n vector).

u is the conditional upper-bound constraint (n vector).

n is the number of assets in the universe.

`PortfolioMAD` object properties to specify the bound constraint are:

- `LowerBound` for l_B
- `UpperBound` for u_B
- `NumAssets` for n

The default is to ignore this constraint.

Budget Constraints

Budget constraints are specialized linear constraints that confine the sum of portfolio weights to fall either above or below specific bounds. The constraints take the form

$$l_S \leq 1^T x \leq u_S$$

where:

x is the portfolio (n vector).

`1` is the vector of ones (n vector).

l_S is the lower-bound budget constraint (scalar).

u_S is the upper-bound budget constraint (scalar).

n is the number of assets in the universe.

`PortfolioMAD` object properties to specify budget constraints are:

- `LowerBudget` for l_S
- `UpperBudget` for u_S
- `NumAssets` for n

The default is to ignore this constraint.

The default portfolio optimization problem (see “Default Portfolio Problem” on page 6-14) has $l_S = u_S = 1$, which means that the portfolio weights sum to 1. If the portfolio optimization problem includes possible movements in and out of cash, the budget constraint specifies how far portfolios can go into cash. For example, if $l_S = 0$ and $u_S = 1$, then the portfolio can have 0–100% invested in cash. If cash is to be a portfolio choice, set RiskFreeRate (r_0) to a suitable value (see “Return Proxy” on page 6-3 and “Working with a Riskless Asset” on page 6-43).

Group Constraints

Group constraints are specialized linear constraints that enforce “membership” among groups of assets. The constraints take the form

$$l_G \le Gx \le u_G$$

where:

x is the portfolio (n vector).

l_G is the lower-bound group constraint (n_G vector).

u_G is the upper-bound group constraint (n_G vector).

G is the matrix of group membership indexes (n_G-by-n matrix).

Each row of G identifies which assets belong to a group associated with that row. Each row contains either 0s or 1s with 1 indicating that an asset is part of the group or 0 indicating that the asset is not part of the group.

PortfolioMAD object properties to specify group constraints are:

- GroupMatrix for G
- LowerGroup for l_G
- UpperGroup for u_G
- NumAssets for n

The default is to ignore these constraints.

Group Ratio Constraints

Group ratio constraints are specialized linear constraints that enforce relationships among groups of assets. The constraints take the form

$$l_{Ri}(G_Bx)_i \le (G_Ax)_i \le u_{Ri}(G_Bx)_i$$

for $i = 1,\ldots, n_R$ where:

x is the portfolio (n vector).

l_R is the vector of lower-bound group ratio constraints (n_R vector).

u_R is the vector matrix of upper-bound group ratio constraints (n_R vector).

G_A is the matrix of base group membership indexes (n_R-by-n matrix).

G_B is the matrix of comparison group membership indexes (n_R-by-n matrix).

n is the number of assets in the universe and n_R is the number of constraints.

Each row of G_A and G_B identifies which assets belong to a base and comparison group associated with that row.

Each row contains either `0`s or `1`s with `1` indicating that an asset is part of the group or `0` indicating that the asset is not part of the group.

`PortfolioMAD` object properties to specify group ratio constraints are:

- `GroupA` for G_A
- `GroupB` for G_B
- `LowerRatio` for l_R
- `UpperRatio` for u_R
- `NumAssets` for n

The default is to ignore these constraints.

Average Turnover Constraints

Turnover constraint is a linear absolute value constraint that ensures estimated optimal portfolios differ from an initial portfolio by no more than a specified amount. Although portfolio turnover is defined in many ways, the turnover constraints implemented in Financial Toolbox compute portfolio turnover as the average of purchases and sales. Average turnover constraints take the form

$$\frac{1}{2}1^T\left|x - x_0\right| \leq \tau$$

where:

x is the portfolio (n vector).

`1` is the vector of ones (n vector).

x_0 is the initial portfolio (n vector).

τ is the upper bound for turnover (scalar).

n is the number of assets in the universe.

`PortfolioMAD` object properties to specify the average turnover constraint are:

- `Turnover` for τ
- `InitPort` for x_0
- `NumAssets` for n

The default is to ignore this constraint.

One-way Turnover Constraints

One-way turnover constraints ensure that estimated optimal portfolios differ from an initial portfolio by no more than specified amounts according to whether the differences are purchases or sales. The constraints take the forms

$$1^T \times \max\{0, x - x_0\} \leq \tau_B$$

$$1^T \times \max\{0, x_0 - x\} \leq \tau_S$$

where:

x is the portfolio (n vector)

`1` is the vector of ones (n vector).

x_0 is the Initial portfolio (n vector).

τ_B is the upper bound for turnover constraint on purchases (scalar).

τ_S is the upper bound for turnover constraint on sales (scalar).

To specify one-way turnover constraints, use the following properties in the `PortfolioMAD` object:

- `BuyTurnover` for τ_B
- `SellTurnover` for τ_S
- `InitPort` for x_0

The default is to ignore this constraint.

Note The average turnover constraint (see “Working with Average Turnover Constraints Using PortfolioMAD Object” on page 6-70) with τ is not a combination of the one-way turnover constraints with $\tau = \tau_B = \tau_S$.

Cardinality Constraints

Cardinality constraint limits the number of assets in the optimal allocation for an `PortfolioMAD` object. Use `setMinMaxNumAssets` to specify the `'MinNumAssets'` and `'MaxNumAssets'` constraints. To mathematically formulate this type of constraints, a binary variable v_i is needed. $v_i = 0$ indicates that asset i is not selected and $v_i = 1$ indicates that the asset was selected. Thus

$$MinNumAssets \leq \sum_{i=1}^{NumAssets} v_i \leq MaxNumAssets$$

The default is to ignore this constraint.

More About

- "PortfolioMAD Object" on page 6-16
- "Default Portfolio Problem" on page 6-14
- "PortfolioMAD Object Workflow" on page 6-15

Default Portfolio Problem

The default portfolio optimization problem has a risk and return proxy associated with a given problem, and a portfolio set that specifies portfolio weights to be nonnegative and to sum to 1. The lower bound combined with the budget constraint is sufficient to ensure that the portfolio set is nonempty, closed, and bounded. The default portfolio optimization problem characterizes a long-only investor who is fully invested in a collection of assets.

- For mean-variance portfolio optimization, it is sufficient to set up the default problem. After setting up the problem, data in the form of a mean and covariance of asset returns are then used to solve portfolio optimization problems.
- For conditional value-at-risk portfolio optimization, the default problem requires the additional specification of a probability level that must be set explicitly. Generally, “typical” values for this level are 0.90 or 0.95. After setting up the problem, data in the form of scenarios of asset returns are then used to solve portfolio optimization problems.
- For MAD portfolio optimization, it is sufficient to set up the default problem. After setting up the problem, data in the form of scenarios of asset returns are then used to solve portfolio optimization problems.

PortfolioMAD Object Workflow

The `PortfolioMAD` object workflow for creating and modeling a MAD portfolio is:

1. Create a MAD Portfolio.

   Create a `PortfolioMAD` object for mean-absolute deviation (MAD) portfolio optimization. For more information, see “Creating the PortfolioMAD Object” on page 6-21.
2. Define asset returns and scenarios.

   Evaluate scenarios for portfolio asset returns, including assets with missing data and financial time series data. For more information, see “Asset Returns and Scenarios Using PortfolioMAD Object” on page 6-34.
3. Specify the MAD Portfolio Constraints.

   Define the constraints for portfolio assets such as linear equality and inequality, bound, budget, group, group ratio, and turnover constraints, `'Conditional'` `BoundType`, and `MinNumAssets`, `MaxNumAssets` constraints. For more information, see “Working with MAD Portfolio Constraints Using Defaults” on page 6-48 and “Working with 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints Using PortfolioMAD Objects” on page 6-67.
4. Validate the MAD Portfolio.

   Identify errors for the portfolio specification. For more information, see “Validate the MAD Portfolio Problem” on page 6-76.
5. Estimate the efficient portfolios and frontiers.

   Analyze the efficient portfolios and efficient frontiers for a portfolio. For more information, see “Estimate Efficient Portfolios Along the Entire Frontier for PortfolioMAD Object” on page 6-80 and “Estimate Efficient Frontiers for PortfolioMAD Object” on page 6-97.
6. Postprocess the results.

   Use the efficient portfolios and efficient frontiers results to set up trades. For more information, see “Postprocessing Results to Set Up Tradable Portfolios” on page 6-105.

In this section...

PortfolioMAD Object Properties and Functions

The `PortfolioMAD` object implements mean absolute-deviation (MAD) portfolio optimization and is derived from the abstract class `AbstractPortfolio`. Every property and function of the `PortfolioMAD` object is public, although some properties and functions are hidden. The `PortfolioMAD` object is a value object where every instance of the object is a distinct version of the object. Since the `PortfolioMAD` object is also a MATLAB object, it inherits the default functions associated with MATLAB objects.

Working with PortfolioMAD Objects

The `PortfolioMAD` object and its functions are an interface for mean absolute-deviation portfolio optimization. So, almost everything you do with the `PortfolioMAD` object can be done using the functions. The basic workflow is:

1. Design your portfolio problem.
2. Use `PortfolioMAD` to create the `PortfolioMAD` object or use the various set functions to set up your portfolio problem.
3. Use estimate functions to solve your portfolio problem.

In addition, functions are available to help you view intermediate results and to diagnose your computations. Since MATLAB features are part of a `PortfolioMAD` object, you can save and load objects from your workspace and create and manipulate arrays of objects. After settling on a problem, which, in the case of MAD portfolio optimization, means that you have either scenarios, data, or moments for asset returns, and a collection of constraints on your portfolios, use `PortfolioMAD` to set the properties for the `PortfolioMAD` object.

`PortfolioMAD` lets you create an object from scratch or update an existing object. Since the `PortfolioMAD` object is a value object, it is easy to create a basic object, then use functions to build upon the basic object to create new versions of the basic object. This is useful to compare a basic problem with alternatives derived from the basic problem. For details, see “Creating the PortfolioMAD Object” on page 6-21.

Setting and Getting Properties

You can set properties of a PortfolioMAD object using either PortfolioMAD or various set functions.

Note Although you can also set properties directly, it is not recommended since error-checking is not performed when you set a property directly.

The PortfolioMAD object supports setting properties with name-value pair arguments such that each argument name is a property and each value is the value to assign to that property. For example, to set the LowerBound and Budget properties in an existing PortfolioMAD object p, use the syntax:

```
p = PortfolioMAD(p,'LowerBound', 0,'Budget',1);
```

In addition to the PortfolioMAD object, which lets you set individual properties one at a time, groups of properties are set in a PortfolioMAD object with various “set” and “add” functions. For example, to set up an average turnover constraint, use the setTurnover function to specify the bound on portfolio turnover and the initial portfolio. To get individual properties from a PortfolioMAD object, obtain properties directly or use an assortment of “get” functions that obtain groups of properties from a PortfolioMAD object. The PortfolioMAD object and set functions have several useful features:

- The PortfolioMAD object and set functions try to determine the dimensions of your problem with either explicit or implicit inputs.
- The PortfolioMAD object and set functions try to resolve ambiguities with default choices.
- The PortfolioMAD object and set functions perform scalar expansion on arrays when possible.
- The PortfolioMAD functions try to diagnose and warn about problems.

Displaying PortfolioMAD Objects

The PortfolioMAD object uses the default display function provided by MATLAB, where display and disp display a PortfolioMAD object and its properties with or without the object variable name.

Saving and Loading PortfolioMAD Objects

Save and load PortfolioMAD objects using the MATLAB save and load commands.

Estimating Efficient Portfolios and Frontiers

Estimating efficient portfolios and efficient frontiers is the primary purpose of the MAD portfolio optimization tools. An efficient portfolio are the portfolios that satisfy the criteria of minimum risk for a given level of return and maximum return for a given level of risk. A collection of “estimate” and “plot” functions provide ways to explore the efficient frontier. The “estimate” functions obtain either efficient portfolios or risk and return proxies to form efficient frontiers. At the portfolio level, a collection of functions estimates efficient portfolios on the efficient frontier with functions to obtain efficient portfolios:

- At the endpoints of the efficient frontier
- That attain targeted values for return proxies
- That attain targeted values for risk proxies
- Along the entire efficient frontier

These functions also provide purchases and sales needed to shift from an initial or current portfolio to each efficient portfolio. At the efficient frontier level, a collection of functions plot the efficient frontier and estimate either risk or return proxies for efficient portfolios on the efficient frontier. You can use the resultant efficient portfolios or risk and return proxies in subsequent analyses.

Arrays of PortfolioMAD Objects

Although all functions associated with a `PortfolioMAD` object are designed to work on a scalar `PortfolioMAD` object, the array capabilities of MATLAB enable you to set up and work with arrays of `PortfolioMAD` objects. The easiest way to do this is with the `repmat` function. For example, to create a 3-by-2 array of `PortfolioMAD` objects:

```
p = repmat(PortfolioMAD, 3, 2);
disp(p)
```

```
3×2 PortfolioMAD array with properties:

    BuyCost
    SellCost
    RiskFreeRate
    Turnover
    BuyTurnover
    SellTurnover
    NumScenarios
    Name
    NumAssets
    AssetList
    InitPort
    AInequality
    bInequality
    AEquality
    bEquality
    LowerBound
    UpperBound
    LowerBudget
    UpperBudget
    GroupMatrix
    LowerGroup
    UpperGroup
    GroupA
    GroupB
    LowerRatio
    UpperRatio
    MinNumAssets
    MaxNumAssets
    BoundType
```

After setting up an array of `PortfolioMAD` objects, you can work on individual `PortfolioMAD` objects in the array by indexing. For example:

```
p(i,j) = PortfolioMAD(p(i,j), ... );
```

This example calls `PortfolioMAD` for the (`i`,`j`) element of a matrix of `PortfolioMAD` objects in the variable `p`.

If you set up an array of `PortfolioMAD` objects, you can access properties of a particular `PortfolioMAD` object in the array by indexing so that you can set the lower and upper bounds `lb` and `ub` for the (`i`,`j`,`k`) element of a 3-D array of `PortfolioMAD` objects with

```
p(i,j,k) = setBounds(p(i,j,k),lb, ub);
```

and, once set, you can access these bounds with

```
[lb, ub] = getBounds(p(i,j,k));
```

`PortfolioMAD` object functions work on only one `PortfolioMAD` object at a time.

Subclassing PortfolioMAD Objects

You can subclass the `PortfolioMAD` object to override existing functions or to add new properties or functions. To do so, create a derived class from the `PortfolioMAD` class. This gives you all the properties and functions of the `PortfolioMAD` class along with any new features that you choose to add to your subclassed object. The `PortfolioMAD` class is derived from an abstract class called `AbstractPortfolio`. Because of this, you can also create a derived class from `AbstractPortfolio` that implements an entirely different form of portfolio optimization using properties and functions of the `AbstractPortfolio` class.

Conventions for Representation of Data

The MAD portfolio optimization tools follow these conventions regarding the representation of different quantities associated with portfolio optimization:

- Asset returns or prices for scenarios are in matrix form with samples for a given asset going down the rows and assets going across the columns. In the case of prices, the earliest dates must be at the top of the matrix, with increasing dates going down.
- Portfolios are in vector or matrix form with weights for a given portfolio going down the rows and distinct portfolios going across the columns.
- Constraints on portfolios are formed in such a way that a portfolio is a column vector.
- Portfolio risks and returns are either scalars or column vectors (for multiple portfolio risks and returns).

Creating the PortfolioMAD Object

In this section...

To create a fully specified MAD portfolio optimization problem, instantiate the `PortfolioMAD` object using `PortfolioMAD`. For information on the workflow when using `PortfolioMAD` objects, see "PortfolioMAD Object Workflow" on page 6-15.

Syntax

Use `PortfolioMAD` to create an instance of an object of the `PortfolioMAD` class. You can use the `PortfolioMAD` object in several ways. To set up a portfolio optimization problem in a `PortfolioMAD` object, the simplest syntax is:

```
p = PortfolioMAD;
```

This syntax creates a `PortfolioMAD` object, `p`, such that all object properties are empty.

The `PortfolioMAD` object also accepts collections of argument name-value pair arguments for properties and their values. The `PortfolioMAD` object accepts inputs for public properties with the general syntax:

```
    p = PortfolioMAD('property1', value1, 'property2', value2, ... );
```

If a `PortfolioMAD` object already exists, the syntax permits the first (and only the first argument) of `PortfolioMAD` to be an existing object with subsequent argument name-value pair arguments for properties to be added or modified. For example, given an existing `PortfolioMAD` object in `p`, the general syntax is:

```
p = PortfolioMAD(p, 'property1', value1, 'property2', value2, ... );
```

Input argument names are not case-sensitive, but must be completely specified. In addition, several properties can be specified with alternative argument names (see "Shortcuts for Property Names" on page 6-25). The `PortfolioMAD` object tries to detect problem dimensions from the inputs and, once set, subsequent inputs can undergo various scalar or matrix expansion operations that simplify the overall process to formulate a problem. In addition, a `PortfolioMAD` object is a value object so that, given portfolio `p`, the following code creates two objects, `p` and `q`, that are distinct:

```
q = PortfolioMAD(p, ...)
```

PortfolioMAD Problem Sufficiency

A MAD portfolio optimization problem is completely specified with the `PortfolioMAD` object if the following three conditions are met:

- You must specify a collection of asset returns or prices known as scenarios such that all scenarios are finite asset returns or prices. These scenarios are meant to be samples from the underlying probability distribution of asset returns. This condition can be satisfied by the `setScenarios` function or with several canned scenario simulation functions.

- The set of feasible portfolios must be a nonempty compact set, where a compact set is closed and bounded. You can satisfy this condition using an extensive collection of properties that define different types of constraints to form a set of feasible portfolios. Since such sets must be bounded, either explicit or implicit constraints can be imposed and several tools, such as the `estimateBounds` function, provide ways to ensure that your problem is properly formulated.

  Although the general sufficient conditions for MAD portfolio optimization go beyond these conditions, the `PortfolioMAD` object handles all these additional conditions.

PortfolioMAD Function Examples

If you create a `PortfolioMAD` object, `p`, with no input arguments, you can display it using `disp`:

```
p = PortfolioMAD;
disp(p)
```

```
 PortfolioMAD with properties:

         BuyCost: []
        SellCost: []
    RiskFreeRate: []
        Turnover: []
     BuyTurnover: []
    SellTurnover: []
    NumScenarios: []
            Name: []
       NumAssets: []
       AssetList: []
        InitPort: []
     AInequality: []
     bInequality: []
       AEquality: []
       bEquality: []
      LowerBound: []
      UpperBound: []
     LowerBudget: []
     UpperBudget: []
     GroupMatrix: []
      LowerGroup: []
      UpperGroup: []
          GroupA: []
          GroupB: []
      LowerRatio: []
      UpperRatio: []
    MinNumAssets: []
    MaxNumAssets: []
       BoundType: []
```

The approaches listed provide a way to set up a portfolio optimization problem with the `PortfolioMAD` object. The custom set functions offer additional ways to set and modify collections of properties in the `PortfolioMAD` object.

Using the PortfolioMAD Function for a Single-Step Setup

You can use the `PortfolioMAD` object to directly set up a “standard” portfolio optimization problem. Given scenarios of asset returns in the variable `AssetScenarios`, this problem is completely specified as follows:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD('Scenarios', AssetScenarios, ...
'LowerBound', 0, 'LowerBudget', 1, 'UpperBudget', 1)
```

```
p = 

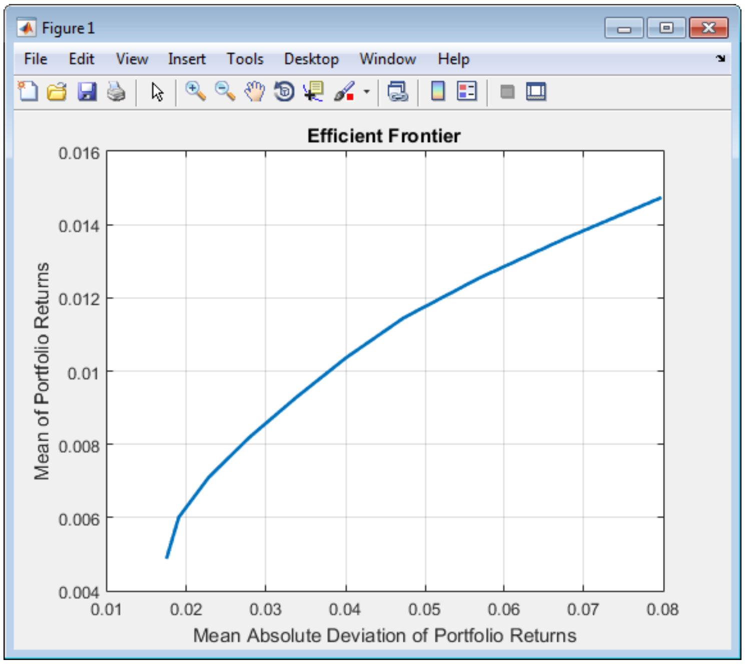
  PortfolioMAD with properties:

         BuyCost: []
        SellCost: []
    RiskFreeRate: []
        Turnover: []
     BuyTurnover: []
    SellTurnover: []
    NumScenarios: 20000
            Name: []
       NumAssets: 4
       AssetList: []
        InitPort: []
     AInequality: []
     bInequality: []
       AEquality: []
       bEquality: []
      LowerBound: [4×1 double]
      UpperBound: []
     LowerBudget: 1
     UpperBudget: 1
     GroupMatrix: []
      LowerGroup: []
      UpperGroup: []
          GroupA: []
          GroupB: []
      LowerRatio: []
      UpperRatio: []
    MinNumAssets: []
    MaxNumAssets: []
       BoundType: []
```

The LowerBound property value undergoes scalar expansion since AssetScenarios provides the dimensions of the problem.

You can use dot notation with the function plotFrontier.

```
p.plotFrontier
```



Using the PortfolioMAD Function with a Sequence of Steps

An alternative way to accomplish the same task of setting up a “standard” MAD portfolio optimization problem, given `AssetScenarios` variable is:

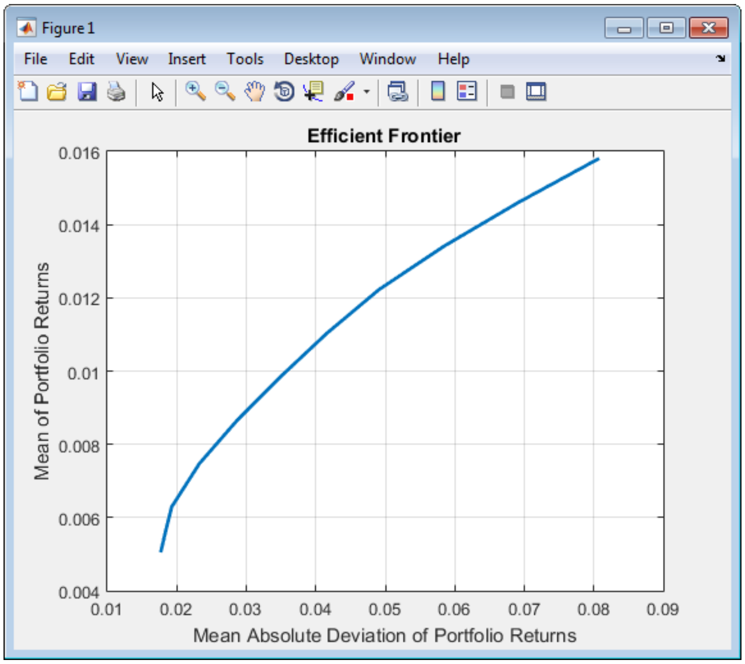
```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = PortfolioMAD(p, 'LowerBound', 0);
p = PortfolioMAD(p, 'LowerBudget', 1, 'UpperBudget', 1);

plotFrontier(p);
```



This way works because the calls to the `PortfolioMAD` object are in this particular order. In this case, the call to initialize `AssetScenarios` provides the dimensions for the problem. If you were to do this step last, you would have to explicitly dimension the `LowerBound` property as follows:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = PortfolioMAD(p, 'LowerBound', zeros(size(m)));
p = PortfolioMAD(p, 'LowerBudget', 1, 'UpperBudget', 1);
p = setScenarios(p, AssetScenarios);
```

Note If you did not specify the size of `LowerBound` but, instead, input a scalar argument, the `PortfolioMAD` object assumes that you are defining a single-asset problem and produces an error at the call to set asset scenarios with four assets.

Shortcuts for Property Names

The `PortfolioMAD` object has shorter argument names that replace longer argument names associated with specific properties of the `PortfolioMAD` object. For example, rather than enter `'AInequality'`, the `PortfolioMAD` object accepts the case-insensitive name `'ai'` to set the `AInequality` property in a `PortfolioMAD` object. Every shorter argument name corresponds with a single property in the `PortfolioMAD` object. The one exception is the alternative argument name 'budget', which signifies both the LowerBudget and UpperBudget properties. When 'budget' is used, then the LowerBudget and UpperBudget properties are set to the same value to form an equality budget constraint.

Shortcuts for Property Names

Shortcut Argument Name	Equivalent Argument / Property Name
ae	AEquality
ai	AInequality
assetnames or assets	AssetList
be	bEquality
bi	bInequality
budget	UpperBudget and LowerBudget
group	GroupMatrix
lb	LowerBound
n or num	NumAssets
rfr	RiskFreeRate
scenario or assetscenarios	Scenarios
ub	UpperBound

For example, this call to PortfolioMAD uses these shortcuts for properties:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD('scenario', AssetScenarios, 'lb', 0, 'budget', 1);
plotFrontier(p);
```

Direct Setting of Portfolio Object Properties

Although not recommended, you can set properties directly using dot notation, however no error-checking is done on your inputs:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;

p = setScenarios(p, AssetScenarios);
```

```
p.LowerBudget = 1;
p.UpperBudget = 1;
p.LowerBound = zeros(size(m));

plotFrontier(p);
```

Note Scenarios cannot be assigned directly using dot notation to a `PortfolioMAD` object. Scenarios must always be set through either the `PortfolioMAD` object, the `setScenarios` function, or any of the scenario simulation functions.

Common Operations on the PortfolioMAD Object

In this section...

Naming a PortfolioMAD Object

To name a `PortfolioMAD` object, use the `Name` property. `Name` is informational and has no effect on any portfolio calculations. If the `Name` property is nonempty, `Name` is the title for the efficient frontier plot generated by `plotFrontier`. For example, if you set up an asset allocation fund, you could name the `PortfolioMAD` object Asset Allocation Fund:

```
p = PortfolioMAD('Name','Asset Allocation Fund');
disp(p.Name);
Asset Allocation Fund
```

Configuring the Assets in the Asset Universe

The fundamental quantity in the `PortfolioMAD` object is the number of assets in the asset universe. This quantity is maintained in the `NumAssets` property. Although you can set this property directly, it is usually derived from other properties such as the number of assets in the scenarios or the initial portfolio. In some instances, the number of assets may need to be set directly. This example shows how to set up a `PortfolioMAD` object that has four assets:

```
p = PortfolioMAD('NumAssets', 4);
disp(p.NumAssets)
```

```
4
```

After setting the `NumAssets` property, you cannot modify it (unless no other properties are set that depend on `NumAssets`). The only way to change the number of assets in an existing `PortfolioMAD` object with a known number of assets is to create a new `PortfolioMAD` object.

Setting Up a List of Asset Identifiers

When working with portfolios, you must specify a universe of assets. Although you can perform a complete analysis without naming the assets in your universe, it is helpful to have an identifier associated with each asset as you create and work with portfolios. You can create a list of asset identifiers as a cell vector of character vectors in the property `AssetList`. You can set up the list using the next two methods.

Setting Up Asset Lists Using the PortfolioMAD Function

Suppose that you have a `PortfolioMAD` object, `p`, with assets with symbols `'AA''`, `'BA'`, `'CAT'`, `'DD'`, and `'ETR'`. You can create a list of these asset symbols in the object using `PortfolioMAD`:

```
p = PortfolioMAD('assetlist', { 'AA', 'BA', 'CAT', 'DD', 'ETR' });
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

Notice that the property `AssetList` is maintained as a cell array that contains character vectors, and that it is necessary to pass a cell array into `PortfolioMAD` to set `AssetList`. In addition, notice that the property `NumAssets` is set to `5` based on the number of symbols used to create the asset list:

```
disp(p.NumAssets)
```

```
5
```

Setting Up Asset Lists Using the setAssetList Function

You can also specify a list of assets using the `setAssetList` function. Given the list of asset symbols `'AA'`, `'BA'`, `'CAT'`, `'DD'`, and`'ETR'`, you can use `setAssetList` with:

```
p = PortfolioMAD;
p = setAssetList(p, { 'AA', 'BA', 'CAT', 'DD', 'ETR' });
disp(p.AssetList)
```

```
 'AA'    'BA'    'CAT'    'DD'    'ETR'
```

`setAssetList` also enables you to enter symbols directly as a comma-separated list without creating a cell array of character vectors. For example, given the list of assets symbols `'AA'`, `'BA'`, `'CAT'`, `'DD'`, and `'ETR'`, use `setAssetList`:

```
p = PortfolioMAD;
p = setAssetList(p, 'AA', 'BA', 'CAT', 'DD', 'ETR');
disp(p.AssetList)
```

```
 'AA'    'BA'    'CAT'    'DD'    'ETR'
```

`setAssetList` has many additional features to create lists of asset identifiers. If you use `setAssetList` with just a `PortfolioMAD` object, it creates a default asset list according to the name specified in the hidden public property `defaultforAssetList` (which is `'Asset'` by default). The number of asset names created depends on the number of assets in the property `NumAssets`. If `NumAssets` is not set, then `NumAssets` is assumed to be `1`.

For example, if a `PortfolioMAD` object `p` is created with `NumAssets` = `5`, then this code fragment shows the default naming behavior:

```
p = PortfolioMAD('numassets',5);
p = setAssetList(p);
disp(p.AssetList)
```

```
'Asset1'    'Asset2'    'Asset3'    'Asset4'    'Asset5'
```

Suppose that your assets are, for example, ETFs and you change the hidden property `defaultforAssetList` to `'ETF'`, you can then create a default list for ETFs:

```
p = PortfolioMAD('numassets',5);
p.defaultforAssetList = 'ETF';
p = setAssetList(p);
disp(p.AssetList)
```

```
'ETF1'    'ETF2'    'ETF3'    'ETF4'    'ETF5'
```

Truncating and Padding Asset Lists

If the NumAssets property is already set and you pass in too many or too few identifiers, the PortfolioMAD object, and the setAssetList function truncate or pad the list with numbered default asset names that use the name specified in the hidden public property defaultforAssetList. If the list is truncated or padded, a warning message indicates the discrepancy. For example, assume that you have a PortfolioMAD object with five ETFs and you only know the first three CUSIPs '921937835', '922908769', and '922042775'. Use this syntax to create an asset list that pads the remaining asset identifiers with numbered 'UnknownCUSIP' placeholders:

```
p = PortfolioMAD('numassets',5);
p.defaultforAssetList = 'UnknownCUSIP';
p = setAssetList(p, '921937835', '922908769', '922042775');
disp(p.AssetList)
```

```
Warning: Input list of assets has 2 too few identifiers. Padding with numbered
assets.
> In PortfolioMAD.setAssetList at 121
  Columns 1 through 4

    '921937835'    '922908769'    '922042775'    'UnknownCUSIP4'

  Column 5

    'UnknownCUSIP5'
```

Alternatively, suppose that you have too many identifiers and need only the first four assets. This example illustrates truncation of the asset list using the PortfolioMAD object:

```
p = PortfolioMAD('numassets',4);
p = PortfolioMAD(p, 'assetlist', { 'AGG', 'EEM', 'MDY', 'SPY', 'VEU' });
disp(p.AssetList)
```

```
Warning: AssetList has 1 too many identifiers. Using first 4 assets.
> In PortfolioMAD.checkarguments at 410
  In PortfolioMAD.PortfolioMAD>PortfolioMAD.PortfolioMAD at 187
    'AGG'    'EEM'    'MDY'    'SPY'
```

The hidden public property uppercaseAssetList is a Boolean flag to specify whether to convert asset names to uppercase letters. The default value for uppercaseAssetList is false. This example shows how to use the uppercaseAssetList flag to force identifiers to be uppercase letters:

```
p = PortfolioMAD;
p.uppercaseAssetList = true;
p = setAssetList(p, { 'aa', 'ba', 'cat', 'dd', 'etr' });
disp(p.AssetList)
```

```
'AA'    'BA'    'CAT'    'DD'    'ETR'
```

Setting Up an Initial or Current Portfolio

In many applications, creating a new optimal portfolio requires comparing the new portfolio with an initial or current portfolio to form lists of purchases and sales. The PortfolioMAD object property InitPort lets you identify an initial or current portfolio. The initial portfolio also plays an essential role if you have either transaction costs or turnover constraints. The initial portfolio need not be feasible within the constraints of the problem. This can happen if the weights in a portfolio have shifted such that some constraints become violated. To check if your initial portfolio is feasible, use thecheckFeasibility function described in “Validating MAD Portfolios” on page 6-77. Suppose that you have an initial portfolio in x0, then use the PortfolioMAD object to set up an initial portfolio:

```
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = PortfolioMAD('InitPort', x0);
disp(p.InitPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

As with all array properties, you can set InitPort with scalar expansion. This is helpful to set up an equally weighted initial portfolio of, for example, 10 assets:

```
p = PortfolioMAD('NumAssets', 10, 'InitPort', 1/10);
disp(p.InitPort)
```

```
0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
 0.1000
```

To clear an initial portfolio from your PortfolioMAD object, use either the PortfolioMAD object or the setInitPort function with an empty input for the InitPort property. If transaction costs or turnover constraints are set, it is not possible to clear the InitPort property in this way. In this case, to clear InitPort, first clear the dependent properties and then clear theInitPort property.

The InitPort property can also be set with setInitPort which lets you specify the number of assets if you want to use scalar expansion. For example, given an initial portfolio in x0, use setInitPort to set the InitPort property:

```
p = PortfolioMAD;
x0 = [ 0.3; 0.2; 0.2; 0.0 ];
p = setInitPort(p, x0);
disp(p.InitPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

To create an equally weighted portfolio of four assets, use `setInitPort`:

```
p = PortfolioMAD;
p = setInitPort(p, 1/4, 4);
disp(p.InitPort)
```

```
 0.2500
 0.2500
 0.2500
 0.2500
```

`PortfolioMAD` object functions that work with either transaction costs or turnover constraints also depend on the `InitPort` property. So, the set functions for transaction costs or turnover constraints permit the assignment of a value for the `InitPort` property as part of their implementation. For details, see “Working with Average Turnover Constraints Using PortfolioMAD Object” on page 6-70, “Working with One-Way Turnover Constraints Using PortfolioMAD Object” on page 6-73, and “Working with Transaction Costs” on page 6-44. If either transaction costs or turnover constraints are used, then the `InitPort` property must have a nonempty value. Absent a specific value assigned through the `PortfolioMAD` object or various set functions, the `PortfolioMAD` object sets `InitPort` to `0` and warns if `BuyCost`, `SellCost`, or `Turnover` properties are set. This example shows what happens if you specify an average turnover constraint with an initial portfolio:

```
p = PortfolioMAD('Turnover', 0.3, 'InitPort', [ 0.3; 0.2; 0.2; 0.0 ]);
disp(p.InitPort)
```

```
 0.3000
 0.2000
 0.2000
      0
```

In contrast, this example shows what happens if an average turnover constraint is specified without an initial portfolio:

```
p = PortfolioMAD('Turnover', 0.3);
disp(p.InitPort)
```

```
Warning: InitPort and NumAssets are empty and either transaction costs or
turnover constraints specified. Will set NumAssets = 1 and InitPort = 0.
> In PortfolioMAD.checkarguments at 446
  In PortfolioMAD.PortfolioMAD>PortfolioMAD.PortfolioMAD at 190
     0
```

Asset Returns and Scenarios Using PortfolioMAD Object

In this section...

How Stochastic Optimization Works

The MAD of a portfolio is mean-absolute deviation. For the definition of the MAD function, see “Risk Proxy” on page 6-4. Although analytic solutions for MAD exist for a few probability distributions, an alternative is to compute the expectation for MAD with samples from the probability distribution of asset returns. These samples are called scenarios and, given a collection of scenarios, the portfolio optimization problem becomes a stochastic optimization problem.

As a function of the portfolio weights, the MAD of the portfolio is a convex non-smooth function (see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5). The PortfolioMAD object computes MAD as this nonlinear function which can be handled by the solver `fmincon` Optimization Toolbox. The nonlinear programming solver `fmincon` has several algorithms that can be selected with the `setSolver` function, the two algorithms that work best in practice are `'sqp'` and `'active-set'`.

There are reformulations of the MAD portfolio optimization problem (see Konno and Yamazaki [50] at “Portfolio Optimization” on page A-5) that result in a linear programming problem, which can be solved either with standard linear programming techniques or with stochastic programming solvers. The `PortfolioMAD` object, however, does not reformulate the problem in such a manner. The `PortfolioMAD` object computes the MAD as a nonlinear function. The convexity of the MAD, as a function of the portfolio weights and the dull edges when the number of scenarios is large, make the MAD portfolio optimization problem tractable, in practice, for certain nonlinear programming solvers, such as `fmincon` from Optimization Toolbox. To learn more about the workflow when using `PortfolioMAD` objects, see “PortfolioMAD Object Workflow” on page 6-15.

What Are Scenarios?

Since mean absolute deviation portfolio optimization works with scenarios of asset returns to perform the optimization, several ways exist to specify and simulate scenarios. In many applications with MAD portfolio optimization, asset returns may have distinctly nonnormal probability distributions with either multiple modes, binning of returns, truncation of distributions, and so forth. In other applications, asset returns are modeled as the result of various simulation methods that might include Monte-Carlo simulation, quasi-random simulation, and so forth. Often, the underlying probability distribution for risk factors may be multivariate normal but the resultant transformations are sufficiently nonlinear to result in distinctively nonnormal asset returns.

For example, this occurs with bonds and derivatives. In the case of bonds with a nonzero probability of default, such scenarios would likely include asset returns that are −100% to indicate default and some values slightly greater than −100% to indicate recovery rates.

Although the PortfolioMAD object has functions to simulate multivariate normal scenarios from either data or moments (simulateNormalScenariosByData and simulateNormalScenariosByMoments), the usual approach is to specify scenarios directly from your own simulation functions. These scenarios are entered directly as a matrix with a sample for all assets across each row of the matrix and with samples for an asset down each column of the matrix. The architecture of the MAD portfolio optimization tools references the scenarios through a function handle so scenarios that have been set cannot be accessed directly as a property of the PortfolioMAD object.

Setting Scenarios Using the PortfolioMAD Function

Suppose that you have a matrix of scenarios in the AssetScenarios variable. The scenarios are set through the PortfolioMAD object with:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD('Scenarios', AssetScenarios);

disp(p.NumAssets)
disp(p.NumScenarios)
```

```
4

20000
```

Notice that the PortfolioMAD object determines and fixes the number of assets in NumAssets and the number of scenarios in NumScenarios based on the scenario’s matrix. You can change the number of scenarios by calling the PortfolioMAD object with a different scenario matrix. However, once the NumAssets property has been set in the object, you cannot enter a scenario matrix with a different number of assets. The getScenarios function lets you recover scenarios from a PortfolioMAD object. You can also obtain the mean and covariance of your scenarios using estimateScenarioMoments.

Although not recommended for the casual user, an alternative way exists to recover scenarios by working with the function handle that points to scenarios in the PortfolioMAD object. To access some or all the scenarios from a PortfolioMAD object, the hidden property localScenarioHandle is a function handle that points to a function to obtain scenarios that have already been set. To get scenarios directly from a PortfolioMAD object p, use

```
scenarios = p.localScenarioHandle([], []);
```

and to obtain a subset of scenarios from rows `startrow` to `endrow`, use

```
scenarios = p.localScenarioHandle(startrow, endrow);
```

where 1 ≤ `startrow` ≤ `endrow` ≤ `numScenarios`.

Setting Scenarios Using the setScenarios Function

You can also set scenarios using `setScenarios`. For example, given the mean and covariance of asset returns in the variables `m` and `C`, the asset moment properties can be set:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);

disp(p.NumAssets)
disp(p.NumScenarios)
```

```
4

20000
```

Estimating the Mean and Covariance of Scenarios

The `estimateScenarioMoments` function obtains estimates for the mean and covariance of scenarios in a `PortfolioMAD` object.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
[mean, covar] = estimateScenarioMoments(p)
```

```
mean =

    0.0044
    0.0084
    0.0108
    0.0155

covar =

    0.0005    0.0003    0.0002   -0.0000
    0.0003    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0047    0.0028
   -0.0000    0.0010    0.0028    0.0103
```

Simulating Normal Scenarios

As a convenience, the two functions (simulateNormalScenariosByData and simulateNormalScenariosByMoments) exist to simulate scenarios from data or moments under an assumption that they are distributed as multivariate normal random asset returns.

Simulating Normal Scenarios from Returns or Prices

Given either return or price data, use the simulateNormalScenariosByData function to simulate multivariate normal scenarios. Either returns or prices are stored as matrices with samples going down the rows and assets going across the columns. In addition, returns or prices can be stored in a table or timetable (see “Simulating Normal Scenarios from Time Series Data” on page 6-39). To illustrate using simulateNormalScenariosByData, generate random samples of 120 observations of asset returns for four assets from the mean and covariance of asset returns in the variables m and C with portsim. The default behavior of portsim creates simulated data with estimated mean and covariance identical to the input moments m and C. In addition to a return series created by portsim in the variable *X*, a price series is created in the variable *Y*:

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];

X = portsim(m', C, 120);
Y = ret2tick(X);
```

Note Portfolio optimization requires that you use total returns and not just price returns. So, “returns” should be total returns and “prices” should be total return prices.

Given asset returns and prices in variables *X* and *Y* from above, this sequence of examples demonstrates equivalent ways to simulate multivariate normal scenarios for the PortfolioMAD object. Assume a PortfolioMAD object created in p that uses the asset returns in *X* uses simulateNormalScenariosByData:

```
p = PortfolioMAD;
p = simulateNormalScenariosByData(p, X, 20000);

[passetmean, passetcovar] = estimateScenarioMoments(p)

passetmean =
    0.0033
    0.0085
    0.0095
    0.1503

passetcovar =

    0.0055    0.0004    0.0002    0.0001
    0.0004    0.0024    0.0017    0.0010
    0.0002    0.0017    0.0049    0.0028
    0.0001    0.0010    0.0028    0.0102
```

The moments that you obtain from this simulation will likely differ from the moments listed here because the scenarios are random samples from the estimated multivariate normal probability distribution of the input returns *X*.

The default behavior of `simulateNormalScenariosByData` is to work with asset returns. If, instead, you have asset prices as in the variable *Y*, `simulateNormalScenariosByData` accepts a name-value pair argument name `'DataFormat'` with a corresponding value set to `'prices'` to indicate that the input to the function is in the form of asset prices and not returns (the default value for the `'DataFormat'` argument is `'returns'`). This example simulates scenarios with the asset price data in *Y* for the `PortfolioMAD` object `q`:

```
p = PortfolioMAD;
p = simulateNormalScenariosByData(p, Y, 20000, 'dataformat', 'prices');

[passetmean, passetcovar] = estimateScenarioMoments(p)
```

```
passetmean =

    0.0043
    0.0083
    0.0099
    0.1500

passetcovar =

    0.0053    0.0003    0.0001    0.0002
    0.0003    0.0024    0.0017    0.0010
    0.0001    0.0017    0.0047    0.0027
    0.0002    0.0010    0.0027    0.0100
```

Simulating Normal Scenarios with Missing Data

Often when working with multiple assets, you have missing data indicated by `NaN` values in your return or price data. Although “Multivariate Normal Regression” on page 9-2 goes into detail about regression with missing data, the `simulateNormalScenariosByData` function has a name-value pair argument name `'MissingData'` that indicates with a Boolean value whether to use the missing data capabilities of Financial Toolbox. The default value for `'MissingData'` is `false` which removes all samples with `NaN` values. If, however, `'MissingData'` is set to `true`, `simulateNormalScenariosByData` uses the ECM algorithm to estimate asset moments. This example shows how this works on price data with missing values:

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];

X = portsim(m', C, 120);
Y = ret2tick(X);
Y(1:20,1) = NaN;
Y(1:12,4) = NaN;
```

Notice that the prices above in `Y` have missing values in the first and fourth series.

```
p = PortfolioMAD;
p = simulateNormalScenariosByData(p, Y, 20000, 'dataformat', 'prices');

q = PortfolioMAD;
q = simulateNormalScenariosByData(q, Y, 20000, 'dataformat', 'prices', 'missingdata', true);

[passetmean, passetcovar] = estimateScenarioMoments(p)
[qassetmean, qassetcovar] = estimateScenarioMoments(q)
```

```
passetmean =

    0.0095
    0.0103
    0.0124
    0.1505

passetcovar =

    0.0054    0.0000   -0.0005   -0.0006
    0.0000    0.0021    0.0015    0.0010
   -0.0005    0.0015    0.0046    0.0026
   -0.0006    0.0010    0.0026    0.0100

qassetmean =

    0.0092
    0.0082
    0.0094
    0.1463

qassetcovar =

    0.0071   -0.0000   -0.0006   -0.0006
   -0.0000    0.0032    0.0023    0.0015
   -0.0006    0.0023    0.0064    0.0036
   -0.0006    0.0015    0.0036    0.0133
```

The first `PortfolioMAD` object, `p`, contains scenarios obtained from price data in `Y` where `NaN` values are discarded and the second `PortfolioMAD` object, `q`, contains scenarios obtained from price data in `Y` that accommodate missing values. Each time you run this example, you get different estimates for the moments in `p` and `q`.

Simulating Normal Scenarios from Time Series Data

The `simulateNormalScenariosByData` function accepts asset returns or prices stored in `table` or `timetable`. The `simulateNormalScenariosByData` function implicitly works with matrices of data or data in a table or timetable object using the same rules for whether the data are returns or prices. To illustrate, use `array2timetable` to create a timetable for 14 assets from `CAPMuniverse` and the use the timetable to simulate scenarios for PortfolioCVaR.

```
load CAPMuniverse
time = datetime(Dates,'ConvertFrom','datenum');
stockTT = array2timetable(Data,'RowTimes',time, 'VariableNames', Assets);
stockTT.Properties
% Notice that GOOG has missing data, because it was not listed before Aug 2004
head(stockTT, 5)
```

```
ans = 

  TimetableProperties with properties:

             Description: ''
                UserData: []
          DimensionNames: {'Time'  'Variables'}
           VariableNames: {'AAPL'  'AMZN'  'CSCO'  'DELL'  'EBAY'  'GOOG'  'HPQ'  'IBM'  'INTC'
    VariableDescriptions: {}
           VariableUnits: {}

    0.0003
    0.0006
   -0.0001
```

```
    0.0005
    0.0011
    0.0002
    0.0001

passetcovar =

    0.0014    0.0005    0.0006    0.0006    0.0006    0.0003    0.0005    0.0003    0.0006    0.0
    0.0005    0.0025    0.0007    0.0005    0.0010    0.0005    0.0005    0.0003    0.0006    0.0
    0.0006    0.0007    0.0013    0.0006    0.0007    0.0004    0.0006    0.0004    0.0008    0.0
    0.0006    0.0005    0.0006    0.0009    0.0006    0.0002    0.0005    0.0003    0.0006    0.0
    0.0006    0.0010    0.0007    0.0006    0.0018    0.0007    0.0005    0.0003    0.0006    0.0
    0.0003    0.0005    0.0004    0.0002    0.0007    0.0013    0.0002    0.0002    0.0002    0.0
    0.0005    0.0005    0.0006    0.0005    0.0005    0.0002    0.0010    0.0003    0.0005    0.0
    0.0003    0.0003    0.0004    0.0003    0.0003    0.0002    0.0003    0.0005    0.0004    0.0
    0.0006    0.0006    0.0008    0.0006    0.0006    0.0002    0.0005    0.0004    0.0011    0.0
    0.0004    0.0004    0.0005    0.0004    0.0005    0.0002    0.0003    0.0002    0.0005    0.0
    0.0005    0.0006    0.0008    0.0005    0.0007    0.0003    0.0005    0.0004    0.0007    0.0
    0.0007    0.0012    0.0008    0.0006    0.0011    0.0011    0.0006    0.0004    0.0007    0.0
    0.0002    0.0002    0.0002    0.0002    0.0002    0.0001    0.0002    0.0002    0.0002    0.0
   -0.0000   -0.0000   -0.0000   -0.0000    0.0000   -0.0000   -0.0000   -0.0000   -0.0000   -0.0
```

Use the name-value input `'DataFormat'` to handle return or price data and `'MissingData'` to ignore or use samples with missing values. In addition, `simulateNormalScenariosByData` extracts asset names or identifiers from a `table` or `timetable` if the argument `'GetAssetList'` is set to `true` (the default value is `false`). If the `'GetAssetList'` value is `true`, the identifiers are used to set the `AssetList` property of the `PortfolioMAD` object. Thus, repeating the formation of the `PortfolioMAD` object `p` from the previous example with the `'GetAssetList'` flag set to `true` extracts the column names from the timetable object:

```
p = simulateNormalScenariosByData(p, stockTT, 20000 ,'missingdata',true, 'GetAssetList', true);
disp(p.AssetList)
```

```
  'AAPL'    'AMZN'    'CSCO'    'DELL'    'EBAY'    'GOOG'    'HPQ'    'IBM'    'INTC'    'MSFT'
```

If you set the`'GetAssetList'` flag set to `true` and your input data is in a matrix, `simulateNormalScenariosByData` uses the default labeling scheme from `setAssetList` as described in “Setting Up a List of Asset Identifiers” on page 5-29.

Simulating Normal Scenarios for Mean and Covariance

Given the mean and covariance of asset returns, use the `simulateNormalScenariosByMoments` function to simulate multivariate normal scenarios. The mean can be either a row or column vector and the covariance matrix must be a symmetric positive-semidefinite matrix. Various rules for scalar expansion apply. To illustrate using `simulateNormalScenariosByMoments`, start with moments in `m` and `C` and generate 20,000 scenarios:

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];

p = PortfolioMAD;
p = simulateNormalScenariosByMoments(p, m, C, 20000);
[passetmean, passetcovar] = estimateScenarioMoments(p)
```

```
passetmean =

    0.0040
    0.0084
    0.0105
    0.1513

passetcovar =

    0.0053    0.0003    0.0002    0.0001
    0.0003    0.0024    0.0017    0.0009
    0.0002    0.0017    0.0048    0.0028
    0.0001    0.0009    0.0028    0.0102
```

simulateNormalScenariosByMoments performs scalar expansion on arguments for the moments of asset returns. If NumAssets has not already been set, a scalar argument is interpreted as a scalar with NumAssets set to 1. simulateNormalScenariosByMoments provides an additional optional argument to specify the number of assets so that scalar expansion works with the correct number of assets. In addition, if either a scalar or vector is input for the covariance of asset returns, a diagonal matrix is formed such that a scalar expands along the diagonal and a vector becomes the diagonal.

Working with a Riskless Asset

The `PortfolioMAD` object has a separate `RiskFreeRate` property that stores the rate of return of a riskless asset. Thus, you can separate your universe into a riskless asset and a collection of risky assets. For example, assume that your riskless asset has a return in the scalar variable `r0`, then the property for the `RiskFreeRate` is set using the `PortfolioMAD` object:

```
r0 = 0.01/12;

p = PortfolioMAD;
p = PortfolioMAD('RiskFreeRate', r0);
disp(p.RiskFreeRate)
```

```
 8.3333e-04
```

Note If your portfolio problem has a budget constraint such that your portfolio weights must sum to `1`, then the riskless asset is irrelevant.

Working with Transaction Costs

The difference between net and gross portfolio returns is transaction costs. The net portfolio return proxy has distinct proportional costs to purchase and to sell assets which are maintained in the PortfolioMAD object properties BuyCost and SellCost. Transaction costs are in units of total return and, as such, are proportional to the price of an asset so that they enter the model for net portfolio returns in return form. For example, suppose that you have a stock currently priced $40 and your usual transaction costs are 5 cents per share. Then the transaction cost for the stock is 0.05/40 = 0.00125 (as defined in “Net Portfolio Returns” on page 6-3). Costs are entered as positive values and credits are entered as negative values.

Setting Transaction Costs Using the PortfolioMAD Function

To set up transaction costs, you must specify an initial or current portfolio in the InitPort property. If the initial portfolio is not set when you set up the transaction cost properties, InitPort is 0. The properties for transaction costs can be set using the PortfolioMAD object. For example, assume that purchase and sale transaction costs are in the variables bc and sc and an initial portfolio is in the variable x0, then transaction costs are set:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioMAD('BuyCost', bc, 'SellCost', sc, 'InitPort', x0);
disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)
```

```

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

Setting Transaction Costs Using the setCosts Function

You can also set the properties for transaction costs using setCosts. Assume that you have the same costs and initial portfolio as in the previous example. Given a PortfolioMAD object p with an initial portfolio already set, use setCosts to set up transaction costs:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];

p = PortfolioMAD('InitPort', x0);
p = setCosts(p, bc, sc);

disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)
```

```
    5

    0.0013
    0.0013
    0.0013
    0.0013
    0.0013

    0.0070
    0.0013
    0.0013
    0.0024

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

You can also set up the initial portfolio's `InitPort` value as an optional argument to `setCosts` so that the following is an equivalent way to set up transaction costs:

```
bc = [ 0.00125; 0.00125; 0.00125; 0.00125; 0.00125 ];
sc = [ 0.00125; 0.007; 0.00125; 0.00125; 0.0024 ];
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];

p = PortfolioMAD;
p = setCosts(p, bc, sc, x0);

disp(p.NumAssets)
disp(p.BuyCost)
disp(p.SellCost)
disp(p.InitPort)
```

```
    5

    0.0013
    0.0013
    0.0013
    0.0013
    0.0013

    0.0013
    0.0070
    0.0013
    0.0013
    0.0024

    0.4000
    0.2000
    0.2000
    0.1000
    0.1000
```

Setting Transaction Costs with Scalar Expansion

Both the `PortfolioMAD` object and `setCosts` function implement scalar expansion on the arguments for transaction costs and the initial portfolio. If the `NumAssets` property is already set in the `PortfolioMAD` object, scalar arguments for these properties are expanded to have the same value across all dimensions. In addition, `setCosts` lets you specify `NumAssets` as an optional final argument. For example, assume that you have an initial portfolio `x0` and you want to set common transaction costs on all assets in your universe. You can set these costs in any of these equivalent ways:

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioMAD('InitPort', x0, 'BuyCost', 0.002, 'SellCost', 0.002);
```

or

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioMAD('InitPort', x0);
p = setCosts(p, 0.002, 0.002);
```

or

```
x0 = [ 0.4; 0.2; 0.2; 0.1; 0.1 ];
p = PortfolioMAD;
p = setCosts(p, 0.002, 0.002, x0);
```

To clear costs from your `PortfolioMAD` object, use either the`PortfolioMAD` object or `setCosts` with empty inputs for the properties to be cleared. For example, you can clear sales costs from the `PortfolioMAD` object `p` in the previous example:

```
p = PortfolioMAD(p, 'SellCost', []);
```

Working with MAD Portfolio Constraints Using Defaults

The final element for a complete specification of a portfolio optimization problem is the set of feasible portfolios, which is called a portfolio set. A portfolio set $X \subset R^n$ is specified by construction as the intersection of sets formed by a collection of constraints on portfolio weights. A portfolio set necessarily and sufficiently must be a nonempty, closed, and bounded set.

When setting up your portfolio set, ensure that the portfolio set satisfies these conditions. The most basic or “default” portfolio set requires portfolio weights to be nonnegative (using the lower-bound constraint) and to sum to 1 (using the budget constraint). For information on the workflow when using PortfolioMAD objects, see “PortfolioMAD Object Workflow” on page 6-15.

Setting Default Constraints for Portfolio Weights Using PortfolioMAD Object

The “default” MAD portfolio problem has two constraints on portfolio weights:

- Portfolio weights must be nonnegative.
- Portfolio weights must sum to 1.

Implicitly, these constraints imply that portfolio weights are no greater than 1, although this is a superfluous constraint to impose on the problem.

Setting Default Constraints Using the PortfolioMAD Function

Given a portfolio optimization problem with NumAssets = 20 assets, use the PortfolioMAD object to set up a default problem and explicitly set bounds and budget constraints:

```
p = PortfolioMAD('NumAssets', 20, 'LowerBound', 0, 'Budget', 1);
disp(p)
```

```
  PortfolioMAD with properties:

         BuyCost: []
        SellCost: []
    RiskFreeRate: []
        Turnover: []
     BuyTurnover: []
    SellTurnover: []
    NumScenarios: []
            Name: []
       NumAssets: 20
       AssetList: []
        InitPort: []
     AInequality: []
     bInequality: []
       AEquality: []
       bEquality: []
      LowerBound: [20×1 double]
      UpperBound: []
     LowerBudget: 1
     UpperBudget: 1
     GroupMatrix: []
      LowerGroup: []
      UpperGroup: []
          GroupA: []
          GroupB: []
      LowerRatio: []
      UpperRatio: []
    MinNumAssets: []
    MaxNumAssets: []
       BoundType: []
```

Setting Default Constraints Using the setDefaultConstraints Function

An alternative approach is to use the `setDefaultConstraints` function. If the number of assets is already known in a `PortfolioMAD` object, use `setDefaultConstraints` with no arguments to set up the necessary bound and budget constraints. Suppose that you have 20 assets to set up the portfolio set for a default problem:

```
p = PortfolioMAD('NumAssets', 20);
p = setDefaultConstraints(p);
disp(p)
```

```
 PortfolioMAD with properties:

         BuyCost: []
        SellCost: []
    RiskFreeRate: []
        Turnover: []
     BuyTurnover: []
    SellTurnover: []
    NumScenarios: []
            Name: []
       NumAssets: 20
       AssetList: []
        InitPort: []
     AInequality: []
     bInequality: []
       AEquality: []
       bEquality: []
      LowerBound: [20×1 double]
      UpperBound: []
     LowerBudget: 1
     UpperBudget: 1
     GroupMatrix: []
      LowerGroup: []
      UpperGroup: []
          GroupA: []
          GroupB: []
      LowerRatio: []
      UpperRatio: []
    MinNumAssets: []
    MaxNumAssets: []
       BoundType: [20×1 categorical]
```

If the number of assets is unknown, `setDefaultConstraints` accepts `NumAssets` as an optional argument to form a portfolio set for a default problem. Suppose that you have 20 assets:

```
p = PortfolioMAD;
p = setDefaultConstraints(p, 20);
disp(p)
```

```
PortfolioMAD with properties:

          BuyCost: []
         SellCost: []
     RiskFreeRate: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
     NumScenarios: []
             Name: []
        NumAssets: 20
        AssetList: []
         InitPort: []
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []
       LowerBound: [20×1 double]
       UpperBound: []
      LowerBudget: 1
      UpperBudget: 1
      GroupMatrix: []
       LowerGroup: []
       UpperGroup: []
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
     MinNumAssets: []
     MaxNumAssets: []
        BoundType: [20×1 categorical]
```

Working with 'Simple' Bound Constraints Using PortfolioMAD Object

'Simple' bound constraints are optional linear constraints that maintain upper and lower bounds on portfolio weights (see “'Simple' Bound Constraints” on page 6-8). Although every portfolio set must be bounded, it is not necessary to specify a portfolio set with explicit bound constraints. For example, you can create a portfolio set with an implicit upper bound constraint or a portfolio set with average turnover constraints. The bound constraints have properties LowerBound for the lower-bound constraint and UpperBound for the upper-bound constraint. Set default values for these constraints using the setDefaultConstraints function (see “Setting Default Constraints for Portfolio Weights Using Portfolio Object” on page 4-57).

Setting 'Simple' Bounds Using the PortfolioMAD Function

The properties for bound constraints are set through the PortfolioMAD object. Suppose that you have a balanced fund with stocks that can range from 50% to 75% of your portfolio and bonds that can range from 25% to 50% of your portfolio. The bound constraints for a balanced fund are set with:

```
lb = [ 0.5; 0.25 ];
ub = [ 0.75; 0.5 ];
p = PortfolioMAD('LowerBound', lb, 'UpperBound', ub, 'BoundType', 'Simple');
disp(p.NumAssets)
disp(p.LowerBound)
disp(p.UpperBound)
```

```
 2

 0.5000
 0.2500

 0.7500
 0.5000
```

To continue with this example, you must set up a budget constraint. For details, see “Working with Budget Constraints Using Portfolio Object” on page 4-64.

Setting 'Simple' Bounds Using the setBounds Function

You can also set the properties for bound constraints using setBounds. Suppose that you have a balanced fund with stocks that can range from 50% to 75% of your portfolio and bonds that can range from 25% to 50% of your portfolio. Given a PortfolioMAD object p, use setBounds to set the bound constraints:

```
lb = [ 0.5; 0.25 ];
ub = [ 0.75; 0.5 ];
p = PortfolioMAD;
p = setBounds(p, lb, ub,'BoundType', 'Simple');
disp(p.NumAssets)
disp(p.LowerBound)
disp(p.UpperBound)
```

```
  2

  0.5000
```

```
   0.2500

   0.7500
   0.5000
```

Setting 'Simple' Bounds Using the PortfolioMAD Function or setBounds Function

Both the PortfolioMAD object and setBounds function implement scalar expansion on either the LowerBound or UpperBound properties. If the NumAssets property is already set in the PortfolioMAD object, scalar arguments for either property expand to have the same value across all dimensions. In addition, setBounds lets you specify NumAssets as an optional argument. Suppose that you have a universe of 500 assets and you want to set common bound constraints on all assets in your universe. Specifically, you are a long-only investor and want to hold no more than 5% of your portfolio in any single asset. You can set these bound constraints in any of these equivalent ways:

```
p = PortfolioMAD('NumAssets', 500, 'LowerBound', 0, 'UpperBound', 0.05,'BoundType', 'Simple');
```

or

```
p = PortfolioMAD('NumAssets', 500);
p = setBounds(p, 0, 0.05,'BoundType','Simple');
```

or

```
p = PortfolioMAD;
p = setBounds(p, 0, 0.05,'NumAssets', 500,'BoundType','Simple');
```

To clear bound constraints from your PortfolioMAD object, use either the PortfolioMAD object or setBounds with empty inputs for the properties to be cleared. For example, to clear the upper-bound constraint from the PortfolioMAD object p in the previous example:

```
p = PortfolioMAD(p, 'UpperBound', []);
```

More About

- “PortfolioMAD Object” on page 6-16
- “Portfolio Optimization Theory” on page 6-2
- “PortfolioMAD Object Workflow” on page 6-15

Working with Budget Constraints Using PortfolioMAD Object

The budget constraint is an optional linear constraint that maintains upper and lower bounds on the sum of portfolio weights (see “Budget Constraints” on page 5-10). Budget constraints have properties `LowerBudget` for the lower budget constraint and `UpperBudget` for the upper budget constraint. If you set up a MAD portfolio optimization problem that requires portfolios to be fully invested in your universe of assets, you can set `LowerBudget` to be equal to `UpperBudget`. These budget constraints can be set with default values equal to `1` using `setDefaultConstraints` (see “Setting Default Constraints for Portfolio Weights Using PortfolioMAD Object” on page 6-48).

Setting Budget Constraints Using the PortfolioMAD Function

The properties for the budget constraint can also be set using the `PortfolioMAD` object. Suppose that you have an asset universe with many risky assets and a riskless asset and you want to ensure that your portfolio never holds more than 1% cash, that is, you want to ensure that you are 99–100% invested in risky assets. The budget constraint for this portfolio can be set with:

```
p = PortfolioMAD('LowerBudget', 0.99, 'UpperBudget', 1);
disp(p.LowerBudget)
disp(p.UpperBudget)
```

```
 0.9900

1
```

Setting Budget Constraints Using the setBudget Function

You can also set the properties for a budget constraint using `setBudget`. Suppose that you have a fund that permits up to 10% leverage which means that your portfolio can be from 100% to 110% invested in risky assets. Given a `PortfolioMAD` object `p`, use `setBudget` to set the budget constraints:

```
p = PortfolioMAD;
p = setBudget(p, 1, 1.1);
disp(p.LowerBudget)
disp(p.UpperBudget)
```

```
 1

 1.1000
```

If you were to continue with this example, then set the `RiskFreeRate` property to the borrowing rate to finance possible leveraged positions. For details on the `RiskFreeRate` property, see “Working with a Riskless Asset” on page 6-43. To clear either bound for the budget constraint from your `PortfolioMAD` object, use either the `PortfolioMAD` object or `setBudget` with empty inputs for the properties to be cleared. For example, clear the upper-budget constraint from the `PortfolioMAD` object `p` in the previous example with:

```
p = PortfolioMAD(p, 'UpperBudget', []);
```

Working with Group Constraints Using PortfolioMAD Object

Group constraints are optional linear constraints that group assets together and enforce bounds on the group weights (see “Group Constraints” on page 6-10). Although the constraints are implemented as general constraints, the usual convention is to form a group matrix that identifies membership of each asset within a specific group with Boolean indicators (either `true` or `false` or with `1` or `0`) for each element in the group matrix. Group constraints have properties `GroupMatrix` for the group membership matrix, `LowerGroup` for the lower-bound constraint on groups, and `UpperGroup` for the upper-bound constraint on groups.

Setting Group Constraints Using the PortfolioMAD Function

The properties for group constraints are set through the `PortfolioMAD` object. Suppose that you have a portfolio of five assets and want to ensure that the first three assets constitute no more than 30% of your portfolio, then you can set group constraints:

```
G = [ 1 1 1 0 0 ];
p = PortfolioMAD('GroupMatrix', G, 'UpperGroup', 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

The group matrix `G` can also be a logical matrix so that the following code achieves the same result.

```
G = [ true true true false false ];
p = PortfolioMAD('GroupMatrix', G, 'UpperGroup', 0.3);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.UpperGroup)
```

```
5

1     1     1     0     0

0.3000
```

Setting Group Constraints Using the setGroups and addGroups Functions

You can also set the properties for group constraints using `setGroups`. Suppose that you have a portfolio of five assets and want to ensure that the first three assets constitute no more than 30% of your portfolio. Given a `PortfolioMAD` object `p`, use `setGroups` to set the group constraints:

```
G = [ true true true false false ];
p = PortfolioMAD;
p = setGroups(p, G, [], 0.3);
disp(p.NumAssets);
disp(p.GroupMatrix);
disp(p.UpperGroup);
```

```
5

1     1     1     0     0

0.3000
```

In this example, you would set the `LowerGroup` property to be empty (`[]`).

Suppose that you want to add another group constraint to make odd-numbered assets constitute at least 20% of your portfolio. Set up an augmented group matrix and introduce infinite bounds for unconstrained group bounds or use the `addGroups` function to build up group constraints. For this example, create another group matrix for the second group constraint:

```
p = PortfolioMAD;
G = [ true true true false false ];    % group matrix for first group constraint
p = setGroups(p, G, [], 0.3);
G = [ true false true false true ];    % group matrix for second group constraint
p = addGroups(p, G, 0.2);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.LowerGroup)
disp(p.UpperGroup)
```

```
 5

1     1     1     0     0
1     0     1     0     1

  -Inf
0.2000

0.3000
  Inf
```

`addGroups` determines which bounds are unbounded so you only need to focus on the constraints that you want to set.

The `PortfolioMAD` object, `setGroups`, and `addGroups` implement scalar expansion on either the `LowerGroup` or `UpperGroup` properties based on the dimension of the group matrix in the property `GroupMatrix`. Suppose that you have a universe of 30 assets with 6 asset classes such that assets 1–5, assets 6–12, assets 13–18, assets 19–22, assets 23–27, and assets 28–30 constitute each of your asset classes and you want each asset class to fall from 0% to 25% of your portfolio. Let the following group matrix define your groups and scalar expansion define the common bounds on each group:

```
p = PortfolioMAD;
G = blkdiag(true(1,5), true(1,7), true(1,6), true(1,4), true(1,5), true(1,3));
p = setGroups(p, G, 0, 0.25);
disp(p.NumAssets)
disp(p.GroupMatrix)
disp(p.LowerGroup)
disp(p.UpperGroup)
```

```

Working with Group Ratio Constraints Using PortfolioMAD Object

Group ratio constraints are optional linear constraints that maintain bounds on proportional relationships among groups of assets (see “Group Ratio Constraints” on page 6-10). Although the constraints are implemented as general constraints, the usual convention is to specify a pair of group matrices that identify membership of each asset within specific groups with Boolean indicators (either `true` or `false` or with `1` or `0`) for each element in each of the group matrices. The goal is to ensure that the ratio of a base group compared to a comparison group fall within specified bounds. Group ratio constraints have properties:

- `GroupA` for the base membership matrix
- `GroupB` for the comparison membership matrix
- `LowerRatio` for the lower-bound constraint on the ratio of groups
- `UpperRatio` for the upper-bound constraint on the ratio of groups

Setting Group Ratio Constraints Using the PortfolioMAD Function

The properties for group ratio constraints are set using `PortfolioMAD` object. For example, assume that you want the ratio of financial to nonfinancial companies in your portfolios to never go above 50%. Suppose that you have six assets with three financial companies (assets 1–3) and three nonfinancial companies (assets 4–6). To set group ratio constraints:

```
GA = [ 1 1 1 0 0 0 ];    % financial companies
GB = [ 0 0 0 1 1 1 ];    % nonfinancial companies
p = PortfolioMAD('GroupA', GA, 'GroupB', GB, 'UpperRatio', 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

Group matrices `GA` and `GB` in this example can be logical matrices with `true` and `false` elements that yield the same result:

```
GA = [ true true true false false false ];    % financial companies
GB = [ false false false true true true ];    % nonfinancial companies
p = PortfolioMAD('GroupA', GA, 'GroupB', GB, 'UpperRatio', 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

Setting Group Ratio Constraints Using the setGroupRatio and addGroupRatio Functions

You can also set the properties for group ratio constraints using `setGroupRatio`. For example, assume that you want the ratio of financial to nonfinancial companies in your portfolios to never go above 50%. Suppose that you have six assets with three financial companies (assets 1–3) and three nonfinancial companies (assets 4–6). Given a `PortfolioMAD` object `p`, use `setGroupRatio` to set the group constraints:

```
GA = [ true true true false false false ];   % financial companies
GB = [ false false false true true true ];   % nonfinancial companies
p = PortfolioMAD;
p = setGroupRatio(p, GA, GB, [], 0.5);
disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0

0     0     0     1     1     1

0.5000
```

In this example, you would set the `LowerRatio` property to be empty (`[]`).

Suppose that you want to add another group ratio constraint to ensure that the weights in odd-numbered assets constitute at least 20% of the weights in nonfinancial assets your portfolio. You can set up augmented group ratio matrices and introduce infinite bounds for unconstrained group ratio bounds, or you can use the `addGroupRatio` function to build up group ratio constraints. For this example, create another group matrix for the second group constraint:

```
p = PortfolioMAD;
GA = [ true true true false false false ];   % financial companies
GB = [ false false false true true true ];   % nonfinancial companies
p = setGroupRatio(p, GA, GB, [], 0.5);

GA = [ true false true false true false ];   % odd-numbered companies
GB = [ false false false true true true ];   % nonfinancial companies
p = addGroupRatio(p, GA, GB, 0.2);

disp(p.NumAssets)
disp(p.GroupA)
disp(p.GroupB)
disp(p.LowerRatio)
disp(p.UpperRatio)
```

```
6

1     1     1     0     0     0
1     0     1     0     1     0

0     0     0     1     1     1
0     0     0     1     1     1

  -Inf
0.2000

0.5000
  Inf
```

Notice that addGroupRatio determines which bounds are unbounded so you only need to focus on the constraints you want to set.

ThePortfolioMAD object, setGroupRatio, and addGroupRatio implement scalar expansion on either the LowerRatio or UpperRatio properties based on the dimension of the group matrices in GroupA and GroupB properties.

Working with Linear Equality Constraints Using PortfolioMAD Object

Linear equality constraints are optional linear constraints that impose systems of equalities on portfolio weights (see “Linear Equality Constraints” on page 6-8). Linear equality constraints have properties AEquality, for the equality constraint matrix, and bEquality, for the equality constraint vector.

Setting Linear Equality Constraints Using the PortfolioMAD Function

The properties for linear equality constraints are set using the PortfolioMAD object. Suppose that you have a portfolio of five assets and want to ensure that the first three assets are 50% of your portfolio. To set this constraint:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioMAD('AEquality', A, 'bEquality', b);
disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)
```

```
5

1     1     1     0     0

0.5000
```

Setting Linear Equality Constraints Using the setEquality and addEquality Functions

You can also set the properties for linear equality constraints using setEquality. Suppose that you have a portfolio of five assets and want to ensure that the first three assets are 50% of your portfolio. Given a PortfolioMAD object p, use setEquality to set the linear equality constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioMAD;
p = setEquality(p, A, b);
disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)
```

```
5

1     1     1     0     0

0.5000
```

Suppose that you want to add another linear equality constraint to ensure that the last three assets also constitute 50% of your portfolio. You can set up an augmented system of linear equalities or use addEquality to build up linear equality constraints. For this example, create another system of equalities:

```
p = PortfolioMAD;
A = [ 1 1 1 0 0 ];    % first equality constraint
```

```
b = 0.5;
p = setEquality(p, A, b);

A = [ 0 0 1 1 1 ];    % second equality constraint
b = 0.5;
p = addEquality(p, A, b);

disp(p.NumAssets)
disp(p.AEquality)
disp(p.bEquality)
```

```
5

1     1     1     0     0
0     0     1     1     1

0.5000
0.5000
```

The `PortfolioMAD` object, `setEquality`, and `addEquality` implement scalar expansion on the `bEquality` property based on the dimension of the matrix in the `AEquality` property.

Working with Linear Inequality Constraints Using PortfolioMAD Object

Linear inequality constraints are optional linear constraints that impose systems of inequalities on portfolio weights (see “Linear Inequality Constraints” on page 6-7). Linear inequality constraints have properties `AInequality` for the inequality constraint matrix, and `bInequality` for the inequality constraint vector.

Setting Linear Inequality Constraints Using the PortfolioMAD Function

The properties for linear inequality constraints are set using the `PortfolioMAD` object. Suppose that you have a portfolio of five assets and you want to ensure that the first three assets are no more than 50% of your portfolio. To set up these constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioMAD('AInequality', A, 'bInequality', b);
disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0

0.5000
```

Setting Linear Inequality Constraints Using the setInequality and addInequality Functions

You can also set the properties for linear inequality constraints using `setInequality`. Suppose that you have a portfolio of five assets and you want to ensure that the first three assets constitute no more than 50% of your portfolio. Given a `PortfolioMAD` object `p`, use `setInequality` to set the linear inequality constraints:

```
A = [ 1 1 1 0 0 ];
b = 0.5;
p = PortfolioMAD;
p = setInequality(p, A, b);
disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0

0.5000
```

Suppose that you want to add another linear inequality constraint to ensure that the last three assets constitute at least 50% of your portfolio. You can set up an augmented system of linear inequalities or use the `addInequality` function to build up linear inequality constraints. For this example, create another system of inequalities:

```
p = PortfolioMAD;
A = [ 1 1 1 0 0 ];    % first inequality constraint
b = 0.5;
p = setInequality(p, A, b);

A = [ 0 0 -1 -1 -1 ];    % second inequality constraint
b = -0.5;
p = addInequality(p, A, b);

disp(p.NumAssets)
disp(p.AInequality)
disp(p.bInequality)
```

```
5

1     1     1     0     0
0     0    -1    -1    -1

0.5000
-0.5000
```

The `PortfolioMAD` object, `setInequality`, and `addInequality` implement scalar expansion on the `bInequality` property based on the dimension of the matrix in the `AInequality` property.

Working with 'Conditional' BoundType, MinNumAssets, and MaxNumAssets Constraints Using PortfolioMAD Objects

When any one, or any combination of 'Conditional' BoundType, MinNumAssets, or MaxNumAssets constraints are active, the portfolio problem is formulated by adding NumAssets binary variables, where 0 indicates not invested, and 1 is invested. For example, to explain the 'Conditional' BoundType and MinNumAssets and MaxNumAssets constraints, assume that your portfolio has a universe of 100 assets that you want to invest:

- 'Conditional' BoundType (also known as semicontinuous constraints), set by setBounds, is often used in situations where you do not want to invest small values. A standard example is a portfolio optimization problem where many small allocations are not attractive because of transaction costs. Instead, you prefer fewer instruments in the portfolio with larger allocations. This situation can be handled using'Conditional' BoundType constraints for a PortfolioMAD object.

  For example, the weight you invest in each asset is either 0 or between [0.01, 0.5]. Generally, a semicontinuous variable *x* is a continuous variable between bounds [lb, ub] that also can assume the value 0, where lb > 0, lb ≤ ub. Applying this to portfolio optimization requires that very small or large positions should be avoided, that is values that fall in (0, lb) or are more than ub.
- MinNumAssets and MaxNumAssets (also known as cardinality constraints), set by setMinMaxNumAssets, limit the number of assets in a PortfolioMAD object. For example, if you have 100 assets in your portfolio and you want the number of assets allocated in the portfolio to be from 40 through 60. Using MinNumAssets and MaxNumAssets you can limit the number of assets in the optimized portfolio, which allows you to limit transaction and operational costs or to create an index tracking portfolio.

Setting 'Conditional' BoundType Constraints Using the setBounds Function

Use setBounds with a 'conditional' BoundType to set *xi* = 0 or 0.02 <= *xi* <= 0.5 for all *i*=1,...NumAssets:

```
p = PortfolioMAD;
p = setBounds(p, 0.02, 0.5,'BoundType', 'Conditional', 'NumAssets', 3)
```

```
p =
  Portfolio with properties:

          BuyCost: []
         SellCost: []

Setting the Limits on the Number of Assets Invested Using the setMinMaxNumAssets Function

You can also set the `MinNumAssets` and `MaxNumAssets` properties to define a limit on the number of assets invested using `setMinMaxNumAssets`. For example, by setting `MinNumAssets=MaxNumAssets=2`, only two of the three assets are invested in the portfolio.

```
p = PortfolioMAD;
p = setBounds(p, 0.02, 0.5,'BoundType', 'Conditional', 'NumAssets', 3)
p = setMinMaxNumAssets(p, 2, 2)
```

```
 p = 

  PortfolioMAD with properties:

Working with Average Turnover Constraints Using PortfolioMAD Object

The turnover constraint is an optional linear absolute value constraint (see “Average Turnover Constraints” on page 6-11) that enforces an upper bound on the average of purchases and sales. The turnover constraint can be set using the `PortfolioMAD` object or the `setTurnover` function. The turnover constraint depends on an initial or current portfolio, which is assumed to be zero if not set when the turnover constraint is set. The turnover constraint has properties `Turnover`, for the upper bound on average turnover, and `InitPort`, for the portfolio against which turnover is computed.

Setting Average Turnover Constraints Using the PortfolioMAD Function

The properties for the turnover constraints are set using the `PortfolioMAD` object. Suppose that you have an initial portfolio of 10 assets in a variable `x0` and you want to ensure that average turnover is no more than 30%. To set this turnover constraint:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioMAD('Turnover', 0.3, 'InitPort', x0);
disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```

0.1000
0.1000
0.1500
0.1100
0.0800
0.1000
```

Note if the `NumAssets` or `InitPort` properties are not set before or when the turnover constraint is set, various rules are applied to assign default values to these properties (see “Setting Up an Initial or Current Portfolio” on page 6-32).

Setting Average Turnover Constraints Using the setTurnover Function

You can also set properties for portfolio turnover using `setTurnover` to specify both the upper bound for average turnover and an initial portfolio. Suppose that you have an initial portfolio of 10 assets in a variable `x0` and want to ensure that average turnover is no more than 30%. Given a `PortfolioMAD` object `p`, use `setTurnover` to set the turnover constraint with and without the initial portfolio being set previously:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioMAD('InitPort', x0);
p = setTurnover(p, 0.3);

disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```

```

or

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioMAD;
p = setTurnover(p, 0.3, x0);
disp(p.NumAssets)
disp(p.Turnover)
disp(p.InitPort)
```

```

`setTurnover` implements scalar expansion on the argument for the initial portfolio. If the `NumAssets` property is already set in the `PortfolioMAD` object, a scalar argument for `InitPort` expands to have the same value across all dimensions. In addition, `setTurnover` lets you specify `NumAssets` as an optional argument. To clear turnover from your `PortfolioMAD` object, use the `PortfolioMAD` object or `setTurnover` with empty inputs for the properties to be cleared.

Working with One-Way Turnover Constraints Using PortfolioMAD Object

One-way turnover constraints are optional constraints (see “One-way Turnover Constraints” on page 6-12) that enforce upper bounds on net purchases or net sales. One-way turnover constraints can be set using the PortfolioMAD object or the setOneWayTurnover function. One-way turnover constraints depend upon an initial or current portfolio, which is assumed to be zero if not set when the turnover constraints are set. One-way turnover constraints have properties BuyTurnover, for the upper bound on net purchases, SellTurnover, for the upper bound on net sales, and InitPort, for the portfolio against which turnover is computed.

Setting One-Way Turnover Constraints Using the PortfolioMAD Function

The Properties for the one-way turnover constraints are set using the PortfolioMAD object. Suppose that you have an initial portfolio with 10 assets in a variable x0 and you want to ensure that turnover on purchases is no more than 30% and turnover on sales is no more than 20% of the initial portfolio. To set these turnover constraints:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioMAD('BuyTurnover', 0.3, 'SellTurnover', 0.2, 'InitPort', x0);
disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```
10

0.3000

0.2000

0.1200
0.0900

0.1000
0.1000
0.1500
0.1100
0.0800
0.1000
```

If the NumAssets or InitPort properties are not set before or when the turnover constraint is set, various rules are applied to assign default values to these properties (see “Setting Up an Initial or Current Portfolio” on page 6-32).

Setting Turnover Constraints Using the setOneWayTurnover Function

You can also set properties for portfolio turnover using setOneWayTurnover to specify to the upper bounds for turnover on purchases (BuyTurnover) and sales (SellTurnover) and an initial portfolio. Suppose that you have an initial portfolio of 10 assets in a variable x0 and want to ensure that turnover on purchases is no more than 30% and that turnover on sales is no more than 20% of the initial portfolio. Given a PortfolioMAD object p, use setOneWayTurnover to set the turnover constraints with and without the initial portfolio being set previously:

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioMAD('InitPort', x0);
p = setOneWayTurnover(p, 0.3, 0.2);

disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

or

```
x0 = [ 0.12; 0.09; 0.08; 0.07; 0.1; 0.1; 0.15; 0.11; 0.08; 0.1 ];
p = PortfolioMAD;
p = setOneWayTurnover(p, 0.3, 0.2, x0);
disp(p.NumAssets)
disp(p.BuyTurnover)
disp(p.SellTurnover)
disp(p.InitPort)
```

```

Validate the MAD Portfolio Problem

In this section...
"Validating a MAD Portfolio Set" on page 6-76
"Validating MAD Portfolios" on page 6-77

Sometimes, you may want to validate either your inputs to, or outputs from, a portfolio optimization problem. Although most error checking that occurs during the problem setup phase catches most difficulties with a portfolio optimization problem, the processes to validate MAD portfolio sets and portfolios are time consuming and are best done offline. So, the portfolio optimization tools have specialized functions to validate MAD portfolio sets and portfolios. For information on the workflow when using `PortfolioMAD` objects, see "PortfolioMAD Object Workflow" on page 6-15.

Validating a MAD Portfolio Set

Since it is necessary and sufficient that your MAD portfolio set must be a nonempty, closed, and bounded set to have a valid portfolio optimization problem, the `estimateBounds` function lets you examine your portfolio set to determine if it is nonempty and, if nonempty, whether it is bounded. Suppose that you have the following MAD portfolio set which is an empty set because the initial portfolio at `0` is too far from a portfolio that satisfies the budget and turnover constraint:

```
p = PortfolioMAD('NumAssets', 3, 'Budget', 1);
p = setTurnover(p, 0.3, 0);
```

If a MAD portfolio set is empty, `estimateBounds` returns `NaN` bounds and sets the `isbounded` flag to `[]`:

```
[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

   NaN
   NaN
   NaN

ub =

   NaN
   NaN
   NaN

isbounded =

     []
```

Suppose that you create an unbounded MAD portfolio set as follows:

```
p = PortfolioMAD('AInequality', [1 -1; 1 1 ], 'bInequality', 0);
[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

  -Inf
  -Inf
```

```
ub =

  1.0e-008 *

   -0.3712
       Inf

isbounded =

     0
```

In this case, estimateBounds returns (possibly infinite) bounds and sets the isbounded flag to false. The result shows which assets are unbounded so that you can apply bound constraints as necessary.

Finally, suppose that you created a PortfolioMAD object that is both nonempty and bounded. estimateBounds not only validates the set, but also obtains tighter bounds which are useful if you are concerned with the actual range of portfolio choices for individual assets in your portfolio:

```
p = PortfolioMAD;
p = setBudget(p, 1,1);
p = setBounds(p, [ -0.1; 0.2; 0.3; 0.2 ], [ 0.5; 0.3; 0.9; 0.8 ]);

[lb, ub, isbounded] = estimateBounds(p)
```

```
lb =

   -0.1000
    0.2000
    0.3000
    0.2000

ub =

    0.3000
    0.3000
    0.7000
    0.6000

isbounded =

     1
```

In this example, all but the second asset has tighter upper bounds than the input upper bound implies.

Validating MAD Portfolios

Given a MAD portfolio set specified in a PortfolioMAD object, you often want to check if specific portfolios are feasible with respect to the portfolio set. This can occur with, for example, initial portfolios and with portfolios obtained from other procedures. The checkFeasibility function determines whether a collection of portfolios is feasible. Suppose that you perform the following portfolio optimization and want to determine if the resultant efficient portfolios are feasible relative to a modified problem.

First, set up a problem in the PortfolioMAD object p, estimate efficient portfolios in pwgt, and then confirm that these portfolios are feasible relative to the initial problem:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);

pwgt = estimateFrontier(p);

checkFeasibility(p, pwgt)
```

```
ans =

     1     1     1     1     1     1     1     1     1     1
```

Next, set up a different portfolio problem that starts with the initial problem with an additional a turnover constraint and an equally weighted initial portfolio:

```
q = setTurnover(p, 0.3, 0.25);
checkFeasibility(q, pwgt)
```

```
ans =

     0     0     1     1     1     0     0     0     0     0
```

In this case, only two of the 10 efficient portfolios from the initial problem are feasible relative to the new problem in `PortfolioMAD` object `q`. Solving the second problem using `checkFeasibility` demonstrates that the efficient portfolio for `PortfolioMAD` object `q` is feasible relative to the initial problem:

```
qwgt = estimateFrontier(q);
checkFeasibility(p, qwgt)
```

```
ans =

     1     1     1     1     1     1     1     1     1     1
```

Estimate Efficient Portfolios Along the Entire Frontier for PortfolioMAD Object

There are two ways to look at a portfolio optimization problem that depends on what you are trying to do. One goal is to estimate efficient portfolios and the other is to estimate efficient frontiers. The “Obtaining Portfolios Along the Entire Efficient Frontier” on page 6-81 example focuses on the former goal and “Estimate Efficient Frontiers for PortfolioMAD Object” on page 6-97 focuses on the latter goal. For information on the workflow when using PortfolioMAD objects, see “PortfolioMAD Object Workflow” on page 6-15.

Obtaining Portfolios Along the Entire Efficient Frontier

The most basic way to obtain optimal portfolios is to obtain points over the entire range of the efficient frontier.

Given a portfolio optimization problem in a `PortfolioMAD` object, the `estimateFrontier` function computes efficient portfolios spaced evenly according to the return proxy from the minimum to maximum return efficient portfolios. The number of portfolios estimated is controlled by the hidden property `defaultNumPorts` which is set to `10`. A different value for the number of portfolios estimated is specified as an input argument to `estimateFrontier`. This example shows the default number of efficient portfolios over the entire range of the efficient frontier.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
pwgt = estimateFrontier(p);
disp(pwgt)
```

```
    0.8821    0.7160    0.5498    0.3849    0.2206    0.0530         0         0         0
    0.0429    0.1429    0.2405    0.3392    0.4350    0.5342    0.4706    0.3338    0.1681
    0.0394    0.0426    0.0487    0.0511    0.0559    0.0628    0.0409    0.0029         0
    0.0356    0.0985    0.1609    0.2248    0.2885    0.3499    0.4885    0.6633    0.8319    1.0
```

If you want only four portfolios, you can use `estimateFrontier` with `NumPorts` specified as `4`.

```
pwgt = estimateFrontier(p, 4);
disp(pwgt)
```

```
    0.8821    0.3849         0         0
    0.0429    0.3392    0.4706         0
    0.0394    0.0511    0.0409         0
    0.0356    0.2248    0.4885    1.0000
```

Starting from the initial portfolio, `estimateFrontier` also returns purchases and sales to get from your initial portfolio to each efficient portfolio on the efficient frontier. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontier(p);

display(pwgt)
```

```
pwgt = 4×10

    0.8821    0.7160    0.5498    0.3849    0.2206    0.0530         0         0         0
    0.0429    0.1429    0.2405    0.3392    0.4350    0.5342    0.4706    0.3338    0.1681
    0.0394    0.0426    0.0487    0.0511    0.0559    0.0628    0.0409    0.0029         0
    0.0356    0.0985    0.1609    0.2248    0.2885    0.3499    0.4885    0.6633    0.8319    1.0
```

```
display(pbuy)
```

```
pbuy = 4×10

    0.5821    0.4160    0.2498    0.0849         0         0         0         0         0
         0         0         0    0.0392    0.1350    0.2342    0.1706    0.0338         0
         0         0         0         0         0         0         0         0         0
         0         0    0.0609    0.1248    0.1885    0.2499    0.3885    0.5633    0.7319    0.9
```

```
display(psell)
```

```
psell = 4×10

         0         0         0         0    0.0794    0.2470    0.3000    0.3000    0.3000    0.3
    0.2571    0.1571    0.0595         0         0         0         0         0    0.1319    0.3
    0.1606    0.1574    0.1513    0.1489    0.1441    0.1372    0.1591    0.1971    0.2000    0.2
    0.0644    0.0015         0         0         0         0         0         0         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Endpoints of the Efficient Frontier

Often when using a PortfolioMAD object, you might be interested in the endpoint portfolios for the efficient frontier. Suppose that you want to determine the range of returns from minimum to maximum to refine a search for a portfolio with a specific target return. Use the estimateFrontierLimits function to obtain the endpoint portfolios.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
pwgt = estimateFrontierLimits(p);

disp(pwgt)

    0.8821         0
    0.0429         0
    0.0394         0
    0.0356    1.0000
```

Note that the endpoints of the efficient frontier depend upon the Scenarios in the PortfolioMAD object. If you change the Scenarios, you are likely to obtain different endpoints.

Starting from an initial portfolio, estimateFrontierLimits also returns purchases and sales to get from the initial portfolio to the endpoint portfolios on the efficient frontier. For example, given an initial portfolio in pwgt0, you can obtain purchases and sales:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierLimits(p);

display(pwgt)
```

```
pwgt = 4×2

    0.8860         0
    0.0419         0
    0.0362         0
    0.0359    1.0000
```

```
display(pbuy)
```

```
pbuy = 4×2

    0.5860         0
         0         0
         0         0
         0    0.9000
```

```
display(psell)
```

```
psell = 4×2

         0    0.3000
    0.2581    0.3000
    0.1638    0.2000
    0.0641         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is 0.

Obtaining Efficient Portfolios for Target Returns

To obtain efficient portfolios that have targeted portfolio returns, the `estimateFrontierByReturn` function accepts one or more target portfolio returns and obtains efficient portfolios with the specified returns. For example, assume that you have a universe of four assets where you want to obtain efficient portfolios with target portfolio returns of 7%, 10%, and 12%:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);

pwgt = estimateFrontierByReturn(p, [0.07,  0.10, .12]);
display(pwgt)

pwgt =

    0.7537    0.3899    0.1478
    0.1113    0.2934    0.4136
    0.0545    0.1006    0.1319
    0.0805    0.2161    0.3066
```

Sometimes, you can request a return for which no efficient portfolio exists. Based on the previous example, suppose that you want a portfolio with a 4% return (which is the return of the first asset). A portfolio that is fully invested in the first asset, however, is inefficient. `estimateFrontierByReturn` warns if your target returns are outside the range of efficient portfolio returns and replaces it with the endpoint portfolio of the efficient frontier closest to your target return:

```
 pwgt = estimateFrontierByReturn(p, [0.04]);

Warning: One or more target return values are outside the feasible range [
0.0591121, 0.182542 ].
    Will return portfolios associated with endpoints of the range for these values.
> In PortfolioMAD.estimateFrontierByReturn at 90
```

The best way to avoid this situation is to bracket your target portfolio returns with `estimateFrontierLimits` and `estimatePortReturn` (see “Obtaining Endpoints of the Efficient Frontier” on page 6-83 and “Obtaining MAD Portfolio Risks and Returns” on page 6-97).

```
pret = estimatePortReturn(p, p.estimateFrontierLimits);

display(pret)

pret =

    0.0591
    0.1825
```

This result indicates that efficient portfolios have returns that range from 6.5% to 17.8%. Note, your results for these examples may be different due to the random generation of scenarios.

If you have an initial portfolio, `estimateFrontierByReturn` also returns purchases and sales to get from your initial portfolio to the target portfolios on the efficient frontier. For example, given an initial portfolio in `pwgt0`, to obtain purchases and sales with target returns of 7%, 10%, and 12%:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierByReturn(p, [0.07,  0.10, .12]);

display(pwgt)
display(pbuy)
display(psell)
```

```
pwgt =

    0.7537    0.3899    0.1478
    0.1113    0.2934    0.4136
    0.0545    0.1006    0.1319
    0.0805    0.2161    0.3066

pbuy =

    0.4537    0.0899         0
         0         0    0.1136
         0         0         0
         0    0.1161    0.2066

psell =

         0         0    0.1522
    0.1887    0.0066         0
    0.1455    0.0994    0.0681
    0.0195         0         0
```

If you do not have an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Obtaining Efficient Portfolios for Target Risks

To obtain efficient portfolios that have targeted portfolio risks, the `estimateFrontierByRisk` function accepts one or more target portfolio risks and obtains efficient portfolios with the specified risks. Suppose that you have a universe of four assets where you want to obtain efficient portfolios with target portfolio risks of 12%, 14%, and 16%.

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);

pwgt = estimateFrontierByRisk(p, [0.12, 0.14, 0.16]);

display(pwgt)
```

```
pwgt =

    0.2102    0.0621         0
    0.3957    0.4723    0.4305
    0.1051    0.1204    0.1291
    0.2889    0.3452    0.4404
```

Sometimes, you can request a risk for which no efficient portfolio exists. Based on the previous example, suppose that you want a portfolio with 6% risk (individual assets in this universe have risks ranging from 7% to 42.5%). It turns out that a portfolio with 6% risk cannot be formed with these four assets. `estimateFrontierByRisk` warns if your target risks are outside the range of efficient portfolio risks and replaces it with the endpoint of the efficient frontier closest to your target risk:

```
pwgt = estimateFrontierByRisk(p, 0.06)
```

```
Warning: One or more target risk values are outside the feasible range [
0.0610574, 0.278711 ].
    Will return portfolios associated with endpoints of the range for these values.
> In PortfolioMAD.estimateFrontierByRisk at 82

pwgt =

    0.8867
    0.0396
    0.0404
    0.0332
```

The best way to avoid this situation is to bracket your target portfolio risks with `estimateFrontierLimits` and `estimatePortRisk` (see “Obtaining Endpoints of the Efficient Frontier” on page 6-83 and “Estimate Efficient Frontiers for PortfolioMAD Object” on page 6-97).

```
prsk = estimatePortRisk(p, p.estimateFrontierLimits);

display(prsk)
```

```
prsk =

    0.0611
    0.2787
```

This result indicates that efficient portfolios have risks that range from 7% to 42.5%. Note, your results for these examples may be different due to the random generation of scenarios.

Starting with an initial portfolio, `estimateFrontierByRisk` also returns purchases and sales to get from your initial portfolio to the target portfolios on the efficient frontier. For example, given an initial portfolio in `pwgt0`, you can obtain purchases and sales from the example with target risks of 12%, 14%, and 16%:

```
pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];
p = setInitPort(p, pwgt0);
[pwgt, pbuy, psell] = estimateFrontierByRisk(p, [0.12, 0.14, 0.16]);

display(pwgt)
display(pbuy)
display(psell)
```

```
pwgt =

    0.2102    0.0621         0
    0.3957    0.4723    0.4305
    0.1051    0.1204    0.1291
    0.2889    0.3452    0.4404

pbuy =

         0         0         0
    0.0957    0.1723    0.1305
         0         0         0
    0.1889    0.2452    0.3404

psell =

    0.0898    0.2379    0.3000
         0         0         0
    0.0949    0.0796    0.0709
         0         0         0
```

If you do not specify an initial portfolio, the purchase and sale weights assume that your initial portfolio is `0`.

Choosing and Controlling the Solver for PortfolioMAD Optimizations

When solving portfolio optimizations for a PortfolioMAD object, you are solving nonlinear optimization problems with either nonlinear objective or nonlinear constraints. You can use 'TrustRegionCP' (default) or 'ExtendedCP' solvers that implement Kelley’s cutting plane method (see Kelley [45] at “Portfolio Optimization” on page A-5). Alternatively, you can use fmincon and all variations of fmincon from Optimization Toolbox are supported. When using fmincon as the solverType, 'sqp' is the default algorithm for fmincon.

Using 'TrustRegionCP' and 'ExtendedCP' SolverTypes

The 'TrustRegionCP' and 'ExtendedCP' solvers have options to control the number iterations and stopping tolerances. Moreover, these solvers use linprog as the primary solver, and all linprog options are supported using optimoptions structures. All these options are set using setSolver.

