  For example, in this code snippet, predicate function object `myObj` is wrapped in `std::ref` when passed to `std::remove_if`.

  ```
  class predObj {
      // Defines function object that modifies its state
  };
  void func() {
      std::vector<int> v{0, 1, 2, 3, 4, 5};
      //
      predObj myObj;
      v.erase(std::remove_if(v.begin(), v.end(), std::ref(myObj)), v.end());
      //....
  }
  ```
- Implement a `const` function call operator that does not modify the state of the predicate object. For example, in this code snippet, `predModifies` defines a call operator that modifies `elemPosition` before checking the equality whereas `predDoesNotModify` checks only the equality of `var` without modifying it.

  ```
  class predModifies : public std::unary_function<int, bool>
  {
  public:
  predModifies() : elemPosition(0) {}
  bool operator()(const int &) const { return (++elemPosition) == 3; }
  //call operator modifies elemPosition
  private:
  ```

```
mutable size_t elemPosition;
};

class predDoesNotModify: public std::unary_function<int, bool>
{
public:
bool operator()(const int& var) const { return var == 3; }
//call operator does not modify state of object
};
```

### Polyspace Implementation

Polyspace flags violations of this rule when the following conditions are true:

- You use a STL algorithm that takes a predicate function object. For a full list of STL algorithms, see Algorithms library.
- The state of the function object is modified, where the state is one of the following:
  - The `this` pointer if the predicate object is an instance of a class that defines a function call operator `operator()`.
  - A captured-by-copy value if the predicate object is a lambda function. A lambda function that captures values by reference is compliant.

A function object state is modified if it is written to or if a non-const method is called on it. For example, in this code snippet, non-const method `increment()` modifies the state `elemPosition` of `operator()` :

```
#include <functional>
#include <vector>
#include <algorithm>

class myPred : public std::unary_function<int, bool> {
  public:
    myPred(): elemPosition(0) {}
    void increment() {++elemPosition;} // Non-const method
    bool operator()(const int&) // function call operator
    {
        increment(); // method called on state elemPosition
        return elemPosition == 3;
    }
  private:
    size_t elemPosition;
};

void func(std::vector<int> v) {
    std::remove_if(v.begin(), v.end(), myPred()); // Noncompliant
}
```

Polyspace flags function objects that modify their state even if the function object is not a predicate.

Polyspace does not flag function objects that are wrapped in these:

- `std::ref`
- `std::cref`
- `std::function`

- `std::bind`
- `std::not1`

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Function Object that Modifies Its State

```
#include <functional>
#include <vector>
#include <algorithm>

void lambdaDoesNotModify(std::vector<int> v)
{
  int elemPosition = 0;
  std::remove_if(v.begin(), v.end(),
    [elemPosition](const int & element) mutable {  //Compliant
      return elemPosition == 0 && element == 3;
    });
}

void lambdaCaptureByRef(std::vector<int> v)
{
  int elemPosition = 0;
  std::remove_if(v.begin(), v.end(),
    [&elemPosition](const int & i) { // Compliant
      return ++elemPosition == 3;
    });
}

class nonConstPred : public std::unary_function<int, bool>
{
  public:
    nonConstPred() : elemPosition(0) {}
    void increment() { ++elemPosition; }
    bool operator()(const int &)
    {
      increment();
      return elemPosition == 3;
    }
  private:
    size_t elemPosition;
};

void myFunc(std::vector<int> v)
{
  std::remove_if(v.begin(), v.end(), nonConstPred()); // Noncompliant
}

void myFunc1(std::vector<int> v)
{
  nonConstPred myPred;
  std::remove_if(v.begin(), v.end(), std::ref(myPred)); // Compliant
}
```

In this example, the use of predicate function object `nonConstPred()` inside function `myFunc` is not compliant. The call operator inside class `nonConstPred` uses a non-const method `increment()` that modifies `elemPosition`, the state of the predicate. If the algorithm `std::remove_if` makes a copy of the predicate function object, there might be two instances of `elemPosition == 3` being true, which might cause unexpected results.

The use of the same function object predicate in `myFunc1` is compliant because it is wrapped in `std::ref`. All copies of the wrapper object refer to the same underlying function object and there is only one instance of the state `elemPosition`.

The use of a lambda function as predicate function object in function `lambdaDoesNotModify` is compliant because the state of the function object is not modified. Similarly, the lambda function in `lambdaCaptureByRef` is compliant because the state of the function object is captured by reference.

# AUTOSAR C++14 Rule A25-4-1

Ordering predicates used with associative containers and STL sorting and related algorithms shall adhere to a strict weak ordering relation

## Description

### Rule Definition

*Ordering predicates used with associative containers and STL sorting and related algorithms shall adhere to a strict weak ordering relation.*

### Rationale

Algorithms and containers of the standard template library (STL) use predicates to sort and compare their elements. The predicates must adhere to strict weak ordering. That is, the predicate must adhere to these requirements:

- Irreflexivity: For all `x`, comparing `x` to itself must always evaluate to `false`.
- Assymetry: For all `x, y:` if comparing `x` to `y` evaluates to `true`, then comparing `y` to `x` must evaluate to `false`.
- Transitivity: For all `x, y, z:` if comparing `x` to `y` and `y` to `z` both evaluate to `true`, then comparing `x` to `z` must also evaluate to `true`.

These compare type methods violate at least one of these requirements:

- `std::less_equal`
- `std::greater_equal`
- `std::equal_to`
- `std::not_equal_to`
- `std::logical_or`
- `std::logical_and`

Using the preceding functions as ordering predicates for algorithms and containers from the STL might result in infinite loops, erratic behavior, and bugs that are difficult to diagnose. Instead, use functions that adhere to the strict weak ordering relation. For instance, use functions such as `std::less` or `std::greater`.

### Polyspace Implementation

Polyspace raises a violation of this rule when you use one of these compare types as predicates in standard library algorithms and containers:

- `std::less_equal`
- `std::greater_equal`
- `std::equal_to`
- `std::not_equal_to`
- `std::logical_or`

- `std::logical_and`

For a list of standard library algorithms that expect a predicate with strict weak ordering, see Compare.

If you use a user-defined predicate function, Polyspace does not check if the custom predicate adheres to strict weak ordering.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using Predicates That Do Not Adhere to Strict Weak Ordering with STL Algorithms

```
#include <functional>
#include <iostream>
#include <set>
#include <map>

int main(void)
{
    // GE
    std::set<int, std::greater_equal<int>>//Noncompliant
        s1{2, 5, 8};
    auto r = s1.equal_range(5);
    //returns 0
    std::cout << std::distance(r.first, r.second) << std::endl;

    //LE
    std::map<int, std::string, std::less_equal<int>>//Noncompliant
        m1{{2, "AB"}, {5, "CD"}, {8, "EF"}};
    auto r3 = m1.equal_range(5);
    //returns 0
    std::cout << std::distance(r3.first, r3.second) << std::endl;

    return 0;
}
```

In this example, Polyspace flags the use of inappropriate predicates when declaring STL containers. For instance:

- The predicate `greater_equal` does not return false when comparing the same objects, violating the irreflexivity requirement.
- The predicate `less_equal` does not return false when comparing the same objects, violating the irreflexivity requirement.

Polyspace flags the use of these function as predicates when declaring containers such as `std::set` or `std::map`.

By default, these containers use the function `std::less` as the ordering predicate. Because this function adheres to strict weak ordering relation, Polyspace does not raise a violation when you declare the containers by using the default predicate.

# AUTOSAR C++14 Rule A26-5-1

Pseudorandom numbers shall not be generated using std::rand()

## Description

### Rule Definition

*Pseudorandom numbers shall not be generated using std::rand().*

### Rationale

This cryptographically weak routines is predictable and must not be used for security purposes. When a predictable random value controls the execution flow, your program is vulnerable to malicious attacks.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Random Loop Numbers

```
#include <stdio.h>
#include <stdlib.h>

volatile int rd = 1;
int main(int argc, char *argv[])
{
    int j, r, nloops;
    struct random_data buf;
    int i = 0;

    nloops = rand();

    for (j = 0; j < nloops; j++) {
        if (random_r(&buf, &i))
            exit(1);
        printf("random_r: %ld\n", (long)i);
    }
    return 0;
}
```

This example uses `rand` and `random_r` to generate random numbers. If you use these functions for security purposes, these PRNGs can be the source of malicious attacks.

#### Correction — Use Stronger PRNG

One possible correction is to replace the vulnerable PRNG with a stronger random number generator.

```
#include <stdio.h>
```

```
#include <stdlib.h>
#include <openssl/rand.h>

volatile int rd = 1;
int main(int argc, char* argv[])
{
    int j, r, nloops;
    unsigned char buf;
    unsigned int seed;
    int i = 0;

    if (argc != 3)
    {
        fprintf(stderr, "Usage: %s <seed> <nloops>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    seed = atoi(argv[1]);
    nloops = atoi(argv[2]);

    for (j = 0; j < nloops; j++) {
        if (RAND_bytes(&buf, i) != 1)
            exit(1);
        printf("RAND_bytes: %u\n", (unsigned)buf);
    }
    return 0;
}
```

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule A26-5-2

Random number engines shall not be default-initialized

## Description

### Rule Definition

*Random number engines shall not be default-initialized.*

### Rationale

Pseudorandom number generators depend on an initial seed value to generate a sequence of random numbers. Default initialization of random number engines is done by using a default seed, which is a constant value. If you call a random number generator that has default initialization multiple times, you get the same sequence of random numbers every time. To avoid unexpected program behavior, such as generating the same sequence of random numbers in different program executions, use unique, nondefault seed values each time that you initialize a random number generator.

An exception to this rule is allowed when you might want a deterministic sequence for consistent testing purposes.

### Polyspace Implementation

The checker reports violations on the lines in which:

- A C++ standard random number generator is default-initialized.
- The seeding function of a random number generator is called by using an implicit call to default arguments or an explicit `default_seed` argument..

**Note** The checker does not report random number engine initializations that have constant input arguments.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Noncompliant Random Number Generator Initialization

The declaration of `std::default_random_engine eng1` is noncompliant because it is constructed by using the default argument, the `default_seed` constant.

```
#include <iostream>
#include <random>

int main()
{
  std::default_random_engine eng1{};     //Noncompliant
  std::uniform_int_distribution<int> ud2{0, 100};
  std::random_device rd;
  std::default_random_engine eng2{rd()}; //Compliant
  std::default_random_engine eng3{rd()}; //Compliant
  eng3.seed();                           //Noncompliant

return 0;
}
```

The second declaration `std::default_random_engine eng2` is compliant because it takes a user-defined `random_device` object as its initialization argument.