For example, you can use setSolver to increase the number of iterations for 'TrustRegionCP':

```
p = PortfolioMAD;
p = setSolver(p, 'TrustRegionCP', 'MaxIterations', 2000);
display(p.solverType)
display(p.solverOptions)
```

```
trustregioncp
                MaxIterations: 2000
         AbsoluteGapTolerance: 1.0000e-07
         RelativeGapTolerance: 1.0000e-05
       NonlinearScalingFactor: 1000
       ObjectiveScalingFactor: 1000
          MainSolverOptions: [1×1 optim.options.Linprog]
                      Display: 'off'
                CutGeneration: 'basic'
     MaxIterationsInactiveCut: 30
           ActiveCutTolerance: 1.0000e-07
                  ShrinkRatio: 0.7500
    TrustRegionStartIteration: 2
                   DeltaLimit: 1
```

To change the primary solver algorithm to 'interior-point', with no display, use setSolver to modify 'MainSolverOptions':

```
p = PortfolioMAD;
options = optimoptions('linprog','Algorithm','interior-point','Display','off');
p = setSolver(p,'TrustRegionCP','MainSolverOptions',options);
display(p.solverType)
display(p.solverOptions)
display(p.solverOptions.MainSolverOptions.Algorithm)
display(p.solverOptions.MainSolverOptions.Display)
```

```
trustregioncp
                MaxIterations: 1000
         AbsoluteGapTolerance: 1.0000e-07
         RelativeGapTolerance: 1.0000e-05
       NonlinearScalingFactor: 1000
       ObjectiveScalingFactor: 1000
          MainSolverOptions: [1×1 optim.options.Linprog]
```

```
                      Display: 'off'
                CutGeneration: 'basic'
     MaxIterationsInactiveCut: 30
           ActiveCutTolerance: 1.0000e-07
                  ShrinkRatio: 0.7500
    TrustRegionStartIteration: 2
                   DeltaLimit: 1

interior-point
off
```

Using 'fmincon' SolverType

Unlike Optimization Toolbox which uses the `'interior-point'` algorithm as the default algorithm for `fmincon`, the portfolio optimization for a `PortfolioMAD` object uses the `'sqp'` algorithm as the default. For details about `fmincon` and constrained nonlinear optimization algorithms and options, see “Constrained Nonlinear Optimization Algorithms”.

To modify `fmincon` options for MAD portfolio optimizations, use `setSolver` to set the hidden properties `solverType` and `solverOptions` to specify and control the solver. Since these solver properties are hidden, you cannot set them using the `PortfolioMAD` object. The default for the `fmincon` solver is the `'sqb'` algorithm and no displayed output, so you do not need to use `setSolver` to specify the `'sqp'` algorithm for `fmincon`.

```
p = PortfolioMAD;
p = setSolver(p, 'fmincon');
display(p.solverOptions.Algorithm)
display(p.solverOptions.Display)
```

```
sqp
off
```

If you want to specify additional options associated with the `fmincon` solver, `setSolver` accepts these options as name-value pair arguments. For example, if you want to use `fmincon` with the `'active-set'` algorithm and with displayed output, use `setSolver` with:

```
p = PortfolioMAD;
p = setSolver(p, 'fmincon', 'Algorithm', 'active-set', 'Display', 'final');
display(p.solverOptions)
```

```
fmincon options:

   Options used by current Algorithm ('active-set'):
   (Other available algorithms: 'interior-point', 'sqp', 'sqp-legacy', 'trust-region-reflective'

   Set properties:
                    Algorithm: 'active-set'
                      Display: 'final'

   Default properties:
               CheckGradients: 0
          ConstraintTolerance: 1.0000e-06
     FiniteDifferenceStepSize: 'sqrt(eps)'
         FiniteDifferenceType: 'forward'
            FunctionTolerance: 1.0000e-06
       MaxFunctionEvaluations: '100*numberOfVariables'
                MaxIterations: 400
          OptimalityTolerance: 1.0000e-06
                    OutputFcn: []
```

```
                      PlotFcn: []
    SpecifyConstraintGradient: 0
     SpecifyObjectiveGradient: 0
                StepTolerance: 1.0000e-06
                     TypicalX: 'ones(numberOfVariables,1)'
                  UseParallel: 0
```

Alternatively, the `setSolver` function accepts an `optimoptions` object as the second argument. For example, you can change the algorithm to `'active-set'` with no displayed output as follows:

```
p = PortfolioMAD;
options = optimoptions('fmincon', 'Algorithm', 'active-set', 'Display', 'off');
p = setSolver(p, 'fmincon', options);
display(p.solverOptions.Algorithm)
display(p.solverOptions.Display)
```

```
active-set
off
```

Using the Mixed Integer Nonlinear Programming (MINLP) Solver

The mixed integer nonlinear programming (MINLP) solver, configured using `setSolverMINLP`, enables you to specify associated solver options for portfolio optimization for a `PortfolioMAD` object. The MINLP solver is used when any one, or any combination of `'Conditional'` `BoundType`, `MinNumAssets`, or `MaxNumAssets` constraints are active, the portfolio problem is formulated by adding `NumAssets` binary variables, where `0` indicates not invested, and `1` is invested. For more information on using `'Conditional'` `BoundType`, see `setBounds`. For more information on specifying `MinNumAssets` and `MaxNumAssets`, see `setMinMaxNumAssets`.

When using the `estimate` functions with a `PortfolioMAD` object where `'Conditional'` `BoundType`, `MinNumAssets`, or `MaxNumAssets` constraints are active, the mixed integer nonlinear programming (MINLP) solver is automatically used.

Solver Guidelines for PortfolioMAD Objects

The following table provides guidelines for using `setSolver` and `setSolverMINLP`.

PortfolioMAD Problem	PortfolioMAD Function	Type of Optimization Problem	Main Solver	Helper Solver
PortfolioMAD without active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierByRisk`	Optimizing a portfolio for a certain risk level introduces a nonlinear constraint. Therefore, this problem has a linear objective with linear and nonlinear constraints.	`'TrustRegionCP'`, `'ExtendedCP'`, or `'fmincon'` using `setSolver`	`'linprog'` using `setSolver`

PortfolioMAD Problem	PortfolioMAD Function	Type of Optimization Problem	Main Solver	Helper Solver
PortfolioMAD without active 'Conditional' BoundType, MinNumAssets, and MaxNumAssets	estimateFrontierByReturn	Nonlinear objective with linear constraints	'TrustRegionCP', 'ExtendedCP', or 'fmincon' using setSolver	'linprog' using setSolver
PortfolioMAD without active 'Conditional' BoundType, MinNumAssets, and MaxNumAssets	estimateFrontierLimits	Nonlinear or linear objective with linear constraints	For 'min': nonlinear objective, 'TrustRegionCP', 'ExtendedCP', or 'fmincon' using setSolver For 'max': linear objective, 'linprog' using setSolver	Not applicable
PortfolioMAD with active 'Conditional' BoundType, MinNumAssets, and MaxNumAssets	estimateFrontierByRisk	The problem is formulated by introducing NumAssets binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see setSolverMINLP.	Mixed integer nonlinear programming solver (MINLP) using setSolverMINLP	'fmincon' is used when the estimate functions reduce the problem into NLP. This solver is configured through setSolver.

PortfolioMAD Problem	PortfolioMAD Function	Type of Optimization Problem	Main Solver	Helper Solver
PortfolioMAD with active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierByReturn`	The problem is formulated by introducing `NumAssets` binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see `setSolverMINLP`.	Mixed integer nonlinear programming solver (MINLP) using `setSolverMINLP`	`'fmincon'` is used when the `estimate` functions reduce the problem into NLP. This solver is configured through `setSolver`
PortfolioMAD with active `'Conditional'` `BoundType`, `MinNumAssets`, and `MaxNumAssets`	`estimateFrontierLimits`	The problem is formulated by introducing `NumAssets` binary variables to indicate whether the corresponding asset is invested or not. Therefore, it requires a mixed integer nonlinear programming solver. Three types of MINLP solvers are offered, see `setSolverMINLP`.	Mixed integer nonlinear programming solver (MINLP) using `setSolverMINLP`	`'fmincon'` is used when the `estimate` functions reduce the problem into NLP. This solver is configured through `setSolver`

Estimate Efficient Frontiers for PortfolioMAD Object

In this section...
"Obtaining MAD Portfolio Risks and Returns" on page 6-97
"Obtaining the PortfolioMAD Standard Deviation" on page 6-98

Whereas "Estimate Efficient Portfolios Along the Entire Frontier for PortfolioMAD Object" on page 6-80 focused on estimation of efficient portfolios, this section focuses on the estimation of efficient frontiers. For information on the workflow when using `PortfolioMAD` objects, see "PortfolioMAD Object Workflow" on page 6-15.

Obtaining MAD Portfolio Risks and Returns

Given any portfolio and, in particular, efficient portfolios, the functions `estimatePortReturn` and `estimatePortRisk` provide estimates for the return (or return proxy), risk (or the risk proxy). Each function has the same input syntax but with different combinations of outputs. Suppose that you have this following portfolio optimization problem that gave you a collection of portfolios along the efficient frontier in `pwgt`:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = setInitPort(p, pwgt0);
pwgt = estimateFrontier(p)
```

```
pwgt =

  Columns 1 through 8

    0.8954    0.7264    0.5573    0.3877    0.2176    0.0495    0.0000         0
    0.0310    0.1239    0.2154    0.3081    0.4028    0.4924    0.4069    0.2386
    0.0409    0.0524    0.0660    0.0792    0.0907    0.1047    0.1054    0.1132
    0.0328    0.0973    0.1613    0.2250    0.2890    0.3534    0.4877    0.6482

  Columns 9 through 10

         0    0.0000
    0.0694    0.0000
    0.1221    0.0000
    0.8084    1.0000
```

Note Remember that the risk proxy for MAD portfolio optimization is mean-absolute deviation.

Given pwgt0 and pwgt, use the portfolio risk and return estimation functions to obtain risks and returns for your initial portfolio and the portfolios on the efficient frontier:

```
prsk0 = estimatePortRisk(p, pwgt0);
pret0 = estimatePortReturn(p, pwgt0);
prsk = estimatePortRisk(p, pwgt);
pret = estimatePortReturn(p, pwgt);
display(prsk0)
display(pret0)
display(prsk)
display(pret)
```

You obtain these risks and returns:

```
prsk0 =

    0.0256

pret0 =

    0.0072

prsk =

    0.0178
    0.0193
    0.0233
    0.0286
    0.0348
    0.0414
    0.0489
    0.0584
    0.0692
    0.0809

    0.0047
    0.0059
    0.0072
    0.0084
    0.0096
    0.0108
    0.0120
    0.0133
    0.0145
    0.0157
```

Obtaining the PortfolioMAD Standard Deviation

The PortfolioMAD object has a function to compute standard deviations of portfolio returns, estimatePortStd. This function works with any portfolios, not necessarily efficient portfolios. For example, the following example obtains five portfolios (pwgt) on the efficient frontier and also has an initial portfolio in pwgt0. Various portfolio statistics are computed that include the return, risk, and standard deviation. The listed estimates are for the initial portfolio in the first row followed by estimates for each of the five efficient portfolios in subsequent rows.

```
m = [ 0.0042; 0.0083; 0.01; 0.15 ];
C = [ 0.005333 0.00034 0.00016 0;
0.00034 0.002408 0.0017 0.000992;
0.00016 0.0017 0.0048 0.0028;
0 0.000992 0.0028 0.010208 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioMAD('initport', pwgt0);
p = simulateNormalScenariosByMoments(p, m, C, 20000);
p = setDefaultConstraints(p);

pwgt = estimateFrontier(p, 5);

pret = estimatePortReturn(p, [pwgt0, pwgt]);
prsk = estimatePortRisk(p, [pwgt0, pwgt]);
pstd = estimatePortStd(p, [pwgt0, pwgt]);

[pret, prsk, pstd]
```

```
ans =

    0.0212    0.0305    0.0381
    0.0187    0.0326    0.0407
    0.0514    0.0369    0.0462
    0.0841    0.0484    0.0607
    0.1168    0.0637    0.0796
    0.1495    0.0807    0.1009
```

Plotting the Efficient Frontier for a PortfolioMAD Object

The plotFrontier function creates a plot of the efficient frontier for a given portfolio optimization problem. This function accepts several types of inputs and generates a plot with an optional possibility to output the estimates for portfolio risks and returns along the efficient frontier. plotFrontier has four different ways that it can be used. In addition to a plot of the efficient frontier, if you have an initial portfolio in the InitPort property, plotFrontier also displays the return versus risk of the initial portfolio on the same plot. If you have a well-posed portfolio optimization problem set up in a PortfolioMAD object and you use plotFrontier, you get a plot of the efficient frontier with the default number of portfolios on the frontier (the default number is 10 and is maintained in the hidden property defaultNumPorts). This example illustrates a typical use of plotFrontier to create a new plot:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

AssetScenarios = mvnrnd(m, C, 20000);

p = PortfolioMAD;
p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);

plotFrontier(p)
```

Mean Absolute Deviation of Portfolio Returns

The Name property appears as the title of the efficient frontier plot if you set it in the PortfolioMAD object. Without an explicit name, the title on the plot would be “Efficient Frontier.” If you want to obtain a specific number of portfolios along the efficient frontier, use plotFrontier with the number of portfolios that you want. Suppose that you have the PortfolioMAD object from the previous example and you want to plot 20 portfolios along the efficient frontier and to obtain 20 risk and return values for each portfolio:

```
[prsk, pret] = plotFrontier(p, 20);
display([pret, prsk])

ans =

    0.0049    0.0176
    0.0054    0.0179

Plotting Existing Efficient Portfolios

If you already have efficient portfolios from any of the "estimateFrontier" functions (see “Estimate Efficient Frontiers for PortfolioMAD Object” on page 6-97), pass them into `plotFrontier` directly to plot the efficient frontier:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
    0.00408 0.0289 0.0204 0.0119;
    0.00192 0.0204 0.0576 0.0336;
    0 0.0119 0.0336 0.1225 ];
m = m/12;
C = C/12;

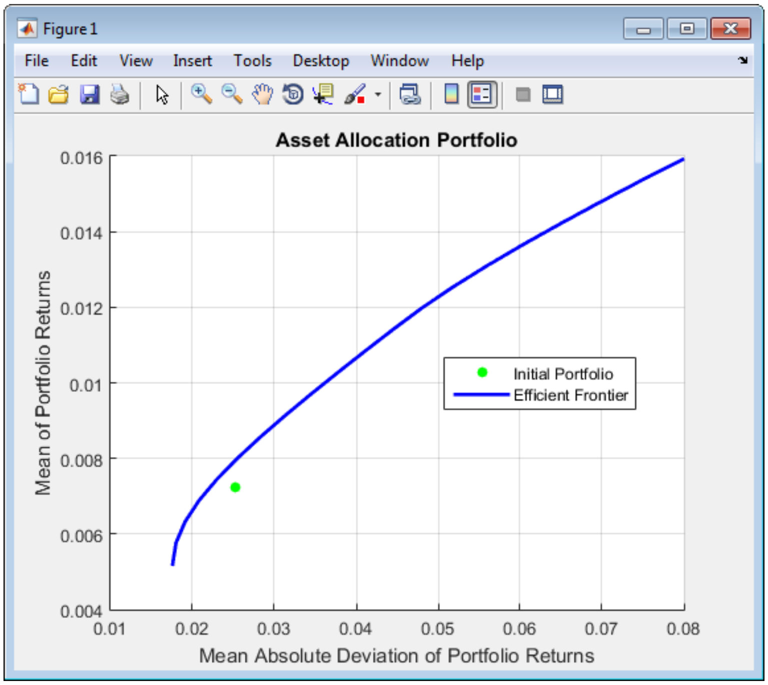
AssetScenarios = mvnrnd(m, C, 20000);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioMAD('Name', 'Asset Allocation Portfolio', 'InitPort', pwgt0);

p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);

pwgt = estimateFrontier(p, 20);
plotFrontier(p, pwgt)
```



Plotting Existing Efficient Portfolio Risks and Returns

If you already have efficient portfolio risks and returns, you can use the interface to `plotFrontier` to pass them into `plotFrontier` to obtain a plot of the efficient frontier:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
      0.00408 0.0289 0.0204 0.0119;
      0.00192 0.0204 0.0576 0.0336;
      0 0.0119 0.0336 0.1225 ];

AssetScenarios = mvnrnd(m, C, 20000);

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioMAD('Name', 'Asset Allocation Portfolio', 'InitPort', pwgt0);

p = setScenarios(p, AssetScenarios);
p = setDefaultConstraints(p);
```

```
pwgt = estimateFrontier(p);

pret= estimatePortReturn(p, pwgt)
prsk = estimatePortRisk(p, pwgt)

plotFrontier(p, prsk, pret)
```

```
pret =

    0.0590
    0.0723
    0.0857
    0.0991
    0.1124
    0.1258
    0.1391
    0.1525
    0.1658
    0.1792

prsk =

    0.0615
    0.0664
    0.0795
    0.0976
    0.1184
    0.1408
    0.1663
    0.1992
    0.2368
    0.2787
```

Postprocessing Results to Set Up Tradable Portfolios

After obtaining efficient portfolios or estimates for expected portfolio risks and returns, use your results to set up trades to move toward an efficient portfolio. For information on the workflow when using `PortfolioMAD` objects, see “PortfolioMAD Object Workflow” on page 6-15.

Setting Up Tradable Portfolios

Suppose that you set up a portfolio optimization problem and obtained portfolios on the efficient frontier. Use the `dataset` object from Statistics and Machine Learning Toolbox to form a blotter that lists your portfolios with the names for each asset. For example, suppose that you want to obtain five portfolios along the efficient frontier. You can set up a blotter with weights multiplied by 100 to view the allocations for each portfolio:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioMAD;
p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');
p = setInitPort(p, pwgt0);
p = simulateNormalScenariosByMoments(p, m, C, 20000);
p = setDefaultConstraints(p);

pwgt = estimateFrontier(p, 5);

pnames = cell(1,5);
for i = 1:5
pnames{i} = sprintf('Port%d',i);
end

Blotter = dataset([{100*pwgt},pnames],'obsnames',p.AssetList);
display(Blotter)
```

```
Blotter = 

                          Port1     Port2     Port3     Port4     Port5     
    Bonds                 88.154    50.867    13.611         0    1.0609e-12
    Large-Cap Equities    4.0454    22.571    41.276     23.38    7.9362e-13
    Small-Cap Equities    4.2804    9.3108    14.028    17.878    6.4823e-14
    Emerging Equities     3.5202    17.252    31.084    58.743           100
```

Note Your results may differ from this result due to the simulation of scenarios.

This result indicates that you would invest primarily in bonds at the minimum-risk/minimum-return end of the efficient frontier (`Port1`), and that you would invest completely in emerging equity at the maximum-risk/maximum-return end of the efficient frontier (`Port5`). You can also select a particular efficient portfolio, for example, suppose that you want a portfolio with 15% risk and you add purchase and sale weights outputs obtained from the “estimateFrontier” functions to set up a trade blotter:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioMAD;
p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');

p = setInitPort(p, pwgt0);
p = simulateNormalScenariosByMoments(p, m, C, 20000);
```

```
p = p.setDefaultConstraints;

[pwgt, pbuy, psell] = estimateFrontierByRisk(p, 0.15);

Blotter = dataset([{100*[pwgt0, pwgt, pbuy, psell]}, ...
{'Initial','Weight', 'Purchases','Sales'}],'obsnames',p.AssetList);
display(Blotter)
```

```
Blotter = 

                          Initial    Weight        Purchases    Sales 
    Bonds                 30         6.0364e-18         0           30
    Large-Cap Equities    30             50.179    20.179            0
    Small-Cap Equities    20              13.43         0       6.5696
    Emerging Equities     10             36.391    26.391            0
```

If you have prices for each asset (in this example, they can be ETFs), add them to your blotter and then use the tools of the `dataset` object to obtain shares and shares to be traded.

Working with Other Portfolio Objects

The PortfolioMAD object is for MAD portfolio optimization. The PortfolioCVaR object is for CVaR portfolio optimization. The Portfolio object is for mean-variance portfolio optimization. Sometimes, you might want to examine portfolio optimization problems according to different combinations of return and risk proxies. A common example is that you want to do a MAD portfolio optimization and then want to work primarily with moments of portfolio returns. Suppose that you set up a MAD portfolio optimization problem with:

```
m = [ 0.05; 0.1; 0.12; 0.18 ];
C = [ 0.0064 0.00408 0.00192 0;
0.00408 0.0289 0.0204 0.0119;
0.00192 0.0204 0.0576 0.0336;
0 0.0119 0.0336 0.1225 ];

pwgt0 = [ 0.3; 0.3; 0.2; 0.1 ];

p = PortfolioMAD;
p = setAssetList(p, 'Bonds','Large-Cap Equities','Small-Cap Equities','Emerging Equities');
p = setInitPort(p, pwgt0);
p = simulateNormalScenariosByMoments(p, m, C, 20000);
p = setDefaultConstraints(p);
```

To work with the same problem in a mean-variance framework, you can use the scenarios from the PortfolioMAD object to set up a Portfolio object so that p contains a MAD optimization problem and q contains a mean-variance optimization problem based on the same data.

```
q = Portfolio('AssetList', p.AssetList);
q = estimateAssetMoments(q, p.getScenarios);
q = setDefaultConstraints(q);

pwgt = estimateFrontier(p);
qwgt = estimateFrontier(q);
```

Since each object has a different risk proxy, it is not possible to compare results side by side. To obtain means and standard deviations of portfolio returns, you can use the functions associated with each object to obtain:

```
pret = estimatePortReturn(p, pwgt);
pstd = estimatePortStd(p, pwgt);
qret = estimatePortReturn(q, qwgt);
qstd = estimatePortStd(q, qwgt);

[pret, qret]
[pstd, qstd]

ans =

    0.0592    0.0590
    0.0730    0.0728
    0.0868    0.0867
    0.1006    0.1005
    0.1145    0.1143
    0.1283    0.1282
    0.1421    0.1420
    0.1559    0.1558
    0.1697    0.1697
    0.1835    0.1835

ans =
    0.0767    0.0767
    0.0829    0.0828
    0.0989    0.0987
    0.1208    0.1206
    0.1461    0.1459
    0.1732    0.1730
    0.2042    0.2040
    0.2453    0.2452
    0.2929    0.2928
    0.3458    0.3458
```

To produce comparable results, you can use the returns or risks from one portfolio optimization as target returns or risks for the other portfolio optimization.

```
qwgt = estimateFrontierByReturn(q, pret);
qret = estimatePortReturn(q, qwgt);
qstd = estimatePortStd(q, qwgt);

[pret, qret]
[pstd, qstd]
```

```
ans =

    0.0592    0.0592
    0.0730    0.0730
    0.0868    0.0868
    0.1006    0.1006
    0.1145    0.1145
    0.1283    0.1283
    0.1421    0.1421
    0.1559    0.1559
    0.1697    0.1697
    0.1835    0.1835

ans =

    0.0767    0.0767
    0.0829    0.0829
    0.0989    0.0989
    0.1208    0.1208
    0.1461    0.1461
    0.1732    0.1732
    0.2042    0.2042
    0.2453    0.2453
    0.2929    0.2929
    0.3458    0.3458
```

Now it is possible to compare standard deviations of portfolio returns from either type of portfolio optimization.

Troubleshooting MAD Portfolio Optimization Results

PortfolioMAD Object Destroyed When Modifying

If a PortfolioMAD object is destroyed when modifying, remember to pass an existing object into the PortfolioMAD object if you want to modify it, otherwise it creates a new object. See "Creating the PortfolioMAD Object" on page 6-21 for details.

Matrix Incompatibility and "Non-Conformable" Errors

If you get matrix incompatibility or "non-conformable" errors, the representation of data in the tools follows a specific set of basic rules described in "Conventions for Representation of Data" on page 6-19.

Missing Data Estimation Fails

If asset return data has missing or NaN values, the simulateNormalScenariosByData function with the 'missingdata' flag set to true may fail with either too many iterations or a singular covariance. To correct this problem, consider this:

- If you have asset return data with no missing or NaN values, you can compute a covariance matrix that may be singular without difficulties. If you have missing or NaN values in your data, the supported missing data feature requires that your covariance matrix must be positive-definite, that is, nonsingular.
- simulateNormalScenariosByData uses default settings for the missing data estimation procedure that might not be appropriate for all problems.

In either case, you might want to estimate the moments of asset returns separately with either the ECM estimation functions such as ecmnmle or with your own functions.

mad_optim_transform Errors

If you obtain optimization errors such as:

```
Error using mad_optim_transform (line 276)
Portfolio set appears to be either empty or unbounded. Check constraints.

Error in PortfolioMAD/estimateFrontier (line 64)
    [AI, bI, AE, bE, lB, uB, f0, f, x0] = mad_optim_transform(obj);
```

or

```
Error using mad_optim_transform (line 281)
Cannot obtain finite lower bounds for specified portfolio set.

Error in PortfolioMAD/estimateFrontier (line 64)
    [AI, bI, AE, bE, lB, uB, f0, f, x0] = mad_optim_transform(obj);
```

Since the portfolio optimization tools require a bounded portfolio set, these errors (and similar errors) can occur if your portfolio set is either empty and, if nonempty, unbounded. Specifically, the portfolio optimization algorithm requires that your portfolio set have at least a finite lower bound. The best way to deal with these problems is to use the validation methods in "Validate the MAD Portfolio Problem" on page 6-76. Specifically, use estimateBounds to examine your portfolio set, and use checkFeasibility to ensure that your initial portfolio is either feasible and, if infeasible, that you have sufficient turnover to get from your initial portfolio to the portfolio set.

Tip To correct this problem, try solving your problem with larger values for turnover and gradually reduce to the value that you want.

Efficient Portfolios Do Not Make Sense

If you obtain efficient portfolios that, do not seem to make sense, this can happen if you forget to set specific constraints or you set incorrect constraints. For example, if you allow portfolio weights to fall between `0` and `1` and do not set a budget constraint, you can get portfolios that are 100% invested in every asset. Although it may be hard to detect, the best thing to do is to review the constraints you have set with display of the `PortfolioMAD` object. If you get portfolios with 100% invested in each asset, you can review the display of your object and quickly see that no budget constraint is set. Also, you can use `estimateBounds` and `checkFeasibility` to determine if the bounds for your portfolio set make sense and to determine if the portfolios you obtained are feasible relative to an independent formulation of your portfolio set.

Investment Performance Metrics

Performance Metrics Overview

Performance Metrics Types

Sharpe first proposed a ratio of excess return to total risk as an investment performance metric. Subsequent work by Sharpe, Lintner, and Mossin extended these ideas to entire asset markets in what is called the Capital Asset Pricing Model (CAPM). Since the development of the CAPM, various investment performance metrics has evolved.

This section presents four types of investment performance metrics:

- The first type of metrics is absolute investment performance metrics that are called “classic” metrics since they are based on the CAPM. They include the Sharpe ratio, the information ratio, and tracking error. To compute the Sharpe ratio from data, use `sharpe` to calculate the ratio for one or more asset return series. To compute the information ratio and associated tracking error, use `inforatio` to calculate these quantities for one or more asset return series.
- The second type of metrics is relative investment performance metrics to compute risk-adjusted returns. These metrics are also based on the CAPM and include Beta, Jensen's Alpha, the Security Market Line (SML), Modigliani and Modigliani Risk-Adjusted Return, and the Graham-Harvey measures. To calculate risk-adjusted alpha and return, use `portalpha`.
- The third type of metrics is alternative investment performance metrics based on lower partial moments. To calculate lower partial moments, use `lpm` for sample lower partial moments and `elpm` for expected lower partial moments.
- The fourth type of metrics is performance metrics based on maximum drawdown and expected maximum drawdown. Drawdown is the peak to trough decline during a specific record period of an investment or fund. To calculate maximum or expected maximum drawdowns, use `maxdrawdown` and `emaxdrawdown`.

Performance Metrics Illustration

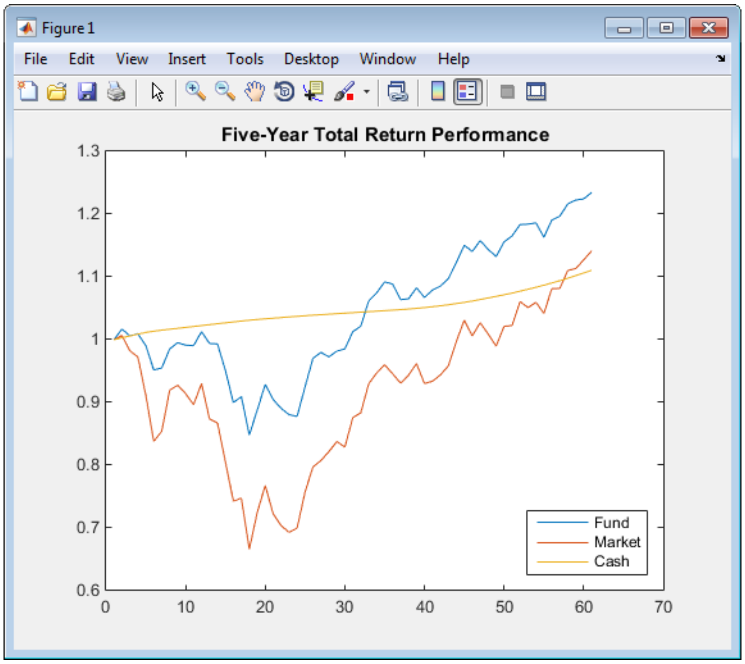
To illustrate the functions for investment performance metrics, you work with three financial time series objects using performance data for:

- An actively managed, large-cap value mutual fund
- A large-cap market index
- 90-day Treasury bills

The data is monthly total return prices that cover a span of five years.

The following plot illustrates the performance of each series in terms of total returns to an initial $1 invested at the start of this 5-year period:

```
load FundMarketCash
plot(TestData)
hold on
title('\bfFive-Year Total Return Performance');
legend('Fund','Market','Cash','Location','SouthEast');
hold off
```



The mean (`Mean`) and standard deviation (`Sigma`) of returns for each series are

```
Returns = tick2ret(TestData);
Assets
Mean = mean(Returns)
Sigma = std(Returns, 1)
```

which gives the following result:

```
Assets =
    'Fund'     'Market'     'Cash'
Mean =
    0.0038    0.0030    0.0017
Sigma =
    0.0229    0.0389    0.0009
```

Note Functions for investment performance metrics use total return price and total returns. To convert between total return price and total returns, use `ret2tick` and `tick2ret`.

Using the Sharpe Ratio

In this section...

Introduction

The Sharpe ratio is the ratio of the excess return of an asset divided by the asset's standard deviation of returns. The Sharpe ratio has the form:

```
(Mean − Riskless) / Sigma
```

Here `Mean` is the mean of asset returns, `Riskless` is the return of a riskless asset, and `Sigma` is the standard deviation of asset returns. A higher Sharpe ratio is better than a lower Sharpe ratio. A negative Sharpe ratio indicates “anti-skill” since the performance of the riskless asset is superior. For more information, see `sharpe`.

Sharpe Ratio

To compute the Sharpe ratio, the mean return of the cash asset is used as the return for the riskless asset. Thus, given asset return data and the riskless asset return, the Sharpe ratio is calculated with

```
load FundMarketCash
Returns = tick2ret(TestData);
Riskless = mean(Returns(:,3))
Sharpe = sharpe(Returns, Riskless)
```

which gives the following result:

```
Riskless =
    0.0017
Sharpe =
    0.0886    0.0315         0
```

The Sharpe ratio of the example fund is significantly higher than the Sharpe ratio of the market. As is demonstrated with `portalpha`, this translates into a strong risk-adjusted return. Since the `Cash` asset is the same as `Riskless`, it makes sense that its Sharpe ratio is 0. The Sharpe ratio was calculated with the mean of cash returns. It can also be calculated with the cash return series as input for the riskless asset

```
Sharpe = sharpe(Returns, Returns(:,3))
```

which gives the following result:

```
Sharpe =
    0.0886    0.0315         0
```

When using the `Portfolio` object, you can use the `estimateMaxSharpeRatio` function to estimate an efficient portfolio that maximizes the Sharpe ratio. For more information, see “Efficient Portfolio That Maximizes Sharpe Ratio” on page 4-107.

Using the Information Ratio

Introduction

Although originally called the "appraisal ratio" by Treynor and Black, the information ratio is the ratio of relative return to relative risk (known as "tracking error"). Whereas the Sharpe ratio looks at returns relative to a riskless asset, the information ratio is based on returns relative to a risky benchmark which is known colloquially as a "bogey." Given an asset or portfolio of assets with random returns designated by `Asset` and a benchmark with random returns designated by `Benchmark`, the information ratio has the form:

```
Mean(Asset − Benchmark) / Sigma (Asset − Benchmark)
```

Here `Mean(Asset − Benchmark)` is the mean of `Asset` minus `Benchmark` returns, and `Sigma(Asset - Benchmark)` is the standard deviation of `Asset` minus `Benchmark` returns. A higher information ratio is considered better than a lower information ratio. For more information, see `inforatio`.

Information Ratio

To calculate the information ratio using the example data, the mean return of the market series is used as the return of the benchmark. Thus, given asset return data and the riskless asset return, compute the information ratio with

```
load FundMarketCash
Returns = tick2ret(TestData);
Benchmark = Returns(:,2);
InfoRatio = inforatio(Returns, Benchmark)
```

which gives the following result:

```
InfoRatio =
    0.0432       NaN   -0.0315
```

Since the market series has no risk relative to itself, the information ratio for the second series is undefined (which is represented as `NaN` in MATLAB software). Its standard deviation of relative returns in the denominator is 0.

Using Tracking Error

In this section...

Introduction

Given an asset or portfolio of assets and a benchmark, the relative standard deviation of returns between the asset or portfolio of assets and the benchmark is called tracking error.

Tracking Error

The function `inforatio` computes tracking error and returns it as a second argument

```
load FundMarketCash
Returns = tick2ret(TestData);
Benchmark = Returns(:,2);
[InfoRatio, TrackingError] = inforatio(Returns, Benchmark)
```

which gives the following results:

```
InfoRatio =
    0.0432       NaN   -0.0315
TrackingError =
    0.0187         0    0.0390
```

Tracking error, also know as active risk, measures the volatility of active returns. Tracking error is a useful measure of performance relative to a benchmark since it is in units of asset returns. For example, the tracking error of 1.87% for the fund relative to the market in this example is reasonable for an actively managed, large-cap value fund.

Using Risk-Adjusted Return

In this section...

Introduction

Risk-adjusted return either shifts the risk (which is the standard deviation of returns) of a portfolio to match the risk of a market portfolio or shifts the risk of a market portfolio to match the risk of a fund. According to the Capital Asset Pricing Model (CAPM), the market portfolio and a riskless asset are points on a Security Market Line (SML). The return of the resultant shifted portfolio, levered or unlevered, to match the risk of the market portfolio, is the risk-adjusted return. The SML provides another measure of risk-adjusted return, since the difference in return between the fund and the SML, return at the same level of risk.

Risk-Adjusted Return

Given our example data with a fund, a market, and a cash series, you can calculate the risk-adjusted return and compare it with the fund and market's mean returns

```
load FundMarketCash
Returns = tick2ret(TestData);
Fund = Returns(:,1);
Market = Returns(:,2);
Cash = Returns(:,3);
MeanFund = mean(Fund)
MeanMarket = mean(Market)

[MM, aMM] = portalpha(Fund, Market, Cash, 'MM')
[GH1, aGH1] = portalpha(Fund, Market, Cash, 'gh1')
[GH2, aGH2] = portalpha(Fund, Market, Cash, 'gh2')
[SML, aSML] = portalpha(Fund, Market, Cash, 'sml')
```

which gives the following results:

```
MeanFund =

    0.0038

MeanMarket =

    0.0030

MM =

    0.0022

aMM =

    0.0052

GH1 =
    0.0013

aGH1 =

    0.0025

GH2 =

    0.0022

aGH2 =

    0.0052

SML =

    0.0013

aSML =

    0.0025
```

Since the fund's risk is much less than the market's risk, the risk-adjusted return of the fund is much higher than both the nominal fund and market returns.

Using Sample and Expected Lower Partial Moments

In this section...

Introduction

Use lower partial moments to examine what is colloquially known as "downside risk." The main idea of the lower partial moment framework is to model moments of asset returns that fall below a minimum acceptable level of return. To compute lower partial moments from data, use lpm to calculate lower partial moments for multiple asset return series and for multiple moment orders. To compute expected values for lower partial moments under several assumptions about the distribution of asset returns, use elpm to calculate lower partial moments for multiple assets and for multiple orders.

Sample Lower Partial Moments

The following example demonstrates lpm to compute the zero-order, first-order, and second-order lower partial moments for the three time series, where the mean of the third time series is used to compute MAR (minimum acceptable return) with the so-called risk-free rate.

```
load FundMarketCash
Returns = tick2ret(TestData);
Assets
MAR = mean(Returns(:,3))
LPM = lpm(Returns, MAR, [0 1 2])
```

which gives the following results:

```
Assets =
    'Fund'    'Market'    'Cash'
MAR =
    0.0017
LPM =
    0.4333    0.4167    0.6167
    0.0075    0.0140    0.0004
    0.0003    0.0008    0.0000
```

The first row of LPM contains zero-order lower partial moments of the three series. The fund and market index fall below MAR about 40% of the time and cash returns fall below its own mean about 60% of the time.

The second row contains first-order lower partial moments of the three series. The fund and market have large average shortfall returns relative to MAR by 75 and 140 basis points per month. On the other hand, cash underperforms MAR by about only four basis points per month on the downside.

The third row contains second-order lower partial moments of the three series. The square root of these quantities provides an idea of the dispersion of returns that fall below the MAR. The market index has a much larger variation on the downside when compared to the fund.

Expected Lower Partial Moments

To compare realized values with expected values, use `elpm` to compute expected lower partial moments based on the mean and standard deviations of normally distributed asset returns. The `elpm` function works with the mean and standard deviations for multiple assets and multiple orders.

```
load FundMarketCash
Returns = tick2ret(TestData);
MAR = mean(Returns(:,3))
Mean = mean(Returns)
Sigma = std(Returns, 1)
Assets
ELPM = elpm(Mean, Sigma, MAR, [0 1 2])
```

which gives the following results:

```
Assets =
    'Fund'    'Market'    'Cash'
ELPM =
    0.4647    0.4874    0.5000
    0.0082    0.0149    0.0004
    0.0002    0.0007    0.0000
```

Based on the moments of each asset, the expected values for lower partial moments imply better than expected performance for the fund and market and worse than expected performance for cash. This function works with either degenerate or nondegenerate normal random variables. For example, if cash were truly riskless, its standard deviation would be 0. You can examine the difference in average shortfall.

```
RisklessCash = elpm(Mean(3), 0, MAR, 1)
```

which gives the following result:

```
RisklessCash =
     0
```

- “Using Tracking Error” on page 7-9
- “Using Risk-Adjusted Return” on page 7-10
- “Using Maximum and Expected Maximum Drawdown” on page 7-14

Using Maximum and Expected Maximum Drawdown

Introduction

Maximum drawdown is the maximum decline of a series, measured as return, from a peak to a nadir over a period of time. Although additional metrics exist that are used in the hedge fund and commodity trading communities (see Pederson and Rudholm-Alfvin [20] in “Bibliography” on page A-2), the original definition and subsequent implementation of these metrics is not yet standardized.

It is possible to compute analytically the expected maximum drawdown for a Brownian motion with drift (see Magdon-Ismail, Atiya, Pratap, and Abu-Mostafa [16] “Bibliography” on page A-2). These results are used to estimate the expected maximum drawdown for a series that approximately follows a geometric Brownian motion.

Use maxdrawdown and emaxdrawdown to calculate the maximum and expected maximum drawdowns.

Maximum Drawdown

This example demonstrates how to compute the maximum drawdown (MaxDD) using example data with a fund, a market, and a cash series:

```
load FundMarketCash
MaxDD = maxdrawdown(TestData)
```

which gives the following results:

```
MaxDD =
    0.1658    0.3381         0
```

The maximum drop in the given time period is 16.58% for the fund series and 33.81% for the market. There is no decline in the cash series, as expected, because the cash account never loses value.

maxdrawdown can also return the indices (MaxDDIndex) of the maximum drawdown intervals for each series in an optional output argument:

```
[MaxDD, MaxDDIndex] = maxdrawdown(TestData)
```

which gives the following results:

```
MaxDD =

    0.1658    0.3381         0

MaxDDIndex =

     2     2   NaN
    18    18   NaN
```

The first two series experience their maximum drawdowns from the second to the 18th month in the data. The indices for the third series are NaNs because it never has a drawdown.

The 16.58% value loss from month 2 to month 18 for the fund series is verified using the reported indices:

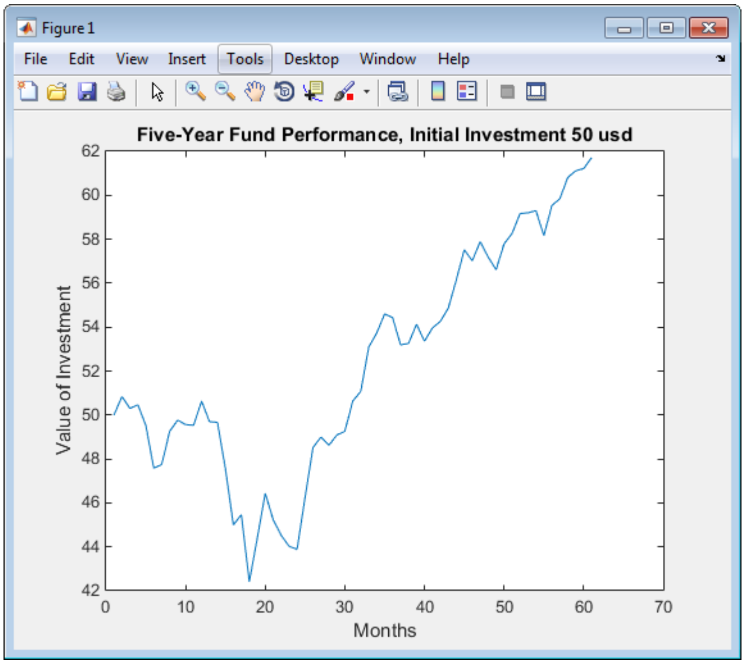
```
Start = MaxDDIndex(1,:);
End = MaxDDIndex(2,:);
(TestData(Start(1),1) - TestData(End(1),1))/TestData(Start(1),1)
```

```
ans =

    0.1658
```

Although the maximum drawdown is measured in terms of returns, `maxdrawdown` can measure the drawdown in terms of absolute drop in value, or in terms of log-returns. To contrast these alternatives more clearly, you can work with the fund series assuming, an initial investment of 50 dollars:

```
Fund50 = 50*TestData(:,1);
plot(Fund50);
title('\bfFive-Year Fund Performance, Initial Investment 50 usd');
xlabel('Months');
ylabel('Value of Investment');
```



First, compute the standard maximum drawdown, which coincides with the results above because returns are independent of the initial amounts invested:

```
MaxDD50Ret = maxdrawdown(Fund50)
```

```
MaxDD50Ret =

    0.1658
```

Next, compute the maximum drop in value, using the `arithmetic` argument:

```
[MaxDD50Arith, Ind50Arith] = maxdrawdown(Fund50,'arithmetic')
```

```
MaxDD50Arith =

    8.4285
```

```
Ind50Arith =

     2
    18
```

The value of this investment is $50.84 in month 2, but by month 18 the value is down to $42.41, a drop of $8.43. This is the largest loss in dollar value from a previous high in the given time period. In this case, the maximum drawdown period, 2nd to 18th month, is the same independently of whether drawdown is measured as return or as dollar value loss.

Finally, you can compute the maximum decline based on log-returns using the `geometric` argument. In this example, the log-returns result in a maximum drop of 18.13%, again from the second to the 18th month, not far from the 16.58% obtained using standard returns.

```
[MaxDD50LogRet, Ind50LogRet] = maxdrawdown(Fund50,'geometric')
```

```
MaxDD50LogRet =

    0.1813

Ind50LogRet =

     2
    18
```

Note, the last measure is equivalent to finding the arithmetic maximum drawdown for the log of the series:

```
MaxDD50LogRet2 = maxdrawdown(log(Fund50),'arithmetic')
```

```
MaxDD50LogRet2 =

    0.1813
```

Expected Maximum Drawdown

This example demonstrates using the log-return moments of the fund to compute the expected maximum drawdown (`EMaxDD`) and then compare it with the realized maximum drawdown (`MaxDD`).

```
load FundMarketCash
logReturns = log(TestData(2:end,:) ./ TestData(1:end - 1,:));
Mu = mean(logReturns(:,1));
Sigma = std(logReturns(:,1),1);
T = size(logReturns,1);

MaxDD = maxdrawdown(TestData(:,1),'geometric')
EMaxDD = emaxdrawdown(Mu, Sigma, T)
```

which gives the following results:

```
MaxDD =

    0.1813
```

```
EMaxDD =

    0.1545
```

The drawdown observed in this time period is above the expected maximum drawdown. There is no contradiction here. The expected maximum drawdown is not an upper bound on the maximum losses from a peak, but an estimate of their average, based on a geometric Brownian motion assumption.

Credit Risk Analysis

Estimation of Transition Probabilities

In this section...

Introduction

Credit ratings rank borrowers according to their credit worthiness. Though this ranking is, in itself, useful, institutions are also interested in knowing how likely it is that borrowers in a particular rating category will be upgraded or downgraded to a different rating, and especially, how likely it is that they will default.

Transition probabilities offer one way to characterize the past changes in credit quality of obligors (typically firms), and are cardinal inputs to many risk management applications. Financial Toolbox software supports the estimation of transition probabilities using both cohort and duration (also known as hazard rate or intensity) approaches using `transprob` and related functions.

Note The sample dataset used throughout this section is simulated using a single transition matrix. No attempt is made to match historical trends in transition rates.

Estimate Transition Probabilities

The `Data_TransProb.mat` file contains sample credit ratings data.

```
load Data_TransProb
data(1:10,:)
```

```
ans = 

        ID              Date          Rating
    ___________    _____________    ______

    '00010283'    '10-Nov-1984'    'CCC'
    '00010283'    '12-May-1986'    'B'
    '00010283'    '29-Jun-1988'    'CCC'
    '00010283'    '12-Dec-1991'    'D'
    '00013326'    '09-Feb-1985'    'A'
    '00013326'    '24-Feb-1994'    'AA'
    '00013326'    '10-Nov-2000'    'BBB'
    '00014413'    '23-Dec-1982'    'B'
    '00014413'    '20-Apr-1988'    'BB'
    '00014413'    '16-Jan-1998'    'B'
```

The sample data is formatted as a cell array with three columns. Each row contains an ID (column 1), a date (column 2), and a credit rating (column 3). The assigned credit rating corresponds to the associated ID on the associated date. All information corresponding to the same ID must be stored in contiguous rows. In this example, IDs, dates, and ratings are stored in character vector format, but you also can enter them in numeric format.

In this example, the simplest calling syntax for `transprob` passes the `nRecords`-by-`3` cell array as the only input argument. The default `startDate` and `endDate` are the earliest and latest dates in the data. The default estimation algorithm is the duration method and one-year transition probabilities are estimated:

```
transMat0 = transprob(data)

transMat0 =

93.1170    5.8428    0.8232    0.1763    0.0376    0.0012    0.0001    0.0017
 1.6166   93.1518    4.3632    0.6602    0.1626    0.0055    0.0004    0.0396

```

Provide explicit start and end dates, otherwise, the estimation window for two different datasets can differ, and the estimates might not be comparable. From this point, assume that the time window of interest is the five-year period from the end of 1995 to the end of 2000. For comparisons, compute the estimates for this time window. First use the `duration` algorithm (default option), and then the `cohort` algorithm explicitly set.

```
startDate = '31-Dec-1995';
endDate = '31-Dec-2000';
transMat1 = transprob(data,'startDate',startDate,'endDate',endDate)
transMat2 = transprob(data,'startDate',startDate,'endDate',endDate,...
'algorithm','cohort')

transMat1 =

```

By default, the `cohort` algorithm internally gets yearly snapshots of the credit ratings, but the number of snapshots per year is definable using the parameter/value pair `snapsPerYear`. To get the estimates using quarterly snapshots:

```
transMat3 = transprob(data,'startDate',startDate,'endDate',endDate,...
'algorithm','cohort','snapsPerYear',4)
```

```
transMat3 =

90.4765    8.0881    1.0072    0.4069    0.0164    0.0015    0.0002    0.0032

```

Both `duration` and `cohort` compute one-year transition probabilities by default, but the time interval for the transitions is definable using the parameter/value pair `transInterval`. For example, to get the two-year transition probabilities using the `cohort` algorithm with the same snapshot periodicity and estimation window:

```
transMat4 = transprob(data,'startDate',startDate,'endDate',endDate,...
'algorithm','cohort','snapsPerYear',4,'transInterval',2)
```

```
transMat4 =

Estimate Transition Probabilities for Different Rating Scales

The dataset `data` from `Data_TransProb.mat` contains sample credit ratings using the default rating scale `{'AAA', 'AA','A', 'BBB', 'BB', 'B', 'CCC', 'D'}`. It also contains the dataset `dataIGSG` with ratings investment grade (`'IG'`), speculative grade (`'SG'`), and default (`'D'`). To estimate the transition matrix for this dataset, use the `labels` argument.

```
load Data_TransProb
startDate = '31-Dec-1995';
endDate = '31-Dec-2000';
dataIGSG(1:10,:)
transMatIGSG = transprob(dataIGSG,'labels',{'IG','SG','D'},...
'startDate',startDate,'endDate',endDate)
```

```
ans =

    '00011253'    '04-Apr-1983'    'IG'
    '00012751'    '17-Feb-1985'    'SG'
    '00012751'    '19-May-1986'    'D'
    '00014690'    '17-Jan-1983'    'IG'
    '00012144'    '21-Nov-1984'    'IG'
    '00012144'    '25-Mar-1992'    'SG'
    '00012144'    '07-May-1994'    'IG'
    '00012144'    '23-Jan-2000'    'SG'
    '00012144'    '20-Aug-2001'    'IG'
    '00012937'    '07-Feb-1984'    'IG'

transMatIGSG =

   98.1986    1.5179    0.2835
    8.5396   89.4891    1.9713
         0         0  100.0000
```

There is another dataset, `dataIGSGnum`, with the same information as `dataIGSG`, except the ratings are mapped to a numeric scale where `'IG'=1`, `'SG'=2`, and `'D'=3`. To estimate the transition matrix, use the `labels` optional argument specifying the numeric scale as a cell array.

```
dataIGSGnum(1:10,:)
% Note {1,2,3} and num2cell(1:3) are equivalent; num2cell is convenient
% when the number of ratings is larger
transMatIGSGnum = transprob(dataIGSGnum,'labels',{1,2,3},...
'startDate',startDate,'endDate',endDate)
```

```
ans =

    '00011253'    '04-Apr-1983'    [1]
    '00012751'    '17-Feb-1985'    [2]
    '00012751'    '19-May-1986'    [3]
    '00014690'    '17-Jan-1983'    [1]
    '00012144'    '21-Nov-1984'    [1]
    '00012144'    '25-Mar-1992'    [2]
    '00012144'    '07-May-1994'    [1]
    '00012144'    '23-Jan-2000'    [2]
    '00012144'    '20-Aug-2001'    [1]
    '00012937'    '07-Feb-1984'    [1]

transMatIGSGnum =

   98.1986    1.5179    0.2835
    8.5396   89.4891    1.9713
         0         0  100.0000
```

Any time the input dataset contains ratings not included in the default rating scale `{'AAA', 'AA', 'A', 'BBB', 'BB', 'B', 'CCC', 'D'}`, the full rating scale must be specified using the `labels` optional argument. For example, if the dataset contains ratings `'AAA', ..., 'CCC, 'D'`, and `'NR'` (not rated), use `labels` with this cell array `{'AAA', 'AA', 'A','BBB','BB','B','CCC','D','NR'}`.

Working with a Transition Matrix Containing NR Rating

This example demonstrates how `'NR'` (not rated) ratings are handled by `transprob`, and how to get transition matrix that use the `'NR'` rating information for the estimation, but that do not show the `'NR'` rating in the final transition probabilities.

The dataset `data` from `Data_TransProb.mat` contains sample credit ratings using the default rating scale `{'AAA', 'AA','A', 'BBB', 'BB', 'B', 'CCC', 'D'}`.

```
load Data_TransProb
head(data,12)
```

```
ans =

  12×3 table

        ID              Date          Rating
    ___________    _____________    ______

    '00010283'    '10-Nov-1984'    'CCC'
    '00010283'    '12-May-1986'    'B'
    '00010283'    '29-Jun-1988'    'CCC'
    '00010283'    '12-Dec-1991'    'D'
    '00013326'    '09-Feb-1985'    'A'  
    '00013326'    '24-Feb-1994'    'AA' 
    '00013326'    '10-Nov-2000'    'BBB'
    '00014413'    '23-Dec-1982'    'B'  
    '00014413'    '20-Apr-1988'    'BB' 
    '00014413'    '16-Jan-1998'    'B'  
    '00014413'    '25-Nov-1999'    'BB' 
    '00012126'    '17-Feb-1985'    'CCC'
```

Replace a transition to `'B'` with a transition to `'NR'` for the first company. Note that there is a subsequent transition from `'NR'` to `'CCC'`.

```
dataNR = data;
dataNR.Rating{2} = 'NR';
dataNR.Rating{7} = 'NR';

head(dataNR,12)

ans =

  12×3 table

```

`'NR'` is treated as another rating. The transition matrix shows the estimated probability of transitioning into and out of `'NR'`. In this example, the `transprob` function uses the`'cohort'` algorithm, and the `'NR'` rating is treated as another rating. The same behavior exists when using the `transprob` function with the `'duration'` algorithm.

```
RatingsLabelsNR = {'AAA','AA','A','BBB','BB','B','CCC','D','NR'};
[MatrixNRCohort,TotalsNRCohort] = transprob(dataNR,...
   'Labels',RatingsLabelsNR,...
   'Algorithm','cohort');

fprintf('Transition probability, cohort, including NR:\n')
disp(array2table(MatrixNRCohort,'VariableNames',RatingsLabelsNR,...
   'RowNames',RatingsLabelsNR))

fprintf('Total transitions out of given rating, including 6 out of NR (5 NR->NR, 1 NR->CCC):\n')
disp(array2table(TotalsNRCohort.totalsVec,'VariableNames',RatingsLabelsNR))

Transition probability, cohort, including NR:
             AAA        AA          A          BBB         BB          B          CCC

```

To remove transitions to `'NR'` from the transition matrix, you need to use the `'excludeLabels'` optional name-value input argument to `transprob`.

The `'labels'` input to `transprob` may or may not include the label that needs to be excluded. In the following example, the NR rating is removed from the labels for display purposes, but passing `RatingsLabelsNR` to `transprob` would also work.

```
RatingsLabels = {'AAA','AA','A','BBB','BB','B','CCC','D'};
```

```
[MatrixCohort,TotalsCohort] = transprob(dataNR,'Labels',RatingsLabels,'ExcludeLabels','NR','Algo
```

```
fprintf('Transition probability, cohort, after postprocessing to remove NR:\n')
```

```
Transition probability, cohort, after postprocessing to remove NR:
```

```
disp(array2table(MatrixCohort,'VariableNames',RatingsLabels,...
   'RowNames',RatingsLabels))
```

```
Transition probability, cohort, after postprocessing to remove NR:
             AAA         AA          A          BBB         BB          B          CCC          D

    3219    5126    5519    4751    4525    2626    1292    4050
```

All transitions involving `'NR'` are removed from the sample, but all other transitions are still used to estimate the transition probabilities. In this example, the transition from `'NR'` to `'CCC'` has been removed, as well as the transition from `'AA'` to `'NR'` (and five more transitions from `'NR'` to `'NR'`). That means the first company is still contributing transitions from`'CCC'` to `'CCC'` for the estimation, only the periods overlapping with the time this company spent in `'NR'` have been removed from the sample, and similarly for the other company.

This procedure is different from removing the `'NR'` rows from the data itself.

For example, if you remove the `'NR'` rows in this example, the first company seems to stay in its initial rating of `'CCC'` all the way from the initial date in 1984 to the default event in 1991. With the previous approach, the estimation knows that the company transitioned out of `'CCC'` at some point, it knows it was not staying at `'CCC'` all the time.

If the `'NR'` row is removed for the second company, this company seems to have stayed in the sample as an `'AA'` company until the end of the sample. With the previous approach, the estimation knows that this company stopped being an `'AA'` earlier.

```
dataNR2 = dataNR;
dataNR2([2 7],:) = [];

head(dataNR2,12)
```

```
ans =

  12×3 table

        ID              Date           Rating
    __________    _____________    ______

    '00010283'    '10-Nov-1984'    'CCC'
    '00010283'    '29-Jun-1988'    'CCC'
    '00010283'    '12-Dec-1991'    'D'
    '00013326'    '09-Feb-1985'    'A'
    '00013326'    '24-Feb-1994'    'AA'

Estimate Point-in-Time and Through-the-Cycle Probabilities

Transition probability estimates are sensitive to the length of the estimation window. When the estimation window is small, the estimates only capture recent credit events, and these can change significantly from one year to the next. These are called point-in-time (PIT) estimates. In contrast, a large time window yields fairly stable estimates that average transition rates over a longer period of time. These are called through-the-cycle (TTC) estimates.

The estimation of PIT probabilities requires repeated calls to `transprob` with a rolling estimation window. Use `transprobprep` every time repeated calls to `transprob` are required. `transprobprep` performs a preprocessing step on the raw dataset that is independent of the estimation window. The benefits of `transprobprep` are greater as the number of repeated calls to `transprob` increases. Also, the performance gains from `transprobprep` are more significant for the `cohort` algorithm.

```
load Data_TransProb
prepData = transprobprep(data);

Years = 1991:2000;
nYears = length(Years);
nRatings = length(prepData.ratingsLabels);
```

```
transMatPIT = zeros(nRatings,nRatings,nYears);
algorithm = 'duration';
sampleTotals(nYears,1) = struct('totalsVec',[],'totalsMat',[],...
'algorithm',algorithm);
for t = 1:nYears
   startDate = ['31-Dec-' num2str(Years(t)-1)];
   endDate = ['31-Dec-' num2str(Years(t))];
   [transMatPIT(:,:,t),sampleTotals(t)] = transprob(prepData,...
    'startDate',startDate,'endDate',endDate,'algorithm',algorithm);
end
```

Here is the PIT transition matrix for 1993. Recall that the sample dataset contains simulated credit migrations so the PIT estimates in this example do not match actual historical transition rates.

```
transMatPIT(:,:,Years==1993)
```

```
ans =

```

A structure array stores the `sampleTotals` optional output from `transprob`. The `sampleTotals` structure contains summary information on the total time spent on each rating, and the number of transitions out of each rating, for each year under consideration. For more information on the `sampleTotals` structure, see `transprob`.

As an example, the `sampleTotals` structure for 1993 is used here. The total time spent on each rating is stored in the `totalsVec` field of the structure. The total transitions out of each rating are stored in the `totalsMat` field. A third field, `algorithm`, indicates the algorithm used to generate the structure.

```
sampleTotals(Years==1993).totalsVec
sampleTotals(Years==1993).totalsMat
sampleTotals(Years==1993).algorithm
```

```

duration
```

To get the TTC transition matrix, pass the `sampleTotals` structure array to `transprobbytotals`. Internally, `transprobbytotals` aggregates the information in the `sampleTotals` structures to get the total time spent on each rating over the 10 years considered in this example, and the total number of transitions out of each rating during the same period. `transprobbytotals` uses the aggregated information to get the TTC matrix, or average one-year transition matrix.

```
transMatTTC = transprobbytotals(sampleTotals)
```

```
transMatTTC =
   92.8544    6.1068    0.7463    0.2761    0.0123    0.0009    0.0001    0.0032

    0.2410    4.5963   90.3468    3.9572    0.6909    0.0521    0.0025    0.1133
    0.0530    0.4729    7.9221   87.2751    3.5075    0.4650    0.0791    0.2254
    0.0460    0.1636    1.1873    9.3442   85.4305    2.9520    0.1150    0.7615
    0.0031    0.0152    0.2608    1.5563   10.4468   83.8525    1.9771    1.8882
    0.0009    0.0041    0.0542    0.8378    2.9996    7.3614   82.4758    6.2662
         0         0         0         0         0         0         0  100.0000
```

The same TTC matrix could be obtained with a direct call to `transprob`, setting the estimation window to the 10 years under consideration. But it is much more efficient to use the `sampleTotals` structures, whenever they are available. (Note, for the `duration` algorithm, these alternative workflows can result in small numerical differences in the estimates whenever leap years are part of the sample.)

In “Estimate Transition Probabilities” on page 8-2, a 1-year transition matrix is estimated using the 5-year time window from 1996 through 2000. This is another example of a TTC matrix and this can also be computed using the `sampleTotals` structure array.

```
transprobbytotals(sampleTotals(Years>=1996&Years<=2000))
```

```

Estimate t-Year Default Probabilities

By varying the start and end dates, the amount of data considered for the estimation is changed, but the output still contains, by default, one-year transition probabilities. You can change the default behavior by specifying the `transInterval` argument, as illustrated in “Estimate Transition Probabilities” on page 8-2.

However, when *t*-year transition probabilities are required for a whole range of values of *t*, for example, 1-year, 2-year, 3-year, 4-year, and 5-year transition probabilities, it is more efficient to call `transprob` once to get the optional output `sampleTotals`. You can use the same `sampleTotals` structure can be used to get the *t*-year transition matrix for any transition interval *t*. Given a `sampleTotals` structure and a transition interval, you can get the corresponding transition matrix by using `transprobbytotals`.

```
load Data_TransProb
startDate = '31-Dec-1995';
endDate = '31-Dec-2000';

[~,sampleTotals] = transprob(data,'startDate', ...
startDate, 'endDate',endDate);

DefProb = zeros(7,5);
for t = 1:5
   transMatTemp = transprobbytotals(sampleTotals,'transInterval',t);
   DefProb(:,t) = transMatTemp(1:7,8);
end
DefProb
```

```
DefProb =

    0.0043    0.0169    0.0377    0.0666    0.1033
    0.0754    0.1542    0.2377    0.3265    0.4213
    0.0832    0.1936    0.3276    0.4819    0.6536

    3.0860    5.6994    7.9281    9.8418   11.4963
    5.3484    9.8053   13.5320   16.6599   19.2964
```

Estimate Bootstrap Confidence Intervals

transprob also returns the idTotals structure array which contains, for each ID, or company, the total time spent on each rating, and the total transitions out of each rating. For more information on the idTotals structure, see transprob. The idTotals structure is similar to the sampleTotals structures (see “Estimate Point-in-Time and Through-the-Cycle Probabilities” on page 8-9), but idTotals has the information at an ID level. Because most companies only migrate between few ratings, the numeric arrays in idTotals are stored as sparse arrays to reduce memory requirements.

You can use the idTotals structure array to estimate confidence intervals for the transition probabilities using a bootstrapping procedure, as the following example demonstrates. To do this, call transprob and keep the third output argument, idTotals. The idTotals fields are displayed for the last company in the sample. Within the estimation window, this company spends almost a year as 'AA' and it is then upgraded to 'AAA'.

```
load Data_TransProb
startDate = '31-Dec-1995';
endDate = '31-Dec-2000';

[transMat,~,idTotals] = transprob(data,...
   'startDate',startDate,'endDate',endDate);

% Total time spent on each rating
full(idTotals(end).totalsVec)
% Total transitions out of each rating
full(idTotals(end).totalsMat)
% Algorithm
idTotals(end).algorithm
```

```

ans =

duration
```

Next, use bootstrp from Statistics and Machine Learning Toolbox with transprobbytotals as the bootstrap function and idTotals as the data to sample from. Each bootstrap sample corresponds to a dataset made of companies sampled with replacement from the original data. However, you do not have to draw companies from the original data, because a bootstrap idTotals sample contains all the information required to compute the transition probabilities. transprobbytotals aggregates all structures in each bootstrap idTotals sample and finds the corresponding transition matrix.

To estimate 95% confidence intervals for the transition matrix and display the probabilities of default together with its upper and lower confidence bounds:

```
PD = transMat(1:7,8);

bootstat = bootstrp(100,@(totals)transprobbytotals(totals),idTotals);
ci = prctile(bootstat,[2.5 97.5]); % 95% confidence
CIlower = reshape(ci(1,:),8,8);
CIupper = reshape(ci(2,:),8,8);
PD_LB = CIlower(1:7,8);
PD_UB = CIupper(1:7,8);

[PD_LB PD PD_UB]

ans =

    0.0004    0.0043    0.0106
    0.0028    0.0754    0.2192
    0.0126    0.0832    0.2180
    0.1659    0.3992    0.6617
    0.5703    1.0980    1.7260
    1.7264    3.0860    4.7602
    1.7678    5.3484    9.5055
```

Group Credit Ratings

Credit rating scales can be more or less granular. For example, there are ratings with qualifiers (such as, `'AA+'`, `'BB-'`, and so on), whole ratings (`'AA'`, `'BB'`, and so on), and investment or speculative grade (`'IG'`, `'SG'`) categories. Given a dataset with credit ratings at a more granular level, transition probabilities for less granular categories can be of interest. For example, you might be interested in a transition matrix for investment and speculative grades given a dataset with whole ratings. Use `transprobgrouptotals` for this evaluation, as illustrated in the following examples. The sample dataset data has whole credit ratings:

```
load Data_TransProb
startDate = '31-Dec-1995';
endDate = '31-Dec-2000';
data(1:5,:)

ans =

    '00010283'    '10-Nov-1984'    'CCC'
    '00010283'    '12-May-1986'    'B'
    '00010283'    '29-Jun-1988'    'CCC'
    '00010283'    '12-Dec-1991'    'D'
    '00013326'    '09-Feb-1985'    'A'
```

A call to `transprob` returns the transition matrix and totals structures for the eight (`'AAA'` to `'D'`) whole credit ratings. The array with number of transitions out of each credit rating is displayed after the call to `transprob`:

```
[transMat,sampleTotals,idTotals] = transprob(data,'startDate',startDate,...
'endDate',endDate);
sampleTotals.totalsMat

ans =

     0    67     7     3     0     0     0     0
    67     0    68    15     3     0     0     1
     4   101     0    93    11     1     0     1
     1     7   163     0    62    10     2     5
     1     3    16   168     0    37     0    11
     0     0     2    10    83     0    10    14
     0     0     0     2     8    16     0     7
     0     0     0     0     0     0     0     0
```

Next, use `transprobgrouptotals` to group whole ratings into investment and speculative grades. This function takes a totals structure as the first argument. The second argument indicates the edges between rating categories. In this case, ratings 1 through 4 (`'AAA'` through `'BBB'`) correspond to the first category (`'IG'`), ratings 5 through 7 (`'BB'` through `'CCC'`) to the second category (`'SG'`), and rating 8 (`'D'`) is a category of its own. `transprobgrouptotals` adds up the total time spent on ratings that belong to the same category. For example, total times spent on `'AAA'` through `'BBB'` are added up as the total time spent on `'IG'`. `transprobgrouptotals` also adds up the total number of transitions between any `'IG'` rating and any `'SG'` rating, for example, a credit migration from `'BBB'` to `'BB'`.

The grouped totals can then be passed to `transprobbytotals` to obtain the transition matrix for investment and speculative grades. Both `totalsMat` and the new transition matrix are both 3-by-3, corresponding to the grouped categories `'IG'`, `'SG'`, and `'D'`.

```
sampleTotalsIGSG = transprobgrouptotals(sampleTotals,[4 7 8])
transMatIGSG = transprobbytotals(sampleTotalsIGSG)
```

```
sampleTotalsIGSG = 

    totalsVec: [4.8591e+003 1.5034e+003 1.1621e+003]
    totalsMat: [3x3 double]
    algorithm: 'duration'

transMatIGSG =

   98.1591    1.6798    0.1611
   12.3228   85.6961    1.9811
         0         0  100.0000
```

When a totals structure array is passed to `transprobgrouptotals`, this function groups each structure in the array individually and preserves sparsity, if the fields in the input structures are sparse. One way to exploit this feature is to compute confidence intervals for the investment grade default rate and the speculative grade default rate (see also “Estimate Bootstrap Confidence Intervals” on page 8-12).

```
PDIGSG = transMatIGSG(1:2,3);

idTotalsIGSG = transprobgrouptotals(idTotals,[4 7 8]);
bootstat = bootstrp(100,@(totals)transprobbytotals(totals),idTotalsIGSG);
ci = prctile(bootstat,[2.5 97.5]); % 95% confidence
CIlower = reshape(ci(1,:),3,3);
CIupper = reshape(ci(2,:),3,3);
PDIGSG_LB = CIlower(1:2,3);
PDIGSG_UB = CIupper(1:2,3);

[PDIGSG_LB PDIGSG PDIGSG_UB]
```

```
ans =

    0.0603    0.1611    0.2538
    1.3470    1.9811    2.6195
```

Work with Nonsquare Matrices

Transition probabilities and the number of transitions between ratings are usually reported without the `'D'` (`'Default'`) row. For example, a credit report can contain the following table, indicating the number of issuers starting in each rating (first column), and the number of transitions between ratings (remaining columns):

	Initial	AAA	AA	A	BBB	BB	B	CCC	D
AAA	98	88	9	1	0	0	0	0	0
AA	389	0	368	19	2	0	0	0	0
A	1165	1	21	1087	56	0	0	0	0
BBB	1435	0	2	89	1289	45	8	0	2
BB	915	0	0	1	60	776	73	2	3
B	867	0	0	1	7	88	715	39	17
CCC	112	0	0	0	1	3	34	61	13

You can store the information in this table in a totals structure compatible with the `cohort` algorithm. For more information on the `cohort` algorithm and the totals structure, see `transprob`. The `totalsMat` field is a nonsquare array in this case.

```
% Define totals structure
totals.totalsVec = [98 389 1165 1435 915 867 112];
totals.totalsMat = [
   88    9    1    0    0    0    0    0;
    0  368   19    2    0    0    0    0;
    1   21 1087   56    0    0    0    0;
    0    2   89 1289   45    8    0    2;
    0    0    1   60  776   73    2    3;
    0    0    1    7   88  715   39   17;
    0    0    0    1    3   34   61   13];
totals.algorithm = 'cohort';
```

`transprobbytotals` and `transprobgrouptotals` accept totals inputs with nonsquare `totalsMat` fields. To get the transition matrix corresponding to the previous table, and to group ratings into investment and speculative grade with the corresponding matrix:

```
transMat = transprobbytotals(totals)

% Group into IG/SG and get IG/SG transition matrix
totalsIGSG = transprobgrouptotals(totals,[4 7]);
transMatIGSG = transprobbytotals(totalsIGSG)
```

```
transMat =

   89.7959    9.1837    1.0204         0         0         0         0         0
         0   94.6015    4.8843    0.5141         0         0         0         0
    0.0858    1.8026   93.3047    4.8069         0         0         0         0
         0    0.1394    6.2021   89.8258    3.1359    0.5575         0    0.1394
         0         0    0.1093    6.5574   84.8087    7.9781    0.2186    0.3279
         0         0    0.1153    0.8074   10.1499   82.4683    4.4983    1.9608
         0         0         0    0.8929    2.6786   30.3571   54.4643   11.6071

transMatIGSG =

   98.2183    1.7169    0.0648
    3.6959   94.5618    1.7423
```

Remove Outliers

The `idTotals` output from `transprob` can also be exploited to update the transition probability estimates after removing some outlier information. For more information on `idTotals`, see `transprob`. For example, if you know that the credit rating migration information for the 4th and 27th companies in the data have problems, you can remove those companies and efficiently update the transition probabilities as follows:

```
load Data_TransProb
startDate = '31-Dec-1995';
```

```
endDate = '31-Dec-2000';
[transMat,~,idTotals] = transprob(data,'startDate', ...
startDate, 'endDate',endDate);
transMat

transMat =

      0         0         0         0         0         0         0  100.0000
```

Deciding which companies to remove is a case-by-case situation. Reasons to remove a company can include a typo in one of the ratings histories, or an unusual migration between ratings whose impact on the transition probability estimates must be measured. `transprob` does not reorder the companies in any way. The ordering of companies in the input data is the same as the ordering in the `idTotals` array.

Estimate Probabilities for Different Segments

You can use `idTotals` efficiently to get estimates over different segments of the sample. For more information on `idTotals`, see `transprob`. For example, assume that the companies in the example are grouped into three geographic regions and that the companies were grouped by geographic regions previously, so that the first 340 companies correspond to the first region, the next 572 companies to the second region, and the rest to the third region. You can efficiently get transition probabilities for each region as follows:

```
load Data_TransProb
startDate = '31-Dec-1995';
endDate = '31-Dec-2000';
[~,~,idTotals] = transprob(data,'startDate', ...
startDate, 'endDate',endDate);

n1 = 340;
n2 = 572;
transMatG1 = transprobbytotals(idTotals(1:n1))
transMatG2 = transprobbytotals(idTotals(n1+1:n1+n2))
transMatG3 = transprobbytotals(idTotals(n1+n2+1:end))

transMatG1 =

90.8299    7.6501    0.3178    1.1700    0.0255    0.0044    0.0021    0.0002

      0         0         0         0         0         0         0  100.0000
```

Work with Large Datasets

This example shows how to aggregate estimates from two (or more) datasets. It is possible that two datasets, coming from two different databases, must be considered for the estimation of the transition probabilities. Also, if a dataset is too large and cannot be loaded into memory, the dataset can be split into two (or more) datasets. In these cases, it is simple to apply `transprob` to each individual dataset, and then get the final estimates corresponding to the aggregated data with a call to `transprobbytotals` at the end.

For example, the dataset data is artificially split into two sections in this example. In practice the two datasets would come from different files or databases. When aggregating multiple datasets, the history of a company cannot be split across datasets. You can analyze that this condition is satisfied for the arbitrarily chosen cut-off point.

```
load Data_TransProb

cutoff = 2099;
data(cutoff-5:cutoff,:)
data(cutoff+1:cutoff+6,:)
```

```
ans =

    '00011166'    '24-Aug-1995'    'BBB'
    '00011166'    '25-Jan-1997'    'A'
    '00011166'    '01-Feb-1998'    'AA'
    '00014878'    '15-Mar-1983'    'B'
    '00014878'    '21-Sep-1986'    'BB'
    '00014878'    '17-Jan-1998'    'BBB'

ans =

    '00012043'    '09-Feb-1985'    'BBB'
    '00012043'    '03-Jan-1988'    'A'
    '00012043'    '15-Jan-1994'    'AAA'
    '00011157'    '24-Jun-1984'    'A'
    '00011157'    '09-Dec-1999'    'BBB'
    '00011157'    '28-Mar-2001'    'A'
```

When working with multiple datasets, it is important to set the start and end dates explicitly. Otherwise, the estimation window differs for each dataset because the default start and end dates used by `transprob` are the earliest and latest dates found in the input data.

```
startDate = '31-Dec-1995';
endDate = '31-Dec-2000';
```

In practice, this is the point where you can read in the first dataset. Now, the dataset is already obtained. Call `transprob` with the first dataset and the explicit start and end dates. Keep only the `sampleTotals` output. For details on `sampleTotals`, see `transprob`.

```
[~,sampleTotals(1)] = transprob(data(1:cutoff,:),...
   'startDate',startDate,'endDate',endDate);
```

Repeat for the remaining datasets. Note the different `sampleTotals` structures are stored in a structured array.

```
[~,sampleTotals(2)] = transprob(data(cutoff+1:end,:),...
   'startDate',startDate,'endDate',endDate);
```

To get the transition matrix corresponding to the aggregated dataset, use `transprobbytotals`. When the totals input is a structure array, `transprobbytotals` aggregates the information over all structures, and returns a single transition matrix.

```
transMatAggr = transprobbytotals(sampleTotals)
```

```
transMatAggr =

   90.6236    7.9051    1.0314    0.4123    0.0210    0.0020    0.0003    0.0043
    4.4780   89.5558    4.5298    1.1225    0.2284    0.0094    0.0009    0.0754
    0.3983    6.1164   87.0641    5.4801    0.7637    0.0892    0.0050    0.0832
    0.1029    0.8572   10.7918   83.0204    3.9971    0.7001    0.1313    0.3992
    0.1043    0.3745    2.2962   14.0954   78.9840    3.0013    0.0463    1.0980
    0.0113    0.0544    0.7055    3.2925   15.4350   75.5988    1.8166    3.0860
    0.0044    0.0189    0.1903    1.9743    6.2320   10.2334   75.9983    5.3484
         0         0         0         0         0         0         0  100.0000
```

As a sanity check, for this example you can analyze that the aggregation procedure yields the same estimates (up to numerical differences) as estimating the probabilities directly over the entire sample:

```
transMatWhole = transprob(data,'startDate',startDate,'endDate',endDate)
aggError = max(max(abs(transMatAggr - transMatWhole)))
```

```
transMatWhole =

   90.6236    7.9051    1.0314    0.4123    0.0210    0.0020    0.0003    0.0043
    4.4780   89.5558    4.5298    1.1225    0.2284    0.0094    0.0009    0.0754
    0.3983    6.1164   87.0641    5.4801    0.7637    0.0892    0.0050    0.0832
    0.1029    0.8572   10.7918   83.0204    3.9971    0.7001    0.1313    0.3992
    0.1043    0.3745    2.2962   14.0954   78.9840    3.0013    0.0463    1.0980
    0.0113    0.0544    0.7055    3.2925   15.4350   75.5988    1.8166    3.0860
    0.0044    0.0189    0.1903    1.9743    6.2320   10.2334   75.9983    5.3484
         0         0         0         0         0         0         0  100.0000

aggError =

  2.8422e-014
```

Forecasting Corporate Default Rates

This example shows how to build a forecasting model for corporate default rates.

Risk parameters are dynamic in nature, and understanding how these parameters change in time is a fundamental task for risk management.

In the first part of this example, we work with historical credit migrations data to construct some time series of interest, and to visualize default rates dynamics. In the second part of this example, we use some of the series constructed in the first part, and some additional data, to fit a forecasting model for corporate default rates, and to show some backtesting and stress testing concepts. A linear regression model for corporate default rates is presented, but the tools and concepts described can be used with other forecasting methodologies. The appendix at the end references the handling of models for full transition matrices.

People interested in forecasting, backtesting, and stress testing can go directly to the second part of this example. The first part of this example is more relevant for people who work with credit migration data.

Part I: Working with Credit Migrations Data

We work with historical transition probabilities for corporate issuers (variable `TransMat`). This is yearly data for the period 1981-2005, from [10 on page 8-42]. The data includes, for each year, the number of issuers per rating at the beginning of the year (variable `nIssuers`), and the number of new issuers per rating per year (variable `nNewIssuers`). There is also a corporate profits forecast, from [9 on page 8-42], and a corporate spread, from [4 on page 8-41] (variables `CPF` and `SPR`). A variable indicating recession years (`Recession`), consistent with recession dates from [7 on page 8-42], is used mainly for visualizations.

```
Example_LoadData
```

Getting Default Rates for Different Ratings Categories

We start by performing some aggregations to get corporate default rates for Investment Grade (IG) and Speculative Grade (SG) issuers, and the overall corporate default rate.

Aggregation and segmentation are relative terms. IG is an aggregate with respect to credit ratings, but a segment from the perspective of the overall corporate portfolio. Other segments are of interest in practice, for example, economic sectors, industries, or geographic regions. The data we use, however, is aggregated by credit ratings, so further segmentation is not possible. Nonetheless, the tools and workflow discussed here can be useful to work with other segment-specific models.

Use functionality in Financial Toolbox™, specifically, the functions `transprobgrouptotals` and `transprobbytotals`, to perform the aggregation. These functions take as inputs structures with credit migration information in a particular format. We set up the inputs here and visualize them below to understand their information and format.

```
% Pre-allocate the struct array
totalsByRtg(nYears,1) = struct('totalsVec',[],'totalsMat',[],...
   'algorithm','cohort');
for t = 1:nYears
   % Number of issuers per rating at the beginning of the year
   totalsByRtg(t).totalsVec = nIssuers(t,:);
   % Number of transitions between ratings during the year
   totalsByRtg(t).totalsMat = round(diag(nIssuers(t,:))*...
      (0.01*TransMat(:,:,t)));
   % Algorithm
   totalsByRtg(t).algorithm = 'cohort';
end
```

It is useful to see both the original data and the data stored in these totals structures side to side. The original data contains number of issuers and transition probabilities for each year. For example, for 2005:

```
fprintf('\nTransition matrix for 2005:\n\n')
```

```
Transition matrix for 2005:
```

```
Example_DisplayTransitions(squeeze(TransMat(:,:,end)),nIssuers(end,:),...
   {'AAA','AA','A','BBB','BB','B','CCC'},...
   {'AAA','AA','A','BBB','BB','B','CCC','D','NR'})
```

```
         Init     AAA      AA       A     BBB      BB       B     CCC       D      NR
   AAA     98   88.78    9.18    1.02       0       0       0       0       0    1.02
    AA    407       0   90.66    4.91    0.49       0       0       0       0    3.93
     A   1224    0.08    1.63   88.89    4.41       0       0       0       0    4.98
   BBB   1535       0     0.2    5.93   84.04    3.06    0.46       0    0.07    6.25
    BB   1015       0       0       0    5.71   76.75     6.9     0.2     0.2   10.25
     B   1010       0       0     0.1    0.59    8.51   70.59    3.76    1.58   14.85
   CCC    126       0       0       0    0.79    0.79    25.4   46.83    8.73   17.46
```

The totals structure stores the total number of issuers per rating at the beginning of the year in the `totalsVec` field, and the total *number of migrations* between ratings (instead of transition probabilities) in the `totalsMat` field. Here is the information for 2005:

```
fprintf('\nTransition counts (totals struct) for 2005:\n\n')
```

```
Transition counts (totals struct) for 2005:
```

```
Example_DisplayTransitions(totalsByRtg(end).totalsMat,...
   totalsByRtg(end).totalsVec,...
   {'AAA','AA','A','BBB','BB','B','CCC'},...
   {'AAA','AA','A','BBB','BB','B','CCC','D','NR'})
```

```
         Init     AAA      AA       A     BBB      BB       B     CCC       D      NR
   AAA     98      87       9       1       0       0       0       0       0       1
    AA    407       0     369      20       2       0       0       0       0      16
     A   1224       1      20    1088      54       0       0       0       0      61
   BBB   1535       0       3      91    1290      47       7       0       1      96
    BB   1015       0       0       0      58     779      70       2       2     104
     B   1010       0       0       1       6      86     713      38      16     150
   CCC    126       0       0       0       1       1      32      59      11      22
```

The third field in the totals structure, `algorithm`, indicates that we are working with the `cohort` method (`duration` is also supported, although the information in `totalsVec` and `totalsMat` would be different). These structures are obtained as optional outputs from `transprob`, but this example shows how you can define these structures directly.

Use `transprobgrouptotals` to group the ratings `'AAA'` to `'BBB'` (ratings 1 to 4) into the IG category and ratings `'BB'` to `'CCC'` (ratings 5 to 7) into the SG category. The `edges` argument tells the function which ratings are to be grouped together (1 to 4, and 5 to 7). We also group all non-default ratings into one category. These are preliminary steps to get the IG, SG, and overall default rates for each year.

```
edgesIGSG = [4 7];
totalsIGSG = transprobgrouptotals(totalsByRtg,edgesIGSG);
edgesAll = 7; % could also use edgesAll = 2 with totalsIGSG
totalsAll = transprobgrouptotals(totalsByRtg,edgesAll);
```

Here are the 2005 totals grouped at IG/SG level, and the corresponding transition matrix, recovered using `transprobbytotals`.

```
fprintf('\nTransition counts for 2005 at IG/SG level:\n\n')
```

```
Transition counts for 2005 at IG/SG level:
```

```
Example_DisplayTransitions(totalsIGSG(end).totalsMat,...
   totalsIGSG(end).totalsVec,...
   {'IG','SG'},...
   {'IG','SG','D','NR'})
```

```
         Init     IG     SG      D     NR
    IG   3264   3035     54      1    174
    SG   2151     66   1780     29    276
```

```
fprintf('\nTransition matrix for 2005 at IG/SG level:\n\n')
```

```
Transition matrix for 2005 at IG/SG level:
```

```
Example_DisplayTransitions(transprobbytotals(totalsIGSG(end)),[],...
   {'IG','SG'},...
   {'IG','SG','D','NR'})
```

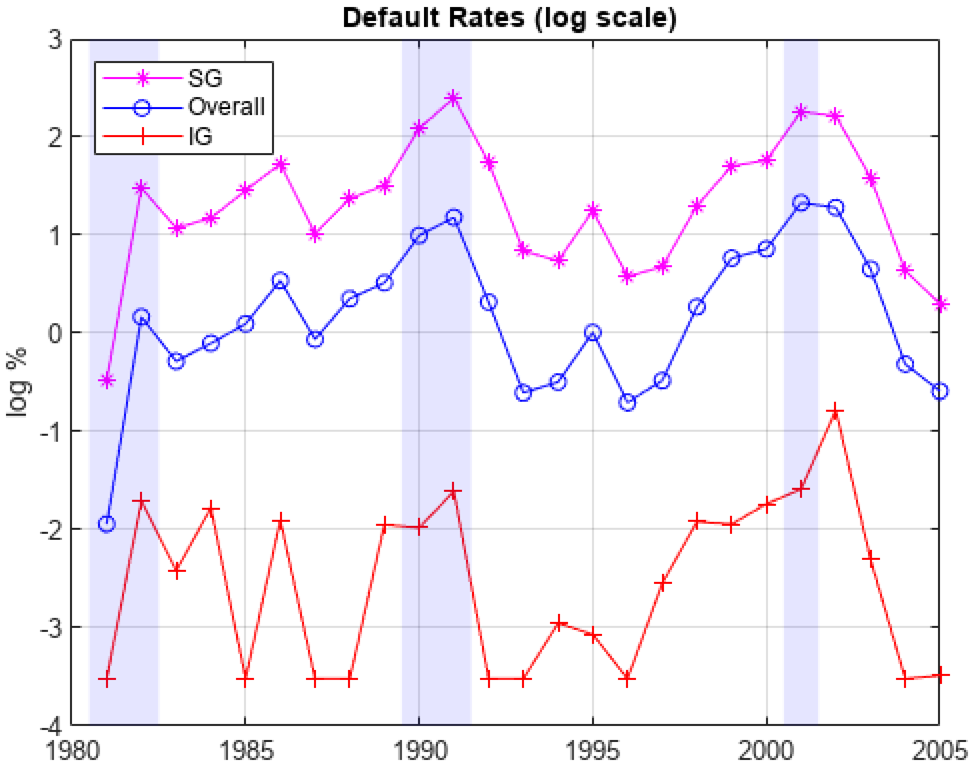
```
           IG     SG      D     NR
    IG  92.98   1.65   0.03   5.33
    SG   3.07  82.75   1.35  12.83
```

Now get transition matrices for every year both at IG/SG and non-default/default levels and store the default rates only (we do not use the rest of the transition probabilities).

```
DefRateIG = zeros(nYears,1);
DefRateSG = zeros(nYears,1);
DefRate = zeros(nYears,1);
for t=1:nYears
   % Get transition matrix at IG/SG level and extract IG default rate and
   % SG default rate for year t
   tmIGSG = transprobbytotals(totalsIGSG(t));
   DefRateIG(t) = tmIGSG(1,3);
   DefRateSG(t) = tmIGSG(2,3);
   % Get transition matrix at most aggregate level and extract overall
   % corporate default rate for year t
   tmAll = transprobbytotals(totalsAll(t));
   DefRate(t) = tmAll(1,2);
end
```

Here is a visualization of the dynamics of IG, SG, and overall corporate default rates together. To emphasize their patterns, rather than their magnitudes, a log scale is used. The shaded bands indicate recession years. The patterns of SG and IG are slightly different. For example, the IG rate is higher in 1994 than in 1995, but the opposite is true for SG. More noticeably, the IG default rate peaked after the 2001 recession, in 2002, whereas the peak for SG is in 2001. This suggests that models for the dynamics of the IG and SG default rates could have important differences, a common situation when working with different segments. The overall corporate default rate is by construction a combination of the other two, and its pattern is closer to SG, most likely due to the relative magnitude of SG versus IG.

```
minIG = min(DefRateIG(DefRateIG~=0));
figure
plot(Years,log(DefRateSG),'m-*')
hold on
plot(Years,log(DefRate),'b-o')
plot(Years,log(max(DefRateIG,minIG-0.001)),'r-+')
Example_RecessionBands
hold off
grid on
title('{\bf Default Rates (log scale)}')
ylabel('log %')
legend({'SG','Overall','IG'},'location','NW')
```



Getting Default Rates for Different Time Periods

The default rates obtained are examples of point-in-time (PIT) rates, only the most recent information is used to estimate them. On the other extreme, we can use all the migrations observed in the 25 years spanned by the dataset to estimate long-term, or through-the-cycle (TTC) default rates. Other rates of interest are the average default rates over recession or expansion years.

All of these are easy to estimate with the data we have and the same tools. For example, to estimate the average transition probabilities over recession years, pass to `transprobbytotals` the totals structures corresponding to the recession years only. We use logical indexing below, taking advantage of the `Recession` variable. `transprobbytotals` aggregates the information over time and returns the corresponding transition matrix.

```
tmAllRec = transprobbytotals(totalsAll(Recession));
DefRateRec = tmAllRec(1,2);

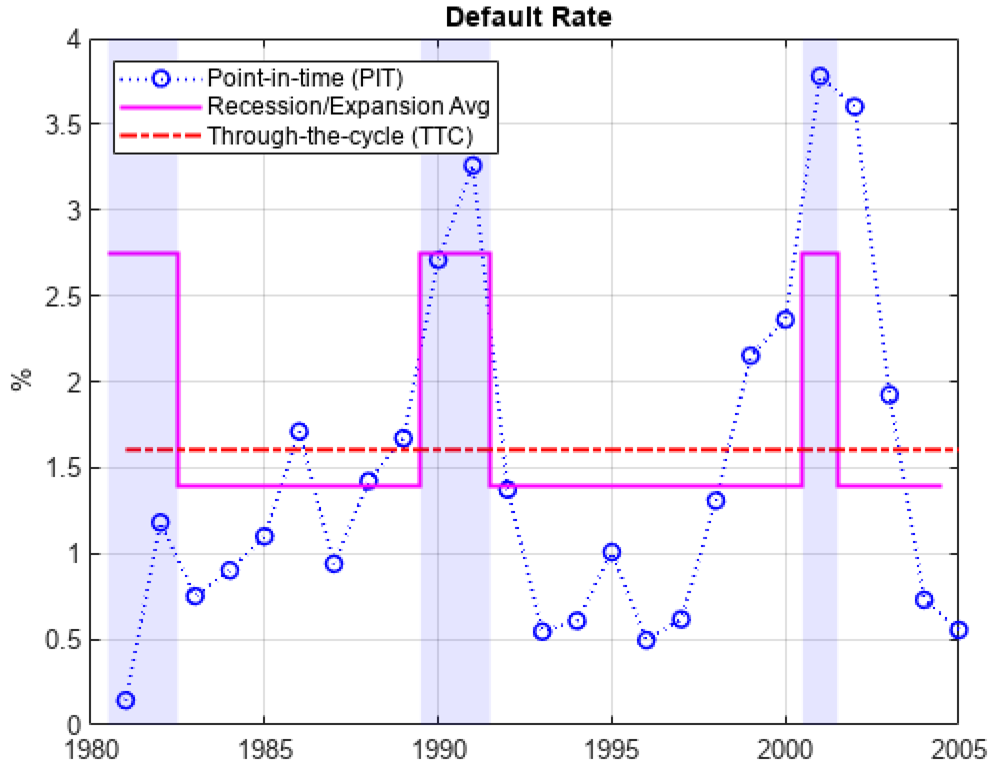
tmAllExp = transprobbytotals(totalsAll(~Recession));
DefRateExp = tmAllExp(1,2);

tmAllTTC = transprobbytotals(totalsAll);
DefRateTTC = tmAllTTC(1,2);
```

The following figure shows the estimated PIT rates, TTC rates, and recession and expansion rates.

```
DefRateTwoValues = DefRateExp*ones(nYears,1);
DefRateTwoValues(Recession) = DefRateRec;

figure
plot(Years,DefRate,'bo:','LineWidth',1.2)
hold on
stairs(Years-0.5,DefRateTwoValues,'m-','LineWidth',1.5)
plot(Years,DefRateTTC*ones(nYears,1),'r-.','LineWidth',1.5)
Example_RecessionBands
hold off
grid on
title('{\bf Default Rate}')
ylabel('%')
legend({'Point-in-time (PIT)','Recession/Expansion Avg',...
   'Through-the-cycle (TTC)'},'location','NW')
```



Some analyses (see, for example, [11 on page 8-42]) use simulations where the default rate is conditional on the general state of the economy, for example, recession v. expansion. The recession and expansion estimates obtained can be useful in such a framework. These are all historical averages, however, and may not work well if used as predictions for the actual default rates expected on any particular year. In the second part of this example, we revisit the use of these types of historical averages as forecasting tools in a backtesting exercise.

Building Predictors Using Credit Ratings Data

Using the credit data, you can build new time series of interest. We start with an age proxy that is used as predictor in the forecasting model in the second part of this example.

Age is known to be an important factor in predicting default rates; see, for example, [1 on page 8-41] and [5 on page 8-41]. Age here means the number of years since a bond was issued. By extension, the age of a portfolio is the average age of its bonds. Certain patterns have been observed historically. Many low-quality borrowers default just a few years after issuing a bond. When troubled companies issue bonds, the amount borrowed helps them make payments for a year or two. Beyond that point, their only source of money is their cash flows, and if they are insufficient, default occurs.

We cannot calculate the exact age of the portfolio, because there is no information at issuer level in the dataset. We follow [6 on page 8-42], however, and use the number of new issuers in year *t*-3 divided by the total number of issuers at the end of year *t* as an age proxy. Because of the lag, the age proxy starts in 1984. For the numerator, we have explicit information on the number of new issuers. For the denominator, the number of issuers at the end of a year equals the number of issuers at the beginning of next year. This is known for all years but the last one, which is set to the total transitions into a non-default rating plus the number of new issuers on that year.

```
% Total number of issuers at the end of the year
nEOY = zeros(nYears,1);
% nIssuers is number of issuers per ratings at the beginning of the year
% nEOY ( 1981 ) = sum nIssuers ( 1982 ), etc until 2004
nEOY(1:end-1) = sum(nIssuers(2:end,:),2);
% nEOY ( 2005 ) = issuers in non-default state at end of 2005 plus
% new issuers in 2005
nEOY(end) = totalsAll(end).totalsMat(1,1) + sum(nNewIssuers(end,:));
% Age proxy
AGE = 100*[nan(3,1); sum(nNewIssuers(1:end-3,:),2)./nEOY(4:end)];
```

Examples of other time series of interest are the proportion of SG issuers at the end of each year, or an age proxy for SG.

```
% nSGEOY: Number of SG issuers at the end of the year
% nSGEOY is similar to nEOY, but for SG only, from 5 ('BB') to 7 ('CCC')
indSG = 5:7;
nSGEOY = zeros(nYears,1);
nSGEOY(1:end-1) = sum(nIssuers(2:end,indSG),2);
nSGEOY(end) = sum(totalsIGSG(end).totalsMat(:,2)) +...
   sum(nNewIssuers(end,indSG));
% Proportion of SG issuers
SG = 100*nSGEOY./nEOY;
% SG age proxy: new SG issuers in t-3 / total issuers at the end of year t
AGESG = 100*[nan(3,1); sum(nNewIssuers(1:end-3,indSG),2)./nEOY(4:end)];
```

Part II: A Forecasting Model for Default Rates

We work with the following linear regression model for corporate default rates

$$DefRate = \beta_0 + \beta_{age}AGE + \beta_{cpf}CPF + \beta_{spr}SPR$$

where

- AGE: Age proxy defined above
- CPF: Corporate profits forecast
- SPR: Corporate spread over treasuries

This is the same model as in [6 on page 8-42], except the model in [6 on page 8-42] is for IG only.

As previously discussed, age is known to be an important factor regarding default rates. The corporate profits provide information on the economic environment. The corporate spread is a proxy for credit quality. Age, environment, and quality are three dimensions frequently found in credit analysis models.

```
inSample = 4:nYears-1;
T = length(inSample);
varNames = {'AGE','CPF','SPR'};
X = [AGE CPF SPR];
X = X(inSample,:);
y = DefRate(inSample+1); % DefaultRate, year t+1
stats = regstats(y,X);

fprintf('\nConst   AGE   CPF   SPR   adjR^2\n')
```

```
Const   AGE   CPF   SPR   adjR^2
```

```
fprintf('%1.2f  %1.2f %1.2f  %1.2f   %1.4f\n',...
   [stats.beta;stats.adjrsquare])
```

```
-1.19  0.15 -0.10  0.71   0.7424
```

The coefficients have the expected sign: default rates tend to increase with a higher proportion of 3-year issuers, decrease with good corporate profits, and increase when the corporate yields are higher. The adjusted R square shows a good fit.

The in-sample fit, or how close the model predictions are from the sample points used to fit the model, is shown in the following figure.

```
bHat = stats.beta;
yHat = [ones(T,1),X]*bHat;

figure
plot(Years(inSample+1),DefRate(inSample+1),'ko','LineWidth',1.5,...
   'MarkerSize',10,'MarkerFaceColor','g')
hold on

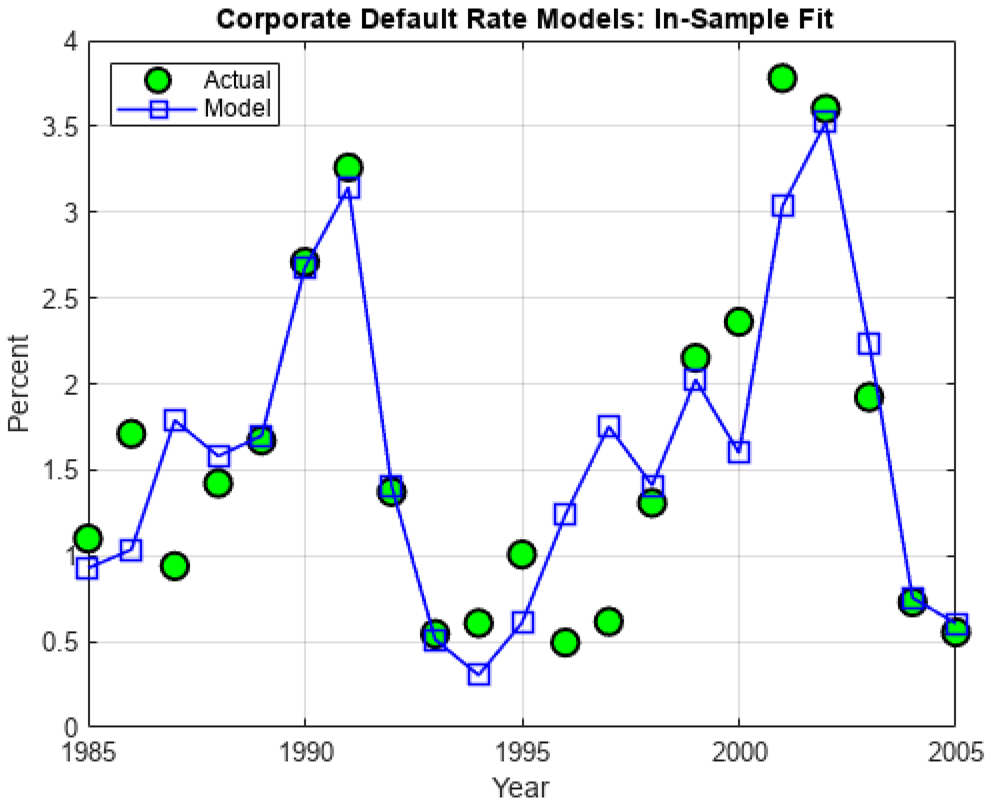
xlabel('Year')
ylabel('Percent')
```



It can be shown that there is no strong statistical evidence to conclude that the linear regression assumptions are violated. It is apparent that default rates are not normally distributed. The model, however, does not make that assumption. The only normality assumption in the model is that, given the predictors values, the error between the predicted and the observed default rates is normally distributed. By looking at the in-sample fit, this does not seem unreasonable. The magnitude of the errors certainly seems independent of whether the default rates are high or low. Year 2001 has a high default rate and a high error, but years 1991 or 2002 also have high rates and yet very small errors. Likewise, low default rate years like 1996 and 1997 show considerable errors, but years 2004 or 2005 have similarly low rates and tiny errors.