The declaration of `std::default_random_engine eng3` is also compliant. `eng3.seed()` is noncompliant because the seeding function `std::default_random_engine seed` uses the `default_seed` constant as an argument, which overwrites the seed of `eng3` that is correctly initialized.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule A27-0-1

Inputs from independent components shall be validated.

## Description

### Rule Definition

*Inputs from independent components shall be validated.*

### Rationale

When inputs from independent components are directly used in the source code, attackers might get complete or partial control of an application buffer. This control enables an attacker to terminate the program, view the content of the stack, access the content of the memory, modify the memory in random places, and execute unwanted code disguised as the program source code.

To prevent such vulnerabilities, validate the input from independent components. This rule applies to inputs received from external sources, such as:

- Inputs received from networks
- Inputs received from other processes and software through interprocess communication (IPC)
- Inputs received from components API

### Polyspace Implementation

Polyspace raises a flag when inputs from independent components are used without validation. The flagged uses include:

- Routines such as `sethostid` (Linux) or `SetComputerName` (Windows) use externally controlled arguments to change the host ID. See `Host change using externally controlled elements`.
- Functions such as `putenv` and `setenv` obtain new environment variable values or from unsecure sources. See `Use of externally controlled environment variable`.
- Functions such as `printf` use a format specifier that is constructed from unsecure sources. See `Tainted string format`.
- Arrays or pointers use an index that is obtained from unsecure sources. See `Array access with tainted index`.
- The program obtains the path to a command from an external unsecure source. See `Command executed from externally controlled path`.
- The program execute a command that is fully or partially constructed from externally controlled input. See `Execution of externally controlled command`.
- The program loads libraries from fixed or externally controlled unsecure paths that can be partially or fully controlled by attackers. See `Library loaded from externally controlled path`.
- A loop uses values obtained from unsecure sources as its boundary. See `Loop bounded with tainted value`.
- Memory allocation functions, such as `calloc` or `malloc`, use a size argument from an unsecure source. See `Size argument to memory function is from an unsecure source`.

- A pointer dereference uses an offset variable from an unknown or unsecure source. See `Pointer dereference with tainted offset`.
- One or both integer operands in a division operation comes from unsecure sources. See `Tainted division operand`.
- One or both integer operands in a remainder operation (`%`) comes from unsecure sources. See `Tainted modulo operand`.
- String manipulation functions that implicitly dereference the string buffer such as `strcpy` or `sprintf` use strings from unsecure sources. See `Tainted NULL or non-null-terminated string`.
- Values from unsecure sources are implicitly or explicitly converted from signed to unsigned values. See `Tainted sign change conversion`.
- The program dereferences a pointer from an unsecure source that might be NULL or point to unknown memory. See `Use of tainted pointer`.

Polyspace considers these inputs as input from an independent component or tainted:

- Volatile objects
- Object that interact with the user
- Objects that interact with the hardware
- Objects that use random numbers or the current date and time

To consider all input from outside the current analysis perimeter as unsecure, use `-consider-analysis-perimeter-as-trust-boundary`. See “Sources of Tainting in a Polyspace Analysis”.

When an input from an independent component is used without validation multiple times in a code, Polyspace flags the first use.

### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Change Host ID from Function Argument

```
#include <unistd.h>
#include <stdlib.h>

void bug_taintedhostid(void) {
    long userhid = strtol(getenv("HID"),NULL,10);
    sethostid(userhid);//Noncompliant
}
```

This example sets a new host ID using the argument passed to the function. Before using the host ID, check the value passed in.

#### Correction — Predefined Host ID

One possible correction is to change the host ID to a predefined ID. This example uses the host argument as a switch variable to choose between the different, predefined host IDs.

```
#include <unistd.h>
#include <stdlib.h>

extern long called_taintedhostid_sanitize(long);
enum { HI0 = 1, HI1, HI2, HI3 };

void taintedhostid(void) {
    long host = strtol(getenv("HID"),NULL,10);
    long hid = 0;
    switch(host) {
        case HI0:
            hid = 0x7f0100;
            break;
        case HI1:
            hid = 0x7f0101;
            break;
        case HI2:
            hid = 0x7f0102;
            break;
        case HI3:
            hid = 0x7f0103;
            break;
        default:
            /* do nothing */
        break;
    }
    if (hid > 0) {
        sethostid(hid);
    }
}
```

### Set Path in Environment

```
#define _XOPEN_SOURCE
#define _GNU_SOURCE
#include "stdlib.h"

void taintedenvvariable(void)
{
    char* path = getenv("APP_PATH");
    putenv(path); //Noncompliant
}
```

In this example, `putenv` changes an environment variable. The path `path` has not been checked to make sure that it is the intended path.