A thorough statistical analysis of the model is out of scope here, but there are several detailed examples in Statistics and Machine Learning Toolbox™ and Econometrics Toolbox™.

Backtesting

To evaluate how this model performs out-of-sample, we set up a backtesting exercise. Starting at the end of 1995, we fit the linear regression model with the information available up to that date, and compare the model prediction to the actual default rate observed the following year. We repeat the same for all subsequent years until the end of the sample.

For backtesting, relative performance of a model, when compared to alternatives, is easier to assess than the performance of a model in isolation. Here we include two alternatives to determine next year's default rate, both likely candidates in practice. One is the TTC default rate, estimated with data from the beginning of the sample to the current year, a very stable default rate estimate. The other is the PIT rate, estimated using data from the most recent year only, much more sensitive to recent events.

```
XBT = [AGE,CPF,SPR];
yBT = DefRate;

iYear0 = find(Years==1984); % index of first year in sample, 1984
T = find(Years==1995); % ind "current" year, start at 1995, updated in loop
YearsBT = 1996:2005; % years predicted in BT exercise
iYearsBT = find(Years==1996):find(Years==2005); % corresponding indices
nYearsBT = length(YearsBT); % number of years in BT exercise

MethodTags = {'Model','PIT','TTC'};
nMethods = length(MethodTags);
PredDefRate = zeros(nYearsBT,nMethods);
ErrorBT = zeros(nYearsBT,nMethods);

alpha = 0.05;
PredDefLoBnd = zeros(nYearsBT,1);
PredDefUpBnd = zeros(nYearsBT,1);

for k=1:nYearsBT
   % In sample years for predictors, from 1984 to "last" year (T-1)
   inSampleBT = iYear0:T-1;

   % Method 1: Linear regression model
   %   Fit regression model with data up to "current" year (T)
   s = regstats(yBT(inSampleBT+1),XBT(inSampleBT,:));
   %   Predict default rate for "next" year (T+1)
   PredDefRate(k,1) = [1 XBT(T,:)]*s.beta;
   %   Compute prediction intervals
   tCrit = tinv(1-alpha/2,s.tstat.dfe);
```

```
    PredStd = sqrt([1 XBT(T,:)]*s.covb*[1 XBT(T,:)]'+s.mse);
    PredDefLoBnd(k) = max(0,PredDefRate(k,1) - tCrit*PredStd);
    PredDefUpBnd(k) = PredDefRate(k,1) + tCrit*PredStd;

    % Method 2: Point-in-time (PIT) default rate
    PredDefRate(k,2) = DefRate(T);

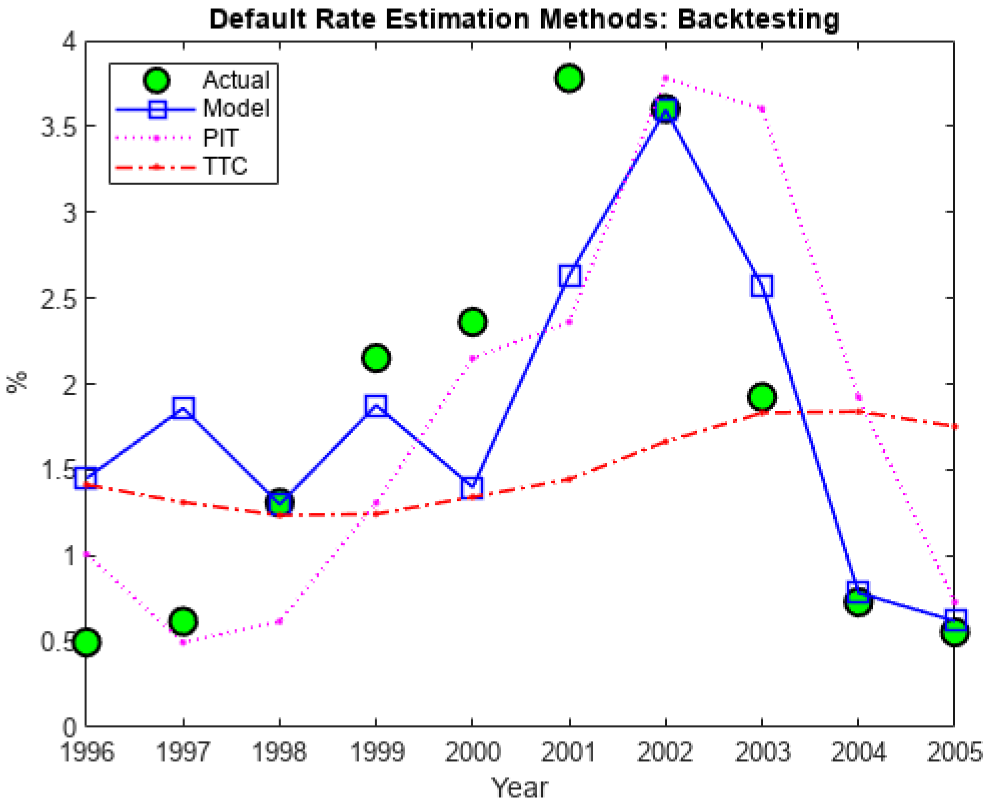
    % Method 3: Through-the-cycle (TTC) default rate
    tmAll = transprobbytotals(totalsAll(iYear0:T));
    PredDefRate(k,3) = tmAll(1,2);

    % Update error
    ErrorBT(k,:) = PredDefRate(k,:) - DefRate(T+1);

    % Move to next year
    T = T + 1;
end
```

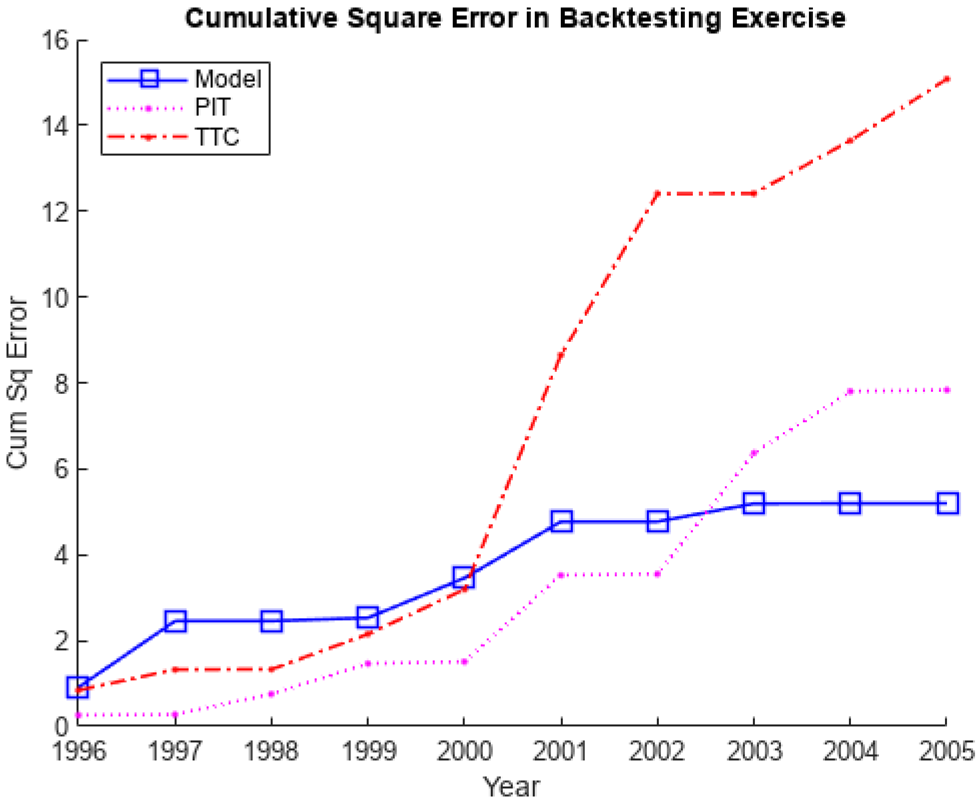
Here are the predictions of the three alternative approaches, compared to the actual default rates observed. Unsurprisingly, TTC shows a very poor predictive power. However, it is not obvious whether PIT or the linear regression model makes better predictions in this 10-year time span.

```
Example_BacktestPlot(YearsBT,DefRate(iYearsBT),PredDefRate,'Year','%',...
   '{\bf Default Rate Estimation Methods: Backtesting}',...
   ['Actual' MethodTags],'NW')
```



The following plot keeps track of cumulative square error, a measure often used for comparisons in backtesting exercises. This confirms TTC as a poor alternative. PIT shows lower cumulative error than the linear regression model in the late nineties, but after the 2001 recession the situation is reversed. Cumulative square error, however, is not an intuitive measure, it is hard to get a sense of what the difference between these alternatives means in practical terms.

```
CumSqError = cumsum(ErrorBT.^2);
Example_BacktestPlot(YearsBT,[],CumSqError,'Year','Cum Sq Error',...
   '{\bf Cumulative Square Error in Backtesting Exercise}',...
   MethodTags,'NW')
```



It makes sense to translate the prediction errors into a monetary measure. Here we measure the impact of the prediction error on a simplified framework for generating loss reserves in an institution.

We assume a homogeneous portfolio, where all credits have the same probability of default, the same loss given default (LGD), and the same exposure at default (EAD). Both LGD and EAD are assumed to be known. For simplicity, we keep these values constant for the 10 years of the exercise. We set LGD at 45%, and EAD per bond at 100 million. The portfolio is assumed to have a thousand bonds, so the total value of the portfolio, the total EAD, is 100 billion.

The predicted default rate for year *t*, determined at the end of year *t*-1, is used to calculate the expected loss for year *t*

$$EL_t = EAD_t \times LGD_t \times PredictedDefaultRate_t$$

This is the amount added to the loss reserves at the start of year *t*. At the end of the year, the actual losses are known

$$AL_t = EAD_t \times LGD_t \times ObservedDefaultRate_t$$

We assume that unused loss reserves remain in the reserves fund. The starting balance in reserves at the beginning of the exercise is set to zero. If the actual losses surpass the expected loss, unused reserves accumulated over the years are used first, and only if these run out, capital is used to cover a shortfall. All this translates into the following formula

$$Reserves_t = Reserves_{t-1} + (EL_t - AL_t)$$

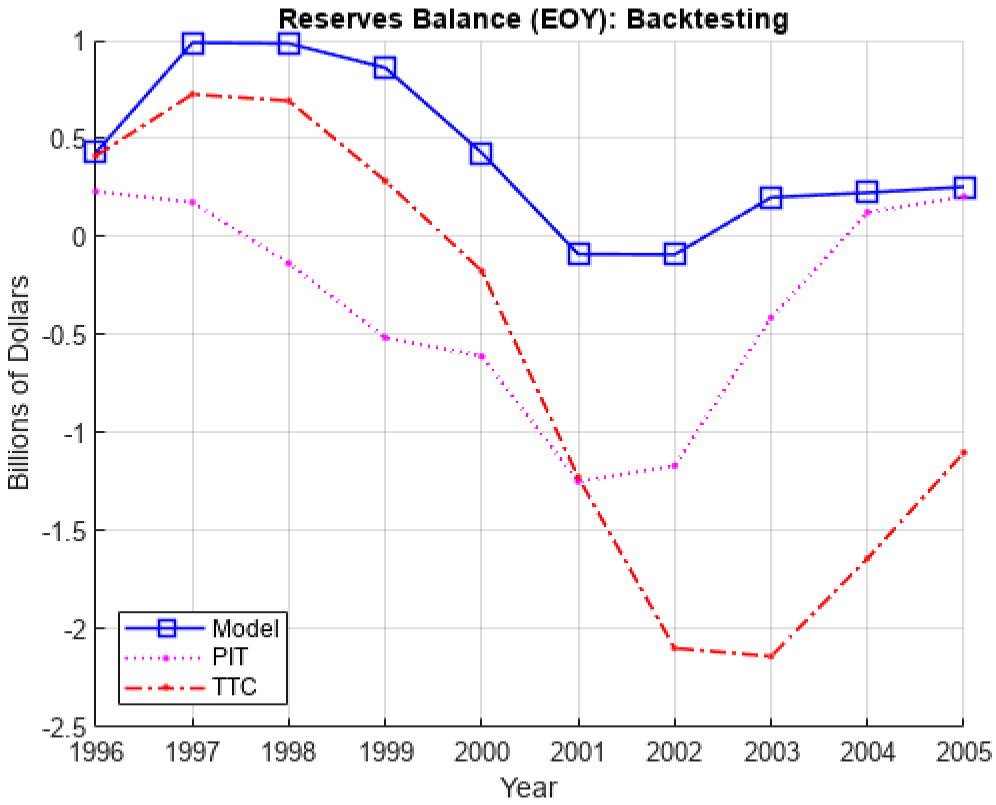
or equivalently

$$Reserves_t = \sum_{s=1}^{t} (EL_t - AL_t)$$

The following figure shows the loss reserves balance for each of the three alternatives in the backtesting exercise.

```
EAD = 100*ones(nYearsBT,1); % in billions
LGD = 0.45*ones(nYearsBT,1); % Loss given default, 45%
% Reserves excess or shortfall for each year, in billions
ReservesExcessShortfall = bsxfun(@times,EAD.*LGD,ErrorBT/100);
% Cumulative reserve balance for each year, in billions
ReservesBalanceEOY = cumsum(ReservesExcessShortfall);

Example_BacktestPlot(YearsBT,[],ReservesBalanceEOY,'Year',...
   'Billions of Dollars',...
   '{\bf Reserves Balance (EOY): Backtesting}',...
   MethodTags,'SW')
grid on
```



Using the linear regression model we only observe a deficit in reserves in two out of ten years, and the maximum deficit, in 2001, is 0.09 billion, only nine basis points of the portfolio value.

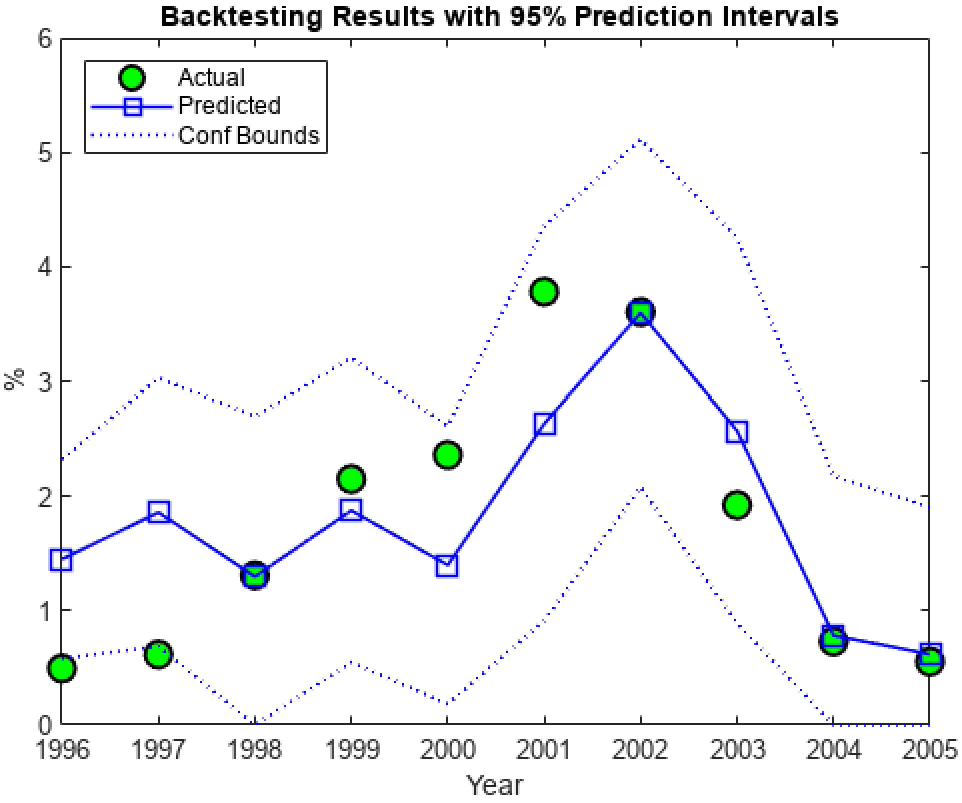
In contrast, both TTC and PIT reach a deficit of 1.2 billion by 2001. Things get worse for TTC in the next two years, reaching a deficit of 2.1 billion by 2003. PIT does make a correction quickly after 2001, and by 2004 the reserves have a surplus. Yet, both TTC and PIT lead to more deficit years than surplus years in this exercise.

The linear regression model shows more of a counter-cyclical effect than the alternatives in this exercise. The money set aside using the linear regression model reaches close to a billion in 1997 and 1998. High levels of unused reserves translate into a slower pace of lending (not reflected in the exercise, because we exogenously impose the portfolio value). Moreover, capital is only slightly impacted during the 2001 recession thanks to the reserves accumulated over the previous expansion. This translates into more capital available to back up further lending, if desired, during the economic recovery.

The last backtesting tool we discuss is the use of prediction intervals. Linear regression models provide standard formulas to compute confidence intervals for the values of new observations. These intervals are shown in the next figure for the 10 years spanned in the backtesting exercise.

```
figure
plot(YearsBT,DefRate(iYearsBT),'ko','LineWidth',1.5,'MarkerSize',10,...
   'MarkerFaceColor','g')
hold on
plot(YearsBT,PredDefRate(:,1),'b-s','LineWidth',1.2,'MarkerSize',10)
plot(YearsBT,[PredDefLoBnd PredDefUpBnd],'b:','LineWidth',1.2)
```

```
hold off
strConf = num2str((1-alpha)*100);
title(['{\bf Backtesting Results with ' strConf '% Prediction Intervals}'])
xlabel('Year');
ylabel('%');
legend({'Actual','Predicted','Conf Bounds'},'location','NW');
```



The observed default rates fall outside the prediction intervals for two years, 1996 and 1997, where very low default rates are observed. For a 95% confidence level, two out of 10 seems high. Yet, the observed values in these cases fall barely outside the prediction interval, which is a positive sign for the model. It is also positive that the prediction intervals contain the observed values around the 2001 recession.

Stress Testing

Stress testing is a broad area that reaches far beyond computational tools; see, for example, [3 on page 8-41]. We show some tools that can be incorporated into a comprehensive stress testing framework. We build on the linear regression model presented above, but the concepts and tools are compatible with other forecasting methodologies.

The first tool is the use of prediction intervals to define a worst-case scenario forecasts. This is to account for uncertainty in the model only, not in the value of the predictors.

We take a baseline scenario of predictors, in our case, the latest known values of our age proxy AGE, corporate profits forecast, CPF, and corporate spread, SPR. We then use the linear regression model to compute a 95% confidence upper bound for the predicted default rate. The motivation for this is illustrated in the last plot of the backtesting section, where the 95% confidence upper limit acts as a conservative bound when the prediction underestimates the actual default rates.

```
tCrit = tinv(1-alpha/2,stats.tstat.dfe);
XLast = [AGE(end),CPF(end),SPR(end)];

yPred = [1 XLast]*stats.beta;
PredStd = sqrt([1 XLast]*stats.covb*[1 XLast]'+stats.mse);
yPredUB = yPred + tCrit*PredStd;

fprintf('\nPredicted default rate:\n');
```

```
Predicted default rate:
```

```
fprintf('     Baseline: %4.2f%%\n',yPred);
```

```
     Baseline: 1.18%
```

```
fprintf('     %g%% Upper Bound: %4.2f%%\n',(1-alpha)*100,yPredUB);
```

```
     95% Upper Bound: 2.31%
```

The next step is to incorporate stressed scenarios of the predictors in the analysis. CPF and SPR can change in the short term, whereas AGE cannot. This is important. The corporate profits forecast and the corporate spread are influenced by world events, including, for example, natural disasters. These predictors can significantly change overnight. On the other hand, AGE depends on managerial decisions that can alter the proportion of old and new loans in time, but these decisions take months, if not years, to reflect in the AGE time series. Scenarios for AGE are compatible with longer term analyses. Here we look at one year ahead only, and keep AGE fixed for the remainder of this section.

It is convenient to define the predicted default rate and the confidence bounds as functions of CPF and SPR to simplify the scenario analysis.

```
yPredFn = @(cpf,spr) [1 AGE(end) cpf spr]*stats.beta;
PredStdFn = @(cpf,spr) sqrt([1 AGE(end) cpf spr]*stats.covb*...
   [1 AGE(end) cpf spr]'+stats.mse);
yPredUBFn = @(cpf,spr) (yPredFn(cpf,spr) + tCrit*PredStdFn(cpf,spr));
yPredLBFn = @(cpf,spr) (yPredFn(cpf,spr) - tCrit*PredStdFn(cpf,spr));
```

Two extreme scenarios of interest can be a drop in the corporate profits forecast of 4% relative to the baseline, and an increase in the corporate spread of 100 basis points over the baseline.

Moving one predictor at a time is not unreasonable in this case, because the correlation between CPF and SPR is very low. Moderate correlation levels may require perturbing predictors together to get more reliable results. Highly correlated predictors usually do not coexist in the same model, since they offer redundant information.

```
fprintf('\n\n         What-if Analysis\n');
```

```
         What-if Analysis
```

```
fprintf('Scenario         LB    Pred    UB\n');
```

```
Scenario         LB    Pred    UB
```

```
cpf = CPF(end)-4;
spr = SPR(end);
yPredRange = [yPredLBFn(cpf,spr),yPredFn(cpf,spr),yPredUBFn(cpf,spr)];
fprintf('CPF drops 4%%    %4.2f%%  %4.2f%%  %4.2f%%\n',yPredRange);
```

```
CPF drops 4%    0.42%  1.57%  2.71%
```

```
cpf = CPF(end);
spr = SPR(end)+1;
yPredRange = [yPredLBFn(cpf,spr),yPredFn(cpf,spr),yPredUBFn(cpf,spr)];
fprintf('SPR rises 1%%    %4.2f%%  %4.2f%%  %4.2f%%\n',yPredRange);
```

```
SPR rises 1%    0.71%  1.88%  3.05%
```

```
cpf = CPF(end);
spr = SPR(end);
yPredRange = [yPredLBFn(cpf,spr),yPredFn(cpf,spr),yPredUBFn(cpf,spr)];
fprintf('    Baseline    %4.2f%%  %4.2f%%  %4.2f%%\n',yPredRange);
```

```
    Baseline    0.04%  1.18%  2.31%
```

```
fprintf('\nCorrelation between CPF and SPR: %4.3f\n',corr(CPF,SPR));
```

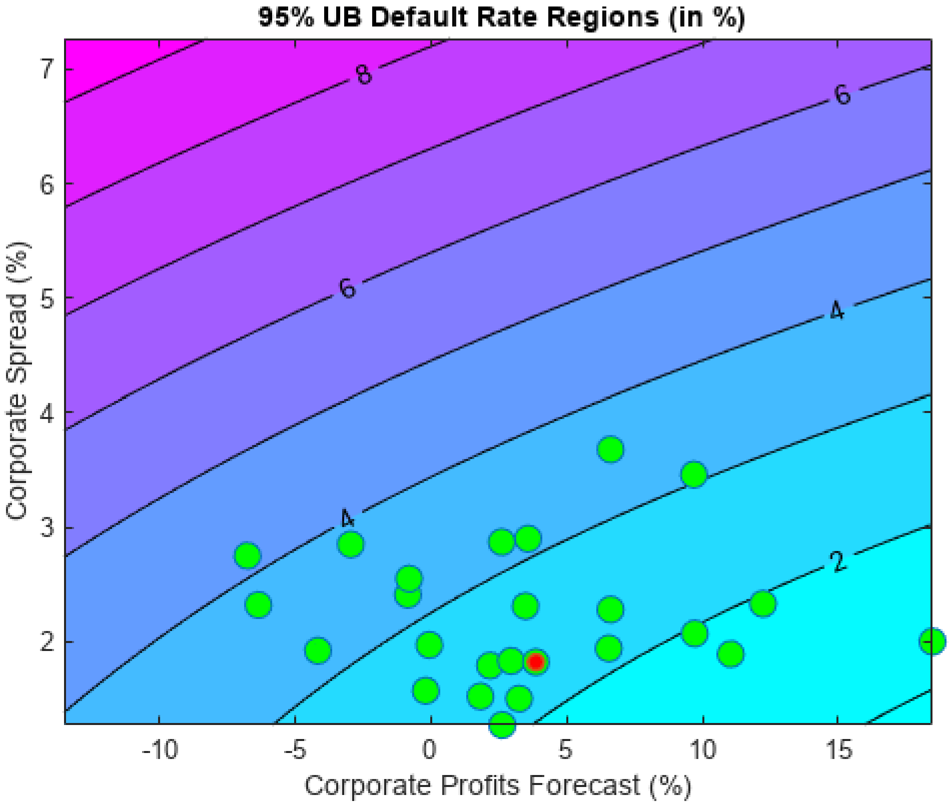
```
Correlation between CPF and SPR: 0.012
```

We now take a more global view of the scenario analysis. Instead of analyzing one scenario at a time, we visualize the default rate forecasts as a function of CPF and SPR. More precisely, we plot default rate contours over a whole grid of CPF and SPR values. We use the conservative 95% upper bound.

If we assumed a particular bivariate distribution for the values of CPF and SPR, we could plot the contours of their distribution in the same figure. That would give visual information on the probability of falling on each region. Lacking such a distribution, we simply add to the plot the CPF - SPR pairs observed in our sample, as a historical, empirical distribution. The last observation in the sample, the baseline scenario, is marked in red.

```
gridCPF = 2*min(CPF):0.1:max(CPF);
gridSPR = min(SPR):0.1:2*max(SPR);
nGridCPF = length(gridCPF);
nGridSPR = length(gridSPR);

DefRateUB = zeros(nGridCPF,nGridSPR);
for i=1:nGridCPF
   for j=1:nGridSPR
      DefRateUB(i,j) = yPredUBFn(gridCPF(i),gridSPR(j));
   end
end
Example_StressTestPlot(gridCPF,gridSPR,DefRateUB,CPF,SPR,...
   'Corporate Profits Forecast (%)','Corporate Spread (%)',...
   ['{\bf ' strConf '% UB Default Rate Regions (in %)}'])
```



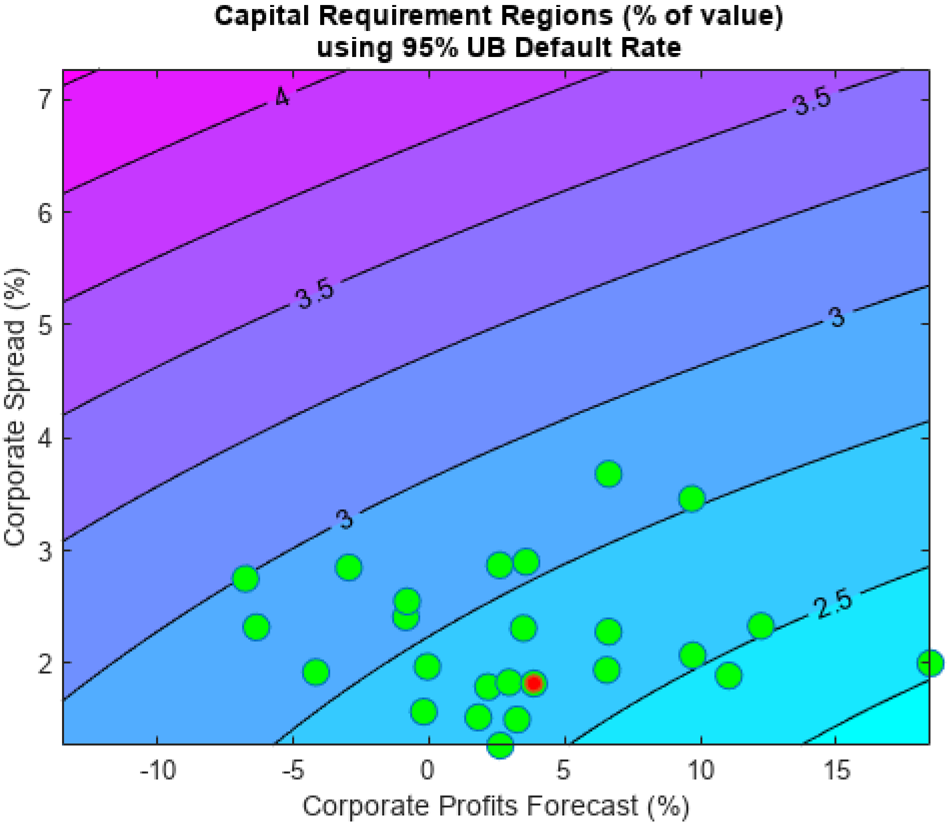
Very different predictor values result in similar default rate levels. For example, consider a profits forecast around 10% with a spread of 3.5%, and a profits forecast of -2.5% with a spread of 2%, they both result in a default rate slightly above 3%. Also, only one point in the available history yields a default rate higher than 4%.

Monetary terms, once again, may be more meaningful. We use the Basel II capital requirements formula (see [2 on page 8-41]) to translate the default rates into a monetary measure. The Basel II formula is convenient because it is analytic (there is no need to simulate to estimate the capital requirements), but also because it depends only on the probabilities of default. We define the Basel II capital requirements as a function K.

```
% Correlation as a function of PD
w = @(pd) (1-exp(-50*pd))/(1-exp(-50)); % weight
R = @(pd) (0.12*w(pd)+0.24*(1-w(pd))); % correlation
% Vasicek formula
V = @(pd) normcdf(norminv(pd)+R(pd).*norminv(0.999)./sqrt(1-R(pd)));
% Parameter b for maturity adjustment
b = @(pd) (0.11852-0.05478*log(pd)).^2;
% Basel II capital requirement with LGD=45% and maturity M=2.5 (numerator
% in maturity adjustment term becomes 1)
K = @(pd) 0.45*(V(pd)-pd).*(1./(1-1.5*b(pd)));
```

Worst-case default rates for a whole grid of CPF - SPR pairs are stored in DefRateUB. By applying the function K to DefRateUB, we can visualize the capital requirements over the same grid.

```
CapReq = 100*K(DefRateUB/100);
Example_StressTestPlot(gridCPF,gridSPR,CapReq,CPF,SPR,...
   'Corporate Profits Forecast (%)','Corporate Spread (%)',...
   {'{\bf Capital Requirement Regions (% of value)}';...
   ['{\bf using ' strConf '% UB Default Rate}']})
```



The contour levels now indicate capital requirements as a percentage of portfolio value. The two scenarios above, profits of 10% with spread of 3.5%, and profits of -2.5% and spread of 2%, result in capital requirements near 2.75%. The worst-case point from the historical data yields a capital requirement of about 3%.

This visualization can also be used, for example, as part of a reverse stress test analysis. Critical levels of capital can be determined first, and the figure can be used to determine regions of risk factor values (in this case CPF and SPR) that lead to those critical levels.

Instead of historical observations of CPF and SPR, an empirical distribution for the risk factors can be simulated using, for example, a vector autoregressive (VAR) model from Econometrics Toolbox™. The capital requirements corresponding to each default probability level can be found by simulation if a closed form formula is not available, and the same plots can be generated. For large simulations, a distributed computing implementation using Parallel Computing Toolbox™ or MATLAB® Parallel Server™ can make the process more efficient.

Appendix: Modeling Full Transition Matrices

Transition matrices change in time, and a full description of their dynamics requires working with multi-dimensional time series. There are, however, techniques that exploit the particular structure of transition matrices to reduce the dimensionality of the problem. In [8 on page 8-42], for example, a single parameter related to the proportion of downgrades is used, and both [6 on page 8-42] and [8 on page 8-42] describe a method to shift transition probabilities using a single parameter. The latter approach is shown in this appendix.

The method takes the TTC transition matrix as a baseline.

```
tmTTC = transprobbytotals(totalsByRtg);
Example_DisplayTransitions(tmTTC,[],...
   {'AAA','AA','A','BBB','BB','B','CCC'},...
   {'AAA','AA','A','BBB','BB','B','CCC','D','NR'})
```

```
          AAA     AA       A     BBB      BB       B     CCC       D      NR
   AAA   88.2   7.67    0.49    0.09    0.06       0       0       0    3.49
    AA   0.58  87.16    7.63    0.58    0.06    0.11    0.02    0.01    3.85
     A   0.05    1.9   87.24    5.59    0.42    0.15    0.03    0.04    4.58
   BBB   0.02   0.16    3.85   84.13    4.27    0.76    0.17    0.27    6.37
    BB   0.03   0.04    0.25    5.26   75.74    7.36     0.9    1.12    9.29
     B      0   0.05    0.19    0.31    5.52   72.67    4.21    5.38   11.67
   CCC      0      0    0.28    0.41    1.24   10.92   47.06   27.02   13.06
```

An equivalent way to represent this matrix is by transforming it into credit quality thresholds, that is, critical values of a standard normal distribution that yield the same transition probabilities (row by row).

```
thresholdMat = transprobtothresholds(tmTTC);
Example_DisplayTransitions(thresholdMat,[],...
   {'AAA','AA','A','BBB','BB','B','CCC'},...
   {'AAA','AA','A','BBB','BB','B','CCC','D','NR'})
```

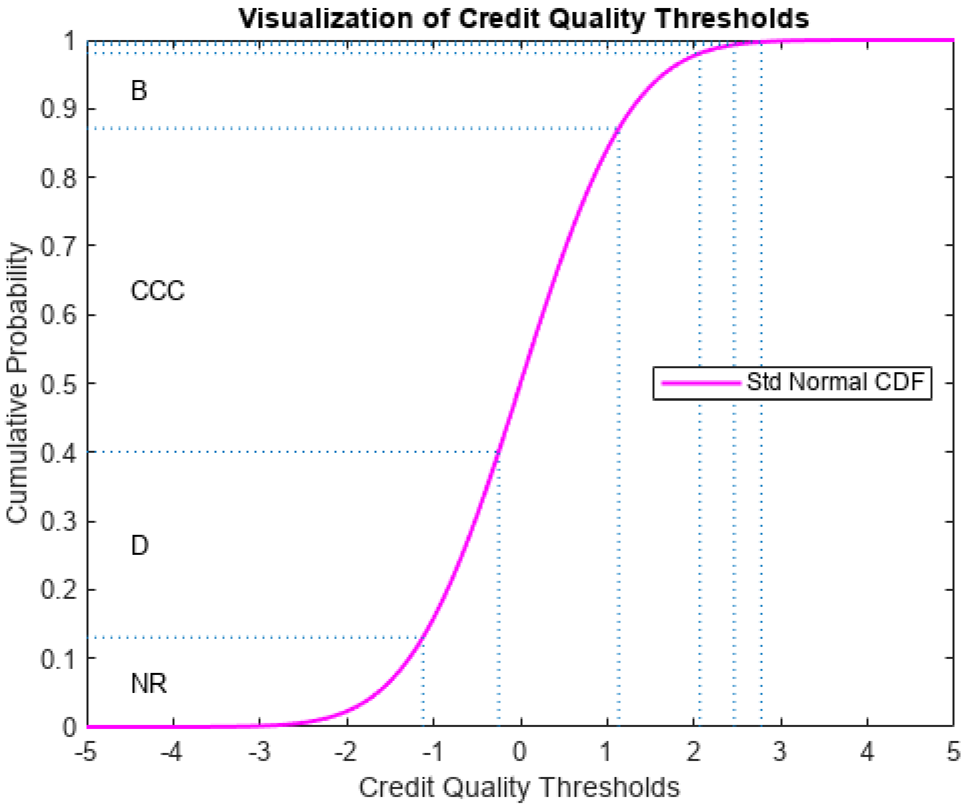
```
          AAA     AA       A     BBB      BB       B     CCC       D      NR
   AAA    Inf  -1.19   -1.74    -1.8   -1.81   -1.81   -1.81   -1.81   -1.81
    AA    Inf   2.52   -1.16   -1.68   -1.75   -1.75   -1.76   -1.77   -1.77
     A    Inf   3.31    2.07   -1.24   -1.62   -1.66   -1.68   -1.68   -1.69
   BBB    Inf   3.57    2.91    1.75   -1.18   -1.43   -1.49    -1.5   -1.52
    BB    Inf   3.39    3.16    2.72    1.59   -0.89   -1.21   -1.26   -1.32
     B    Inf    Inf    3.28    2.82    2.54    1.55    -0.8   -0.95   -1.19
   CCC    Inf    Inf     Inf    2.77    2.46    2.07    1.13   -0.25   -1.12
```

Credit quality thresholds are illustrated in the following figure. The segments in the vertical axis represent transition probabilities, and the boundaries between them determine the critical values in the horizontal axis, via the standard normal distribution. Each row in the transition matrix determines a set of thresholds. The figure shows the thresholds for the 'CCC' rating.

```
xliml = -5;
xlimr = 5;
step = 0.1;
x = xliml:step:xlimr;
thresCCC = thresholdMat(7,:);
centersY = (normcdf([thresCCC(2:end) xliml])+...
   normcdf([xlimr thresCCC(2:end)]))/2;
labels = {'AAA','AA','A','BBB','BB','B','CCC','D','NR'};

figure
plot(x,normcdf(x),'m','LineWidth',1.5)
for i=2:length(labels)
   val = thresCCC(i);
   line([val val],[0 normcdf(val)],'LineStyle',':');
   line([x(1) val],[normcdf(val) normcdf(val)],'LineStyle',':');
   if (centersY(i-1)-centersY(i))>0.05
```

```
      text(-4.5,centersY(i),labels{i});
   end
end
xlabel('Credit Quality Thresholds')
ylabel('Cumulative Probability')
title('{\bf Visualization of Credit Quality Thresholds}')
legend('Std Normal CDF','Location','E')
```



Shifting the critical values to the right or left changes the transition probabilities. For example, here is the transition matrix obtained by shifting the TTC thresholds by 0.5 to the right. Note that default probabilities increase.

```
shiftedThresholds = thresholdMat+0.5;
Example_DisplayTransitions(transprobfromthresholds(shiftedThresholds),...
   [],{'AAA','AA','A','BBB','BB','B','CCC'},...
   {'AAA','AA','A','BBB','BB','B','CCC','D','NR'})
```

```
          AAA     AA      A    BBB     BB      B    CCC      D     NR
   AAA  75.34  13.84   1.05   0.19   0.13      0      0      0   9.45
    AA   0.13  74.49  13.53   1.21   0.12   0.22   0.04   0.02  10.24
     A   0.01   0.51   76.4  10.02   0.83   0.31   0.06   0.08  11.77
   BBB      0   0.03    1.2  74.03   7.22   1.39   0.32   0.51  15.29
    BB      0   0.01   0.05   1.77  63.35  10.94   1.47   1.88  20.52
     B      0   0.01   0.04   0.07   1.91  59.67   5.74    8.1  24.46
   CCC      0      0   0.05    0.1   0.36   4.61  35.06  33.18  26.65
```

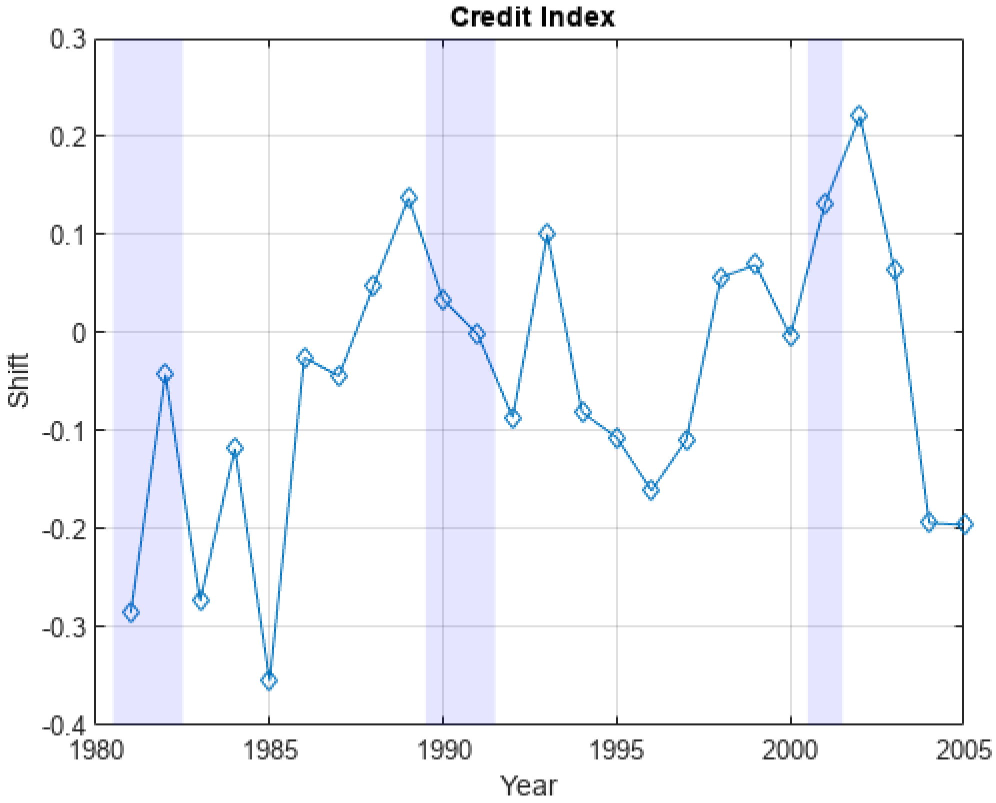
Given a particular PIT matrix, the idea in [6 on page 8-42] and [8 on page 8-42] is to vary the shifting parameter applied to the TTC thresholds so that the resulting transition matrix is as close as possible to the PIT matrix. Closeness is measured as the sum of squares of differences between corresponding transition probabilities. The optimal shifting value is called credit index. A credit index is determined for every PIT transition matrix in the sample.

Here we use `fminunc` from Optimization Toolbox™ to find the credit indices.

```
CreditIndex = zeros(nYears,1);
ExitFlag = zeros(nYears,1);
options = optimset('LargeScale','Off','Display','Off');
for i=1:nYears
   errorfun = @(z)norm(squeeze(TransMat(:,:,i))-...
      transprobfromthresholds(...
      transprobtothresholds(tmTTC)+z),'fro');
   [CreditIndex(i),~,ExitFlag(i)] = fminunc(errorfun,0,options);
end
```

In general, one expects that higher credit indices correspond to riskier years. The series of credit indices found does not entirely match this pattern. There may be different reasons for this. First, transition probabilities may deviate from their long-term averages in different ways that may lead to confounding effects in the single parameter trying to capture these differences, the credit index. Having separate credit indices for IG and SG, for example, may help separate confounding effects. Second, a difference of five basis points may be very significant for the `'BBB'` default rate, but not as important for the `'CCC'` default rate, yet the norm used weights them equally. Other norms can be considered. Also, it is always a good idea to check the exit flags of optimization solvers, in case the algorithm could not find a solution. Here we get valid solutions for each year (all exit flags are `1`).

```
figure
plot(Years,CreditIndex,'-d')
hold on
Example_RecessionBands
hold off
grid on
xlabel('Year')
ylabel('Shift')
title('{\bf Credit Index}')
```



The workflow above can be adapted to work with the series of credit indices instead of the series of corporate default rates. A model can be fit to predict a credit index for the following year, and a predicted transition matrix can be inferred and used for risk analyses.

Credit Quality Thresholds

In this section...

Introduction

An equivalent way to represent transition probabilities is by transforming them into credit quality thresholds. These are critical values of a standard normal distribution that yield the same transition probabilities.

An `M`-by-`N` matrix of transition probabilities `TRANS` and the corresponding `M`-by-`N` matrix of credit quality thresholds `THRESH` are related as follows. The thresholds `THRESH`(*i*,*j*) are critical values of a standard normal distribution *z*, such that

```
TRANS(i,N) = P[z < THRESH(i,N)],

TRANS(i,j) = P[z < THRESH(i,j)] - P[z < THRESH(i,j+1)], for 1<=j<N
```

Financial Toolbox supports the transformation between transition probabilities and credit quality thresholds with the functions `transprobtothresholds` and `transprobfromthresholds`.

Compute Credit Quality Thresholds

To compute credit quality thresholds, transition probabilities are required as input. Here is a transition matrix estimated from credit ratings data:

```
load Data_TransProb
trans = transprob(data)
```

```
trans =

   93.1170    5.8428    0.8232    0.1763    0.0376    0.0012    0.0001    0.0017
    1.6166   93.1518    4.3632    0.6602    0.1626    0.0055    0.0004    0.0396
    0.1237    2.9003   92.2197    4.0756    0.5365    0.0661    0.0028    0.0753
    0.0236    0.2312    5.0059   90.1846    3.7979    0.4733    0.0642    0.2193
    0.0216    0.1134    0.6357    5.7960   88.9866    3.4497    0.2919    0.7050
    0.0010    0.0062    0.1081    0.8697    7.3366   86.7215    2.5169    2.4399
    0.0002    0.0011    0.0120    0.2582    1.4294    4.2898   81.2927   12.7167
         0         0         0         0         0         0         0  100.0000
```

Convert the transition matrix to credit quality thresholds using `transprobtothresholds`:

```
thresh = transprobtothresholds(trans)
```

```
thresh =

       Inf   -1.4846   -2.3115   -2.8523   -3.3480   -4.0083   -4.1276   -4.1413
       Inf    2.1403   -1.6228   -2.3788   -2.8655   -3.3166   -3.3523   -3.3554
       Inf    3.0264    1.8773   -1.6690   -2.4673   -2.9800   -3.1631   -3.1736
       Inf    3.4963    2.8009    1.6201   -1.6897   -2.4291   -2.7663   -2.8490
       Inf    3.5195    2.9999    2.4225    1.5089   -1.7010   -2.3275   -2.4547
       Inf    4.2696    3.8015    3.0477    2.3320    1.3838   -1.6491   -1.9703
       Inf    4.6241    4.2097    3.6472    2.7803    2.1199    1.5556   -1.1399
       Inf       Inf       Inf       Inf       Inf       Inf       Inf       Inf
```

Conversely, given a matrix of thresholds, you can compute transition probabilities using `transprobfromthresholds`. For example, take the thresholds computed previously as input to recover the original transition probabilities:

```
trans1 = transprobfromthresholds(thresh)
```

```
trans1 =

   93.1170    5.8428    0.8232    0.1763    0.0376    0.0012    0.0001    0.0017
    1.6166   93.1518    4.3632    0.6602    0.1626    0.0055    0.0004    0.0396
    0.1237    2.9003   92.2197    4.0756    0.5365    0.0661    0.0028    0.0753
    0.0236    0.2312    5.0059   90.1846    3.7979    0.4733    0.0642    0.2193
    0.0216    0.1134    0.6357    5.7960   88.9866    3.4497    0.2919    0.7050
    0.0010    0.0062    0.1081    0.8697    7.3366   86.7215    2.5169    2.4399
    0.0002    0.0011    0.0120    0.2582    1.4294    4.2898   81.2927   12.7167
         0         0         0         0         0         0         0  100.0000
```

Visualize Credit Quality Thresholds

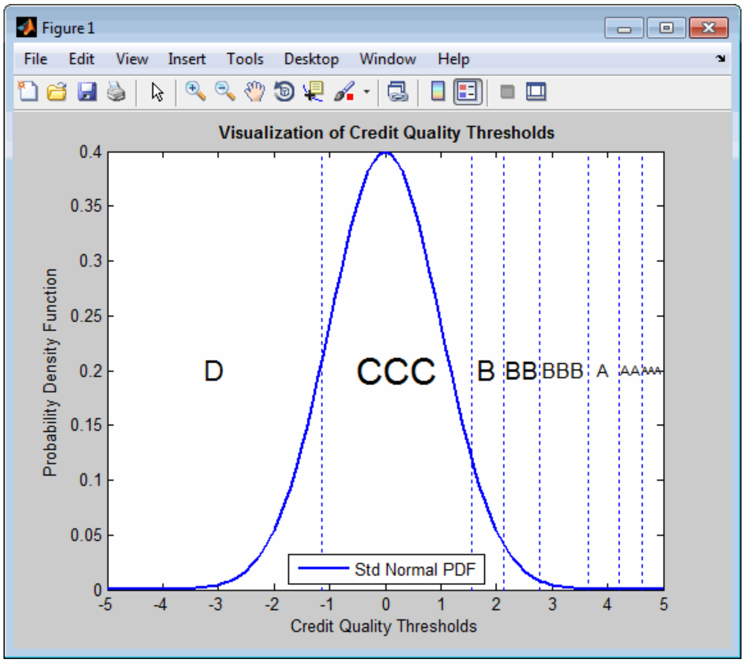
You can graphically represent the relationship between credit quality thresholds and transition probabilities. Here, this example shows the relationship for the `'CCC'` credit rating. In the plot, the thresholds are marked by the vertical lines and the transition probabilities are the area below the standard normal density curve:

```
load Data_TransProb
trans = transprob(data);
thresh = transprobtothresholds(trans);

xliml = -5;
xlimr = 5;
step = 0.1;
x=xliml:step:xlimr;
thresCCC = thresh(7,:);
labels = {'AAA','AA','A','BBB','BB','B','CCC','D'};

centersX = ([5 thresCCC(2:end)]+[thresCCC(2:end) -5])*0.5;
omag = round(log10(trans(7,:)));
omag(omag>0)=omag(omag>0).^2;
fs = 14+2*omag;

figure
plot(x,normpdf(x),'LineWidth',1.5)
text(centersX(1),0.2,labels{1},'FontSize',fs(1),...
   'HorizontalAlignment','center')
for i=2:length(labels)
   val = thresCCC(i);
   line([val val],[0 0.4],'LineStyle',':')
   text(centersX(i),0.2,labels{i},'FontSize',fs(i),...
      'HorizontalAlignment','center')
end
xlabel('Credit Quality Thresholds')
ylabel('Probability Density Function')
title('{\bf Visualization of Credit Quality Thresholds}')
legend('Std Normal PDF','Location','S')
```



The second plot uses the cumulative density function instead. The thresholds are represented by vertical lines. The transition probabilities are given by the distance between horizontal lines.

```
figure
plot(x,normcdf(x),'m','LineWidth',1.5)
text(centersX(1),0.2,labels{1},'FontSize',fs(1),...
   'HorizontalAlignment','center')
for i=2:length(labels)
   val = thresCCC(i);
   line([val val],[0 normcdf(val)],'LineStyle',':');
   line([x(1) val],[normcdf(val) normcdf(val)],'LineStyle',':');
   text(centersX(i),0.2,labels{i},'FontSize',fs(i),...
      'HorizontalAlignment','center')
end
xlabel('Credit Quality Thresholds')
ylabel('Cumulative Probability')
title('{\bf Visualization of Credit Quality Thresholds}')
legend('Std Normal CDF','Location','W')
```

About Credit Scorecards

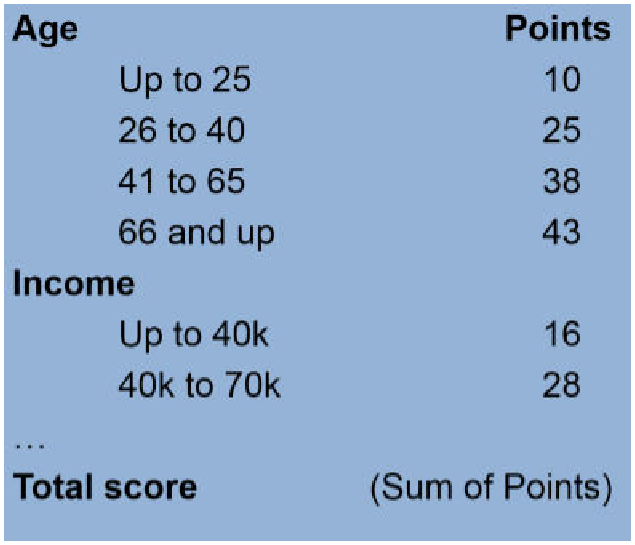
In this section...

What Is a Credit Scorecard?

Credit scoring is one of the most widely used credit risk analysis tools. The goal of credit scoring is ranking borrowers by their credit worthiness. In the context of retail credit (credit cards, mortgages, car loans, and so on), credit scoring is performed using a credit scorecard. Credit scorecards represent different characteristics of a customer (age, residential status, time at current address, time at current job, and so on) translated into points and the total number of points becomes the credit score. The credit worthiness of customers is summarized by their credit score; high scores usually correspond to low-risk customers, and conversely. Scores are also used for corporate credit analysis of small and medium enterprises, and, large corporations.

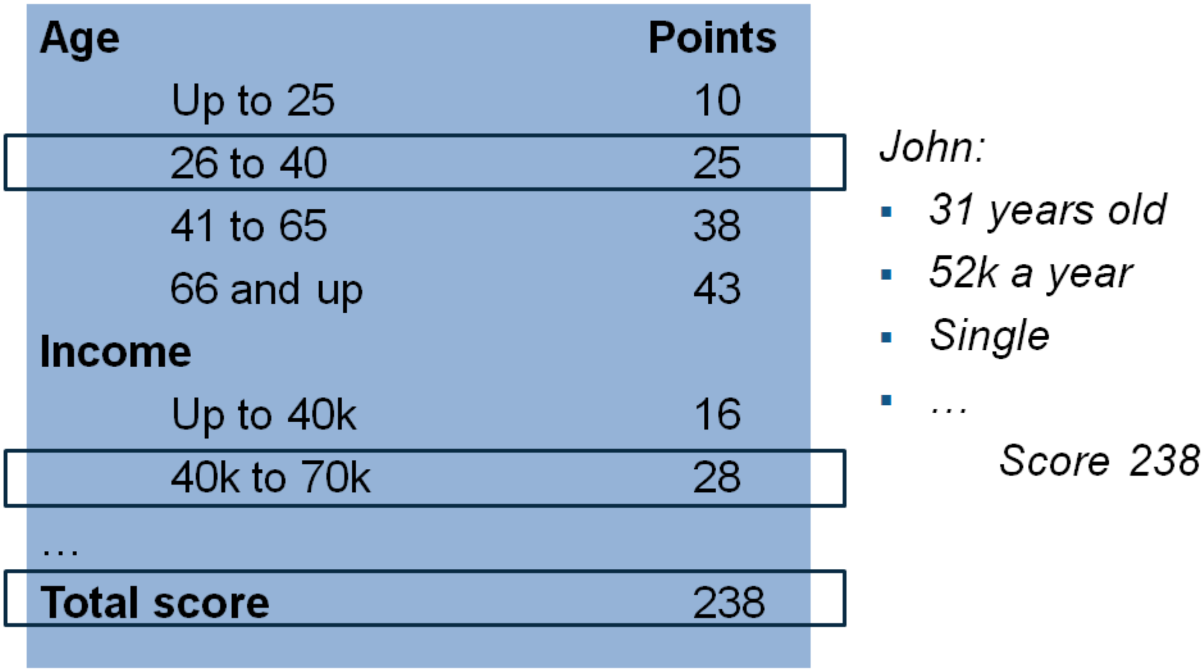
A credit scorecard is a lookup table that maps specific characteristics of a borrower into points. The total number of points becomes the credit score. Credit scorecards are a widely used type of credit scoring model. As such, the goal of a credit scorecard is to distinguish between customers who repay their loans ("good" customers), and customers who will not ("bad" customers). Like other credit scoring models, credit scorecards quantify the risk that a borrower will not repay a loan in the form of a score and a probability of default.

For example, a credit scorecard can give individual borrowers points for their age and income according to the following table. Other characteristics such as residential status, employment status, might also be included, although, for brevity, they are not shown in this table.



Age	Points
Up to 25	10
26 to 40	25
41 to 65	38
66 and up	43
Income	
Up to 40k	16
40k to 70k	28
...	
Total score	(Sum of Points)

Using the credit scorecard in this example, a particular customer who is 31 and has an income of $52,000 a year, is placed into the second age group (26–40) and receives 25 points for their age, and similarly, receives 28 points for their income. Other characteristics (not shown here) might contribute additional points to their score. The total score is the sum of all points, which in this example is assumed to give the customer a total of 238 points (this is a fictitious example on an arbitrary scoring scale).



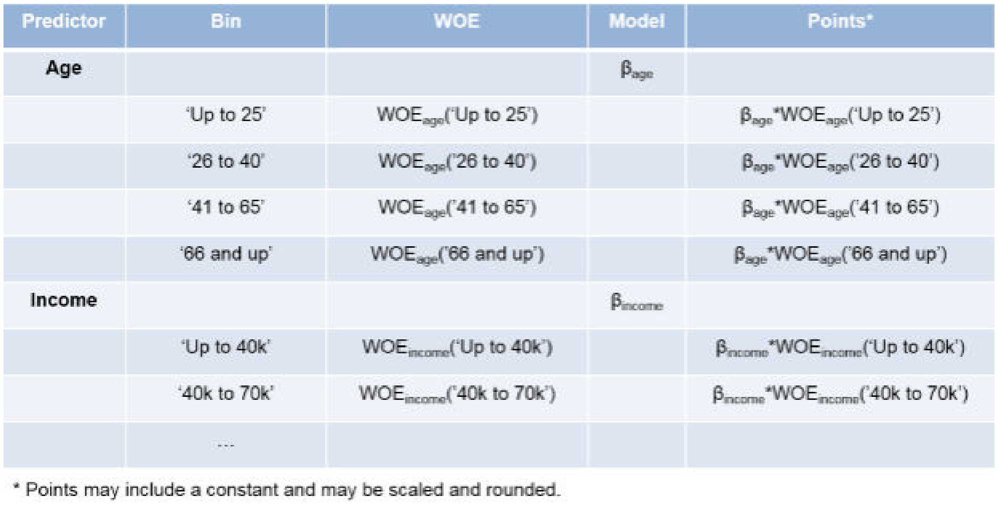
Age		Points
	Up to 25	10
	26 to 40	25
	41 to 65	38
	66 and up	43
Income		
	Up to 40k	16
	40k to 70k	28
…		
Total score		238

John:

- *31 years old*
- *52k a year*
- *Single*
- …

Score 238

Technically, to determine the credit scorecard points, start out by selecting a set of potential predictors (column 1 in the next figure). Then, bin data into groups (for example, ages ‘Up to 25’, ’25 to 40’ (column 2 in the figure). This grouping helps to distinguish between “good” and “bad” customers. The Weight of Evidence (WOE) is a way to measure how well the distribution of “good” and “bad” are separated across bins or groups for each individual predictor (column 3 in the figure). By fitting a logistic regression model, you can identify which predictors, when put together, do a better job distinguishing between “good” and “bad” customers. The model is summarized by its coefficients (column 4 in the figure). Finally, the combination of WOE’s and model coefficients (commonly scaled, shifted, and rounded) make up the scorecard points (column 5 in the figure).



Predictor	Bin	WOE	Model	Points*
Age			β_{age}	
	'Up to 25'	WOE$_{age}$('Up to 25')		β_{age}*WOE$_{age}$('Up to 25')
	'26 to 40'	WOE$_{age}$('26 to 40')		β_{age}*WOE$_{age}$('26 to 40')
	'41 to 65'	WOE$_{age}$('41 to 65')		β_{age}*WOE$_{age}$('41 to 65')
	'66 and up'	WOE$_{age}$('66 and up')		β_{age}*WOE$_{age}$('66 and up')
Income			β_{income}	
	'Up to 40k'	WOE$_{income}$('Up to 40k')		β_{income}*WOE$_{income}$('Up to 40k')
	'40k to 70k'	WOE$_{income}$('40k to 70k')		β_{income}*WOE$_{income}$('40k to 70k')
	...			

* Points may include a constant and may be scaled and rounded.

Credit Scorecard Development Process

1 Data gathering and preparation phase

   This includes data gathering and integration, such as querying, merging, aligning. It also includes treatment of missing information and outliers. There is a prescreening step based on reports of association measures between the predictors and the response variable. Finally, there is a sampling step, to produce a training set, sometimes called the modeling view, and usually a validation set, too. The training set, in the form of a table, is the required data input to the `creditscorecard` object, and this training set table must be prepared before creating a `creditscorecard` object in the Modeling phase.

2 Modeling phase

   Use the `creditscorecard` object and associated object functions to develop a credit scorecard model. You can bin the data, apply the Weight of Evidence (WOE) transformation, and compute other statistics, such as the Information Value. You can fit a logistic regression model and also review the resulting scorecard points and format their scaling and rounding. For details on using the `creditscorecard` object, see `creditscorecard`.

3 Deployment phase

   Deployment entails integrating a credit scorecard model into an IT production environment and keeping tracking logs, performance reports, and so on.

The `creditscorecard` object is designed for the Modeling phase of the credit scorecard workflow. Support for all three phases requires other MathWorks products.

Credit Scorecard Modeling Workflow

Create, model, and analyze credit scorecards as follows.

1. Use `screenpredictors` from Risk Management Toolbox™ to pare down a potentially large set of predictors to a subset that is most predictive of the credit score card response variable. Use this subset of predictors when creating the `creditscorecard` object. In addition, you can use **Threshold Predictors** to interactively set credit scorecard predictor thresholds using the output from `screenpredictors`.

   Create a `creditscorecard` object for credit scorecard analysis by specifying “training” data in table format. The training data, sometimes called the modeling view, is the result of multiple data preparation tasks (see “About Credit Scorecards” on page 8-47) that must be performed before creating a `creditscorecard` object.

   You can use optional input arguments for `creditscorecard` to specify scorecard properties such as the response variable and the `GoodLabel`. Perform some initial data exploration when the `creditscorecard` object is created, although data analysis is usually done in combination with data binning (see step 2). For more information and examples, see `creditscorecard` and step 1 in “Case Study for Credit Scorecard Analysis” on page 8-70.
2. Create a `creditscorecard` object using training data.

   When you create a `creditscorecard` object for credit scorecard, you can specify “training” data in table format. The training data, sometimes called the modeling view, is the result of multiple data preparation tasks (see “About Credit Scorecards” on page 8-47) that must be performed before creating a `creditscorecard` object.

   You can use optional input arguments for `creditscorecard` to specify scorecard properties such as the response variable and the `GoodLabel`. Perform some initial data exploration when the `creditscorecard` object is created, although data analysis is usually done in combination with data binning (see step 2). For more information and examples, see `creditscorecard` and step 1 in “Case Study for Credit Scorecard Analysis” on page 8-70.
3. Bin the data.

   Perform manual or automatic binning of the data loaded into the `creditscorecard` object.

   A common starting point is to apply automatic binning to all or selected variables using `autobinning`, report using `bininfo`, and visualize bin information with respect to bin counts and statistics or association measures such as Weight of Evidence (WOE) using `plotbins`. The bins can be modified or fine-tuned either manually using `modifybins` or with a different automatic binning algorithm using `autobinning`. Bins that show a close-to-linear trend in the WOE are frequently desired in the credit scorecard context.

   Alternatively, with Risk Management Toolbox, you can use the **Binning Explorer** app to interactively bin. The **Binning Explorer** enables you to interactively apply a binning algorithm and modify bins. For more information, see **Binning Explorer**.

   For more information and examples, see `autobinning`, `modifybins`, `bininfo`, and `plotbins` and step 2 in “Case Study for Credit Scorecard Analysis” on page 8-70.
4. Fit a logistic regression model.

Fit a logistic regression model to the WOE data from the `creditscorecard` object. The `fitmodel` function internally bins the training data, transforms it into WOE values, maps the response variable so that `'Good'` is `1`, and fits a linear logistic regression model.

By default, `fitmodel` uses a stepwise procedure to determine which predictors should be in the model, but optional input arguments can also be used, for example, to fit a full model. For more information and examples, see `fitmodel` and step 3 in “Case Study for Credit Scorecard Analysis” on page 8-70.

Alternatively, you can apply equality, inequality, or bound constraints to fit a logistic regression model to the WOE data from the `creditscorecard` object using `fitConstrainedModel`.

5 Review and format credit scorecard points.

After fitting the logistic model, use `displaypoints` to summarize the scorecard points. By default, the points are unscaled and come directly from the combination of Weight of Evidence (WOE) values and model coefficients.

The `formatpoints` function lets you control scaling and rounding of scorecard points. For more information and examples, see `displaypoints` and `formatpoints` and step 4 in “Case Study for Credit Scorecard Analysis” on page 8-70.

Optionally, you can create a compact credit scorecard using

To create a `compactCreditScorecard` object, use `compact` to create a `compactCreditScorecard` object. You can then use the following functions `displaypoints`, `score`, and `probdefault` from the Risk Management Toolbox with the `compactCreditScorecard` object..

6 Score the data.

The `score` function computes the scores for the training data.

An optional data input can also be passed to `score`, for example, validation data. The points per predictor for each customer are also provided as an optional output. For more information and examples, see `score` and step 5 in “Case Study for Credit Scorecard Analysis” on page 8-70.

7 Calculate the probability of default for credit scorecard scores.

The `probdefault` function to calculate the probability of default for training data.

In addition, you can compute likelihood of default for a different dataset (for example, a validation data set) using the `probdefault` function. For more information and examples, see `probdefault` and step 6 in “Case Study for Credit Scorecard Analysis” on page 8-70.

8 Validate the credit scorecard model.

Use the `validatemodel` function to validate the quality of the credit scorecard model.

You can obtain the Cumulative Accuracy Profile (CAP), Receiver Operating Characteristic (ROC), and Kolmogorov-Smirnov (KS) plots and statistics for a given dataset using the `validatemodel` function. For more information and examples, see `validatemodel` and step 7 in “Case Study for Credit Scorecard Analysis” on page 8-70.

For an example of this workflow, see “Case Study for Credit Scorecard Analysis” on page 8-70.

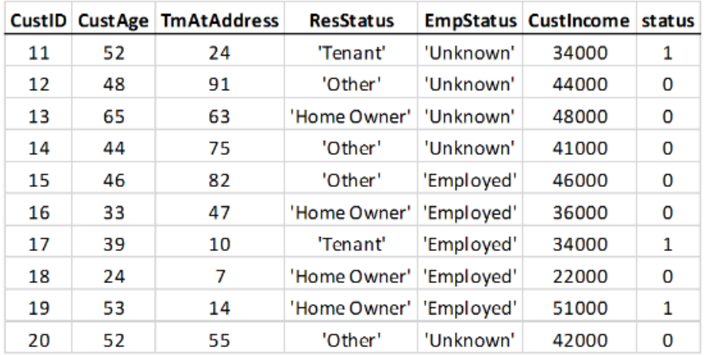
Credit Scorecard Modeling Using Observation Weights

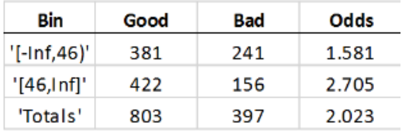
When creating a `creditscorecard` object, the table used for the input `data` argument either defines or does not define observational weights. If the `data` does not use weights, then the "counts" for `Good`, `Bad`, and `Odds` are used by credit score card functions. However, if the optional `WeightsVar` argument is specified when creating a `creditscorecard` object, then the "counts" for `Good`, `Bad`, and `Odds` are the sum of weights.

For example, here is a snippet of an input table that does not define observational weights:



CustID	CustAge	TmAtAddress	ResStatus	EmpStatus	CustIncome	status
11	52	24	'Tenant'	'Unknown'	34000	1
12	48	91	'Other'	'Unknown'	44000	0
13	65	63	'Home Owner'	'Unknown'	48000	0
14	44	75	'Other'	'Unknown'	41000	0
15	46	82	'Other'	'Employed'	46000	0
16	33	47	'Home Owner'	'Employed'	36000	0
17	39	10	'Tenant'	'Employed'	34000	1
18	24	7	'Home Owner'	'Employed'	22000	0
19	53	14	'Home Owner'	'Employed'	51000	1
20	52	55	'Other'	'Unknown'	42000	0

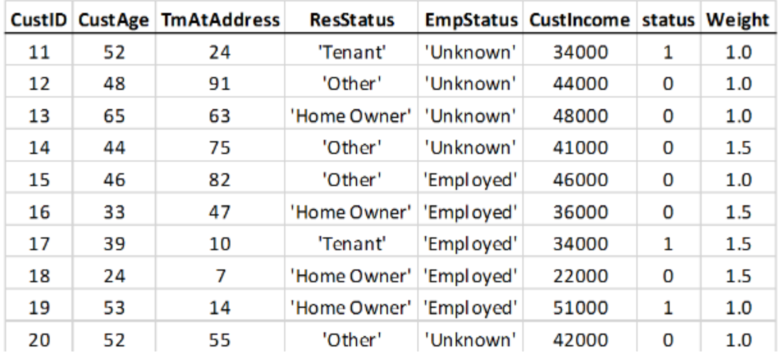
If you bin the customer age predictor data, with customers up to 45 years old in one bin, and 46 and up in another bin, you get these statistics:



Bin	Good	Bad	Odds
'[-Inf,46)'	381	241	1.581
'[46,Inf]'	422	156	2.705
'Totals'	803	397	2.023

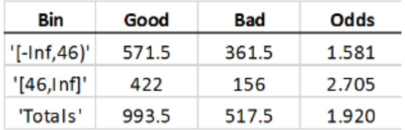
`Good` means the total number of rows with a `0` value in the `status` response variable. `Bad` the number of `1`’s in the `status` column. `Odds` is the ratio of `Good` to `Bad`. The `Good`, `Bad`, and `Odds` is reported for each bin. This means that there are 381 people in the sample who are 45 and under who paid their loans, 241 in the same age range who defaulted, and therefore, the odds of being good for that age range is `1.581`.

Suppose that the modeler thinks that people 45 and younger are underrepresented in this sample. The modeler wants to give all rows with ages up to 45 a higher weight. Assume that the modeler thinks the up to 45 age group should have 50% more weight than rows with ages 46 and up. The table data is expanded to include the observation weights. A `Weight` column is added to the table, where all rows with ages 45 and under have a weight of `1.5`, and all other rows a weight of `1`. There are other reasons to use weights, for example, recent data points may be given higher weights than older data points.



CustID	CustAge	TmAtAddress	ResStatus	EmpStatus	CustIncome	status	Weight
11	52	24	'Tenant'	'Unknown'	34000	1	1.0
12	48	91	'Other'	'Unknown'	44000	0	1.0
13	65	63	'Home Owner'	'Unknown'	48000	0	1.0
14	44	75	'Other'	'Unknown'	41000	0	1.5
15	46	82	'Other'	'Employed'	46000	0	1.0
16	33	47	'Home Owner'	'Employed'	36000	0	1.5
17	39	10	'Tenant'	'Employed'	34000	1	1.5
18	24	7	'Home Owner'	'Employed'	22000	0	1.5
19	53	14	'Home Owner'	'Employed'	51000	1	1.0
20	52	55	'Other'	'Unknown'	42000	0	1.0

If you bin the weighted data based on age (45 and under, versus 46 and up) the expectation is that each row with age 45 and under must count as 1.5 observations, and therefore the `Good` and `Bad` “counts” are increased by 50%:



Bin	Good	Bad	Odds
'[-Inf,46)'	571.5	361.5	1.581
'[46,Inf]'	422	156	2.705
'Totals'	993.5	517.5	1.920

The “counts” are now “weighted frequencies” and are no longer integer values. The `Odds` do not change for the first bin. The particular weights given in this example have the effect of scaling the total `Good` and `Bad` counts in the first bin by the same scaling factor, therefore their ratio does not change. However, the `Odds` value of the total sample does change; the first bin now carries a higher weight, and because the odds in that bin are lower, the total `Odds` are now lower, too. Other credit scorecard statistics not shown here, such as `WOE` and `Information Value` are affected in a similar way.

In general, the effect of weights is not simply to scale frequencies in a particular bin, because members of that bin will have different weights. The goal of this example is to demonstrate the concept of switching from counts to the sum of weights.

Credit Scorecard Modeling with Missing Values

This example shows how to handle missing values when you work with creditscorecard objects. First, the example shows how to use the creditscorecard functionality to create an explicit bin for missing data with corresponding points. Then, this example describes four different ways to "treat" the missing data on page 8-61 to get a final credit scorecard with no explicit bins for missing values.

Develop a Credit Scorecard with Explicit Bins for Missing Values

When you create a creditscorecard object, the data can contain missing values. When using creditscorecard to create a creditscorecard object, you can set the name-value pair argument for 'BinMissingData' set to true. In this case, the missing data for numeric predictors (NaN values) and for categorical predictors (<undefined> values) is binned in a separate bin labeled <missing> that appears at the end of the bins. Predictors with no missing values in the training data have no <missing> bin. If you do not specify the 'BinMissingData' argument or if you set 'BinMissingData' to false, the creditscorecard function discards missing observations when computing frequencies of Good and Bad, and neither the bininfo nor plotbins functions reports such observations.

The <missing> bin remains in place throughout the scorecard modeling process. The final scorecard explicitly indicates the points to be assigned to missing values for predictors that have a <missing> bin. These points are determined from the weight-of-evidence (WOE) value of the <missing> bin and the predictor's coefficient in the logistic model. For predictors without an explicit <missing> bin, you can assign points to missing values using the name-value pair argument 'Missing' in formatpoints, as described in this example, or by using one of the four different ways to "treat" the missing data on page 8-61.

The dataMissing table in the CreditCardData.mat file has two predictors with missing values — CustAge and ResStatus, .

```
load CreditCardData.mat
head(dataMissing,5)
```

```
    CustID     CustAge    TmAtAddress      ResStatus       EmpStatus     CustIncome     TmWBank     Othe

      1          53           62          <undefined>     Unknown         50000          55          Ye
      2          61           22          Home Owner      Employed        52000          25          Ye
      3          47           30          Tenant          Employed        37000          61          No
      4         NaN           75          Home Owner      Employed        53000          20          Ye
      5          68           56          Home Owner      Employed        53000          14          Ye
```

Create a creditscorecard object using the CreditCardData.mat file to load the dataMissing table with missing values. Set the 'BinMissingData' argument to true. Apply automatic binning.

```
sc = creditscorecard(dataMissing,'IDVar','CustID','BinMissingData',true);
sc = autobinning(sc);
```

The bin information and bin plots for the predictors that have missing data both show a <missing> bin at the end.

```
bi = bininfo(sc,'CustAge');
disp(bi)
```

```

```

```
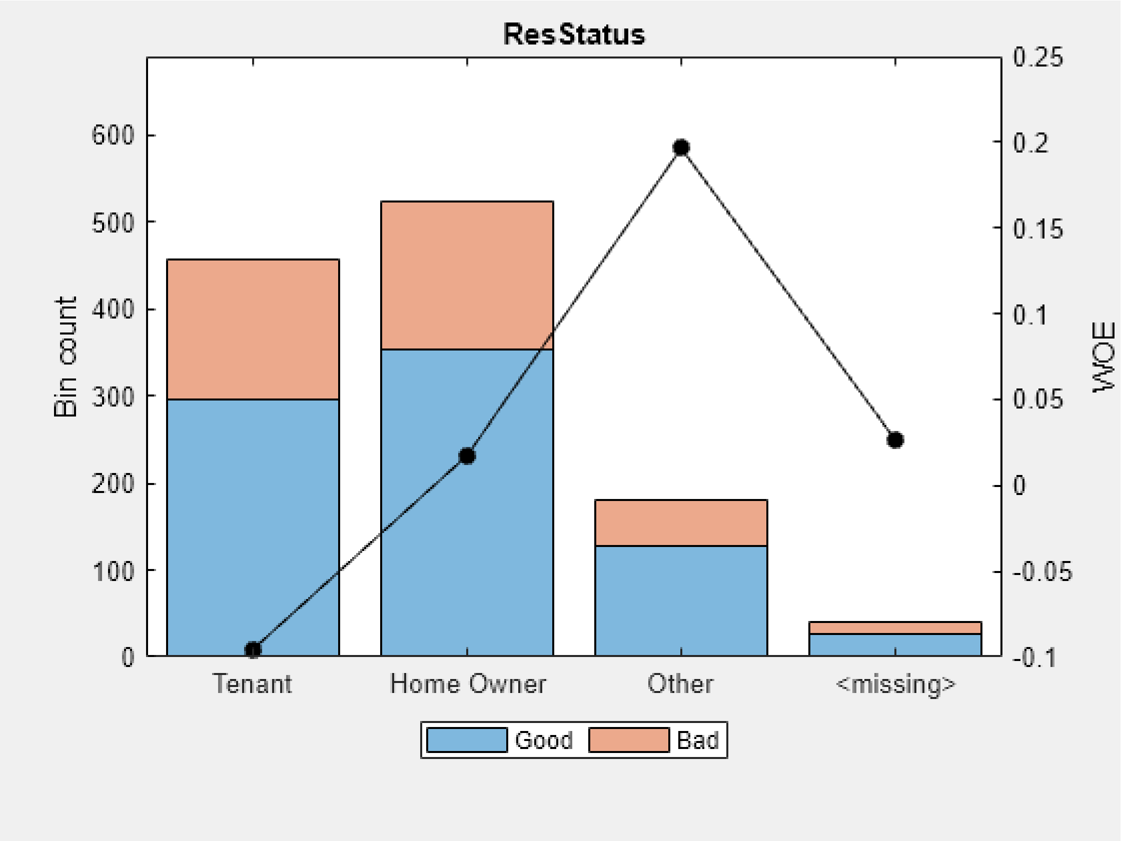
plotbins(sc,'ResStatus')
```



The training data for the `'CustAge'` and `'ResStatus'` predictors has missing data (`NaN`s and `<undefined>`). The binning process estimates WOE values of `-0.15787` and `0.026469`, respectively, for the missing data in these predictors.

The training data for `EmpStatus` and `CustIncome` has no explicit bin for `<missing>` values because there are no missing values for these predictors.

```
bi = bininfo(sc,'EmpStatus');
disp(bi)

    {'Totals'       }    803     397      2.0227          NaN       0.12285
```

Use `fitmodel` to fit a logistic regression model using WOE values. `fitmodel` internally transforms all the predictor variables into WOE values, using the bins found during the automatic binning process. By default, `fitmodel` then fits a logistic regression model using a stepwise method. For predictors that have missing data, there is an explicit `<missing>` bin with a corresponding WOE value computed from the data. When you use `fitmodel`, the corresponding WOE value for the `<missing>` bin is applied when the function performs the WOE transformation.

```
[sc,mdl] = fitmodel(sc,'display','off');
```

Scale the scorecard points by the points-to-double-the-odds (PDO) method using the `'PointsOddsAndPDO'` argument of `formatpoints`. Suppose that you want a score of 500 points to have odds of 2 (twice as likely to be good than to be bad) and that the odds double every 50 points (so that 550 points would have odds of 4).

Display the scorecard showing the scaled points for predictors retained in the fitting model.

```
sc = formatpoints(sc,'PointsOddsAndPDO',[500 2 50]);
PointsInfo = displaypoints(sc)
```

```
PointsInfo=38×3 table
     Predictors           Bin           Points
    _____________    ______________    ______

    {'CustAge'  }    {'[-Inf,33)' }    54.062
    {'CustAge'  }    {'[33,37)'   }    56.282
    {'CustAge'  }    {'[37,40)'   }    60.012
    {'CustAge'  }    {'[40,46)'   }    69.636
    {'CustAge'  }    {'[46,48)'   }    77.912
    {'CustAge'  }    {'[48,51)'   }     78.86
    {'CustAge'  }    {'[51,58)'   }     80.83
    {'CustAge'  }    {'[58,Inf]'  }     96.76
    {'CustAge'  }    {'<missing>' }    64.984
    {'ResStatus'}    {'Tenant'    }    62.138
    {'ResStatus'}    {'Home Owner'}    73.248
    {'ResStatus'}    {'Other'     }    90.828
    {'ResStatus'}    {'<missing>' }    74.125
    {'EmpStatus'}    {'Unknown'   }    58.807
    {'EmpStatus'}    {'Employed'  }    86.937
    {'EmpStatus'}    {'<missing>' }       NaN
      ⋮
```

Notice that points for the `<missing>` bins for `CustAge` and `ResStatus` are explicitly shown (as `64.9836` and `74.1250`, respectively). These points are computed from the WOE value for the `<missing>` bin and the logistic model coefficients.

Points for predictors that have no missing data in the training set, by default, are set to `NaN` and they lead to a score of `NaN` when you run `score`. This can be changed by updating the name-value pair argument `'Missing'` in `formatpoints` to indicate how to treat missing data for scoring purposes.

The scorecard is ready for scoring new data sets. You can also use the scorecard to compute probabilities of default or perform model validation. For details, see `score`, `probdefault`, and validatemodel. To further explore the handling of missing data, take a few rows from the original data as test data and introduce some missing data.

```
tdata = dataMissing(11:14,mdl.PredictorNames); % Keep only the predictors retained in the model
% Set some missing values
tdata.CustAge(1) = NaN;
tdata.ResStatus(2) = '<undefined>';
tdata.EmpStatus(3) = '<undefined>';
tdata.CustIncome(4) = NaN;
disp(tdata)
```

```
    CustAge      ResStatus      EmpStatus     CustIncome    TmWBank    OtherCC    AMBalance
    _______    ___________    ___________    __________    _______    _______    _________

      NaN      Tenant         Unknown          34000          44         Yes         119.8
       48      <undefined>    Unknown          44000          14         Yes        403.62
       65      Home Owner     <undefined>      48000           6         No         111.88
       44      Other          Unknown            NaN          35         No         436.41
```

Score the new data and see how points for missing data are differently assigned for CustAge and ResStatus and for EmpStatus and CustIncome. CustAge and ResStatus have an explicit <missing> bin for missing data. However, for EmpStatus and CustIncome, the score function sets the points to NaN.

```
[Scores,Points] = score(sc,tdata);
disp(Scores)
```

```
  481.2231
  520.8353
       NaN
       NaN
```

```
disp(Points)
```

```
    CustAge    ResStatus    EmpStatus    CustIncome    TmWBank    OtherCC    AMBalance
    _______    _________    _________    __________    _______    _______    _________

    64.984      62.138       58.807        67.893      61.858     75.622      89.922  
     78.86      74.125       58.807        82.439      61.061     75.622      89.922  
     96.76      73.248          NaN        96.969      51.132     50.914      89.922  
    69.636      90.828       58.807           NaN      61.858     50.914      89.922  
```

Use the name-value pair argument 'Missing' in formatpoints to choose how to assign points to missing values for predictors that do not have an explicit <missing> bin. For this example, use the 'MinPoints' option for the 'Missing' argument. For EmpStatus and CustIncome, the minimum numbers of points in the scorecard are 58.8072 and 29.3753, respectively. You can also treat missing values using one of the four different ways to "treat" the missing data on page 8-61.

```
sc = formatpoints(sc,'Missing','MinPoints');
[Scores,Points] = score(sc,tdata);
disp(Scores)
```

```

    _______    _________    _________    __________    _______    _______    _________

    64.984      62.138       58.807        67.893      61.858     75.622      89.922
     78.86      74.125       58.807        82.439      61.061     75.622      89.922
     96.76      73.248       58.807        96.969      51.132     50.914      89.922
    69.636      90.828       58.807        29.375      61.858     50.914      89.922
```

Four Approaches for Treating Missing Data and Developing a New Credit Scorecard

There are four different approaches for treating missing data.

Approach 1: Fill missing data using the `fillmissing` function of the `creditscorecard` object

The `creditscorecard` object supports a `fillmissing` function. When you call the function on a predictor or group of predictors, the `fillmissing` function fills the missing data with the user-specified statistic. `fillmissing` supports the fill values `'mean'`, `'median'`, `'mode'`, and `'constant'`, as well as the option to switch back to the original data.

The advantage of using `fillmissing` is that the `creditscorecard` object keeps track of the fill value and also applies it to the validation data. The limitation of this approach is that only basic statistics are used to fill missing data.

For more information on **Approach 1**, see `fillmissing`.

Approach 2: Fill missing data using the MATLAB® `fillmissing` function

MATLAB® supports a `fillmissing` function that you can use before creating a `creditscorecard` object to treat missing values in numeric and categorical data. The advantage of this method is that you can use all the options available in `fillmissing` to fill missing data, as well as other MATLAB functionality, such as `standardizeMissing` and features for the treatment of outliers. However, the downside is that you are responsible for the same transformations to the validation data before scoring as the `fillmissing` function is outside of the `creditscorecard` object.

For more information on **Approach 2**, see “Treat Missing Data in a Credit Scorecard Workflow Using MATLAB® fillmissing” on page 8-130.

Approach 3: Impute missing data using the k-nearest neighbors (KNN) algorithm

This KNN approach considers multiple predictors as compared to Approach 1 and Approach 2. Like **Approach 2**, the KNN approach is done outside the `creditscoreacrd` workflow, and consequently, you need to perform imputation for both the training and validation data.

For more information on **Approach 3**, see “Impute Missing Data in the Credit Scorecard Workflow Using the k-Nearest Neighbors Algorithm” on page 8-118.

Approach 4: Impute missing data using the random forest algorithm

This random forest approach is similar to **Approach 3** and uses multiple predictors to impute missing values. Because the approach is outside the `creditscorecard` workflow, you need to perform imputation for both the training and validation data.

For more information on **Approach 4**, see “Impute Missing Data in the Credit Scorecard Workflow Using the Random Forest Algorithm” on page 8-125.

Troubleshooting Credit Scorecard Results

In this section...

This topic shows some of the results when using credit scorecards that need troubleshooting. These examples cover the full range of the credit score card workflow. For details on the overall process of creating and developing credit scorecards, see "Credit Scorecard Modeling Workflow" on page 8-51.

Predictor Name Is Unspecified and the Parser Returns an Error

If you attempt to use `modifybins`, `bininfo`, or `plotbins` and omit the predictor's name, the parser returns an error.

```
load CreditCardData
sc = creditscorecard(data,'IDVar','CustID','GoodLabel',0);
modifybins(sc,'CutPoints',[20 30 50 65])
```

```
Error using creditscorecard/modifybins (line 79)
Expected a string for the parameter name, instead the input type was 'double'.
```

Solution: Make sure to include the predictor's name when using these functions. Use this syntax to specify the `PredictorName` when using `modifybins`.

```
load CreditCardData
sc = creditscorecard(data,'IDVar','CustID','GoodLabel',0);
modifybins(sc,'CustIncome','CutPoints',[20 30 50 65]);
```

Using bininfo or plotbins Before Binning

If you use `bininfo` or `plotbins` before binning, the results might be unusable.

```
load CreditCardData
sc = creditscorecard(data,'IDVar','CustID','GoodLabel',0);
bininfo(sc,'CustAge')
plotbins(sc,'CustAge')
```

```
ans =

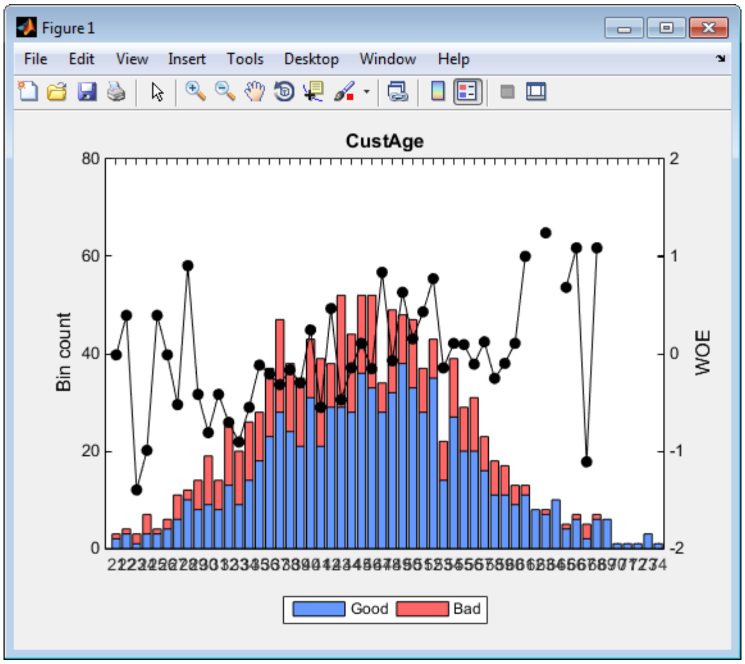
```



The plot for CustAge is not readable because it has too many bins. Also, bininfo returns data that have Inf values for the WOE due to zero observations for either **Good** or **Bad**.

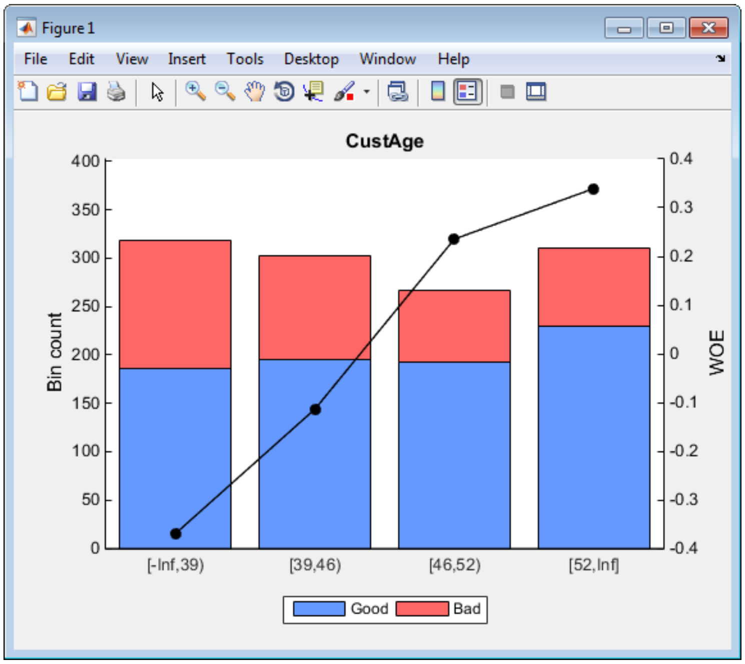
Solution: Bin the data using `autobinning` or `modifybins` before plotting or inquiring about the bin statistics, to avoid having too many bins or having `NaN`s and `Inf`s. For example, you can use the name-value pair argument for `AlgoOptions` with the `autobinning` function to define the number of bins.

```
load CreditCardData
sc = creditscorecard(data,'IDVar','CustID','GoodLabel',0);
AlgoOptions = {'NumBins',4};
sc = autobinning(sc,'CustAge','Algorithm','EqualFrequency',...
'AlgorithmOptions',AlgoOptions);
bininfo(sc,'CustAge','Totals','off')
plotbins(sc,'CustAge')
```

```
ans = 

        Bin           Good    Bad     Odds        WOE        InfoValue
    ___________       ____    ___    ______    ________     _________

    '[-Inf,39)'       186     133    1.3985    -0.36902       0.03815
    '[39,46)'         195     108    1.8056    -0.11355     0.0033158
    '[46,52)'         192      75      2.56     0.23559      0.011823
    '[52,Inf]'        230      81    2.8395     0.33921       0.02795
```



If Categorical Data Is Given as Numeric

Categorical data is often recorded using numeric values, and can be stored in a numeric array. Although you know that the data should be interpreted as categorical information, for `creditscorecard` this predictor looks like a numeric array.

To show the case where categorical data is given as numeric data, the data for the variable `ResStatus` is intentionally converted to numeric values.

```
load CreditCardData
data.ResStatus = double(data.ResStatus);
sc = creditscorecard(data,'IDVar','CustID')
```

```
sc =
  creditscorecard with properties:

                GoodLabel: 0
              ResponseVar: 'status'
                 VarNames: {1x11 cell}
        NumericPredictors: {1x7 cell}
    CategoricalPredictors: {'EmpStatus'  'OtherCC'}
                    IDVar: 'CustID'
            PredictorVars: {1x9 cell}
```

Note that `'ResStatus'` appears as part of the `NumericPredictors` property. If we applied automatic binning, the resulting bin information raises flags regarding the predictor type.

```
sc = autobinning(sc,'ResStatus');
[bi,cg] = bininfo(sc,'ResStatus')
```

```
bi = 

        Bin         Good    Bad     Odds        WOE       InfoValue 
    ____________    ____    ___    ______    _________    __________

    '[-Inf,2)'      365     177    2.0621     0.019329     0.0001682
    '[2,Inf]'       438     220    1.9909    -0.015827    0.00013772
    'Totals'        803     397    2.0227          NaN    0.00030592

cg =

     2
```

The numeric ranges in the bin labels show that `'ResStatus'` is being treated as a numeric variable. This is also confirmed by the fact that the optional output from `bininfo` is a numeric array of cut points, as opposed to a table with category groupings. Moreover, the output from `predictorinfo` confirms that the credit scorecard is treating the data as numeric.

```
[T,Stats] = predictorinfo(sc,'ResStatus')
```

```
T = 

                 PredictorType         LatestBinning      
                 _____________    ______________________

    ResStatus    'Numeric'        'Automatic / Monotone'

Stats = 

             Value 
            _______

    Min           1
    Max           3
    Mean     1.7017
    Std     0.71863
```

Solution: For `creditscorecard`, `'Categorical'` means a MATLAB categorical data type. For more information, see `categorical`. To treat`'ResStatus'` as categorical, change the `'PredictorType'` of the `PredictorName` `'ResStatus'` from `'Numeric'` to `'Categorical'` using `modifypredictor`.

```
sc = modifypredictor(sc,'ResStatus','PredictorType','Categorical')
[T,Stats] = predictorinfo(sc,'ResStatus')
```

```
sc = 

  creditscorecard with properties:

                GoodLabel: 0
```

```
             ResponseVar: 'status'
                VarNames: {1x11 cell}
       NumericPredictors: {1x6 cell}
   CategoricalPredictors: {'ResStatus'  'EmpStatus'  'OtherCC'}
                   IDVar: 'CustID'
           PredictorVars: {1x9 cell}

T = 

                 PredictorType    Ordinal     LatestBinning 
                 _____________    _______    _______________

    ResStatus    'Categorical'    false      'Original Data'

Stats = 

          Count
          _____

    C1    542  
    C2    474  
    C3    184  
```

Note that 'ResStatus' now appears as part of the Categorical predictors. Also, predictorinfo now describes 'ResStatus' as categorical and displays the category counts.

If you apply autobinning, the categories are now reordered, as shown by calling bininfo, which also shows the category labels, as opposed to numeric ranges. The optional output of bininfo is now a category grouping table.

```
sc = autobinning(sc,'ResStatus');
[bi,cg] = bininfo(sc,'ResStatus')
```

```
bi = 

      Bin       Good    Bad     Odds         WOE       InfoValue

    'Totals'    803     397    2.0227          NaN    0.0097738

cg = 

    Category    BinNumber
    ________    _________

    'C2'        1        
    'C1'        2        
    'C3'        3        
```

NaNs Returned When Scoring a “Test” Dataset

When applying a creditscorecard model to a “test” dataset using the score function, if an observation in the “test” dataset has a NaN or <undefined> value, a NaN total score is returned for each of these observations. For example, a creditscorecard object is created using “training” data.

```
load CreditCardData
sc = creditscorecard(data,'IDVar','CustID');
sc = autobinning(sc);
sc = fitmodel(sc);
```

```

    -0.14036      0.12696    -0.076317    -0.10466      -0.033752     0.15842    -0.017472
     0.23039      0.37641      0.31449     0.43693      -0.033752    -0.19168     -0.21206
     0.23039    -0.031252    -0.076317     0.43693      -0.033752     0.15842      0.35551
     0.23039      0.12696    -0.076317     0.43693      -0.033752     0.15842    -0.017472
```

Also, notice that because the CustAge predictor for the first observation is NaN, the corresponding Scores output is NaN also.

Solution: To resolve this issue, use the formatpoints function with the name-value pair argument Missing. When using Missing, you can replace a predictor's NaN value according to three alternative criteria ('ZeroWoe', 'MinPoints', or 'MaxPoints').

For example, use Missing to replace the missing value with the 'MinPoints' option. The row with the missing data now has a score corresponding to assigning it the minimum possible points for CustAge.

```
sc = formatpoints(sc,'Missing','MinPoints');
[Scores,Points] = score(sc,newdata)
PointsTable = displaypoints(sc);
PointsTable(1:7,:)
```

```

Case Study for Credit Scorecard Analysis

This example shows how to create a `creditscorecard` object, bin data, display, and plot binned data information. This example also shows how to fit a logistic regression model, obtain a score for the scorecard model, and determine the probabilities of default and validate the credit scorecard model using three different metrics.

Step 1. Create a creditscorecard object.

Use the `CreditCardData.mat` file to load the `data` (using a dataset from Refaat 2011). If your `data` contains many predictors, you can first use `screenpredictors` (Risk Management Toolbox) to pare down a potentially large set of predictors to a subset that is most predictive of the credit scorecard response variable. You can then use this subset of predictors when creating the `creditscorecard` object. In addition, you can use Threshold Predictors (Risk Management Toolbox) to interactively set credit scorecard predictor thresholds using the output from `screenpredictors` (Risk Management Toolbox).

When creating a `creditscorecard` object, by default, `'ResponseVar'` is set to the last column in the data (`'status'` in this example) and the `'GoodLabel'` to the response value with the highest count (`0` in this example). The syntax for `creditscorecard` indicates that `'CustID'` is the `'IDVar'` to remove from the list of predictors. Also, while not demonstrated in this example, when creating a `creditscorecard` object using `creditscorecard`, you can use the optional name-value pair argument `'WeightsVar'` to specify observation (sample) weights or `'BinMissingData'` to bin missing data.

```
load CreditCardData
head(data)
```

```

```
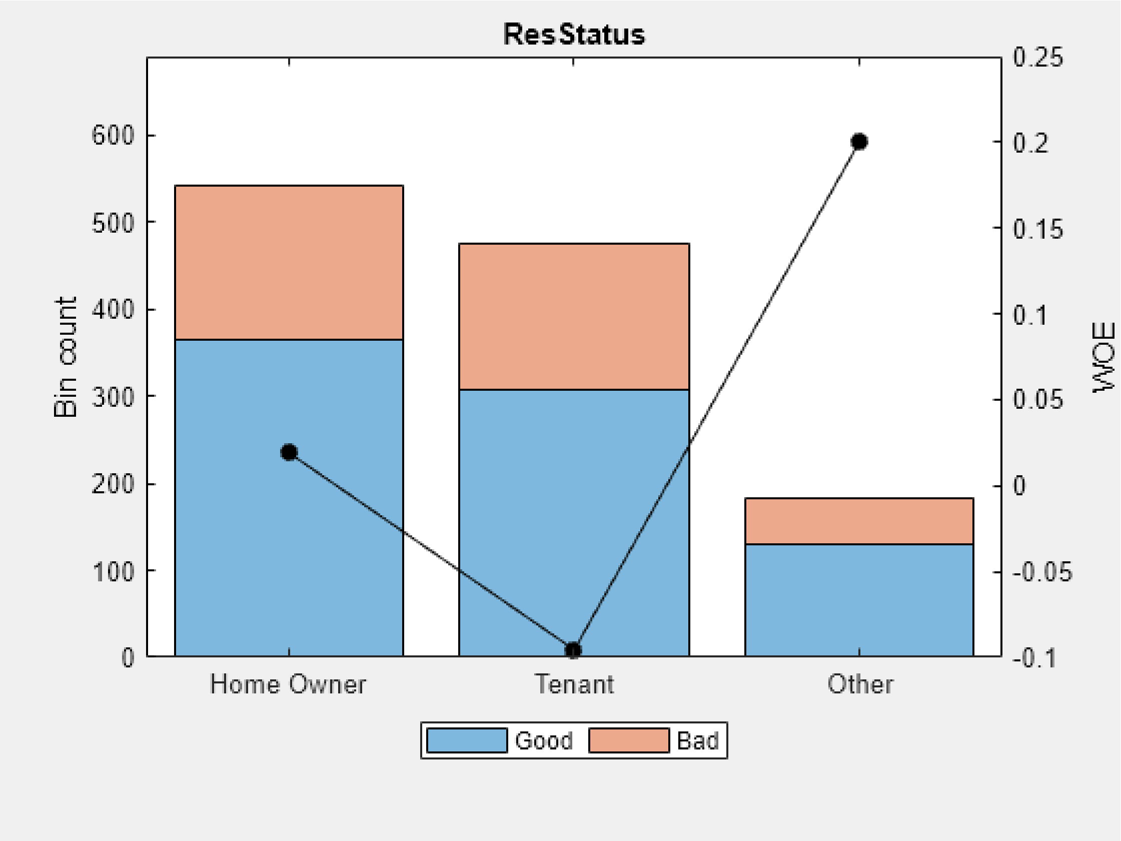
plotbins(sc,'ResStatus')
```



This bin information contains the frequencies of “Good” and “Bad,” and bin statistics. Avoid having bins with frequencies of zero because they lead to infinite or undefined (`NaN`) statistics. Use the `modifybins` or `autobinning` functions to bin the data accordingly.

For numeric data, a common first step is "fine classing." This means binning the data into several bins, defined with a regular grid. To illustrate this point, use the predictor `'CustIncome'`.

```
cp = 20000:5000:60000;
```

```
sc = modifybins(sc,'CustIncome','CutPoints',cp);
```

```
bininfo(sc,'CustIncome')
```

```

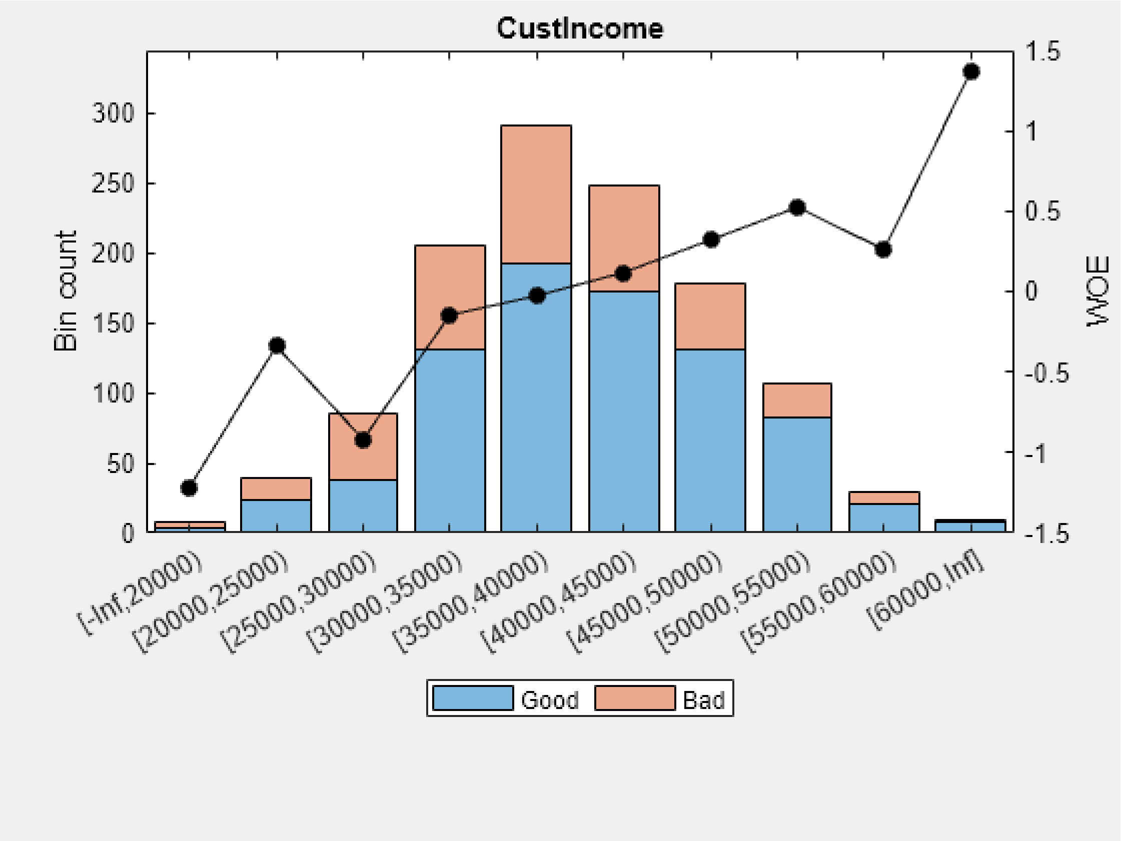
    {'[45000,50000)'}      131     47      2.7872      0.32063      0.014348
    {'[50000,55000)'}       82     24      3.4167      0.52425      0.021842
    {'[55000,60000)'}       21      8       2.625      0.26066     0.0015642
    {'[60000,Inf]'   }       8      1           8        1.375      0.010235
    {'Totals'        }     803    397      2.0227          NaN       0.13469
```

```
plotbins(sc,'CustIncome')
```



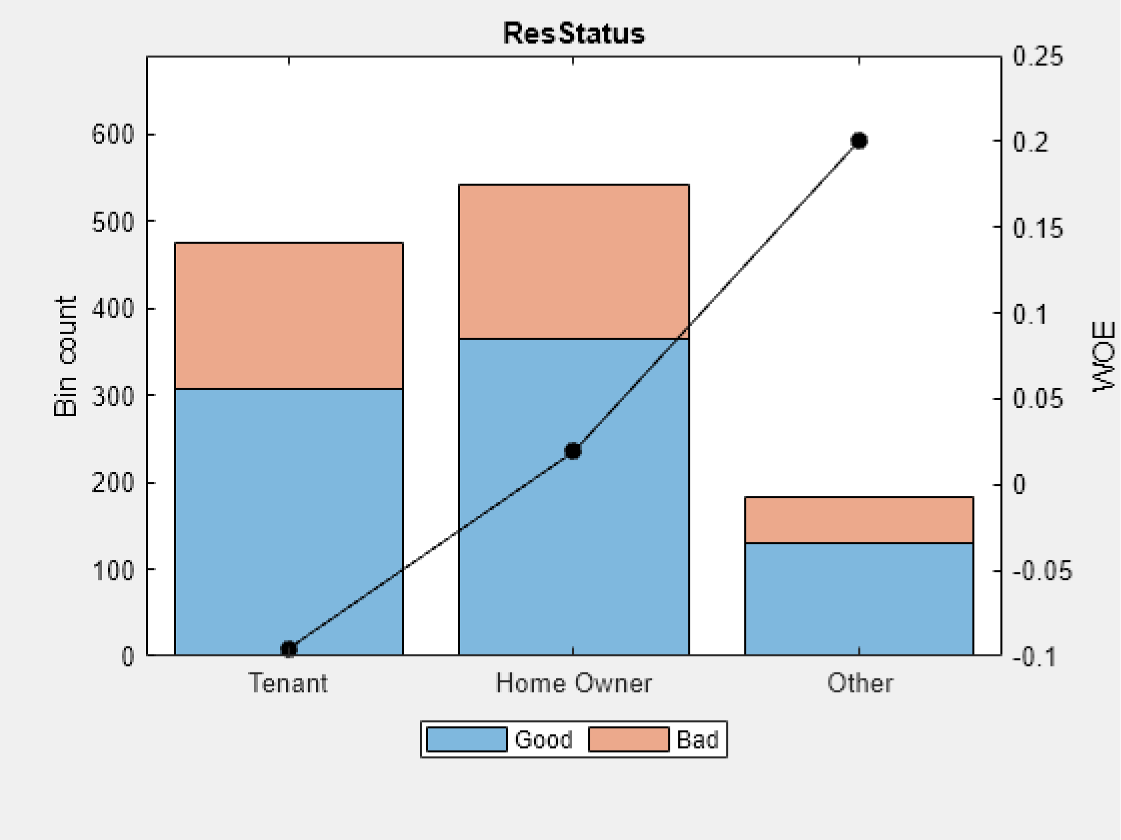
Step 2a. Automatically bin the data.

Use the `autobinning` function to perform automatic binning for every predictor variable, using the default `'Monotone'` algorithm with default algorithm options.

```
sc = autobinning(sc);
```

After the automatic binning step, every predictor bin must be reviewed using the `bininfo` and `plotbins` functions and fine-tuned. A monotonic, ideally linear trend in the Weight of Evidence (WOE) is desirable for credit scorecards because this translates into linear points for a given predictor. The WOE trends can be visualized using `plotbins`.

```
Predictor = ResStatus ▾;
plotbins(sc,Predictor)
```



Unlike the initial plot of `'ResStatus'` when the scorecard was created, the new plot for `'ResStatus'` shows an increasing WOE trend. This is because the `autobinning` function, by default, sorts the order of the categories by increasing odds.

These plots show that the `'Monotone'` algorithm does a good job finding monotone WOE trends for this dataset. To complete the binning process, it is necessary to make only a few manual adjustments for some predictors using the `modifybins` function.

Step 2b. Fine-tune the bins using manual binning.

Common steps to manually modify bins are:

- Use the `bininfo` function with two output arguments where the second argument contains binning rules.
- Manually modify the binning rules using the second output argument from `bininfo`.
- Set the updated binning rules with `modifybins` and then use `plotbins` or `bininfo` to review the updated bins.

For example, based on the plot for `'CustAge'` in Step 2a, bins number 1 and 2 have similar WOE's as do bins number 5 and 6. To merge these bins using the steps outlined above:

```
Predictor = CustAge ;
[bi,cp] = bininfo(sc,Predictor)
```

```

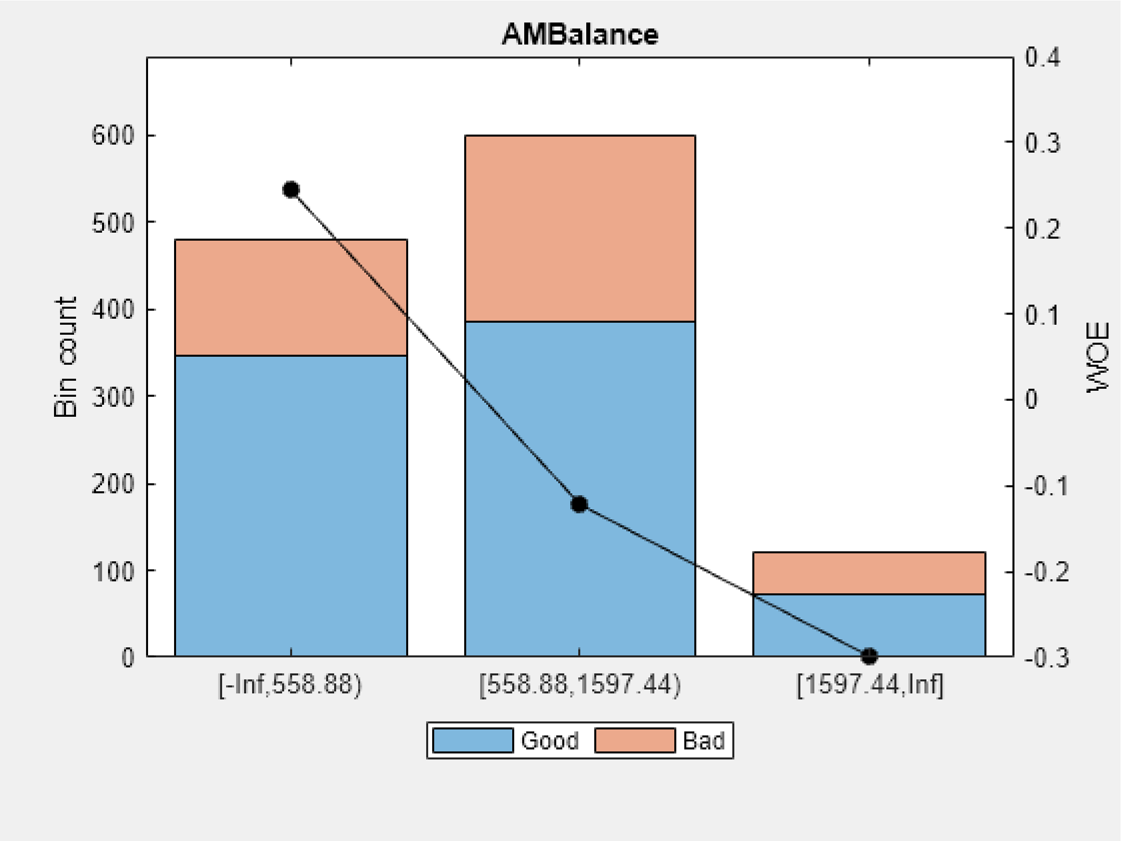
    1.2543
    1.5974
```

```
cp(2) = []; % To merge bins 2 and 3
sc = modifybins(sc,'AMBalance','CutPoints',cp);
plotbins(sc,'AMBalance')
```



Now that the binning fine-tuning is completed, the bins for all predictors have close-to-linear WOE trends.

Step 3. Fit a logistic regression model.

The `fitmodel` function fits a logistic regression model to the WOE data. `fitmodel` internally bins the training data, transforms it into WOE values, maps the response variable so that `'Good'` is `1`, and fits a linear logistic regression model. By default, `fitmodel` uses a stepwise procedure to determine which predictors should be in the model.

```
sc = fitmodel(sc);
```

```
1. Adding CustIncome, Deviance = 1490.8954, Chi2Stat = 32.545914, PValue = 1.1640961e-08
2. Adding TmWBank, Deviance = 1467.3249, Chi2Stat = 23.570535, PValue = 1.2041739e-06
3. Adding AMBalance, Deviance = 1455.858, Chi2Stat = 11.466846, PValue = 0.00070848829
4. Adding EmpStatus, Deviance = 1447.6148, Chi2Stat = 8.2432677, PValue = 0.0040903428
```

```
5. Adding CustAge, Deviance = 1442.06, Chi2Stat = 5.5547849, PValue = 0.018430237
6. Adding ResStatus, Deviance = 1437.9435, Chi2Stat = 4.1164321, PValue = 0.042468555
7. Adding OtherCC, Deviance = 1433.7372, Chi2Stat = 4.2063597, PValue = 0.040272676

Generalized linear regression model:
    logit(status) ~ 1 + CustAge + ResStatus + EmpStatus + CustIncome + TmWBank + OtherCC + AMBala
    Distribution = Binomial

Estimated Coefficients:
                   Estimate      SE       tStat       pValue   
                   ________    _______    ______    __________

    (Intercept)     0.7024       0.064    10.975    5.0407e-28
    CustAge        0.61562     0.24783    2.4841      0.012988
    ResStatus       1.3776     0.65266    2.1107      0.034799
    EmpStatus      0.88592     0.29296     3.024     0.0024946
    CustIncome     0.69836     0.21715     3.216     0.0013001
    TmWBank          1.106     0.23266    4.7538    1.9958e-06
    OtherCC         1.0933     0.52911    2.0662      0.038806
    AMBalance       1.0437     0.32292    3.2322     0.0012285

1200 observations, 1192 error degrees of freedom
Dispersion: 1
Chi^2-statistic vs. constant model: 89.7, p-value = 1.42e-16
```

Step 4. Review and format scorecard points.

After fitting the logistic model, by default the points are unscaled and come directly from the combination of WOE values and model coefficients. The `displaypoints` function summarizes the scorecard points.

```
p1 = displaypoints(sc);
disp(p1)
```

```

```

This is a good time to modify the bin labels, if this is something of interest for cosmetic reasons. To do so, use `modifybins` to change the bin labels.

```
sc = modifybins(sc,'CustAge','BinLabels',...
{'Up to 36' '37 to 39' '40 to 45' '46 to 57' '58 and up'});

sc = modifybins(sc,'CustIncome','BinLabels',...
{'Up to 28999' '29000 to 32999' '33000 to 41999' '42000 to 46999' '47000 and up'});

sc = modifybins(sc,'TmWBank','BinLabels',...
{'Up to 11' '12 to 44' '45 to 70' '71 and up'});

sc = modifybins(sc,'AMBalance','BinLabels',...
{'Up to 558.87' '558.88 to 1597.43' '1597.44 and up'});

p1 = displaypoints(sc);
disp(p1)
```

```

    {'AMBalance' }    {'<missing>'          }          NaN
```

Points are usually scaled and also often rounded. To do this, use the `formatpoints` function. For example, you can set a target level of points corresponding to a target odds level and also set the required points-to-double-the-odds (PDO).

```
TargetPoints = 500;
TargetOdds = 2;
PDO = 50; % Points to double the odds

sc = formatpoints(sc,'PointsOddsAndPDO',[TargetPoints TargetOdds PDO]);
p2 = displaypoints(sc);
disp(p2)
```

```

    99.166      73.445       86.976         95.69      61.524     75.732       62.353 
    99.166      73.445       86.976         95.69      92.829     75.732       62.353 
    53.239      73.445       58.777        56.805      61.524     75.732       62.353 
    80.796      91.446       86.976         95.69      61.524     50.364       49.016 
    80.796      62.028       58.777         95.69      61.524     75.732       89.908 
    80.796      73.445       58.777         95.69      61.524     75.732       62.353 
```

Step 6. Calculate the probability of default.

To calculate the probability of default, use the `probdefault` function.

```
pd = probdefault(sc);
```

Define the probability of being “Good” and plot the predicted odds versus the formatted scores. Visually analyze that the target points and target odds match and that the points-to-double-the-odds (PDO) relationship holds.

```
ProbGood = 1-pd;
PredictedOdds = ProbGood./pd;

figure
scatter(Scores,PredictedOdds)
title('Predicted Odds vs. Score')
xlabel('Score')
ylabel('Predicted Odds')

hold on

xLimits = xlim;
```

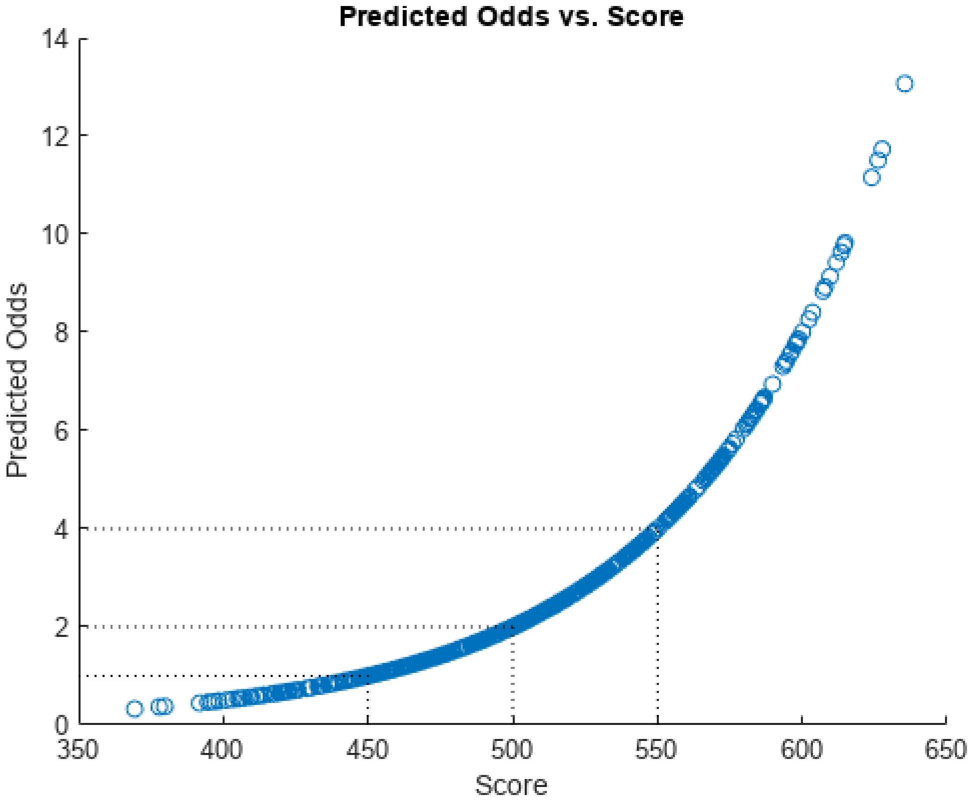
```
yLimits = ylim;

% Target points and odds
plot([TargetPoints TargetPoints],[yLimits(1) TargetOdds],'k:')
plot([xLimits(1) TargetPoints],[TargetOdds TargetOdds],'k:')

% Target points plus PDO
plot([TargetPoints+PDO TargetPoints+PDO],[yLimits(1) 2*TargetOdds],'k:')
plot([xLimits(1) TargetPoints+PDO],[2*TargetOdds 2*TargetOdds],'k:')

% Target points minus PDO
plot([TargetPoints-PDO TargetPoints-PDO],[yLimits(1) TargetOdds/2],'k:')
plot([xLimits(1) TargetPoints-PDO],[TargetOdds/2 TargetOdds/2],'k:')

hold off
```



Step 7. Validate the credit scorecard model using the CAP, ROC, and Kolmogorov-Smirnov statistic

The `creditscorecard` class supports three validation methods, the Cumulative Accuracy Profile (CAP), the Receiver Operating Characteristic (ROC), and the Kolmogorov-Smirnov (KS) statistic. For more information on CAP, ROC, and KS, see “Cumulative Accuracy Profile (CAP)” on page 15-1867, “Receiver Operating Characteristic (ROC)” on page 15-1867, and “Kolmogorov-Smirnov statistic (KS)” on page 15-1867.

```
[Stats,T] = validatemodel(sc,'Plot',{'CAP','ROC','KS'});

Credit Scorecards with Constrained Logistic Regression Coefficients

To compute scores for a creditscorecard object with constraints for equality, inequality, or bounds on the coefficients of the logistic regression model, use fitConstrainedModel. Unlike fitmodel, fitConstrainedModel solves for both the unconstrained and constrained problem. The current solver used to minimize an objective function for fitConstrainedModel is fmincon, from the Optimization Toolbox™.

This example has three main sections. First, fitConstrainedModel is used to solve for the coefficients in the unconstrained model. Then, fitConstrainedModel demonstrates how to use several types of constraints. Finally, fitConstrainedModel uses bootstrapping for the significance analysis to determine which predictors to reject from the model.

Create the creditscorecard Object and Bin data

```
load CreditCardData.mat
sc = creditscorecard(data,'IDVar','CustID');
sc = autobinning(sc);
```

Unconstrained Model Using fitConstrainedModel

Solve for the unconstrained coefficients using fitConstrainedModel with default values for the input parameters. fitConstrainedModel uses the internal optimization solver fmincon from the Optimization Toolbox™. If you do not set any constraints, fmincon treats the model as an unconstrained optimization problem. The default parameters for the LowerBound and UpperBound are -Inf and +Inf, respectively. For the equality and inequality constraints, the default is an empty numeric array.

```
[sc1,mdl1] = fitConstrainedModel(sc);
coeff1 = mdl1.Coefficients.Estimate;
disp(mdl1.Coefficients);
```

```
                   Estimate 
                   _________

    (Intercept)      0.70246
    CustAge           0.6057
    TmAtAddress       1.0381
    ResStatus         1.3794
    EmpStatus        0.89648
    CustIncome       0.70179
    TmWBank           1.1132
    OtherCC           1.0598
    AMBalance         1.0572
    UtilRate       -0.047597
```

Unlike fitmodel which gives *p*-values, when using fitConstrainedModel, you must use bootstrapping to find out which predictors are rejected from the model, when subject to constraints. This is illustrated in the "Significance Bootstrapping" section.

Using fitmodel to Compare the Results and Calibrate the Model

fitmodel fits a logistic regression model to the Weight-of-Evidence (WOE) data and there are no constraints. You can compare the results from the "Unconstrained Model Using fitConstrainedModel" section with those of fitmodel to verify that the model is well calibrated.

Now, solve the unconstrained problem by using fitmodel. Note that fitmodel and fitConstrainedModel use different solvers. While fitConstrainedModel uses fmincon, fitmodel uses stepwiseglm by default. To include all predictors from the start, set the 'VariableSelection' name-value pair argument of fitmodel to 'fullmodel'.

```
[sc2,mdl2] = fitmodel(sc,'VariableSelection','fullmodel','Display','off');
coeff2 = mdl2.Coefficients.Estimate;
disp(mdl2.Coefficients);
```

```
                   Estimate       SE         tStat       pValue   
                   _________    ________    _________    __________

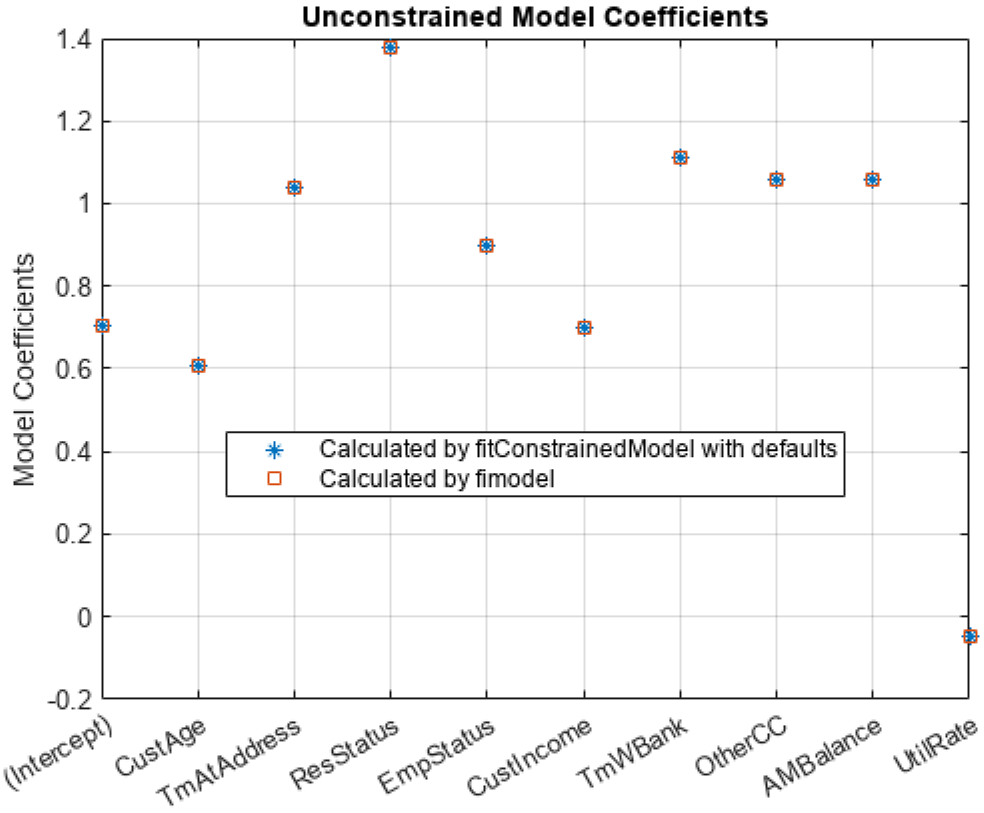
ylabel('Model Coefficients')
title('Unconstrained Model Coefficients')
legend({'Calculated by fitConstrainedModel with defaults','Calculated by fimodel'},'Location','be
grid on
```



As both the tables and the plot show, the model coefficients match. You can be confident that this implementation of `fitConstrainedModel` is well calibrated.

Constrained Model

In the constrained model approach, you solve for the values of the coefficients b_i of the logistic model, subject to constraints. The supported constraints are bound, equality, or inequality. The coefficients maximize the likelihood-of-default function defined, for observation i, as:

$$L_i = p(\text{Default}_i)^{y_i} \times (1 - p(\text{Default}_i))^{1 - y_i}$$

where:

- $$p(\text{Default}_i) = \frac{1}{1 + e^{-b\text{x}_i}}$$
- $\boldsymbol{b} = [b_1\, b_2\, . . .\, b_K]$ is an unknown model coefficient
- $\mathbf{x}_{\boldsymbol{i}} = [x_{\text{i}1}\, x_2\, . . .\, x_{\text{iK}}]$ is the predictor values at observation i
- y_i is the response value; a value of 1 represents default and a value of 0 represents non-default

This formula is for non-weighted data. When observation i has weight w_i, it means that there are w_i as many observations i. Therefore, the probability that default occurs at observation i is the product of the probabilities of default:

$$p_i \; = \; \underbrace{p(\text{Default}_i)^{y_i} * p(\text{Default}_i)^{y_i} * \; . \; . \; . \; * p(\text{Default}_i)^{y_i}}_{w_i \, \text{times}} = p(\text{Default}_i)^{w_i * y_i}$$

Likewise, the probability of non-default for weighted observation i is:

$$\widehat{p}_i \; = \; \underbrace{p(\sim\text{Default}_i)^{1 - y_i} * p(\sim\text{Default}_i)^{1 - y_i} * \; . \; . \; . \; * p(\sim\text{Default}_i)^{1 - y_i}}_{w_i \, \text{times}} = (1 - p(\text{Default}_i))^{w_i * (1 - y_i)}$$

For weighted data, if there is default at a given observation i whose weight is w_i, it is as if there was a w_i count of that one observation, and all of them either all default, or all non-default. w_i may or may not be an integer.

Therefore, for the weighted data, the likelihood-of-default function for observation i in the first equation becomes

$$L_i = p(\text{Default}_i)^{w_i * y_i} \times (1 - p(\text{Default}_i))^{w_i * (1 - y_i)}$$

By assumption, all defaults are independent events, so the objective function is

$$L = L_1 \times L_2 \times \; . \; . \; . \; \times \; L_N$$

or, in more convenient logarithmic terms:

$$\log(L) = \sum_{i = 1}^{N} w_i * [y_i \log(p(\text{Default}_i)) + (1 - y_i)\log(1 - p(\text{Default}_i))]$$

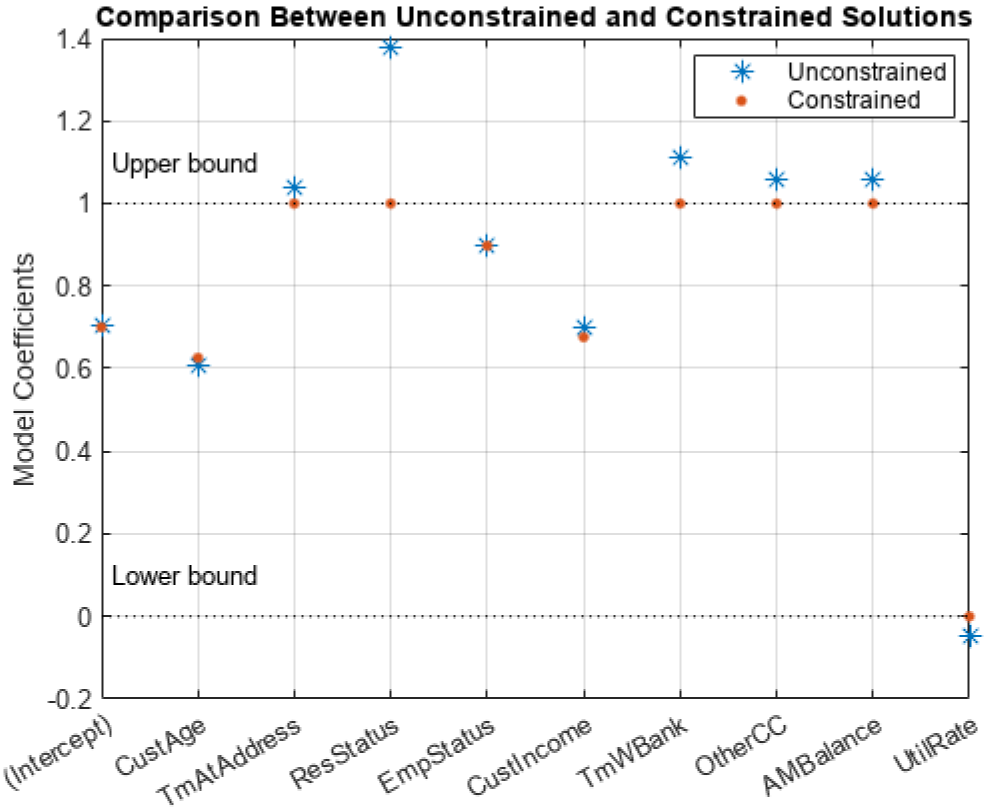
Apply Constraints on the Coefficients

After calibrating the unconstrained model as described in the "Unconstrained Model Using fitConstrainedModel" section, you can solve for the model coefficients subject to constraints. You can choose lower and upper bounds such that $0 \leq b_i \leq 1, \forall i = 1 \; . \; . \; . \; K$, except for the intercept. Also, since the customer age and customer income are somewhat correlated, you can also use additional constraints on their coefficients, for example, $|b_{CusAge} - b_{CustIncome}| < 0.1$. The coefficients corresponding to the predictors `'CustAge'` and `'CustIncome'` in this example are b_2 and b_6, respectively.

```
K  = length(sc.PredictorVars);
lb = [-Inf;zeros(K,1)];
ub = [Inf;ones(K,1)];
AIneq = [0 -1 0 0 0 1 0 0 0 0;0 -1 0 0 0 -1 0 0 0 0];
bIneq = [0.05;0.05];
Options = optimoptions('fmincon','SpecifyObjectiveGradient',true,'Display','off');
[sc3,mdl] = fitConstrainedModel(sc,'AInequality',AIneq,'bInequality',bIneq,...
    'LowerBound',lb,'UpperBound',ub,'Options',Options);

figure
plot(coeff1,'*','MarkerSize',8)
hold on
plot(mdl.Coefficients.Estimate,'.','MarkerSize',12)
line(xlim,[0 0],'color','k','linestyle',':')
line(xlim,[1 1],'color','k','linestyle',':')
text(1.1,0.1,'Lower bound')
text(1.1,1.1,'Upper bound')
grid on
```

```
xticklabels(mdl.Coefficients.Properties.RowNames)
ylabel('Model Coefficients')
title('Comparison Between Unconstrained and Constrained Solutions')
legend({'Unconstrained','Constrained'},'Location','best')
```



Significance Bootstrapping

For the unconstrained problem, standard formulas are available for computing *p*-values, which you use to evaluate which coefficients are significant and which are to be rejected. However, for the constrained problem, standard formulas are not available, and the derivation of formulas for significance analysis is complicated. A practical alternative is to perform significance analysis through *bootstrapping*.

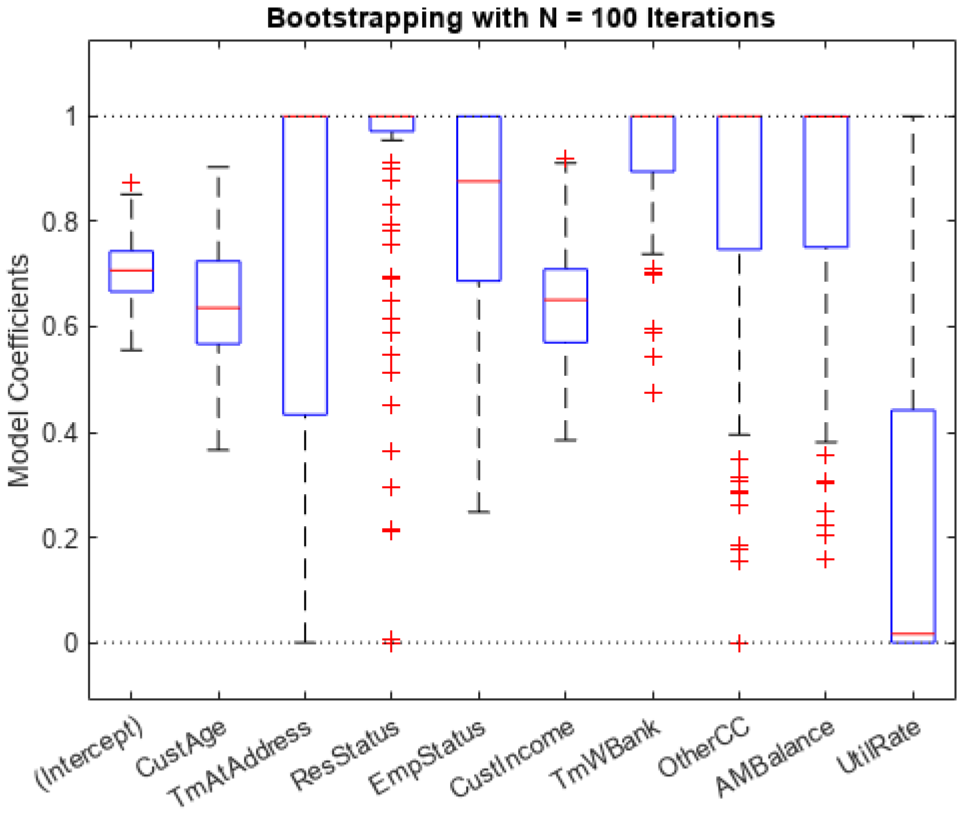
In the bootstrapping approach, when using `fitConstrainedModel`, you set the name-value argument `'Bootstrap'` to `true` and chose a value for the name-value argument `'BootstrapIter'`. Bootstrapping means that *NIter* samples (with replacement) from the original observations are selected. In each iteration, `fitConstrainedModel` solves for the same constrained problem as the "Constrained Model" section. `fitConstrainedModel` obtains several values (solutions) for each coefficient b_i and you can plot these as a `boxplot` or `histogram`. Using the boxplot or histogram, you can examine the median values to evaluate whether the coefficients are away from zero and how much the coefficients deviate from their means.

```
lb = [-Inf;zeros(K,1)];
ub = [Inf;ones(K,1)];
AIneq = [0 -1 0 0 0 1 0 0 0 0;0 1 0 0 0 -1 0 0 0 0];
bIneq = [0.05;0.05];
```

```
c0 = zeros(K,1);
NIter = 100;
Options = optimoptions('fmincon','SpecifyObjectiveGradient',true,'Display','off');
rng('default')

[sc,mdl] = fitConstrainedModel(sc,'AInequality',AIneq,'bInequality',bIneq,...
    'LowerBound',lb,'UpperBound',ub,'Bootstrap',true,'BootstrapIter',NIter,'Options',Options);

figure
boxplot(mdl.Bootstrap.Matrix,mdl.Coefficients.Properties.RowNames)
hold on
line(xlim,[0 0],'color','k','linestyle',':')
line(xlim,[1 1],'color','k','linestyle',':')
title('Bootstrapping with N = 100 Iterations')
ylabel('Model Coefficients')
```

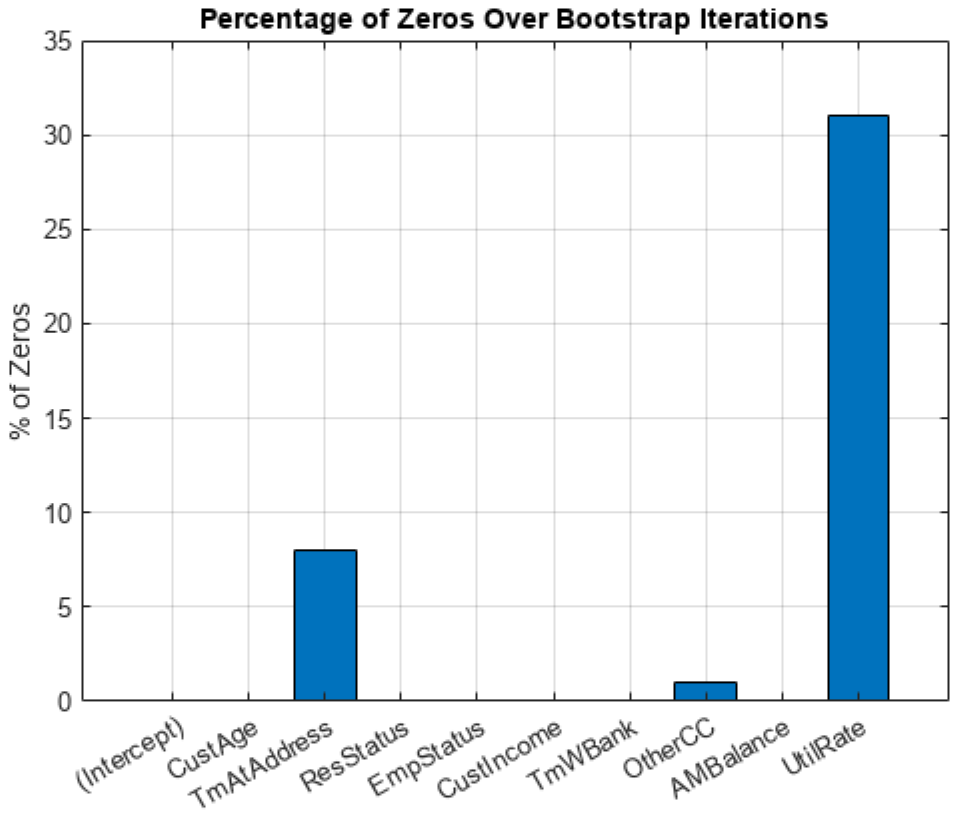


The solid red lines in the boxplot indicate that the median values and the bottom and top edges are for the 25th and 75th percentiles. The "whiskers" are the minimum and maximum values, not including outliers. The dotted lines represent the lower and upper bound constraints on the coefficients. In this example, the coefficients cannot be negative, by construction.

To help decide which predictors to keep in the model, assess the proportion of times each coefficient is zero.

```
Tol = 1e-6;
figure
bar(100*sum(mdl.Bootstrap.Matrix<= Tol)/NIter)
```

```
ylabel('% of Zeros')
title('Percentage of Zeros Over Bootstrap Iterations')
xticklabels(mdl.Coefficients.Properties.RowNames)
grid on
```



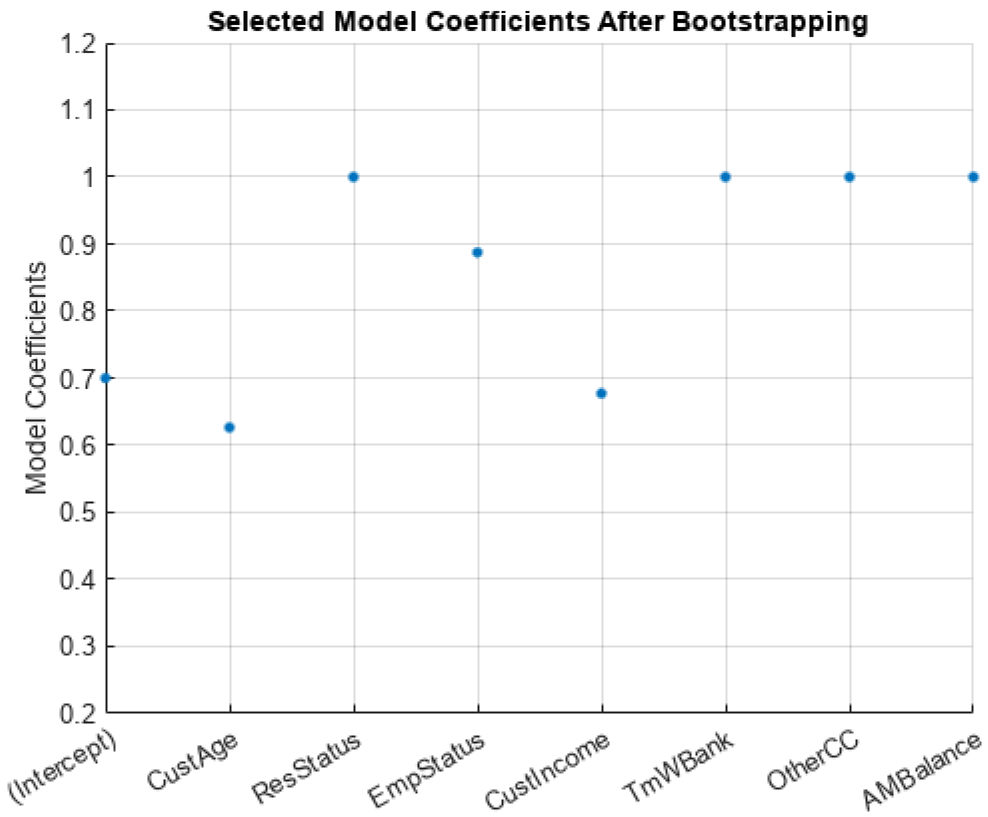
Based on the plot, you can reject `'UtilRate'` since it has the highest number of zero values. You can also decide to reject `'TmAtAddress'` since it shows a peak, albeit small.

Set the Corresponding Coefficients to Zero

To set the corresponding coefficients to zero, set their upper bound to zero and solve the model again using the original data set.

```
ub(3) = 0;
ub(end) = 0;
[sc,mdl] = fitConstrainedModel(sc,'AInequality',AIneq,'bInequality',bIneq,'LowerBound',lb,'Upper
Ind = (abs(mdl.Coefficients.Estimate) <= Tol);
ModelCoeff = mdl.Coefficients.Estimate(~Ind);
ModelPreds = mdl.Coefficients.Properties.RowNames(~Ind)';

figure
hold on
plot(ModelCoeff,'.','MarkerSize',12)
ylim([0.2 1.2])
ylabel('Model Coefficients')
xticklabels(ModelPreds)
title('Selected Model Coefficients After Bootstrapping')
grid on
```



Set Constrained Coefficients Back Into the `creditscorecard`

Now that you have solved for the constrained coefficients, use `setmodel` to set the model's coefficients and predictors. Then you can compute the (unscaled) points.

```
ModelPreds = ModelPreds(2:end);
sc = setmodel(sc,ModelPreds,ModelCoeff);
p = displaypoints(sc);

disp(p)
```

```

Credit Default Swap (CDS)

A credit default swap (CDS) is a contract that protects against losses resulting from credit defaults. The transaction involves two parties, the protection buyer and the protection seller, and also a reference entity, usually a bond. The protection buyer pays a stream of premiums to the protection seller, who in exchange offers to compensate the buyer for the loss in the bond's value if a credit event occurs. The stream of premiums is called the premium leg, and the compensation when a credit event occurs is called the protection leg. Credit events usually include situations in which the bond issuer goes bankrupt, misses coupon payments, or enters a restructuring process. Financial Instruments Toolbox software supports the following objects and functions:

CDS Objects

Object	Purpose
`CDS`	`CDS` instrument object.
`CDSOption`	`CDSOption` instrument object.

CDS Functions

Function	Purpose
`cdsbootstrap`	Compute default probability parameters from CDS market quotes.
`cdsspread`	Compute breakeven spreads for the CDS contracts.
`cdsprice`	Compute the price for the CDS contracts.

Bootstrapping a Default Probability Curve

This example shows how to bootstrap default probabilities from CDS market quotes. To bootstrap default probabilities from bond market data, see `bondDefaultBootstrap`. In a typical workflow, pricing a new CDS contract involves first estimating a default probability term structure using `cdsbootstrap`. This requires market quotes of existing CDS contracts, or quotes of CDS indices (e.g., iTraxx). The estimated default probability curve is then used as input to `cdsspread` or `cdsprice`. If the default probability information is already known, `cdsbootstrap` can be bypassed and `cdsspread` or `cdsprice` can be called directly.

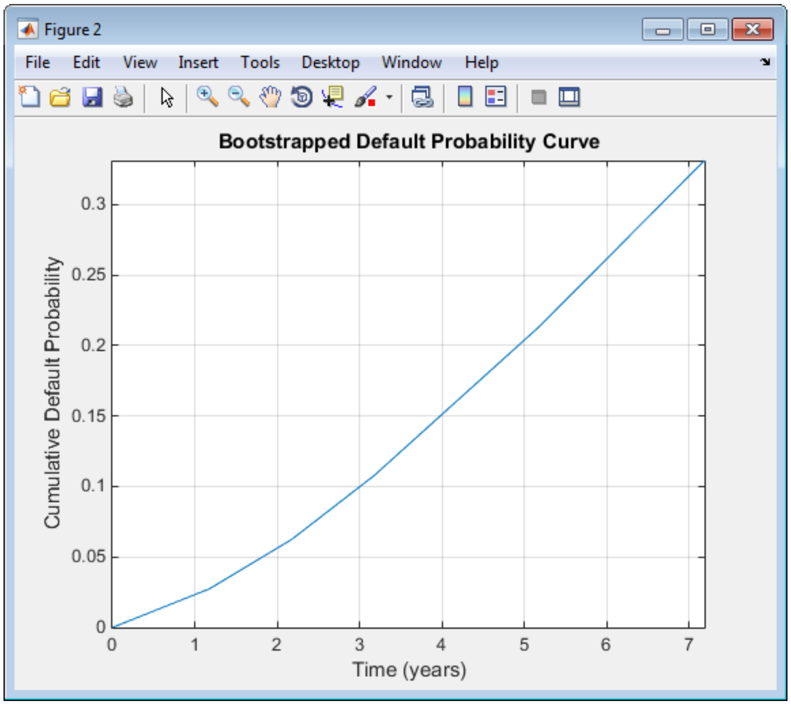
The market information in this example is provided in the form of running spreads of CDS contracts maturing on the CDS standard payment dates closest to 1, 2, 3, 5, and 7 years from the valuation date.

```
Settle = '17-Jul-2009'; % valuation date for the CDS
MarketDates = datenum({'20-Sep-10','20-Sep-11','20-Sep-12','20-Sep-14',...
'20-Sep-16'});
MarketSpreads = [140 175 210 265 310]';
MarketData = [MarketDates MarketSpreads];
ZeroDates = datenum({'17-Jan-10','17-Jul-10','17-Jul-11','17-Jul-12',...
'17-Jul-13','17-Jul-14'});
ZeroRates = [1.35 1.43 1.9 2.47 2.936 3.311]'/100;
ZeroData = [ZeroDates ZeroRates];

[ProbData,HazData] = cdsbootstrap(ZeroData,MarketData,Settle);
```

The bootstrapped default probability curve is plotted against time, in years, from the valuation date.

```
ProbTimes = yearfrac(Settle,ProbData(:,1));
figure
plot([0; ProbTimes],[0; ProbData(:,2)])
grid on
axis([0 ProbTimes(end,1) 0 ProbData(end,2)])
xlabel('Time (years)')
ylabel('Cumulative Default Probability')
title('Bootstrapped Default Probability Curve')
```



The associated hazard rates are returned as an optional output. The convention is that the first hazard rate applies from the settlement date to the first market date, the second hazard rate from the first to the second market date, and so on, and the last hazard rate applies from the second-to-last market date onwards. The following plot displays the bootstrapped hazard rates, plotted against time, in years, from the valuation date:

```
HazTimes = yearfrac(Settle,HazData(:,1));
figure
stairs([0; HazTimes(1:end-1,1); HazTimes(end,1)+1],...
[HazData(:,2);HazData(end,2)])
grid on
axis([0 HazTimes(end,1)+1 0.9*HazData(1,2) 1.1*HazData(end,2)])
xlabel('Time (years)')
ylabel('Hazard Rate')
title('Bootstrapped Hazard Rates')
```

Finding Breakeven Spread for New CDS Contract

The breakeven, or running, spread is the premium a protection buyer must pay, with no upfront payments involved, to receive protection for credit events associated to a given reference entity. Spreads are expressed in basis points (bp). There is a notional amount associated to the CDS contract to determine the monetary amounts of the premium payments.

New quotes for CDS contracts can be obtained with `cdsspread`. After obtaining a default probability curve using `cdsbootstrap`, you get quotes that are consistent with current market conditions.

In this example, instead of standard CDS payment dates, define new maturity dates. Using the period from three to five years (CDS standard dates), maturities are defined within this range spaced at quarterly intervals (measuring time from the valuation date):

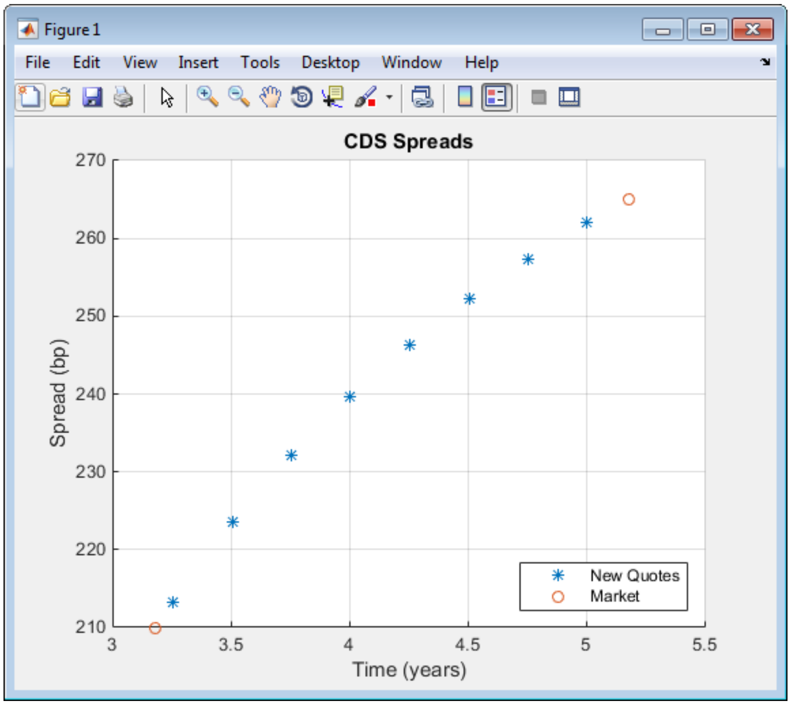
```
Settle = '17-Jul-2009';  % valuation date for the CDS
MarketDates = datenum({'20-Sep-10','20-Sep-11','20-Sep-12','20-Sep-14',...
'20-Sep-16'});
MarketSpreads = [140 175 210 265 310]';
MarketData = [MarketDates MarketSpreads];
ZeroDates = datenum({'17-Jan-10','17-Jul-10','17-Jul-11','17-Jul-12',...
'17-Jul-13','17-Jul-14'});
ZeroRates = [1.35 1.43 1.9 2.47 2.936 3.311]'/100;
ZeroData = [ZeroDates ZeroRates];

[ProbData,HazData] = cdsbootstrap(ZeroData,MarketData,Settle);

Maturity1 = datestr(daysadd('17-Jul-09',360*(3.25:0.25:5),1));
Spread1 = cdsspread(ZeroData,ProbData,Settle,Maturity1);

figure
scatter(yearfrac(Settle,Maturity1),Spread1,'*')
hold on
scatter(yearfrac(Settle,MarketData(3:4,1)),MarketData(3:4,2))
hold off
grid on
xlabel('Time (years)')
ylabel('Spread (bp)')
title('CDS Spreads')
legend('New Quotes','Market','location','SouthEast')
```

This plot displays the resulting spreads:



To evaluate the effect of the recovery rate parameter, instead of 40% (default value), use a recovery rate of 35%:

```
Spread1Rec35 = cdsspread(ZeroData,ProbData,Settle,Maturity1,...
'RecoveryRate',0.35);

figure
plot(yearfrac(Settle,Maturity1),Spread1,...
yearfrac(Settle,Maturity1),Spread1Rec35,'--')
grid on
xlabel('Time (years)')
ylabel('Spread (bp)')
title('CDS Spreads with Different Recovery Rates')
legend('40%','35%','location','SouthEast')
```

The resulting plot shows that smaller recovery rates produce higher premia, as expected, since in the event of default, the protection payments are higher:

Valuing an Existing CDS Contract

The current value, or mark-to-market, of an existing CDS contract is the amount of money the contract holder would receive (if positive) or pay (if negative) to unwind this contract. The upfront of the contract is the current value expressed as a fraction of the notional amount of the contract, and it is commonly used to quote market values.

The value of existing CDS contracts is obtained with `cdsprice`. By default, `cdsprice` treats contracts as long positions. Whether a contract position is long or short is determined from a protection standpoint, that is, long means that protection was bought, and short means protection was sold. In the following example, an existing CDS contract pays a premium that is lower than current market conditions. The price is positive, as expected, since it would be more costly to buy the same type of protection today.

```
Settle = '17-Jul-2009';   % valuation date for the CDS
MarketDates = datenum({'20-Sep-10','20-Sep-11','20-Sep-12','20-Sep-14',...
'20-Sep-16'});
MarketSpreads = [140 175 210 265 310]';
MarketData = [MarketDates MarketSpreads];

ZeroDates = datenum({'17-Jan-10','17-Jul-10','17-Jul-11','17-Jul-12',...
'17-Jul-13','17-Jul-14'});
ZeroRates = [1.35 1.43 1.9 2.47 2.936 3.311]'/100;
ZeroData = [ZeroDates ZeroRates];

[ProbData,HazData] = cdsbootstrap(ZeroData,MarketData,Settle);

Maturity2 = '20-Sep-2012';
Spread2 = 196;

[Price,AccPrem,PaymentDates,PaymentTimes,PaymentCF] = cdsprice(ZeroData,...
ProbData,Settle,Maturity2,Spread2);

fprintf('Dirty Price: %8.2f\n',Price+AccPrem);
fprintf('Accrued Premium: %8.2f\n',AccPrem);
fprintf('Clean Price: %8.2f\n',Price);
fprintf('\nPayment Schedule:\n\n');
fprintf('Date \t\t Time Frac \t Amount\n');
for k = 1:length(PaymentDates)
   fprintf('%s \t %5.4f \t %8.2f\n',datestr(PaymentDates(k)),...
      PaymentTimes(k),PaymentCF(k));
end
```

This resulting payment schedule is:

```
Dirty Price: 56872.94
Accrued Premium: 15244.44
Clean Price: 41628.50

Payment Schedule:

Date             Time Frac      Amount
20-Sep-2009         0.1806      35388.89
20-Dec-2009         0.2528      49544.44
20-Mar-2010         0.2500      49000.00
20-Jun-2010         0.2556      50088.89
20-Sep-2010         0.2556      50088.89
20-Dec-2010         0.2528      49544.44
20-Mar-2011         0.2500      49000.00
20-Jun-2011         0.2556      50088.89
20-Sep-2011         0.2556      50088.89
20-Dec-2011         0.2528      49544.44
```

```
20-Mar-2012      0.2528      49544.44
20-Jun-2012      0.2556      50088.89
20-Sep-2012      0.2556      50088.89
```

Also, you can use `cdsprice` to value a portfolio of CDS contracts. In the following example, a simple hedged position with two vanilla CDS contracts, one long, one short, with slightly different spreads is priced in a single call and the value of the portfolio is the sum of the returned prices:

```
[Price2,AccPrem2] = cdsprice(ZeroData,ProbData,Settle,...
repmat(datenum(Maturity2),2,1),[Spread2;Spread2+3],...
'Notional',[1e7; -1e7]);

fprintf('Contract \t Dirty Price \t Acc Premium \t  Clean Price\n');
fprintf('    Long \t $ %9.2f \t $ %9.2f \t $ %9.2f \t\n',...
   Price2(1)+AccPrem2(1), AccPrem2(1), Price2(1));
fprintf('   Short \t $ %8.2f \t $ %8.2f \t $ %8.2f \t\n',...
   Price2(2)+AccPrem2(2), AccPrem2(2), Price2(2));
fprintf('Mark-to-market of hedged position: $ %8.2f\n',sum(Price2)+sum(AccPrem2));
```

This resulting value of the portfolio is:

```
Contract      Dirty Price      Acc Premium       Clean Price
    Long      $  56872.94      $  15244.44      $  41628.50
   Short      $ -48185.88      $ -15477.78      $ -32708.11
Mark-to-market of hedged position: $  8687.06
```

Converting from Running to Upfront

A CDS market quote is given in terms of a standard spread (usually 100 bp or 500 bp) and an upfront payment, or in terms of an equivalent running or breakeven spread, with no upfront payment. The functions `cdsbootstrap`, `cdsspread`, and `cdsprice` perform upfront to running or running to upfront conversions.

For example, to convert the market quotes to upfront quotes for a standard spread of 100 bp:

```
Settle = '17-Jul-2009';  % valuation date for the CDS
MarketDates = datenum({'20-Sep-10','20-Sep-11','20-Sep-12','20-Sep-14',...
'20-Sep-16'});
MarketSpreads = [140 175 210 265 310]';
MarketData = [MarketDates MarketSpreads];

ZeroDates = datenum({'17-Jan-10','17-Jul-10','17-Jul-11','17-Jul-12',...
'17-Jul-13','17-Jul-14'});
ZeroRates = [1.35 1.43 1.9 2.47 2.936 3.311]'/100;
ZeroData = [ZeroDates ZeroRates];

[ProbData,HazData] = cdsbootstrap(ZeroData,MarketData,Settle);

Maturity3 = MarketData(:,1);
Spread3Run = MarketData(:,2);
Spread3Std = 100*ones(size(Maturity3));
Price3 = cdsprice(ZeroData,ProbData,Settle,Maturity3,Spread3Std);
Upfront3 = Price3/10000000; % Standard notional of 10MM
display(Upfront3);
```

This resulting value is:

```
Upfront3 =

    0.0047
    0.0158
    0.0327
    0.0737
    0.1182
```

The conversion can be reversed to convert upfront quotes to market quotes:

```
ProbData3Upf = cdsbootstrap(ZeroData,[Maturity3 Upfront3 Spread3Std],Settle);
Spread3RunFromUpf = cdsspread(ZeroData,ProbData3Upf,Settle,Maturity3);
display([Spread3Run Spread3RunFromUpf]);
```

Comparing the results of this conversion to the original market spread demonstrates the reversal:

```
ans =

  140.0000  140.0000
  175.0000  175.0000
  210.0000  210.0000
  265.0000  265.0000
  310.0000  310.0000
```

Under the flat-hazard rate (FHR) quoting convention, a single market quote is used to calibrate a probability curve. This convention yields a single point in the probability curve, and a single hazard rate value. For example, assume a four-year (standard dates) CDS contract with a current FHR-based running spread of 550 bp needs conversion to a CDS contract with a standard spread of 500 bp:

```
Maturity4 = datenum('20-Sep-13');
Spread4Run = 550;
ProbData4Run = cdsbootstrap(ZeroData,[Maturity4 Spread4Run],Settle);
```

```
Spread4Std = 500;
Price4 = cdsprice(ZeroData,ProbData4Run,Settle,Maturity4,Spread4Std);
Upfront4 = Price4/10000000;
fprintf('A running spread of %5.2f is equivalent to\n',Spread4Run);
fprintf('   a standard spread of %5.2f with an upfront of %8.7f\n',...
   Spread4Std,Upfront4);
```

```
A running spread of 550.00 is equivalent to
   a standard spread of 500.00 with an upfront of 0.0167576
```

To reverse the conversion:

```
ProbData4Upf = cdsbootstrap(ZeroData,[Maturity4 Upfront4 Spread4Std],Settle);
Spread4RunFromUpf = cdsspread(ZeroData,ProbData4Upf,Settle,Maturity4);
fprintf('A standard spread of %5.2f with an upfront of %8.7f\n',...
   Spread4Std,Upfront4);
fprintf('    is equivalent to a running spread of %5.2f\n',Spread4RunFromUpf);
```

```
A standard spread of 500.00 with an upfront of 0.0167576
    is equivalent to a running spread of 550.00
```

As discussed in Beumee et. al., 2009 (see “Credit Derivatives” on page A-5), the FHR approach is a quoting convention only, and leads to quotes inconsistent with market data. For example, calculating the upfront for the three-year (standard dates) CDS contract with a standard spread of 100 bp using the FHR approach and comparing the results to the upfront amounts previously calculated, demonstrates that the FHR-based approach yields a different upfront amount:

```
Maturity5 = MarketData(3,1);
Spread5Run = MarketData(3,2);
ProbData5Run = cdsbootstrap(ZeroData,[Maturity5 Spread5Run],Settle);
Spread5Std = 100;
Price5 = cdsprice(ZeroData,ProbData5Run,Settle,Maturity5,Spread5Std);
Upfront5 = Price5/10000000;
fprintf('Relative error of FHR-based upfront amount: %3.1f%%\n',...
   ((Upfront5-Upfront3(3))/Upfront3(3))*100);
```

```
Relative error of FHR-based upfront amount: -0.8%
```

Bootstrapping from Inverted Market Curves

The following two examples demonstrate the behavior of bootstrapping with inverted CDS market curves, that is, market quotes with higher spreads for short-term CDS contracts. The first example is handled normally by `cdsbootstrap`:

```
Settle = '17-Jul-2009';  % valuation date for the CDS
MarketDates = datenum({'20-Sep-10','20-Sep-11','20-Sep-12','20-Sep-14',...
'20-Sep-16'});

ZeroDates = datenum({'17-Jan-10','17-Jul-10','17-Jul-11','17-Jul-12',...
'17-Jul-13','17-Jul-14'});
ZeroRates = [1.35 1.43 1.9 2.47 2.936 3.311]'/100;
ZeroData = [ZeroDates ZeroRates];

MarketSpreadsInv1 = [750 650 550 500 450]';
MarketDataInv1 = [MarketDates MarketSpreadsInv1];
[ProbDataInv1,HazDataInv1] = cdsbootstrap(ZeroData,MarketDataInv1,Settle)
```

```
ProbDataInv1 =

   1.0e+05 *

    7.3440    0.0000
    7.3477    0.0000
    7.3513    0.0000
    7.3586    0.0000
    7.3659    0.0000

HazDataInv1 =

   1.0e+05 *

    7.3440    0.0000
    7.3477    0.0000
    7.3513    0.0000
    7.3586    0.0000
    7.3659    0.0000
```

In the second example, `cdsbootstrap` generates a warning:

```
MarketSpreadsInv2 = [800 550 400 250 100]';
MarketDataInv2 = [MarketDates MarketSpreadsInv2];

[ProbDataInv2,HazDataInv2] = cdsbootstrap(ZeroData,MarketDataInv2,Settle);
```

```
Warning: Found non-monotone default probabilities (negative hazard rates)
```

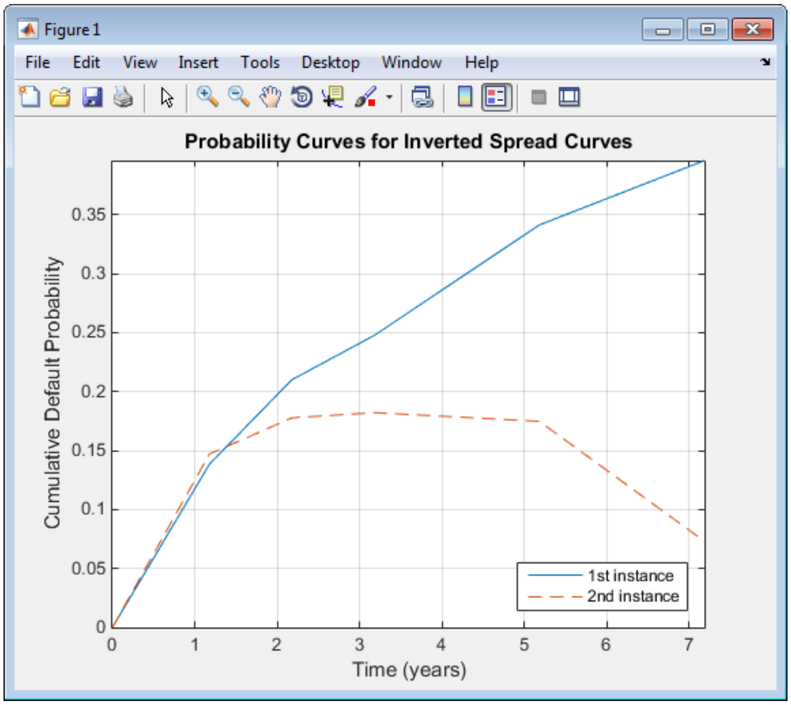
A non-monotone bootstrapped probability curve implies negative default probabilities and negative hazard rates for certain time intervals. Extreme market conditions can lead to these types of situations. In these cases, you must assess the reliability and usefulness of the bootstrapped results.

The following plot illustrates these bootstrapped probability curves. The curves are concave, meaning that the marginal default probability decreases with time. This result is consistent with the market information that indicates a higher default risk in the short term. The second bootstrapped curve is non-monotone, as indicated by the warning.

```
ProbTimes = yearfrac(Settle, MarketDates);
figure
plot([0; ProbTimes],[0; ProbDataInv1(:,2)])
```

```
hold on
plot([0; ProbTimes],[0; ProbDataInv2(:,2)],'--')
hold off
grid on
axis([0 ProbTimes(end,1) 0 ProbDataInv1(end,2)])
xlabel('Time (years)')
ylabel('Cumulative Default Probability')
title('Probability Curves for Inverted Spread Curves')
legend('1st instance','2nd instance','location','SouthEast')
```

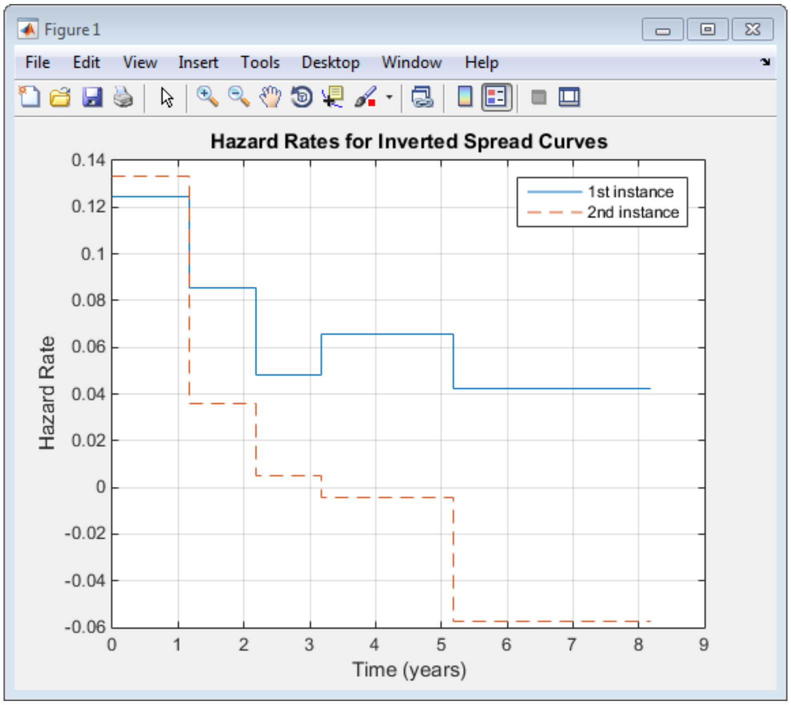
The resulting plot



Also in line with the previous plot, the hazard rates for these bootstrapped curves are decreasing because the short-term risk is higher. Some bootstrapped parameters in the second curve are negative, as indicated by the warning.

```
HazTimes = yearfrac(Settle, MarketDates);
figure
stairs([0; HazTimes(1:end-1,1); HazTimes(end,1)+1],...
   [HazDataInv1(:,2);HazDataInv1(end,2)])
hold on
stairs([0; HazTimes(1:end-1,1); HazTimes(end,1)+1],...
   [HazDataInv2(:,2);HazDataInv2(end,2)],'--')
hold off
grid on
xlabel('Time (years)')
ylabel('Hazard Rate')
title('Hazard Rates for Inverted Spread Curves')
legend('1st instance','2nd instance','location','NorthEast')
```

The resulting plot shows the hazard rates for both bootstrapped curves:



For further discussion on inverted curves, and their relationship to arbitrage, see O'Kane and Turnbull, 2003 ("Credit Derivatives" on page A-5).

Visualize Transitions Data for transprob

This example shows how to visualize credit rating transitions that are used as an input to the `transprob` function. The example also describes how the `transprob` function treats rating transitions when the company data starts after the start date of the analysis, or when the end date of the analysis is after the last transition observed.

Sample Data

Set up fictitious sample data for illustration purposes.

```
data = {'ABC','17-Feb-2015','AA';
    'ABC','6-Jul-2017','A';
    'LMN','12-Aug-2014','B';
    'LMN','9-Nov-2015','CCC';
    'LMN','7-Sep-2016','D';
    'XYZ','14-May-2013','BB';
    'XYZ','21-Jun-2016','BBB'};
data = cell2table(data,'VariableNames',{'ID','Date','Rating'});
disp(data)
```

```
      ID             Date            Rating
    _______    ________________    _______

    {'ABC'}    {'17-Feb-2015'}    {'AA' }
    {'ABC'}    {'6-Jul-2017' }    {'A'  }
    {'LMN'}    {'12-Aug-2014'}    {'B'  }
    {'LMN'}    {'9-Nov-2015' }    {'CCC'}
    {'LMN'}    {'7-Sep-2016' }    {'D'  }
    {'XYZ'}    {'14-May-2013'}    {'BB' }
    {'XYZ'}    {'21-Jun-2016'}    {'BBB'}
```

The `transprob` function understands that this panel-data format indicates the dates when a new rating is assigned to a given company. `transprob` assumes that such ratings remain unchanged, unless a subsequent row explicitly indicates a rating change. For example, for company `'ABC'`, `transprob` understands that the `'A'` rating is unchanged for any date after `'6-Jul-2017'` (indefinitely).

Compute Transition Matrix and Transition Counts

The `transprob` function returns a transition probability matrix as the primary output. There are also optional outputs that contain additional information for how many transitions occurred. For more information, see `transprob` for information on the optional outputs for both the `'cohort'` and the `'duration'` methods.

For illustration purposes, this example allows you to pick the `StartYear` (limited to `2014` or `2015` for this example) and the `EndYear` (`2016` or `2017`). This example also uses the `hDisplayTransitions` helper function (see the Local Functions on page 8-117 section) to format the transitions information for ease of reading.

```
StartYear = 2014 ;
EndYear = 2017 ;
startDate = datetime(StartYear,12,31,'Locale','en_US');
```

```
endDate = datetime(EndYear,12,31,'Locale','en_US');
RatingLabels = ["AAA","AA","A","BBB","BB","B","CCC","D"];

[tm,st,it] = transprob(data,'startDate',startDate,'endDate',endDate,'algorithm','cohort','labels
```

The transition probabilities of the TransMat output indicate the probability of migrating between ratings. The probabilities are expressed in %, that is, they are multiplied by 100.

```
hDisplayTransitions(tm,RatingLabels,"Transition Matrix")
```

```
Transition Matrix

           AAA    AA     A      BBB    BB    B    CCC     D
           ___    __    ___    ___    __    _    ___    ___

    AAA    100     0      0      0     0    0      0      0
    AA       0    50     50      0     0    0      0      0
    A        0     0    100      0     0    0      0      0
    BBB      0     0      0    100     0    0      0      0
    BB       0     0      0     50    50    0      0      0
    B        0     0      0      0     0    0    100      0
    CCC      0     0      0      0     0    0      0    100
    D        0     0      0      0     0    0      0    100
```

The transition counts are stored in the sampleTotals optional output and indicate how many transitions occurred between ratings for the entire sample (that is, all companies).

```
hDisplayTransitions(st.totalsMat,RatingLabels,"Transition counts, all companies")
```

```
Transition counts, all companies

           AAA    AA    A    BBB    BB    B    CCC    D
           ___    __    _    ___    __    _    ___    _

    AAA     0     0     0     0     0     0     0     0
    AA      0     1     1     0     0     0     0     0
    A       0     0     0     0     0     0     0     0
    BBB     0     0     0     1     0     0     0     0
    BB      0     0     0     1     1     0     0     0
    B       0     0     0     0     0     0     1     0
    CCC     0     0     0     0     0     0     0     1
    D       0     0     0     0     0     0     0     1
```

The third output of transprob is idTotals that contains information about transitions at an ID level, company by company (in the same order that the companies appear in the input data).

Select a company to display the transition counts and a corresponding visualization of the transitions. The hPlotTransitions helper function (see the Local Functions on page 8-117 section) shows the transitions history for a company.

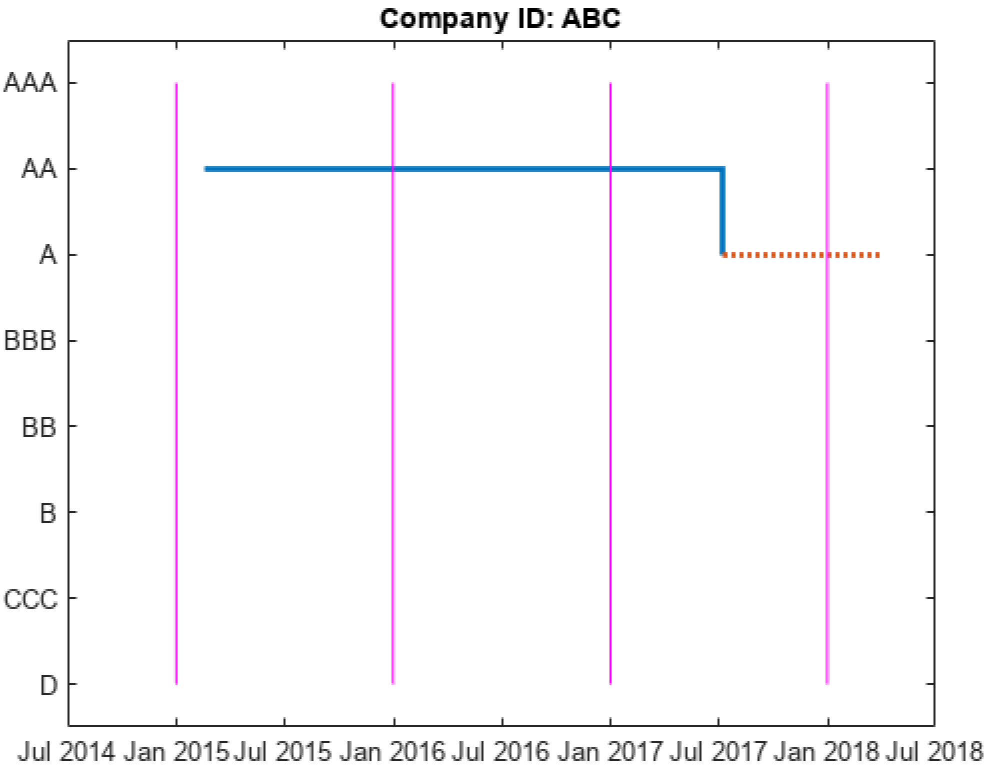
```
CompanyID = ABC ;
UniqueIDs = unique(data.ID,'stable');
[~,CompanyIndex] = ismember(CompanyID,UniqueIDs);
hDisplayTransitions(it(CompanyIndex).totalsMat,RatingLabels,strcat("Transition counts, company II
```

```
Transition counts, company ID: ABC
```

```
              AAA    AA    A    BBB    BB    B    CCC    D
              ___    __    _    ___    __    _    ___    _

       AAA     0     0     0     0     0     0     0     0
       AA      0     1     1     0     0     0     0     0
       A       0     0     0     0     0     0     0     0
       BBB     0     0     0     0     0     0     0     0
       BB      0     0     0     0     0     0     0     0
       B       0     0     0     0     0     0     0     0
       CCC     0     0     0     0     0     0     0     0
       D       0     0     0     0     0     0     0     0
```

```
hPlotTransitions(CompanyID,startDate,endDate,data,RatingLabels)
```



To understand how `transprob` handles data when the first observed date is after the start date of the analysis, or whose last observed date occurs before the end date of the analysis, consider the following example. For company `'ABC'` suppose that the analysis has a start date of `31-Dec-2014` and end date of `31-Dec-2017`. There are only two transitions reported for this company for that analysis time window. The first observation for `'ABC'` happened on `17-Feb-2015`. So the `31-Dec-2015` snapshot is the first time the company is observed. By `31-Dec-2016`, the company remained in the original `'AA'` rating. By `31-Dec-2017`, a downgrade to `'A'` is recorded. Consistent with this, the transition counts show one transition from `'AA'` to `'AA'` (from the end of 2015 to the end of 2016), and one transition from `'AA'` to `'A'` (from the end of 2016 to the end of 2017). The plot shows the last rating as a dotted red line to emphasize that the last rating in the data is extrapolated indefinitely into the future. There is no extrapolation into the past; the company's history is ignored until a company rating is known for an entire transition period (`31-Dec-2015` through `31-Dec-2016` in the case of `'ABC'`).

Compute Transition Matrix Containing NR (Not Rated) Rating

Consider a different sample data containing only a single company `'DEF'`. The data contains transitions of company `'DEF'` from `'A'` to `'NR'` rating and a subsequent transition from `'NR'` to `'BBB'`.

```
dataNR = {'DEF','17-Mar-2011','A';
    'DEF','24-Mar-2014','NR';
    'DEF','26-Sep-2016','BBB'};
dataNR = cell2table(dataNR,'VariableNames',{'ID','Date','Rating'});
disp(dataNR)
```

```
      ID             Date            Rating
    _______    _______________    _______

    {'DEF'}    {'17-Mar-2011'}    {'A'  }
    {'DEF'}    {'24-Mar-2014'}    {'NR' }
    {'DEF'}    {'26-Sep-2016'}    {'BBB'}
```

`transprob` treats `'NR'` as another rating. The transition matrix below shows the estimated probability of transitioning into and out of `'NR'`.

```
StartYearNR = 2010;
EndYearNR = 2018;
startDateNR = datetime(StartYearNR,12,31,'Locale','en_US');
endDateNR = datetime(EndYearNR,12,31,'Locale','en_US');
CompanyID_NR = "DEF";

RatingLabelsNR = ["AAA","AA","A","BBB","BB","B","CCC","D","NR"];

[tmNR,~,itNR] = transprob(dataNR,'startDate',startDateNR,'endDate',endDateNR,'algorithm','cohort
hDisplayTransitions(tmNR,RatingLabelsNR,"Transition Matrix")
```

```
Transition Matrix

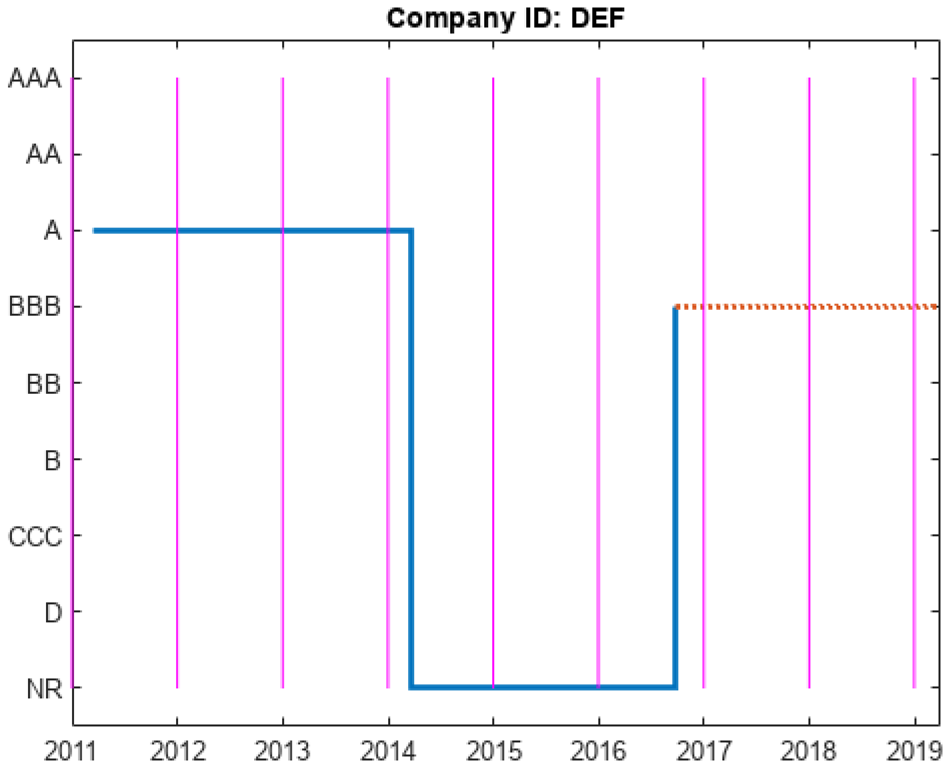
Transition counts, company ID: DEF

           AAA    AA    A    BBB    BB    B    CCC    D    NR
```

```
              ___     __     _     ___     __     _     ___     _     __

    AAA       0      0      0      0      0      0      0      0      0
    AA        0      0      0      0      0      0      0      0      0
    A         0      0      2      0      0      0      0      0      1
    BBB       0      0      0      2      0      0      0      0      0
    BB        0      0      0      0      0      0      0      0      0
    B         0      0      0      0      0      0      0      0      0
    CCC       0      0      0      0      0      0      0      0      0
    D         0      0      0      0      0      0      0      0      0
    NR        0      0      0      1      0      0      0      0      1
```

```
hPlotTransitions(CompanyID_NR,startDateNR,endDateNR,dataNR,RatingLabelsNR)
```



To remove the `'NR'` from the transition matrix, use the `'excludeLabels'` name-value input argument in `transprob`. The list of labels to exclude may or may not be specified in the name-value pair argument `labels`. For example, both `RatingLabels` and `RatingLabelsNR` generate the same output from `transprob`.

```
[tmNR,stNR,itNR] = transprob(dataNR,'startDate',startDateNR,'endDate',endDateNR,'algorithm','coho
hDisplayTransitions(tmNR,RatingLabels,"Transition Matrix")
```

```
Transition Matrix

              AAA    AA      A     BBB    BB      B     CCC     D

    D        0      0      0      0      0      0      0    100
```

Display the transition counts and corresponding visualization of the transitions.

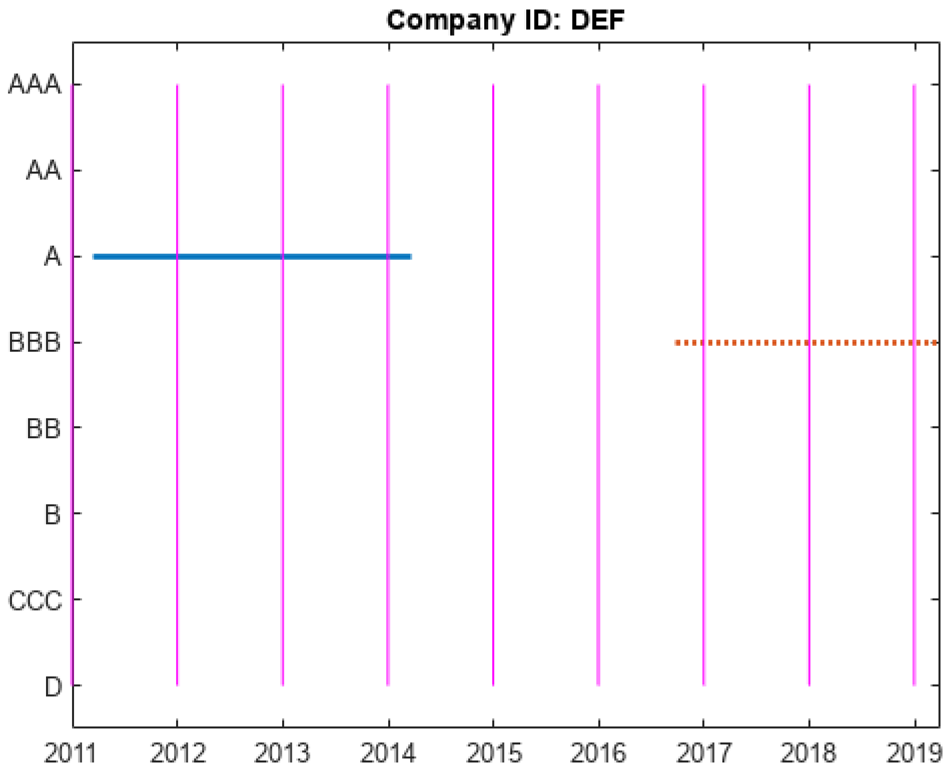
```
hDisplayTransitions(itNR.totalsMat,RatingLabels,strcat("Transition counts, company ID: ",CompanyI
```

```
Transition counts, company ID: DEF

           AAA    AA    A    BBB    BB    B    CCC    D
           ___    __    _    ___    __    _    ___    _

    AAA     0     0     0     0     0     0     0     0
    AA      0     0     0     0     0     0     0     0
    A       0     0     2     0     0     0     0     0
    BBB     0     0     0     2     0     0     0     0
    BB      0     0     0     0     0     0     0     0
    B       0     0     0     0     0     0     0     0
    CCC     0     0     0     0     0     0     0     0
    D       0     0     0     0     0     0     0     0
```

```
hPlotTransitions(CompanyID_NR,startDateNR,endDateNR,dataNR,RatingLabels)
```



Consistent with the previous plot, the transition counts still show two transitions from `'A'` to `'A'` (from the end of 2012 to the end of 2014), and two transitions from `'BBB'` to `'BBB'` (from the end of 2017 to the end of 2019).

However, different from the previous plot, specifying `'NR'` using the `'excludeLabels'` name-value input argument of `transprob` removes any transitions into and out of the `'NR'` rating.

Local Functions

```
function hDisplayTransitions(TransitionsData,RatingLabels,Title)
% Helper function to format transition information outputs

TransitionsAsTable = array2table(TransitionsData,...
   'VariableNames',RatingLabels,'RowNames',RatingLabels);

fprintf('\n%s\n\n',Title)
disp(TransitionsAsTable)

end

function hPlotTransitions(CompanyID,startDate,endDate,data,RatingLabels)
% Helper function to visualize transitions between ratings

   Ind = string(data.ID)==CompanyID;
   DatesOriginal = datetime(data.Date(Ind),'Locale','en_US');

   for ii=1:length(snapDates)
      line([snapDates(ii) snapDates(ii)],yLimits,'Color','m')
   end
   title(strcat("Company ID: ",CompanyID))
end
```

Impute Missing Data in the Credit Scorecard Workflow Using the k-Nearest Neighbors Algorithm

This example shows how to perform imputation of missing data in the credit scorecard workflow using the k-nearest neighbors (kNN) algorithm.

The kNN algorithm is a nonparametric method used for classification and regression. In both cases, the input consists of the k-closest training examples in the feature space. The output depends on whether kNN is used for classification or regression. In kNN classification, an object is classified by a plurality vote of its neighbors, and the object is assigned to the class most common among its k-nearest neighbors. In kNN regression, the output is the average of the values of k-nearest neighbors. For more information on the kNN algorithm, see `fitcknn`.

For additional information on alternative approaches for "treating" missing data, see “Credit Scorecard Modeling with Missing Values” on page 8-56.

Impute Missing Data Using kNN Algorithm

Use the `dataMissing` data set to impute missing values for the `CustAge` (numeric) and `ResStatus` (categorical) predictors.

```
load CreditCardData.mat
disp(head(dataMissing));
```

```
    CustID    CustAge    TmAtAddress     ResStatus     EmpStatus    CustIncome    TmWBank    Othe
    ______    _______    ___________    ___________    _________    __________    _______    ____

      1          53          62         <undefined>    Unknown        50000         55         Ye
      2          61          22         Home Owner     Employed       52000         25         Ye
      3          47          30         Tenant         Employed       37000         61         No
      4         NaN          75         Home Owner     Employed       53000         20         Ye
      5          68          56         Home Owner     Employed       53000         14         Ye
      6          65          13         Home Owner     Employed       48000         59         Ye
      7          34          32         Home Owner     Unknown        32000         26         Ye
      8          50          57         Other          Employed       51000         33         No
```

In this example, the `'CustID'` and `'status'` columns are removed in the imputation process as those are the `id` and `response` values respectively. Alternatively, you can choose to leave the `'status'` column in.

```
dataToImpute = dataMissing(:,setdiff(dataMissing.Properties.VariableNames,...
    {'CustID','status'},'stable'));
```

Create dummy variables for all categorical predictors so that the kNN algorithm can compute the Euclidean distances.

```
dResStatus = dummyvar(dataToImpute.ResStatus);
dEmpStatus = dummyvar(dataToImpute.EmpStatus);
dOtherCC = dummyvar(dataToImpute.OtherCC);
```

`'k'` in the kNN algorithm is based on feature similarity. Choosing the right value of `'k'` is a process called parameter tuning, which is important for greater accuracy. There is no physical way to determine the "best" value for `'k'`, so you have to try a few values before settling on one. Small values of `'k'` can be noisy and subject to the effects of outliers. Larger values of `'k'` have smoother decision boundaries, which mean lower variance but increased bias.

For the purpose of this example, choose `'k'` as the square root of the number of samples in the data set. This is a generally accepted value for `'k'`. Choose a value of `'k'` that is odd in order to break a tie between two classes of data.

```
numObs = height(dataToImpute);
k = round(sqrt(numObs));
if ~mod(k,2)
    k = k+1;
end
```

Get the missing values from the `CustAge` and `ResStatus` predictors.

```
missingResStatus = ismissing(dataToImpute.ResStatus);
missingCustAge = ismissing(dataToImpute.CustAge);
```

Next, follow these steps:

- Modify the dataset to incorporate the dummy variables.
- Call the `fitcknn` function to create a k-nearest neighbor classifier.
- Call the `predict` method on that class to predict the imputed values.

```
custAgeToImpute = dataToImpute;
custAgeToImpute.HomeOwner = dResStatus(:,1);
custAgeToImpute.Tenant = dResStatus(:,2);
custAgeToImpute.Employed = dEmpStatus(:,1);
custAgeToImpute.HasOtherCC = dOtherCC(:,2);
custAgeToImpute = removevars(custAgeToImpute, 'ResStatus');
custAgeToImpute = removevars(custAgeToImpute, 'EmpStatus');
custAgeToImpute = removevars(custAgeToImpute, 'OtherCC');

knnCustAge = fitcknn(custAgeToImpute, 'CustAge', 'NumNeighbors', k, 'Standardize',true);
imputedCustAge = predict(knnCustAge,custAgeToImpute(missingCustAge,:));

resStatusToImpute = dataToImpute;
resStatusToImpute.Employed = dEmpStatus(:,1);
resStatusToImpute.HasOtherCC = dOtherCC(:,2);
resStatusToImpute = removevars(resStatusToImpute, 'EmpStatus');
resStatusToImpute = removevars(resStatusToImpute, 'OtherCC');

knnResStatus = fitcknn(resStatusToImpute, 'ResStatus', 'NumNeighbors', k, 'Standardize', true);
imputedResStatus = predict(knnResStatus,resStatusToImpute(missingResStatus,:));
```

Compare Imputed Data to Original Data

Create a new data set with the imputed data.

```
knnImputedData = dataMissing;
knnImputedData.CustAge(missingCustAge) = imputedCustAge;
knnImputedData.ResStatus(missingResStatus) = imputedResStatus;
disp(knnImputedData(5:10,:));
```

```
    CustID    CustAge    TmAtAddress     ResStatus     EmpStatus    CustIncome    TmWBank    Othe
    ______    _______    ___________    __________    _________    __________    _______    ____

      5         68           56         Home Owner    Employed       53000         14         Ye
      6         65           13         Home Owner    Employed       48000         59         Ye
      7         34           32         Home Owner    Unknown        32000         26         Ye
      8         50           57         Other         Employed       51000         33         No
```

```

Calculate Scores and Probability of Default for New Applicants

Create a data set of `'new customers'` and then calculate the scores and probabilities of default.

```
dataNewCustomers = dataMissing(1:20,1:end-1);
disp(head(dataNewCustomers));
```

```
    CustID    CustAge    TmAtAddress     ResStatus     EmpStatus    CustIncome    TmWBank    Othe
    ______    _______    ___________    ___________    _________    __________    _______    ____

      1         53           62         <undefined>    Unknown        50000         55         Ye
      2         61           22         Home Owner     Employed       52000         25         Ye
      3         47           30         Tenant         Employed       37000         61         No
      4        NaN           75         Home Owner     Employed       53000         20         Ye
      5         68           56         Home Owner     Employed       53000         14         Ye
      6         65           13         Home Owner     Employed       48000         59         Ye
      7         34           32         Home Owner     Unknown        32000         26         Ye
      8         50           57         Other          Employed       51000         33         No
```

Perform the same preprocessing on the `'new customers'` data as on the training data.

```
dResStatusNewCustomers = dummyvar(dataNewCustomers.ResStatus);
dEmpStatusNewCustomers = dummyvar(dataNewCustomers.EmpStatus);
dOtherCCNewCustomers = dummyvar(dataNewCustomers.OtherCC);

dataNewCustomersCopy = dataNewCustomers;
dataNewCustomersCopy.HomeOwner = dResStatusNewCustomers(:,1);
dataNewCustomersCopy.Tenant = dResStatusNewCustomers(:,2);
dataNewCustomersCopy.Employed = dEmpStatusNewCustomers(:,1);
dataNewCustomersCopy.HasOtherCC = dOtherCCNewCustomers(:,2);
dataNewCustomersCopy = removevars(dataNewCustomersCopy, 'ResStatus');
dataNewCustomersCopy = removevars(dataNewCustomersCopy, 'EmpStatus');
dataNewCustomersCopy = removevars(dataNewCustomersCopy, 'OtherCC');
```

Predict the missing data in the scoring data set with the same imputation model as before.

```
missingCustAgeNewCustomers = isnan(dataNewCustomers.CustAge);
missingResStatusNewCustomers = ismissing(dataNewCustomers.ResStatus);
imputedCustAgeNewCustomers = round(predict(knnCustAge, dataNewCustomersCopy(missingCustAgeNewCust
imputedResStatusNewCustomers = predict(knnResStatus, dataNewCustomersCopy(missingResStatusNewCust
dataNewCustomers.CustAge(missingCustAgeNewCustomers) = imputedCustAgeNewCustomers;
dataNewCustomers.ResStatus(missingResStatusNewCustomers) = imputedResStatusNewCustomers;
```

Use `score` to calculate scores of new customers.

```
[scores, points] = score(sc, dataNewCustomers);
disp(scores);
```

Impute Missing Data in the Credit Scorecard Workflow Using the Random Forest Algorithm

This example shows how to perform imputation of missing data in the credit scorecard workflow using the random forest algorithm.

Random forests are an ensemble learning method for classification or regression that operates by constructing a multitude of decision trees at training time and obtaining the class that is the mode of the classes (classification) or mean prediction (regression) of the individual trees. Random forests correct for the tendency of decision trees to overfit to the training set. For more information on the random forest algorithm, see `fitrensemble` and `fitcensemble`.

For additional information on alternative approaches for "treating" missing data, see “Credit Scorecard Modeling with Missing Values” on page 8-56.

Impute Missing Data Using Random Forest Algorithm

Use the `dataMissing` data set to impute missing values for the `CustAge` (numeric) and `ResStatus` (categorical) predictors.

```
load CreditCardData.mat
disp(head(dataMissing));
```

```
    CustID     CustAge     TmAtAddress      ResStatus       EmpStatus     CustIncome     TmWBank     Othe
    ______     _______     ___________     ___________     _________     __________     _______     ____

      1          53            62          <undefined>     Unknown         50000          55         Ye
      2          61            22          Home Owner      Employed        52000          25         Ye
      3          47            30          Tenant          Employed        37000          61         No
      4         NaN            75          Home Owner      Employed        53000          20         Ye
      5          68            56          Home Owner      Employed        53000          14         Ye
      6          65            13          Home Owner      Employed        48000          59         Ye
      7          34            32          Home Owner      Unknown         32000          26         Ye
      8          50            57          Other           Employed        51000          33         No
```

Remove the `'CustID'` and `'status'` columns in the imputation process as these are the `id` and `response` values respectively. Alternatively, you can choose to leave the `'status'` column in.