#### Correction — Sanitize Path

One possible correction is to sanitize the path, checking that it matches what you expect.

```
#define _POSIX_C_SOURCE
#include <stdlib.h>
```

```
#include <string.h>

/* Function to sanitize a path */
const char * sanitize_path(const char* str) {
    /* secure allowlist of paths */
    static const char *const authorized_paths[] = {
        "/bin",
        "/usr/bin"
    };
    if (str != NULL) {
        for (int i = 0; i < sizeof(authorized_paths) / sizeof(authorized_paths[0]); i++)
        if (strcmp(authorized_paths[i], str) == 0) {
            return authorized_paths[i];
        }
    }
    return NULL;
}

void taintedenvvariable(void)
{
    const char* path = getenv("APP_PATH");
    path = sanitize_path(path);
    if (path != NULL) {
        if (setenv("PATH", path, /* overwrite = */1) != 0) {
            /* fatal error */
            exit(1);
        }
    }
}
```

### Get Elements from User Input

```
#include <stdio.h>
#include <unistd.h>
#define MAX 40
void taintedstringformat(void) {
    char userstr[MAX];
    read(0,userstr,MAX);
    printf(userstr);//Noncompliant
}
```

This example prints the input argument `userstr`. The string is unknown. If it contains elements such as `%`, `printf` can interpret `userstr` as a string format instead of a string, causing your program to crash.

#### Correction — Print as String

One possible correction is to print `userstr` explicitly as a string so that there is no ambiguity.

```
#include "stdio.h"
#include <unistd.h>
#define MAX 40

void taintedstringformat(void) {
    char userstr[MAX];
    read(0,userstr,MAX);
    printf("%.20s", userstr);
}
```

### Use Index to Return Buffer Value

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
  return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    return tab[num];//Noncompliant
}
```

In this example, the index `num` accesses the array `tab`. The index `num` is obtained from an unsecure source and the function `taintedarrayindex` does not check to see if `num` is inside the range of `tab`.

#### Correction — Check Range Before Use

One possible correction is to check that `num` is in range before using it.

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
    return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    if (num >= 0 && num < SIZE100) {
        return tab[num];
    } else {
        return -1;
    }
}
```

### Executing Path from Environment Variable

```
#include <stdlib.h>
#include <stdio.h>
#include <string.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedpathcmd() {
    char cmd[SIZE128] = "";
    char* userpath = getenv("MYAPP_PATH");

    strncpy(cmd, userpath, SIZE100);//Noncompliant
    strcat(cmd, "/ls *");
    /* Launching command */
    system(cmd);//Noncompliant
}
```

This example obtains a path from an environment variable MYAPP_PATH. The path string is tainted. Polyspace flags its use in the strncopy function. system runs a command from the tainted path without checking the value of the path. If the path is not the intended path, your program executes in the wrong location.

**Correction — Use Trusted Path**

One possible correction is to use a list of allowed paths to match against the environment variable path.

```
#include <stdlib.h>
#include <stdio.h>
#include <string.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

/* Function to sanitize a string */
/* Any defect is localized here */
int sanitize_str(char* s, size_t n) {
    int res = 0;
    /* String is ok if */
    if (s && n>0 && n<SIZE128) {
        /* - string is not null                     */
        /* - string has a positive and limited size */
        s[n-1] = '\0';  /* Add a security \0 char at end of string *///Noncompliant
        /* Tainted pointer detected above, used as "firewall" */
        res = 1;
    }
    return res;
}

/* Authorized path ids */
enum { PATH0=1, PATH1, PATH2 };

void taintedpathcmd() {
    char cmd[SIZE128] = "";

    char* userpathid = getenv("MYAPP_PATH_ID");
    if (sanitize_str(userpathid, SIZE100)) {
        int pathid = atoi(userpathid);

        char path[SIZE128] = "";
        switch(pathid) {
            case PATH0:
                strcpy(path, "/usr/local/my_app0");
                break;
            case PATH1:
                strcpy(path, "/usr/local/my_app1");
                break;
            case PATH2:
                strcpy(path, "/usr/local/my_app2");
                break;
            default:
                /* do nothing */
        break;
        }
        if (strlen(path)>0) {
            strncpy(cmd, path, SIZE100);
            strcat(cmd, "/ls *");
            system(cmd);
        }
    }
}
```

### Call External Command

```
#include "stdlib.h"
#include "stdio.h"
#include "string.h"
#include "unistd.h"
#include "dlfcn.h"
#include "limits.h"
#define MAX 128

void taintedexternalcmd(void)
{
    char* usercmd;
    fgets(usercmd,MAX,stdin);
    char cmd[MAX] = "/usr/bin/cat ";
    strcat(cmd, usercmd);
    system(cmd);//Noncompliant
}
```

This example function calls a command from a user input without checking the command variable.

#### Correction — Use a Predefined Command

One possible correction is to use a `switch` statement to run a predefined command, using the user input as the switch variable.

```
#define _XOPEN_SOURCE
#define _GNU_SOURCE

#include "stdlib.h"
#include "stdio.h"
#include "string.h"
#include "unistd.h"
#include "dlfcn.h"
#include "limits.h"

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
enum { CMD0 = 1, CMD1, CMD2 };

void taintedexternalcmd(void)
{
    int usercmd = strtol(getenv("cmd"),NULL,10);
    char cmd[SIZE128] = "/usr/bin/cat ";

    switch(usercmd) {
        case CMD0:
            strcat(cmd, "*.c");
            break;
        case CMD1:
            strcat(cmd, "*.h");
            break;
        case CMD2:
            strcat(cmd, "*.cpp");
            break;
        default:
            strcat(cmd, "*.c");
    }
    system(cmd);
}
```

**Call Custom Library**

```
#include <stdlib.h>
#include <stdio.h>
#include <string.h>
#include <unistd.h>
#include <dlfcn.h>
#include <limits.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void* taintedpathlib() {
    void* libhandle = NULL;
    char lib[SIZE128] = "";
    char* userpath = getenv("LD_LIBRARY_PATH");
    strncpy(lib, userpath, SIZE128);//Noncompliant- userpath is tainted
    strcat(lib, "/libX.so");
    libhandle = dlopen(lib, 0x00001);//Noncompliant
    return libhandle;
}
```

This example loads the library `libX.so` from an environment variable `LD_LIBRARY_PATH`. An attacker can change the library path in this environment variable. The actual library you load could be a different library from the one that you intend.

**Correction — Change and Check Path**

One possible correction is to change how you get the library path and check the path of the library before opening the library. This example receives the path as an input argument but then performs the following checks on the path:

- The function `sanitize_str` protects against possible buffer overflows.
- The function `identified_safe_libX_folder` checks if the path belongs to a list of allowed paths.

```
#include <stdlib.h>
#include <stdio.h>
#include <string.h>
#include <unistd.h>
#include <dlfcn.h>
#include <limits.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

/* Use allowlist */
static const char *libX_safe_folder[] = {
  "/usr/",
  "/usr/lib",
  "/lib"
};

/* Return the index if the input is in the allowlist */
int identified_safe_libX_folder(const char* path)
{
  for (int i = 0; i < sizeof(libX_safe_folder) / sizeof(libX_safe_folder[0]); i ++)
    {
      if (strcmp(path, libX_safe_folder[i]) == 0)
      return i;
    }
  return -1;
}

/* Function to sanitize a string */
char *sanitize_str(char* s, size_t n) {
  /* strlen is used here as a kind of firewall for tainted string errors */
  if (strlen(s) > 0 && strlen(s) < n)
    return s;
  else
    return NULL;
}

void* taintedpathlib(char* userpath) {
  void* libhandle = NULL;
  const char *const checked_userpath = sanitize_str(userpath, SIZE128);
  if (checked_userpath != NULL) {
    int index = identified_safe_libX_folder(checked_userpath);
    if (index > 0) {
      char lib[SIZE128] = "";
      strncpy(lib, libX_safe_folder[index], SIZE128);
      strcat(lib, "/libX.so");
      libhandle = dlopen(lib, RTLD_LAZY);
    }
  }
  return libhandle;
}
```

### Loop Boundary From User Input

```
#include<stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

int taintedloopboundary(void) {
    int count;
    scanf("%d", &count);
    int res = 0;
    for (int i=0 ; i < count; ++i) {//Noncompliant
        res += i;
    }
    return res;
}
```

In this example, the function uses a user input to loop `count` times. `count` could be any number because the value is not checked before starting the `for` loop.

#### Correction: Clamp Tainted Loop Control

One possible correction is to clamp the tainted loop control. To validate the tainted loop variable `count`, this example limits `count` to a minimum value and a maximum value by using inline functions `min` and `max`. Regardless of the user input, the value of `count` remains within a known range.

```
#include<stdio.h>
#include<algorithm>
#define MIN 50
#define MAX 128
static  inline int max(int a, int b) { return a > b ? a : b;}
static inline int min(int a, int b) { return a < b ? a : b; }

int taintedloopboundary(void) {
    int count;
    scanf("%d", &count);
    int res = 0;
    count = max(MIN, min(count, MAX));
    for (int i=0 ; i<count ; ++i) {
        res += i;
    }
    return res;
}
```

#### Correction — Check Tainted Loop Control

Another possible correction is to check the low bound and the high bound of the tainted loop boundary variable before starting the `for` loop. This example checks the low and high bounds of `count` and executes the loop only when `count` is between 0 and 127.

```
#include<stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

int taintedloopboundary(void) {
    int count;
    scanf("%d", &count);
    int res = 0;

    if (count>=0 && count<SIZE128) {
        for (int i=0 ; i<count ; ++i) {
            res += i;
        }
    }
    return res;
}
```

### Allocate Memory Using Input From User

```
#include<stdio.h>
#include <stdlib.h>

int* bug_taintedmemoryallocsize(void) {
    size_t size;
    scanf("%zu", &size);
    int* p = (int*)malloc(size);//Noncompliant
    return p;
}
```

In this example, `malloc` allocates `size` bytes of memory for the pointer `p`. The variable `size` comes from the user of the program. Its value is not checked, and it could be larger than the amount of available memory. If `size` is larger than the number of available bytes, your program could crash.

#### Correction — Check Size of Memory to be Allocated

One possible correction is to check the size of the memory that you want to allocate before performing the `malloc` operation. This example checks to see if `size` is positive and less than the maximum size.

```
#include<stdio.h>
#include <stdlib.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

int* corrected_taintedmemoryallocsize(void) {
    size_t size;
    scanf("%zu", &size);
    int* p = NULL;
    if (size>0 && size<SIZE128) {          /* Fix: Check entry range before use */
        p = (int*)malloc((unsigned int)size);
    }
    return p;
}
```

### Dereference Pointer Array

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

#### Correction — Check Index Before Dereference

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

### Division of Function Arguments

```
#include <limits.h>
#include <stdio.h>

extern void print_int(int);

int taintedintdivision(void) {
    long num, denum;
    scanf("%lf %lf", &num, &denum);
    int r =  num/denum; //Noncompliant
    print_int(r);
    return r;
}
```

This example function divides two argument variables, then prints and returns the result. The argument values are unknown and can cause division by zero or integer overflow.