```
dataToImpute = dataMissing(:,setdiff(dataMissing.Properties.VariableNames,...
    {'CustID','status'},'stable'));

rfImputedData = dataMissing;
```

Because multiple predictors contain missing data, turn on the `'Surrogate'` flag when you create the decision tree template.

```
rng('default');
tmp = templateTree('Surrogate','on','Reproducible',true);
```

Next, use the `fitrensemble` and `fitcensemble` functions, which return the trained regression and classification ensemble model objects contain the results of boosting 100 regression and classification trees using `LSBoost`, respectively.

```
missingCustAge = ismissing(dataToImpute.CustAge);
% Fit ensemble of regression learners
```

```
rfCustAge = fitrensemble(dataToImpute,'CustAge','Method','Bag',...
    'NumLearningCycles',200,'Learners',tmp,'CategoricalPredictors',...
    {'ResStatus','EmpStatus','OtherCC'});
rfImputedData.CustAge(missingCustAge) = predict(rfCustAge,...
    dataToImpute(missingCustAge,:));

missingResStatus = ismissing(dataToImpute.ResStatus);
% Fit ensemble of classification learners
rfResStatus = fitcensemble(dataToImpute,'ResStatus','Method','Bag',...
    'NumLearningCycles',200,'Learners',tmp,'CategoricalPredictors',...
    {'EmpStatus','OtherCC'});
rfImputedData.ResStatus(missingResStatus) = predict(rfResStatus,...
    dataToImpute(missingResStatus,:));

% Optionally, round the age to the nearest integer
rfImputedData.CustAge = round(rfImputedData.CustAge);
```

Compare Imputed Data to Original Data

```
disp(rfImputedData(5:10,:));
```

```
    CustID    CustAge    TmAtAddress     ResStatus     EmpStatus    CustIncome    TmWBank    Othe
    ______    _______    ___________    __________    _________    __________    _______    ____

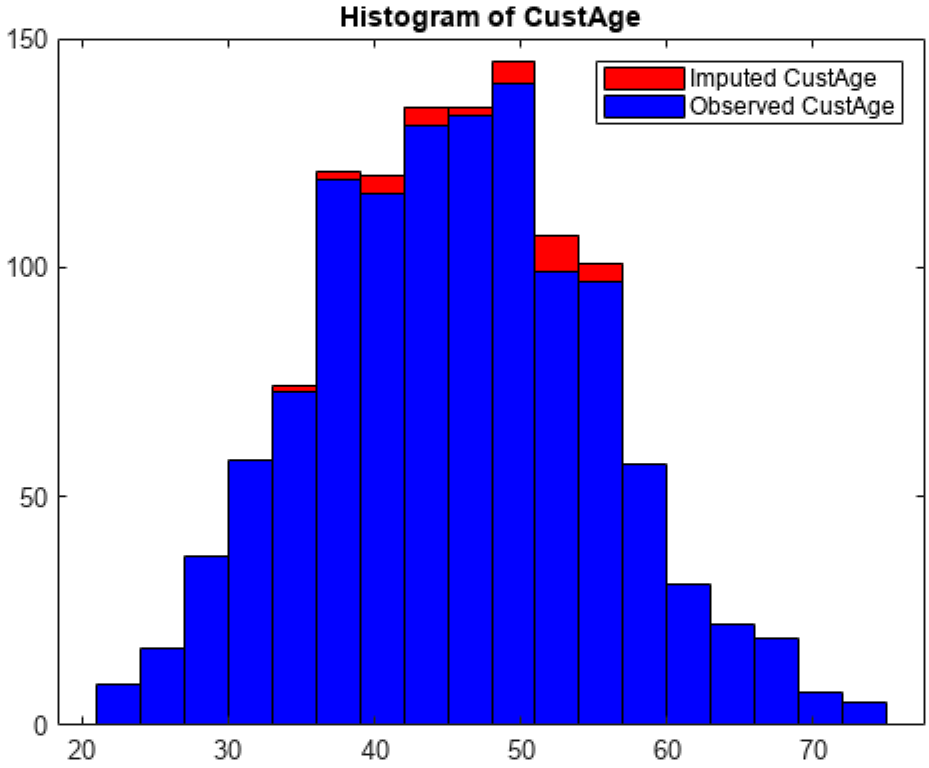
Plot a histogram of the predictor values before and after imputation.

```
Predictor = Customer Age ;
f1 = figure;
ax1 = axes(f1);
```

```
histogram(ax1,rfImputedData.(Predictor),'FaceColor','red','FaceAlpha',1);
hold on
histogram(ax1,dataMissing.(Predictor),'FaceColor','blue','FaceAlpha',1);
legend(strcat("Imputed ", Predictor), strcat("Observed ", Predictor));
title(strcat("Histogram of ", Predictor));
```



Create Credit Scorecard Model Using New Imputed Data

Use the imputed data to create the `creditscorecard` object, and then use `autobinning`, `fitmodel`, and `formatpoints` to create a credit scorecard model.

```
sc = creditscorecard(rfImputedData,'IDVar','CustID');
sc = autobinning(sc);
[sc,mdl] = fitmodel(sc,'display','off');
sc = formatpoints(sc,'PointsOddsAndPDO',[500 2 50]);
PointsInfo = displaypoints(sc);
disp(PointsInfo);
```

```

Treat Missing Data in a Credit Scorecard Workflow Using MATLAB® fillmissing

This example shows a workflow to gather missing data, manually treat the training data, develop a new `creditscorecard`, and treat new data before scoring using the MATLAB® `fillmissing`.

The advantage of this method is that you can use all the options available in `fillmissing` to fill missing data, as well as other MATLAB functionality such as `standardizeMissing` and features for the treatment of outliers. In this approach, note that you must ensure that the treatment of the training data and the treatment of any new data set that requires scoring must be the same.

Alternatively, after you create a `creditscorecard` object, you can use the `fillmissing` function for the `creditscorecard` object to fill missing values. For additional information on alternative approaches for "treating" missing data, see “Credit Scorecard Modeling with Missing Values” on page 8-56.

The `dataMissing` table in the `CreditCardData.mat` file has two predictors with missing values — `CustAge` and `ResStatus`.

```
load CreditCardData.mat
head(dataMissing)
```

```
    CustID    CustAge    TmAtAddress     ResStatus     EmpStatus    CustIncome    TmWBank    Othe
    ______    _______    ___________    ___________    _________    __________    _______    ____

      1          53          62         <undefined>    Unknown        50000         55        Ye
      2          61          22         Home Owner     Employed       52000         25        Ye
      3          47          30         Tenant         Employed       37000         61        No
      4         NaN          75         Home Owner     Employed       53000         20        Ye
      5          68          56         Home Owner     Employed       53000         14        Ye
      6          65          13         Home Owner     Employed       48000         59        Ye
      7          34          32         Home Owner     Unknown        32000         26        Ye
      8          50          57         Other          Employed       51000         33        No
```

First, analyze the missing data information using the untreated training data.

Create a `creditscorecard` object using the `CreditCardData.mat` file to load the `dataMissing` that contains missing values. Set the `'BinMissingData'` argument for `creditscorecard` to `true` to explicitly report information on missing values. Then apply automatic binning using `autobinning`.

```
sc = creditscorecard(dataMissing,'IDVar','CustID','BinMissingData',true);
sc = autobinning(sc);
```

The bin information and bin plots for predictors that have missing data both show a `<missing>` bin at the end. The two predictors with missing values in this data set are `CustAge` and `ResStatus`.

```
bi = bininfo(sc,'CustAge');
disp(bi)
```

```

The missing bin can be left as is, although a common alternative is to treat the missing values. Note that treating the missing values must be done with care because it changes the data and can introduce bias.

To treat missing values, you can apply different criteria. This example follows a straightforward approach to replace missing observations with the most common or typical value in the data distribution, which is the value of `mode` for the data. For this example, the `mode` happens to have a similar WOE value as the original `<missing>` bin. The similarity in values is favorable because similar WOE values means similar points in a scorecard.

For `CustAge`, bin `4` is the bin with the most observations and the `mode` value of the original data is `43`.

```
modeCustAge = mode(dataMissing.CustAge);
disp(modeCustAge)
```

```
    43
```

The WOE value of the `<missing>` bin is similar to the WOE value of bin `4`. Therefore, replacing the missing values in `CustAge` with the value of `mode` is reasonable.

To treat the data, create a copy of the data and fill the missing values.

```
dataTreated = dataMissing;
dataTreated.CustAge = fillmissing(dataTreated.CustAge,'constant',modeCustAge);
```

For `ResStatus`, the value of `'Home Owner'` is the value of the `mode` of the data, and the WOE value of the `<missing>` bin is closest to that of the `'Home Owner'` bin.

```
modeResStatus = mode(dataMissing.ResStatus);
disp(modeResStatus)
```

```
     Home Owner
```

Use MATLAB® `fillmissing` to replace the missing data with `'Home Owner'`.

```
dataTreated.ResStatus = fillmissing(dataTreated.ResStatus,'constant',string(modeResStatus));
```

The treated data set now has no missing values.

```
disp(any(any(ismissing(dataTreated))))
```

```
   0
```

Using the treated data set, apply the typical `creditscorecard` workflow. First, create a `creditscorecard` object with the treated data and then apply automatic binning.

```
scTreated = creditscorecard(dataTreated,'IDVar','CustID');
scTreated = autobinning(scTreated);
```

Compare the bin information of the untreated data for `CustAge` with the bin information of the treated data for `CustAge`.

```
bi = bininfo(sc,'CustAge');
disp(bi)
```

```

The first few bins are the same, but the treatment of missing values influences the binning results, starting with the bin where the missing data is placed. You can further explore your binning results using `autobinning` with a different algorithm or you can manually modify the bins using `modifybins`.

For `ResStatus`, the results for the treated data look similar to the initial results, except for the higher counts in the `'Home Owner'` bin due to the treatment. For a categorical variable with more categories (or levels), an automatic algorithm can find category groups and the results can show more differences for before and after the treatment.

The new scorecard does not know that the data was treated, hence it assigns NaNs to the <missing> bins. If you need to score a new data set and it contains missing data, by default, the `score` function sets the points to NaN. To further explore the handling of missing data, take a few rows from the original data as test data and introduce some missing data.

```
tdata = dataTreated(11:14,mdl.PredictorNames); % Keep only the predictors retained in the model
% Set some missing values
tdata.CustAge(1) = NaN;
tdata.ResStatus(2) = '<undefined>';
tdata.EmpStatus(3) = '<undefined>';
tdata.CustIncome(4) = NaN;
disp(tdata)
```

```
    CustAge     ResStatus       EmpStatus      CustIncome    TmWBank    OtherCC    AMBalance
    _______    ___________    ___________    __________    _______    _______    _________

      NaN      Tenant         Unknown          34000         44         Yes         119.8 
       48      <undefined>    Unknown          44000         14         Yes        403.62 
       65      Home Owner     <undefined>      48000          6         No         111.88

```

To assign points to missing data, one possibility is to use the name-value pair argument `'Missing'` in `formatpoints` to choose how to assign points to missing values.

Use the `'MinPoints'` option for the `'Missing'` argument. This option assigns the minimum number of possible points in the scorecard to the missing data. In this example, the minimum number of possible points for `CustIncome` is `29.906`, so the last row in the table gets `29.906` points for the missing `CustIncome` value.

```
scTreated = formatpoints(scTreated,'Missing','MinPoints');
[Scores,Points] = score(scTreated,tdata);

```

However, for predictors treated in the training data, such as `CustAge`, the effect of the `'Missing'` argument is inconsistent with the treatment of the training data. For example, for `CustAge`, the first observation gets `53.507` points for the missing value, yet if the new data were "treated," and the missing value for `CustAge` were replaced with the `mode` of the training data (age of `43`), this observation falls in the `[40,45)` bin and receives `66.868` points.

Therefore, before scoring, data sets must be treated the same way the training data was treated. The use of the `'Missing'` argument is still important to assign points for untreated predictors and the treated predictors receive points in a way that is consistent with the way the model was developed.

```
tdataTreated = tdata;
tdataTreated.CustAge = fillmissing(tdataTreated.CustAge,'constant',modeCustAge);
tdataTreated.ResStatus = fillmissing(tdataTreated.ResStatus,'constant',string(modeResStatus));

Regression with Missing Data

Multivariate Normal Regression

In this section...

Introduction

This section focuses on using likelihood-based methods for multivariate normal regression. The parameters of the regression model are estimated via maximum likelihood estimation. For multiple series, this requires iteration until convergence. The complication due to the possibility of missing data is incorporated into the analysis with a variant of the EM algorithm known as the ECM algorithm.

The underlying theory of maximum likelihood estimation and the definition and significance of the Fisher information matrix can be found in Caines [1] and Cramér [2]. The underlying theory of the ECM algorithm can be found in Meng and Rubin [8] and Sexton and Swensen [9].

In addition, these two examples of maximum likelihood estimation are presented:

- "Portfolios with Missing Data" on page 9-21
- "Estimation of Some Technology Stock Betas" on page 9-27

Multivariate Normal Linear Regression

Suppose that you have a multivariate normal linear regression model in the form

$$\begin{bmatrix} Z_1 \\ \vdots \\ Z_m \end{bmatrix} \sim N\left(\begin{bmatrix} H_1 b \\ \vdots \\ H_m b \end{bmatrix}, \begin{bmatrix} C & & 0 \\ & \ddots & \\ 0 & & C \end{bmatrix}\right),$$

where the model has m observations of n-dimensional random variables $Z_1, ..., Z_m$ with a linear regression model that has a p-dimensional model parameter vector b. In addition, the model has a sequence of m design matrices $H_1, ..., H_m$, where each design matrix is a known n-by-p matrix.

Given a parameter vector b and a collection of design matrices, the collection of m independent variables Z_k is assumed to have independent identically distributed multivariate normal residual errors $Z_k - H_k\, b$ with n-vector mean 0 and n-by-n covariance matrix C for each $k = 1, ..., m$.

A concise way to write this model is

$$Z_k \sim N(H_k b,\ C)$$

for $k = 1, ..., m$.

The goal of multivariate normal regression is to obtain maximum likelihood estimates for b and C given a collection of m observations $z_1, ..., z_m$ of the random variables $Z_1, ..., Z_m$. The estimated parameters are the p distinct elements of b and the $n\ (n + 1)/2$ distinct elements of C (the lower-triangular elements of C).

Note Quasi-maximum likelihood estimation works with the same models but with a relaxation of the assumption of normally distributed residuals. In this case, however, the parameter estimates are asymptotically optimal.

Maximum Likelihood Estimation

To estimate the parameters of the multivariate normal linear regression model using maximum likelihood estimation, it is necessary to maximize the log-likelihood function over the estimation parameters given observations $z_1, \dots , z_m$.

Given the multivariate normal model to characterize residual errors in the regression model, the log-likelihood function is

$$L(z_1, \dots, z_m;\ b,\ C) = \frac{1}{2}mn\log(2\pi) + \frac{1}{2}m\log(\det(C))$$
$$+\frac{1}{2}\sum_{k=1}^{m}(z_k - H_k b)^T C^{-1}(z_k - H_k b)\,.$$

Although the cross-sectional residuals must be independent, you can use this log-likelihood function for quasi-maximum likelihood estimation. In this case, the estimates for the parameters b and C provide estimates to characterize the first and second moments of the residuals. See Caines [1] for details.

Except for a special case (see “Special Case of Multiple Linear Regression Model” on page 9-4), if both the model parameters in b and the covariance parameters in C are to be estimated, the estimation problem is intractably nonlinear and a solution must use iterative methods. Denote estimates for the parameters b and C for iteration $t = 0, 1, \dots$ with the superscript notation $b^{(t)}$ and $C^{(t)}$.

Given initial estimates $b^{(0)}$ and $C^{(0)}$ for the parameters, the maximum likelihood estimates for b and C are obtained using a two-stage iterative process with

$$b^{(t+1)} = \left(\sum_{k=1}^{m} H_k{}^T\left(C^{(t)}\right)^{-1}H_k\right)^{-1}\left(\sum_{k=1}^{m} H_k{}^T\left(C^{(t)}\right)^{-1}z_k\right)$$

and

$$C^{(t+1)} = \frac{1}{m}\sum_{k=1}^{m}\left(z_k - H_k b^{(t+1)}\right)\left(z_k - H_k b^{(t+1)}\right)^T$$

for $t = 0, 1, \dots$.

Special Case of Multiple Linear Regression Model

The special case mentioned in “Maximum Likelihood Estimation” on page 9-3 occurs if $n = 1$ so that the sequence of observations is a sequence of scalar observations. This model is known as a multiple linear regression model. In this case, the covariance matrix C is a 1-by-1 matrix that drops out of the maximum likelihood iterates so that a single-step estimate for b and C can be obtained with converged estimates $b^{(1)}$ and $C^{(1)}$.

Least-Squares Regression

Another simplification of the general model is called least-squares regression. If $b^{(0)} = 0$ and $C^{(0)} = I$, then $b^{(1)}$ and $C^{(1)}$ from the two-stage iterative process are least-squares estimates for b and C, where

$$b^{LS} = \left(\sum_{k=1}^{m} H_k{}^T H_k\right)^{-1} \left(\sum_{k=1}^{m} H_k{}^T z_k\right)$$

and

$$C^{LS} = \frac{1}{m} \sum_{k=1}^{m} \left(z_k - H_k b^{LS}\right)\left(z_k - H_k b^{LS}\right)^T .$$

Mean and Covariance Estimation

A final simplification of the general model is to estimate the mean and covariance of a sequence of n-dimensional observations $z_1, ..., z_m$. In this case, the number of series is equal to the number of model parameters with $n = p$ and the design matrices are identity matrices with $H_k = I$ for $i = 1, ..., m$ so that b is an estimate for the mean and C is an estimate of the covariance of the collection of observations $z_1, ..., z_m$.

Convergence

If the iterative process continues until the log-likelihood function increases by no more than a specified amount, the resultant estimates are said to be maximum likelihood estimates b^{ML} and C^{ML}.

If $n = 1$ (which implies a single data series), convergence occurs after only one iterative step, which, in turn, implies that the least-squares and maximum likelihood estimates are identical. If, however, $n > 1$, the least-squares and maximum likelihood estimates are usually distinct.

In Financial Toolbox software, both the changes in the log-likelihood function and the norm of the change in parameter estimates are monitored. Whenever both changes fall below specified tolerances (which should be something between machine precision and its square root), the toolbox functions terminate under an assumption that convergence has been achieved.

Fisher Information

Since maximum likelihood estimates are formed from samples of random variables, their estimators are random variables; an estimate derived from such samples has an uncertainty associated with it. To characterize these uncertainties, which are called standard errors, two quantities are derived from the total log-likelihood function.

The Hessian of the total log-likelihood function is

$$\nabla^2 L(z_1, \ldots, z_m;\ \theta)$$

and the Fisher information matrix is

$$I(\theta) = -E\left[\nabla^2 L(z_1, \ldots, z_m;\ \theta)\right],$$

where the partial derivatives of the ∇^2 operator are taken with respect to the combined parameter vector Θ that contains the distinct components of b and C with a total of $q = p + n\ (n + 1)/2$ parameters.

Since maximum likelihood estimation is concerned with large-sample estimates, the central limit theorem applies to the estimates and the Fisher information matrix plays a key role in the sampling distribution of the parameter estimates. Specifically, maximum likelihood parameter estimates are asymptotically normally distributed such that

$$\left(\theta^{(t)} - \theta\right) \sim N\left(0,\ I^{-1},\ \left(\theta^{(t)}\right)\right) \text{ as } t \to \infty,$$

where Θ is the combined parameter vector and $\Theta^{(t)}$ is the estimate for the combined parameter vector at iteration t = 0, 1, ...

The Fisher information matrix provides a lower bound, called a Cramér-Rao lower bound, for the standard errors of estimates of the model parameters.

Statistical Tests

Given an estimate for the combined parameter vector Θ, the squared standard errors are the diagonal elements of the inverse of the Fisher information matrix

$$s^2\left(\widehat{\theta}_i\right) = \left(I^{-1}\left(\widehat{\theta}_i\right)\right)_{ii}$$

for i = 1, ..., q.

Since the standard errors are estimates for the standard deviations of the parameter estimates, you can construct confidence intervals so that, for example, a 95% interval for each parameter estimate is approximately

$$\widehat{\theta}_i \pm 1.96 s\left(\widehat{\theta}_i\right)$$

for i = 1, ..., q.

Error ellipses at a level-of-significance α ε [0, 1] for the parameter estimates satisfy the inequality

$$\left(\theta - \widehat{\theta}\right)^T I\left(\widehat{\theta}\right)\left(\theta - \widehat{\theta}\right) \leq \chi^2_{1-\alpha,\, q}$$

and follow a χ^2 distribution with q degrees-of-freedom. Similar inequalities can be formed for any subcollection of the parameters.

In general, given parameter estimates, the computed Fisher information matrix, and the log-likelihood function, you can perform numerous statistical tests on the parameters, the model, and the regression.

Maximum Likelihood Estimation with Missing Data

In this section...

Introduction

Suppose that a portion of the sample data is missing, where missing values are represented as `NaN`s. If the missing values are missing-at-random and ignorable, where Little and Rubin [7] have precise definitions for these terms, it is possible to use a version of the Expectation Maximization, or EM, algorithm of Dempster, Laird, and Rubin [3] to estimate the parameters of the multivariate normal regression model. The algorithm used in Financial Toolbox software is the ECM (Expectation Conditional Maximization) algorithm of Meng and Rubin [8] with enhancements by Sexton and Swensen [9].

Each sample z_k for $k = 1, ..., m$, is either complete with no missing values, empty with no observed values, or incomplete with both observed and missing values. Empty samples are ignored since they contribute no information.

To understand the missing-at-random and ignorable conditions, consider an example of stock price data before an IPO. For a counterexample, censored data, in which all values greater than some cutoff are replaced with `NaN`s, does not satisfy these conditions.

In sample k, let x_k represent the missing values in z_k and y_k represent the observed values. Define a permutation matrix P_k so that

$$z_k = P_k \begin{bmatrix} x_k \\ y_k \end{bmatrix}$$

for $k = 1, ..., m$.

ECM Algorithm

The ECM algorithm has two steps – an E, or expectation step, and a CM, or conditional maximization, step. As with maximum likelihood estimation, the parameter estimates evolve according to an iterative process, where estimates for the parameters after t iterations are denoted as $b^{(t)}$ and $C^{(t)}$.

The E step forms conditional expectations for the elements of missing data with

$$E\left[X_k | Y_k = y_k;\, b^{(t)},\, C^{(t)}\right]$$
$$cov\left[X_k | Y_k = y_k;\, b^{(t)},\, C^{(t)}\right]$$

for each sample $k \in \{1, \ldots, m\}$ that has missing data.

The CM step proceeds in the same manner as the maximum likelihood procedure without missing data. The main difference is that missing data moments are imputed from the conditional expectations obtained in the E step.

The E and CM steps are repeated until the log-likelihood function ceases to increase. One of the important properties of the ECM algorithm is that it is always guaranteed to find a maximum of the log-likelihood function and, under suitable conditions, this maximum can be a global maximum.

Standard Errors

The negative of the expected Hessian of the log-likelihood function and the Fisher information matrix are identical if no data is missing. However, if data is missing, the Hessian, which is computed over available samples, accounts for the loss of information due to missing data. So, the Fisher information matrix provides standard errors that are a Cramér-Rao lower bound whereas the Hessian matrix provides standard errors that may be greater if there is missing data.

Data Augmentation

The ECM functions do not “fill in” missing values as they estimate model parameters. In some cases, you may want to fill in the missing values. Although you can fill in the missing values in your data with conditional expectations, you would get optimistic and unrealistic estimates because conditional estimates are not random realizations.

Several approaches are possible, including resampling methods and multiple imputation (see Little and Rubin [7] and Shafer [10] for details). A somewhat informal sampling method for data augmentation is to form random samples for missing values based on the conditional distribution for the missing values. Given parameter estimates for $X \subset R^n$ and $\widehat{C}$, each observation has moments

$$E[Z_k] = H_k\widehat{b}$$

and

$$cov(Z_k) = H_k\widehat{C}H_k{}^T$$

for $k = 1, ..., m$, where you have dropped the parameter dependence on the left sides for notational convenience.

For observations with missing values partitioned into missing values X_k and observed values $Y_k = y_k$, you can form conditional estimates for any subcollection of random variables within a given observation. Thus, given estimates $E[\ Z_k\ ]$ and $cov(Z_k)$ based on the parameter estimates, you can create conditional estimates

$$E[X_k|y_k]$$

and

$$cov(X_k|y_k)$$

using standard multivariate normal distribution theory. Given these conditional estimates, you can simulate random samples for the missing values from the conditional distribution

$$X_k \sim N(E[X_k|y_k],\ cov(X_k|y_k))\,.$$

The samples from this distribution reflect the pattern of missing and nonmissing values for observations $k = 1, ..., m$. You must sample from conditional distributions for each observation to preserve the correlation structure with the nonmissing values at each observation.

If you follow this procedure, the resultant filled-in values are random and generate mean and covariance estimates that are asymptotically equivalent to the ECM-derived mean and covariance estimates. Note, however, that the filled-in values are random and reflect likely samples from the distribution estimated over all the data and may not reflect “true” values for a particular observation.

Multivariate Normal Regression Functions

In this section...

Financial Toolbox software has a number of functions for multivariate normal regression with or without missing data. The toolbox functions solve four classes of regression problems with functions to estimate parameters, standard errors, log-likelihood functions, and Fisher information matrices. The four classes of regression problems are:

- “Multivariate Normal Regression Without Missing Data” on page 9-11
- “Multivariate Normal Regression With Missing Data” on page 9-11
- “Least-Squares Regression With Missing Data” on page 9-11
- “Multivariate Normal Parameter Estimation With Missing Data” on page 9-12

Additional support functions are also provided, see “Support Functions” on page 9-12.

In all functions, the MATLAB representation for the number of observations (or samples) is `NumSamples = `m, the number of data series is `NumSeries = `n, and the number of model parameters is `NumParams = `p. The moment estimation functions have `NumSeries = NumParams`.

The collection of observations (or samples) is stored in a MATLAB matrix `Data` such that

$$\text{Data(k, :)} = z_k^T$$

for `k = 1, ..., NumSamples`, where `Data` is a `NumSamples`-by-`NumSeries` matrix.

For the multivariate normal regression or least-squares functions, an additional required input is the collection of design matrices that is stored as either a MATLAB matrix or a vector of cell arrays denoted as `Design`.

If `Numseries = 1`, `Design` can be a `NumSamples`-by-`NumParams` matrix. This is the “standard” form for regression on a single data series.

If `Numseries = 1`, `Design` can be either a cell array with a single cell or a cell array with `NumSamples` cells. Each cell in the cell array contains a `NumSeries`-by-`NumParams` matrix such that

$$\text{Design\{k\}} = H_k$$

for `k = 1, ..., NumSamples`. If `Design` has a single cell, it is assumed to be the same `Design` matrix for each sample such that

$$\text{Design\{1\}} = H_1 = \ldots = H_m\,.$$

Otherwise, `Design` must contain individual design matrices for each sample.

The main distinction among the four classes of regression problems depends upon how missing values are handled and where missing values are represented as the MATLAB value `NaN`. If a sample is to be ignored given any missing values in the sample, the problem is said to be a problem "without missing data." If a sample is to be ignored if and only if every element of the sample is missing, the problem is said to be a problem "with missing data" since the estimation must account for possible `NaN` values in the data.

In general, `Data` may or may not have missing values and `Design` should have no missing values. In some cases, however, if an observation in `Data` is to be ignored, the corresponding elements in `Design` are also ignored. Consult the function reference pages for details.

Multivariate Normal Regression Without Missing Data

You can use the following functions for multivariate normal regression without missing data.

`mvnrmle`	Estimate model parameters, residuals, and the residual covariance.
`mvnrstd`	Estimate standard errors of model and covariance parameters.
`mvnrfish`	Estimate the Fisher information matrix.
`mvnrobj`	Calculate the log-likelihood function.

The first two functions are the main estimation functions. The second two are supporting functions that can be used for more detailed analyses.

Multivariate Normal Regression With Missing Data

You can use the following functions for multivariate normal regression with missing data.

`ecmmvnrmle`	Estimate model parameters, residuals, and the residual covariance.
`ecmmvnrstd`	Estimate standard errors of model and covariance parameters.
`ecmmvnrfish`	Estimate the Fisher information matrix.
`ecmmvnrobj`	Calculate the log-likelihood function.

The first two functions are the main estimation functions. The second two are supporting functions used for more detailed analyses.

Least-Squares Regression With Missing Data

You can use the following functions for least-squares regression with missing data or for covariance-weighted least-squares regression with a fixed covariance matrix.

`ecmlsrmle`	Estimate model parameters, residuals, and the residual covariance.
`ecmlsrobj`	Calculate the least-squares objective function (pseudo log-likelihood).

To compute standard errors and estimates for the Fisher information matrix, the multivariate normal regression functions with missing data are used.

`ecmmvnrstd`	Estimate standard errors of model and covariance parameters.
`ecmmvnrfish`	Estimate the Fisher information matrix.

Multivariate Normal Parameter Estimation With Missing Data

You can use the following functions to estimate the mean and covariance of multivariate normal data.

`ecmnmle`	Estimate the mean and covariance of the data.
`ecmnstd`	Estimate standard errors of the mean and covariance of the data.
`ecmnfish`	Estimate the Fisher information matrix.
`ecmnhess`	Estimate the Fisher information matrix using the Hessian.
`ecmnobj`	Calculate the log-likelihood function.

These functions behave slightly differently from the more general regression functions since they solve a specialized problem. Consult the function reference pages for details.

Support Functions

Two support functions are included.

`convert2sur`	Convert a multivariate normal regression model into an SUR model.
`ecmninit`	Obtain initial estimates for the mean and covariance of a `Data` matrix.

The `convert2sur` function converts a multivariate normal regression model into a seemingly unrelated regression, or SUR, model. The second function `ecmninit` is a specialized function to obtain initial ad hoc estimates for the mean and covariance of a `Data` matrix with missing data. (If there are no missing values, the estimates are the maximum likelihood estimates for the mean and covariance.)

Multivariate Normal Regression Types

In this section...

Regressions

Each regression function has a specific operation. This section shows how to use these functions to perform specific types of regressions. To illustrate use of the functions for various regressions, "typical" usage is shown with optional arguments kept to a minimum. For a typical regression, you estimate model parameters and residual covariance matrices with the `mle` functions and estimate the standard errors of model parameters with the `std` functions. The regressions "without missing data" essentially ignore samples with any missing values, and the regressions "with missing data" ignore samples with every value missing.

Multivariate Normal Regression

Multivariate normal regression, or MVNR, is the "standard" implementation of the regression functions in Financial Toolbox software.

Multivariate Normal Regression Without Missing Data

Estimate parameters using `mvnrmle`:

```
[Parameters, Covariance] = mvnrmle(Data, Design);
```

Estimate standard errors using `mvnrstd`:

```
StdParameters = mvnrstd(Data, Design, Covariance);
```

Multivariate Normal Regression With Missing Data

Estimate parameters using `ecmmvnrmle`:

```
[Parameters, Covariance] = ecmmvnrmle(Data, Design);
```

Estimate standard errors using `ecmmvnrstd`:

```
StdParameters = ecmmvnrstd(Data, Design, Covariance);
```

Least-Squares Regression

Least-squares regression, or LSR, sometimes called ordinary least-squares or multiple linear regression, is the simplest linear regression model. It also enjoys the property that, independent of the underlying distribution, it is a best linear unbiased estimator (BLUE).

Given m = `NumSamples` observations, the typical least-squares regression model seeks to minimize the objective function

$$\sum_{k=1}^{m} (Z_k - H_k b)^T (Z_k - H_k b),$$

which, within the maximum likelihood framework of the multivariate normal regression routine `mvnrmle`, is equivalent to a single-iteration estimation of just the parameters to obtain `Parameters` with the initial covariance matrix `Covariance` held fixed as the identity matrix. In the case of missing data, however, the internal algorithm to handle missing data requires a separate routine `ecmlsrmle` to do least-squares instead of multivariate normal regression.

Least-Squares Regression Without Missing Data

Estimate parameters using `mvnrmle`:

```
[Parameters, Covariance] = mvnrmle(Data, Design, 1);
```

Estimate standard errors using `mvnrstd`:

```
StdParameters = mvnrstd(Data, Design, Covariance);
```

Least-Squares Regression With Missing Data

Estimate parameters using `ecmlsrmle`:

```
[Parameters, Covariance] = ecmlsrmle(Data, Design);
```

Estimate standard errors using `ecmmvnrstd`:

```
StdParameters = ecmmvnrstd(Data, Design, Covariance);
```

Covariance-Weighted Least Squares

Given m = `NUMSAMPLES` observations, the typical covariance-weighted least squares, or CWLS, regression model seeks to minimize the objective function

$$\sum_{k=1}^{m} (Z_k - H_k b)^T C_0 (Z_k - H_k b)$$

with fixed covariance C_0.

In most cases, C_0 is a diagonal matrix. The inverse matrix $W = C_0^{-1}$ has diagonal elements that can be considered relative “weights” for each series. Thus, CWLS is a form of weighted least squares with the weights applied across series.

Covariance-Weighted Least Squares Without Missing Data

Estimate parameters using `mvnrmle`:

```
[Parameters, Covariance] = mvnrmle(Data, Design, 1, [], [], [], Covar0);
```

Estimate standard errors using `mvnrstd`:

```
StdParameters = mvnrstd(Data, Design, Covariance);
```

Covariance-Weighted Least Squares With Missing Data

Estimate parameters using `ecmlsrmle`:

```
[Parameters, Covariance] = ecmlsrmle(Data, Design, [], [], [], [], Covar0);
```

Estimate standard errors using `ecmmvnrstd`:

```
StdParameters = ecmmvnrstd(Data, Design, Covariance);
```

Feasible Generalized Least Squares

An *ad hoc* form of least squares that has surprisingly good properties for misspecified or nonnormal models is known as feasible generalized least squares, or FGLS. The basic procedure is to do least-squares regression and then to do covariance-weighted least-squares regression with the resultant residual covariance from the first regression.

Feasible Generalized Least Squares Without Missing Data

Estimate parameters using `mvnrmle`:

```
[Parameters, Covariance] = mvnrmle(Data, Design, 2, 0, 0);
```

or (to illustrate the FGLS process explicitly)

```
[Parameters, Covar0] = mvnrmle(Data, Design, 1);
[Parameters, Covariance] = mvnrmle(Data, Design, 1, [], [], [], Covar0);
```

Estimate standard errors using `mvnrstd`:

```
StdParameters = mvnrstd(Data, Design, Covariance);
```

Feasible Generalized Least Squares With Missing Data

Estimate parameters using ecmlsrmle:

```
[Parameters, Covar0] = ecmlsrmle(Data, Design);
[Parameters, Covariance] = ecmlsrmle(Data, Design, [], [], [], [], Covar0);
```

Estimate standard errors using ecmmvnrstd:

```
StdParameters = ecmmvnrstd(Data, Design, Covariance);
```

Seemingly Unrelated Regression

Given a multivariate normal regression model in standard form with a Data matrix and a Design array, it is possible to convert the problem into a seemingly unrelated regression (SUR) problem by a simple transformation of the Design array. The main idea of SUR is that instead of having a common parameter vector over all data series, you have a separate parameter vector associated with each separate series or with distinct groups of series that, nevertheless, share a common residual covariance. It is this ability to aggregate and disaggregate series and to perform comparative tests on each design that is the power of SUR.

To make the transformation, use the function convert2sur, which converts a standard-form design array into an equivalent design array to do SUR with a specified mapping of the series into NUMGROUPS groups. The regression functions are used in the usual manner, but with the SUR design array instead of the original design array. Instead of having NUMPARAMS elements, the SUR output parameter vector has NUMGROUPS of stacked parameter estimates, where the first NUMPARAMS elements of Parameters contain parameter estimates associated with the first group of series, the next NUMPARAMS elements of Parameters contain parameter estimates associated with the second group of series, and so on. If the model has only one series, for example, NUMSERIES = 1, then the SUR design array is the same as the original design array since SUR requires two or more series to generate distinct parameter estimates.

Given NUMPARAMS parameters and NUMGROUPS groups with a parameter vector (Parameters) with NUMGROUPS * NUMPARAMS elements from any of the regression routines, the following MATLAB code fragment shows how to print a table of SUR parameter estimates with rows that correspond to each parameter and columns that correspond to each group or series:

```
fprintf(1,'Seemingly Unrelated Regression Parameter
   Estimates\n');
fprintf(1,'   %7s ',' ');
fprintf(1,'  Group(%3d) ',1:NumGroups);
fprintf(1,'\n');
for i = 1:NumParams
    fprintf(1,'   %7d ',i);
    ii = i;
        for j = 1:NumGroups
            fprintf(1,'%12g ',Param(ii));
            ii = ii + NumParams;
            end
            fprintf(1,'\n');
end
fprintf(1,'\n');
```

Seemingly Unrelated Regression Without Missing Data

Form a SUR design using `convert2sur`:

```
DesignSUR = convert2sur(Design, Group);
```

Estimate parameters using `mvnrmle`:

```
[Parameters, Covariance] = mvnrmle(Data, DesignSUR);
```

Estimate standard errors using `mvnrstd`:

```
StdParameters = mvnrstd(Data, DesignSUR, Covariance);
```

Seemingly Unrelated Regression With Missing Data

Form a SUR design using `convert2sur`:

```
DesignSUR = convert2sur(Design, Group);
```

Estimate parameters using `ecmmvnrmle`:

```
[Parameters, Covariance] = ecmmvnrmle(Data, DesignSUR);
```

Estimate standard errors using `ecmmvnrstd`:

```
StdParameters = ecmmvnrstd(Data, DesignSUR, Covariance);
```

Mean and Covariance Parameter Estimation

Without missing data, you can estimate the mean of your `Data` with the function `mean` and the covariance with the function `cov`. Nevertheless, the function `ecmnmle` does this for you if it detects an absence of missing values. Otherwise, it uses the ECM algorithm to handle missing values.

Estimate parameters using `ecmnmle`:

```
[Mean, Covariance] = ecmnmle(Data);
```

Estimate standard errors using `ecmnstd`:

```
StdMean = ecmnstd(Data, Mean, Covariance);
```

Troubleshooting Multivariate Normal Regression

This section provides a few pointers to handle various technical and operational difficulties that might occur.

Biased Estimates

If samples are ignored, the number of samples used in the estimation is less than `NumSamples`. Clearly the actual number of samples used must be sufficient to obtain estimates. In addition, although the model parameters `Parameters` (or mean estimates `Mean`) are unbiased maximum likelihood estimates, the residual covariance estimate `Covariance` is biased. To convert to an unbiased covariance estimate, multiply `Covariance` by

$$\text{Count}/(\text{Count}-1),$$

where `Count` is the actual number of samples used in the estimation with `Count` ≤ `NumSamples`. None of the regression functions perform this adjustment.

Requirements

The regression functions, particularly the estimation functions, have several requirements. First, they must have consistent values for `NumSamples`, `NumSeries`, and `NumParams`. As a rule, the multivariate normal regression functions require

$$\text{Count} \times \text{NumSeries} \le \max\{\text{NumParams},\ \text{NumSeries} \times (\text{NumSeries}+1)/2\}$$

and the least-squares regression functions require

$$\text{Count} \times \text{NumSeries} \le \text{NumParams},$$

where `Count` is the actual number of samples used in the estimation with

$$\text{Count} \le \text{NumSamples}.$$

Second, they must have enough nonmissing values to converge. Third, they must have a nondegenerate covariance matrix.

Although some necessary and sufficient conditions can be found in the references, general conditions for existence and uniqueness of solutions in the missing-data case, do not exist. Nonconvergence is usually due to an ill-conditioned covariance matrix estimate, which is discussed in greater detail in “Nonconvergence” on page 9-19.

Slow Convergence

Since worst-case convergence of the ECM algorithm is linear, it is possible to execute hundreds and even thousands of iterations before termination of the algorithm. If you are estimating with the ECM algorithm regularly with regular updates, you can use prior estimates as initial guesses for the next period's estimation. This approach often speeds up things since the default initialization in the regression functions sets the initial parameters `b` to zero and the initial covariance `C` to be the identity matrix.

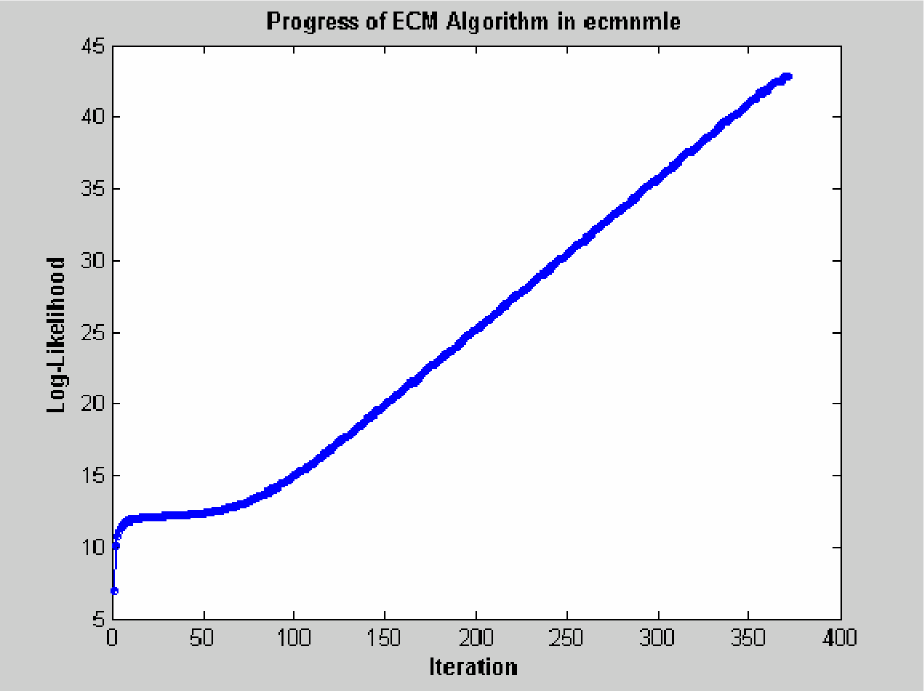
Other improvised approaches are possible although most approaches are problem-dependent. In particular, for mean and covariance estimation, the estimation function `ecmnmle` uses a function `ecmninit` to obtain an initial estimate.

Nonrandom Residuals

Simultaneous estimates for parameters `b` and covariances `C` require `C` to be positive-definite. So, the general multivariate normal regression routines require nondegenerate residual errors. If you are faced with a model that has exact results, the least-squares routine `ecmlsrmle` still works, although it provides a least-squares estimate with a singular residual covariance matrix. The other regression functions fail.

Nonconvergence

Although the regression functions are robust and work for most "typical" cases, they can fail to converge. The main failure mode is an ill-conditioned covariance matrix, where failures are either soft or hard. A soft failure wanders endlessly toward a nearly singular covariance matrix and can be spotted if the algorithm fails to converge after about 100 iterations. If `MaxIterations` is increased to 500 and display mode is initiated (with no output arguments), a typical soft failure looks like this.



This case, which is based on 20 observations of five assets with 30% of data missing, shows that the log-likelihood goes linearly to infinity as the likelihood function goes to 0. In this case, the function converges but the covariance matrix is effectively singular with a smallest eigenvalue on the order of machine precision (`eps`).

For the function `ecmnmle`, a hard error looks like this:

```
> In ecmninit at 60
  In ecmnmle at 140
```

```
??? Error using ==> ecmnmle
Full covariance not positive-definite in iteration 218.
```

From a practical standpoint, if in doubt, test your residual covariance matrix from the regression routines to ensure that it is positive-definite. This is important because a soft error has a matrix that appears to be positive-definite but actually has a near-zero-valued eigenvalue to within machine precision. To do this with a covariance estimate `Covariance`, use `cond(Covariance)`, where any value greater than `1/eps` should be considered suspect.

If either type of failure occurs, however, note that the regression routine is indicating that something is probably wrong with the data. (Even with no missing data, two time series that are proportional to one another produce a singular covariance matrix.)

Portfolios with Missing Data

This example shows how to use the missing data algorithms for portfolio optimization and for valuation. This example works with five years of daily total return data for 12 computer technology stocks, with six hardware and six software companies. The example estimates the mean and covariance matrix for these stocks, forms efficient frontiers with both a naïve approach and the ECM approach, and then compares results.

Load the data file.

```
load ecmtechdemo.mat
```

This data file contains these three quantities:

- `Assets` is a cell array of the tickers for the 12 stocks in the example.
- `Data` is a `1254`-by-`12` matrix of 1254 daily total returns for each of the 12 stocks.
- `Dates` is a `1254`-by-`1` column vector of the dates associated with the data.

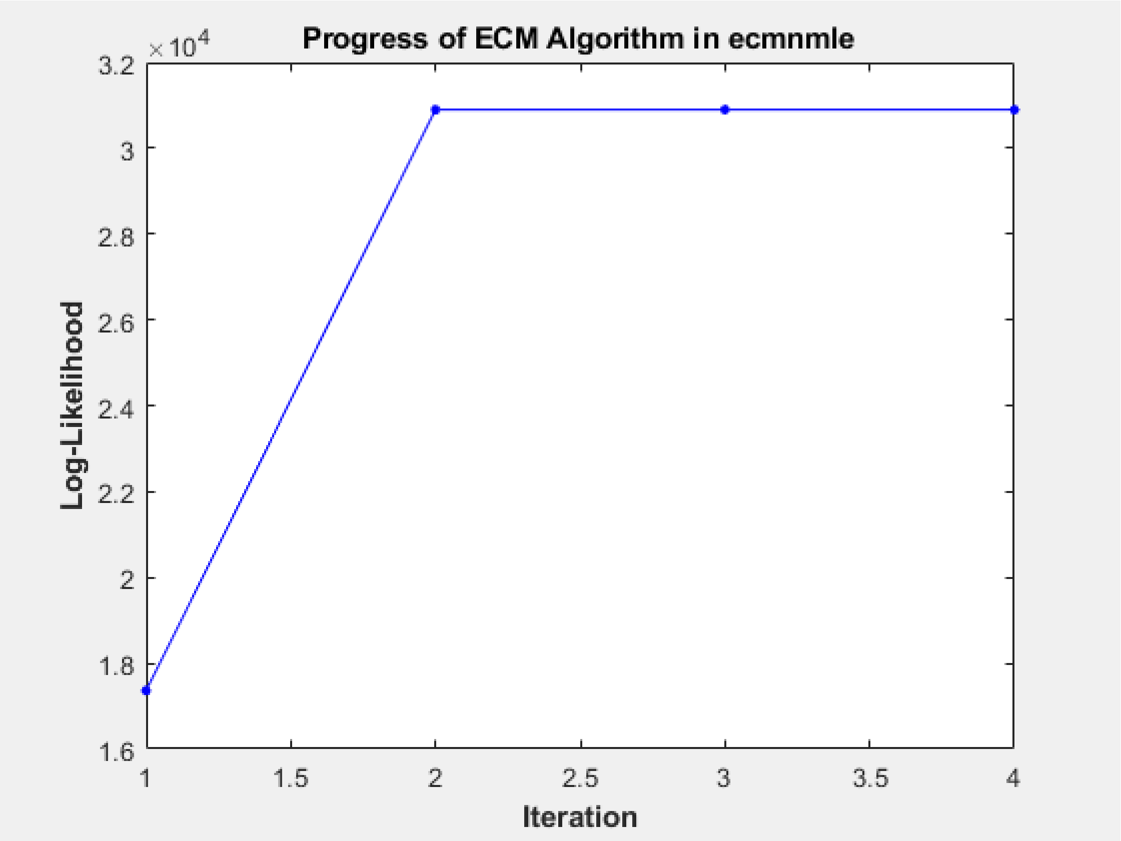
The time period for the data extends from April 19, 2000 to April 18, 2005. The sixth stock in `Assets` is Google (GOOG), which started trading on August 19, 2004. So, all returns before August 20, 2004 are missing and represented as `NaN`s. Also, Amazon (AMZN) had a few days with missing values scattered throughout the past five years.

A naïve approach to the estimation of the mean and covariance for these 12 assets is to eliminate all days that have missing values for any of the 12 assets. Use the function `ecmninit` with the `'nanskip'` option to do this.

```
[NaNMean, NaNCovar] = ecmninit(Data,'nanskip');
```

Contrast the result of this approach with using all available data and the function `ecmnmle` to compute the mean and covariance. First, call `ecmnmle` with no output arguments to establish that enough data is available to obtain meaningful estimates.

```
ecmnmle(Data);
```



This plot shows that, even with almost 87% of the Google data being `NaN` values, the algorithm converges after only four iterations.

Estimate the mean and covariance as computed by `ecmnmle`.

```
[ECMMean, ECMCovar] = ecmnmle(Data)
```

```
ECMMean = 12×1

      ⋮
```

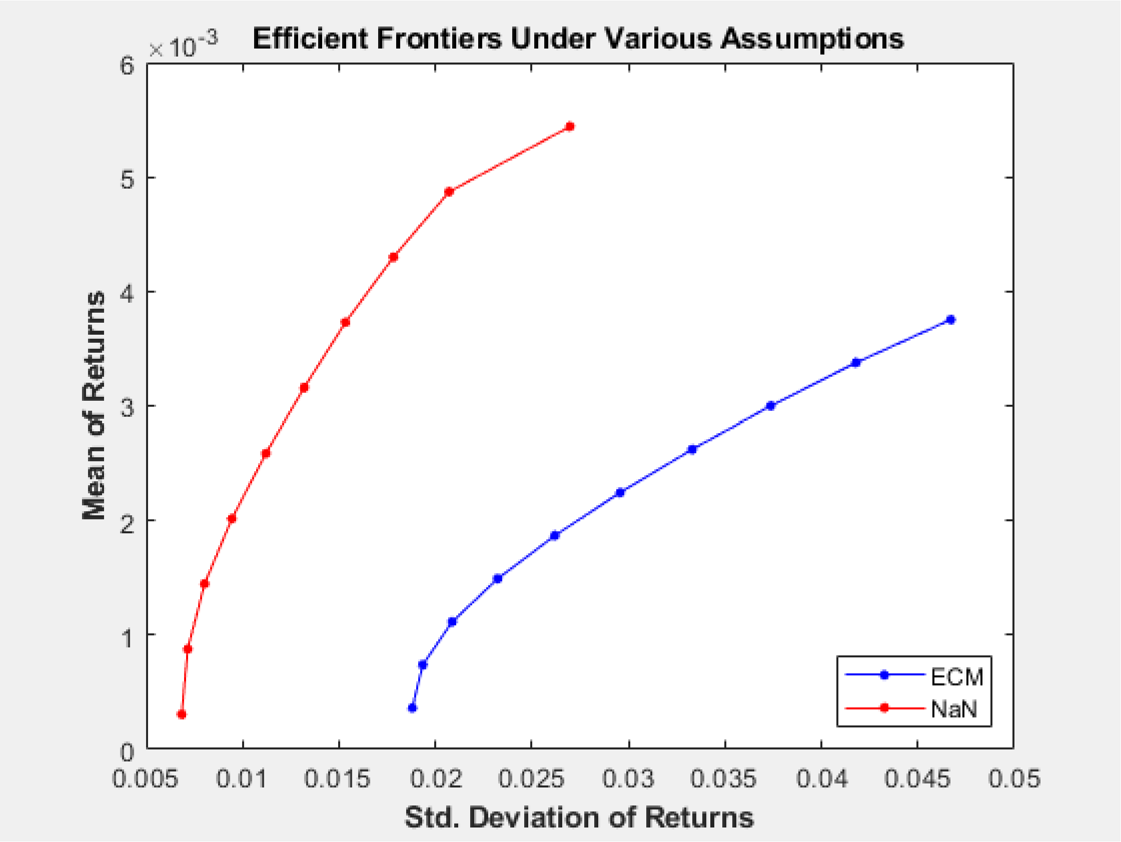
Given estimates for the mean and covariance of asset returns derived from the naïve and ECM approaches, estimate portfolios, and associated expected returns and risks on the efficient frontier for both approaches.

```
[ECMRisk, ECMReturn, ECMWts] = portopt(ECMMean',ECMCovar,10);
[NaNRisk, NaNReturn, NaNWts] = portopt(NaNMean',NaNCovar,10);
```

Plot the results on the same graph to illustrate the differences.

```
figure(gcf)
plot(ECMRisk,ECMReturn,'-bo','MarkerFaceColor','b','MarkerSize', 3);
hold on
plot(NaNRisk,NaNReturn,'-ro','MarkerFaceColor','r','MarkerSize', 3);
title('\bfEfficient Frontiers Under Various Assumptions');
legend('ECM','NaN','Location','SouthEast');
xlabel('\bfStd. Deviation of Returns');
ylabel('\bfMean of Returns');
hold off
```



Clearly, the naïve approach is optimistic about the risk-return trade-offs for this universe of 12 technology stocks. The proof, however, lies in the portfolio weights. To view the weights:

```
Assets
```

```
Assets = 1x12 cell

         0         0         0         0         0    1.0000         0         0         0
```

```
NaNWts
```

```
NaNWts = 10×12

         0         0         0    0.1185         0    0.0522    0.0824    0.1779         0    0.5
    0.0576         0         0    0.1219         0    0.0854    0.1274    0.0460         0    0.5
    0.1248         0         0    0.0952         0    0.1195    0.1674         0         0    0.4
    0.1969         0         0    0.0529         0    0.1551    0.2056         0         0    0.3
    0.2690         0         0    0.0105         0    0.1906    0.2438         0         0    0.2
    0.3414         0         0         0         0    0.2265    0.2782         0         0    0.0
    0.4235         0         0         0         0    0.2639    0.2788         0         0
    0.5245         0         0         0         0    0.3034    0.1721         0         0
    0.6269         0         0         0         0    0.3425    0.0306         0         0
    1.0000         0         0         0         0         0         0         0         0
```

The naïve portfolios in `NaNWts` tend to favor AAPL which happened to do well over the period from the Google IPO to the end of the estimation period, while the ECM portfolios in `ECMWts` tend to underweight AAPL and to recommend increased weights in GOOG relative to the naïve weights.

To evaluate the impact of the estimation error and, in particular, the effect of missing data, use `ecmnstd` to calculate standard errors. Although it is possible to estimate the standard errors for both the mean and covariance, the standard errors for the mean estimates alone are usually the main quantities of interest.

```
StdMeanF = ecmnstd(Data,ECMMean,ECMCovar,'fisher');
```

Calculate standard errors that use the data-generated Hessian matrix (which accounts for the possible loss of information due to missing data) with the option `'hessian'`.

```
StdMeanH = ecmnstd(Data,ECMMean,ECMCovar,'hessian');
```

The difference in the standard errors shows the increase in uncertainty of estimation of asset expected returns due to missing data. To view the differences:

```
Assets
```

```
Assets = 1x12 cell
    {'AAPL'}    {'AMZN'}    {'CSCO'}    {'DELL'}    {'EBAY'}    {'GOOG'}    {'HPQ'}    {'IBM'}
```

```
StdMeanH'
```

```
ans = 1×12

    0.0010    0.0014    0.0010    0.0009    0.0011    0.0021    0.0009    0.0006    0.0009    0.0
```

```
StdMeanF'
```

```
ans = 1×12

    0.0010    0.0014    0.0010    0.0009    0.0011    0.0013    0.0009    0.0006    0.0009    0.0
```

```
StdMeanH' - StdMeanF'
```

```
ans = 1×12
10^-3 ×

   -0.0000    0.0021   -0.0000   -0.0000   -0.0000    0.7742   -0.0000   -0.0000   -0.0000   -0.0
```

The two assets with missing data, AMZN and GOOG, are the only assets to have differences due to missing information.

Valuation with Missing Data

In this section...

Introduction

The Capital Asset Pricing Model (CAPM) is a venerable but often maligned tool to characterize comovements between asset and market prices. Although many issues arise in CAPM implementation and interpretation, one problem that practitioners face is to estimate the coefficients of the CAPM with incomplete stock price data.

The following example shows how to use the missing data regression functions to estimate the coefficients of the CAPM.

Capital Asset Pricing Model

Given a host of assumptions that can be found in the references (see Sharpe [11], Lintner [6], Jarrow [5], and Sharpe, et. al. [12]), the CAPM concludes that asset returns have a linear relationship with market returns. Specifically, given the return of all stocks that constitute a market denoted as M and the return of a riskless asset denoted as C, the CAPM states that the return of each asset R_{i} in the market has the expectational form

$$E[R_i] = \alpha_i + C + \beta_i(E[M] - C)$$

for assets $i = 1, ..., n$, where β_i is a parameter that specifies the degree of comovement between a given asset and the underlying market. In other words, the expected return of each asset is equal to the return on a riskless asset plus a risk-adjusted expected market return net of riskless asset returns. The collection of parameters $\beta_1, ..., \beta_n$ is called asset betas.

The beta of an asset has the form

$$\beta_i = \frac{\mathrm{cov}(R_i, M)}{\mathrm{var}(M)},$$

which is the ratio of the covariance between asset and market returns divided by the variance of market returns.Beta is the price volatility of a financial instrument relative to the price volatility of a market or index as a whole. Beta is commonly used with respect to equities. A high-beta instrument is riskier than a low-beta instrument. If an asset has a beta = 1, the asset is said to move with the market; if an asset has a beta > 1, the asset is said to be more volatile than the market. Conversely, if an asset has a beta < 1, the asset is said to be less volatile than the market.

Estimation of the CAPM

The standard CAPM model is a linear model with additional parameters for each asset to characterize residual errors. For each of n assets with m samples of observed asset returns $R_{k,i}$, market returns M_k, and riskless asset returns C_k, the estimation model has the form

$$R_{k,\,i} = \alpha_i + C_k + \beta_i(M_k - C_k) + V_{k,\,i}$$

for samples $k = 1, \ldots, m$ and assets $i = 1, \ldots, n$, where α_i is a parameter that specifies the nonsystematic return of an asset, β_i is the asset beta, and $V_{k,i}$ is the residual error for each asset with associated random variable V_i.

The collection of parameters $\alpha_1, \ldots, \alpha_n$ are called asset alphas. The strict form of the CAPM specifies that alphas must be zero and that deviations from zero are the result of temporary disequilibria. In practice, however, assets may have nonzero alphas, where much of active investment management is devoted to the search for assets with exploitable nonzero alphas.

To allow for the possibility of nonzero alphas, the estimation model generally seeks to estimate alphas and to perform tests to determine if the alphas are statistically equal to zero.

The residual errors V_i are assumed to have moments

$$E[V_i] = 0$$

and

$$E\left[V_i V_j\right] = S_{ij}$$

for assets $i,j = 1, \ldots, n$, where the parameters $S_{11}, \ldots, S_{nn}$ are called residual or nonsystematic variances/covariances.

The square root of the residual variance of each asset, for example, sqrt(S_{ii}) for $i = 1, \ldots, n$, is said to be the residual or nonsystematic risk of the asset since it characterizes the residual variation in asset prices that are not explained by variations in market prices.

Estimation with Missing Data

Although betas can be estimated for companies with sufficiently long histories of asset returns, it is difficult to estimate betas for recent IPOs. However, if a collection of sufficiently observable companies exists that can be expected to have some degree of correlation with the new company's stock price movements, that is, companies within the same industry as the new company, it is possible to obtain imputed estimates for new company betas with the missing-data regression routines.

Estimation of Some Technology Stock Betas

To illustrate how to use the missing-data regression routines, estimate betas for 12 technology stocks, where a single stock (GOOG) is an IPO.

1 Load dates, total returns, and ticker symbols for the 12 stocks from the MAT-file `CAPMuniverse`.

```
load CAPMuniverse
whos Assets Data Dates
```

```
  Name            Size              Bytes  Class     Attributes
  Assets         1x14              1568  cell
  Data        1471x14            164752  double
  Dates       1471x1              11768  double
```

The assets in the model have the following symbols, where the last two series are proxies for the market and the riskless asset:

```
Assets(1:7)
Assets(8:14)

ans =

  'AAPL'    'AMZN'    'CSCO'    'DELL'    'EBAY'    'GOOG'    'HPQ'

ans =

  'IBM'    'INTC'    'MSFT'    'ORCL'    'YHOO'    'MARKET'    'CASH'
```

The data covers the period from January 1, 2000 to November 7, 2005 with daily total returns. Two stocks in this universe have missing values that are represented by NaNs. One of the two stocks had an IPO during this period and, so, has significantly less data than the other stocks.

2. Compute separate regressions for each stock, where the stocks with missing data have estimates that reflect their reduced observability.

```
[NumSamples, NumSeries] = size(Data);
NumAssets = NumSeries - 2;

StartDate = Dates(1);
EndDate = Dates(end);

fprintf(1,'Separate regressions with ');
fprintf(1,'daily total return data from %s to %s ...\n', ...
    datestr(StartDate,1),datestr(EndDate,1));

```

The `Alpha` column contains alpha estimates for each stock that are near zero as expected. In addition, the t-statistics (which are enclosed in parentheses) generally reject the hypothesis that the alphas are nonzero at the 99.5% level of significance.

The `Beta` column contains beta estimates for each stock that also have t-statistics enclosed in parentheses. For all stocks but GOOG, the hypothesis that the betas are nonzero is accepted at the 99.5% level of significance. It seems, however, that GOOG does not have enough data to obtain a meaningful estimate for beta since its t-statistic would imply rejection of the hypothesis of a nonzero beta.

The `Sigma` column contains residual standard deviations, that is, estimates for nonsystematic risks. Instead of *t*-statistics, the associated standard errors for the residual standard deviations are enclosed in parentheses.

Grouped Estimation of Some Technology Stock Betas

To estimate stock betas for all 12 stocks, set up a joint regression model that groups all 12 stocks within a single design. (Since each stock has the same design matrix, this model is actually an example of seemingly unrelated regression.) The routine to estimate model parameters is `ecmmvnrmle`, and the routine to estimate standard errors is `ecmmvnrstd`.

Because GOOG has a significant number of missing values, a direct use of the missing data routine `ecmmvnrmle` takes 482 iterations to converge. This can take a long time to compute. For the sake of brevity, the parameter and covariance estimates after the first 480 iterations are contained in a MAT-file and are used as initial estimates to compute stock betas.

```
load CAPMgroupparam
whos Param0 Covar0
```

```
Name         Size            Bytes  Class     Attributes

  Covar0      12x12            1152  double
  Param0      24x1              192  double
```

Now estimate the parameters for the collection of 12 stocks.

```
fprintf(1,'\n');
fprintf(1,'Grouped regression with ');
fprintf(1,'daily total return data from %s to %s ...\n', ...
    datestr(StartDate,1),datestr(EndDate,1));
fprintf(1,'  %4s %-20s %-20s %-20s\n','','Alpha','Beta','Sigma');
fprintf(1,'  ---- -------------------- ');
fprintf(1,'-------------------- --------------------\n');
```

```
NumParams = 2 * NumAssets;

% Set up grouped asset data and design matrices
TestData = zeros(NumSamples, NumAssets);
TestDesign = cell(NumSamples, 1);
Design = zeros(NumAssets, NumParams);

for k = 1:NumSamples
    for i = 1:NumAssets
        TestData(k,i) = Data(k,i) - Data(k,14);
        Design(i,2*i - 1) = 1.0;
        Design(i,2*i) = Data(k,13) - Data(k,14);
    end
    TestDesign{k} = Design;
end

% Estimate CAPM for all assets together with initial parameter
% estimates
[Param, Covar] = ecmmvnrmle(TestData, TestDesign, [], [], [],...
    Param0, Covar0);

% Estimate ideal standard errors for covariance parameters
[StdParam, StdCovar] = ecmmvnrstd(TestData, TestDesign, Covar,...
    'fisher');

% Estimate sample standard errors for model parameters
StdParam = ecmmvnrstd(TestData, TestDesign, Covar, 'hessian');

% Set up results for output
Alpha = Param(1:2:end-1);
Beta = Param(2:2:end);
Sigma = sqrt(diag(Covar));

StdAlpha = StdParam(1:2:end-1);
StdBeta = StdParam(2:2:end);
StdSigma = sqrt(diag(StdCovar));

% Display estimates

```

Although the results for complete-data stocks are the same, the beta estimates for AMZN and GOOG (the two stocks with missing values) are different from the estimates derived for each stock separately. Since AMZN has few missing values, the differences in the estimates are small. With GOOG, however, the differences are more pronounced.

The *t*-statistic for the beta estimate of GOOG is now significant at the 99.5% level of significance. However, the *t*-statistics for beta estimates are based on standard errors from the sample Hessian which, in contrast to the Fisher information matrix, accounts for the increased uncertainty in an estimate due to missing values. If the *t*-statistic is obtained from the more optimistic Fisher information matrix, the *t*-statistic for GOOG is `8.25`. Thus, despite the increase in uncertainty due to missing data, GOOG nonetheless has a statistically significant estimate for beta.

Finally, note that the beta estimate for GOOG is `0.62` — a value that may require some explanation. Although the market has been volatile over this period with sideways price movements, GOOG has steadily appreciated in value. So, it is less tightly correlated with the market, implying that it is less volatile than the market (beta < 1).

Capital Asset Pricing Model with Missing Data

This example illustrates implementation of the Capital Asset Pricing Model (CAPM) in the presence of missing data.

The Capital Asset Pricing Model

The Capital Asset Pricing Model (CAPM) is a venerable but often-maligned tool to characterize comovements between asset and market prices. Although many issues arise in its implementation and interpretation, one problem that practitioners face is to estimate the coefficients of the CAPM with incomplete stock price data.

Given a host of assumptions that can be found in the references (see Sharpe [3 on page 9-38], Lintner [2 on page 9-38], Jarrow [1 on page 9-38], and Sharpe, et. al. [4 on page 9-38]), the CAPM concludes that asset returns have a linear relationship with market returns. Specifically, given the return of all stocks that constitute a market denoted as `M` and the return of a riskless asset denoted as `C`, the CAPM states that the return of each asset `R(i)` in the market has the expectational form

```
E[R(i)] = C + b(i) * (E[M] - C)
```

for assets `i = 1, ... , n`, where `b(i)` is a parameter that specifies the degree of comovement between a given asset and the underlying market. In words, the expected return of each asset is equal to the return on a riskless asset plus a risk-adjusted expected market return net of riskless asset returns. The collection of parameters `b(1), ... , b(n)` are called asset betas.

Note that the beta of an asset has the form

```
b(i) = cov(R(i),M)/var(M)
```

which is the ratio of the covariance between asset and market returns divided by the variance of market returns. If an asset has a beta equal to 1, the asset is said to move with the market; if an asset has a beta greater 1, the asset is said to be more volatile than the market; and if an asset has a beta less than 1, the asset is said to be less volatile than the market.

Estimation of the CAPM

The standard form of the CAPM model for estimation is a linear model with additional parameters for each asset to characterize residual errors. For each of `n` assets with `m` samples of observed asset returns `R(k, i)`, market returns `M(k)`, and riskless asset returns `C(k)`, the estimation model has the form

```
R(k,i) = a(i) + C(k) + b(i) * (M(k) - C(k)) + V(k,i)
```

for samples `k = 1, ... , m` and assets `i = 1, ... , n`, where `a(i)` is a parameter that specifies the non-systematic return of an asset, `b(i)` is the asset beta, and `V(k,i)` is the residual error for each asset with associated random variable `V(i)`.

The collection of parameters `a(1), ... , a(n)` are called asset alphas. The strict form of the CAPM specifies that alphas must be zero and that deviations from zero are the result of temporary disequilibria. In practice, however, assets may have non-zero alphas, where much of active investment management is devoted to the search for assets with exploitable non-zero alphas.

To allow for the possibility of non-zero alphas, the estimation model generally seeks to estimate alphas and to perform tests to determine if the alphas are statistically equal to zero.

The residual errors V(i) are assumed to have moments

```
E[V(i)] = 0
```

and

```
E[V(i) * V(j)] = S(i,j)
```

for assets i,j = 1, ... , n, where the parameters S(1,1), ... , S(n,n) are called residual or non-systematic variances/covariances.

The square root of the residual variance of each asset, i.e., sqrt(S(i,i)) for i = 1, ... , n, is said to be the residual or non-systematic risk of the asset since it characterizes the residual variation in asset prices that cannot be explained by variations in market prices.

Estimation with Missing Data

Although betas can be estimated for companies with sufficiently long histories of asset returns, it is extremely difficult to estimate betas for recent IPOs. However, if a collection of sufficiently-observable companies exists that can be expected to have some degree of correlation with the new company's stock price movements, for example, companies within the same industry as the new company, then it is possible to obtain imputed estimates for new company betas with the missing-data regression routines in the Financial Toolbox™.

Separate Estimation of Some Technology Stock Betas

To illustrate how to use the missing-data regression routines, we will estimate betas for twelve technology stocks, where one stock (GOOG) is an IPO.

First, load dates, total returns, and ticker symbols for the twelve stocks from the MAT-file CAPMuniverse.

```
load CAPMuniverse
whos Assets Data Dates
```

```
  Name            Size                Bytes  Class     Attributes

  Assets          1x14                 1568  cell                
  Data         1471x14               164752  double              
  Dates        1471x1                 11768  double              
```

```
Dates = datetime(Dates,'ConvertFrom','datenum');
```

The assets in the model have the following symbols, where the last two series are proxies for the market and the riskless asset.

```
Assets(1:7)
```

```
ans = 1x7 cell
    {'AAPL'}    {'AMZN'}    {'CSCO'}    {'DELL'}    {'EBAY'}    {'GOOG'}    {'HPQ'}
```

```
Assets(8:14)
```

```
ans = 1x7 cell
    {'IBM'}    {'INTC'}    {'MSFT'}    {'ORCL'}    {'YHOO'}    {'MARKET'}    {'CASH'}
```

The data covers the period from January 1, 2000 to November 7, 2005 with daily total returns. Two stocks in this universe have missing values that are represented by NaNs. One of the two stocks had an IPO during this period and, consequently, has significantly less data than the other stocks.

The first step is to compute separate regressions for each stock, where the stocks with missing data have estimates that reflect their reduced observability.

```
[NumSamples, NumSeries] = size(Data);
NumAssets = NumSeries - 2;

StartDate = Dates(1);
EndDate = Dates(end);

Alpha = NaN(1, length(NumAssets));
Beta = NaN(1, length(NumAssets));
Sigma = NaN(1, length(NumAssets));
StdAlpha = NaN(1, length(NumAssets));
StdBeta = NaN(1, length(NumAssets));
StdSigma = NaN(1, length(NumAssets));
for i = 1:NumAssets
    % Set up separate asset data and design matrices
    TestData = zeros(NumSamples,1);
    TestDesign = zeros(NumSamples,2);

    TestData(:) = Data(:,i) - Data(:,14);

```

The Alpha column contains alpha estimates for each stock that are near zero as expected. In addition, the *t*-statistics (which are enclosed in parentheses) generally reject the hypothesis that the alphas are nonzero at the 99.5% level of significance.

The Beta column contains beta estimates for each stock that also have *t*-statistics enclosed in parentheses. For all stocks but GOOG, the hypothesis that the betas are nonzero is accepted at the 99.5% level of significance. It would seem, however, that GOOG does not have enough data to obtain a meaningful estimate for beta since its *t*-statistic would imply rejection of the hypothesis of a nonzero beta.

The Sigma column contains residual standard deviations, that is, estimates for non-systematic risks. Instead of *t*-statistics, the associated standard errors for the residual standard deviations are enclosed in parentheses.

Grouped Estimation of Some Technology Stock Betas

To estimate stock betas for all twelve stocks, set up a joint regression model that groups all twelve stocks within a single design (since each stock has the same design matrix, this model is actually an example of seemingly-unrelated regression). The function to estimate model parameters is ecmmvnrmle and the function to estimate standard errors is ecmmvnrstd.

Since GOOG has a significant number of missing values, a direct use of the missing data function ecmmvnrmle takes 482 iterations to converge. This can take a long time to compute. For the sake of brevity, the parameter and covariance estimates after the first 480 iterations are contained in a MAT-file (CAPMgroupparam) and is used as initial estimates to compute stock betas.

```
load CAPMgroupparam
whos Param0 Covar0
```

```
  Name          Size            Bytes  Class     Attributes

  Covar0      12x12             1152  double              
  Param0      24x1               192  double              
```

Now estimate the parameters for the collection of twelve stocks.

```
NumParams = 2 * NumAssets;

% Set up the grouped asset data and design matrices.
TestData = zeros(NumSamples, NumAssets);
TestDesign = cell(NumSamples, 1);
Design = zeros(NumAssets, NumParams);

for    k = 1:NumSamples
    for i = 1:NumAssets
        TestData(k,i) = Data(k,i) - Data(k,14);

Although the results for complete-data stocks are the same, notice that the beta estimates for AMZN and GOOG (which are the two stocks with missing values) are different from the estimates derived for each stock separately. Since AMZN has few missing values, the differences in the estimates are small. With GOOG, however, the differences are more pronounced.

The *t*-statistic for the beta estimate of GOOG is now significant at the 99.5% level of significance. Note, however, that the *t*-statistics for beta estimates are based on standard errors from the sample Hessian which, in contrast to the Fisher information matrix, accounts for the increased uncertainty in an estimate due to missing values. If the *t*-statistic is obtained from the more optimistic Fisher information matrix, the *t*-statistic for GOOG is `8.25`. Thus, despite the increase in uncertainty due to missing data, GOOG nonetheless has a statistically-significant estimate for beta.

Finally, note that the beta estimate for GOOG is `0.62` - a value that may require some explanation. Whereas the market has been volatile over this period with sideways price movements, GOOG has steadily appreciated in value. Consequently, it is less correlated than the market, which, in turn, implies that it is less volatile than the market with a beta less than 1.

Solving Sample Problems

Sensitivity of Bond Prices to Interest Rates

Macaulay and *modified duration* measure the sensitivity of a bond's price to changes in the level of interest rates. *Convexity* measures the change in duration for small shifts in the yield curve, and thus measures the second-order price sensitivity of a bond. Both measures can gauge the vulnerability of a bond portfolio's value to changes in the level of interest rates.

Alternatively, analysts can use duration and convexity to construct a bond portfolio that is partly hedged against small shifts in the term structure. If you combine bonds in a portfolio whose duration is zero, the portfolio is insulated, to some extent, against interest rate changes. If the portfolio convexity is also zero, this insulation is even better. However, since hedging costs money or reduces expected return, you must know how much protection results from hedging duration alone compared to hedging both duration and convexity.

This example demonstrates a way to analyze the relative importance of duration and convexity for a bond portfolio using some of the SIA-compliant bond functions in Financial Toolbox software. Using duration, it constructs a first-order approximation of the change in portfolio price to a level shift in interest rates. Then, using convexity, it calculates a second-order approximation. Finally, it compares the two approximations with the true price change resulting from a change in the yield curve.

Step 1

Define three bonds using values for the settlement date, maturity date, face value, and coupon rate. For simplicity, accept default values for the coupon payment periodicity (semiannual), end-of-month payment rule (rule in effect), and day-count basis (actual/actual). Also, synchronize the coupon payment structure to the maturity date (no odd first or last coupon dates). Any inputs for which defaults are accepted are set to empty matrices (`[]`) as placeholders where appropriate.

```
Settle     = '19-Aug-1999';
Maturity   = ['17-Jun-2010'; '09-Jun-2015'; '14-May-2025'];
Face       = [100; 100; 1000];
CouponRate = [0.07; 0.06; 0.045];
```

Also, specify the yield curve information.

```
Yields = [0.05; 0.06; 0.065];
```

Step 2

Use Financial Toolbox functions to calculate the price, modified duration in years, and convexity in years of each bond.

The true price is quoted (clean) price plus accrued interest.

```
[CleanPrice, AccruedInterest] = bndprice(Yields, CouponRate,...
Settle, Maturity, 2, 0, [], [], [], [], [], Face);

Durations = bnddury(Yields, CouponRate, Settle, Maturity, 2, 0,...
[], [], [], [], [], Face);

Convexities = bndconvy(Yields, CouponRate, Settle, Maturity, 2, 0,...
[], [], [], [], [], Face);

Prices  =  CleanPrice + AccruedInterest
```

```
Prices =

  117.7622
  101.1534
  763.3932
```

Step 3

Choose a hypothetical amount by which to shift the yield curve (here, 0.2 percentage point or 20 basis points).

```
dY = 0.002;
```

Weight the three bonds equally, and calculate the actual quantity of each bond in the portfolio, which has a total value of $100,000.

```
PortfolioPrice   = 100000;
PortfolioWeights = ones(3,1)/3;
PortfolioAmounts = PortfolioPrice * PortfolioWeights ./ Prices
```

```
PortfolioAmounts =

  283.0562
  329.5324
   43.6647
```

Step 4

Calculate the modified duration and convexity of the portfolio. The portfolio duration or convexity is a weighted average of the durations or convexities of the individual bonds. Calculate the first- and second-order approximations of the percent price change as a function of the change in the level of interest rates.

```
PortfolioDuration  = PortfolioWeights' * Durations;
PortfolioConvexity = PortfolioWeights' * Convexities;
PercentApprox1 = -PortfolioDuration * dY * 100

PercentApprox2 =  PercentApprox1 + ...
PortfolioConvexity*dY^2*100/2.0
```

```
PercentApprox1 =

   -2.0636

PercentApprox2 =

   -2.0321
```

Step 5

Estimate the new portfolio price using the two estimates for the percent price change.

```
PriceApprox1  =  PortfolioPrice + ...
PercentApprox1 * PortfolioPrice/100

PriceApprox2  =  PortfolioPrice + ...
PercentApprox2 * PortfolioPrice/100
```

```
PriceApprox1 =

   9.7936e+04

PriceApprox2 =

   9.7968e+04
```

Step 6

Calculate the true new portfolio price by shifting the yield curve.

```
[CleanPrice, AccruedInterest] = bndprice(Yields + dY,...
CouponRate, Settle, Maturity, 2, 0, [], [], [], [], [],...
Face);

NewPrice = PortfolioAmounts' * (CleanPrice + AccruedInterest)
```

```
NewPrice =

   9.7968e+04
```

Step 7

Compare the results. The analysis results are as follows:

- The original portfolio price was $100,000.
- The yield curve shifted up by 0.2 percentage point or 20 basis points.
- The portfolio duration and convexity are 10.3181 and 157.6346, respectively. These are needed for "Bond Portfolio for Hedging Duration and Convexity" on page 10-6.
- The first-order approximation, based on modified duration, predicts the new portfolio price (`PriceApprox1`), which is $97,936.37.
- The second-order approximation, based on duration and convexity, predicts the new portfolio price (`PriceApprox2`), which is $97,968.90.
- The true new portfolio price (`NewPrice`) for this yield curve shift is $97,968.51.
- The estimate using duration and convexity is good (at least for this fairly small shift in the yield curve), but only slightly better than the estimate using duration alone. The importance of convexity increases as the magnitude of the yield curve shift increases. Try a larger shift (`dY`) to see this effect.

The approximation formulas in this example consider only parallel shifts in the term structure, because both formulas are functions of `dY`, the change in yield. The formulas are not well-defined unless each yield changes by the same amount. In actual financial markets, changes in yield curve level typically explain a substantial portion of bond price movements. However, other changes in the yield curve, such as slope, may also be important and are not captured here. Also, both formulas give local approximations whose accuracy deteriorates as `dY` increases in size. You can demonstrate this by running the program with larger values of `dY`.

Bond Portfolio for Hedging Duration and Convexity

This example constructs a bond portfolio to hedge the portfolio of “Sensitivity of Bond Prices to Interest Rates” on page 10-2. It assumes a long position in (holding) the portfolio, and that three other bonds are available for hedging. It chooses weights for these three other bonds in a new portfolio so that the duration and convexity of the new portfolio match those of the original portfolio. Taking a short position in the new portfolio, in an amount equal to the value of the first portfolio, partially hedges against parallel shifts in the yield curve.

Recall that portfolio duration or convexity is a weighted average of the durations or convexities of the individual bonds in a portfolio. As in the previous example, this example uses modified duration in years and convexity in years. The hedging problem therefore becomes one of solving a system of linear equations, which is an easy thing to do in MATLAB software.

Step 1

Define three bonds available for hedging the original portfolio. Specify values for the settlement date, maturity date, face value, and coupon rate. For simplicity, accept default values for the coupon payment periodicity (semiannual), end-of-month payment rule (rule in effect), and day-count basis (actual/actual). Also, synchronize the coupon payment structure to the maturity date (that is, no odd first or last coupon dates). Set any inputs for which defaults are accepted to empty matrices ([]) as placeholders where appropriate. The intent is to hedge against duration and convexity and constrain total portfolio price.

```
Settle     = '19-Aug-1999';
Maturity   = ['15-Jun-2005'; '02-Oct-2010'; '01-Mar-2025'];
Face       = [500; 1000; 250];
CouponRate = [0.07; 0.066; 0.08];
```

Also, specify the yield curve for each bond.

```
Yields = [0.06; 0.07; 0.075];
```

Step 2

Use Financial Toolbox functions to calculate the price, modified duration in years, and convexity in years of each bond.

The true price is quoted (clean price plus accrued interest).

```
[CleanPrice, AccruedInterest] = bndprice(Yields,CouponRate,...
Settle, Maturity, 2, 0, [], [], [], [], [], Face);

Durations = bnddury(Yields, CouponRate, Settle, Maturity,...
2, 0, [], [], [], [], [], Face);

Convexities = bndconvy(Yields, CouponRate, Settle,...
Maturity, 2, 0, [], [], [], [], [], Face);

Prices  =  CleanPrice + AccruedInterest
```

```
Prices =

  530.4248
  994.4065
  273.4051
```

Step 3

Set up and solve the system of linear equations whose solution is the weights of the new bonds in a new portfolio with the same duration and convexity as the original portfolio. In addition, scale the weights to sum to 1; that is, force them to be portfolio weights. You can then scale this unit portfolio to have the same price as the original portfolio. Recall that the original portfolio duration and convexity are 10.3181 and 157.6346, respectively. Also, note that the last row of the linear system ensures that the sum of the weights is unity.

```
A = [Durations'
     Convexities'
     1 1 1];

b = [ 10.3181
     157.6346
       1];

Weights = A\b

Weights =

   -0.3043
    0.7130
    0.5913
```

Step 4

Compute the duration and convexity of the hedge portfolio, which should now match the original portfolio.

```
PortfolioDuration  = Weights' * Durations
PortfolioConvexity = Weights' * Convexities

PortfolioDuration =

   10.3181

PortfolioConvexity =

  157.6346
```

Step 5

Finally, scale the unit portfolio to match the value of the original portfolio and find the number of bonds required to insulate against small parallel shifts in the yield curve.

```
PortfolioValue = 100000;
HedgeAmounts   = Weights ./ Prices * PortfolioValue

HedgeAmounts =

  -57.3716
   71.7044
  216.2653
```

Step 6

Compare the results.

- As required, the duration and convexity of the new portfolio are `10.3181` and `157.6346`, respectively.
- The hedge amounts for bonds 1, 2, and 3 are `-57.37`, `71.70`, and `216.27`, respectively.

Notice that the hedge matches the duration, convexity, and value ($100,000) of the original portfolio. If you are holding that first portfolio, you can hedge by taking a short position in the new portfolio.

Just as the approximations of the first example are appropriate only for small parallel shifts in the yield curve, the hedge portfolio is appropriate only for reducing the impact of small level changes in the term structure.

Bond Prices and Yield Curve Parallel Shifts

This example uses Financial Toolbox™ bond pricing functions to evaluate the impact of time-to-maturity and yield variation on the price of a bond portfolio. Also, this example shows how to visualize the price behavior of a portfolio of bonds over a wide range of yield curve scenarios, and as time progresses toward maturity.

Specify values for the settlement date, maturity date, face value, coupon rate, and coupon payment periodicity of a four-bond portfolio. For simplicity, accept default values for the end-of-month payment rule (rule in effect) and day-count basis (actual/actual). Also, synchronize the coupon payment structure to the maturity date (no odd first or last coupon dates). Any inputs for which defaults are accepted are set to empty matrices ([]) as placeholders where appropriate. Also, specify the points on the yield curve for each bond.

```
Settle     = datetime(1995,1,15);
Maturity   = datetime( [2020, 4, 3;...
                         2025, 5,14;...
                         2019, 6, 9;...
                         2019, 2,25])
```

```
Maturity = 4x1 datetime
   03-Apr-2020
   14-May-2025
   09-Jun-2019
   25-Feb-2019
```

```
Face       = [1000; 1000; 1000; 1000];
CouponRate = [0; 0.05; 0; 0.055];
Periods    = [0; 2; 0; 2];

Yields = [0.078; 0.09; 0.075; 0.085];
```

Use Financial Toolbox functions to calculate the true bond prices as the sum of the quoted price plus accrued interest.

```
[CleanPrice, AccruedInterest] = bndprice(Yields,...
CouponRate,Settle, Maturity, Periods,...
[], [], [], [], [], [], Face);

Prices  =  CleanPrice + AccruedInterest
```

```
Prices = 4×1

  145.2452
  594.7757
  165.8949
  715.7584
```

Assume that the value of each bond is $25,000, and determine the quantity of each bond such that the portfolio value is $100,000.

```
BondAmounts = 25000 ./ Prices;
```

Compute the portfolio price for a rolling series of settlement dates over a range of yields. The evaluation dates occur annually on January 15, beginning on 15-Jan-1995 (settlement) and extending out to 15-Jan-2018. Thus, this step evaluates portfolio price on a grid of time of progression (dT) and interest rates (dY).

```
dy = -0.05:0.005:0.05;               % Yield changes

D  = datevec(Settle);                % Get date components
dt = datetime(year(Settle):2018, month(Settle), day(Settle)); % Get evaluation dates

[dT, dY]  =  meshgrid(dt, dy); % Create grid

NumTimes  =  length(dt);       % Number of time steps
NumYields =  length(dy);       % Number of yield changes
NumBonds  =  length(Maturity); % Number of bonds

% Preallocate vector
Prices = zeros(NumTimes*NumYields, NumBonds);
```

Now that the grid and price vectors have been created, compute the price of each bond in the portfolio on the grid one bond at a time.

```
for i = 1:NumBonds

   [CleanPrice, AccruedInterest] = bndprice(Yields(i)+...
   dY(:), CouponRate(i), dT(:), Maturity(i), Periods(i),...
   [], [], [], [], [], [], Face(i));

   Prices(:,i) = CleanPrice + AccruedInterest;

end
```

Scale the bond prices by the quantity of bonds and reshape the bond values to conform to the underlying evaluation grid.

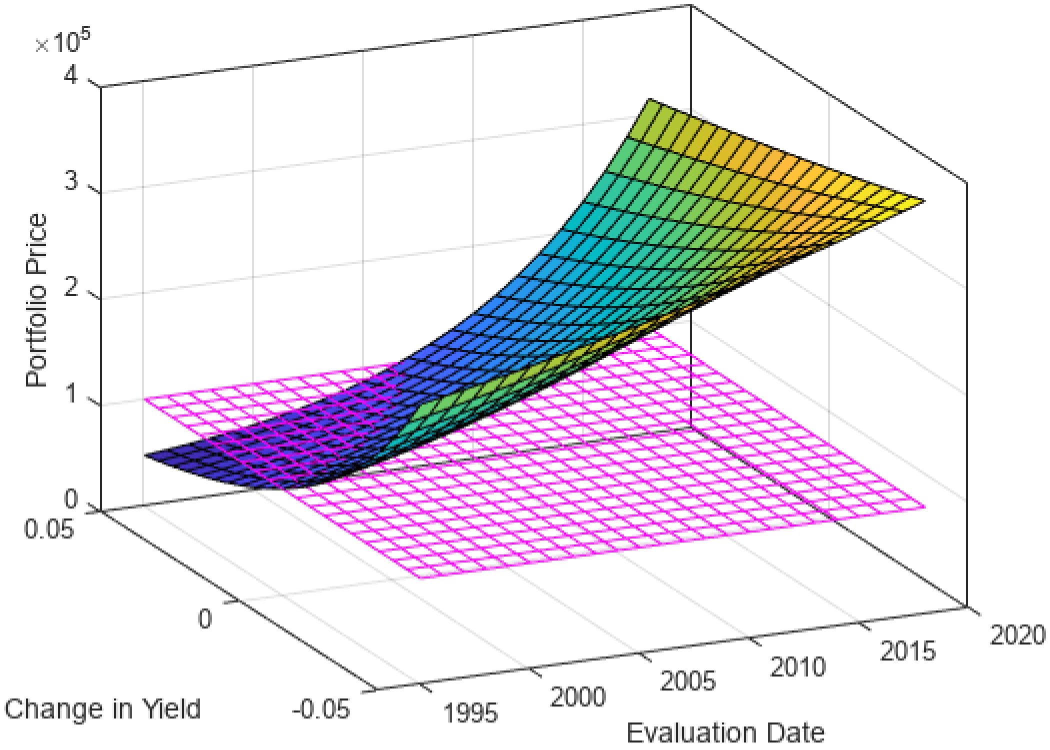
```
Prices = Prices * BondAmounts;
Prices = reshape(Prices, NumYields, NumTimes);
```

Plot the price of the portfolio as a function of settlement date and a range of yields, and as a function of the change in yield (dY). This plot illustrates the interest-rate sensitivity of the portfolio as time progresses (dT), under a range of interest-rate scenarios. With the following graphics commands, you can visualize the three-dimensional surface relative to the current portfolio value (that is, $100,000).

```
figure                   % Open a new figure window
surf(dt, dy, Prices)     % Draw the surface

hold on                  % Add the current value for reference
basemesh = mesh(dt, dy, 100000*ones(NumYields, NumTimes));
set(basemesh, 'facecolor', 'none');
set(basemesh, 'edgecolor', 'm');
set(gca, 'box', 'on');

xlim(datetime([1993,2020],1,1))
xlabel('Evaluation Date');
ylabel('Change in Yield');
zlabel('Portfolio Price');
hold off
view(-25,25);
```



MATLAB® three-dimensional graphics allow you to visualize the interest-rate risk experienced by a bond portfolio over time. This example assumed parallel shifts in the term structure, but it might similarly have allowed other components to vary, such as the level and slope.

Bond Prices and Yield Curve Nonparallel Shifts

This example shows how to construct a bond portfolio to hedge the interest-rate risk of a Treasury bond maturing in 20 years. Key rate duration enables you to determine the sensitivity of the price of a bond to nonparallel shifts in the yield curve. This example uses `bndkrdur` to construct a portfolio to hedge the interest-rate risk of a U.S. Treasury bond maturing in 20 years.

Specify the bond.

```
Settle = datetime(2008,12,2);
CouponRate = 5.500/100;
Maturity = datetime(2028,8,15);
Price = 128.68;
```

The interest-rate risk of this bond is hedged with the following four on-the-run Treasury bonds:

```
Maturity_30 = datetime(2038,5,15);  % 30-year bond
Coupon_30 = .045;
Price_30 = 124.69;

Maturity_10 = datetime(2018,11,15);  %10-year note
Coupon_10 = .0375;
Price_10 = 109.35;

Maturity_05 = datetime(2013,11,30);  % 5-year note
Coupon_05 = .02;
Price_05 = 101.67;

Maturity_02 = datetime(2010,11,30);  % 2-year note
Coupon_02 = .01250;
Price_02 =  100.72;
```

You can get the Treasury spot or zero curve from https://www.treas.gov/offices/domestic-finance/debt-management/interest-rate/yield.shtml:

```
ZeroDates = daysadd(Settle,[30 90 180 360 360*2 360*3 360*5 ...
360*7 360*10 360*20 360*30]);
ZeroRates = ([0.09 0.07 0.44 0.81 0.90 1.16 1.71 2.13 2.72 3.51 3.22]/100)';
```

Compute the key rate durations for both the bond and the hedging portfolio.

```
BondKRD = bndkrdur(table(ZeroDates, ZeroRates), CouponRate, Settle,...
Maturity,'keyrates',[2 5 10 20]);
HedgeMaturity = [Maturity_02;Maturity_05;Maturity_10;Maturity_30];
HedgeCoupon = [Coupon_02;Coupon_05;Coupon_10;Coupon_30];
HedgeKRD = bndkrdur(table(ZeroDates, ZeroRates), HedgeCoupon,...
Settle, HedgeMaturity, 'keyrates',[2 5 10 20])
```

```
HedgeKRD = 4×4

    1.9675         0         0         0
    0.1269    4.6152         0         0
    0.2129    0.7324    7.4010         0
    0.2229    0.7081    2.1487   14.5172
```

Compute the dollar durations for each of the instruments and each of the key rates (assuming holding 100 bonds).

```
PortfolioDD = 100*Price* BondKRD;
HedgeDD = HedgeKRD.*[Price_30;Price_10;Price_05;Price_02]
```

```
HedgeDD = 4×4
10^3 ×

    0.2453         0         0         0
    0.0139    0.5047         0         0
    0.0216    0.0745    0.7525         0
    0.0224    0.0713    0.2164    1.4622
```

Compute the number of bonds to sell short to obtain a key rate duration that is `0` for the entire portfolio.

```
NumBonds = PortfolioDD/HedgeDD
```

```
NumBonds = 1×4

    3.8973    6.1596   23.0282   80.0522
```

These results indicate selling 4, 6, 23 and 80 bonds respectively of the 2-, 5-, 10-, and 30-year bonds achieves a portfolio that is neutral with respect to the 2-, 5-, 10-, and 30-year spot rates.

Greek-Neutral Portfolios of European Stock Options

The option sensitivity measures familiar to most option traders are often referred to as the *greeks*: *delta*, *gamma*, *vega*, *lambda*, *rho*, and *theta*. Delta is the price sensitivity of an option with respect to changes in the price of the underlying asset. It represents a first-order sensitivity measure analogous to duration in fixed income markets. Gamma is the sensitivity of an option's delta to changes in the price of the underlying asset, and represents a second-order price sensitivity analogous to convexity in fixed income markets. Vega is the price sensitivity of an option with respect to changes in the volatility of the underlying asset. For more information, see “Pricing and Analyzing Equity Derivatives” on page 2-39.

The greeks of a particular option are a function of the model used to price the option. However, given enough different options to work with, a trader can construct a portfolio with any desired values for its greeks. For example, to insulate the value of an option portfolio from small changes in the price of the underlying asset, one trader might construct an option portfolio whose delta is zero. Such a portfolio is then said to be “delta neutral.” Another trader may want to protect an option portfolio from larger changes in the price of the underlying asset, and so might construct a portfolio whose delta and gamma are both zero. Such a portfolio is both delta and gamma neutral. A third trader may want to construct a portfolio insulated from small changes in the volatility of the underlying asset in addition to delta and gamma neutrality. Such a portfolio is then delta, gamma, and vega neutral.

Using the Black-Scholes model for European options, this example creates an equity option portfolio that is simultaneously delta, gamma, and vega neutral. The value of a particular greek of an option portfolio is a weighted average of the corresponding greek of each individual option. The weights are the quantity of each option in the portfolio. Hedging an option portfolio thus involves solving a system of linear equations, an easy process in MATLAB.

Step 1

Create an input data matrix to summarize the relevant information. Each row of the matrix contains the standard inputs to Financial Toolbox Black-Scholes suite of functions: column 1 contains the current price of the underlying stock; column 2 the strike price of each option; column 3 the time to-expiry of each option in years; column 4 the annualized stock price volatility; and column 5 the annualized dividend rate of the underlying asset. Rows 1 and 3 are data related to call options, while rows 2 and 4 are data related to put options.

```
DataMatrix = [100.000  100  0.2  0.3   0        % Call
              119.100  125  0.2  0.2   0.025    % Put
               87.200   85  0.1  0.23  0        % Call
              301.125  315  0.5  0.25  0.0333]; % Put
```

Also, assume that the annualized risk-free rate is 10% and is constant for all maturities of interest.

```
RiskFreeRate = 0.10;
```

For clarity, assign each column of `DataMatrix` to a column vector whose name reflects the type of financial data in the column.

```
StockPrice   = DataMatrix(:,1);
StrikePrice  = DataMatrix(:,2);
ExpiryTime   = DataMatrix(:,3);
Volatility   = DataMatrix(:,4);
DividendRate = DataMatrix(:,5);
```

Step 2

Based on the Black-Scholes model, compute the prices, and the delta, gamma, and vega sensitivity greeks of each of the four options. The functions `blsprice` and `blsdelta` have two outputs, while `blsgamma` and `blsvega` have only one. The price and delta of a call option differ from the price and delta of an otherwise equivalent put option, in contrast to the gamma and vega sensitivities, which are valid for both calls and puts.

```
[CallPrices, PutPrices] = blsprice(StockPrice, StrikePrice,...
RiskFreeRate, ExpiryTime, Volatility, DividendRate);

[CallDeltas, PutDeltas] = blsdelta(StockPrice,...
StrikePrice, RiskFreeRate, ExpiryTime, Volatility,...
DividendRate);

Gammas = blsgamma(StockPrice, StrikePrice, RiskFreeRate,...
                  ExpiryTime, Volatility , DividendRate)'

Vegas  = blsvega(StockPrice, StrikePrice, RiskFreeRate,...
                 ExpiryTime, Volatility , DividendRate)'
```

```
Gammas =

    0.0290    0.0353    0.0548    0.0074

Vegas =

   17.4293   20.0347    9.5837   83.5225
```

Extract the prices and deltas of interest to account for the distinction between call and puts.

```
Prices = [CallPrices(1) PutPrices(2) CallPrices(3)...
PutPrices(4)]

Deltas = [CallDeltas(1) PutDeltas(2) CallDeltas(3)...
PutDeltas(4)]
```

```
Prices =

    6.3441    6.6035    4.2993   22.7694

Deltas =

    0.5856   -0.6255    0.7003   -0.4830
```

Step 3

Now, assuming an arbitrary portfolio value of $17,000, set up and solve the linear system of equations such that the overall option portfolio is simultaneously delta, gamma, and vega-neutral. The solution computes the value of a particular greek of a portfolio of options as a weighted average of the corresponding greek of each individual option in the portfolio. The system of equations is solved using the back slash (\) operator discussed in “Solving Simultaneous Linear Equations” on page 1-11.

```
A = [Deltas; Gammas; Vegas; Prices];
b = [0; 0; 0; 17000];
OptionQuantities = A\b % Quantity (number) of each option.
OptionQuantities =

   1.0e+04 *

    2.2333
    0.6864
   -1.5655
   -0.4511
```

Step 4

Finally, compute the market value, delta, gamma, and vega of the overall portfolio as a weighted average of the corresponding parameters of the component options. The weighted average is computed as an inner product of two vectors.