#### Correction — Check Values

One possible correction is to check the values of the numerator and denominator before performing the division.

```
#include <limits.h>
#include <stdio.h>

extern void print_long(long);

int taintedintdivision(void) {
    long num, denum;
    scanf("%lf %lf", &num, &denum);
    long res= 0;
    if (denum!=0 && !(num==INT_MIN && denum==-1)) {
        res = num/denum;
    }
    print_long(res);
    return res;
}
```

### Modulo with User Input

```
#include <stdio.h>
extern void print_int(int);

int taintedintmod(void) {
    int userden;
    scanf("%d", &userden);
    int rem =  128%userden; //Noncompliant
    print_int(rem);
    return rem;
}
```

In this example, the function performs a modulo operation by using a user input. The input is not checked before calculating the remainder for values that can crash the program, such as 0 and -1.

#### Correction — Check Operand Values

One possible correction is to check the values of the operands before performing the modulo operation. In this corrected example, the modulo operation continues only if the second operand is greater than zero.

```
#include<stdio.h>
extern void print_int(int);

int taintedintmod(void) {
    int userden;
    scanf("%d", &userden);
    int rem = 0;
    if (userden > 0 ) {
        rem = 128 % userden;
    }
    print_int(rem);
    return rem;
}
```

### Getting String from Input

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));//Noncompliant
    print_str(str);
}
```

In this example, the string `str` is concatenated with the argument `userstr`. The value of `userstr` is unknown. If the size of `userstr` is greater than the space available, the concatenation overflows.

#### Correction — Validate the Data

One possible correction is to check the size of `userstr` and make sure that the string is null-terminated before using it in `strncat`. This example uses a helper function, `sansitize_str`, to validate the string. The defects are concentrated in this function.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
int sanitize_str(char* s) {
    int res = 0;
    if (s && (strlen(s) > 0)) { // Noncompliant-TAINTED_STRING only flagged here
        // - string is not null
        // - string has a positive and limited size
        // - TAINTED_STRING on strlen used as a firewall
        res = 1;
    }
    return res;
}
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    if (sanitize_str(userstr))
        strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

**Correction — Validate the Data**

Another possible correction is to call function `errorMsg` and `warningMsg` with specific strings.

```
#include <stdio.h>
#include <string.h>
#include <stdlib.h>

#define SIZE128 128

extern void print_str(const char*);

void warningMsg(char* userstr)
{
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}

void errorMsg(char* userstr)
{
  char str[SIZE128] = "Error: ";
  strncat(str, userstr, SIZE128-(strlen(str)+1));
  print_str(str);
}

int manageSensorValue(int sensorValue) {
  int ret = sensorValue;
  if ( sensorValue < 0 ) {
    errorMsg("sensor value should be positive");
    exit(1);
  } else if ( sensorValue > 50 ) {
    warningMsg("sensor value greater than 50 (applying threshold)...");
    sensorValue = 50;
  }

  return sensorValue;
}
```

### Set Memory Value with Size Argument

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

#### Correction — Check Value of `size`

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

### Function That Dereferences an External Pointer

```
#include<stdlib.h>
void taintedptr(void) {
    char *p = getenv("ARG");
    char x = *(p+10);//Noncompliant
}
```

In this example, the pointer `*p` points to an string of unknown size. During the dereferencing operation, the pointer might be null or point to unknown memory, which can result in segmentation fault.

#### Correction — Check Pointer

One possible correction is to sanitize the pointer before using it. This example checks whether the pointer is `nullptr` before it is dereferenced.

```
#include<stdlib.h>
#include <string.h>
void taintedptr(void) {
    char *p = getenv("ARG");
    if(p!=nullptr && strlen(p)>10)
    {
    char x = *(p+10);
    }
}
```

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule A27-0-2

A C-style string shall guarantee sufficient space for data and the null terminator

## Description

### Rule Definition

*A C-style string shall guarantee sufficient space for data and the null terminator.*

### Rationale

C-style strings not only require space for the character data written but require one explicit character at the end for the additional null terminator. Failure to accommodate for the space required causes buffer overflow, leading to memory corruption, security vulnerabilities, and other issues.

### Polyspace Implementation

The checker looks for these issues:

- Use of a dangerous standard function.

  This issue occurs when you use C functions such as `gets` and `strcpy`, which write data to a buffer but do not inherently provide controls on the length of data written.

  For a more complete list of functions and their safer alternatives, see `Use of dangerous standard function`.
- Buffer overflow from incorrect string format specifier.

  This issue occurs when the format specifier argument for C functions such as `sscanf` leads to an overflow or underflow in the memory buffer argument.
- Destination buffer overflow in string manipulation.

  This issue occurs when certain C string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

  For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.
- Insufficient destination buffer size

  This occurs when the destination buffer in a `strcpy` operation cannot accommodate the source buffer and a null terminator. The issue is reported if the size of the source buffer is unknown.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of a dangerous standard function

```
#include <cstdio>
#include <cstring>

#define BUFF_SIZE 128

int noncompliant_func(char *str) {
    char dst[BUFF_SIZE];
    int r = 0;

    if (sprintf(dst, "%s", str) == 1) { //Noncompliant
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}

int compliant_func(char *str) {
    char dst[BUFF_SIZE];
    int r = 0;

    if (snprintf(dst, sizeof(dst), "%s", str) == 1) { //Compliant
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}
```

In this example, the rule is violated when you use the `sprintf` function, which does not allow control on the length of data written. To avoid the possible buffer overflow, use the safer alternative function `snprintf`.

### Buffer overflow from incorrect string format specifier

```
#include <cstdio>

void noncompliant_func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%33c", buf); //Noncompliant
}

void compliant_func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%32c", buf); //Compliant
}
```

In this example, the buffer `buf` can contain 32 `char` elements. Therefore, the format specifier `%33c` causes a buffer overflow and violates the rule. To avoid the rule violation, read a smaller number of elements into the buffer.

### Destination buffer overflow in string manipulation

```
#include <cstdio>

void noncompliant_func(void) {
    char buf[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buf, fmt_string); //Noncompliant
}

void compliant_func(void) {
    char buf[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buf, 20, fmt_string); //Compliant
}
```

In this example, the buffer `buf` can contain 20 `char` elements. Therefore, the greater size of `fmt_string` causes a buffer overflow and violates the rule. To avoid the rule violation, use `snprintf` to enforce length control and read fewer than 20 elements into the buffer.

### Destination Buffer Too Small

In this example, the size of the `source` buffer is unknown, while the size of the `destination` buffer is fixed at `128`. The size of the `destination` buffer might not be sufficient to accommodate the characters from the `source` buffer and terminate the buffer with a null. Polyspace reports a violation of the rule.

```
#include <string.h>

int main(int argc, char *argv[]) {
  const char *const source = (argc && argv[0]) ? argv[0] : "";
  char destination[128];
  strcpy(const_cast<char*>(source), destination);//Noncompliant

  return 0;
}
```

#### Correction — Allocate Sufficient Memory for Destination

This violation is resolved by allocating sufficient memory for the `destination` buffer. For instance, use the function `strlen()` to calculate the size of the `source` buffer and allocate sufficient memory for the `destination` buffer so that it can accommodate all characters from the `source` buffer and the null terminator (`'\0'` ).

```
#include <stdlib.h>
#include <string.h>

int main(int argc, char *argv[]) {
  const char *const source = (argc && argv[0]) ? argv[0] : "";
  char* destination = (char *)malloc(strlen(source)+ 1);
  if(destination!=NULL){
      strcpy(const_cast<char*>(source), destination);//Compliant
  }else{
      /*Handle Error*/
  }
  //...
  free(destination);
  return 0;
}
```

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule A27-0-3

Alternate input and output operations on a file stream shall not be used without an intervening flush or positioning call

## Description

### Rule Definition

*Alternate input and output operations on a file stream shall not be used without an intervening flush or positioning call.*

### Rationale

Alternating input and output operations on a stream without an intervening flush or positioning call is undefined behavior.

### Polyspace Implementation

The checker checks for situations when:

- You do not perform a flush or function positioning call between an output operation and a following input operation on a file stream in update mode.

  To resolve the rule violation, call `fflush()` or a file positioning function such as `fseek()` or `fsetpos()` between output and input operations on an update stream.
- You do not perform a function positioning call between an input operation and a following output operation on a file stream in update mode.

  To resolve the rule violation, call a file positioning function between input and output operations on an update stream.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Read After Write Without Intervening Flush

```
#include <stdio.h>
#define SIZE20 20

void initialize_data(char* data, size_t s) {};
const char *temp_filename = "/tmp/demo.txt";

void funcNonCompliant()
{
    char data[SIZE20];
    char append_data[SIZE20];
    FILE *file;
    file = fopen(temp_filename, "a+");
    if (file == NULL)
      {
        /* Handle error. */;
      }

    initialize_data(append_data, SIZE20);

    if (fwrite(append_data, 1, SIZE20, file) != SIZE20)
      {
        (void)fclose(file);
        /* Handle error. */;
      }
    /* Read operation after write without
    intervening flush. */
    if (fread(data, 1, SIZE20, file) < SIZE20)  //Noncompliant
      {
          (void)fclose(file);
          /* Handle error. */;
      }

    if (fclose(file) == EOF)
      {
        /* Handle error. */;
      }
}

void funcCompliant()
{
    char data[SIZE20];
    char append_data[SIZE20];
    FILE *file;

    file = fopen(temp_filename, "a+");
    if (file == NULL)
      {
        /* Handle error. */;
      }

    initialize_data(append_data, SIZE20);

    if (fwrite(append_data, 1, SIZE20, file) != SIZE20)
      {
        (void)fclose(file);
        /* Handle error. */;
      }
    /* Buffer flush after write and before read */
    if (fflush(file) != 0)
      {
        (void)fclose(file);
        /* Handle error. */;
      }
    if (fread(data, 1, SIZE20, file) < SIZE20) //Compliant
      {
        (void)fclose(file);
        /* Handle error. */;
      }
    if (fclose(file) == EOF)
      {
        /* Handle error. */;
      }
}
```

In this example, in the function `funcNonCompliant`, the file `demo.txt` is opened for reading and appending. After the call to `fwrite()`, a call to `fread()` without an intervening flush operation is undefined behavior and violates the rule.

The function `funcCompliant` shows an alternative solution where a flush call is performed after writing data to the file and before calling `fread()`.

# AUTOSAR C++14 Rule A27-0-4

C-style strings shall not be used

## Description

### Rule Definition

*C-style strings shall not be used.*

### Rationale

The underlying character array that stores a C-style string has many disadvantages such as:

- You must explicitly handle memory allocation and deallocation if you perform operations on the string that require non-trivial memory manipulations.
- It is not always clear whether a `char*` points to a single character or to a C-style string.
- You might accidentally convert an array to a raw pointer when you pass it by value or by pointer to a function, which results in a loss of information about the array size (array decay). For example, in this code snippet, `func` prints the size of the pointer to the first character of `cString` (8) , while the actual size of `cString` is 6.