```
PortfolioValue =  Prices * OptionQuantities
PortfolioDelta =  Deltas * OptionQuantities
PortfolioGamma =  Gammas * OptionQuantities
PortfolioVega  =  Vegas  * OptionQuantities
```

```
PortfolioValue =

       17000

PortfolioDelta =

   1.8190e-12

PortfolioGamma =

     0

PortfolioVega =

     0
```

The output for these computations is:

```
Option  Price    Delta    Gamma    Vega     Quantity
   1   6.3441   0.5856   0.0290  17.4293   22332.6131
   2   6.6035  -0.6255   0.0353  20.0347    6864.0731
   3   4.2993   0.7003   0.0548   9.5837  -15654.8657
   4  22.7694  -0.4830   0.0074  83.5225   -4510.5153
```

You can verify that the portfolio value is $17,000 and that the option portfolio is indeed delta, gamma, and vega neutral, as desired. Hedges based on these measures are effective only for small changes in the underlying variables.

Term Structure Analysis and Interest-Rate Swaps

This example illustrates some of the term-structure analysis functions found in Financial Toolbox software. Specifically, it illustrates how to derive implied zero (*spot*) and forward curves from the observed market prices of coupon-bearing bonds. The zero and forward curves implied from the market data are then used to price an interest rate swap agreement.

In an interest rate swap, two parties agree to a periodic exchange of cash flows. One of the cash flows is based on a fixed interest rate held constant throughout the life of the swap. The other cash flow stream is tied to some variable index rate. Pricing a swap at inception amounts to finding the fixed rate of the swap agreement. This fixed rate, appropriately scaled by the notional principal of the swap agreement, determines the periodic sequence of fixed cash flows.

In general, interest rate swaps are priced from the forward curve such that the variable cash flows implied from the series of forward rates and the periodic sequence of fixed-rate cash flows have the same current value. Thus, interest rate swap pricing and term structure analysis are intimately related.

Step 1

Specify values for the settlement date, maturity dates, coupon rates, and market prices for 10 U.S. Treasury Bonds. This data allows you to price a five-year swap with net cash flow payments exchanged every six months. For simplicity, accept default values for the end-of-month payment rule (rule in effect) and day-count basis (actual/actual). To avoid issues of accrued interest, assume that all Treasury Bonds pay semiannual coupons and that settlement occurs on a coupon payment date.

```
Settle   = datenum('15-Jan-1999');

BondData = {'15-Jul-1999'  0.06000   99.93
            '15-Jan-2000'  0.06125   99.72
            '15-Jul-2000'  0.06375   99.70
            '15-Jan-2001'  0.06500   99.40
            '15-Jul-2001'  0.06875   99.73
            '15-Jan-2002'  0.07000   99.42
            '15-Jul-2002'  0.07250   99.32
            '15-Jan-2003'  0.07375   98.45
            '15-Jul-2003'  0.07500   97.71
            '15-Jan-2004'  0.08000   98.15};
```

`BondData` is an instance of a MATLAB *cell array*, indicated by the curly braces ({}).

Next assign the date stored in the cell array to `Maturity`, `CouponRate`, and `Prices` vectors for further processing.

```
Maturity   = datenum(char(BondData{:,1}));
CouponRate = [BondData{:,2}]';
Prices     = [BondData{:,3}]';
Period     = 2; % semiannual coupons
```

Step 2

Now that the data has been specified, use the term structure function `zbtprice` to bootstrap the zero curve implied from the prices of the coupon-bearing bonds. This implied zero curve represents the series of zero-coupon Treasury rates consistent with the prices of the coupon-bearing bonds such that arbitrage opportunities will not exist.

```
ZeroRates = zbtprice([Maturity CouponRate], Prices, Settle)
```

```
ZeroRates =

    0.0614
    0.0642
    0.0660
    0.0684
    0.0702
    0.0726
    0.0754
    0.0795
    0.0827
    0.0868
```

The zero curve, stored in `ZeroRates`, is quoted on a semiannual bond basis (the periodic, six-month, interest rate is doubled to annualize). The first element of `ZeroRates` is the annualized rate over the next six months, the second element is the annualized rate over the next 12 months, and so on.

Step 3

From the implied zero curve, find the corresponding series of implied forward rates using the term structure function `zero2fwd`.

```
ForwardRates = zero2fwd(ZeroRates, Maturity, Settle)
```

```
ForwardRates =

    0.0614
    0.0670
    0.0695
    0.0758
    0.0774
    0.0846
    0.0925
    0.1077
    0.1089
    0.1239
```

The forward curve, stored in `ForwardRates`, is also quoted on a semiannual bond basis. The first element of `ForwardRates` is the annualized rate applied to the interval between settlement and six months after settlement, the second element is the annualized rate applied to the interval from six months to 12 months after settlement, and so on. This implied forward curve is also consistent with the observed market prices such that arbitrage activities will be unprofitable. Since the first forward rate is also a zero rate, the first element of `ZeroRates` and `ForwardRates` are the same.

Step 4

Now that you have derived the zero curve, convert it to a sequence of discount factors with the term structure function `zero2disc`.

```
DiscountFactors = zero2disc(ZeroRates, Maturity, Settle)
DiscountFactors =

    0.9704
    0.9387
    0.9073
    0.8739
    0.8416
    0.8072
    0.7718
    0.7320
    0.6945
    0.6537
```

Step 5

From the discount factors, compute the present value of the variable cash flows derived from the implied forward rates. For plain interest rate swaps, the notional principal remains constant for each payment date and cancels out of each side of the present value equation. The next line assumes unit notional principal.

```
PresentValue = sum((ForwardRates/Period) .* DiscountFactors)
```

```
PresentValue =

    0.3460
```

Step 6

Compute the swap's price (the fixed rate) by equating the present value of the fixed cash flows with the present value of the cash flows derived from the implied forward rates. Again, since the notional principal cancels out of each side of the equation, it is assumed to be 1.

```
SwapFixedRate = Period * PresentValue / sum(DiscountFactors)
```

```
SwapFixedRate =

    0.0845
```

The output for these computations is:

```
  Zero Rates  Forward Rates
    0.0614       0.0614
    0.0642       0.0670
    0.0660       0.0695
    0.0684       0.0758
    0.0702       0.0774
    0.0726       0.0846
    0.0754       0.0925
    0.0795       0.1077
    0.0827       0.1089
    0.0868       0.1239

  Swap Price (Fixed Rate) = 0.0845
```

All rates are in decimal format. The swap price, 8.45%, would likely be the mid-point between a market-maker's bid/ask quotes.

Plotting an Efficient Frontier Using portopt

This example plots the efficient frontier of a hypothetical portfolio of three assets. It illustrates how to specify the expected returns, standard deviations, and correlations of a portfolio of assets, how to convert standard deviations and correlations into a covariance matrix, and how to compute and plot the efficient frontier from the returns and covariance matrix. The example also illustrates how to randomly generate a set of portfolio weights, and how to add the random portfolios to an existing plot for comparison with the efficient frontier.

First, specify the expected returns, standard deviations, and correlation matrix for a hypothetical portfolio of three assets.

```
Returns      = [0.1 0.15 0.12];
STDs         = [0.2 0.25 0.18];

Correlations = [ 1  0.3  0.4
                0.3  1   0.3
                0.4 0.3   1 ];
```

Convert the standard deviations and correlation matrix into a variance-covariance matrix with the function `corr2cov`.

```
Covariances = corr2cov(STDs, Correlations)
```

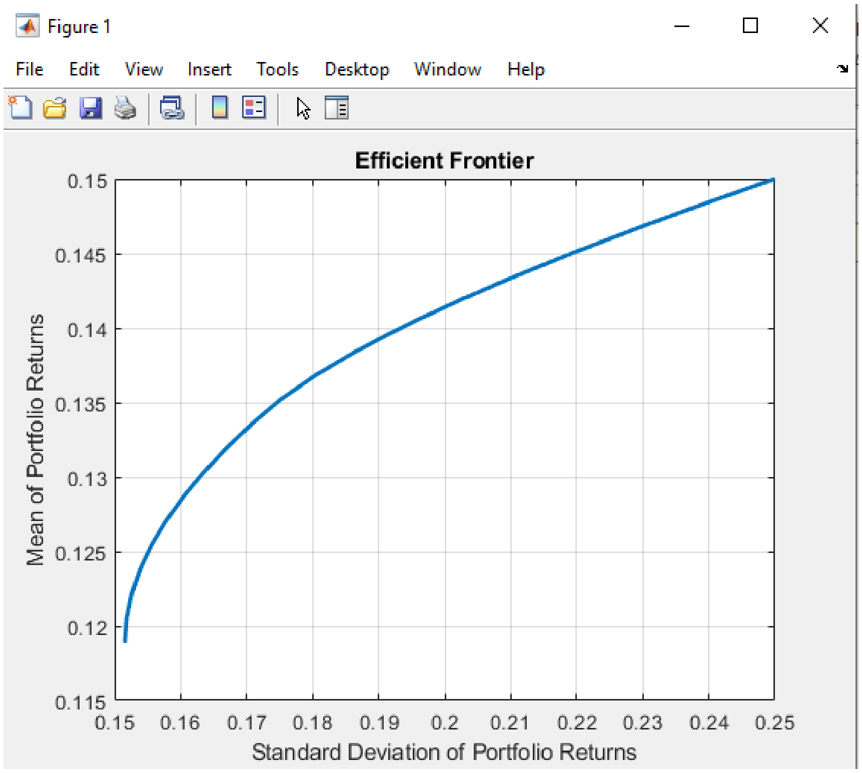
```
Covariances =

    0.0400    0.0150    0.0144
    0.0150    0.0625    0.0135
    0.0144    0.0135    0.0324
```

Evaluate and plot the efficient frontier at 20 points along the frontier, using the function `portopt` and the expected returns and corresponding covariance matrix. Although rather elaborate constraints can be placed on the assets in a portfolio, for simplicity accept the default constraints and scale the total value of the portfolio to 1 and constrain the weights to be positive (no short-selling).

Note `portopt` has been partially removed and will no longer accept `ConSet` or `varargin` arguments. Use `Portfolio` object instead to solve portfolio problems that are more than a long-only fully-invested portfolio. For information on the workflow when using Portfolio objects, see “Portfolio Object Workflow” on page 4-17. For more information on migrating `portopt` code to `Portfolio`, see “portopt Migration to Portfolio Object” on page 3-11.

```
portopt(Returns, Covariances, 20)
```



Now that the efficient frontier is displayed, randomly generate the asset weights for 1000 portfolios starting from the MATLAB initial state.

```
rng('default')
Weights = rand(1000, 3);
```

The previous line of code generates three columns of uniformly distributed random weights, but does not guarantee they sum to 1. The following code segment normalizes the weights of each portfolio so that the total of the three weights represent a valid portfolio.

```
Total = sum(Weights, 2);     % Add the weights
Total = Total(:,ones(3,1)); % Make size-compatible matrix
Weights = Weights./Total;    % Normalize so sum = 1
```

Given the 1000 random portfolios created, compute the expected return and risk of each portfolio associated with the weights.

```
[PortRisk, PortReturn] = portstats(Returns, Covariances, Weights);
```

Finally, hold the current graph, and plot the returns and risks of each portfolio on top of the existing efficient frontier for comparison. After plotting, annotate the graph with a title and return the graph to default holding status (any subsequent plots will erase the existing data). The efficient frontier appears in blue, while the 1000 random portfolios appear as a set of red dots on or below the frontier.

```
hold on
plot (PortRisk, PortReturn, '.r')
title('Mean-Variance Efficient Frontier and Random Portfolios')
hold off
```

Plotting Sensitivities of an Option

This example creates a three-dimensional plot showing how gamma changes relative to price for a Black-Scholes option.

Recall that gamma is the second derivative of the option price relative to the underlying security price. The plot in this example shows a three-dimensional surface whose *z*-value is the gamma of an option as price (*x*-axis) and time (*y*-axis) vary. The plot adds yet a fourth dimension by showing option delta (the first derivative of option price to security price) as the color of the surface. First set the price range of the options, and set the time range to one year divided into half-months and expressed as fractions of a year.

```
Range = 10:70;
Span = length(Range);
j = 1:0.5:12;
Newj = j(ones(Span,1),:)'/12;
```

For each time period, create a vector of prices from 10 to 70 and create a matrix of all ones.

```
JSpan = ones(length(j),1);
NewRange = Range(JSpan,:);
Pad = ones(size(Newj));
```

Calculate the gamma and delta sensitivities (greeks) using the `blsgamma` and `blsdelta` functions. Gamma is the second derivative of the option price with respect to the stock price, and delta is the first derivative of the option price with respect to the stock price. The exercise price is $40, the risk-free interest rate is 10%, and volatility is 0.35 for all prices and periods.

```
ZVal = blsgamma(NewRange, 40*Pad, 0.1*Pad, Newj, 0.35*Pad);
Color = blsdelta(NewRange, 40*Pad, 0.1*Pad, Newj, 0.35*Pad);
```

Display the greeks as a function of price and time. Gamma is the *z*-axis; delta is the color.

```
mesh(Range, j, ZVal, Color);
xlabel('Stock Price ($)');
ylabel('Time (months)');
zlabel('Gamma');
title('Call Option Price Sensitivity');
axis([10 70  1 12  -inf inf]);
view(-40, 50);
colorbar('horiz');
```

Plotting Sensitivities of a Portfolio of Options

This example plots *gamma* as a function of price and time for a portfolio of ten Black-Scholes options.

The plot in this example shows a three-dimensional surface. For each point on the surface, the height (*z*-value) represents the sum of the gammas for each option in the portfolio weighted by the amount of each option. The *x*-axis represents changing price, and the *y*-axis represents time. The plot adds a fourth dimension by showing delta as surface color. This example has applications in hedging. First set up the portfolio with arbitrary data. Current prices range from $20 to $90 for each option. Then, set the corresponding exercise prices for each option.

```
Range = 20:90;
PLen = length(Range);
ExPrice = [75 70 50 55 75 50 40 75 60 35];
```

Set all risk-free interest rates to 10%, and set times to maturity in days. Set all volatilities to 0.35. Set the number of options of each instrument, and allocate space for matrices.

```
Rate = 0.1*ones(10,1);
Time = [36  36  36  27  18  18  18  9  9  9];
Sigma = 0.35*ones(10,1);
NumOpt = 1000*[4  8  3  5  5.5  2  4.8  3  4.8  2.5];
ZVal = zeros(36, PLen);
Color = zeros(36, PLen);
```

For each instrument, create a matrix (of size `Time` by `PLen`) of prices for each period.

```
for i = 1:10
    Pad = ones(Time(i),PLen);
    NewR = Range(ones(Time(i),1),:);
```

Create a vector of time periods `1` to `Time` and a matrix of times, one column for each price.

```
  T = (1:Time(i))';
  NewT = T(:,ones(PLen,1));
```

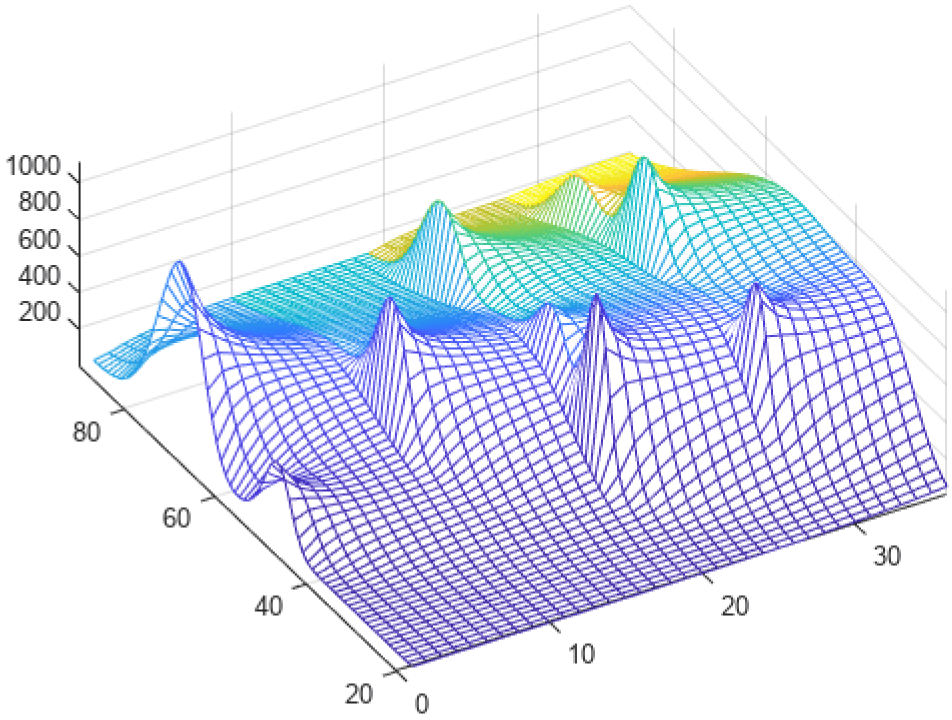
Use the Black-Scholes gamma and delta sensitivity functions `blsgamma` and `blsdelta` to compute *gamma* and *delta*.

```
    ZVal(36-Time(i)+1:36,:) = ZVal(36-Time(i)+1:36,:) ...
        + NumOpt(i) * blsgamma(NewR, ExPrice(i)*Pad, ...
        Rate(i)*Pad, NewT/36, Sigma(i)*Pad);

    Color(36-Time(i)+1:36,:) = Color(36-Time(i)+1:36,:) ...
        + NumOpt(i) * blsdelta(NewR, ExPrice(i)*Pad, ...
        Rate(i)*Pad, NewT/36, Sigma(i)*Pad);
end
```

Draw the surface as a mesh, set the viewpoint, and reverse the *x*-axis because of the viewpoint. The axes range from `20` to `90`, `0` to `36`, and -∞ to ∞.

```
mesh(Range, 1:36, ZVal, Color);
view(60,60);
set(gca, 'xdir','reverse', 'tag', 'mesh_axes_3');
axis([20 90  0 36  -inf inf]);
```



Add a title and axis labels and draw a box around the plot. Annotate the colors with a bar and label the color bar.

```
title('Call Option Portfolio Sensitivity');
xlabel('Stock Price ($)');
ylabel('Time (months)');
zlabel('Gamma');
set(gca, 'box', 'on');
colorbar('horiz');
```

Bond Portfolio Optimization Using Portfolio Object

This example shows how to use a `Portfolio` object to construct an optimal portfolio of 10, 20, and 30 year treasuries that will be held for a period of one month. The workflow for the overall asset allocation process is:

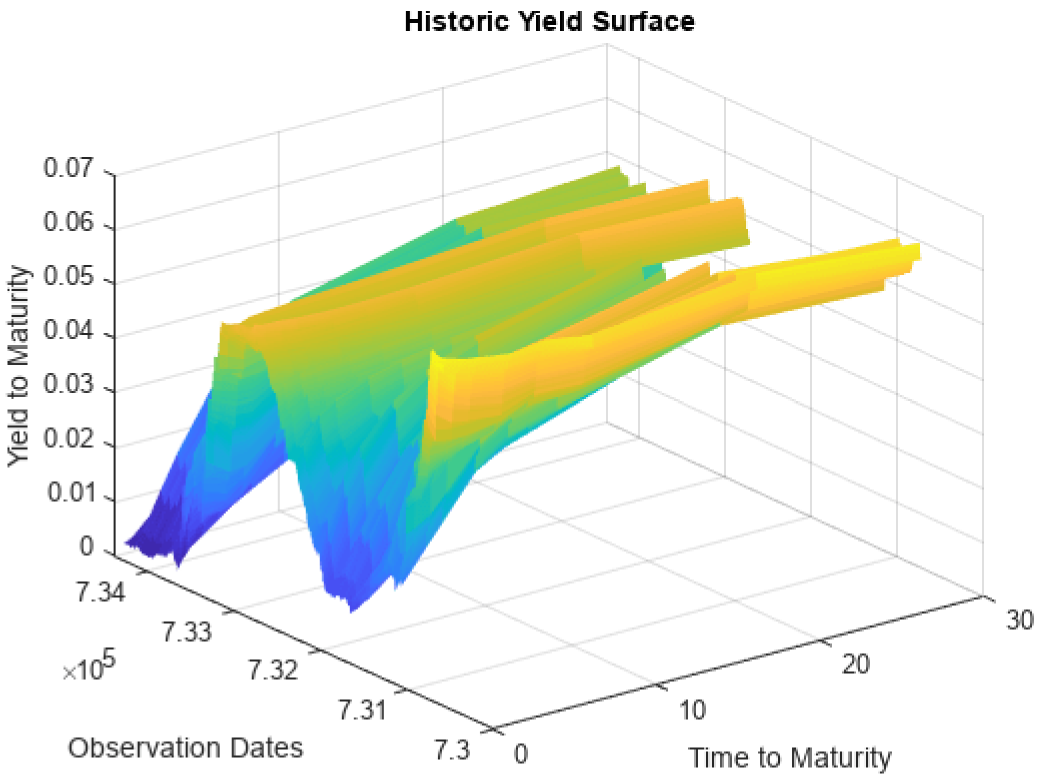
1. Load market data — Historic daily treasury yields downloaded from FRED® are loaded.
2. Calculate market invariants — Daily changes in yield to maturity are chosen as invariants and assumed to be multivariate normal. Due to missing data for the 30 year bonds, an expectation maximization algorithm is used to estimate the mean and covariance of the invariants. The invariant's statistics are projected to the investment horizon.
3. Simulate invariants at horizon — Due to the high correlation and inherent structure in the yield curves, a principal component analysis is applied to the invariant statistics. Multivariate normal random draws are done in the PCA space. The simulations are transformed back into the invariant space using the PCA loadings.
4. Calculate distribution of returns at horizon — The simulated monthly changes in the yield curve are used to calculate the yield for the portfolio securities at the horizon. This requires interpolating values off of the simulated yield curves since the portfolio securities will have maturities that are one month less than 10, 20 and 30 years. Profit and loss for each scenario/security is calculated by pricing the treasuries using the simulated and interpolated yields. Simulated linear returns and their statistics are calculated from the prices.
5. Optimize asset allocation — Using a `Portfolio` object, mean-variance optimization is performed on the treasury returns statistics to calculate optimal portfolio weights for ten points along the efficient frontier. The investor preference is to choose the portfolio that is closest to the mean value of possible Sharpe ratios.

Load Market Data

Load the historic yield-to-maturity data for the series: DGS6MO, DGS1, DGS2, DGS3, DGS5, DGS7, DGS10, DGS20, DGS30 for the dates: Sep 1, 2000 to Sep 1, 2010 obtained from: https://fred.stlouisfed.org/categories/115 Note: Data is downloaded using Datafeed Toolbox™ using commands like: `>> conn = fred; >> data = fetch(conn,'DGS10','9/1/2000','9/1/2010');` results have been aggregated and stored in a binary `HistoricalYTMData.mat` file for convinience.

```
histData = load('HistoricalYTMData.mat');
% Time to maturity for each series
tsYTMMats = histData.tsYTMMats;
% Dates that rates were observed
tsYTMObsDates = histData.tsYTMObsDates;
% Observed rates
tsYTMRates = histData.tsYTMRates;

% Visualize the yield surface
[X,Y] = meshgrid(tsYTMMats,tsYTMObsDates);
surf(X,Y,tsYTMRates,EdgeColor='none')
xlabel('Time to Maturity')
ylabel('Observation Dates')
zlabel('Yield to Maturity')
title('Historic Yield Surface')
```



Calculate Market Invariants

For market invariants, use the standard: daily changes in yield to maturity for each series. You can estimate their statistical distribution to be multivariate normal. IID analysis on each invariant series produces decent results - more so in the "independent" factor than "identical". A more thorough modeling using more complex distributions and/or time series models is beyond the scope of this example. What will need to be accounted for is the estimation of distribution parameters in the the presence of missing data. The 30 year bonds were discontinued for a period between Feb 2002 and Feb 2006, so there are no yields for this time period.

```
% Invariants are assumed to be daily changes in YTM rates.
tsYTMRateDeltas = diff(tsYTMRates);
```

About 1/3 of the 30 year rates (column 9) are missing from the original data set. Rather than throw out all these observations, an expectation maximization routine `ecmnmle` is used to estimate the mean and covariance of the invariants. The default option (NaN skip for initial estimates) is used.

```
[tsInvMu,tsInvCov] = ecmnmle(tsYTMRateDeltas);
```

Calculate standard deviations and correlations using `cov2corr`.

```
[tsInvStd,tsInvCorr] = cov2corr(tsInvCov);
```

The investment horizon is 1 month. (21 business days between 9/1/2010 and 10/1/2010). Since the invariants are summable and the means and variances of normal distributions are normal, you can project the invariants to the investment horizon as follows:

```
hrznInvMu = 21*tsInvMu';
hrznInvCov = 21*tsInvCov;
[hrznInvStd,hrznInvCor] = cov2corr(hrznInvCov);
```

The market invariants projected to the horizon have the following statistics:

```

```

Simulate Market Invariants at Horizon

The high correlation is not ideal for simulation of the distribution of invariants at the horizon (and ultimately security prices). Use a principal component decomposition to extract orthogonal invariants. This could also be used for dimension reduction, however since the number of invariants is still relatively small, retain all nine components for more accurate reconstruction. However, missing values in the market data prevents you from estimating directly off of the time series data. Instead, this can be done directly off of the covariance matrix

```
% Perform PCA decomposition using the invariants' covariance.
[pcaFactorCoeff,pcaFactorVar,pcaFactorExp] = pcacov(hrznInvCov);

% Keep all components of pca decompositon.
numFactors = 9;

% Create a PCA factor covariance matrix.
pcaFactorCov = corr2cov(sqrt(pcaFactorVar),eye(numFactors));

% Define the number of simulations (random draws).
numSim = 10000;
```

```
% Fix the random seed for reproducible results.
stream = RandStream('mrg32k3a');
RandStream.setGlobalStream(stream);

% Take random draws from a multivariate normal distribution with zero mean
% and diagonal covariance.
pcaFactorSims = mvnrnd(zeros(numFactors,1),pcaFactorCov,numSim);

% Transform to horizon invariants and calculate the statistics.
hrznInvSims = pcaFactorSims*pcaFactorCoeff + repmat(hrznInvMu,numSim,1);
hrznInvSimsMu = mean(hrznInvSims);
hrznInvSimsCov = cov(hrznInvSims);
[hrznInvSimsStd,hrznInvSimsCor] = cov2corr(hrznInvSimsCov);
```

The simulated invariants have very similar statistics to the original invariants:

```

Calculate Distribution of Security Returns at Horizon

The portfolio will consist of 10, 20, and 30 year maturity treasuries. For simplicity, assume that these are new issues on the settlement date and are priced at market value inferred from the current yield curve. Profit and loss distributions are calculated by pricing each security along each simulated yield at the horizon and subtracting the purchase price. The horizon prices require nonstandard time to maturity yields. These are calculated using cubic spline interpolation. Simulated linear returns are their statistics that are calculated from the profit and loss scenarios.

```
% Define the purchase and investment horizon dates.
settleDate = datetime(2010,9,1);
hrznDate = datetime(2010,10,1);

% Define the maturity dates for new issue treasuries purchased on the
% settle date.
treasuryMaturities = [datetime(2020,9,1) , datetime(2030,9,1) , datetime(2040,9,1)];

% Select the observed yields for the securities of interest on the
% settle date.
treasuryYTMAtSettle = tsYTMRates(end,7:9);

% Initialize arrays for later use.
treasuryYTMAtHorizonSim = zeros(numSim,3);
treasuryPricesAtSettle = zeros(1,3);
treasuryPricesAtHorizonSim = zeros(numSim,3);

% Use actual/actual day count basis with annualized yields.
basis = 8;
```

Price the treasuries at settle date with `bndprice` using the known yield to maturity. For simplicity, assume that none of these securities include coupon payments. Although the prices may not be accurate, the overall structure/relationships between values is preserved for the asset allocation process.

```
for j=1:3
    treasuryPricesAtSettle(j) = bndprice(treasuryYTMAtSettle(j),0,settleDate,...
                                         treasuryMaturities(j),'basis',basis);
end
```

To price the treasuries at the horizon, you need to know yield to maturity at 9 years 11 months, 19 years 11 months, and 29 years 11 months for each simulation. You can approximate these using cubic spline interpolation using `interp1`.

```
% Transform the simulated invariants to YTM at the horizon.
hrznYTMRatesSims = repmat(tsYTMRates(end,:),numSim,1) + hrznInvSims;

hrznYTMMaturities = [datetime(2011,4,1),datetime(2011,10,1),datetime(2012,10,1),datetime(2013,10

% Convert the dates to numeric serial dates.
x = datenum(hrznYTMMaturities);
xi = datenum(treasuryMaturities);

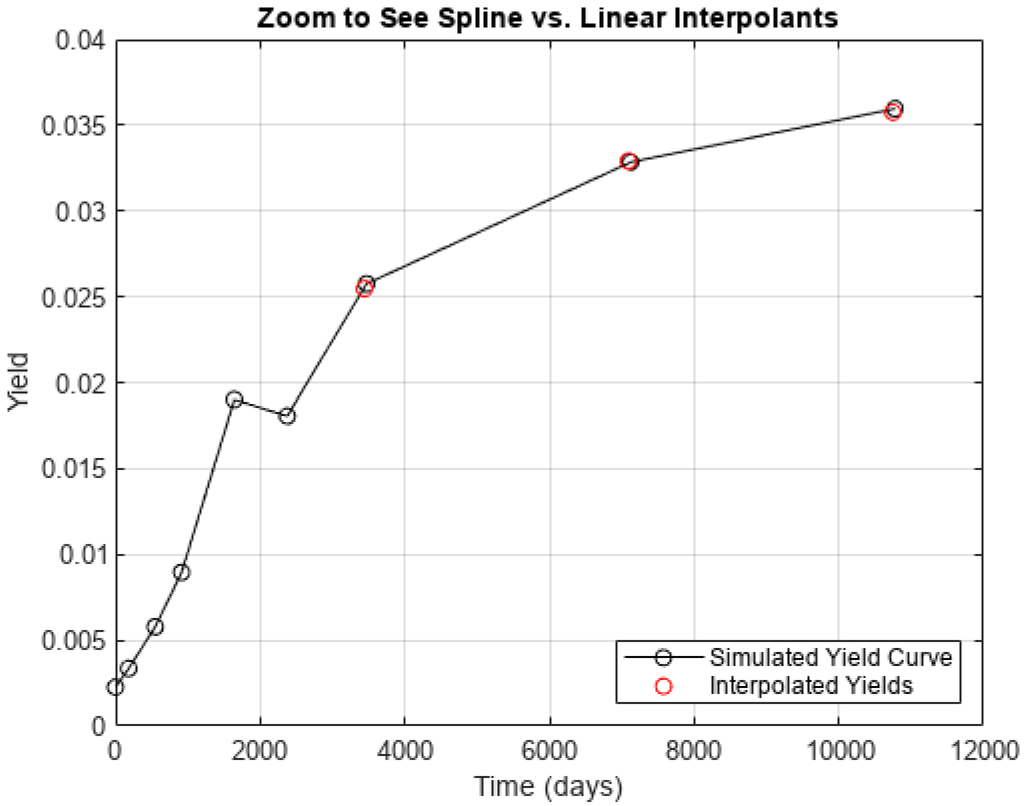
% For numerical accuracy, shift the x values to start at zero.
minDate = min(x);
x = x - minDate;
xi = xi - minDate;
```

For each simulation and maturity approximate yield near 10,20, and 30 year nodes. Note that the effects of a spline fit vs. linear fit have a significant effect on the resulting ideal allocation. This is due to significant under-estimation of yield when using a linear fit for points just short of the known nodes.

```
for i=1:numSim
    treasuryYTMAtHorizonSim(i,:) = interp1(x,hrznYTMRatesSims(i,:),xi,'spline');
end

% Visualize a simulated yield curve with interpolation.
```

```
figure;
plot(x,hrznYTMRatesSims(1,:),'k-o',xi,treasuryYTMAtHorizonSim(1,:),'ro');
xlabel('Time (days)');
ylabel('Yield');
legend({'Simulated Yield Curve','Interpolated Yields'},'location','se');
grid on;
title('Zoom to See Spline vs. Linear Interpolants');
```



Price the treasuries at the horizon for each simulated yield to maturity. Note that the same assumptions are being made here as in the previous call to `bndprice`.

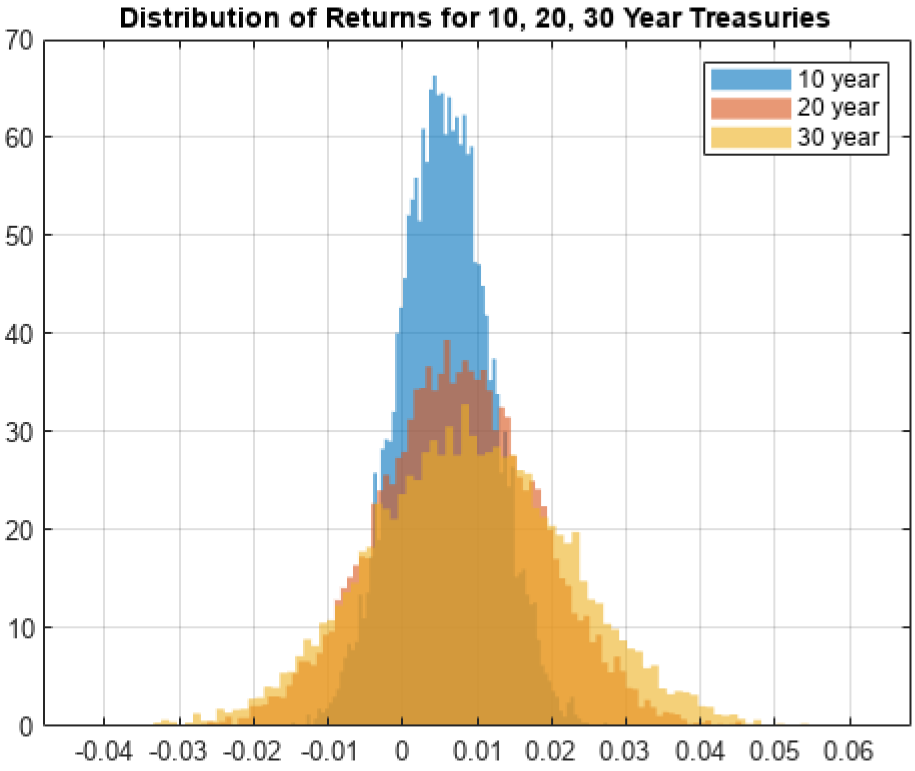
```
basis = 8*ones(numSim,1);
for j=1:3
    treasuryPricesAtHorizonSim(:,j) = bndprice(treasuryYTMAtHorizonSim(:,j),0,...
                                           hrznDate,treasuryMaturities(j),'basis',basis);
end

% Calculate the distribution of linear returns.
treasuryReturns = ( treasuryPricesAtHorizonSim - repmat(treasuryPricesAtSettle,numSim,1) )./repma

% Calculate the returns statistics.
retsMean = mean(treasuryReturns);
retsCov  = cov(treasuryReturns);
[retsStd,retsCor] = cov2corr(retsCov);

% Visualize the results for the 30 year treasury.
figure
histogram(treasuryReturns(:,1),100,Normalization='pdf',EdgeColor='none')
```

```
hold on
histogram(treasuryReturns(:,2),100,Normalization='pdf',EdgeColor='none')
histogram(treasuryReturns(:,3),100,Normalization='pdf',EdgeColor='none')
hold off
title('Distribution of Returns for 10, 20, 30 Year Treasuries');
grid on
legend({'10 year','20 year','30 year'});
```



Optimize Asset Allocation Using Portfolio Object

Asset allocation is optimized using a `Portfolio` object. Ten optimal portfolios (`NumPorts`) are calculated using `estimateFrontier` and their Sharpe ratios are calculated. The optimal portfolio, based on investor preference, is chosen to be the one that is closest to the maximum value of the Sharpe ratio.

Create a `Portfolio` object using `Portfolio`. You can use `setAssetMoments` to set moments (mean and covariance) of asset returns for the `Portfolio` object and `setDefaultConstraints` to set up the portfolio constraints with nonnegative weights that sum to 1.

```
% Create a portfolio object.
p = Portfolio;
p = setAssetMoments(p,retsMean,retsCov);
p = setDefaultConstraints(p)
```

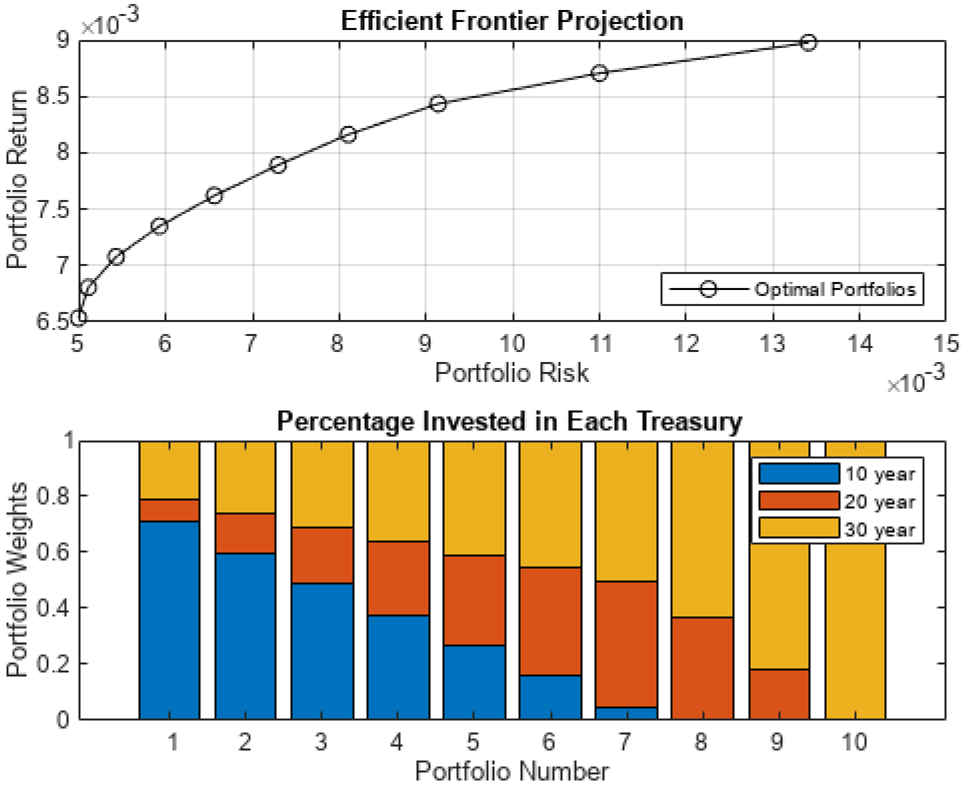
```
p = 
  Portfolio with properties:
          BuyCost: []
         SellCost: []
     RiskFreeRate: []
        AssetMean: [3×1 double]
       AssetCovar: [3×3 double]
    TrackingError: []
     TrackingPort: []
         Turnover: []
      BuyTurnover: []
     SellTurnover: []
             Name: []
        NumAssets: 3
        AssetList: []
         InitPort: []
      AInequality: []
      bInequality: []
        AEquality: []
        bEquality: []
       LowerBound: [3×1 double]
       UpperBound: []
      LowerBudget: 1
      UpperBudget: 1
      GroupMatrix: []
       LowerGroup: []
       UpperGroup: []
           GroupA: []
           GroupB: []
       LowerRatio: []
       UpperRatio: []
     MinNumAssets: []
     MaxNumAssets: []
        BoundType: [3×1 categorical]
```

Calculate ten points along the projection of the efficient frontier using `estimateFrontier` and `estimatePortMoments` to estimate moments of portfolio returns for the `Portfolio` object.

```
NumPorts = 10;
PortWts = estimateFrontier(p,NumPorts);
[PortRisk, PortReturn] = estimatePortMoments(p,PortWts);

% Visualize the portfolio.
figure;
subplot(2,1,1)
plot(PortRisk,PortReturn,'k-o');
xlabel('Portfolio Risk');
ylabel('Portfolio Return');
title('Efficient Frontier Projection');
legend('Optimal Portfolios','location','se');
grid on;

subplot(2,1,2)
bar(PortWts','stacked');
xlabel('Portfolio Number');
ylabel('Portfolio Weights');
title('Percentage Invested in Each Treasury');
legend({'10 year','20 year','30 year'});
```



Use `estimateMaxSharpeRatio` to estimate efficient portfolio that maximizes Sharpe ratio for the `Portfolio` object.

```
investorPortfolioWts = estimateMaxSharpeRatio(p);
```

The investor percentage allocation in 10,20, and 30 year treasuries is:

```
disp(investorPortfolioWts);
```

```
    0.6078
    0.1374
    0.2548
```

Hedge Options Using Reinforcement Learning Toolbox™

Outperform the traditional BSM approach using an optimal option hedging policy.

Option Modeling Using Black-Scholes-Merton Model

The Black-Scholes-Merton (BSM) model, which earned its creators a Nobel Prize in Economics in 1997, provides a modeling framework for pricing and analyzing financial derivatives or options. Options are financial instruments that derive their value from a particular underlying asset. The concept of *dynamic hedging* is fundamental to the BSM model. Dynamic hedging is the idea that, by continuously buying and selling shares in the relevant underlying asset, you can hedge the risk of the derivative instrument such that the risk is zero. This "risk-neutral" pricing framework is used to derive pricing formulae for many different financial instruments.

The simplest financial derivative is a European call option, which provides the buyer with the right, but not the obligation, to buy the underlying asset at a previously specified value (strike price) at a previously specified time (maturity).

You can use a BSM model to price a European call option. The BSM model makes the following simplifying assumptions:

- The behavior of the underlying asset is defined by geometric Brownian motion (GBM).
- There are no transaction costs.
- Volatility is constant.

The BSM dynamic hedging strategy is also called "delta-hedging," after the quantity *Delta*, which is the sensitivity of the option with respect to the underlying asset. In an environment that meets the previously stated BSM assumptions, using a delta-hedging strategy is an optimal approach to hedging an option. However, it is well-known that in an environment with transaction costs, the use of the BSM model leads to an inefficient hedging strategy. The goal of this example is to use Reinforcement Learning Toolbox™ to learn a strategy that outperforms the BSM hedging strategy, in the presence of transaction costs.

The goal of reinforcement learning (RL) is to train an agent to complete a task within an unknown environment. The agent receives observations and a reward from the environment and sends actions to the environment. The reward is a measure of how successful an action is with respect to completing the task goal.

The agent contains two components: a policy and a learning algorithm.

- The policy is a mapping that selects actions based on the observations from the environment. Typically, the policy is a function approximator with tunable parameters, such as a deep neural network.
- The learning algorithm continuously updates the policy parameters based on the actions, observations, and reward. The goal of the learning algorithm is to find an optimal policy that maximizes the cumulative reward received during the task.

In other words, reinforcement learning involves an agent learning the optimal behavior through repeated trial-and-error interactions with the environment without human involvement. For more information on reinforcement learning, see “What Is Reinforcement Learning?” (Reinforcement Learning Toolbox).

Cao [2 on page 10-47] describes the setup for reinforcement learning as:

- S_i is the state at time i.
- A_i is the action taken at i.
- R_{i+1} is the resulting reward at time $i + 1$.

The aim of reinforcement learning is to maximize expected future rewards. In this financial application of reinforcement learning, maximizing expected rewards is learning a delta-hedging strategy as an optimal approach to hedging a European call option.

This example follows the framework outlined in Cao [2 on page 10-47]. Specifically, an accounting profit and loss (P&L) formulation from that paper is used to set up the reinforcement learning problem and a deep deterministic policy gradient (DDPG) agent is used. This example does not exactly reproduce the approach from [2 on page 10-47] because Cao *et. al*. recommend a Q-learning approach with two separate Q-functions (one for the hedging cost and one for the expected square of the hedging cost), but this example uses instead a simplified reward function.

Define Training Parameters

Next, specify an at-the-money option with three months to maturity is hedged. For simplicity, both the interest rate and dividend yield are set to `0`.

```
% Option parameters
Strike = 100;
Maturity = 21*3/250;

% Asset parameters
SpotPrice = 100;
ExpVol = .2;
ExpReturn = .05;

% Simulation parameters
rfRate = 0;
dT = 1/250;
nSteps = Maturity/dT;
nTrials = 5000;

% Transacation cost and cost function parameters
c = 1.5;
kappa = .01;
InitPosition = 0;

% Set the random generator seed for reproducibility.
rng(3)
```

Define Environment

In this section, the action and observation parameters, `actInfo` and `obsInfo`. The agent action is the current `hedge` value which can range between `0` and `1`. There are three variables in the agent observation:

- Moneyness (ratio of the spot price to the strike price)
- Time to maturity
- Position or amount of the underlying asset that is held

```
ObservationInfo             = rlNumericSpec([3 1],'LowerLimit',0,'UpperLimit',[10 Maturity 1]');
ObservationInfo.Name        = 'Hedging State';
ObservationInfo.Description = ['Moneyness', 'TimeToMaturity','Position'];

ActionInfo = rlNumericSpec([1 1],'LowerLimit',0,'UpperLimit',1);
ActionInfo.Name = 'Hedge';
```

Define Reward

From Cao [2 on page 10-47], the accounting P&L formulation and rewards (negative costs) are

$$R_{i+1} = V_{i+1} - V_i + H_{i+1}(S_{i+1} - S_i) - \kappa|S_{i+1}(H_{i+1} - H_i)|$$

where

R_i: Reward

V_i: Value of option

S_i: Spot price of underlying asset

H_i: Holding

κ: Transaction costs

A final reward at the last time step liquidates the hedge that is $\kappa|S_n(H_n)|$.

In this implementation, the reward (R_i) is penalized by the square of the reward multiplied by a constant to punish large swings in the value of the hedged position:

$$R_{i+1} = R_{i+1} - c(R_{i+1})^2$$

The reward is defined in `stepFcn` which is called at each step of the simulation.

```
env = rlFunctionEnv(ObservationInfo,ActionInfo, ...
    @(Hedge, LoggedSignals) stepFcn(Hedge,LoggedSignals,rfRate,ExpVol,dT,Strike,ExpReturn,c,kappa
    @() resetFcn(SpotPrice/Strike,Maturity,InitPosition));

obsInfo = getObservationInfo(env);
actInfo = getActionInfo(env);
```

Create Environment Interface for RL Agent

Create the DDPG agent using `rlDDPGAgent` (Reinforcement Learning Toolbox). While it is possible to create custom actor and critic networks, this example uses the default networks.

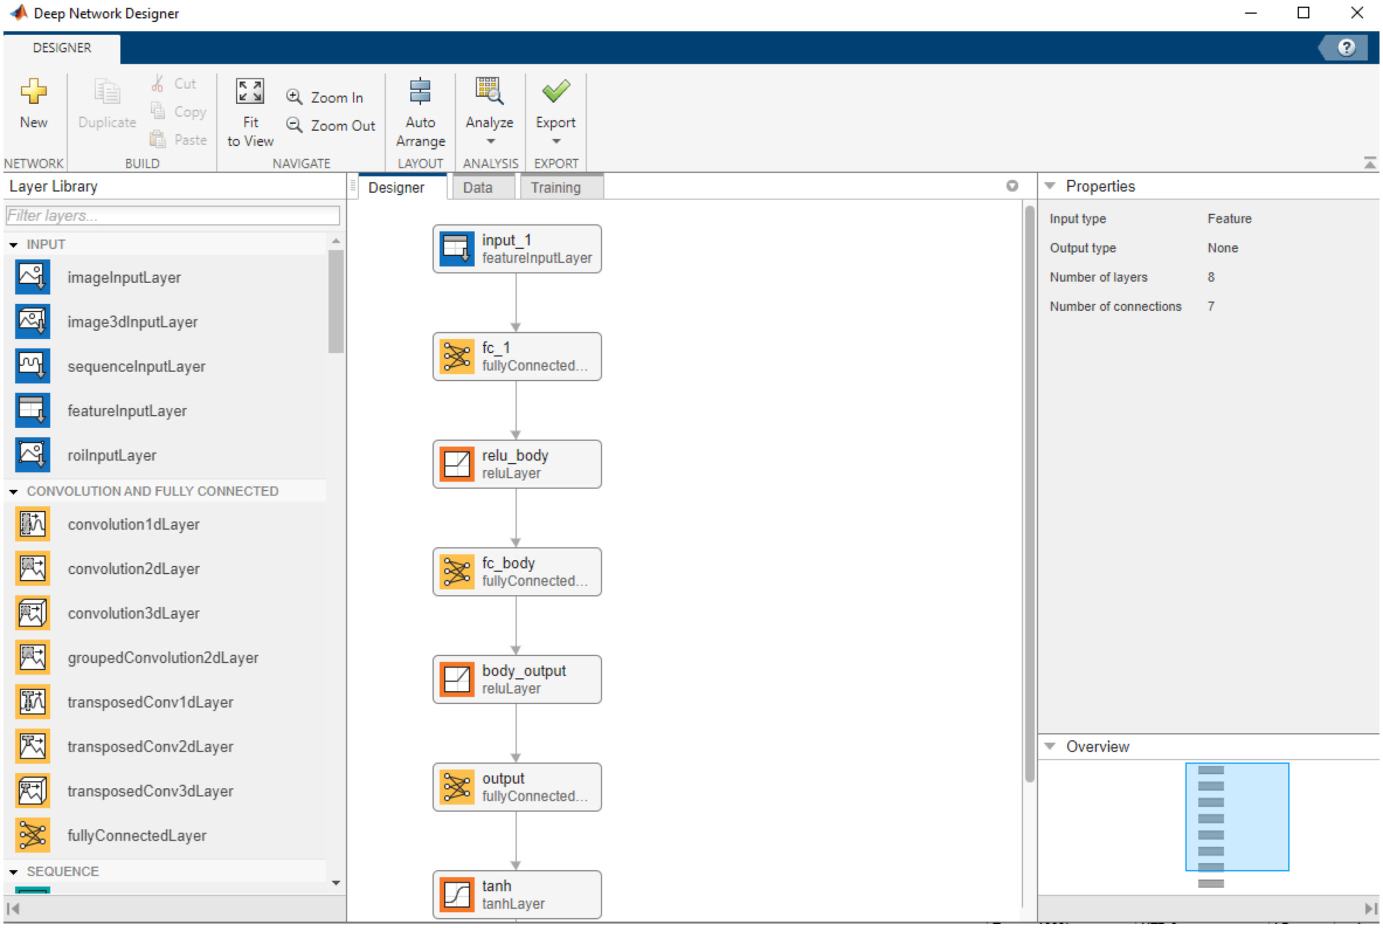
```
initOpts = rlAgentInitializationOptions('NumHiddenUnit',64);
criticOpts = rlOptimizerOptions("LearnRate",1e-4);
actorOpts = rlOptimizerOptions("LearnRate",1e-4);

agentOptions = rlDDPGAgentOptions(...
    "ActorOptimizerOptions",actorOpts,...
    "CriticOptimizerOptions",criticOpts,...
    "DiscountFactor",.9995,...
    "TargetSmoothFactor",5e-4);
agent = rlDDPGAgent(obsInfo,actInfo,initOpts,agentOptions);
```

Visualize Actor and Critic Networks

Visualize the actor and critic networks using the Deep Network Designer.

```
deepNetworkDesigner(layerGraph(getModel(getActor(agent))))
```



Input type Feature
Output type None
Number of layers 8
Number of connections 7

Train Agent

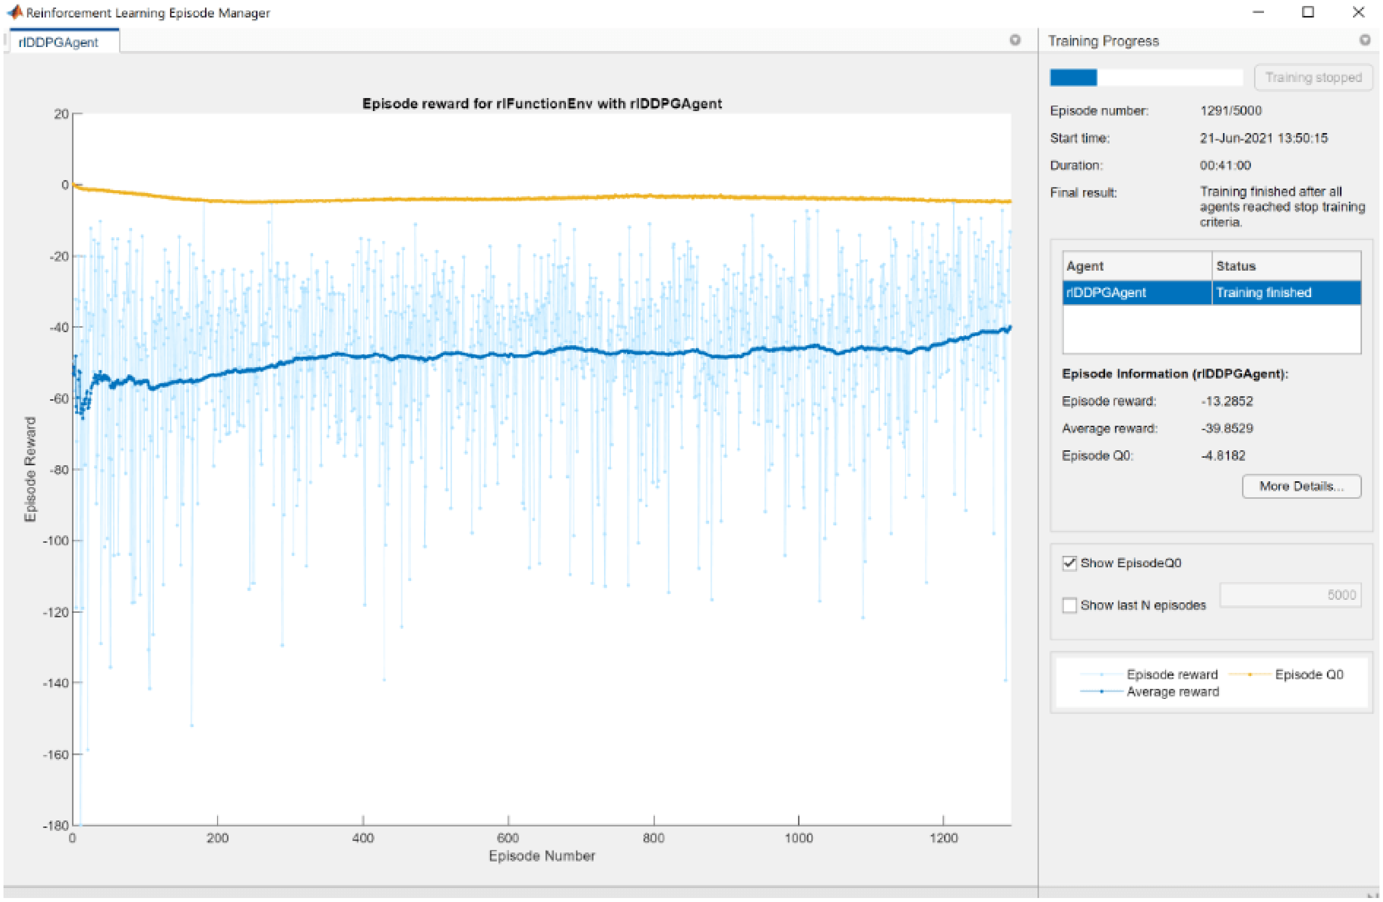
Train the agent using the `train` (Reinforcement Learning Toolbox) function.

```
trainOpts = rlTrainingOptions( ...
    'MaxEpisodes', nTrials, ...
    'MaxStepsPerEpisode',nSteps, ...
    'Verbose', false, ...
    'ScoreAveragingWindowLength',200,...
    'StopTrainingCriteria',"AverageReward", ...
    'StopTrainingValue',-40, ...
    'StopOnError',"on", ...
    "UseParallel",false);

doTraining = false;
if doTraining
    % Train the agent.
    trainingStats = train(agent,env,trainOpts);
else
```

```
    % Load the pretrained agent for the example.
    load('DeepHedgingDDPG.mat','agent')
end
```

To avoid waiting for the training, load pretrained networks by setting the `doTraining` flag to `false`. If you set `doTraining` to `true`, the Reinforcement Learning Episode Manager displays the training progress.



Episode number: 1291/5000
Start time: 21-Jun-2021 13:50:15
Duration: 00:41:00
Final result: Training finished after all agents reached stop training criteria.

Agent	Status
rlDDPGAgent	Training finished

Episode Information (rlDDPGAgent):
Episode reward: -13.2852
Average reward: -39.8529
Episode Q0: -4.8182

□ Show last N episodes 5000

Validate Agent

Use the Financial Toolbox™ functions `blsdelta` and `blsprice` for a conventional approach to calculate the price as a European call option. When comparing the conventional approach to the RL approach, the results are similar to the findings of Cao [2 on page 10-47] in Exhibit 4. This example demonstrates that the RL approach significantly reduces hedging costs.

```
% Simulation parameters
nTrials = 1000;

policy_BSM = @(mR,TTM,Pos) blsdelta(mR,1,rfRate,max(TTM,eps),ExpVol);

policy_RL = @(mR,TTM,Pos) arrayfun(@(mR,TTM,Pos) cell2mat(getAction(agent,[mR TTM Pos]')),mR,TTM

OptionPrice = blsprice(SpotPrice,Strike,rfRate,Maturity,ExpVol);

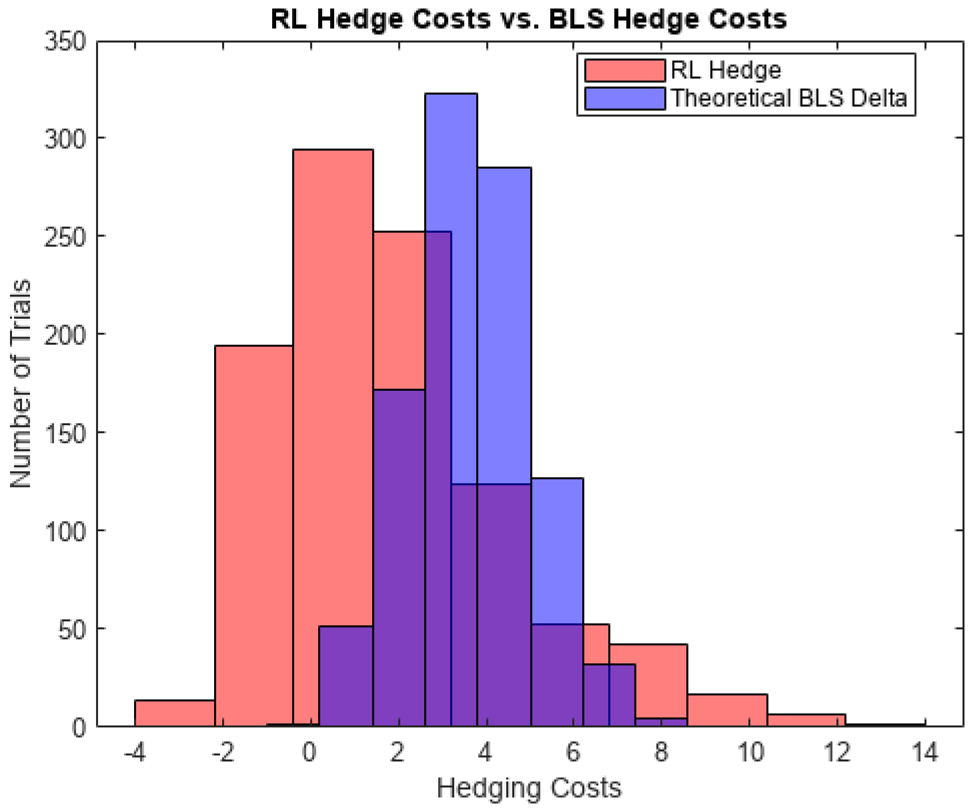
Costs_BSM = computeCosts(policy_BSM,nTrials,nSteps,SpotPrice,Strike,Maturity,rfRate,ExpVol,InitP
Costs_RL = computeCosts(policy_RL,nTrials,nSteps,SpotPrice,Strike,Maturity,rfRate,ExpVol,InitPos
HedgeComp = table(100*[-mean(Costs_BSM) std(Costs_BSM)]'/OptionPrice, ...
    100*[-mean(Costs_RL) std(Costs_RL)]'/OptionPrice, ...
    'RowNames',["Average Hedge Cost (% of Option Price)","STD Hedge Cost (% of Option Price)"],
    'VariableNames',["BSM","RL"]);
disp(HedgeComp)
```

```
                                               BSM       RL  
                                              ______    ______

    Average Hedge Cost (% of Option Price)    91.259    47.022
    STD Hedge Cost (% of Option Price)        35.712    68.119
```

The following histogram shows the range of different hedging costs for both approaches. The RL approach performs better, but with a larger variance than the BSM approach. The RL appraoch in this example would likely benefit from the two Q-function approach that Cao [2 on page 10-47] discusses and implements.

```
figure
numBins = 10;
histogram(-Costs_RL,numBins,'FaceColor','r','FaceAlpha',.5)
hold on
histogram(-Costs_BSM,numBins,'FaceColor','b','FaceAlpha',.5)
xlabel('Hedging Costs')
ylabel('Number of Trials')
title('RL Hedge Costs vs. BLS Hedge Costs')
legend('RL Hedge','Theoretical BLS Delta','location','best')
```



A plot of the hedge Ratio with respect to moneyness shows the differences between the BSM and RL approaches. As discussed in Cao [2 on page 10-47], in the presence of transaction costs, the agent learns that "when delta hedging would require shares to be purchased, it tends to be optimal for a trader to be underhedged relative to delta. Similarly, when delta hedging would require shares to be sold, it tends to be optimal for a trader to be over-hedged relative to delta."

```
policy_RL_mR = @(mR,TTM,Pos) cell2mat(getAction(agent,[mR TTM Pos]'));

mRange = (.8:.01:1.2)';

figure
t_plot = 2/12;
plot(mRange,blsdelta(mRange,1,rfRate,t_plot,ExpVol),'b')
hold on
plot(mRange,arrayfun(@(mR) policy_RL_mR(mR,t_plot,blsdelta(mR,1,rfRate,t_plot,ExpVol)),mRange),'
plot(mRange,arrayfun(@(mR) policy_RL_mR(mR,t_plot,blsdelta(mR+.1,1,rfRate,t_plot,ExpVol)),mRange
plot(mRange,arrayfun(@(mR) policy_RL_mR(mR,t_plot,blsdelta(mR-.1,1,rfRate,t_plot,ExpVol)),mRange
legend('Theoretical BLS Delta','RL Hedge -- ATM','RL Hedge -- Selling','RL Hedge -- Buying', ...
    'location','best')
xlabel('Moneyness')
ylabel('Hedge Ratio')
title('RL Hedge vs. BLS Delta for TTM of 2/12')
```

Using Financial Timetables

Convert Financial Time Series Objects (fints) to Timetables

In this section...

In R2023a, financial time series (`fints`), and its associated methods have been removed and are replaced with a MATLAB `timetable` function. If you use `fints` or the associated methods, you receive an error. To help you convert from the older `fints` to the newer `timetable` functionality, use the following information.

Create Time Series

I/O Related Operations

Task	Removed Functionality	Use This Functionality
Construct by passing in data and dates	`fints(dates,data,datanames)`	Use `timetable`: `timetable(rowTimes,var1,...,varN,'VariableNames',{'a','b',...})`

Construct by conversion of files	`ascii2fts(filename,descrow,colheadrow,skiprows)`	Use `readtable` and `table2timetable`:
		`T = readtable(filename,opts,Name,Value)`
		`TT = table2timetable(T,'RowTimes',timeVarName)`

Write files	`fts2ascii(filename,tsobj,exttext)`	Use `writetable`: `writetable(TT,filename)`

Convert to matrix	`fts2mat(tsobj)`	`S = vartype('numeric');`
		`TT2 = TT(:,S)`
		`TT2.Variables`

Index an Object

Indexing an Object

Task	Removed Functionality	Use This Functionality
Indexing with a date	`myfts('05/11/99')`	`TT({'1999-05-11'},:)`

Indexing with a date range	`myfts ('05/11/99::05/15/99')`	Use `timerange`:
		`S = timerange('1999-05-11','1999-05-15');`
		`TT2 = TT(S,:)`

Indexing with integers for rows	`myfts.series2(1)`
	`myfts.series2([1, 3, 5])`
	`myfts.series2(16:20)`
		`TT(1,{'series2'})`
		`TT([1, 3, 5],{'series2'})`
		`TT(16:20,{'series2'})`

Contents of a specific time field	`myfts.times`	Use `timeofday`: `timeofday(TT.Properties.RowTimes)`
Contents for a specific field in a matrix	`fts2mat(myfts.series2)`	`TT.series2`

Transform Time Series

Assume that all variables are numeric within a timetable, or the operations can be applied on TT2:

```
S = vartype('numeric');
```

```
TT2 = TT(:,S)
```

Filter Time Series

Task	Removed Functionality	Use This Functionality
Boxcox transformation	`newfts = boxcox(oldfts)`	Use `boxcox`: `TT.Variables = boxcox(TT.Variables)`

Differencing	`diff(myfts)`	`TT{2:end,:} = diff(TT.Variables)`
		`TT(1,:) = []`

Indexing with integers for rows	`fillts(oldfts,fill_method)`	Use `fillmissing`: `fillmissing(TT,method)` (Assumes no missing dates)
Linear filtering	`filter(B,A, myfts)`	Use `filter`: `TT.Variables = filter(b,a,TT.Variables)`

Lag or lead time series object	`lagts(myfts,lagperiod)`
	`leadts(myfts,leadperiod)`
		Use `lag`:
		`lag(TT,lagperiod)`
		`lag(TT,-leadperiod)`
		(Assumes a regularly spaced timetable)

Periodic average	`peravg(myfts)`	Use `retime`: `retime(TT,newTimes,'mean')`
Downsample data	`resamplets(oldfts,samplestep)`	Use `retime`: `retime(TT,newTimeStep,method)`
Smooth data	`smoothts(input)`	Use `smoothdata`: `smoothdata(TT)`
Moving average	`tsmovavg(tsobj,method,lag)`	Use `movavg`: `movavg(TT,type,windowSize)`

Convert Time Series

Assume that all variables are numeric within a timetable, or the operations can be applied on TT2:

```
S = vartype('numeric');
```

```
TT2 = TT(:,S)
```

Conversion Operations

Task	Removed Functionality	Use This Functionality
Convert to specified frequency	`convertto(oldfts,newfreq)`	Use `retime`: `retime(TT,newTimeStep,method)`
Convert to annual	`toannual(oldfts,...)`	Use `convert2annual`: `convert2annual(TT,…)`
Convert to daily	`todaily(oldfts,...)`	Use `convert2daily`: `convert2daily(TT,…)`
Convert to monthly	`tomonthly(oldfts,...)`	Use `convert2monthly`: `convert2monthly(TT,…)`
Convert to quarterly	`toquarterly(oldfts,...)`	Use `convert2quarterly`: `convert2quarterly(TT,…)`
Convert to semiannual	`tosemi(oldfts,...)`	Use `convert2semiannual`: `convert2semiannual(TT,…)`
Convert to weekly	`toweekly(oldfts,...)`	Use `convert2weekly`: `convert2weekly(TT,…)`

Merge Time Series

Merge Operations

Task	Removed Functionality	Use This Functionality
Merge multiple time series objects	`merge(fts1,fts2)`	`[TT1;TT2]` (requires variable name to be the same) `unique(TT)`
Concatenate financial time series objects horizontally	`horzcat(fts1,fts2)` or `[fts1,fts2]`	Use `horzcat` or `synchronize`: `horzcat[TT1,TT2]` (requires variable name to be the same) or `synchronize(TT1,TT2)`
Concatenate financial time series objects vertically	`vertcat(fts1,fts2)` or `[fts1;fts2]`	Use `vertcat`: `vertcat[TT1;TT2]`

Analyze Time Series

Due to flexibility of a timetable that can hold heterogeneous variables, a timetable does not support math operations or descriptive statistical calculations. If you would like to apply any numeric calculations on a timetable, use the following guidelines.

Assume that all variables are numeric within a timetable, or the operations can be applied on `TT2`:

```
S = vartype('numeric');
```

```
TT2 = TT(:,S)
```

Descriptive Statistics and Arithmetic and Math Operations

Task	Removed Functionality	Use This Functionality
Extract out numerical data	`srs2 = myfts.series2`	`TT.Variables`

Apply some options (statistics)	For example: `min`, `max`, `mean`, `median`, `cov`, `std`, and `var`	Use `cov` (or `max`, `mean`, `median`, `min`, `std`, or `var`):
		`cov(TT.Variables)`

Apply some options (operations)	For example: `sum` and `cumsum`	Use `sum` or `cumsum`: `TT.Variables = cumsum(TT.Variables)`

Data Extraction

Refer to `timetable` documentation for data extraction methods and examples.

Use Timetables in Finance

Use timetables to visualize and calculate weekly statistics from simulated daily stock data.

Step 1. Load the data.

The data for this example is in the MAT-file SimulatedStock.mat, which loads the following:

- Dates corresponding to the closing stock prices, TMW_DATES
- Opening stock prices, TMW_OPEN
- Daily high of stock prices, TMW_HIGH
- Daily low of stock prices, TMW_LOW
- Closing stock prices, TMW_CLOSE, TMW_CLOSE_MISSING
- Daily volume of traded, TMW_VOLUME
- Data in a table, TMW_TB

```
load SimulatedStock.mat TMW_*
```

Step 2. Create timetables.

In timetables, you can work with financial time series rather than with vectors. When using a timetable, you can easily track the dates. You can manipulate the data series based on the dates, because a timetable object tracks the administration of a time series.

Use the MATLAB® timetable function to create a timetable object. Alternatively, you can use the MATLAB conversion function table2timetable to convert a table to a timetable. In this example, the timetable TMW_TT is constructed from a table and is only for illustration purposes. After you create a timetable object, you can use the Description field of the timetable object to store meta-information about the timetable.

```
% Create a timetable from vector input
TMW = timetable(TMW_OPEN,TMW_HIGH,TMW_LOW,TMW_CLOSE_MISSING,TMW_VOLUME, ...
    'VariableNames',{'Open','High','Low','Close','Volume'},'RowTimes',TMW_DATES);

% Convert from a table to a timetable
TMW_TT = table2timetable(TMW_TB,'RowTimes',TMW_DATES);

TMW.Properties.Description = 'Simulated stock data.';

TMW.Properties
```

```
ans = 
  TimetableProperties with properties:

             Description: 'Simulated stock data.'
                UserData: []
          DimensionNames: {'Time'  'Variables'}
           VariableNames: {'Open'  'High'  'Low'  'Close'  'Volume'}
    VariableDescriptions: {}
           VariableUnits: {}
      VariableContinuity: []
                RowTimes: [1000x1 datetime]
               StartTime: 04-Sep-2012
```

```
              SampleRate: NaN
                TimeStep: NaN
                  Events: []
        CustomProperties: No custom properties are set.
      Use addprop and rmprop to modify CustomProperties.
```

Step 3. Calculate basic data statistics, and fill the missing data.

Use the MATLAB `summary` function to view basic statistics of the `timetable` data. By reviewing the summary for each variable, you can identify missing values. You can then use the MATLAB `fillmissing` function to fill in missing data in a timetable by specifying a fill method.

```
summaryTMW = summary(TMW);
summaryTMW.Close
```

```
ans = struct with fields:
           Size: [1000 1]
           Type: 'double'
    Description: ''
          Units: ''
     Continuity: []
            Min: 83.4200
         Median: 116.7500
            Max: 162.1100
     NumMissing: 3
```

```
TMW = fillmissing(TMW,'linear');
summaryTMW = summary(TMW);
summaryTMW.Close
```

```
ans = struct with fields:
           Size: [1000 1]
           Type: 'double'
    Description: ''
          Units: ''
     Continuity: []
            Min: 83.4200
         Median: 116.7050
            Max: 162.1100
     NumMissing: 0
```

```
summaryTMW.Time
```

```
ans = struct with fields:
          Size: [1000 1]
          Type: 'datetime'
           Min: 04-Sep-2012
        Median: 31-Aug-2014
           Max: 24-Aug-2016
    NumMissing: 0
      TimeStep: NaN
```

Step 4. Visualize the data.

To visualize the timetable data, use financial charting functions such as `highlow` or `movavg`. For this example, the moving average information is plotted on the same chart for `highlow` to provide a complete visualization. To obtain the stock performance in 2014, use the MATLAB `timerange` function to select rows of the `timetable`. To visualize a technical indicator such as the Moving Average Convergence Divergence (MACD), pass the `timetable` object into the `macd` function for analysis.

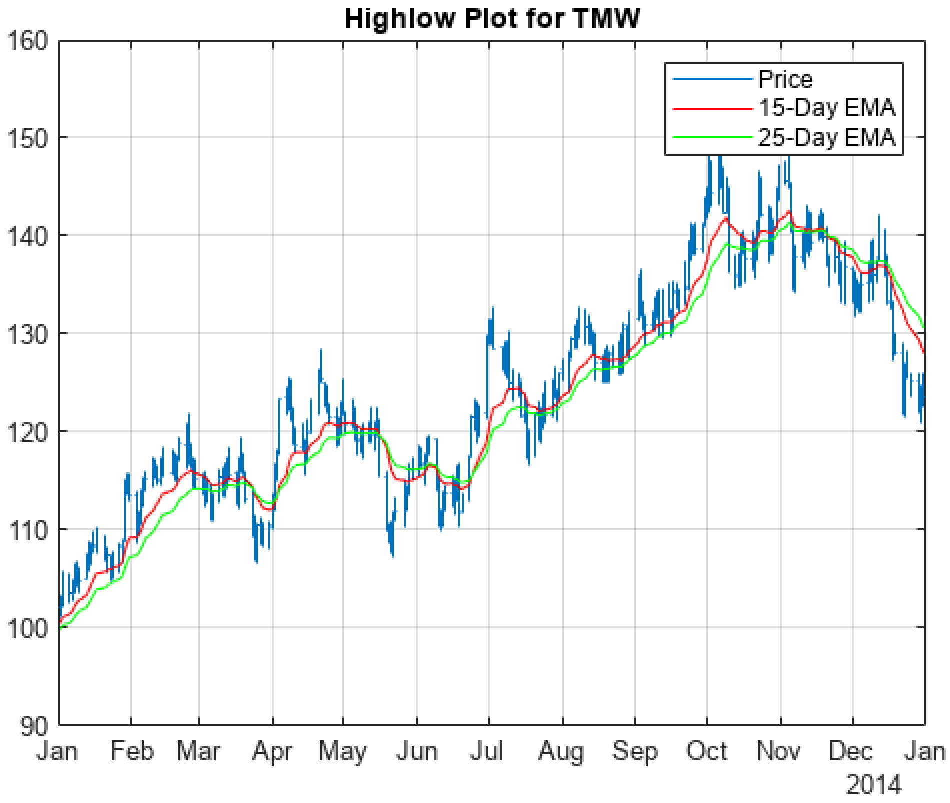
```
index = timerange(datetime('01-Jan-2014','Locale','en_US'),datetime('31-Dec-2014','Locale','en_US

highlow(TMW(index,:));
hold on

ema15 = movavg(TMW(:,'Close'),'exponential',15);
ema25 = movavg(TMW(:,'Close'),'exponential',25);

ema15 = ema15(index,:);
ema25 = ema25(index,:);
plot(ema15.Time,ema15.Close,'r');
plot(ema25.Time,ema25.Close,'g');
hold off

legend('Price','15-Day EMA','25-Day EMA')
title('Highlow Plot for TMW')
```

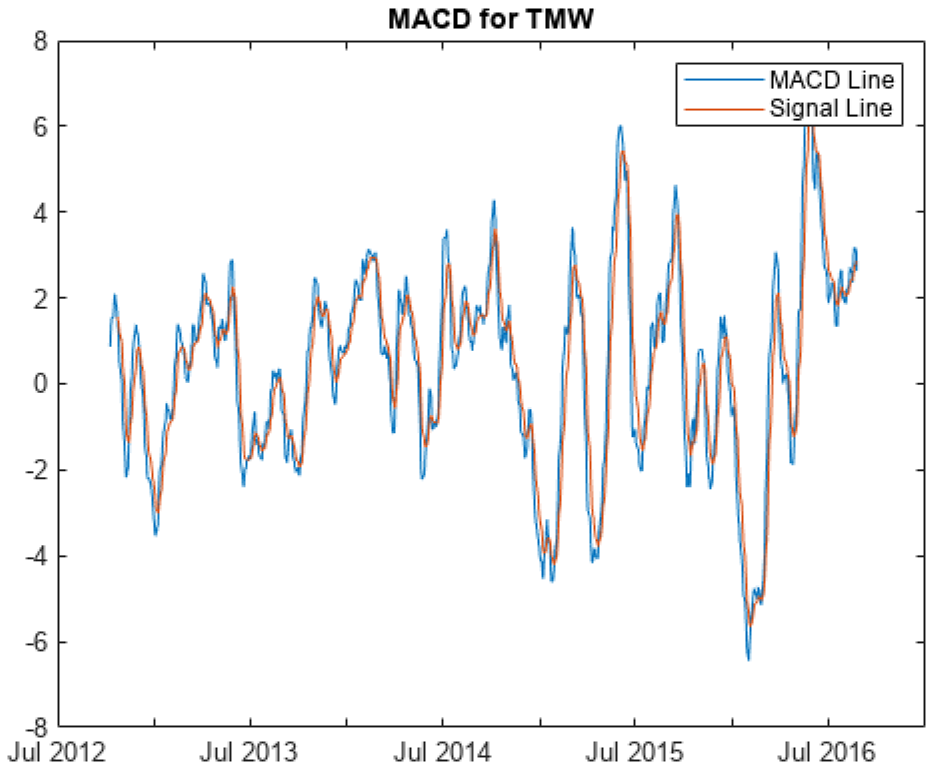


```
[macdLine, signalLine] = macd(TMW(:,'Close'));

plot(macdLine.Time,macdLine.Close);
hold on
plot(signalLine.Time,signalLine.Close);
```

```
hold off

title('MACD for TMW')
legend('MACD Line', 'Signal Line')
```



Step 5. Create a weekly return and volatility series.

To calculate weekly return from the daily stock prices, you must resample the data frequency from daily to weekly. When working with timetables, use the MATLAB functions `retime` or `synchronize` with various aggregation methods to calculate weekly statistics. To adjust the timetable data to a time-vector basis, use `retime` and use `synchronize` with multiple timetables.

```
weeklyOpen = retime(TMW(:,'Open'),'weekly','firstvalue');
weeklyHigh = retime(TMW(:,'High'),'weekly','max');
weeklyLow = retime(TMW(:,'Low'),'weekly','min');
weeklyClose = retime(TMW(:,'Close'),'weekly','lastvalue');
weeklyTMW = [weeklyOpen,weeklyHigh,weeklyLow,weeklyClose];

weeklyTMW = synchronize(weeklyTMW,TMW(:,'Volume'),'weekly','sum');
head(weeklyTMW)
```

```

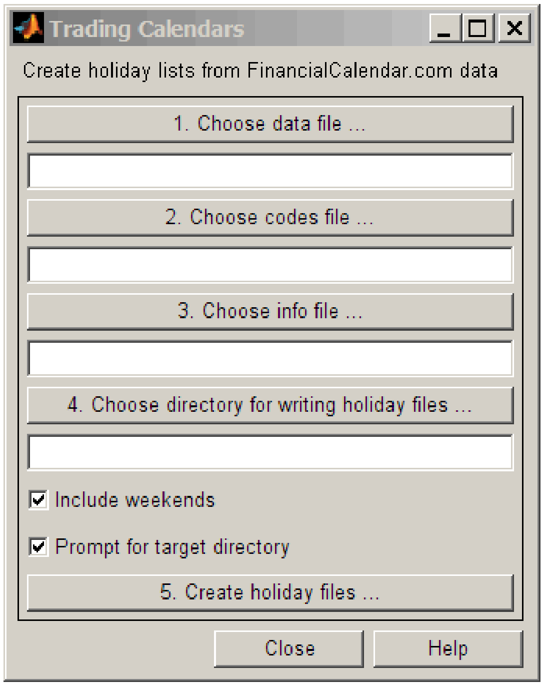
Trading Date Utilities

Trading Calendars User Interface

Use the `createholidays` function to open the Trading Calendars user interface.



Trading Calendars

Create holiday lists from FinancialCalendar.com data

☑ Include weekends

☑ Prompt for target directory

The `createholidays` function supports `https://www.FinancialCalendar.com` trading calendars. This function can be used from the command line or from the Trading Calendars user interface. To use `createholidays` or the Trading Calendars user interface, you must obtain data, codes, and info files from `https://www.FinancialCalendar.com` trading calendars. For more information on using the command line to programmatically generate the market-specific `holidays.m` files without displaying the interface, see `createholidays`.

To use the Trading Calendars user interface:

1. From the command line, type the following command to open the Trading Calendars user interface.

   ```
   createholidays
   ```
2. Click **Choose data file** to select the data file.
3. Click **Choose codes file** to select the codes file.
4. Click **Choose info file** to select the info file.
5. Click **Choose directory for writing holiday files** to select the output folder.
6. Select **Include weekends** to include weekends in the holiday list and click **Prompt for target directory** to be prompted for the file location for each `holidays.m` file that is created.
7. Click **Create holiday files** to convert `FinancialCalendar.com` financial center holiday data into market-specific `holidays.m` files.

   The market-specific `holidays.m` files can be used in place of the standard `holidays.m` that ships with Financial Toolbox software.

UICalendar User Interface

In this section...
"Using UICalendar in Standalone Mode" on page 12-4
"Using UICalendar with an Application" on page 12-4

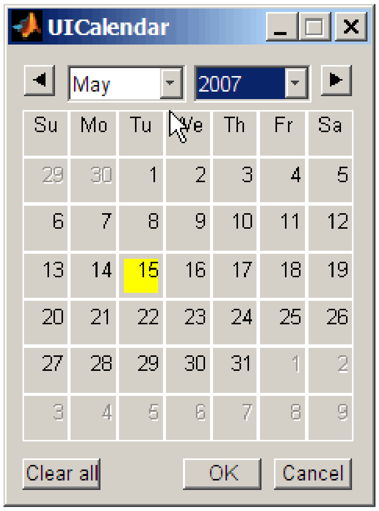
Using UICalendar in Standalone Mode

You can use the UICalendar user interface in standalone mode to look up any date. To use the standalone mode:

1 Type the following command to open the UICalendar GUI:

```
uicalendar
```

The UICalendar interface is displayed:



May 2007

Su	Mo	Tu	We	Th	Fr	Sa
29	30	1	2	3	4	5
6	7	8	9	10	11	12
13	14	15	16	17	18	19
20	21	22	23	24	25	26
27	28	29	30	31	1	2
3	4	5	6	7	8	9

2 Click the date and year controls to locate any date.

Using UICalendar with an Application

You can use the UICalendar user interface with an application to look up any date. To use the UICalendar graphical interface with an application, use the following command:

```
uicalendar('PARAM1', VALUE1, 'PARAM2', VALUE2', ...)
```

For more information, see `uicalendar`.

Example of Using UICalendar with an Application

The UICalendar example creates a function that displays a user interface that lets you select a date from the UICalendar user interface and fill in a text field with that date.

1 Create a figure.

```
function uicalendarGUIExample
f = figure('Name', 'uicalendarGUIExample');
```

2 Add a text control field.

```
dateTextHandle = uicontrol(f, 'Style', 'Text', ...
'String', 'Date:', ...
'Horizontalalignment', 'left', ...
'Position', [100 200 50 20]);
```

3 Add an `uicontrol` editable text field to display the selected date.

```
dateEditBoxHandle = uicontrol(f, 'Style', 'Edit', ...
'Position', [140 200 100 20], ...
'BackgroundColor', 'w');
```

4 Create a push button that starts up the UICalendar.

```
calendarButtonHandle = uicontrol(f, 'Style', 'PushButton', ...
'String', 'Select a single date', ...
'Position', [275 200 200 20], ...
'callback', @pushbutton_cb);
```

5 To start up UICalendar, create a nested function (callback function) for the push button.

```
function pushbutton_cb(hcbo, eventStruct)
% Create a UICALENDAR with the following properties:
% 1) Highlight weekend dates.
% 2) Only allow a single date to be selected at a time.
% 3) Send the selected date to the edit box uicontrol.
uicalendar('Weekend', [1 0 0 0 0 0 1], ...
'SelectionType', 1, ...
'DestinationUI', dateEditBoxHandle);
end
end
```

6 Run the function `uicalendarGUIExample` to display the application interface:

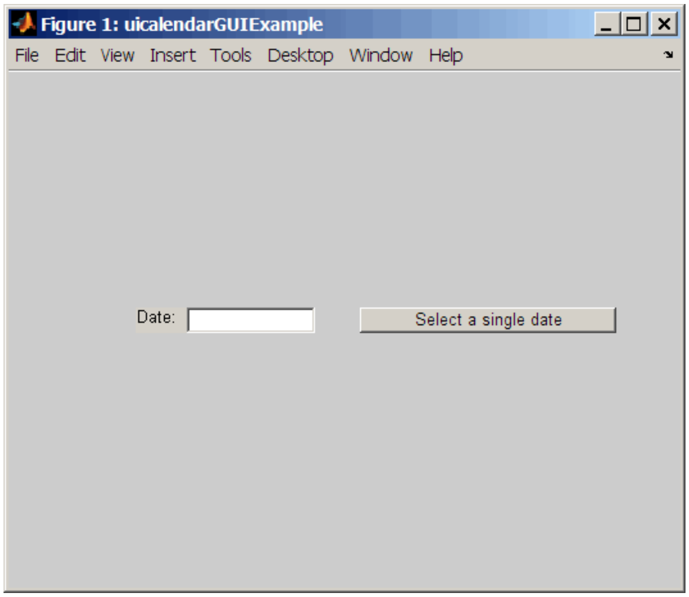


Figure 1: uicalendarGUIExample
File Edit View Insert Tools Desktop Window Help
Date:
Select a single date

7 Click **Select a single date** to display the UICalendar user interface:

Technical Analysis

Technical Indicators

Technical analysis (or charting) is used by some investment managers to help manage portfolios. Technical analysis relies heavily on the availability of historical data. Investment managers calculate different indicators from available data and plot them as charts. Observations of price, direction, and volume on the charts assist managers in making decisions on their investment portfolios.

The technical analysis functions in Financial Toolbox are tools to help analyze your investments. The functions in themselves will not make any suggestions or perform any qualitative analysis of your investment.

Technical Analysis: Oscillators

Function	Type
`adosc`	Accumulation/distribution oscillator
`chaikosc`	Chaikin oscillator
`macd`	Moving Average Convergence/Divergence
`stochosc`	Stochastic oscillator
`tsaccel`	Acceleration
`tsmom`	Momentum

Technical Analysis: Stochastics

Function	Type
`chaikvolat`	Chaikin volatility
`stochosc`	Fast stochastics, slow statistics
`willpctr`	Williams %R

Technical Analysis: Indexes

Function	Type
`negvolidx`	Negative volume index
`posvolidx`	Positive volume index
`rsindex`	Relative strength index

Technical Analysis: Indicators

Function	Type
adline	Accumulation/distribution line
bollinger	Bollinger band
hhigh	Highest high
llow	Lowest low
medprice	Median price
onbalvol	On balance volume
prcroc	Price rate of change
pvtrend	Price-volume trend
typprice	Typical price
volroc	Volume rate of change
wclose	Weighted close
willad	Williams accumulation/distribution

Stochastic Differential Equations

SDEs

In this section...

SDE Modeling

Financial Toolbox enables you to model dependent financial and economic variables, such as interest rates and equity prices, by performing standard Monte Carlo or Quasi-Monte Carlo simulation of stochastic differential equations (SDEs). The flexible architecture of the SDE engine provides efficient simulation methods that allow you to create new simulation and derivative pricing methods.

The following table lists tasks you can perform using the SDE functionality.

To perform this task ...	Use these types of models ...

“Performance Considerations” on page 14-64	All supported models on page 14-11

Trials vs. Paths

Monte Carlo simulation literature often uses different terminology for the evolution of the simulated variables of interest, such as trials and paths. The following sections use the terms *trial* and *path* interchangeably.

However, there are situations where you should distinguish between these terms. Specifically, the term *trial* often implies the result of an independent random experiment (for example, the evolution of the price of a single stock or portfolio of stocks). Such an experiment computes the average or expected value of a variable of interest (for example, the price of a derivative security) and its associated confidence interval.

By contrast, the term *path* implies the result of a random experiment that is different or unique from other results, but that may or may not be independent.

The distinction between these terms is unimportant. It may, however, be useful when applied to variance reduction techniques that attempt to increase the efficiency of Monte Carlo simulation by inducing dependence across sample paths. A classic example involves pairwise dependence induced by antithetic sampling, and applies to more sophisticated variance reduction techniques, such as stratified sampling which is a variance reduction technique that constrains a proportion of sample paths to specific subsets (or *strata*) of the sample space.

NTrials, NPeriods, and NSteps

SDE functions in the Financial Toolbox software use the parameters `NTrials`, `NPeriods`, and `NSteps` as follows:

- The input argument `NTrials` specifies the number of simulated trials or sample paths to generate. This argument always determines the size of the third dimension (the number of pages) of the output three-dimensional time series array `Paths`. Indeed, in a traditional Monte Carlo simulation of one or more variables, each sample path is independent and represents an independent trial.
- The parameters `NPeriods` and `NSteps` represent the number of simulation periods and time steps, respectively. Both periods and time steps are related to time increments that determine the exact sequence of observed sample times. The distinction between these terms applies only to issues of accuracy and memory management. For more information, see “Optimizing Accuracy: About Solution Precision and Error” on page 14-65 and “Managing Memory” on page 14-64.

SDE Class Hierarchy

The Financial Toolbox SDE class structure represents a generalization and specialization hierarchy. The top-level class provides the most general model interface and offers the default Monte Carlo simulation and interpolation methods. In turn, derived classes offer restricted interfaces that simplify model creation and manipulation while providing detail regarding model structure.

The following table lists the SDE classes. The introductory examples in “Available Models” on page 14-11 show how to use these classes to create objects associated with univariate models. Although the Financial Toolbox SDE engine supports multivariate models, univariate models facilitate object creation and display, and allow you to easily associate inputs with object parameters.

SDE Classes

Class Name	For More Information, See ...
`SDE`	`sde` and “Base SDE Models” on page 14-14

SDE Models

In this section...

Introduction

Most models and utilities available with Monte Carlo Simulation of SDEs are represented as MATLAB objects. Therefore, this documentation often uses the terms model and object interchangeably.

However, although all models are represented as objects, not all objects represent models. In particular, `drift`, `diffusion` objects are used in model specification, but neither of these types of objects in and of themselves makes up a complete model. Usually, you do not need to create `drift`, `diffusion` objects directly, so you do not need to differentiate between objects and models. It is important, however, to understand the distinction between these terms.

In many of the following examples, most model parameters are evaluated or invoked like any MATLAB function. Although it is helpful to examine and access model parameters as you would data structures, think of these parameters as *functions* that perform *actions*.

Creating SDE Objects

Creating Objects

For examples and more information on creating SDE objects, see:

- “Available Models” on page 14-11
- “Simulating Equity Prices” on page 14-28
- “Simulating Interest Rates” on page 14-48

Displaying Objects

- Objects display like traditional MATLAB data structures.
- Displayed object parameters appear as nouns that begin with capital letters. In contrast, parameters such as `simulate` and `interpolate` appear as verbs that begin with lowercase letters, which indicate tasks to perform.

Assigning and Referencing Object Parameters

- Objects support referencing similar to data structures. For example, statements like the following are valid:

  ```
  A = obj.A
  ```
- Objects support complete parameter assignment similar to data structures. For example, statements like the following are valid:

  ```
  obj.A = 3
  ```
- Objects do not support partial parameter assignment as data structures do. Therefore, statements like the following are invalid:

  ```
  obj.A(i,j) = 0.3
  ```

Creating and Evaluating Models

- You can create objects of any model class only if enough information is available to determine unambiguously the dimensionality of the model. Because each object offers unique input interfaces, some models require additional information to resolve model dimensionality.
- You need only enter required input parameters in placeholder format, where a given input argument is associated with a specific position in an argument list. You can enter optional inputs in any order as parameter name-value pairs, where the name of a given parameter appears in single quotation marks and precedes its corresponding value.
- Association of dynamic (time-variable) behavior with function evaluation, where *time* and *state* (t,X_t) are passed to a common, published interface, is pervasive throughout the SDE class system. You can use this function evaluation approach to model or construct powerful analytics. For a simple example, see “Example: Univariate GBM Models” on page 14-23.

Specifying SDE Simulation Parameters

The SDE engine allows the simulation of generalized multivariate stochastic processes, and provides a flexible and powerful simulation architecture. The framework also provides you with utilities and model classes that offer various parametric specifications and interfaces. The architecture is fully multidimensional in both the state vector and the Brownian motion, and offers both linear and mean-reverting drift-rate specifications.

You can specify most parameters as MATLAB arrays or as functions accessible by a common interface, that supports general dynamic/nonlinear relationships common in SDE simulation. Specifically, you can simulate correlated paths of any number of state variables driven by a vector-valued Brownian motion of arbitrary dimensionality. This simulation approximates the underlying multivariate continuous-time process using a vector-valued stochastic difference equation.

Consider the following general stochastic differential equation:

$$dX_t = F(t, X_t)dt + G(t, X_t)dW_t \tag{14-1}$$

where:

- *X* is an *NVars*-by-1 state vector of process variables (for example, short rates or equity prices) to simulate.
- *W* is an *NBrowns*-by-1 Brownian motion vector.
- *F* is an *NVars*-by-1 vector-valued drift-rate function.

- G is an *NVars*-by-*NBrowns* matrix-valued diffusion-rate function.

The drift and diffusion rates, F and G, respectively, are general functions of a real-valued scalar sample time t and state vector X_t. Also, static (non-time-variable) coefficients are simply a special case of the more general dynamic (time-variable) situation, just as a function can be a trivial constant; for example, $f(t,X_t) = 4$. The SDE in “Equation 14-1” is useful in implementing derived classes that impose additional structure on the drift and diffusion-rate functions.

Specifying User-Defined Functions as Model Parameters

Several examples in this documentation emphasize the evaluation of object parameters as functions accessible by a common interface. In fact, you can evaluate object parameters by passing to them time and state, regardless of whether the underlying user-specified parameter is a function. However, it is helpful to compare the behavior of object parameters that are specified as functions to that of user-specified noise and end-of-period processing functions.

Model parameters that are specified as functions are evaluated in the same way as user-specified random number (noise) generation functions. (For more information, see “Evaluating Different Types of Functions” on page 14-9.) Model parameters that are specified as functions are inputs to remove object constructors. User-specified noise and processing functions are *optional* inputs to simulation methods.

Because class constructors offer unique interfaces, and simulation methods of any given model have different implementation details, models often call parameter functions for validation purposes a different number of times, or in a different order, during object creation, simulation, and interpolation.

Therefore, although parameter functions, user-specified noise generation functions, and end-of-period processing functions all share the interface and are validated at the same initial time and state (`obj.StartTime` and `obj.StartState`), parameter functions are not guaranteed to be invoked only once before simulation as noise generation and end-of-period processing functions are. In fact, parameter functions might not even be invoked the same number of times during a given Monte Carlo simulation process.

In most applications in which you specify parameters as functions, they are simple, deterministic functions of time and/or state. There is no need to count periods, count trials, or otherwise accumulate information or synchronize time.

However, if parameter functions require more sophisticated bookkeeping, the correct way to determine when a simulation has begun (or equivalently, to determine when model validation is complete) is to determine when the input time and/or state differs from the initial time and state (`obj.StartTime` and `obj.StartState`, respectively). Because the input time is a known scalar, detecting a change from the initial time is likely the best choice in most situations. This is a general mechanism that you can apply to any type of user-defined function.

Evaluating Different Types of Functions

It is useful to compare the evaluation rules of user-specified noise generation functions to those of end-of-period processing functions. These functions have the following in common:

- They both share the same general interface, returning a column vector of appropriate length when evaluated at the current time and state:

  $$X_t = f(t, X_t)$$

  $$z_t = Z(t, X_t)$$

- Before simulation, the simulation method itself calls each function once to validate the size of the output at the initial time and state, `obj.StartTime`, and `obj.StartState`, respectively.
- During simulation, the simulation method calls each function the same number of times: `NPeriods` * `NSteps`.

However, there is an important distinction regarding the timing between these two types of functions. It is most clearly drawn directly from the generic `SDE` model:

$$dX_t = F(t, X_t)dt + G(t, X_t)dW_t$$

This equation is expressed in continuous time, but the simulation methods approximate the model in discrete time as:

$$X_{t + \Delta t} = X_t + F(t, X_t)\Delta t + G(t, X_t)\sqrt{\Delta t}Z(t, X_t)$$

where $\Delta t > 0$ is a small (and not necessarily equal) period or time increment into the future. This equation is often referred to as a *Euler approximation*, a simulation technique that provides a discrete-time approximation of a continuous-time stochastic process. All functions on the rightmost side are evaluated at the current time and state (t, X_t).

In other words, over the next small time increment, the simulation evolves the state vector based only on information available at the current time and state. In this sense, you can think of the noise function as a beginning-of-period function, or as a function evaluated from the left. This is also true for any user-supplied drift or diffusion function.

In contrast, user-specified end-of-period processing functions are applied only at the end of each simulation period or time increment. For more information about processing functions, see “Pricing Equity Options” on page 14-45.

Therefore, all simulation methods evaluate noise generation functions as:

$$z_t = Z(t, X_t)$$

for $t = t_0$, $t_0 + \Delta t$, $t_0 + 2\Delta t$, ..., $T - \Delta t$.

Yet simulation methods evaluate end-of-period processing functions as:

$$X_t = f(t, X_t)$$

for $t = t_0 + \Delta t$, $t_0 + 2\Delta t$, ..., T.

where t_0 and T are the initial time (taken from the object) and the terminal time (derived from inputs to the simulation method), respectively. These evaluations occur on all sample paths. Therefore, during simulation, noise functions are never evaluated at the final (terminal) time, and end-of-period processing functions are never evaluated at the initial (starting) time.

Drift and Diffusion

For example, an SDE with a linear drift rate has the form:

$$F(t, X_t) = A(t) + B(t)X_t \qquad (14\text{-}2)$$

where A is an *NVars*-by-1 vector-valued function and B is an *NVars*-by-*NVars* matrix-valued function.

As an alternative, consider a drift-rate specification expressed in mean-reverting form:

$$F(t, X_t) = S(t)[L(t) - X_t] \tag{14-3}$$

where *S* is an *NVars*-by-*NVars* matrix-valued function of mean reversion speeds (that is, rates of mean reversion), and *L* is an *NVars*-by-1 vector-valued function of mean reversion levels (that is, long run average level).

Similarly, consider the following diffusion-rate specification:

$$G(t, X_t) = D(t, X_t^{\alpha(t)})V(t) \tag{14-4}$$

where *D* is an *NVars*-by-*NVars* diagonal matrix-valued function. Each diagonal element of *D* is the corresponding element of the state vector raised to the corresponding element of an exponent *Alpha*, which is also an *NVars*-by-1 vector-valued function. *V* is an *NVars*-by-*NBrowns* matrix-valued function of instantaneous volatility rates. Each row of *V* corresponds to a particular state variable, and each column corresponds to a particular Brownian source of uncertainty. *V* associates the exposure of state variables with sources of risk.

The parametric specifications for the drift and diffusion-rate functions associate parametric restrictions with familiar models derived from the general SDE class, and provide coverage for many models.

The class system and hierarchy of the SDE engine use industry-standard terminology to provide simplified interfaces for many models by placing user-transparent restrictions on drift and diffusion specifications. This design allows you to mix and match existing models, and customize drift-rate or diffusion-rate functions.

Available Models

For example, the following models are special cases of the general SDE model.

SDE Models

Model Name	Specification
Brownian Motion (BM)	$dX_t = A(t)dt + V(t)dW_t$
Geometric Brownian Motion (GBM)	$dX_t = B(t)X_tdt + V(t)X_tdW_t$
Constant Elasticity of Variance (CEV)	$dX_t = B(t)X_tdt + V(t)X_t^{\alpha(t)}dW_t$
Cox-Ingersoll-Ross (CIR)	$dX_t = S(t)(L(t) - X_t)dt + V(t)X_t^{\frac{1}{2}}dW_t$
Hull-White/Vasicek (HWV)	$dX_t = S(t)(L(t) - X_t)dt + V(t)dW_t$
Heston	$dX_{1t} = B(t)X_{1t}dt + \sqrt{X_{2t}}X_{1t}dW_{1t}$ $dX_{2t} = S(t)[L(t) - X_{2t}]dt + V(t)\sqrt{X_{2t}}dW_{2t}$
Merton	$dX_t = B(t, X_t)X_tdt + D(t, X_t)V(t, x_t)dW_t + Y(t, X_t)X_tdN_t$
Bates	Bates models are bivariate composite models. Each Bates model consists of two coupled univariate models: • A geometric Brownian motion (`gbm`) model with a stochastic volatility function. $dX_{1t} = B(t)X_{1t}dt + \sqrt{X_{2t}}X_{1t}dW_{1t} + Y(t)X_{1t}dN_t$ • A Cox-Ingersoll-Ross (`cir`) square root diffusion model. $dX_{2t} = S(t)[L(t) - X_{2t}]dt + V(t)\sqrt{X_{2t}}dW_{2t}$

SDE Simulation and Interpolation Methods

The `sde` class provides default simulation and interpolation methods for all derived classes:

- `simulate`: High-level wrapper around the user-specified simulation method stored in the `Simulation` property
- `simByEuler`: Default Euler approximation simulation method
- `interpolate`: Stochastic interpolation method (that is, Brownian bridge)

You can use the `simBySolution` function to simulate approximate solutions of diagonal-drift processes for the following classes:

- `gbm` supports `simBySolution`
- `hwv` supports `simBySolution`
- `merton` supports `simBySolution`

You can use the `simBySolution` function with the name-value arguments for `MonteCarloMethod` and `QuasiSequence` to simulates approximate solutions of quasi-Monte Carlo simulations for the following classes:

- `gbm` supports `simBySolution`
- `hwv` supports `simBySolution`

- merton supports simBySolution

In addition, you can also use:

- simByTransition with a cir object to approximates a continuous-time Cox-Ingersoll-Ross (CIR) model by an approximation of the transition density function.
- simByTransition with a bates object to approximates a continuous-time Bates model by an approximation of the transition density function.
- simByTransition with a heston object to approximates a continuous-time Heston model by an approximation of the transition density function.
- simByQuadExp with a heston, bates, or cir object to generate sample paths by using a Quadratic-Exponential discretization scheme.

Base SDE Models

In this section...

Overview

The base sde object

$$dX_t = F(t, X_t)dt + G(t, X_t)dW_t$$

represents the most general model.

Tip The sde class is not an abstract class. You can instantiate sde objects directly to extend the set of core models.

Creating an sde object using sde requires the following inputs:

- A drift-rate function F. This function returns an NVars-by-1 drift-rate vector when run with the following inputs:
  - A real-valued scalar observation time t.
  - An NVars-by-1 state vector X_t.
- A diffusion-rate function G. This function returns an NVars-by-NBrowns diffusion-rate matrix when run with the inputs t and X_t.

Evaluating object parameters by passing (t, X_t) to a common, published interface allows most parameters to be referenced by a common input argument list that reinforces common method programming. You can use this simple function evaluation approach to model or construct powerful analytics, as in the following example.

Example: Base SDE Models

Create an sde object using sde to represent a univariate geometric Brownian Motion model of the form:

$$dX_t = 0.1X_tdt + 0.3X_tdW_t$$

1 Create drift and diffusion functions that are accessible by the common (t,X_t) interface:

```
F = @(t,X) 0.1 * X;
G = @(t,X) 0.3 * X;
```

2 Pass the functions to sde to create an sde object:

```
obj = sde(F, G)    % dX = F(t,X)dt + G(t,X)dW
```

```
obj =
   Class SDE: Stochastic Differential Equation
   -------------------------------------------
   Dimensions: State = 1, Brownian = 1
 ------------------------------------------
    StartTime: 0
   StartState: 1
  Correlation: 1
        Drift: drift rate function F(t,X(t))
    Diffusion: diffusion rate function G(t,X(t))
   Simulation: simulation method/function simByEuler
```

The `sde` object displays like a MATLAB structure, with the following information:

- The object's class
- A brief description of the object
- A summary of the dimensionality of the model

The object's displayed parameters are as follows:

- `StartTime`: The initial observation time (real-valued scalar)
- `StartState`: The initial state vector (`NVars`-by-`1` column vector)
- `Correlation`: The correlation structure between Brownian process
- `Drift`: The drift-rate function $F(t,X_t)$
- `Diffusion`: The diffusion-rate function $G(t,X_t)$
- `Simulation`: The simulation method or function.

Of these displayed parameters, only `Drift` and `Diffusion` are required inputs.

The only exception to the (t, X_t) evaluation interface is `Correlation`. Specifically, when you enter `Correlation` as a function, the SDE engine assumes that it is a deterministic function of time, $C(t)$. This restriction on `Correlation` as a deterministic function of time allows Cholesky factors to be computed and stored before the formal simulation. This inconsistency dramatically improves run-time performance for dynamic correlation structures. If `Correlation` is stochastic, you can also include it within the simulation architecture as part of a more general random number generation function.

Drift and Diffusion Models

In this section...

Overview

Because base-level `sde` objects accept drift and diffusion objects in lieu of functions accessible by (t, X_t), you can create `sde` objects with combinations of customized drift or diffusion functions and objects. The `drift` and `diffusion` rate objects encapsulate the details of input parameters to optimize run-time efficiency for any given combination of input parameters.

Although `drift` and `diffusion` objects differ in the details of their representation, they are identical in their basic implementation and interface. They look, feel like, and are evaluated as functions:

- The `drift` object allows you to create drift-rate objects of the form:

  $$F(t, X_t) = A(t) + B(t)X_t$$

  where:

  - `A` is an `NVars`-by-`1` vector-valued function accessible using the (t, X_t) interface.
  - `B` is an `NVars`-by-`NVars` matrix-valued function accessible using the (t, X_t) interface.
- Similarly, the `diffusion` object allows you to create diffusion-rate objects:

  $$G(t, X_t) = D(t, X_t^{\alpha(t)})V(t)$$

  where:

  - `D` is an `NVars`-by-`NVars` diagonal matrix-valued function.
  - Each diagonal element of `D` is the corresponding element of the state vector raised to the corresponding element of an exponent `Alpha`, which is an `NVars`-by-`1` vector-valued function.
  - `V` is an `NVars`-by-`NBrowns` matrix-valued volatility rate function `Sigma`.
  - `Alpha` and `Sigma` are also accessible using the (t, X_t) interface.

Note You can express `drift` and `diffusion` objects in the most general form to emphasize the functional (t, X_t) interface. However, you can specify the components `A` and `B` as functions that adhere to the common (t, X_t) interface, or as MATLAB arrays of appropriate dimension.

Example: Drift and Diffusion Rates

In this example, you create `drift` and `diffusion` rate objects to create the same model as in "Example: Base SDE Models" on page 14-14.

Create a drift-rate function `F` and a diffusion-rate function `G`:

```
F = drift(0, 0.1)      % Drift rate function F(t,X)

F =
   Class DRIFT: Drift Rate Specification
   -------------------------------------
      Rate: drift rate function F(t,X(t))
         A: 0
         B: 0.1

G = diffusion(1, 0.3)  % Diffusion rate function G(t,X)

G =
   Class DIFFUSION: Diffusion Rate Specification
   ---------------------------------------------
       Rate: diffusion rate function G(t,X(t))
      Alpha: 1
      Sigma: 0.3
```

Each object displays like a MATLAB structure and contains supplemental information, namely, the object's class and a brief description. However, in contrast to the SDE representation, a summary of the dimensionality of the model does not appear, because `drift` and `diffusion` objects create model components rather than models. Neither `F` nor `G` contains enough information to characterize the dimensionality of a problem.

The `drift` object's displayed parameters are:

- `Rate`: The drift-rate function, $F(t,X_t)$
- `A`: The intercept term, $A(t,X_t)$, of $F(t,X_t)$
- `B`: The first order term, $B(t,X_t)$, of $F(t,X_t)$

`A` and `B` enable you to query the original inputs. The function stored in `Rate` fully encapsulates the combined effect of `A` and `B`.

The `diffusion` object's displayed parameters are:

- `Rate`: The diffusion-rate function, $G(t,X_t)$.
- `Alpha`: The state vector exponent, which determines the format of $D(t,X_t)$ of $G(t,X_t)$.
- `Sigma`: The volatility rate, $V(t,X_t)$, of $G(t,X_t)$.

Again, `Alpha` and `Sigma` enable you to query the original inputs. (The combined effect of the individual `Alpha` and `Sigma` parameters is fully encapsulated by the function stored in `Rate`.) The `Rate` functions are the calculation engines for the `drift` and `diffusion` objects, and are the only parameters required for simulation.

Example: SDEDDO Models

The `sdeddo` object derives from the base`sde` object. To use this object, you must pass drift and diffusion-rate objects to `sdeddo`.

1 Create `drift` and `diffusion` rate objects:

   ```
   F = drift(0, 0.1);      % Drift rate function F(t,X)
   G = diffusion(1, 0.3);  % Diffusion rate function G(t,X)
   ```

2 Pass these objects to the `sdeddo` object:

```
obj = sdeddo(F, G)      % dX = F(t,X)dt + G(t,X)dW

obj = 
   Class SDEDDO: SDE from Drift and Diffusion Objects
   --------------------------------------------------
     Dimensions: State = 1, Brownian = 1
   --------------------------------------------------
      StartTime: 0
     StartState: 1
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
              A: 0
              B: 0.1
          Alpha: 1
          Sigma: 0.3
```

In this example, the object displays the additional parameters associated with input drift and diffusion objects.

Linear Drift Models

In this section...

Overview

The `sdeld` class derives from the `sdeddo` class. The `sdeld` objects allow you to simulate correlated paths of `NVars` state variables expressed in linear drift-rate form:

$$dX_t = (A(t) + B(t)X_t)dt + D(t, X_t^{\alpha(t)})V(t)dW_t$$

`sdeld` objects provide a parametric alternative to the mean-reverting drift form, as discussed in “Example: SDEMRD Models” on page 14-23. They also provide an alternative interface to the `sdeddo` parent class, because you can create an object without first having to create its drift and diffusion-rate components.

Example: SDELD Models

Create the same model as in “Example: Base SDE Models” on page 14-14 using `sdeld`:

```
obj = sdeld(0, 0.1, 1, 0.3) % (A, B, Alpha, Sigma)
```

```
obj =
   Class SDELD: SDE with Linear Drift
   ----------------------------------------
     Dimensions: State = 1, Brownian = 1
   ----------------------------------------
      StartTime: 0
     StartState: 1
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
              A: 0
              B: 0.1
          Alpha: 1
          Sigma: 0.3
```

Parametric Models

In this section...

Creating Brownian Motion (BM) Models

The Brownian Motion (BM) model (`bm`) derives directly from the linear drift (`sdeld`) model:

$$dX_t = \mu(t)dt + V(t)dW_t$$

Example: BM Models

Create a univariate Brownian motion (`bm`) object to represent the model using `bm`:

$$dX_t = 0.3dW_t .$$

```
obj = bm(0, 0.3) % (A = Mu, Sigma)
```

```
obj =
   Class BM: Brownian Motion
   ----------------------------------------
     Dimensions: State = 1, Brownian = 1
   ----------------------------------------
      StartTime: 0
     StartState: 0
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
             Mu: 0
          Sigma: 0.3
```

`bm` objects display the parameter `A` as the more familiar `Mu`.

The `bm` object also provides an overloaded Euler simulation method that improves run-time performance in certain common situations. This specialized method is invoked automatically only if *all* the following conditions are met:

- The expected drift, or trend, rate `Mu` is a column vector.
- The volatility rate, `Sigma`, is a matrix.

- No end-of-period adjustments and/or processes are made.
- If specified, the random noise process Z is a three-dimensional array.
- If Z is unspecified, the assumed Gaussian correlation structure is a double matrix.

Creating Constant Elasticity of Variance (CEV) Models

The Constant Elasticity of Variance (CEV) model (`cev`) also derives directly from the linear drift (`sdeld`) model:

$$dX_t = \mu(t)X_t dt + D(t, X_t^{\alpha(t)})V(t)dW_t$$

The `cev` object constrains A to an `NVars`-by-`1` vector of zeros. D is a diagonal matrix whose elements are the corresponding element of the state vector X, raised to an exponent $\alpha(t)$.

Example: Univariate CEV Models

Create a univariate `cev` object to represent the model using `cev`:

$$dX_t = 0.25X_t + 0.3X_t^{\frac{1}{2}}dW_t \,.$$

```
obj = cev(0.25, 0.5, 0.3) % (B = Return, Alpha, Sigma)
```

```
obj = 
   Class CEV: Constant Elasticity of Variance
   ------------------------------------------
     Dimensions: State = 1, Brownian = 1
   ------------------------------------------
      StartTime: 0
     StartState: 1
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
         Return: 0.25
          Alpha: 0.5
          Sigma: 0.3
```

`cev` and `gbm` objects display the parameter `B` as the more familiar `Return`.

Creating Geometric Brownian Motion (GBM) Models

The Geometric Brownian Motion (GBM) model (`gbm`) derives directly from the CEV (`cev`) model:

$$dX_t = \mu(t)X_t dt + D(t, X_t)V(t)dW_t$$

Compared to the `cev` object, a `gbm` object constrains all elements of the *alpha* exponent vector to one such that D is now a diagonal matrix with the state vector X along the main diagonal.

The `gbm` object also provides two simulation methods that can be used by separable models:

- An overloaded Euler simulation method that improves run-time performance in certain common situations. This specialized method is invoked automatically only if *all* the following conditions are true:

  - The expected rate of return (`Return`) is a diagonal matrix.
  - The volatility rate (`Sigma`) is a matrix.
  - No end-of-period adjustments/processes are made.
  - If specified, the random noise process `Z` is a three-dimensional array.
  - If `Z` is unspecified, the assumed Gaussian correlation structure is a double matrix.
- An approximate analytic solution (`simBySolution`) obtained by applying a Euler approach to the transformed (using Ito's formula) logarithmic process. In general, this is *not* the exact solution to this GBM model, as the probability distributions of the simulated and true state vectors are identical *only* for piecewise constant parameters. If the model parameters are piecewise constant over each observation period, the state vector X_t is lognormally distributed and the simulated process is exact for the observation times at which X_t is sampled.

Example: Univariate GBM Models

Create a univariate `gbm` object to represent the model using `gbm`:

$$dX_t = 0.25X_tdt + 0.3X_tdW_t$$

```
obj = gbm(0.25, 0.3)  % (B = Return, Sigma)
```

```
obj = 
   Class GBM: Generalized Geometric Brownian Motion
   ------------------------------------------------
     Dimensions: State = 1, Brownian = 1
   ------------------------------------------------
      StartTime: 0
     StartState: 1
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
         Return: 0.25
          Sigma: 0.3
```

Creating Stochastic Differential Equations from Mean-Reverting Drift (SDEMRD) Models

The `sdemrd` object derives directly from the `sdeddo` object. It provides an interface in which the drift-rate function is expressed in mean-reverting drift form:

$$dX_t = S(t)[L(t) - X_t]dt + D(t, X_t^{\alpha(t)})V(t)dW_t$$

`sdemrd` objects provide a parametric alternative to the linear drift form by reparameterizing the general linear drift such that:

$$A(t) = S(t)L(t), B(t) = -S(t)$$

Example: SDEMRD Models

Create an `sdemrd` object using `sdemrd` with a square root exponent to represent the model:

$$dX_t = 0.2(0.1 - X_t)dt + 0.05X_t^{\frac{1}{2}}dW_t.$$

```
obj = sdemrd(0.2, 0.1, 0.5, 0.05)

obj =
   Class SDEMRD: SDE with Mean-Reverting Drift
   -------------------------------------------
     Dimensions: State = 1, Brownian = 1
   -------------------------------------------
      StartTime: 0
     StartState: 1
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
          Alpha: 0.5
          Sigma: 0.05
          Level: 0.1
          Speed: 0.2

    % (Speed, Level, Alpha, Sigma)
```

sdemrd objects display the familiar Speed and Level parameters instead of A and B.

Creating Cox-Ingersoll-Ross (CIR) Square Root Diffusion Models

The Cox-Ingersoll-Ross (CIR) short-rate object, cir, derives directly from the SDE with mean-reverting drift (sdemrd) class:

$$dX_t = S(t)[L(t) - X_t]dt + D(t, X_t^{\frac{1}{2}})V(t)dW_t$$

where D is a diagonal matrix whose elements are the square root of the corresponding element of the state vector.

Example: CIR Models

Create a cir object using cir to represent the same model as in “Example: SDEMRD Models” on page 14-23:

```
obj = cir(0.2, 0.1, 0.05)  % (Speed, Level, Sigma)

obj =
   Class CIR: Cox-Ingersoll-Ross
   ----------------------------------------
     Dimensions: State = 1, Brownian = 1
   ----------------------------------------
      StartTime: 0
     StartState: 1
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
          Sigma: 0.05
          Level: 0.1
          Speed: 0.2
```

Although the last two objects are of different classes, they represent the same mathematical model. They differ in that you create the cir object by specifying only three input arguments. This distinction is reinforced by the fact that the Alpha parameter does not display – it is defined to be 1/2.

Creating Hull-White/Vasicek (HWV) Gaussian Diffusion Models

The Hull-White/Vasicek (HWV) short-rate object, hwv, derives directly from SDE with mean-reverting drift (sdemrd) class:

$$dX_t = S(t)[L(t) - X_t]dt + V(t)dW_t$$

Example: HWV Models

Using the same parameters as in the previous example, create an hwv object using hwv to represent the model:

$$dX_t = 0.2(0.1 - X_t)dt + 0.05dW_t\,.$$

```
obj = hwv(0.2, 0.1, 0.05)  % (Speed, Level, Sigma)
```

```
obj =
   Class HWV: Hull-White/Vasicek
   ----------------------------------------
     Dimensions: State = 1, Brownian = 1
   ----------------------------------------
      StartTime: 0
     StartState: 1
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
          Sigma: 0.05
          Level: 0.1
          Speed: 0.2
```

cir and hwv share the same interface and display methods. The only distinction is that cir and hwv model objects constrain Alpha exponents to 1/2 and 0, respectively. Furthermore, the hwv object also provides an additional method that simulates approximate analytic solutions (simBySolution) of separable models. This method simulates the state vector X_t using an approximation of the closed-form solution of diagonal drift HWV models. Each element of the state vector X_t is expressed as the sum of NBrowns correlated Gaussian random draws added to a deterministic time-variable drift.

When evaluating expressions, all model parameters are assumed piecewise constant over each simulation period. In general, this is *not* the exact solution to this hwv model, because the probability distributions of the simulated and true state vectors are identical *only* for piecewise constant parameters. If $S(t,X_t)$, $L(t,X_t)$, and $V(t,X_t)$ are piecewise constant over each observation period, the state vector X_t is normally distributed, and the simulated process is exact for the observation times at which X_t is sampled.

Hull-White vs. Vasicek Models

Many references differentiate between Vasicek models and Hull-White models. Where such distinctions are made, Vasicek parameters are constrained to be constants, while Hull-White parameters vary deterministically with time. Think of Vasicek models in this context as constant-coefficient Hull-White models and equivalently, Hull-White models as time-varying Vasicek models. However, from an architectural perspective, the distinction between static and dynamic parameters is trivial. Since both models share the same general parametric specification as previously described, a single hwv object encompasses the models.

Creating Heston Stochastic Volatility Models

The Heston (heston) object derives directly from SDE from the Drift and Diffusion (sdeddo) class. Each Heston model is a bivariate composite model, consisting of two coupled univariate models:

$$dX_{1t} = B(t)X_{1t}dt + \sqrt{X_{2t}}X_{1t}dW_{1t} \tag{14-5}$$

$$dX_{2t} = S(t)[L(t) - X_{2t}]dt + V(t)\sqrt{X_{2t}}dW_{2t} \tag{14-6}$$

“Equation 14-5” is typically associated with a price process. “Equation 14-6” represents the evolution of the price process' variance. Models of type heston are typically used to price equity options.

Example: Heston Models

Create a heston object using heston to represent the model:

$$dX_{1t} = 0.1X_{1t}dt + \sqrt{X_{2t}}X_{1t}dW_{1t}$$
$$dX_{2t} = 0.2[0.1 - X_{2t}]dt + 0.05\sqrt{X_{2t}}dW_{2t}$$

```
obj = heston (0.1, 0.2, 0.1, 0.05)
```

```
obj =
   Class HESTON: Heston Bivariate Stochastic Volatility
   ----------------------------------------------------
     Dimensions: State = 2, Brownian = 2
   ----------------------------------------------------
      StartTime: 0
     StartState: 1 (2x1 double array)
    Correlation: 2x2 diagonal double array
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
         Return: 0.1
          Speed: 0.2
          Level: 0.1
     Volatility: 0.05
```

Simulating Equity Prices

In this section...

Simulating Multidimensional Market Models

This example compares alternative implementations of a separable multivariate geometric Brownian motion process that is often referred to as a *multidimensional market model*. It simulates sample paths of an equity index portfolio using `sde`, `sdeddo`, `sdeld`, `cev`, and `gbm` objects.

The market model to simulate is:

$$dX_t = \mu X_t dt + D(X_t)\sigma dW_t \tag{14-7}$$

where:

- μ is a diagonal matrix of expected index returns.
- D is a diagonal matrix with X_t along the diagonal.
- σ is a diagonal matrix of standard deviations of index returns.

Representing Market Models Using SDE Objects

Create an `sde` object using `sde` to represent the equity market model.

1 Load the `Data_GlobalIdx2` data set:

```
load Data_GlobalIdx2
prices  = [Dataset.TSX Dataset.CAC Dataset.DAX ...
Dataset.NIK Dataset.FTSE Dataset.SP];
```

2 Convert daily prices to returns:

```
returns =  tick2ret(prices);
```

3 Compute data statistics to input to simulation methods:

```
nVariables  = size(returns, 2);
expReturn   = mean(returns);
sigma       = std(returns);
correlation = corrcoef(returns);
t           = 0;
X           = 100;
X           = X(ones(nVariables,1));
```

4 Create simple anonymous drift and diffusion functions accessible by (t, X_t):

```
F = @(t,X) diag(expReturn) * X;
G = @(t,X) diag(X) * diag(sigma);
```

5 Use these functions with `sde` to create an `sde` object to represent the market model in "Equation 14-7":

```
SDE = sde(F, G, 'Correlation', correlation, 'StartState', X)
```

```
SDE =
   Class SDE: Stochastic Differential Equation
   -------------------------------------------
     Dimensions: State = 6, Brownian = 6
   -------------------------------------------
      StartTime: 0
     StartState: 100 (6x1 double array)
    Correlation: 6x6 double array
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
```

The `sde` object requires additional information to determine the dimensionality of the model, because the functions passed to the`sde` object are known only by their (t, X_t) interface. In other words, the`sde` object requires only two inputs: a drift-rate function and a diffusion-rate function, both accessible by passing the sample time and the corresponding state vector (t, X_t).

In this case, this information is insufficient to determine unambiguously the dimensionality of the state vector and Brownian motion. You resolve the dimensionality by specifying an initial state vector, `StartState`. The SDE engine has assigned the default simulation method, `simByEuler`, to the `Simulation` parameter.

Representing Market Models Using SDEDDO Objects

Create an `sdeddo` object using `sdeddo` to represent the market model in "Equation 14-7":

1. Load the `Data_GlobalIdx2` data set:

   ```
   load Data_GlobalIdx2
   prices  = [Dataset.TSX Dataset.CAC Dataset.DAX ...
   Dataset.NIK Dataset.FTSE Dataset.SP];
   ```
2. Convert daily prices to returns:

   ```
   returns =  tick2ret(prices);
   ```
3. Compute data statistics to input to simulation methods:

   ```
   nVariables  = size(returns, 2);
   expReturn   = mean(returns);
   sigma       = std(returns);
   correlation = corrcoef(returns);
   ```
4. Create `drift` and `diffusion` objects using `drift` and `diffusion`:

   ```
   F = drift(zeros(nVariables,1), diag(expReturn))
   ```

   ```
   F =
      Class DRIFT: Drift Rate Specification
      -------------------------------------
         Rate: drift rate function F(t,X(t))
            A: 6x1 double array
            B: 6x6 diagonal double array
   ```

   ```
   G = diffusion(ones(nVariables,1), diag(sigma))
   ```

   ```
   G =
      Class DIFFUSION: Diffusion Rate Specification
   ```

```
   --------------------------------------------
       Rate: diffusion rate function G(t,X(t))
      Alpha: 6x1 double array
      Sigma: 6x6 diagonal double array
```

5 Pass the `drift` and `diffusion` objects to `sdeddo`:

```
SDEDDO = sdeddo(F, G, 'Correlation', correlation, ...
'StartState', 100)
```

```
SDEDDO =
   Class SDEDDO: SDE from Drift and Diffusion Objects
   -------------------------------------------------
     Dimensions: State = 6, Brownian = 6
   -------------------------------------------------
      StartTime: 0
     StartState: 100 (6x1 double array)
    Correlation: 6x6 double array
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
              A: 6x1 double array
              B: 6x6 diagonal double array
          Alpha: 6x1 double array
          Sigma: 6x6 diagonal double array
```

The `sdeddo` object requires two input objects that provide more information than the two functions from step 4 of “Representing Market Models Using SDE Objects” on page 14-28. Thus, the dimensionality is more easily resolved. In fact, the initial price of each index is as a scalar (`StartState = 100`). This is in contrast to the `sde` object, which required an explicit state vector to uniquely determine the dimensionality of the problem.

Once again, the class of each object is clearly identified, and parameters display like fields of a structure. In particular, the `Rate` parameter of drift and diffusion objects is identified as a callable function of time and state, $F(t,X_t)$ and $G(t,X_t)$, respectively. The additional parameters, `A`, `B`, `Alpha`, and `Sigma`, are arrays of appropriate dimension, indicating static (non-time-varying) parameters. In other words, $A(t,X_t)$, $B(t,X_t)$, $Alpha(t,X_t)$, and $Sigma(t,X_t)$ are constant functions of time and state.

Representing Market Models Using SDELD, CEV, and GBM Objects

Create `sdeld`, `cev`, and `gbm` objects to represent the market model in “Equation 14-7”.

1 Load the `Data_GlobalIdx2` data set:

```
load Data_GlobalIdx2
prices  = [Dataset.TSX Dataset.CAC Dataset.DAX ...
    Dataset.NIK Dataset.FTSE Dataset.SP];
```

2 Convert daily prices to returns:

```
returns =  tick2ret(prices);
```

3 Compute data statistics to input to simulation methods:

```
nVariables  = size(returns, 2);
expReturn   = mean(returns);
sigma       = std(returns);
correlation = corrcoef(returns);
```

```
t           = 0;
X           = 100;
X           = X(ones(nVariables,1));
```

4 Create an `sdeld` object using `sdeld`:

```
SDELD = sdeld(zeros(nVariables,1), diag(expReturn), ...
    ones(nVariables,1), diag(sigma),'Correlation', ...
    correlation, 'StartState', X)
```

```
SDELD =
   Class SDELD: SDE with Linear Drift
   ----------------------------------------
     Dimensions: State = 6, Brownian = 6
   ----------------------------------------
      StartTime: 0
     StartState: 100 (6x1 double array)
    Correlation: 6x6 double array
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
              A: 6x1 double array
              B: 6x6 diagonal double array
          Alpha: 6x1 double array
          Sigma: 6x6 diagonal double array
```

5 Create a `cev` object using `cev`:

```
CEV = cev(diag(expReturn), ones(nVariables,1), ...
    diag(sigma), 'Correlation', correlation, ...
    'StartState', X)
```

```
CEV =
   Class CEV: Constant Elasticity of Variance
   ------------------------------------------
     Dimensions: State = 6, Brownian = 6
   ------------------------------------------
      StartTime: 0
     StartState: 100 (6x1 double array)
    Correlation: 6x6 double array
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
         Return: 6x6 diagonal double array
          Alpha: 6x1 double array
          Sigma: 6x6 diagonal double array
```

6 Create a `gbm` object using `gbm`:

```
GBM = gbm(diag(expReturn), diag(sigma), 'Correlation', ...
    correlation, 'StartState', X)
```

```
GBM =
   Class GBM: Generalized Geometric Brownian Motion
   ------------------------------------------------
     Dimensions: State = 6, Brownian = 6
   ------------------------------------------------
      StartTime: 0
     StartState: 100 (6x1 double array)
    Correlation: 6x6 double array
          Drift: drift rate function F(t,X(t))
```

```
  Diffusion: diffusion rate function G(t,X(t))
 Simulation: simulation method/function simByEuler
     Return: 6x6 diagonal double array
      Sigma: 6x6 diagonal double array
```

Note the succession of interface restrictions:

- `sdeld` objects require you to specify `A`, `B`, `Alpha`, and `Sigma`.
- `cev` objects require you to specify `Return`, `Alpha`, and `Sigma`.
- `gbm` objects require you to specify only `Return` and `Sigma`.

However, all three objects represent the same multidimensional market model.

Also, `cev` and `gbm` objects display the underlying parameter `B` derived from the `sdeld` object as `Return`. This is an intuitive name commonly associated with equity models.

Simulating Equity Markets Using the Default Simulate Method

1 Load the `Data_GlobalIdx2` data set and use `sde` to specify the SDE model as in “Representing Market Models Using SDE Objects” on page 14-28.

```
load Data_GlobalIdx2
prices  = [Dataset.TSX Dataset.CAC Dataset.DAX ...
    Dataset.NIK Dataset.FTSE Dataset.SP];

returns =  tick2ret(prices);

nVariables  = size(returns,2);
expReturn   = mean(returns);
sigma       = std(returns);
correlation = corrcoef(returns);
t           = 0;
X           = 100;
X           = X(ones(nVariables,1));

F = @(t,X) diag(expReturn)* X;
G = @(t,X) diag(X) * diag(sigma);

SDE = sde(F, G, 'Correlation', ...
    correlation, 'StartState', X);
```

2 Simulate a single path of correlated equity index prices over one calendar year (defined as approximately 250 trading days) using the default`simulate` method:

```
nPeriods = 249;      % # of simulated observations
dt       =   1;      % time increment = 1 day
rng(142857,'twister')
[S,T] = simulate(SDE, nPeriods, 'DeltaTime', dt);

whos S

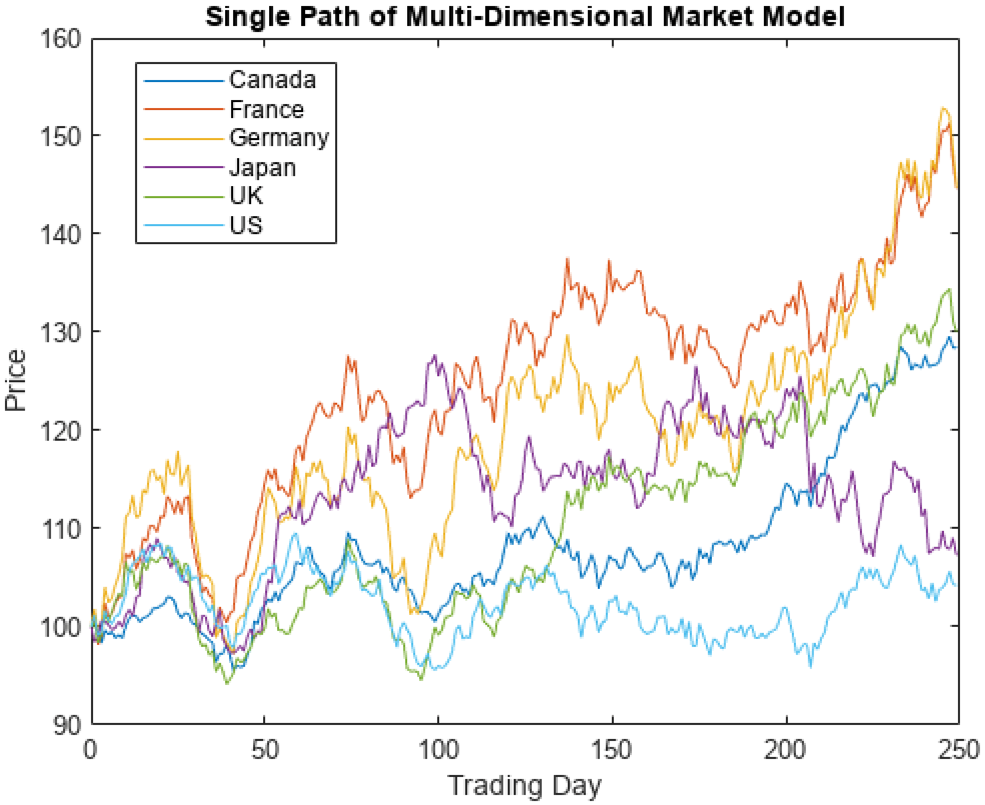
  Name        Size             Bytes  Class     Attributes

  S         250x6              12000  double
```

The output array `S` is a 250-by-6 = (`NPeriods + 1`-by-`nVariables`-by-`1`) array with the same initial value, `100`, for all indices. Each row of `S` is an observation of the state vector X_t at time t.

3 Plot the simulated paths.

```
plot(T, S), xlabel('Trading Day'), ylabel('Price')
title('Single Path of Multi-Dimensional Market Model')
legend({'Canada' 'France' 'Germany' 'Japan' 'UK' 'US'}, ...
    'Location', 'Best')
```



Simulating Equity Markets Using the SimByEuler Method

Because `simByEuler` is a valid simulation method, you can call it directly, overriding the `Simulation` parameter's current method or function (which in this case is `simByEuler`). The following statements produce the same price paths as generated in “Simulating Equity Markets Using the Default Simulate Method” on page 14-32:

1 Load the `Data_GlobalIdx2` data set and use `sde` to specify the SDE model as in “Representing Market Models Using SDE Objects” on page 14-28.

```
load Data_GlobalIdx2
prices  = [Dataset.TSX Dataset.CAC Dataset.DAX ...
    Dataset.NIK Dataset.FTSE Dataset.SP];

returns =  tick2ret(prices);

nVariables  = size(returns,2);
expReturn   = mean(returns);
sigma       = std(returns);
correlation = corrcoef(returns);
```

```
t            = 0;
X            = 100;
X            = X(ones(nVariables,1));

F = @(t,X) diag(expReturn)* X;
G = @(t,X) diag(X) * diag(sigma);

SDE = sde(F, G, 'Correlation', ...
    correlation, 'StartState', X);
```

2 Simulate a single path using simByEuler.

```
nPeriods = 249;      % # of simulated observations
dt       =   1;      % time increment = 1 day
rng(142857,'twister')
[S,T] = simByEuler(SDE, nPeriods, 'DeltaTime', dt);
```

3 Simulate 10 trials with the same initial conditions, and examine S:

```
rng(142857,'twister')
[S,T] = simulate(SDE, nPeriods, 'DeltaTime', dt, 'nTrials', 10);

whos S
```

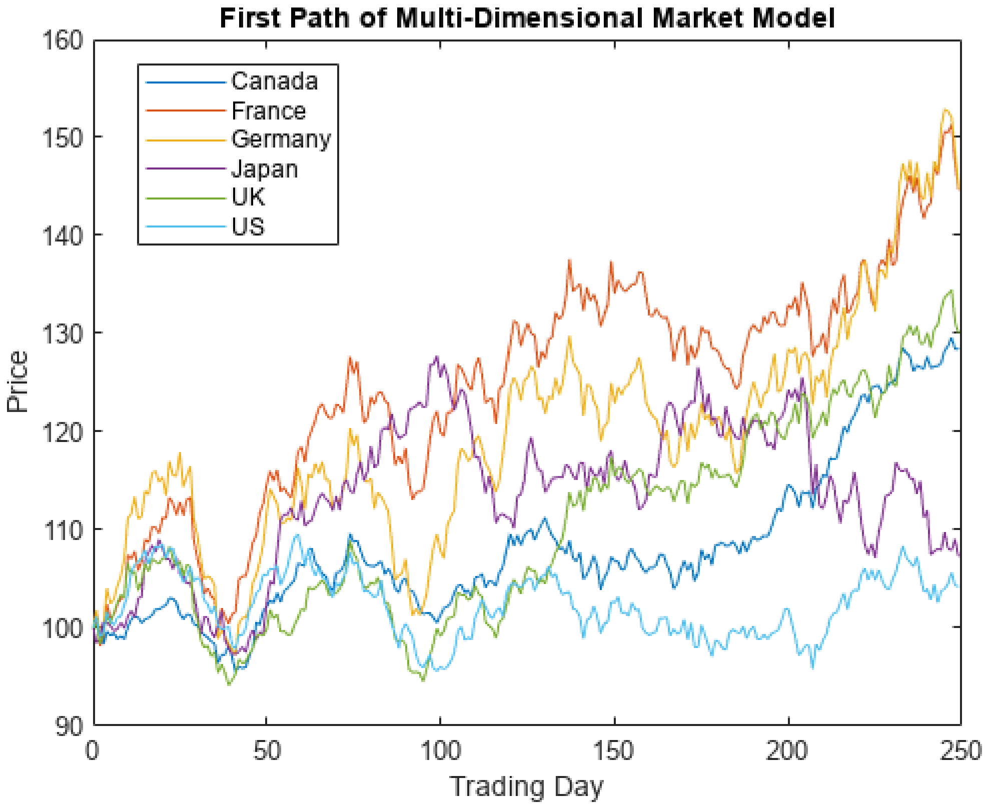
```
  Name         Size                  Bytes  Class     Attributes

  S          250x6x10               120000  double
```

Now the output array S is an NPeriods + 1-by-nVariables-by-NTrials time series array.

4 Plot the first paths.

```
plot(T, S(:,:,1)), xlabel('Trading Day'), ylabel('Price')
title('First Path of Multi-Dimensional Market Model')
legend({'Canada' 'France' 'Germany' 'Japan' 'UK' 'US'},...
    'Location', 'Best')
```



The first realization of S is identical to the paths in the plot.

Simulating Equity Markets Using GBM Simulation Methods

Finally, consider simulation using GBM simulation methods. Separable GBM models have two specific simulation methods:

- An overloaded Euler simulation method, simByEuler, designed for optimal performance
- A function, simBySolution, provides an approximate solution of the underlying stochastic differential equation, designed for accuracy

1 Load the Data_GlobalIdx2 data set and use sde to specify the SDE model as in “Representing Market Models Using SDE Objects” on page 14-28, and the GBM model as in “Representing Market Models Using SDELD, CEV, and GBM Objects” on page 14-30.

```
load Data_GlobalIdx2
prices  = [Dataset.TSX Dataset.CAC Dataset.DAX ...
    Dataset.NIK Dataset.FTSE Dataset.SP];

returns =  tick2ret(prices);

nVariables  = size(returns,2);
expReturn   = mean(returns);
sigma       = std(returns);
correlation = corrcoef(returns);
t           = 0;
X           = 100;
```

```
X           = X(ones(nVariables,1));

F = @(t,X) diag(expReturn)* X;
G = @(t,X) diag(X) * diag(sigma);

SDE = sde(F, G, 'Correlation', ...
    correlation, 'StartState', X);

GBM = gbm(diag(expReturn),diag(sigma), 'Correlation', ...
    correlation, 'StartState', X);
```

2 To illustrate the performance benefit of the overloaded Euler approximation method, increase the number of trials to 10000.

```
nPeriods = 249;      % # of simulated observations
dt       =   1;      % time increment = 1 day
rng(142857,'twister')
[X,T] = simulate(GBM, nPeriods, 'DeltaTime', dt, ...
    'nTrials', 10000);

whos X
```

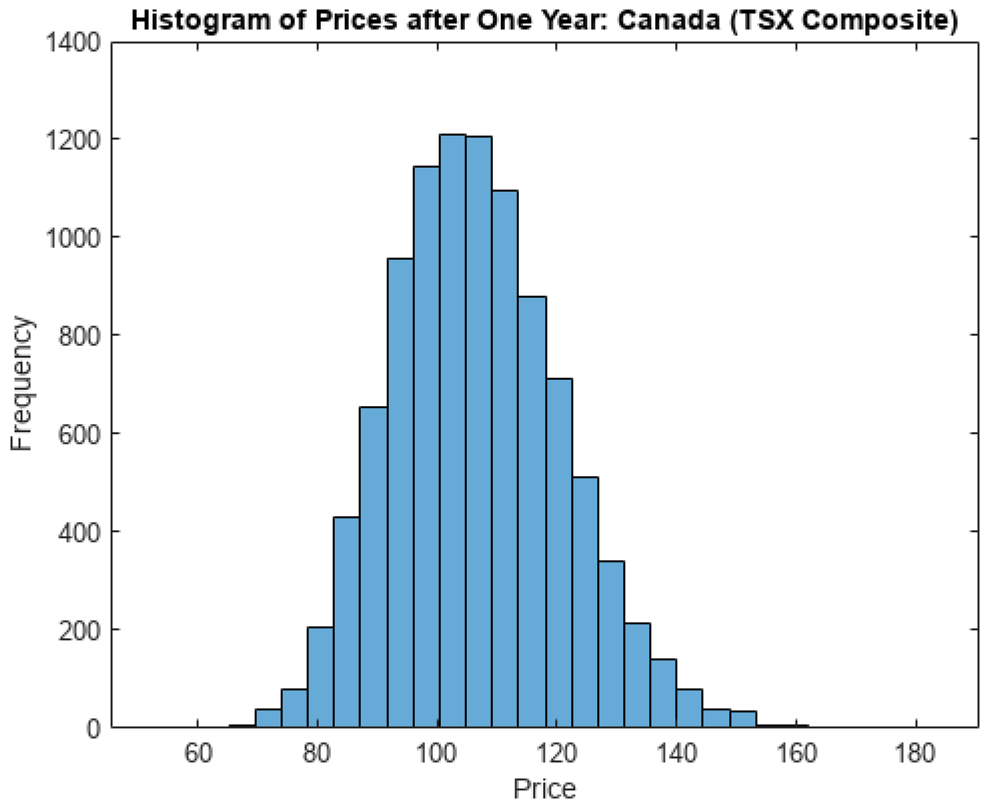
```
  Name        Size                     Bytes  Class     Attributes

  X         250x6x10000            120000000  double
```

The output X is a much larger time series array.

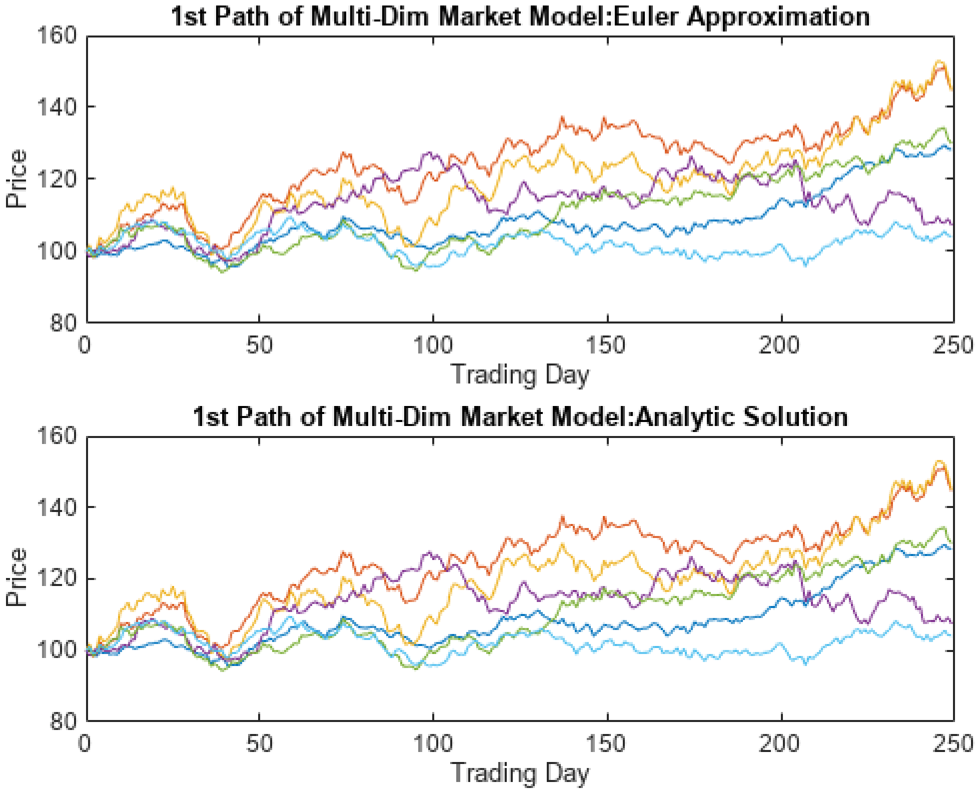
3 Using this sample size, examine the terminal distribution of Canada's TSX Composite to verify qualitatively the lognormal character of the data.

```
histogram(squeeze(X(end,1,:)), 30), xlabel('Price'), ylabel('Frequency')
title('Histogram of Prices after One Year: Canada (TSX Composite)')
```



4 Simulate 10 trials of the solution and plot the first trial:

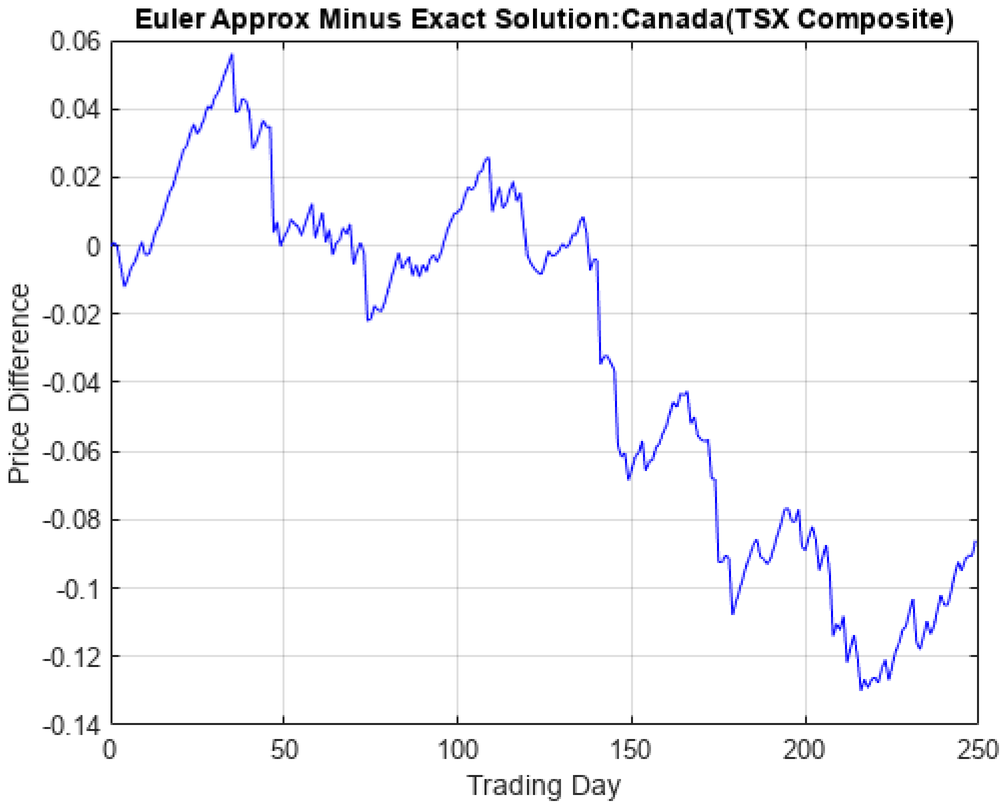
```
rng(142857,'twister')
[S,T] = simulate(SDE, nPeriods, 'DeltaTime', dt, 'nTrials', 10);
rng(142857,'twister')
[X,T] = simBySolution(GBM, nPeriods,...
    'DeltaTime', dt, 'nTrials', 10);
subplot(2,1,1)
plot(T, S(:,:,1)), xlabel('Trading Day'),ylabel('Price')
title('1st Path of Multi-Dim Market Model:Euler Approximation')
subplot(2,1,2)
plot(T, X(:,:,1)), xlabel('Trading Day'),ylabel('Price')
title('1st Path of Multi-Dim Market Model:Analytic Solution')
```



In this example, all parameters are constants, and `simBySolution` does indeed sample the exact solution. The details of a single index for any given trial show that the price paths of the Euler approximation and the exact solution are close, but not identical.

5 The following plot illustrates the difference between the two methods:

```
subplot(1,1,1)
plot(T, S(:,1,1) - X(:,1,1), 'blue'), grid('on')
xlabel('Trading Day'), ylabel('Price Difference')
title('Euler Approx Minus Exact Solution:Canada(TSX Composite)')
```



The `simByEuler` Euler approximation literally evaluates the stochastic differential equation directly from the equation of motion, for some suitable value of the `dt` time increment. This simple approximation suffers from discretization error. This error is attributed to the discrepancy between the choice of the `dt` time increment and what in theory is a continuous-time parameter.

The discrete-time approximation improves as `DeltaTime` approaches zero. The Euler method is often the least accurate and most general method available. All models shipped in the simulation suite have this method.

In contrast, the`simBySolution` method provides a more accurate description of the underlying model. This method simulates the price paths by an approximation of the closed-form solution of separable models. Specifically, it applies a Euler approach to a transformed process, which in general is not the exact solution to this `GBM` model. This is because the probability distributions of the simulated and true state vectors are identical only for piecewise constant parameters.

When all model parameters are piecewise constant over each observation period, the simulated process is exact for the observation times at which the state vector is sampled. Since all parameters are constants in this example,`simBySolution` does indeed sample the exact solution.

For an example of how to use `simBySolution` to optimize the accuracy of solutions, see “Optimizing Accuracy: About Solution Precision and Error” on page 14-65.

Inducing Dependence and Correlation

This example illustrates two techniques that induce dependence between individual elements of a state vector. It also illustrates the interaction between `Sigma` and `Correlation`.

The first technique generates correlated Gaussian variates to form a Brownian motion process with dependent components. These components are then weighted by a diagonal volatility or exposure matrix `Sigma`.

The second technique generates independent Gaussian variates to form a standard Brownian motion process, which is then weighted by the lower Cholesky factor of the desired covariance matrix. Although these techniques can be used on many models, the relationship between them is most easily illustrated by working with a separable `GBM` model (see Simulating Equity Prices Using GBM Simulation Methods on page 14-35). The market model to simulate is:

$$dX_t = \mu X_t dt + \sigma X_t dW_t$$

where μ is a diagonal matrix.

1 Load the data set:

```
load Data_GlobalIdx2
prices  = [Dataset.TSX Dataset.CAC Dataset.DAX ...
    Dataset.NIK Dataset.FTSE Dataset.SP];
```

2 Convert the daily prices to returns:

```
returns =  tick2ret(prices);
```

3 Specify `Sigma` and `Correlation` using the first technique:

   a Using the first technique, specify `Sigma` as a diagonal matrix of asset return standard deviations:

   ```
   expReturn   = diag(mean(returns));  % expected return vector
   sigma       = diag(std(returns));   % volatility of returns
   ```

   b Specify `Correlation` as the sample correlation matrix of those returns. In this case, the components of the Brownian motion are dependent:

   ```
   correlation = corrcoef(returns);
   GBM1        = gbm(expReturn,sigma,'Correlation',...
                     correlation);
   ```

4 Specify `Sigma` and `Correlation` using the second technique:

   a Using the second technique, specify `Sigma` as the lower Cholesky factor of the asset return covariance matrix:

   ```
   covariance = cov(returns);
   sigma      = cholcov(covariance)';
   ```

   b Set `Correlation` to an identity matrix:

   ```
   GBM2       = gbm(expReturn,sigma);
   ```

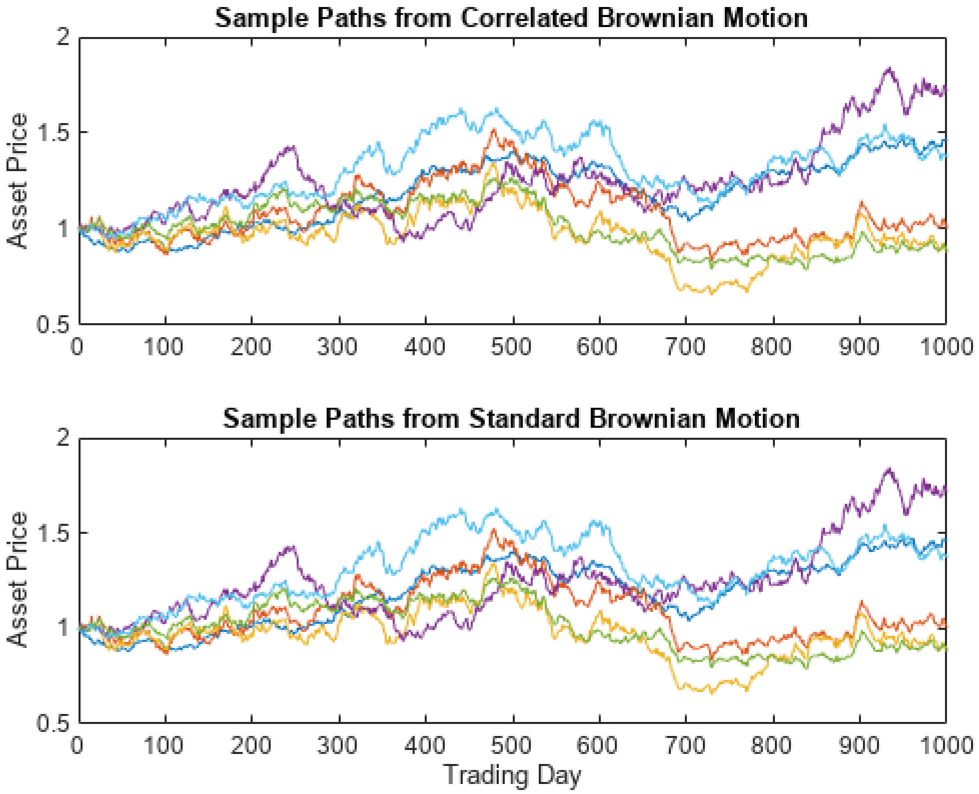
   Here, `sigma` captures both the correlation and magnitude of the asset return uncertainty. In contrast to the first technique, the components of the Brownian motion are independent. Also, this technique accepts the default assignment of an identity matrix to `Correlation`, and is more straightforward.

5. Simulate a single trial of 1000 observations (roughly four years of daily data) using both techniques. By default, all state variables start at 1:

   ```
   rng(22814,'twister')
   [X1,T] = simByEuler(GBM1,1000);  % correlated Brownian motion
   rng(22814,'twister')
   [X2,T] = simByEuler(GBM2,1000);  % standard Brownian motion
   ```

When based on the same initial random number state, each technique generates identical asset price paths:

```
subplot(2,1,1)
plot(T, X1)
title('Sample Paths from Correlated Brownian Motion')
ylabel('Asset Price')
subplot(2,1,2)
plot(T, X2)
title('Sample Paths from Standard Brownian Motion')
xlabel('Trading Day')
ylabel('Asset Price')
```



Sample Paths from Correlated Brownian Motion

Sample Paths from Standard Brownian Motion

Dynamic Behavior of Market Parameters

As discussed in “Creating SDE Objects” on page 14-7, object parameters may be evaluated as if they are MATLAB functions accessible by a common interface. This accessibility provides the impression of dynamic behavior regardless of whether the underlying parameters are truly time-varying.

Furthermore, because parameters are accessible by a common interface, seemingly simple linear constructs may in fact represent complex, nonlinear designs.

For example, consider a univariate geometric Brownian motion (GBM) model of the form:

$$dX_t = \mu(t)X_t dt + \sigma(t)X_t dW_t$$

In this model, the return, *μ(t)*, and volatility, *σ(t)*, are dynamic parameters of time alone. However, when creating a `gbm` object to represent the underlying model, such dynamic behavior must be accessible by the common (t, X_t) interface. This reflects the fact that `GBM` models (and others) are restricted parameterizations that derive from the general `SDE` class.

As a convenience, you can specify parameters of restricted models, such as `GBM` models, as traditional MATLAB arrays of appropriate dimension. In this case, such arrays represent a static special case of the more general dynamic situation accessible by the (t, X_t) interface.

Moreover, when you enter parameters as functions, object constructors can verify that they return arrays of correct size by evaluating them at the initial time and state. Otherwise, object constructors have no knowledge of any particular functional form.

The following example illustrates a technique that includes dynamic behavior by mapping a traditional MATLAB time series array to a callable function with a (t, X_t) interface. It also compares the function with an otherwise identical model with constant parameters.

Because time series arrays represent dynamic behavior that must be captured by functions accessible by the (t, X_t) interface, you need utilities to convert traditional time series arrays into callable functions of time and state. The following example shows how to do this using the conversion function `ts2func` (time series to function).

1 **Load the data.** Load a daily historical data set containing three-month Euribor rates and closing index levels of France's CAC 40 spanning the time interval February 7, 2001 to April 24, 2006:

```
load Data_GlobalIdx2
```

2 **Simulate risk-neutral sample paths.** Simulate risk-neutral sample paths of the CAC 40 index using a geometric Brownian motion (`GBM`) model:

$$dX_t = r(t)X_t dt + \sigma X_t dW_t$$

where *r(t)* represents evolution of the risk-free rate of return.

Furthermore, assume that you need to annualize the relevant information derived from the daily data (annualizing the data is optional, but is useful for comparison to other examples), and that each calendar year comprises 250 trading days:

```
dt      = 1/250;
returns = tick2ret(Dataset.CAC);
sigma   = std(returns)*sqrt(250);
yields  = Dataset.EB3M;
yields  = 360*log(1 + yields);
```

3 **Compare the sample paths from two risk-neutral historical simulation approaches.** Compare the resulting sample paths obtained from two risk-neutral historical simulation approaches, where the daily Euribor yields serve as a proxy for the risk-free rate of return.

a The first approach specifies the risk-neutral return as the sample average of Euribor yields, and therefore assumes a constant (non-dynamic) risk-free return:

```
nPeriods = length(yields);  % Simulated observations
rng(5713,'twister')
obj    = gbm(mean(yields),diag(sigma),'StartState',100)
```

```
obj = 
   Class GBM: Generalized Geometric Brownian Motion
   ------------------------------------------------
     Dimensions: State = 1, Brownian = 1
   ------------------------------------------------
      StartTime: 0
     StartState: 100
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
         Return: 0.0278117
          Sigma: 0.231906
```

```
[X1,T] = simulate(obj,nPeriods,'DeltaTime',dt);
```

b In contrast, the second approach specifies the risk-neutral return as the historical time series of Euribor yields. It therefore assumes a dynamic, yet deterministic, rate of return; this example does not illustrate stochastic interest rates. To illustrate this dynamic effect, use the `ts2func` utility:

```
r = ts2func(yields,'Times',(0:nPeriods - 1)');
```

`ts2func` packages a specified time series array inside a callable function of time and state, and synchronizes it with an optional time vector. For instance:

```
r(0,100)
```

```
ans = 0.0470
```

evaluates the function at ($t = 0, X_t = 100$) and returns the first observed Euribor yield. However, you can also evaluate the resulting function at any intermediate time t and state X_t:

```
r(7.5,200)
```

```
ans = 0.0472
```

Furthermore, the following command produces the same result when called with time alone:

```
r(7.5)
```

```
ans = 0.0472
```

The equivalence of these last two commands highlights some important features.

When you specify parameters as functions, they must evaluate properly when passed a scalar, real-valued sample time (t), and an *NVars*-by-`1` state vector (X_t). They must also generate an array of appropriate dimensions, which in the first case is a scalar constant, and in the second case is a scalar, piecewise constant function of time alone.

You are not required to use either time (t) or state (X_t). In the current example, the function evaluates properly when passed time followed by state, thereby satisfying the minimal requirements. The fact that it also evaluates correctly when passed only time simply indicates that the function does not require the state vector X_t. The important point to make is that it works when you pass it (t, X_t).

Furthermore, the `ts2func` function performs a zero-order-hold (ZOH) piecewise constant interpolation. The notion of piecewise constant parameters is pervasive throughout the SDE architecture, and is discussed in more detail in “Optimizing Accuracy: About Solution Precision and Error” on page 14-65.

4. **Perform a second simulation using the same initial random number state.** Complete the comparison by performing the second simulation using the same initial random number state:

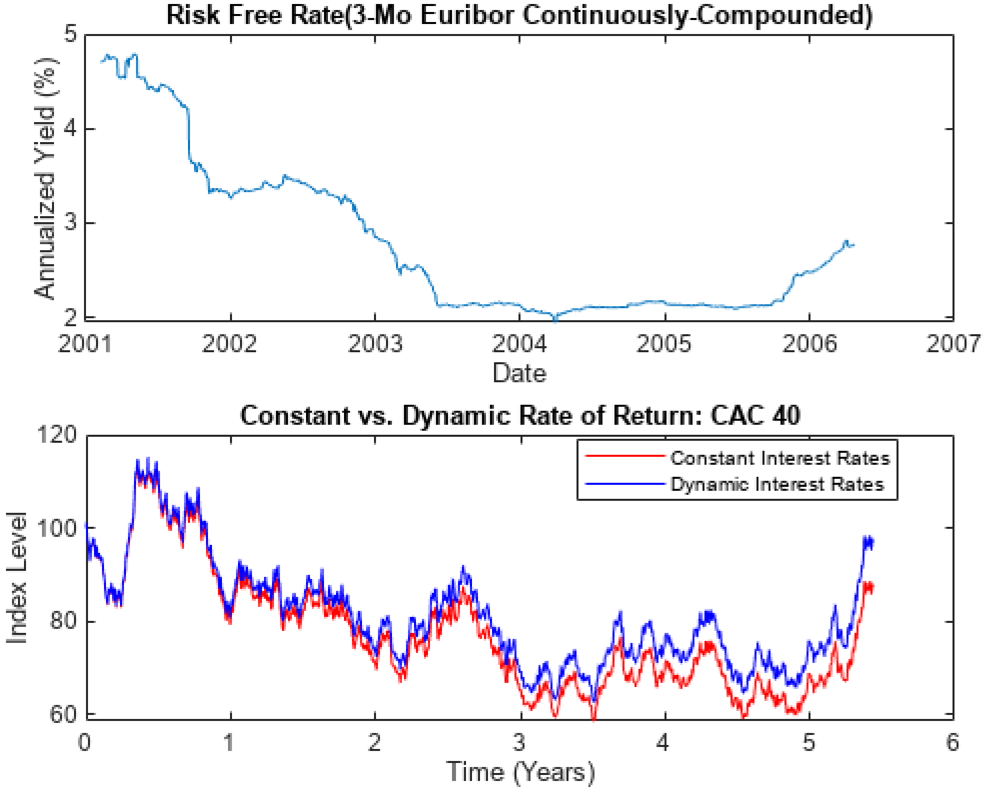
```
rng(5713,'twister')
obj = gbm(r, diag(sigma),'StartState',100)
```

```
obj =
   Class GBM: Generalized Geometric Brownian Motion
   ------------------------------------------------
     Dimensions: State = 1, Brownian = 1
   ------------------------------------------------
      StartTime: 0
     StartState: 100
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
         Return: function ts2func/vector2Function
          Sigma: 0.231906
```

```
X2  = simulate(obj,nPeriods,'DeltaTime',dt);
```

5. **Compare the two simulation trials.** Plot the series of risk-free reference rates to compare the two simulation trials:

```
subplot(2,1,1)
plot(dates,100*yields)
datetick('x')
xlabel('Date')
ylabel('Annualized Yield (%)')
title('Risk Free Rate(3-Mo Euribor Continuously-Compounded)')
subplot(2,1,2)
plot(T,X1,'red',T,X2,'blue')
xlabel('Time (Years)')
ylabel('Index Level')
title('Constant vs. Dynamic Rate of Return: CAC 40')
legend({'Constant Interest Rates' 'Dynamic Interest Rates'},...
    'Location', 'Best')
```



The paths are close but not exact. The blue line in the last plot uses all the historical Euribor data, and illustrates a single trial of a historical simulation.

Pricing Equity Options

As discussed in “Ensuring Positive Interest Rates” on page 14-53, all simulation and interpolation methods allow you to specify one or more functions of the form:

$$X_t = f(t, X_t)$$

to evaluate at the end of every sample time.

The related example illustrates a simple, common end-of-period processing function to ensure nonnegative interest rates. This example illustrates a processing function that allows you to avoid simulation outputs altogether.

Consider pricing European stock options by Monte Carlo simulation within a Black-Scholes-Merton framework. Assume that the stock has the following characteristics:

- The stock currently trades at 100.
- The stock pays no dividends.
- The stock's volatility is 50% per annum.
- The option strike price is 95.

- The option expires in three months.
- The risk-free rate is constant at 10% per annum.

To solve this problem, model the evolution of the underlying stock by a univariate geometric Brownian motion (GBM) model with constant parameters:

$$dX_t = 0.1X_t dt + 0.5X_t dW_t$$

Furthermore, assume that the stock price is simulated daily, and that each calendar month comprises 21 trading days:

The goal is to simulate independent paths of daily stock prices, and calculate the price of European options as the risk-neutral sample average of the discounted terminal option payoff at expiration 63 days from now. This example calculates option prices by two approaches:

- A Monte Carlo simulation that explicitly requests the simulated stock paths as an output. The output paths are then used to price the options.
- An end-of-period processing function, accessible by time and state, that records the terminal stock price of each sample path. This processing function is implemented as a nested function with access to shared information. For more information, see `Example_BlackScholes.m`.

1 Before simulation, invoke the example file to access the end-of-period processing function:

```
nTrials = 10000; % Number of independent trials (i.e., paths)
f = Example_BlackScholes(nPeriods,nTrials)
```

```
f = struct with fields:
    BlackScholes: @Example_BlackScholes/saveTerminalStockPrice
       CallPrice: @Example_BlackScholes/getCallPrice
        PutPrice: @Example_BlackScholes/getPutPrice
```

2 Simulate 10000 independent trials (sample paths). Request the simulated stock price paths as an output, and specify an end-of-period processing function:

```
rng(88161,'twister')
X = simBySolution(obj,nPeriods,'DeltaTime',dt,...
    'nTrials',nTrials,'Processes',f.BlackScholes);
```

3 Calculate the option prices directly from the simulated stock price paths. Because these are European options, ignore all intermediate stock prices:

```
call = mean(exp(-rate*T)*max(squeeze(X(end,:,:)) - strike, 0))
```

```
call = 13.9342
```

```
put  = mean(exp(-rate*T)*max(strike - squeeze(X(end,:,:)), 0))
```

```
put = 6.4166
```

4 Price the options indirectly by invoking the nested functions:

```
f.CallPrice(strike,rate)
```

```
ans = 13.9342
```

```
f.PutPrice(strike,rate)
```

```
ans = 6.4166
```

For reference, the theoretical call and put prices computed from the Black-Scholes option formulas are `13.6953` and `6.3497`, respectively.

5 Although steps 3 and 4 produce the same option prices, the latter approach works directly with the terminal stock prices of each sample path. Therefore, it is much more memory efficient. In this example, there is no compelling reason to request an output.

Simulating Interest Rates

In this section...

Simulating Interest Rates Using Interpolation

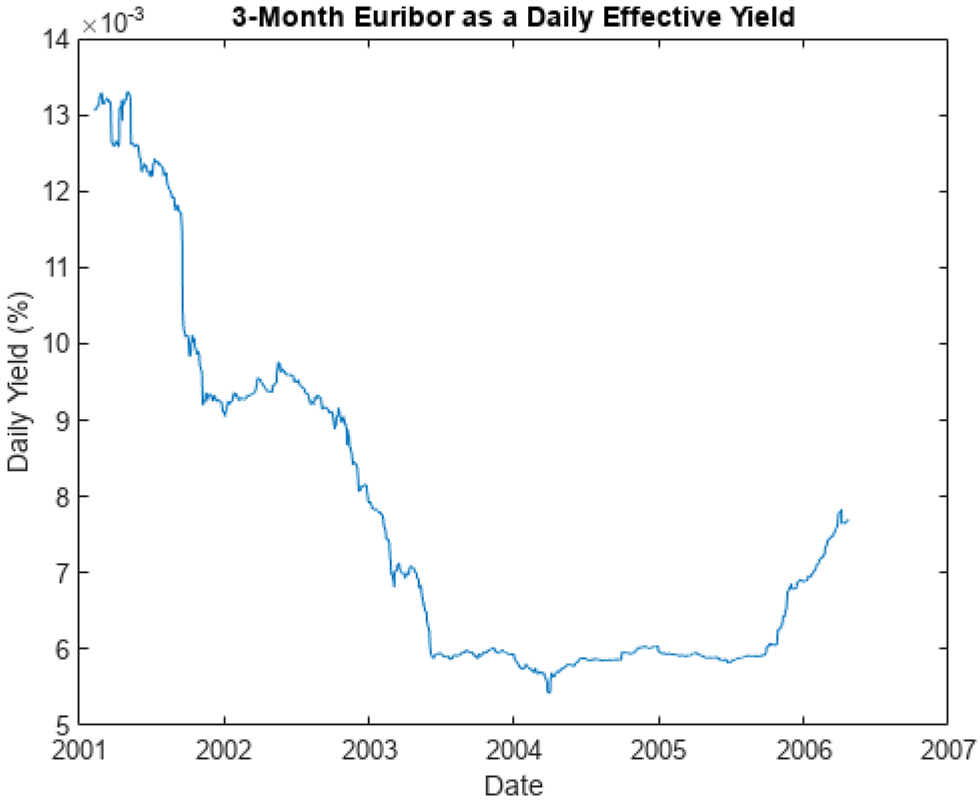
All simulation methods require that you specify a time grid by specifying the number of periods (NPeriods). You can also optionally specify a scalar or vector of strictly positive time increments (DeltaTime) and intermediate time steps (NSteps). These parameters, along with an initial sample time associated with the object (StartTime), uniquely determine the sequence of times at which the state vector is sampled. Thus, simulation methods allow you to traverse the time grid from beginning to end (that is, from left to right).

In contrast, interpolation methods allow you to traverse the time grid in any order, allowing both forward and backward movements in time. They allow you to specify a vector of interpolation times whose elements do not have to be unique.

Many references define the Brownian Bridge as a conditional simulation combined with a scheme for traversing the time grid, effectively merging two distinct algorithms. In contrast, the interpolation method offered here provides additional flexibility by intentionally separating the algorithms. In this method for moving about a time grid, you perform an initial Monte Carlo simulation to sample the state at the terminal time, and then successively sample intermediate states by stochastic interpolation. The first few samples determine the overall behavior of the paths, while later samples progressively refine the structure. Such algorithms are often called *variance reduction techniques*. This algorithm is simple when the number of interpolation times is a power of 2. In this case, each interpolation falls midway between two known states, refining the interpolation using a method like bisection. This example highlights the flexibility of refined interpolation by implementing this power-of-two algorithm.

1 **Load the data.** Load a historical data set of three-month Euribor rates, observed daily, and corresponding trading dates spanning the time interval from February 7, 2001 through April 24, 2006:

```
load Data_GlobalIdx2
plot(dates, 100 * Dataset.EB3M)
datetick('x'), xlabel('Date'), ylabel('Daily Yield (%)')
title('3-Month Euribor as a Daily Effective Yield')
```



2 **Fit a model to the data.** Now fit a simple univariate `Vasicek` model to the daily equivalent yields of the three-month Euribor data:

$$dX_t = S(L - X_t)dt + \sigma dW_t$$

Given initial conditions, the distribution of the short rate at some time *T* in the future is Gaussian with mean:

$$E(X_T) = X_0 e^{-ST} + L(1 - e^{-ST})$$

and variance:

$$Var(X_T) = \sigma^2(1 - e^{-ST})/2S$$

To calibrate this simple short-rate model, rewrite it in more familiar regression format:

$$y_t = \alpha + \beta x_t + \varepsilon_t$$

where:

$$y_t = dX_t, \alpha = SLdt, \beta = \ -Sdt$$

perform an ordinary linear regression where the model volatility is proportional to the standard error of the residuals:

$$\sigma = \sqrt{Var(\varepsilon_t)/dt}$$

```
yields     = Dataset.EB3M;
regressors = [ones(length(yields) - 1, 1) yields(1:end-1)];
[coefficients, intervals, residuals] = ...
   regress(diff(yields), regressors);
dt    = 1;  % time increment = 1 day
speed = -coefficients(2)/dt;
level = -coefficients(1)/coefficients(2);
sigma =  std(residuals)/sqrt(dt);
```

3 **Create an object and set its initial StartState.** Create an hwv object with `StartState` set to the most recently observed short rate:

```
obj = hwv(speed, level, sigma, 'StartState', yields(end))
```

```
obj =
   Class HWV: Hull-White/Vasicek
   ----------------------------------------
     Dimensions: State = 1, Brownian = 1
   ----------------------------------------
      StartTime: 0
     StartState: 7.70408e-05
    Correlation: 1
          Drift: drift rate function F(t,X(t))
      Diffusion: diffusion rate function G(t,X(t))
     Simulation: simulation method/function simByEuler
          Sigma: 4.77637e-07
          Level: 6.00424e-05
          Speed: 0.00228854
```

4 **Simulate the fitted model.** Assume, for example, that you simulate the fitted model over 64 (2^6) trading days, using a refined Brownian bridge with the power-of-two algorithm instead of the usual beginning-to-end Monte Carlo simulation approach. Furthermore, assume that the initial time and state coincide with those of the last available observation of the historical data, and that the terminal state is the expected value of the Vasicek model 64 days into the future. In this case, you can assess the behavior of various paths that all share the same initial and terminal states, perhaps to support pricing path-dependent interest rate options over a three-month interval.

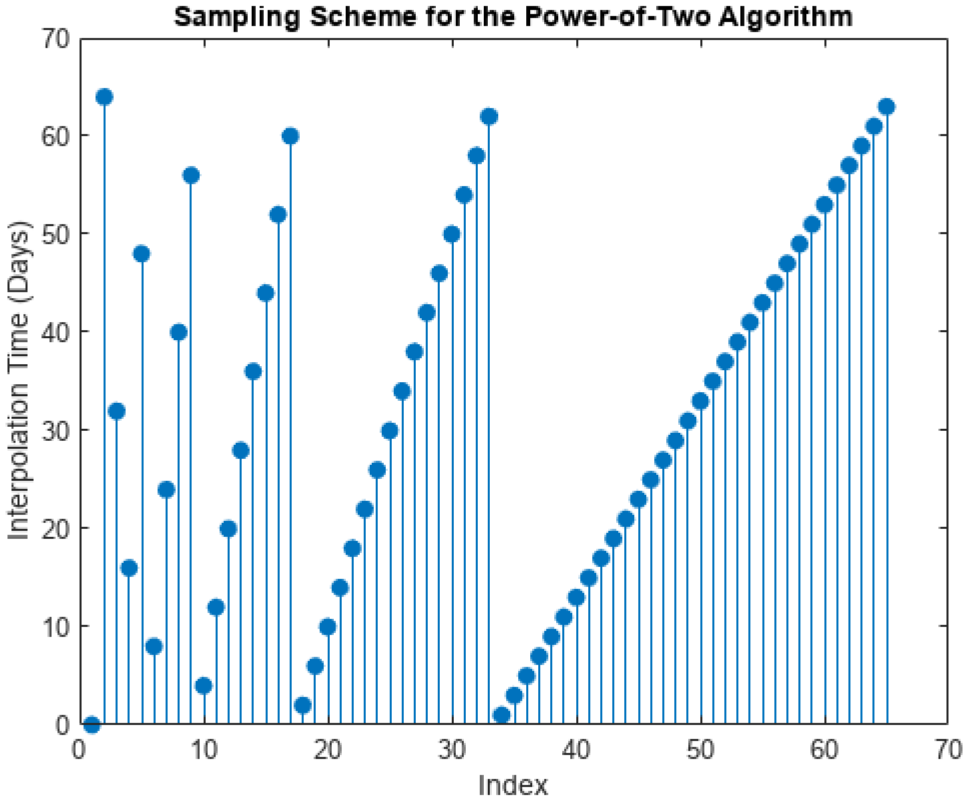
Create a vector of interpolation times to traverse the time grid by moving both forward and backward in time. Specifically, the first interpolation time is set to the most recent short-rate observation time, the second interpolation time is set to the terminal time, and subsequent interpolation times successively sample intermediate states:

```
T      = 64;
times  = (1:T)';
t      = NaN(length(times) + 1, 1);
t(1)   = obj.StartTime;
t(2)   = T;
delta  = T;
jMax   = 1;
iCount = 3;

for k = 1:log2(T)
    i = delta / 2;
    for j = 1:jMax
        t(iCount) = times(i);
        i         = i + delta;
        iCount    = iCount + 1;
    end
    jMax  = 2 * jMax;
    delta = delta / 2;
end
```

5 **Plot the interpolation times.** Examine the sequence of interpolation times generated by this algorithm:

```
stem(1:length(t), t, 'filled')
xlabel('Index'), ylabel('Interpolation Time (Days)')
title ('Sampling Scheme for the Power-of-Two Algorithm')
```



The first few samples are widely separated in time and determine the course structure of the paths. Later samples are closely spaced and progressively refine the detailed structure.

6 **Initialize the time series grid.** Now that you have generated the sequence of interpolation times, initialize a course time series grid to begin the interpolation. The sampling process begins at the last observed time and state taken from the historical short-rate series, and ends 64 days into the future at the expected value of the `Vasicek` model derived from the calibrated parameters:

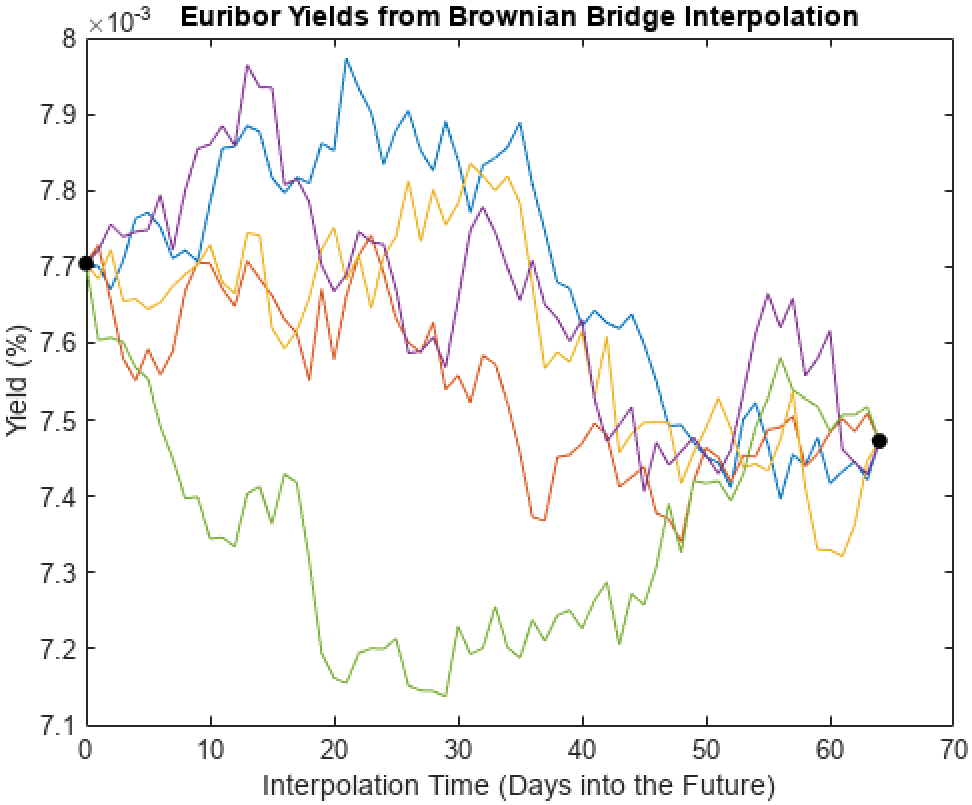
```
average = obj.StartState * exp(-speed * T) + level * ...
(1 - exp(-speed * T));
X       = [obj.StartState ; average];
```

7 **Generate five sample paths.** Generate five sample paths, setting the `Refine` input flag to `TRUE` to insert each new interpolated state into the time series grid as it becomes available. Perform interpolation on a trial-by-trial basis. Because the input time series `X` has five trials (where each page of the three-dimensional time series represents an independent trial), the interpolated output series `Y` also has five pages:

```
nTrials = 5;
rng(63349,'twister')
Y = obj.interpolate(t, X(:,:,ones(nTrials,1)), ...
'Times',[obj.StartTime  T], 'Refine', true);
```

8 **Plot the resulting sample paths.** Because the interpolation times do not monotonically increase, sort the times and reorder the corresponding short rates:

```
[t,i] = sort(t);
Y     = squeeze(Y);
Y     = Y(i,:);
plot(t, 100 * Y), hold('on')
plot(t([1 end]), 100 * Y([1 end],1),'. black','MarkerSize',20)
xlabel('Interpolation Time (Days into the Future)')
ylabel('Yield (%)'), hold('off')
title ('Euribor Yields from Brownian Bridge Interpolation')
```



The short rates in this plot represent alternative sample paths that share the same initial and terminal values. They illustrate a special, though simplistic, case of a broader sampling technique known as stratified sampling. For a more sophisticated example of stratified sampling, see “Stratified Sampling” on page 14-57.

Although this simple example simulated a univariate `Vasicek` interest rate model, it applies to problems of any dimensionality.

Tip Brownian-bridge methods also apply more general variance-reduction techniques. For more information, see “Stratified Sampling” on page 14-57.

Ensuring Positive Interest Rates

All simulation and interpolation methods allow you to specify a sequence of functions, or background processes, to evaluate at the end of every sample time period. This period includes any intermediate time steps determined by the optional `NSteps` input, as discussed in “Optimizing Accuracy: About Solution Precision and Error” on page 14-65. These functions are specified as callable functions of time and state, and must return an updated state vector X_t:

$$X_t = f(t, X_t)$$

You must specify multiple processing functions as a cell array of functions. These functions are invoked in the order in which they appear in the cell array.

Processing functions are not required to use time (t) or state (X_t). They are also not required to update or change the input state vector. In fact, simulation and interpolation methods have no knowledge of any implementation details, and in this respect, they only adhere to a published interface.

Such processing functions provide a powerful modeling tool that can solve various problems. Such functions allow you to, for example, specify boundary conditions, accumulate statistics, plot graphs, and price path-dependent options.

Except for Brownian motion (`BM`) models, the individual components of the simulated state vector typically represent variables whose real-world counterparts are inherently positive quantities, such as asset prices or interest rates. However, by default, most of the simulation and interpolation methods provided here model the transition between successive sample times as a scaled (possibly multivariate) Gaussian draw. So, when approximating a continuous-time process in discrete time, the state vector may not remain positive. The only exception is `simBySolution` for `gbm` objects and `simBySolution` for `hwv` objects, a logarithmic transform of separable geometric Brownian motion models. Moreover, by default, none of the simulation and interpolation methods make adjustments to the state vector. Therefore, you are responsible for ensuring that all components of the state vector remain positive as appropriate.

Fortunately, specifying nonnegative states ensures a simple end-of-period processing adjustment. Although this adjustment is widely applicable, it is revealing when applied to a univariate `cir` square-root diffusion model:

$$dX_t = 0.25(0.1 - X_t)dt + 0.2X_t^{\frac{1}{2}}dW_t = S(L - X_t)dt + \sigma X_t^{\frac{1}{2}}dW_t$$

Perhaps the primary appeal of univariate `cir` models where:

$$2SL \geq \sigma^2$$

is that the short rate remains positive. However, the positivity of short rates only holds for the underlying continuous-time model.

1 **Simulate daily short rates of the `cir` model.** To illustrate the latter statement, simulate daily short rates of the `cir` model, using `cir`, over one calendar year (approximately 250 trading days):

```
rng(14151617,'twister')
obj   = cir(0.25,@(t,X)0.1,0.2,'StartState',0.02);
[X,T] = simByEuler(obj,250,'DeltaTime',1/250,'nTrials',5);
```

```
sprintf('%0.4f\t%0.4f+i%0.4f\n',[T(195:205)';...
    real(X(195:205,1,4))'; imag(X(195:205,1,4))'])

ans =
    '0.7760    0.0003+i0.0000
     0.7800    0.0004+i0.0000
     0.7840    0.0002+i0.0000
     0.7880    -0.0000+i0.0000
     0.7920    0.0001+i0.0000
     0.7960    0.0002+i0.0000
     0.8000    0.0002+i0.0000
     0.8040    0.0008+i0.0001
     0.8080    0.0004+i0.0001
     0.8120    0.0008+i0.0001
     0.8160    0.0008+i0.0001
     '
```

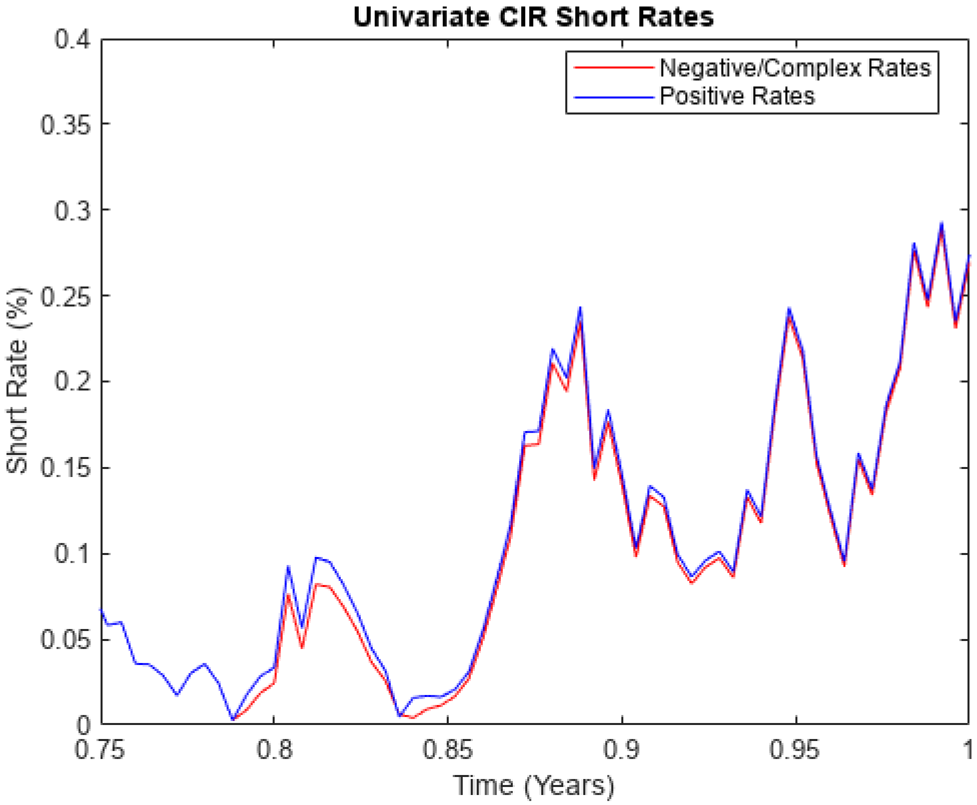
Interest rates can become negative if the resulting paths are simulated in discrete time. Moreover, since `cir` models incorporate a square root diffusion term, the short rates might even become complex.

2 **Repeat the simulation with a processing function.** Repeat the simulation, this time specifying a processing function that takes the absolute magnitude of the short rate at the end of each period. You can access the processing function by time and state (t, X_t), but it only uses the state vector of short rates X_t:

```
rng(14151617,'twister')
[Y,T] = simByEuler(obj,250,'DeltaTime',1/250,...
    'nTrials',5,'Processes',@(t,X)abs(X));
```

3 **Compare the adjusted and non-adjusted paths.** Graphically compare the magnitude of the unadjusted path (with negative and complex numbers!) to the corresponding path kept positive by using an end-of-period processing function over the time span of interest:

```
clf
plot(T,100*abs(X(:,1,4)),'red',T,100*Y(:,1,4),'blue')
axis([0.75 1 0 0.4])
xlabel('Time (Years)'), ylabel('Short Rate (%)')
title('Univariate CIR Short Rates')
legend({'Negative/Complex Rates' 'Positive Rates'}, ...
    'Location', 'Best')
```



Tip You can use this method to obtain more accurate SDE solutions. For more information, see "Performance Considerations" on page 14-64.

Stratified Sampling

Simulation methods allow you to specify a noise process directly, as a callable function of time and state:

$$z_t = Z(t, X_t)$$

Stratified sampling is a variance reduction technique that constrains a proportion of sample paths to specific subsets (or *strata*) of the sample space.

This example specifies a noise function to stratify the terminal value of a univariate equity price series. Starting from known initial conditions, the function first stratifies the terminal value of a standard Brownian motion, and then samples the process from beginning to end by drawing conditional Gaussian samples using a Brownian bridge.

The stratification process assumes that each path is associated with a single stratified terminal value such that the number of paths is equal to the number of strata. This technique is called *proportional sampling*. This example is similar to, yet more sophisticated than, the one discussed in “Simulating Interest Rates” on page 14-48. Since stratified sampling requires knowledge of the future, it also requires more sophisticated time synchronization; specifically, the function in this example requires knowledge of the entire sequence of sample times. For more information, see the example `Example_StratifiedRNG.m`.

The function implements proportional sampling by partitioning the unit interval into bins of equal probability by first drawing a random number uniformly distributed in each bin. The inverse cumulative distribution function of a standard *N(0,1)* Gaussian distribution then transforms these stratified uniform draws. Finally, the resulting stratified Gaussian draws are scaled by the square root of the terminal time to stratify the terminal value of the Brownian motion.

The noise function does not return the actual Brownian paths, but rather the Gaussian draws $Z(t,X_t)$ that drive it.

This example first stratifies the terminal value of a univariate, zero-drift, unit-variance-rate Brownian motion (`bm`) model:

$$dX_t = dW_t$$

1 Assume that 10 paths of the process are simulated daily over a three-month period. Also assume that each calendar month and year consist of 21 and 252 trading days, respectively:

2 Simulate the standard Brownian paths by explicitly passing the stratified sampling function to the simulation method:

```
X = obj.simulate(nPeriods, 'DeltaTime', dt, ...
    'nTrials', nPaths, 'Z', z);
```

3 For convenience, reorder the output sample paths by reordering the three-dimensional output to a two-dimensional equivalent array:

```
X = squeeze(X);
```

4 Verify the stratification:

   a Recreate the uniform draws with proportional sampling:

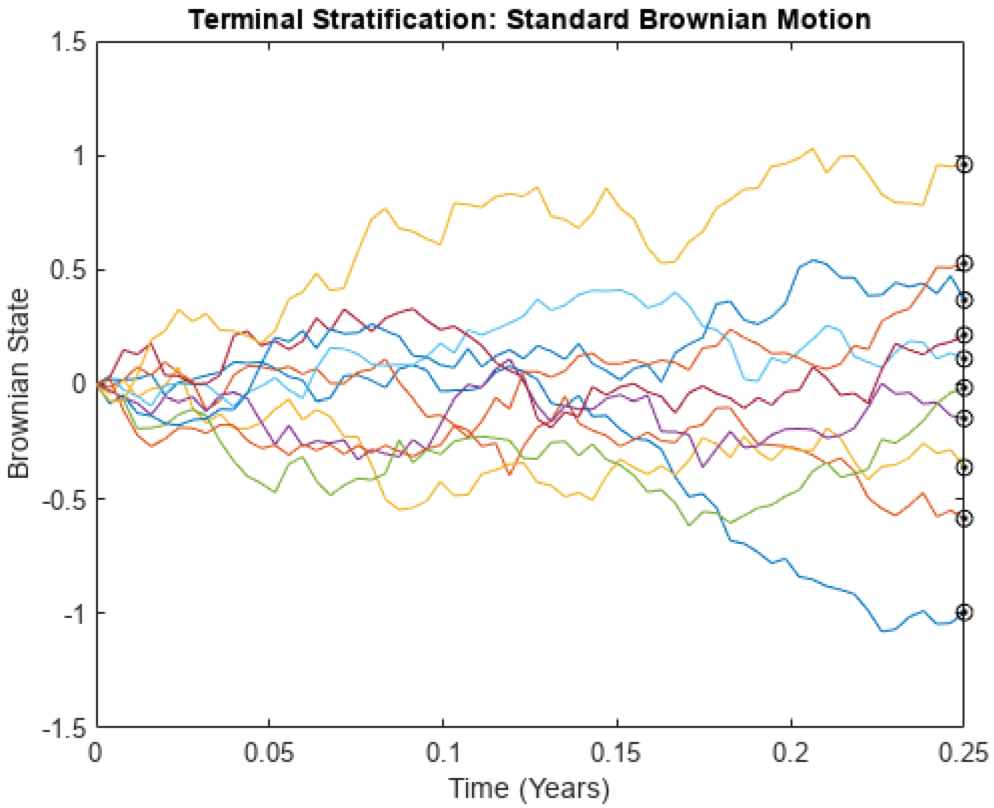
   ```
   rng(10203,'twister')
   U  = ((1:nPaths)' - 1 + rand(nPaths,1))/nPaths;
   ```

b Transform them to obtain the terminal values of standard Brownian motion:

```
WT = norminv(U) * sqrt(T);  % Stratified Brownian motion.
```

c Plot the terminal values and output paths on the same figure:

```
plot(sampleTimes, X), hold('on')
xlabel('Time (Years)'), ylabel('Brownian State')
title('Terminal Stratification: Standard Brownian Motion')
plot(T, WT, '. black', T, WT, 'o black')
hold('off')
```



The last value of each sample path (the last row of the output array X) coincides with the corresponding element of the stratified terminal value of the Brownian motion. This occurs because the simulated model and the noise generation function both represent the same standard Brownian motion.

However, you can use the same stratified sampling function to stratify the terminal price of constant-parameter geometric Brownian motion models. In fact, you can use the stratified sampling function to stratify the terminal value of any constant-parameter model driven by Brownian motion if the model's terminal value is a monotonic transformation of the terminal value of the Brownian motion.

To illustrate this, load the data set and simulate risk-neutral sample paths of the FTSE 100 index using a geometric Brownian motion (GBM) model with constant parameters:

$$dX_t = rX_tdt + \sigma X_tdW_t$$

where the average Euribor yield represents the risk-free rate of return.

1 Assume that the relevant information derived from the daily data is annualized, and that each calendar year comprises 252 trading days:

```
load Data_GlobalIdx2
returns = tick2ret(Dataset.FTSE);
sigma   = std(returns) * sqrt(252);
rate    = Dataset.EB3M;
rate    = mean(360 * log(1 + rate));
```

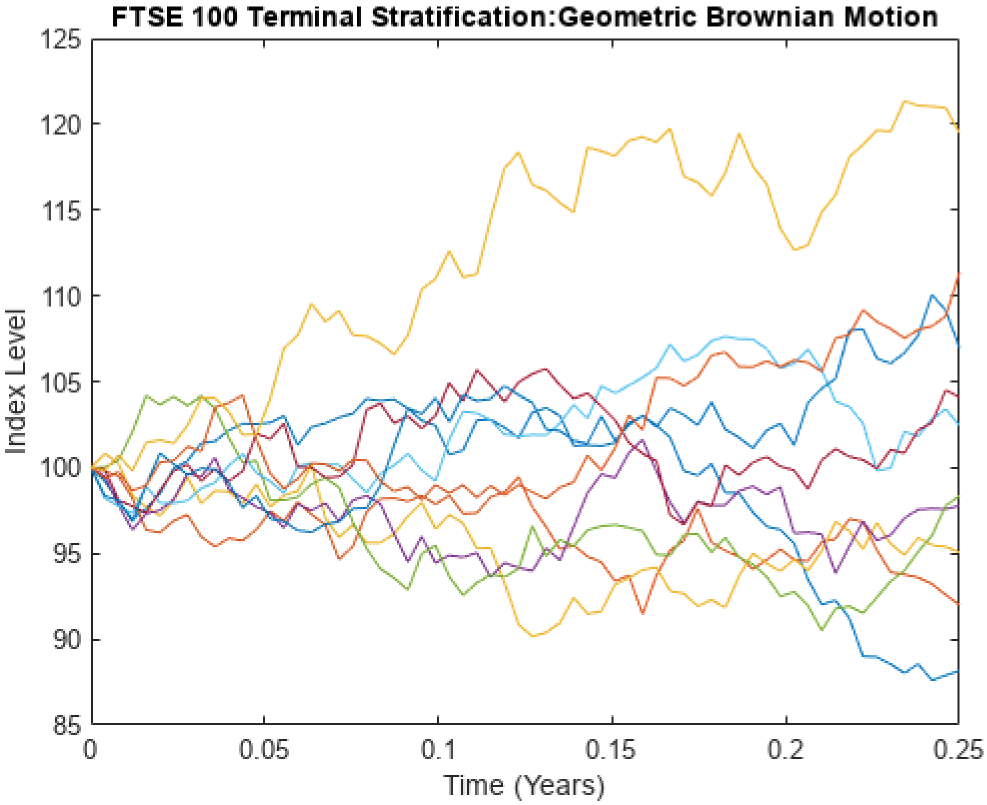
2 Create the GBM model using gbm, assuming the FTSE 100 starts at 100:

```
obj = gbm(rate, sigma, 'StartState', 100);
```

3 Determine the sample time and simulate the price paths.

In what follows, NSteps specifies the number of intermediate time steps within each time increment DeltaTime. Each increment DeltaTime is partitioned into NSteps subintervals of length DeltaTime/NSteps each, refining the simulation by evaluating the simulated state vector at NSteps–1 intermediate points. This refinement improves accuracy by allowing the simulation to more closely approximate the underlying continuous-time process without storing the intermediate information:

```
nSteps      = 1;
sampleTimes = cumsum([obj.StartTime ; ...
dt(ones(nPeriods * nSteps,1))/nSteps]);
z           = Example_StratifiedRNG(nPaths, sampleTimes);
rng(10203,'twister')
[Y, Times]  = obj.simBySolution(nPeriods, 'nTrials', nPaths,...
'DeltaTime', dt, 'nSteps', nSteps,  'Z', z);
Y = squeeze(Y);   % Reorder to a 2-D array
plot(Times, Y)
xlabel('Time (Years)'), ylabel('Index Level')
title('FTSE 100 Terminal Stratification:Geometric Brownian Motion')
```



Although the terminal value of the Brownian motion shown in the latter plot is normally distributed, and the terminal price in the previous plot is lognormally distributed, the corresponding paths of each graph are similar.

Tip For another example of variance reduction techniques, see "Simulating Interest Rates Using Interpolation" on page 14-48.

Quasi-Monte Carlo Simulation

Quasi-Monte Carlo simulation is a Monte Carlo simulation that uses quasi-random sequences instead of pseudo random numbers. The quasi-random sequences, also called low-discrepancy sequences, are deterministic, uniformly distributed sequences that are specifically designed to place sample points as uniformly as possible. In many cases, this distributed sequences improves the performance of Monte Carlo simulations with faster computational times and sometimes higher accuracy.

The standard Monte Carlo simulation using pseudo random numbers has a convergence rate of only $O(N^{-1/2})$, while the quasi-Monte Carlo rate of convergence can be much faster with an error of $O(N^{-1})$ in the best cases. For example, for a standard Monte Carlo simulation, it is necessary to increase 100 times the number of simulations *NTrials* to reduce the error by a factor of 10, whereas a quasi-Monte Carlo simulation requires less, or much less, than 100 times to achieve the same goal.

Quasi-Monte Carlo simulation produces a purely deterministic result. Therefore, when computing the variance and constructing a confidence band for the estimates, randomized quasi-Monte Carlo simulation is useful because of faster computational times and sometimes higher accuracy. You can also use randomized quasi-Monte Carlo to introduce randomization into the low-discrepancy sequences.

The starting point for a Monte Carlo simulation is the construction of a Brownian motion sample path (or Wiener path). Such paths are built from a set of independent Gaussian variates, using either standard discretization, Brownian-bridge construction, or principal components construction.

To perform Quasi-Monte Carlo simulation, the name-value arguments for `MonteCarloMethod`, `QuasiSequence`, and `BrownianMotionMethod` by using the supported methods for the following SDE objects. For example, `[paths,time,z] = simByEuler(cir_obj,10,'ntrials',4096,'method','basic','montecarlomethod','quasi','quasisequence','sobol','brownianmotionmethod','principal-components')` performs a Quasi-Monte Carlo simulation using a principal components construction method with a `cir` model.

Performance Considerations

In this section...

Managing Memory

There are two general approaches for managing memory when solving most problems supported by the SDE engine:

- "Managing Memory with Outputs" on page 14-64
- "Managing Memory Using End-of-Period Processing Functions" on page 14-65

Managing Memory with Outputs

Perform a traditional simulation to simulate the underlying variables of interest, specifically requesting and then manipulating the output arrays.

This approach is straightforward and the best choice for small or medium-sized problems. Since its outputs are arrays, it is convenient to manipulate simulated results in the MATLAB matrix-based language. However, as the scale of the problem increases, the benefit of this approach decreases, because the output arrays must store large quantities of possibly extraneous information.

For example, consider pricing a European option in which the terminal price of the underlying asset is the only value of interest. To ease the memory burden of the traditional approach, reduce the number of simulated periods specified by the required input NPeriods and specify the optional input NSteps. This enables you to manage memory without sacrificing accuracy (see "Optimizing Accuracy: About Solution Precision and Error" on page 14-65).

In addition, simulation methods can determine the number of output arguments and allocate memory accordingly. Specifically, all simulation methods support the same output argument list:

```
[Paths,Times,Z]
```

where Paths and Z can be large, three-dimensional time series arrays. However, the underlying noise array is typically unnecessary, and is only stored if requested as an output. In other words, Z is stored only at your request; do not request it if you do not need it.

If you need the output noise array Z, but do not need the Paths time series array, then you can avoid storing Paths two ways:

- It is best practice to use the ~ output argument placeholder. For example, use the following output argument list to store Z and Times, but not Paths:

  ```
  [~,Times,Z]
  ```

- Use the optional input flag StorePaths, which all simulation methods support. By default, Paths is stored (StorePaths = true). However, setting StorePaths to false returns Paths as an empty matrix.

Managing Memory Using End-of-Period Processing Functions

Specify one or more end-of-period processing functions to manage and store only the information of interest, avoiding simulation outputs altogether.

This approach requires you to specify one or more end-of-period processing functions, and is often the preferred approach for large-scale problems. This approach allows you to avoid simulation outputs altogether. Since no outputs are requested, the three-dimensional time series arrays `Paths` and `Z` are not stored.

This approach often requires more effort, but is far more elegant and allows you to customize tasks and dramatically reduce memory usage. See “Pricing Equity Options” on page 14-45.

Enhancing Performance

The following approaches improve performance when solving SDE problems:

- **Specifying model parameters as traditional MATLAB arrays and functions, in various combinations.** This provides a flexible interface that can support virtually any general nonlinear relationship. However, while functions offer a convenient and elegant solution for many problems, simulations typically run faster when you specify parameters as double-precision vectors or matrices. Thus, it is a good practice to specify model parameters as arrays when possible.
- **Use models that have overloaded Euler simulation methods, when possible.** Using Brownian motion (`BM`) and geometric Brownian motion (`GBM`) models that provide overloaded Euler simulation methods take advantage of separable, constant-parameter models. These specialized methods are exceptionally fast, but are only available to models with constant parameters that are simulated without specifying end-of-period processing and noise generation functions.
- **Replace the simulation of a constant-parameter, univariate model derived from the `SDEDDO` class with that of a diagonal multivariate model**. Treat the multivariate model as a portfolio of univariate models. This increases the dimensionality of the model and enhances performance by decreasing the effective number of simulation trials.

  Note This technique is applicable only to constant-parameter univariate models without specifying end-of-period processing and noise generation functions.
- **Take advantage of the fact that simulation methods are designed to detect the presence of `NaN` (not a number) conditions returned from end-of-period processing functions.** A `NaN` represents the result of an undefined numerical calculation, and any subsequent calculation based on a `NaN` produces another `NaN`. This helps improve performance in certain situations. For example, consider simulating paths of the underlier of a knock-out barrier option (that is, an option that becomes worthless when the price of the underlying asset crosses some prescribed barrier). Your end-of-period function could detect a barrier crossing and return a `NaN` to signal early termination of the current trial.

Optimizing Accuracy: About Solution Precision and Error

The simulation architecture does not, in general, simulate *exact* solutions to any SDE. Instead, the simulation architecture provides a discrete-time approximation of the underlying continuous-time process, a simulation technique often known as a *Euler approximation*.

In the most general case, a given simulation derives directly from an SDE. Therefore, the simulated discrete-time process approaches the underlying continuous-time process only in the limit as the time increment *dt* approaches zero. In other words, the simulation architecture places more importance on ensuring that the probability distributions of the discrete-time and continuous-time processes are close, than on the pathwise proximity of the processes.

Before illustrating techniques to improve the approximation of solutions, it is helpful to understand the source of error. Throughout this architecture, all simulation methods assume that model parameters are piecewise constant over any time interval of length *dt*. In fact, the methods even evaluate dynamic parameters at the beginning of each time interval and hold them fixed for the duration of the interval. This sampling approach introduces *discretization error*.

However, there are certain models for which the piecewise constant approach provides exact solutions:

- "Creating Brownian Motion (BM) Models" on page 14-21 with constant parameters, simulated by Euler approximation (`simByEuler`).
- "Creating Geometric Brownian Motion (GBM) Models" on page 14-22 with constant parameters, simulated by closed-form solution (`simBySolution`).
- "Creating Hull-White/Vasicek (HWV) Gaussian Diffusion Models" on page 14-25 with constant parameters, simulated by closed-form solution (`simBySolution`)

More generally, you can simulate the exact solutions for these models even if the parameters vary with time, if they vary in a piecewise constant way such that parameter changes coincide with the specified sampling times. However, such exact coincidence is unlikely; therefore, the previously discussed constant parameter condition is commonly used in practice.

One obvious way to improve accuracy involves sampling the discrete-time process more frequently. This decreases the time increment (*dt*), causing the sampled process to more closely approximate the underlying continuous-time process. Although decreasing the time increment is universally applicable, however, there is a tradeoff among accuracy, run-time performance, and memory usage.

To manage this tradeoff, specify an optional input argument, `NSteps`, for all simulation methods. `NSteps` indicates the number of intermediate time steps within each time increment *dt*, at which the process is sampled but not reported.

It is important and convenient at this point to emphasize the relationship of the inputs `NSteps`, `NPeriods`, and `DeltaTime` to the output vector `Times`, which represents the actual observation times at which the simulated paths are reported.

- `NPeriods`, a required input, indicates the number of simulation periods of length `DeltaTime`, and determines the number of rows in the simulated three-dimensional `Paths` time series array (if an output is requested).
- `DeltaTime` is optional, and indicates the corresponding `NPeriods`-length vector of positive time increments between successive samples. It represents the familiar *dt* found in stochastic differential equations. If `DeltaTime` is unspecified, the default value of 1 is used.
- `NSteps` is also optional, and is only loosely related to `NPeriods` and `DeltaTime`. `NSteps` specifies the number of intermediate time steps within each time increment `DeltaTime`.

  Specifically, each time increment `DeltaTime` is partitioned into `NSteps` subintervals of length `DeltaTime/NSteps` each, and refines the simulation by evaluating the simulated state vector at `(NSteps - 1)` intermediate times. Although the output state vector (if requested) is not reported at these intermediate times, this refinement improves accuracy by causing the simulation to more closely approximate the underlying continuous-time process. If `NSteps` is unspecified, the default is `1` (to indicate no intermediate evaluation).

- The output `Times` is an `NPeriods + 1`-length column vector of observation times associated with the simulated paths. Each element of `Times` is associated with a corresponding row of `Paths`.

The following example illustrates this intermediate sampling by comparing the difference between a closed-form solution and a sequence of Euler approximations derived from various values of `NSteps`.

Example: Improving Solution Accuracy

Consider a univariate geometric Brownian motion (`GBM`) model using `gbm` with constant parameters:

$$dX_t = 0.1X_tdt + 0.4X_tdW_t\,.$$

Assume that the expected rate of return and volatility parameters are annualized, and that a calendar year comprises 250 trading days.

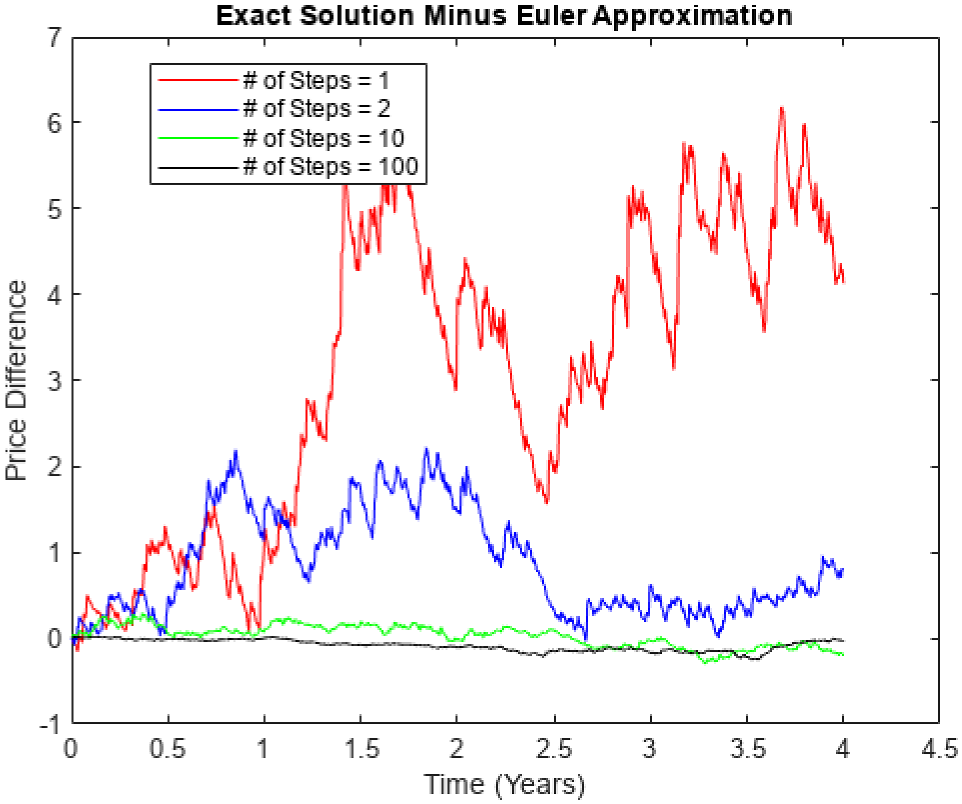
1 Simulate approximately four years of univariate prices for both the exact solution and the Euler approximation for various values of `NSteps`:

```
nPeriods = 1000;
dt       = 1/250;
obj      = gbm(0.1,0.4,'StartState',100);
rng(575,'twister')
[X1,T1]    = simBySolution(obj,nPeriods,'DeltaTime',dt);
rng(575,'twister')
[Y1,T1]    = simByEuler(obj,nPeriods,'DeltaTime',dt);
rng(575,'twister')
[X2,T2]    = simBySolution(obj,nPeriods,'DeltaTime',...
    dt,'nSteps',2);
rng(575,'twister')
[Y2,T2]    = simByEuler(obj,nPeriods,'DeltaTime',...
    dt,'nSteps',2);
rng(575,'twister')
[X3,T3]    = simBySolution(obj,nPeriods, 'DeltaTime',...
    dt,'nSteps',10);
rng(575,'twister')
[Y3,T3]    = simByEuler(obj,nPeriods,'DeltaTime',...
    dt,'nSteps',10);
rng(575,'twister')
[X4,T4]    = simBySolution(obj,nPeriods,'DeltaTime',...
    dt,'nSteps',100);
rng(575,'twister')
[Y4,T4]    = simByEuler(obj,nPeriods,'DeltaTime',...
    dt,'nSteps',100);
```

2 Compare the error (the difference between the exact solution and the Euler approximation) graphically:

```
clf;
plot(T1,X1 - Y1,'red')
hold on;
plot(T2,X2 - Y2,'blue')
plot(T3,X3 - Y3,'green')
plot(T4,X4 - Y4,'black')
hold off
xlabel('Time (Years)')
ylabel('Price Difference')
```

```
title('Exact Solution Minus Euler Approximation')
legend({'# of Steps = 1'  '# of Steps = 2' ...
    '# of Steps = 10' '# of Steps = 100'},...
    'Location', 'Best')
hold off
```



As expected, the simulation error decreases as the number of intermediate time steps increases. Because the intermediate states are not reported, all simulated time series have the same number of observations regardless of the actual value of `NSteps`.

Furthermore, since the previously simulated exact solutions are correct for any number of intermediate time steps, additional computations are not needed for this example. In fact, this assessment is correct. The exact solutions are sampled at intermediate times to ensure that the simulation uses the same sequence of Gaussian random variates in the same order. Without this assurance, there is no way to compare simulated prices on a pathwise basis. However, there might be valid reasons for sampling exact solutions at closely spaced intervals, such as pricing path-dependent options.

Price American Basket Options Using Standard Monte Carlo and Quasi-Monte Carlo Simulation

Model the fat-tailed behavior of asset returns and assess the impact of alternative joint distributions on basket option prices. Using various implementations of a separable multivariate Geometric Brownian Motion (GBM) process, often referred to as a *multi-dimensional market model*, the example simulates risk-neutral sample paths of an equity index portfolio and prices basket put options using the technique of Longstaff & Schwartz.

In addition, this example also illustrates salient features of the Stochastic Differential Equation (SDE) architecture, including

- Customized random number generation functions that compare Brownian motion and Brownian copulas
- End-of-period processing functions that form an equity index basket and price American options on the underlying basket based on the least squares method of Longstaff & Schwartz
- Piecewise probability distributions and Extreme Value Theory (EVT)
- Quasi-Monte Carlo simulation using for a `gbm` object using `simByEuler`.

This example also highlights important issues of volatility and interest rate scaling. It illustrates how equivalent results can be achieved by working with daily or annualized data. For more information about EVT and copulas, see “Using Extreme Value Theory and Copulas to Evaluate Market Risk” (Econometrics Toolbox).

Overview of the Modeling Framework

The ultimate objective of this example is to compare basket option prices derived from different noise processes. The first noise process is a traditional Brownian motion model whose index portfolio price process is driven by correlated Gaussian random draws. As an alternative, the Brownian motion benchmark is compared to noise processes driven by Gaussian and Student's *t* copulas, referred to collectively as a *Brownian copula*.

A copula is a multivariate cumulative distribution function (CDF) with uniformly-distributed margins. Although the theoretical foundations were established decades ago, copulas have experienced a tremendous surge in popularity over the last few years, primarily as a technique for modeling non-Gaussian portfolio risks.

Although numerous families exist, all copulas represent a statistical device for modeling the dependence structure between two or more random variables. In addition, important statistics, such as *rank correlation* and *tail dependence* are properties of a given copula and are unchanged by monotonic transforms of their margins.

These copula draws produce dependent random variables, which are subsequently transformed to individual variables (margins). This transformation is achieved with a semi-parametric probability distribution with generalized Pareto tails.

The risk-neutral market model to simulate is

$$dX_t = rX_t dt + \sigma X_t dW_t$$

where the risk-free rate, `r`, is assumed constant over the life of the option. Because this is a separable multivariate model, the risk-free return is a diagonal matrix in which the same riskless return is applied to all indices. Dividend yields are ignored to simplify the model and its associated data collection.

In contrast, the specification of the exposure matrix, `sigma`, depends on how the driving source of uncertainty is modeled. You can model it directly as a Brownian motion (correlated Gaussian random numbers implicitly mapped to Gaussian margins) or model it as a Brownian copula (correlated Gaussian or *t* random numbers explicitly mapped to semi-parametric margins).

Because the CDF and inverse CDF (quantile function) of univariate distributions are both monotonic transforms, a copula provides a convenient way to simulate dependent random variables whose margins are dissimilar and arbitrarily distributed. Moreover, because a copula defines a given dependence structure regardless of its margins, copula parameter calibration is typically easier than estimation of the joint distribution function.

Once you have simulated sample paths, options are priced by the least squares regression method of Longstaff & Schwartz (see *Valuing American Options by Simulation: A Simple Least-Squares Approach*, The Review of Financial Studies, Spring 2001). This approach uses least squares to estimate the expected payoff of an option if it is not immediately exercised. It does so by regressing the discounted option cash flows received in the future on the current price of the underlier associated with all in-the-money sample paths. The continuation function is estimated by a simple third-order polynomial, in which all cash flows and prices in the regression are normalized by the option strike price, improving numerical stability.

Import the Supporting Historical Dataset

Load a daily historical dataset of 3-month Euribor, the trading dates spanning the interval 07-Feb-2001 to 24-Apr-2006, and the closing index levels of the following representative large-cap equity indices:

- TSX Composite (Canada)
- CAC 40 (France)
- DAX (Germany)
- Nikkei 225 (Japan)
- FTSE 100 (UK)
- S&P 500 (US)

```
clear
load Data_GlobalIdx2
dates = datetime(dates,'ConvertFrom','datenum');
```

The following plots illustrate this data. Specifically, the plots show the relative price movements of each index and the Euribor risk-free rate proxy. The initial level of each index has been normalized to unity to facilitate the comparison of relative performance over the historical record.

```
nIndices  = size(Data,2)-1;     % Number of indices

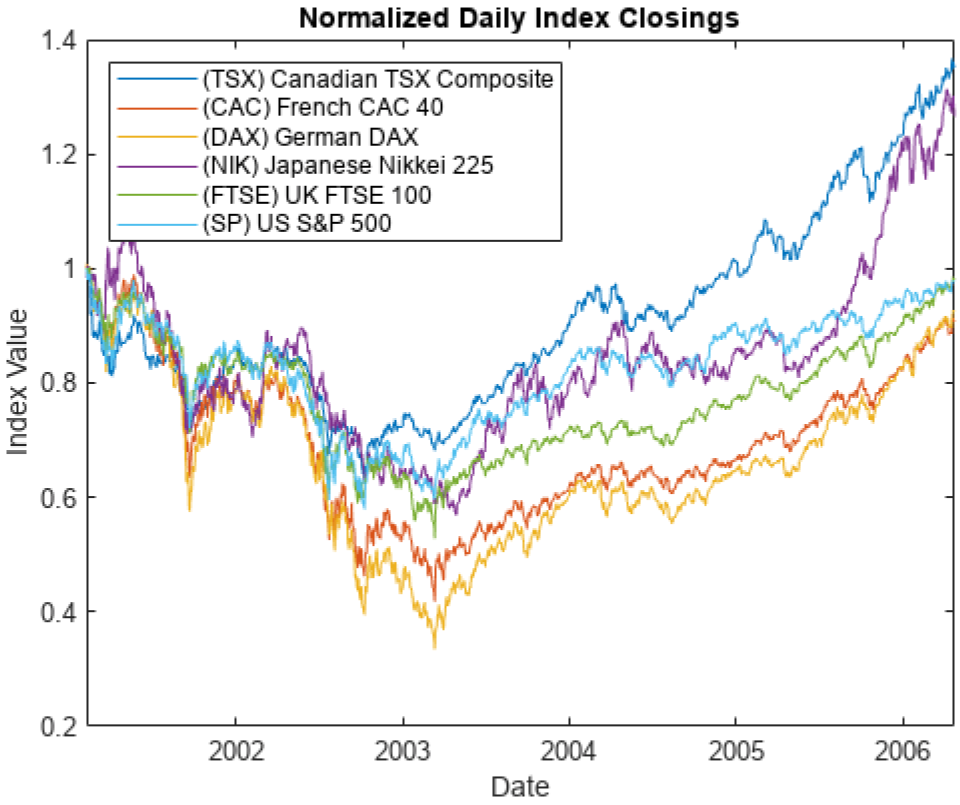
prices = Data(:,1:end-1);

yields = Data(:,end);             % Daily effective yields
yields = 360 * log(1 + yields);   % Continuously-compounded, annualized yield

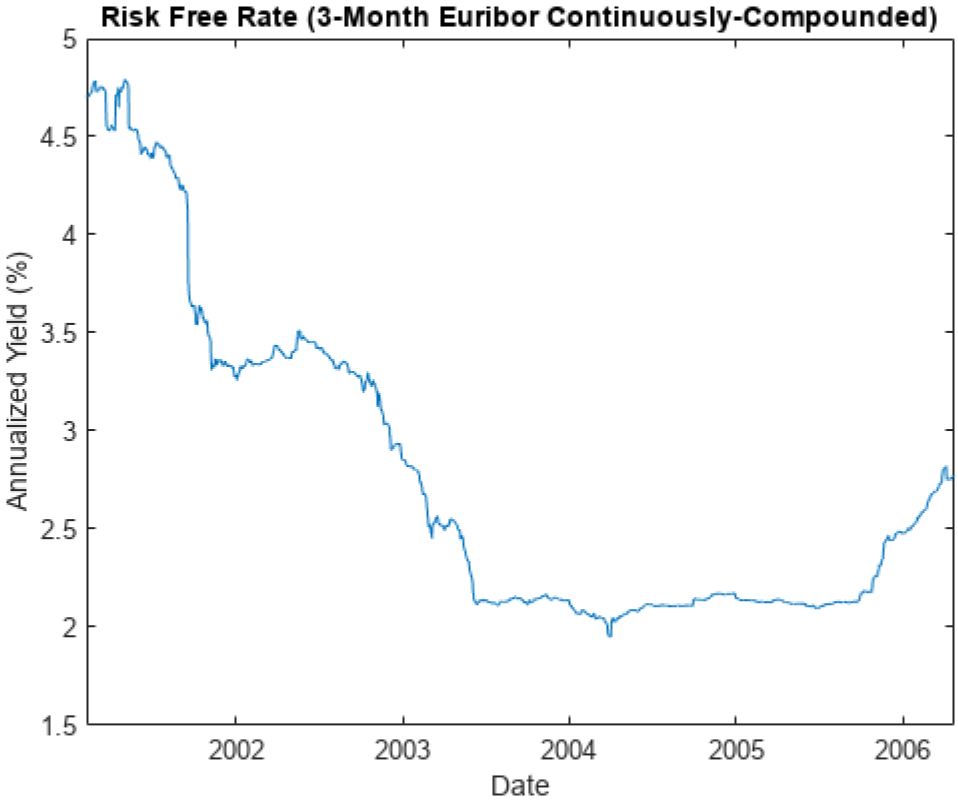
plot(dates, ret2tick(tick2ret(prices,'Method','continuous'),'Method','continuous'))

xlabel('Date')
```

```
ylabel('Index Value')
title ('Normalized Daily Index Closings')
legend(series{1:end-1}, 'Location', 'NorthWest')
```



```
plot(dates, 100 * yields)
xlabel('Date')
ylabel('Annualized Yield (%)')
title('Risk Free Rate (3-Month Euribor Continuously-Compounded)')
```



Extreme Value Theory & Piecewise Probability Distributions

To prepare for copula modeling, characterize individually the distribution of returns of each index. Although the distribution of each return series may be characterized parametrically, it is useful to fit a semi-parametric model using a piecewise distribution with generalized Pareto tails. This uses Extreme Value Theory to better characterize the behavior in each tail.

The Statistics and Machine Learning Toolbox™ software currently supports two univariate probability distributions related to EVT, a statistical tool for modeling the fat-tailed behavior of financial data such as asset returns and insurance losses:

- Generalized Extreme Value (GEV) distribution, which uses a modeling technique known as the *block maxima or minima* method. This approach, divides a historical dataset into a set of sub-intervals, or blocks, and the largest or smallest observation in each block is recorded and fitted to a GEV distribution.
- Generalized Pareto (GP) distribution, uses a modeling technique known as the *distribution of exceedances* or *peaks over threshold* method. This approach sorts a historical dataset and fits the amount by which those observations that exceed a specified threshold to a GP distribution.

The following analysis highlights the Pareto distribution, which is more widely used in risk management applications.

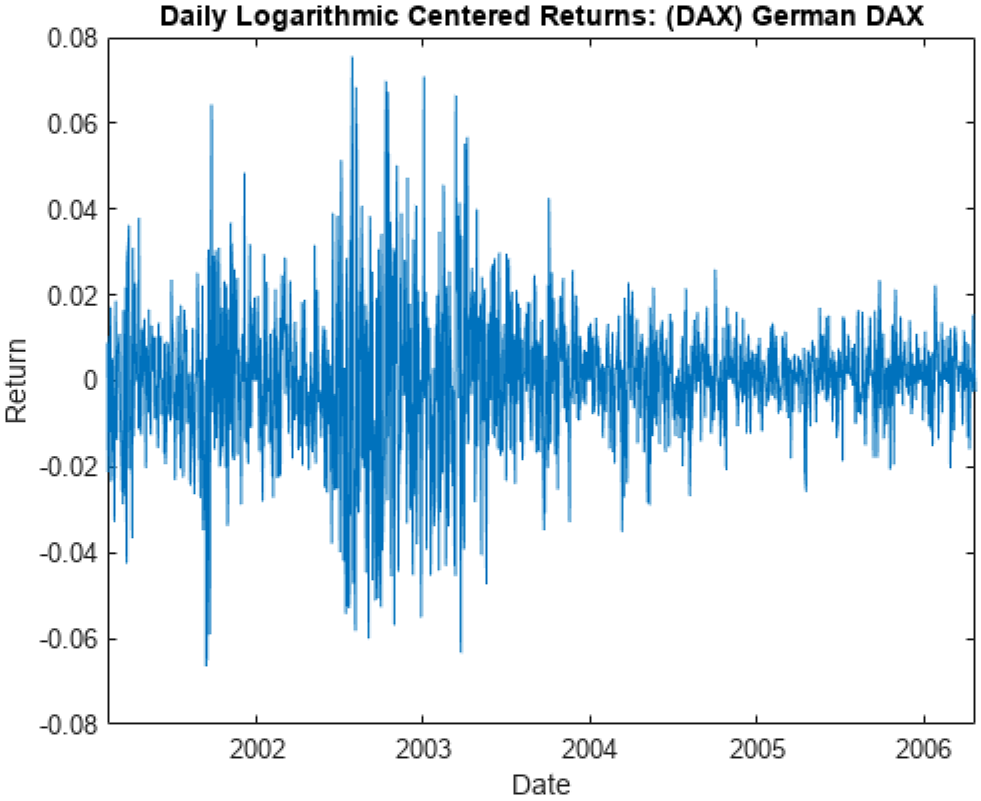
Suppose we want to create a complete statistical description of the probability distribution of daily asset returns of any one of the equity indices. Assume that this description is provided by a piecewise semi-parametric distribution, where the asymptotic behavior in each tail is characterized by a generalized Pareto distribution.

Ultimately, a copula will be used to generate random numbers to drive the simulations. The CDF and inverse CDF transforms will capture the volatility of simulated returns as part of the diffusion term of the SDE. The mean return of each index is governed by the riskless rate and incorporated in the drift term of the SDE. The following code segment centers the returns (that is, extracts the mean) of each index.

Because the following analysis uses extreme value theory to characterize the distribution of each equity index return series, it is helpful to examine details for a particular country:

```
returns = tick2ret(prices,'Method','continuous');  % Convert prices to returns
returns = returns - mean(returns);  % Center the returns
index   = 3;                        % Germany stored in column 3

plot(dates(2:end), returns(:,index))
xlabel('Date')
ylabel('Return')
title(['Daily Logarithmic Centered Returns: ' series{index}])
```



Note that this code segment can be changed to examine details for any country.

Using these centered returns, estimate the empirical, or non-parametric, CDF of each index with a Gaussian kernel. This smoothes the CDF estimates, eliminating the staircase pattern of unsmoothed sample CDFs. Although non-parametric kernel CDF estimates are well-suited for the interior of the distribution, where most of the data is found, they tend to perform poorly when applied to the upper and lower tails. To better estimate the tails of the distribution, apply EVT to the returns that fall in each tail.

Specifically, find the upper and lower thresholds such that 10% of the returns are reserved for each tail. Then fit the amount by which the extreme returns in each tail fall beyond the associated threshold to a Pareto distribution by maximum likelihood.

The following code segment creates one object of type `paretotails` for each index return series. These Pareto tail objects encapsulate the estimates of the parametric Pareto lower tail, the non-parametric kernel-smoothed interior, and the parametric Pareto upper tail to construct a composite semi-parametric CDF for each index.

```
tailFraction = 0.1;        % Decimal fraction allocated to each tail
tails = cell(nIndices,1);  % Cell array of Pareto tail objects

for i = 1:nIndices
    tails{i} = paretotails(returns(:,i), tailFraction, 1 - tailFraction, 'kernel');
end
```

The resulting piecewise distribution object allows interpolation within the interior of the CDF and extrapolation (function evaluation) in each tail. Extrapolation allows estimation of quantiles outside the historical record, which is invaluable for risk management applications.

Pareto tail objects also provide methods to evaluate the CDF and inverse CDF (quantile function), and to query the cumulative probabilities and quantiles of the boundaries between each segment of the piecewise distribution.

Now that three distinct regions of the piecewise distribution have been estimated, graphically concatenate and display the result.

The following code calls the CDF and inverse CDF methods of the Pareto tails object of interest with data other than that upon which the fit is based. The referenced methods have access to the fitted state. They are now invoked to select and analyze specific regions of the probability curve, acting as a powerful data filtering mechanism.

For reference, the plot also includes a zero-mean Gaussian CDF of the same standard deviation. To a degree, the variation in options prices reflect the extent to which the distribution of each asset differs from this normal curve.

```
minProbability = cdf(tails{index}, (min(returns(:,index))));
maxProbability = cdf(tails{index}, (max(returns(:,index))));

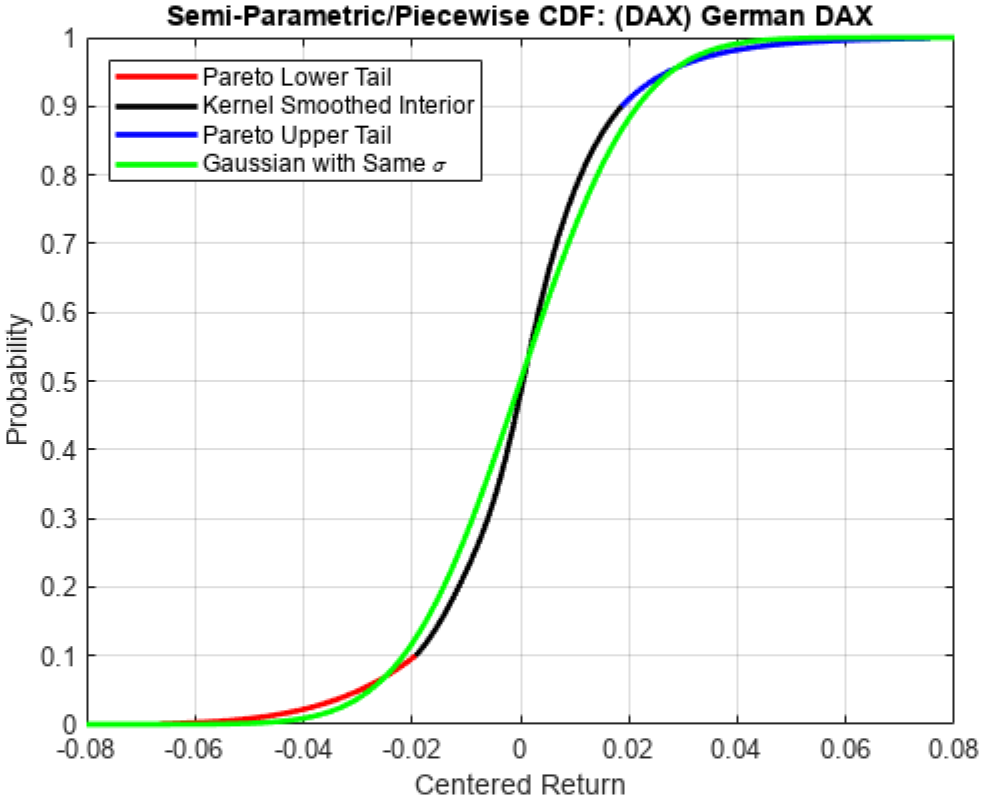
pLowerTail = linspace(minProbability  , tailFraction    , 200); % Lower tail
pUpperTail = linspace(1 - tailFraction, maxProbability  , 200); % Upper tail
pInterior  = linspace(tailFraction    , 1 - tailFraction, 200); % Interior

plot(icdf(tails{index}, pLowerTail), pLowerTail, 'red'  , 'LineWidth', 2)
hold on
grid on
plot(icdf(tails{index}, pInterior) , pInterior , 'black', 'LineWidth', 2)
plot(icdf(tails{index}, pUpperTail), pUpperTail, 'blue' , 'LineWidth', 2)

limits = axis;
x = linspace(limits(1), limits(2));
plot(x, normcdf(x, 0, std(returns(:,index))), 'green', 'LineWidth', 2)

fig = gcf;
fig.Color = [1 1 1];
hold off
```

```
xlabel('Centered Return')
ylabel('Probability')
title (['Semi-Parametric/Piecewise CDF: ' series{index}])
legend({'Pareto Lower Tail' 'Kernel Smoothed Interior' ...
        'Pareto Upper Tail' 'Gaussian with Same \sigma'}, 'Location', 'NorthWest')
```



The lower and upper tail regions, displayed in red and blue, respectively, are suitable for extrapolation, while the kernel-smoothed interior, in black, is suitable for interpolation.

Copula Calibration

The Statistics and Machine Learning Toolbox software includes functionality that calibrates and simulates Gaussian and *t* copulas.

Using the daily index returns, estimate the parameters of the Gaussian and *t* copulas using the function `copulafit`. Since a *t* copula becomes a Gaussian copula as the scalar degrees of freedom parameter (DoF) becomes infinitely large, the two copulas are really of the same family, and therefore share a linear correlation matrix as a fundamental parameter.

Although calibration of the linear correlation matrix of a Gaussian copula is straightforward, the calibration of a *t* copula is not. For this reason, the Statistics and Machine Learning Toolbox software offers two techniques to calibrate a *t* copula:

- The first technique performs maximum likelihood estimation (MLE) in a two-step process. The inner step maximizes the log-likelihood with respect to the linear correlation matrix, given a fixed value for the degrees of freedom. This conditional maximization is placed within a 1-D maximization with respect to the degrees of freedom, thus maximizing the log-likelihood over all parameters. The function being maximized in this outer step is known as the profile log-likelihood for the degrees of freedom.

- The second technique is derived by differentiating the log-likelihood function with respect to the linear correlation matrix, assuming the degrees of freedom is a fixed constant. The resulting expression is a non-linear equation that can be solved iteratively for the correlation matrix. This technique approximates the profile log-likelihood for the degrees of freedom parameter for large sample sizes. This technique is usually significantly faster than the true maximum likelihood technique outlined above; however, you should not use it with small or moderate sample sizes as the estimates and confidence limits may not be accurate.

When the uniform variates are transformed by the empirical CDF of each margin, the calibration method is often known as canonical maximum likelihood (CML). The following code segment first transforms the daily centered returns to uniform variates by the piecewise, semi-parametric CDFs derived above. It then fits the Gaussian and *t* copulas to the transformed data:

```
U = zeros(size(returns));

for i = 1:nIndices
    U(:,i) = cdf(tails{i}, returns(:,i));    % Transform each margin to uniform
end

options     = statset('Display', 'off', 'TolX', 1e-4);
[rhoT, DoF] = copulafit('t', U, 'Method', 'ApproximateML', 'Options', options);
rhoG        = copulafit('Gaussian', U);
```

The estimated correlation matrices are quite similar but not identical.

```
corrcoef(returns)  % Linear correlation matrix of daily returns
```

```
ans = 6×6

    1.0000    0.4813    0.5058    0.1854    0.4573    0.6526
    0.4813    1.0000    0.8485    0.2261    0.8575    0.5102
    0.5058    0.8485    1.0000    0.2001    0.7650    0.6136
    0.1854    0.2261    0.2001    1.0000    0.2295    0.1439
    0.4573    0.8575    0.7650    0.2295    1.0000    0.4617
    0.6526    0.5102    0.6136    0.1439    0.4617    1.0000
```

```
rhoG               % Linear correlation matrix of the optimized Gaussian copula
```

```
rhoG = 6×6

    1.0000    0.4745    0.5018    0.1857    0.4721    0.6622
    0.4745    1.0000    0.8606    0.2393    0.8459    0.4912
    0.5018    0.8606    1.0000    0.2126    0.7608    0.5811
    0.1857    0.2393    0.2126    1.0000    0.2396    0.1494
    0.4721    0.8459    0.7608    0.2396    1.0000    0.4518
    0.6622    0.4912    0.5811    0.1494    0.4518    1.0000
```

```
rhoT               % Linear correlation matrix of the optimized t copula
```

```
rhoT = 6×6

    1.0000    0.4671    0.4858    0.1907    0.4734    0.6521
    0.4671    1.0000    0.8871    0.2567    0.8500    0.5122
    0.4858    0.8871    1.0000    0.2326    0.7723    0.5877
    0.1907    0.2567    0.2326    1.0000    0.2503    0.1539
    0.4734    0.8500    0.7723    0.2503    1.0000    0.4769
    0.6521    0.5122    0.5877    0.1539    0.4769    1.0000
```

Note the relatively low degrees of freedom parameter obtained from the *t* copula calibration, indicating a significant departure from a Gaussian situation.

```
DoF                % Scalar degrees of freedom parameter of the optimized t copula
```

```
DoF = 4.8613
```

Copula Simulation

Now that the copula parameters have been estimated, simulate jointly-dependent uniform variates using the function `copularnd`.

Then, by extrapolating the Pareto tails and interpolating the smoothed interior, transform the uniform variates derived from `copularnd` to daily centered returns via the inverse CDF of each index. These simulated centered returns are consistent with those obtained from the historical dataset. The returns are assumed to be independent in time, but at any point in time possess the dependence and rank correlation induced by the given copula.

The following code segment illustrates the dependence structure by simulating centered returns using the *t* copula. It then plots a 2-D scatter plot with marginal histograms for the French CAC 40 and German DAX using the Statistics and Machine Learning Toolbox `scatterhist` function. The French and German indices were chosen simply because they have the highest correlation of the available data.

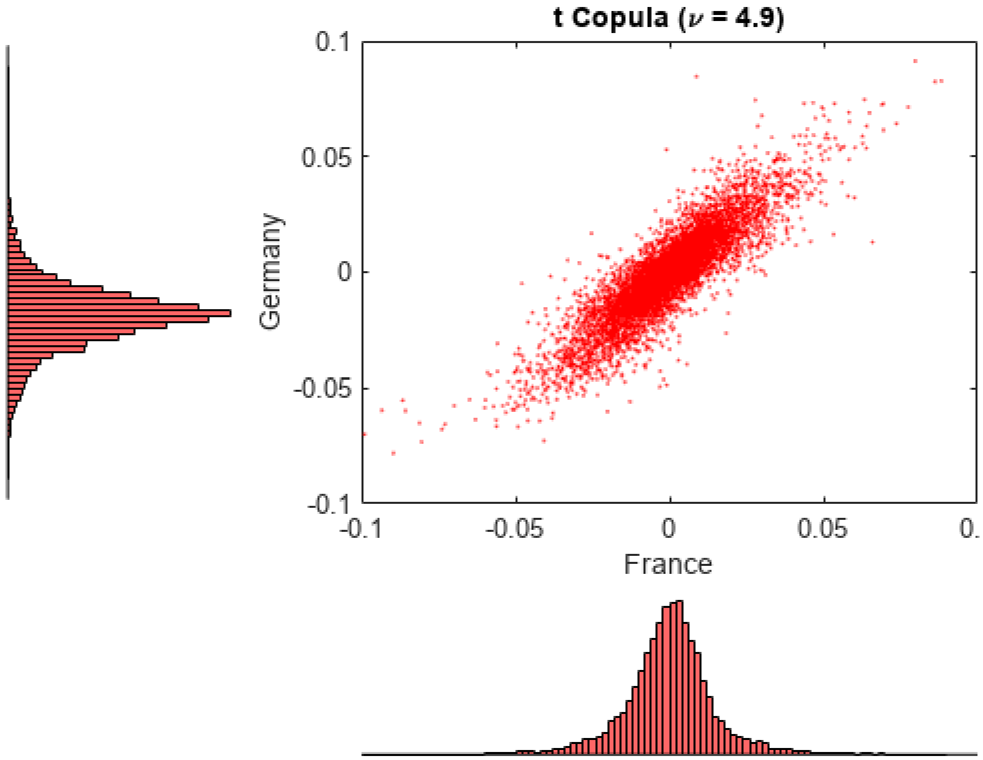
```
nPoints = 10000;                          % Number of simulated observations

s = RandStream.getGlobalStream();
reset(s)

R = zeros(nPoints, nIndices);             % Pre-allocate simulated returns array
U = copularnd('t', rhoT, DoF, nPoints);   % Simulate U(0,1) from t copula

for j = 1:nIndices
    R(:,j) = icdf(tails{j}, U(:,j));
end

h = scatterhist(R(:,2), R(:,3),'Color','r','Marker','.','MarkerSize',1);
fig = gcf;
fig.Color = [1 1 1];
y1 = ylim(h(1));
y3 = ylim(h(3));
xlim(h(1), [-.1 .1])
ylim(h(1), [-.1 .1])
xlim(h(2), [-.1 .1])
ylim(h(3), [(y3(1) + (-0.1 - y1(1)))  (y3(2) + (0.1 - y1(2)))])
xlabel('France')
ylabel('Germany')
title(['t Copula (\nu = ' num2str(DoF,2) ')'])
```

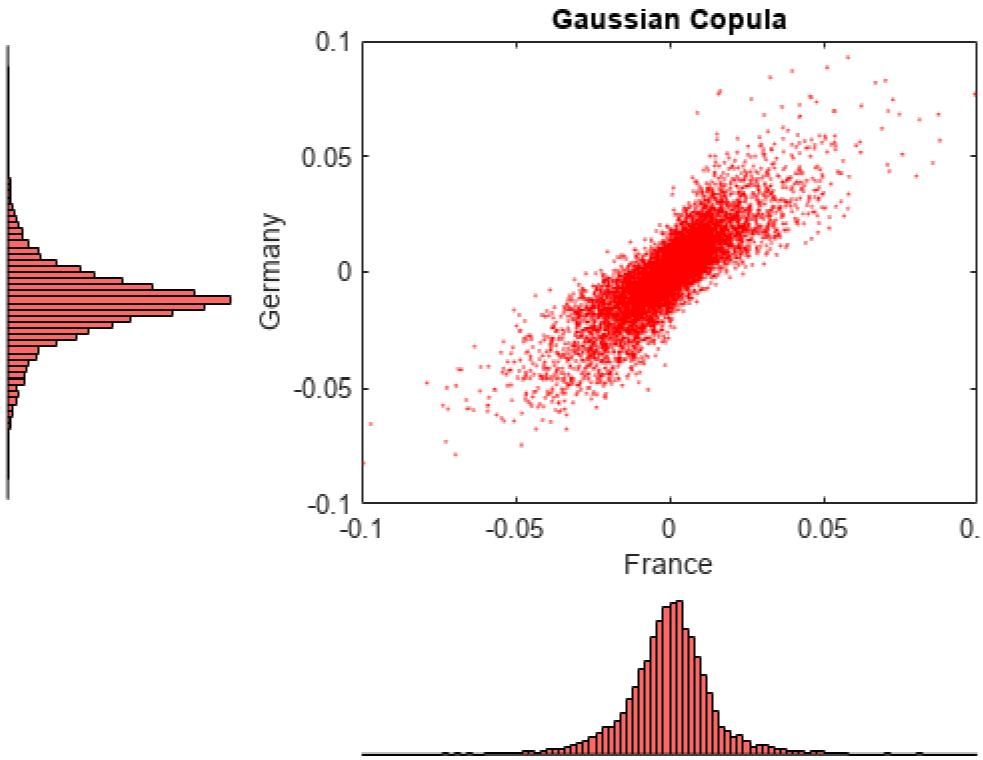


Now simulate and plot centered returns using the Gaussian copula.

```
reset(s)
R = zeros(nPoints, nIndices);             % Pre-allocate simulated returns array
U = copularnd('Gaussian', rhoG, nPoints); % Simulate U(0,1) from Gaussian copula

for j = 1:nIndices
    R(:,j) = icdf(tails{j}, U(:,j));
end

h = scatterhist(R(:,2), R(:,3),'Color','r','Marker','.','MarkerSize',1);
fig = gcf;
fig.Color = [1 1 1];
y1 = ylim(h(1));
y3 = ylim(h(3));
xlim(h(1), [-.1 .1])
ylim(h(1), [-.1 .1])
xlim(h(2), [-.1 .1])
ylim(h(3), [(y3(1) + (-0.1 - y1(1)))  (y3(2) + (0.1 - y1(2)))])
xlabel('France')
ylabel('Germany')
title('Gaussian Copula')
```



Examine these two figures. There is a strong similarity between the miniature histograms on the corresponding axes of each figure. This similarity is not coincidental.

Both copulas simulate uniform random variables, which are then transformed to daily centered returns by the inverse CDF of the piecewise distribution of each index. Therefore, the simulated returns of any given index are identically distributed regardless of the copula.

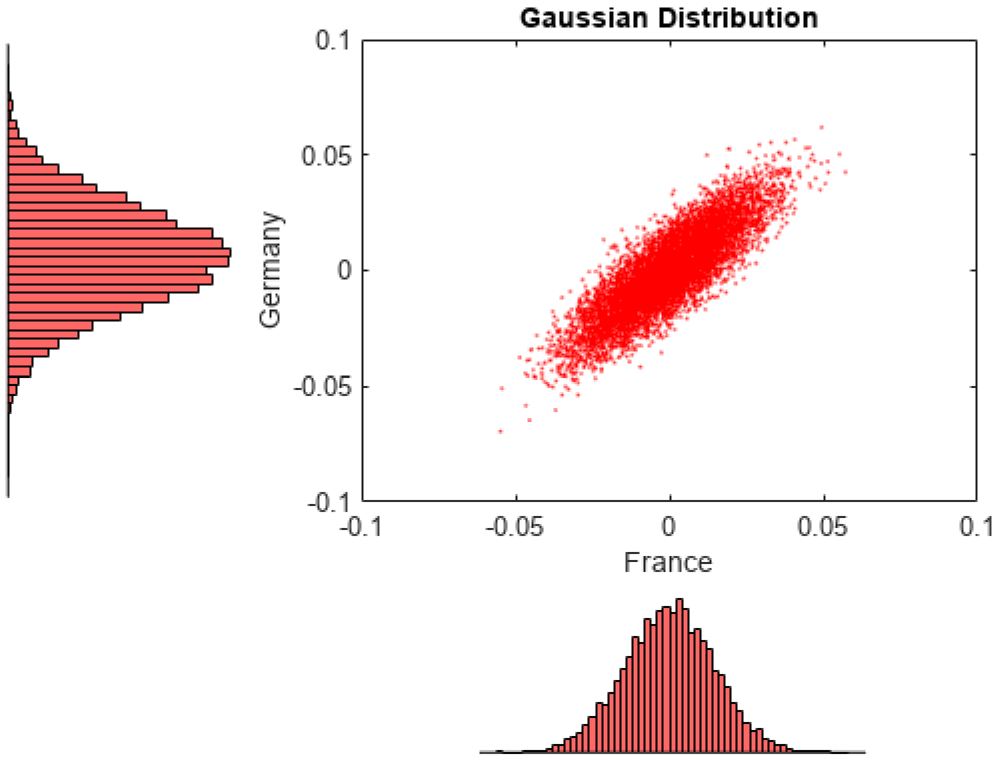
However, the scatter graph of each figure indicates the dependence structure associated with the given copula, and in contrast to the univariate margins shown in the histograms, the scatter graphs are distinct.

Once again, the copula defines a dependence structure regardless of its margins, and therefore offers many features not limited to calibration alone.

For reference, simulate and plot centered returns using the Gaussian distribution, which underlies the traditional Brownian motion model.

```
reset(s)
R = mvnrnd(zeros(1,nIndices), cov(returns), nPoints);
h = scatterhist(R(:,2), R(:,3),'Color','r','Marker','.','MarkerSize',1);
fig = gcf;
fig.Color = [1 1 1];
y1 = ylim(h(1));
y3 = ylim(h(3));
xlim(h(1), [-.1 .1])
ylim(h(1), [-.1 .1])
xlim(h(2), [-.1 .1])
```

```
ylim(h(3), [(y3(1) + (-0.1 - y1(1)))  (y3(2) + (0.1 - y1(2)))])
xlabel('France')
ylabel('Germany')
title('Gaussian Distribution')
```



American Option Pricing Using the Longstaff & Schwartz Approach

Now that the copulas have been calibrated, compare the prices of at-the-money American basket options derived from various approaches. To simply the analysis, assume that:

- All indices begin at 100.
- The portfolio holds a single unit, or share, of each index such that the value of the portfolio at any time is the sum of the values of the individual indices.
- The option expires in 3 months.
- The information derived from the daily data is annualized.
- Each calendar year is composed of 252 trading days.
- Index levels are simulated daily.
- The option may be exercised at the end of every trading day and approximates the American option as a Bermudan option.

Now compute the parameters common to all simulation methods:

```
dt       = 1 / 252;                 % Time increment = 1 day = 1/252 years
yields   = Data(:,end);             % Daily effective yields
yields   = 360 * log(1 + yields);   % Continuously-compounded, annualized yields
```

```
r        = mean(yields);             % Historical 3M Euribor average
X        = repmat(100, nIndices, 1); % Initial state vector
strike   = sum(X);                   % Initialize an at-the-money basket

nTrials  = 100;                      % Number of independent trials
nPeriods = 63;  % Number of simulation periods: 63/252 = 0.25 years = 3 months
```

Now create two separable multi-dimensional market models in which the riskless return and volatility exposure matrices are both diagonal.

While both are diagonal GBM models with identical risk-neutral returns, the first is driven by a correlated Brownian motion and explicitly specifies the sample linear correlation matrix of centered returns. This correlated Brownian motion process is then weighted by a diagonal matrix of annualized index volatilities or standard deviations.

As an alternative, the same model could be driven by an uncorrelated Brownian motion (*standard Brownian motion*) by specifying `correlation` as an identity matrix, or by simply accepting the default value. In this case, the exposure matrix `sigma` is specified as the lower Cholesky factor of the index return covariance matrix. Because the copula-based approaches simulate dependent random numbers, the diagonal exposure form is chosen for consistency. For further details, see “Inducing Dependence and Correlation” on page 14-40.

```
sigma       = std(returns) * sqrt(252);    % Annualized volatility
correlation = corrcoef(returns);           % Correlated Gaussian disturbances
GBM1        = gbm(diag(r(ones(1,nIndices))), diag(sigma), 'StartState', X, ...
                 'Correlation'             , correlation);
```

Now create the second model driven by the Brownian copula with an identity matrix `sigma`.

```
GBM2 = gbm(diag(r(ones(1,nIndices))), eye(nIndices), 'StartState', X);
```

The newly created model may seem unusual, but it highlights the flexibility of the SDE architecture.

When working with copulas, it is often convenient to allow the random number generator function Z(t,X) to induce dependence (of which the traditional notion of linear correlation is a special case) with the copula, and to induce magnitude or scale of variation (similar to volatility or standard deviation) with the semi-parametric CDF and inverse CDF transforms. Since the CDF and inverse CDF transforms of each index inherit the characteristics of historical returns, this also explains why the returns are now centered.

In the following sections, statements like:

```
z = Example_CopulaRNG(returns * sqrt(252), nPeriods, 'Gaussian');
```

or

```
z = Example_CopulaRNG(returns * sqrt(252), nPeriods, 't');
```

fit the Gaussian and *t* copula dependence structures, respectively, and the semi-parametric margins to the centered returns scaled by the square root of the number of trading days per year (252). This scaling does not annualize the daily centered returns. Instead, it scales them such that the volatility remains consistent with the diagonal annualized exposure matrix `sigma` of the traditional Brownian motion model (GBM1) created previously.

In this example, you also specify an end-of-period processing function that accepts time followed by state (t,X), and records the sample times and value of the portfolio as the single-unit weighted average of all indices. This function also shares this information with other functions designed to price American options with a constant riskless rate using the least squares regression approach of Longstaff & Schwartz.

```
f = Example_LongstaffSchwartz(nPeriods, nTrials)
```

```
f = struct with fields:
    LongstaffSchwartz: @Example_LongstaffSchwartz/saveBasketPrices
            CallPrice: @Example_LongstaffSchwartz/getCallPrice
             PutPrice: @Example_LongstaffSchwartz/getPutPrice
               Prices: @Example_LongstaffSchwartz/getBasketPrices
```

Now simulate independent trials of equity index prices over 3 calendar months using the `simByEuler` method for both a standard Monte Carlo simulation and a Quasi-Monte Carlo simulation. No outputs are requested from the simulation methods; in fact, the simulated prices of the individual indices which comprise the basket are unnecessary. Call option prices are reported for convenience:

```
reset(s)

simByEuler(GBM1, nPeriods, 'nTrials'  , nTrials, 'DeltaTime', dt, ...
                          'Processes', f.LongstaffSchwartz);

BrownianMotionCallPrice = f.CallPrice(strike, r);
BrownianMotionPutPrice  = f.PutPrice (strike, r);

reset(s)

f = Example_LongstaffSchwartz(nPeriods, nTrials);

simByEuler(GBM1, nPeriods, 'nTrials'  , nTrials, 'DeltaTime', dt, ...
                          'Processes', f.LongstaffSchwartz, ...
                          'MontecarloMethod','quasi');

QuasiMonteCarloCallPrice = f.CallPrice(strike, r);
QuasiMonteCarloPutPrice  = f.PutPrice (strike, r);

reset(s)

z = Example_CopulaRNG(returns * sqrt(252), nPeriods, 'Gaussian');
f = Example_LongstaffSchwartz(nPeriods, nTrials);

simByEuler(GBM2, nPeriods, 'nTrials'  , nTrials, 'DeltaTime', dt, ...
                          'Processes', f.LongstaffSchwartz, 'Z', z);

GaussianCopulaCallPrice = f.CallPrice(strike, r);
GaussianCopulaPutPrice  = f.PutPrice (strike, r);
```

Now repeat the copula simulation with the *t* copula dependence structure. You use the same model object for both copulas; only the random number generator and option pricing functions need to be re-initialized.

```
reset(s)

z = Example_CopulaRNG(returns * sqrt(252), nPeriods, 't');
f = Example_LongstaffSchwartz(nPeriods, nTrials);
```

```
simByEuler(GBM2, nPeriods, 'nTrials'  , nTrials, 'DeltaTime', dt, ...
                          'Processes', f.LongstaffSchwartz, 'Z', z);

tCopulaCallPrice = f.CallPrice(strike, r);
tCopulaPutPrice  = f.PutPrice (strike, r);
```

Finally, compare the American put and call option prices obtained from all models.

```
disp(' ')
```

```
 
```

```
fprintf('                    # of Monte Carlo Trials: %8d\n'    , nTrials)
```

```
                    # of Monte Carlo Trials:      100
```

```
fprintf('                    # of Time Periods/Trial: %8d\n\n'  , nPeriods)
```

```
                    # of Time Periods/Trial:       63
```

```
fprintf(' Brownian Motion American Call Basket Price: %8.4f\n'  , BrownianMotionCallPrice)
```

```
 Brownian Motion American Call Basket Price:  25.9456
```

```
fprintf(' Brownian Motion American Put  Basket Price: %8.4f\n\n', BrownianMotionPutPrice)
```

```
 Brownian Motion American Put  Basket Price:  16.4132
```

```
fprintf(' Quasi-Monte Carlo American Call Basket Price: %8.4f\n'  , QuasiMonteCarloCallPrice)
```

```
 Quasi-Monte Carlo American Call Basket Price:  21.8202
```

```
fprintf(' Quasi-Monte Carlo American Put  Basket Price: %8.4f\n\n', QuasiMonteCarloPutPrice)
```

```
 Quasi-Monte Carlo American Put  Basket Price:  19.7968
```

```
fprintf(' Gaussian Copula American Call Basket Price: %8.4f\n'  , GaussianCopulaCallPrice)
```

```
 Gaussian Copula American Call Basket Price:  24.5711
```

```
fprintf(' Gaussian Copula American Put  Basket Price: %8.4f\n\n', GaussianCopulaPutPrice)
```

```
 Gaussian Copula American Put  Basket Price:  17.4229
```

```
fprintf('        t Copula American Call Basket Price: %8.4f\n'  , tCopulaCallPrice)
```

```
        t Copula American Call Basket Price:  22.6220
```

```
fprintf('        t Copula American Put  Basket Price: %8.4f\n'  , tCopulaPutPrice)
```

```
        t Copula American Put  Basket Price:  20.9983
```

This analysis represents only a small-scale simulation. If the simulation is repeated with 100,000 trials, the following results are obtained:

```
                   # of Monte Carlo Trials:   100000
                   # of Time Periods/Trial:       63

Brownian Motion American Call Basket Price:  20.0945
Brownian Motion American Put  Basket Price:  16.4808
```

```
Quasi-Monte Carlo American Call Basket Price:  20.1935
Quasi-Monte Carlo American Put  Basket Price:  16.4731

Gaussian Copula American Call Basket Price:  20.9183
Gaussian Copula American Put  Basket Price:  16.4416

       t Copula American Call Basket Price:  21.0133
       t Copula American Put  Basket Price:  16.7050
```

Interestingly, the results agree closely. Put option prices obtained from copulas exceed those of Brownian motion by less than 1%.

A Note on Volatility and Interest Rate Scaling

The same option prices could also be obtained by working with unannualized (in this case, daily) centered returns and riskless rates, where the time increment `dt` = 1 day rather than 1/252 years. In other words, portfolio prices would still be simulated every trading day; the data is simply scaled differently.

Although not executed, and by first resetting the random stream to its initial internal state, the following code segments work with daily centered returns and riskless rates and produce the same option prices.

Gaussian Distribution/Brownian Motion & Daily Data:

```
reset(s)

f    = Example_LongstaffSchwartz(nPeriods, nTrials);
GBM1 = gbm(diag(r(ones(1,nIndices))/252), diag(std(returns)), 'StartState', X, ...
          'Correlation', correlation);

simByEuler(GBM1, nPeriods, 'nTrials'  , nTrials, 'DeltaTime', 1, ...
                          'Processes', f.LongstaffSchwartz);

BrownianMotionCallPrice = f.CallPrice(strike, r/252)
BrownianMotionPutPrice  = f.PutPrice (strike, r/252)

reset(s)

f    = Example_LongstaffSchwartz(nPeriods, nTrials);
GBM1 = gbm(diag(r(ones(1,nIndices))/252), diag(std(returns)), 'StartState', X, ...
          'Correlation', correlation);

simByEuler(GBM1, nPeriods, 'nTrials'  , nTrials, 'DeltaTime', dt, ...
                          'Processes', f.LongstaffSchwartz, ...
                          'MontecarloMethod','quasi');

QuasiMonteCarloCallPrice = f.CallPrice(strike, r/252);
QuasiMonteCarloPutPrice  = f.PutPrice (strike, r/252);
```

Gaussian Copula & Daily Data:

```
reset(s)

z    = Example_CopulaRNG(returns, nPeriods, 'Gaussian');
f    = Example_LongstaffSchwartz(nPeriods, nTrials);
GBM2 = gbm(diag(r(ones(1,nIndices))/252),   eye(nIndices), 'StartState', X);
```

```
simByEuler(GBM2, nPeriods, 'nTrials'  , nTrials, 'DeltaTime',   1, ...
                          'Processes', f.LongstaffSchwartz , 'Z', z);

GaussianCopulaCallPrice = f.CallPrice(strike, r/252)
GaussianCopulaPutPrice  = f.PutPrice (strike, r/252)
```

t Copula & Daily Data:

```
reset(s)

z = Example_CopulaRNG(returns, nPeriods, 't');
f = Example_LongstaffSchwartz(nPeriods, nTrials);

simByEuler(GBM2, nPeriods, 'nTrials'  , nTrials, 'DeltaTime',   1, ...
                          'Processes', f.LongstaffSchwartz , 'Z', z);

tCopulaCallPrice = f.CallPrice(strike, r/252)
tCopulaPutPrice  = f.PutPrice (strike, r/252)
```

Improving Performance of Monte Carlo Simulation with Parallel Computing

This example shows how to improve the performance of a Monte Carlo simulation using Parallel Computing Toolbox.

Consider a geometric Brownian motion (GBM) process in which you want to incorporate alternative asset price dynamics. Specifically, suppose that you want to include a time-varying short rate and a volatility surface. The process to simulate is written as

$$dS(t) = r(t)S(t)dt + V(t,S(t))S(t)dW(t)$$

for stock price *S(t)*, rate of return *r(t)*, volatility *V(t,S(t))*, and Brownian motion *W(t)*. In this example, the rate of return is a deterministic function of time and the volatility is a function of both time and current stock price. Both the return and volatility are defined on a discrete grid such that intermediate values are obtained by linear interpolation. For example, such a simulation can be used to support the pricing of thinly traded options.

To include a time series of riskless short rates, suppose that you derive the following deterministic short-rate process as a function of time.

```
times = [0 0.25 0.5 1 2 3 4 5 6 7 8 9 10];  % in years
rates = [0.1 0.2 0.3 0.4 0.5 0.8 1.25 1.75 2.0 2.2 2.25 2.50 2.75]/100;
```

Suppose that you then derive the following volatility surface whose columns correspond to simple relative moneyness, or the ratio of the spot price to strike price, and whose rows correspond to time to maturity, or tenor.

```
surface = [28.1 25.3 20.6 16.3 11.2  6.2  4.9  4.9  4.9  4.9  4.9  4.9
           22.7 19.8 15.4 12.6  9.6  6.7  5.2  5.2  5.2  5.2  5.2  5.2
           21.7 17.6 13.7 11.5  9.4  7.3  5.7  5.4  5.4  5.4  5.4  5.4
           19.8 16.4 12.9 11.1  9.3  7.6  6.2  5.6  5.6  5.6  5.6  5.6
           18.6 15.6 12.5 10.8  9.3  7.8  6.6  5.9  5.9  5.9  5.9  5.9
           17.4 13.8 11.7 10.8  9.9  9.1  8.5  7.9  7.4  7.3  7.3  7.3
           17.1 13.7 12.0 11.2 10.6 10.0  9.5  9.1  8.8  8.6  8.4  8.0
           17.5 13.9 12.5 11.9 11.4 10.9 10.5 10.2  9.9  9.6  9.4  9.0
           18.3 14.9 13.7 13.2 12.8 12.4 12.0 11.7 11.4 11.2 11.0 10.8
           19.2 19.6 14.2 13.9 13.4 13.0 13.2 12.5 12.1 11.9 11.8 11.4]/100;

tenor = [0 0.25 0.50 0.75 1 2 3 5 7 10];   % in years
moneyness = [0.25 0.5 0.75 0.8 0.9 1 1.10 1.25 1.50 2 3 5];
```

Set the simulation parameters. The following assumes that the price of the underlying asset is initially equal to the strike price and that the price of the underlying asset is simulated monthly for 10 years, or 120 months. As a simple illustration, 100 sample paths are simulated.

```
price = 100;
strike = 100;
dt = 1/12;
NPeriods = 120;
NTrials = 100;
```

For reproducibility, set the random number generator to its default, and draw the Gaussian random variates that drive the simulation. Generating the random variates is not necessary to incur the performance improvement of parallel computation, but doing so allows the resulting simulated paths to match those of the conventional (that is, non-parallelized) simulation. Also, generating independent Gaussian random variates as inputs also guarantees that all simulated paths are independent.

```
rng default
Z = randn(NPeriods,1,NTrials);
```

Create the return and volatility functions and the GBM model using `gbm`. Notice that the rate of return is a deterministic function of time, and therefore accepts simulation time as its only input argument. In contrast, the volatility must account for the moneyness and is a function of both time and stock price. Moreover, since the volatility surface is defined as a function of time to maturity rather than simulation time, the volatility function subtracts the current simulation time from the last time at which the price process is simulated (10 years). This ensures that as the simulation time approaches its terminal value, the time to maturity of the volatility surface approaches zero. Although far more elaborate return and volatility functions could be used if desired, the following assumes simple linear interpolation.

```
mu = @(t) interp1(times,rates,t);
sigma = @(t,S) interp2(moneyness,tenor,surface,S/strike,tenor(end)-t);
mdl = gbm(mu,sigma,'StartState',price);
```

Simulate the paths of the underlying geometric Brownian motion without parallelization.

```
tStart = tic;
paths = simBySolution(mdl,NPeriods,'NTrials',NTrials,'DeltaTime',dt,'Z',Z);
time1 = toc(tStart);
```

Simulate the paths in parallel using a `parfor` loop. For users licensed to access the Parallel Computing Toolbox, the following code segment automatically creates a parallel pool using the default local profile. If desired, this behavior can be changed by first calling the `parpool` function. If a parallel pool is not already created, the following simulation will likely be slower than the previous simulation without parallelization. In this case, rerun the following simulation to assess the true benefits of parallelization.

```
tStart = tic;
parPaths = zeros(NPeriods+1,1,NTrials);
parfor i = 1:NTrials
    parPaths(:,:,i) = simBySolution(mdl,NPeriods,'DeltaTime',dt,'Z',Z(:,:,i));
end
time2 = toc(tStart);
```

If you examine any given path obtained without parallelization to the corresponding path with parallelization, you see that they are identical. Moreover, although relative performance varies, the results obtained with parallelization will generally incur a significant improvement. To assess the performance improvement, examine the runtime of each approach in seconds and the `speedup` gained from simulating the paths in parallel.

```
time1                 % elapsed time of conventional simulation, in seconds
time2                 % elapsed time of parallel simulation, in seconds
speedup = time1/time2 % speedup factor
```

```
time1 =
    6.1329
time2 =
    2.5918
```

```
speedup =
    2.3663
```

Functions

brinsonAttribution

Create brinsonAttribution object to analyze performance attribution

Description

Create a brinsonAttribution object for performance attribution using the Brinson model.

Use this workflow to develop and analyze a Brinson model for performance attribution:

1. Prepare data for the AssetTable input.
2. Use brinsonAttribution to create a brinsonAttribution object.
3. Use the following functions with the brinsonAttribution object:

   - categoryAttribution
   - categoryReturns
   - categoryWeights
   - totalAttribution
   - summary
   - categoryReturnsChart
   - categoryWeightsChart
   - attributionsChart

For more detailed information on this workflow, see “Analyze Performance Attribution Using Brinson Model” on page 4-320.

Creation

Syntax

```
brinsonAttrubtionObj = brinsonAttribution(AssetTable)
```

Description

brinsonAttrubtionObj = brinsonAttribution(AssetTable) creates a brinsonAttribution object and sets the properties on page 15-3. Use the brinsonAttribution object with the categoryAttribution, categoryReturns, categoryWeights, totalAttribution, and summary functions.

Input Arguments

AssetTable — Information about individual asset returns in the portfolio and benchmark
table

Information about individual asset returns in the portfolio and benchmark, specified as a table with the number of rows equal to NumAssets-times-NumPeriods rows. The column variables are in the following order from left to right:

- Period — Column vector of positive whole numbers containing the time Period numbers. For each one of the NumAssets asset names, the Period numbers range from 1 to NumPeriods with increments of 1, so that there are a total of NumAssets-times-NumPeriods rows. Row 1 is for the first period, row 2 is for the second period, and is repeated for each asset. If the Period column is missing from AssetTable, all Period numbers are internally set to 1 and all asset returns in AssetTable are assumed to be for the same single period.
- Name — String column vector containing the individual asset names for the associated returns. There is a total of NumAssets unique names, and the names are repeated for each Period.
- Return — Numeric column vector containing the asset returns in decimals.
- Category — Categorical vector containing the asset categories (sectors) for the associated asset returns. There is a total of NumCategories unique categories.
- Portfolio Weight — Numeric vector containing the asset portfolio weights in decimals. The weights are internally normalized so that they sum to 1 for each Period.

  Note The values for Portfolio Weight must sum to 1 for the Brinson model. If the weights do not sum to 1, the Portfolio Weight values are internally normalized so that they sum to 1 and brinsonAttribution displays a warning. If there is a cash position, you must account for it as an asset with its own weight so that the weights sum to 1.
- Benchmark Weight — Numeric vector containing the asset benchmark weights in decimals. The weights are internally normalized so that they sum to 1 for each Period.

  Note The values for the Benchmark Weight must sum to 1 for the Brinson model. If the weights do not sum to 1, the Benchmark Weight values are internally normalized so that they sum to 1 and brinsonAttribution displays a warning. If there is a cash position, you must account for it as an asset with its own weight so that the weights sum to 1.

Note AssetTable must be a table. Instead of specific dates and times, the Period column of AssetTable must have period numbers that start with 1 and have increments of one. The multiperiod Brinson model assumes that all returns are for time periods of equal intervals (for example, monthly, quarterly, and so on).

Data Types: table

Properties

NumAssets — Total number of assets
numeric

Total number of assets, specified by AssetTable.

Data Types: double

NumPortfolioAssets — Number of assets in portfolio
numeric

Number of assets in the portfolio, specified by AssetTable.

Data Types: double

NumBenchmarkAssets — Number of assets in the benchmark
numeric

Number of assets in the benchmark, specified by AssetTable.

Data Types: double

NumPeriods — Number of time periods
numeric

Number of time periods, specified by AssetTable.

Data Types: double

NumCategories — Number of asset categories
numeric

Number of asset categories, specified by the AssetTable.

Data Types: double

AssetName — Individual asset names
vector

Individual asset names, returned as a NumAssets-by-1 vector.

Data Types: string

AssetReturn — Asset returns
matrix

Asset returns, returned as a NumAssets-by-NumPeriods matrix in decimals.

Data Types: double

AssetCategory — Asset categories
matrix

Asset categories (sectors), returned as a NumAssets-by-NumPeriods matrix.

Data Types: string

PortfolioAssetWeight — Asset portfolio weights
numeric

Asset portfolio weights, returned as a NumAssets-by-NumPeriods matrix in decimals.

Data Types: double

BenchmarkAssetWeight — Asset benchmark weights
numeric

Asset benchmark weights, returned as a NumAssets-by-NumPeriods matrix in decimals.

Data Types: double

PortflioCategoryReturn — Portfolio category returns
numeric

Portfolio category returns, returned as a `NumCategories`-by-`NumPeriods` matrix in decimals.

Data Types: `double`

`BenchmarkCategoryReturn` — Benchmark category returns
numeric

Benchmark category returns, returned as a `NumCategories`-by-`NumPeriods` matrix in decimals.

Data Types: `double`

`PortfolioCategoryWeight` — Portfolio category weights
numeric

Portfolio category weights, returned as a `NumCategories`-by-`NumPeriods` matrix in decimals.

Data Types: `double`

`BenchmarkCategoryWeight` — Benchmark category weights
numeric

Benchmark category weights, returned as a `NumCategories`-by-`NumPeriods` matrix in decimals.

Data Types: `double`

`PortfolioReturn` — Total portfolio return
numeric

Total portfolio return, returned as a scalar decimal.

Data Types: `double`

`BenchmarkReturn` — Total benchmark return
numeric

Total benchmark return, returned as a scalar decimal.

Data Types: `double`

`ActiveReturn` — Total active return
numeric

Total active return, returned as a scalar decimal.

Data Types: `double`

Object Functions

categoryAttribution	Compute performance attribution for portfolio of each category
categoryReturns	Compute aggregate and periodic category returns
categoryWeights	Compute average and periodic category weights
totalAttribution	Compute total performance attribution by Brinson model
summary	Summarize performance attribution by Brinson model
categoryReturnsChart	Create horizontal bar chart of category returns
categoryWeightsChart	Create a horizontal bar chart for category weights
attributionsChart	Create horizontal bar chart of performance attribution

Examples

Create brinsonAttribution Object

This example shows how to create a `brinsonAttribution` object that you can then use with the `categoryAttribution`, `categoryReturns`, `categoryWeights`, `totalAttribution`, and `summary` functions. Also, you can generate plots for the results, using `categoryReturnsChart`, `categoryWeightsChart`, and `attributionsChart`.

Prepare Data

Create a table for the monthly prices for four assets.

```
 GM =[17.82;22.68;19.37;20.28];
 HD = [39.79;39.12;40.67;40.96];
 KO = [38.98;39.44;40.00;40.20];
 PG = [56.38;57.08;57.76;55.54];
 MonthlyPrices  = table(GM,HD,KO,PG);
```

Use `tick2ret` to define the monthly returns.

```
MonthlyReturns = tick2ret(MonthlyPrices.Variables)';
  [NumAssets,NumPeriods] = size(MonthlyReturns);
```

Define the periods.

```
Period = ones(NumAssets*NumPeriods,1);
  for k = 1:NumPeriods
      Period(k*NumAssets+1:end,1) = Period(k*NumAssets,1) + 1;
  end
```

Define the categories (sectors) for the four assets.

```
Name = repmat(string(MonthlyPrices.Properties.VariableNames(:)),NumPeriods,1);
  Categories = repmat(categorical([ ...
      "Consumer Discretionary"; ...
      "Consumer Discretionary"; ...
      "Consumer Staples"; ...
      "Consumer Staples"]),NumPeriods,1);
```

Define benchmark and portfolio weights.

```
BenchmarkWeight = repmat(1./NumAssets.*ones(NumAssets, 1),NumPeriods,1);
  PortfolioWeight = repmat([1;0;1;1]./3,NumPeriods,1);
```

Create AssetTable Input

Create `AssetTable` as the input for the `brinsonAttribution` object.

```
  AssetTable = table(Period, Name, ...
      MonthlyReturns(:), Categories, PortfolioWeight, BenchmarkWeight, ...
      VariableNames=["Period","Name","Return","Category","PortfolioWeight","BenchmarkWeight"])
```

```
AssetTable=12×6 table
    Period    Name    Return              Category              PortfolioWeight    BenchmarkWeight
    ______    ____    _________    ______________________    _______________    _______________
```

```
      1       "GM"      0.27273    Consumer Discretionary        0.33333            0.25
      1       "HD"    -0.016838    Consumer Discretionary              0            0.25
      1       "KO"     0.011801    Consumer Staples              0.33333            0.25
      1       "PG"     0.012416    Consumer Staples              0.33333            0.25
      2       "GM"     -0.14594    Consumer Discretionary        0.33333            0.25
      2       "HD"     0.039622    Consumer Discretionary              0            0.25
      2       "KO"     0.014199    Consumer Staples              0.33333            0.25
      2       "PG"     0.011913    Consumer Staples              0.33333            0.25
      3       "GM"      0.04698    Consumer Discretionary        0.33333            0.25
      3       "HD"    0.0071306    Consumer Discretionary              0            0.25
      3       "KO"        0.005    Consumer Staples              0.33333            0.25
      3       "PG"    -0.038435    Consumer Staples              0.33333            0.25
```

Create brinsonAttribution Object

Use `brinsonAttribution` to create the `brinsonAttribution` object.

```
  BrinsonPAobj = brinsonAttribution(AssetTable)
```

```
BrinsonPAobj = 
  brinsonAttribution with properties:

                  NumAssets: 4
         NumPortfolioAssets: 3
         NumBenchmarkAssets: 4
                 NumPeriods: 3
              NumCategories: 2
                  AssetName: [4x1 string]
                AssetReturn: [4x3 double]
              AssetCategory: [4x3 categorical]
       PortfolioAssetWeight: [4x3 double]
       BenchmarkAssetWeight: [4x3 double]
    PortfolioCategoryReturn: [2x3 double]
    BenchmarkCategoryReturn: [2x3 double]
    PortfolioCategoryWeight: [2x3 double]
    BenchmarkCategoryWeight: [2x3 double]
            PortfolioReturn: 0.0598
            BenchmarkReturn: 0.0540
               ActiveReturn: 0.0059
```

You use `brinsonAttribution` object with the `categoryAttribution`, `categoryReturns`, `categoryWeights`, `totalAttribution`, and `summary` functions for the anlaysis. Also, you can generate plots for the results, using `categoryReturnsChart`, `categoryWeightsChart`, and `attributionsChart`.

More About

Brinson Model

Performance attribution supports methods for single periods over relatively short time spans (monthly) and multiple periods compounded over longer time spans (quarterly or a yearly).

The Brinson single-period sector-based (category-based) performance attribution is represented as:

$$
\begin{aligned}
r_{P,t} &= \sum_{j=1}^{N} w_{Pj,t} r_{Pj,t} \\
r_{B,t} &= \sum_{j=1}^{N} w_{Bj,t} r_{Bj,t} \\
r_{\upsilon,t} = r_{P,t} - r_{B,t} &= \sum_{j=1}^{N} w_{Pj,t} r_{Pj,t} - \sum_{j=1}^{N} w_{Bj,t} r_{Bj,t} \\
&= \sum_{j=1}^{N} (w_{Pj,t} - w_{Bj,t})(r_{Bj,t} - r_{B,t}) + \sum_{j=1}^{N} (w_{Pj,t} - w_{Bj,t})(r_{Pj,t} - r_{Bj,t}) + \sum_{j=1}^{N} w_{Bj,t}(r_{Pj,t} - r_{Bj,t}) \\
&= \sum_{j=1}^{N} (S_{j,t} + U_{j,t} + I_{j,t})
\end{aligned}
$$

where

$r_{P,t}$ — Portfolio return for period t

$r_{b,t}$ — Benchmark return for period t

$r_{\upsilon,t}$ — Value-added return for period t

N — Number of sectors

$w_{Pj,t}$ — Portfolio weight for sector j and period t

$r_{Pj,t}$ — Portfolio return for sector j and period t

$w_{Bj,t}$ — Benchmark weight for sector j and period t

$r_{Bj,t}$ — Benchmark return for sector j and period t

$S_{j,t}$ — Sector allocation effect for sector j and period t

$U_{j,t}$ — Allocation and sector interaction effect for sector j and period t

$I_{j,t}$ — Issue sector effect for sector j and period t

Multiperiod performance attribution, uses two main styles of performance attribution: arithmetic and geometric. In the arithmetic performance attribution, which is the method that the Brinson model uses, the relative performance between the portfolio and benchmark is measured by subtracting the benchmark return from the portfolio return. In the geometric performance attribution, the relative performance between the portfolio and benchmark is measured by a ratio based on the portfolio and benchmark returns.

The optimized linking algorithm by Menchero [3] extends the single-period arithmetic performance attribution to multiple periods by introducing the optimized linking coefficient β_t for each period before adding the single-period attributions. This step overcomes the fact that each single-period attribution does not simply add over multiple periods, because the optimized linking coefficient β_t reconciles the difference that arises between simple arithmetic addition and geometric compounding. As a result, the single-period Brinson model can be extended to multiple periods by using the following optimized linking algorithm:

$$r_v = r_p - r_B = \sum_{t=1}^{T} \beta_t (r_{P,t} - r_{B,t}) = \sum_{j=1}^{N} \left(\sum_{t=1}^{T} \beta_t S_{j,t} + \sum_{t=1}^{T} \beta_t U_{j,t} + \sum_{t=1}^{T} \beta_t I_{j,t} \right) = \sum_{j=1}^{N} (S_j + U_j + I_j)$$

$$\beta_t = A + C(r_{p,t} - r_{B,t})$$

$$A = \frac{\frac{(r_p - r_B)}{T}}{(1 + r_p)^{\frac{1}{T}} - (1 + r_B)^{\frac{1}{T}}}$$

$$C = \frac{r_p - r_B - A\sum_{t=1}^{T}(r_{P,t} - r_{B,t})}{\sum_{t=1}^{T}(r_{P,t} - r_{B,t})^2}$$

where

r_p — Portfolio return over multiple periods

r_B — Benchmark return over multiple periods

r_v — Value-added return over multiple periods

$r_{P,t}$ — Portfolio return for period t

$r_{B,t}$ — Benchmark return for period t

β_t — Optimized linking coefficient for period t

T — Number of periods

N — Number of sectors

$S_{j,t}$ — Sector allocation effect for sector j and period t

$U_{j,t}$ — Allocation and selection interaction effect for sector j and period t

$I_{j,t}$ — Issue selection effect for sector j and period t

$S_{j,t}$ — Sector allocation effect for sector j over multiple periods

$U_{j,t}$ — Allocation and sector interaction effect for sector j over multiple periods

$I_{j,t}$ — Issue sector effect for sector j over multiple periods

In Menchero's optimized linking algorithm shown above, the optimized linking coefficient β_t is computed for each period using r_P, r_B, $r_{P,t}$, $r_{B,t}$, and T. This algorithm allows extending the Brinson model to multiple periods while achieving the resulting desirable properties that are similar to the geometric multiperiod performance attribution.

Version History

Introduced in R2022b

R2023a: Charting functions added for `brinsonAttribution` object

Using a `brinsonAttribution` object, you can use the following charting functions: `categoryReturnsChart`, `categoryWeightsChart`, and `attributesChart`.

categoryAttribution

Compute performance attribution for portfolio of each category

Syntax

```
[AggregateCategoryAttribution,PeriodicCategoryAttribution] =
categoryAttribution(brinsonAttributionObj)
```

Description

`[AggregateCategoryAttribution,PeriodicCategoryAttribution] = categoryAttribution(brinsonAttributionObj)` computes the performance attribution for the portfolio of each category using the Brinson model.

Examples

Compute Performance Attribution Using `brinsonAttribution` Object

This example shows how to create a `brinsonAttribution` object and then use `categoryAttribution` to compute the performance attribution of the portfolio for each category (sector).

Prepare Data

Create a table for the monthly prices for four assets.

```
GM =[17.82;22.68;19.37;20.28];
 HD = [39.79;39.12;40.67;40.96];
 KO = [38.98;39.44;40.00;40.20];
 PG = [56.38;57.08;57.76;55.54];
 MonthlyPrices  = table(GM,HD,KO,PG);
```

Use `tick2ret` to define the monthly returns.

```
 MonthlyReturns = tick2ret(MonthlyPrices.Variables)';
 [NumAssets,NumPeriods] = size(MonthlyReturns);
```

Define the periods.

```
 Period = ones(NumAssets*NumPeriods,1);
 for k = 1:NumPeriods
     Period(k*NumAssets+1:end,1) = Period(k*NumAssets,1) + 1;
 end
```

Define the categories for the four assets.

```
 Name = repmat(string(MonthlyPrices.Properties.VariableNames(:)),NumPeriods,1);
 Categories = repmat(categorical([ ...
     "Consumer Discretionary"; ...
     "Consumer Discretionary"; ...
```

```
    "Consumer Staples"; ...
    "Consumer Staples"]),NumPeriods,1);
```

Define benchmark and portfolio weights.

```
BenchmarkWeight = repmat(1./NumAssets.*ones(NumAssets, 1),NumPeriods,1);
PortfolioWeight = repmat([1;0;1;1]./3,NumPeriods,1);
```

Create AssetTable Input

Create `AssetTable` as the input for the `brinsonAttribution` object.

```
AssetTable = table(Period, Name, ...
     MonthlyReturns(:), Categories, PortfolioWeight, BenchmarkWeight, ...
     VariableNames=["Period","Name","Return","Category","PortfolioWeight","BenchmarkWeight"])
```

```
AssetTable=12×6 table
    Period    Name     Return              Category              PortfolioWeight    BenchmarkWeight
    ______    ____    _________    ______________________    _______________    _______________

      1       "GM"      0.27273    Consumer Discretionary        0.33333             0.25
      1       "HD"    -0.016838    Consumer Discretionary              0             0.25
      1       "KO"     0.011801    Consumer Staples              0.33333             0.25
      1       "PG"     0.012416    Consumer Staples              0.33333             0.25
      2       "GM"     -0.14594    Consumer Discretionary        0.33333             0.25
      2       "HD"     0.039622    Consumer Discretionary              0             0.25
      2       "KO"     0.014199    Consumer Staples              0.33333             0.25
      2       "PG"     0.011913    Consumer Staples              0.33333             0.25
      3       "GM"      0.04698    Consumer Discretionary        0.33333             0.25
      3       "HD"    0.0071306    Consumer Discretionary              0             0.25
      3       "KO"        0.005    Consumer Staples              0.33333             0.25
      3       "PG"    -0.038435    Consumer Staples              0.33333             0.25
```

Create brinsonAttribution Object

Use `brinsonAttribution` to create the `brinsonAttribution` object.

```
BrinsonPAobj = brinsonAttribution(AssetTable)
```

```
BrinsonPAobj = 
  brinsonAttribution with properties:

                  NumAssets: 4
         NumPortfolioAssets: 3
         NumBenchmarkAssets: 4
                 NumPeriods: 3
              NumCategories: 2
                  AssetName: [4x1 string]
                AssetReturn: [4x3 double]
              AssetCategory: [4x3 categorical]
       PortfolioAssetWeight: [4x3 double]
       BenchmarkAssetWeight: [4x3 double]
    PortfolioCategoryReturn: [2x3 double]
    BenchmarkCategoryReturn: [2x3 double]
    PortfolioCategoryWeight: [2x3 double]
    BenchmarkCategoryWeight: [2x3 double]
            PortfolioReturn: 0.0598
            BenchmarkReturn: 0.0540
```

```
           ActiveReturn: 0.0059
```

Compute Performance Attribution

Use the `brinsonAttribution` object with `categoryAttribution` to compute the performance attribution of the portfolio for each category.

```
[AggregateCategoryAttribution,PeriodicCategoryAttribution] = categoryAttribution(BrinsonPAobj)
```

```
AggregateCategoryAttribution=2×5 table
           Category           Allocation     Selection     Interaction    ActiveReturn
    ______________________    __________    ___________    ___________    ____________

    Consumer Discretionary    -0.0071764       0.030316      -0.010105       0.013034 
    Consumer Staples          -0.0071764    -9.4005e-19    -3.1335e-19     -0.0071764 

PeriodicCategoryAttribution=6×7 table
    Period    LinkingCoefficient           Category           Allocation     Selection     Intera

      1            0.97032          Consumer Discretionary     -0.009653       0.072391       -0
      1            0.97032          Consumer Staples           -0.009653              0          
      2             1.0838          Consumer Discretionary     0.0055181      -0.046391       0.0
      2             1.0838          Consumer Staples           0.0055181    -8.6736e-19    -2.891
      3             1.0391          Consumer Discretionary    -0.0036477      0.0099623     -0.00
      3             1.0391          Consumer Staples          -0.0036477              0          
```

Input Arguments

`brinsonAttributionObj` — Brinson attribution model
object

Brinson attribution model, specified as a `brinsonAttribution` object.

Data Types: `object`

Output Arguments

`AggregateCategoryAttribution` — Category attribution aggregated over all periods
table

Category attribution aggregated over all periods, returned as a table with the following columns:

- `Category` — Asset category
- `Allocation` — Category allocation effect for the category
- `Selection` — Effect of selecting individual assets within the category
- `Interaction` — Allocation-selection interaction effect
- `ActiveReturn` — Active return compared with benchmark

`PeriodicCategoryAttribution` — Category attribution for each period
table

Category attribution for each period, returned as a table with the following columns:

- `Period` — Time period numbers (1 for the first period, 2 for the second period, and so on)
- `LinkingCoefficient` — Linking coefficients used to aggregate the attribution results over all time periods
- `Category` — Asset category
- `Allocation` — Category allocation effect for the category
- `Selection` — Effect of selecting individual assets within the category
- `Interaction` — Allocation-selection interaction effect
- `ActiveReturn` — Active return compared with benchmark

categoryReturns

Compute aggregate and periodic category returns

Syntax

`[AggregateCategoryReturns,PeriodicCategoryReturns] = categoryReturns( brinsonAttributionObj)`

Description

`[AggregateCategoryReturns,PeriodicCategoryReturns] = categoryReturns( brinsonAttributionObj)` computes the aggregate and periodic category (sector) returns for the portfolio and the benchmark.

Examples

Compute Category Returns Using `brinsonAttribution` Object

This example shows how to create a `brinsonAttribution` object and then use `categoryReturns` to compute the aggregate and periodic category returns for the portfolio and the benchmark.

Prepare Data

Create a table for the monthly prices for four assets.

```
 GM =[17.82;22.68;19.37;20.28];
 HD = [39.79;39.12;40.67;40.96];
 KO = [38.98;39.44;40.00;40.20];
 PG = [56.38;57.08;57.76;55.54];
 MonthlyPrices  = table(GM,HD,KO,PG);
```

Use `tick2ret` to define the monthly returns.

```
MonthlyReturns = tick2ret(MonthlyPrices.Variables)';
  [NumAssets,NumPeriods] = size(MonthlyReturns);
```

Define the periods.

```
Period = ones(NumAssets*NumPeriods,1);
  for k = 1:NumPeriods
      Period(k*NumAssets+1:end,1) = Period(k*NumAssets,1) + 1;
  end
```

Define the categories for the four assets.

```
Name = repmat(string(MonthlyPrices.Properties.VariableNames(:)),NumPeriods,1);
  Categories = repmat(categorical([ ...
      "Consumer Discretionary"; ...
      "Consumer Discretionary"; ...
      "Consumer Staples"; ...
      "Consumer Staples"]),NumPeriods,1);
```

Define benchmark and portfolio weights.

```
BenchmarkWeight = repmat(1./NumAssets.*ones(NumAssets, 1),NumPeriods,1);
  PortfolioWeight = repmat([1;0;1;1]./3,NumPeriods,1);
```

Create AssetTable Input

Create `AssetTable` as the input for the `brinsonAttribution` object.

```
  AssetTable = table(Period, Name, ...
      MonthlyReturns(:), Categories, PortfolioWeight, BenchmarkWeight, ...
      VariableNames=["Period","Name","Return","Category","PortfolioWeight","BenchmarkWeight"])
```

```
AssetTable=12×6 table
    Period    Name     Return             Category            PortfolioWeight    BenchmarkWeight
    ______    ____    _________    ______________________    _______________    _______________

      1       "GM"      0.27273    Consumer Discretionary        0.33333             0.25
      1       "HD"    -0.016838    Consumer Discretionary              0             0.25
      1       "KO"     0.011801    Consumer Staples              0.33333             0.25
      1       "PG"     0.012416    Consumer Staples              0.33333             0.25
      2       "GM"     -0.14594    Consumer Discretionary        0.33333             0.25
      2       "HD"     0.039622    Consumer Discretionary              0             0.25
      2       "KO"     0.014199    Consumer Staples              0.33333             0.25
      2       "PG"     0.011913    Consumer Staples              0.33333             0.25
      3       "GM"      0.04698    Consumer Discretionary        0.33333             0.25
      3       "HD"    0.0071306    Consumer Discretionary              0             0.25
      3       "KO"        0.005    Consumer Staples              0.33333             0.25
      3       "PG"    -0.038435    Consumer Staples              0.33333             0.25
```

Create brinsonAttribution Object

Use `brinsonAttribution` with the `brinsonAttribution` object to compute aggregate and periodic category returns.

```
  BrinsonPAobj = brinsonAttribution(AssetTable)
```

```
BrinsonPAobj = 
  brinsonAttribution with properties:

                  NumAssets: 4
         NumPortfolioAssets: 3
         NumBenchmarkAssets: 4
                 NumPeriods: 3
              NumCategories: 2
                  AssetName: [4x1 string]
                AssetReturn: [4x3 double]
              AssetCategory: [4x3 categorical]
       PortfolioAssetWeight: [4x3 double]
       BenchmarkAssetWeight: [4x3 double]
    PortfolioCategoryReturn: [2x3 double]
    BenchmarkCategoryReturn: [2x3 double]
    PortfolioCategoryWeight: [2x3 double]
    BenchmarkCategoryWeight: [2x3 double]
            PortfolioReturn: 0.0598
            BenchmarkReturn: 0.0540
               ActiveReturn: 0.0059
```

Compute Category Returns

Use `categoryReturns` with the `brinsonAttribution` object to compute aggregate and periodic category (sector) returns.

```
[AggregateCategoryReturns, PeriodicCategoryReturns] = categoryReturns(BrinsonPAobj)
```

```
AggregateCategoryReturns=2×3 table
           Category            AggregatePortfolioReturn    AggregateBenchmarkReturn
    ______________________    ________________________    ________________________

    Consumer Discretionary             0.13805                     0.096876        
    Consumer Staples                 0.0081816                    0.0081816

      3       Consumer Staples            -0.016717          -0.016717     
```

Input Arguments

`brinsonAttributionObj` — Brinson attribution model

object

Brinson attribution model, specified as a `brinsonAttribution` object.

Data Types: `object`

Output Arguments

`AggregateCategoryReturns` — Category returns aggregated over all periods

table

Category returns aggregated over all periods, returned as a table with the following columns:

- `Category` — Asset category
- `AggregatePortfolioReturn` — Aggregate portfolio returns
- `AggregateBenchmarkReturn` — Aggregate benchmark returns

`PeriodicCategoryReturns` — Category returns for each period

table

Category returns for each period, returned as a table with the following columns:

- `Period` — Time period numbers (1 for the first period, 2 for the second period, and so on)
- `Category` — Asset category

- `PortfolioReturn` — Portfolio returns
- `BenchmarkReturn` — Benchmark returns

categoryWeights

Compute average and periodic category weights

Syntax

```
[AverageCategoryWeights,PeriodicCategoryWeights] = categoryWeights(
brinsonAttributionObj)
```

Description

`[AverageCategoryWeights,PeriodicCategoryWeights] = categoryWeights( brinsonAttributionObj)` computes the average and periodic category weights for the portfolio and the benchmark as well as the corresponding active weights.

Examples

Compute Category Weights Using `brinsonAttribution` Object

This example shows how to create a `brinsonAttribution` object and then use `categoryWeights` to compute average and periodic category (sector) weights.

Prepare Data

Create a table for the monthly prices for four assets.

```
 GM =[17.82;22.68;19.37;20.28];
 HD = [39.79;39.12;40.67;40.96];
 KO = [38.98;39.44;40.00;40.20];
 PG = [56.38;57.08;57.76;55.54];
 MonthlyPrices  = table(GM,HD,KO,PG);
```

Use `tick2ret` to define the monthly returns.

```
MonthlyReturns = tick2ret(MonthlyPrices.Variables)';
  [NumAssets,NumPeriods] = size(MonthlyReturns);
```

Define the periods.

```
Period = ones(NumAssets*NumPeriods,1);
  for k = 1:NumPeriods
      Period(k*NumAssets+1:end,1) = Period(k*NumAssets,1) + 1;
  end
```

Define the categories for the four assets.

```
Name = repmat(string(MonthlyPrices.Properties.VariableNames(:)),NumPeriods,1);
  Categories = repmat(categorical([ ...
      "Consumer Discretionary"; ...
      "Consumer Discretionary"; ...
      "Consumer Staples"; ...
      "Consumer Staples"]),NumPeriods,1);
```

Define benchmark and portfolio weights.

```
BenchmarkWeight = repmat(1./NumAssets.*ones(NumAssets, 1),NumPeriods,1);
  PortfolioWeight = repmat([1;0;1;1]./3,NumPeriods,1);
```

Create AssetTable Input

Create `AssetTable` as the input for the `brinsonAttribution` object.

```
  AssetTable = table(Period, Name, ...
      MonthlyReturns(:), Categories, PortfolioWeight, BenchmarkWeight, ...
      VariableNames=["Period","Name","Return","Category","PortfolioWeight","BenchmarkWeight"])
```

```
AssetTable=12×6 table
    Period    Name      Return              Category            PortfolioWeight    BenchmarkWeight
    ______    ____    _________    ______________________    _______________    _______________

      1       "GM"      0.27273    Consumer Discretionary        0.33333             0.25

```

Create brinsonAttribution Object

Use `brinsonAttribution` to create the `brinsonAttribution` object.

```
  BrinsonPAobj = brinsonAttribution(AssetTable)
```

```
BrinsonPAobj = 
  brinsonAttribution with properties:

                    NumAssets: 4
           NumPortfolioAssets: 3
           NumBenchmarkAssets: 4
                   NumPeriods: 3
                NumCategories: 2
                    AssetName: [4x1 string]
                  AssetReturn: [4x3 double]
                AssetCategory: [4x3 categorical]
         PortfolioAssetWeight: [4x3 double]
         BenchmarkAssetWeight: [4x3 double]
      PortfolioCategoryReturn: [2x3 double]
      BenchmarkCategoryReturn: [2x3 double]
      PortfolioCategoryWeight: [2x3 double]
      BenchmarkCategoryWeight: [2x3 double]
              PortfolioReturn: 0.0598
              BenchmarkReturn: 0.0540
                 ActiveReturn: 0.0059
```

Compute Category Weights

Use `categoryWeights` to compute the average and periodic category weights for the portfolio and the benchmark, as well as, the corresponding active weights.

```
[AverageCategoryWeights,PeriodicCategoryWeights] = categoryWeights(BrinsonPAobj)
```

```
AverageCategoryWeights=2×4 table
           Category            AveragePortfolioWeight    AverageBenchmarkWeight    AverageActiveWe

```

Input Arguments

`brinsonAttributionObj` — Brinson attribution model
object

Brinson attribution model, specified as a `brinsonAttribution` object.

Data Types: `object`

Output Arguments

`AverageCategoryWeights` — Category weights averaged over all periods
table

Category weights averaged over all periods, returned as a table with the following columns:

- `Category` — Asset category
- `AveragePortfolioWeight` — Average portfolio weights
- `AverageBenchmarkWeight` — Average benchmark weights
- `AverageActiveWeight` — Average active weights

`PeriodicCategoryWeights` — Category weights for each period
table

Category weights for each period, returned as a table with the following columns:

- `Period` — Time period numbers (1 for the first period, 2 for the second period, and so on)

- `Category` — Asset category