```
void func(char *c){ //function takes array by value
  cout << sizeof(c);
}

void main(){
  char cString[]{ "pizza" }; //Size is 6 (5 characters + null terminator)
  func(cString); // Size is 8 (size of char*)
}
```

Instead, use the `std::string` class to store a sequence of characters. The class handles allocations and deallocations, and instantiates an object that you can safely pass to functions. The class also has built-in functionalities to manipulate the string such as iterators.

### Polyspace Implementation

Polyspace flags the use of:

- Pointers to char (`char*`) and arrays of char (`char someArray[]`).
- Pointers to and arrays of char with a type qualifier such as `volatile` or `const`. For example `char const*`.
- Pointers to and arrays of type `wchar_t`, `char16_t`, and `char32_t`.

If you have a function declaration and its definition in your source code, Polyspace places the violation on the function definition. For example:

```
const char* greeter(void);
//....
const char* greeter(void){ //Non-compliant
  return "Hello";
}
```

Polyspace does not flag the use of:

- Pointers to or arrays of `signed` or `unsigned` char. For example, `signed_c` and `unsigned_arr` are not flagged in this code snippet:

  ```
  signed char* signed_c;
  unsigned char unsigned_arr[2048];
  ```
- Literal strings. For example, the return value of `greeter()` is not flagged in this code snippet, but the use of `const char*` in the first line is flagged:

  ```
  const char* greeter(void){ //Non-compliant
    return "Hello"; // Compliant
  }
  ```
- The parameters of `main()`.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of C-Style Strings

```
#include<iostream>
#include <string>
#include<cstring>

char* sub_c_str(   //Non-compliant
    const char* str1, const int delim)  //Non-compliant
{
    size_t index {strlen(str1)};
    if (strchr(str1, delim)) {
        index = (size_t)(strchr(str1, delim) - str1);
    }
    char* p = (char*) malloc(index + 1); //Non-compliant
    //memory leak if p is not freed by caller
    strncpy(p, str1, index);
    return p;

}

std::string sub_str(std::string const str2, const char delim)
{
    return str2.substr(0, str2.find(delim));
}

int main()
{
    const char str1[] { "rootFolder/subFolder"}; // Non-compliant
    std::cout << sub_c_str(str1, '/') << std::endl;

    std::string const str2 { "rootFolder/subFolder" };
    std::cout << sub_str(str2, '/') << std::endl;
    return 0;
}
```

In this example, function `sub_c_str` returns a substring of C-style string parameter `str1` up to but not including the first instance of `delim`. The return type and first parameter of `sub_c_str` are both non-compliant pointers to char. Pointer `p`, which stores the substring, is also non-compliant. Note that if you do not free the memory allocated to `p` before the end of the program, this results in a memory leak.

Function `sub_str` takes advantage of the `std::string` class to perform the same operation as `sub_c_str`. The class handles memory allocation and deallocation. The class also has built-in functionalities (`find` and `subst`) to perform the string manipulation.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M0-1-1

A project shall not contain unreachable code

## Description

### Rule Definition

*A project shall not contain unreachable code.*

### Rationale

This rule flags situations where a group of statements is unreachable because of syntactic reasons. For instance, code following a `return` statement are always unreachable.

Unreachable code involve unnecessary maintenance and can often indicate programming errors.

### Polyspace Implementation

Polyspace reports a defect if a statement in your code is not reachable.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Unreachable statements

```
int func(int arg) {
 int temp = 0;
 switch(arg) {
     temp = arg; // Noncompliant
     case 1:
     {
         break;
     }
     default:
     {
         break;
     }
 }
 return arg;
 arg++; // Noncompliant
}
```

These statements are unreachable:

- Statements inside a `switch` statement that do not belong to a `case` or `default` block.
- Statements after a `return` statement.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M0-1-2

A project shall not contain infeasible paths

## Description

### Rule Definition

*A project shall not contain infeasible paths.*

### Rationale

This rule flags situations where a group of statements is redundant because of nonsyntactic reasons. For instance, an `if` condition is always true or false. Code that is unreachable from syntactic reasons are flagged by rule 0-1-1.

Unreachable or redundant code involve unnecessary maintenance and can often indicate programming errors.

### Polyspace Implementation

Polyspace Bug Finder reports a violation of this if your code contains dead code and unnecessary `if` conditionals. See `Dead code` and `Useless if` checkers.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Boolean Operations with Invariant Results

```
void func (unsigned int arg) {
 if (arg >= 0U) //Noncompliant
     arg  = 1U;
 if (arg < 0U) //Noncompliant
     arg = 1U;
}
```

An `unsigned int` variable is nonnegative. Both `if` conditions involving the variable are always true or always false and are therefore redundant.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M0-1-3

A project shall not contain unused variables

## Description

*This checker is deactivated in a default Polyspace* as You Code *analysis. See "Checkers Deactivated in Polyspace as You Code Analysis".*

### Rule Definition

*A project shall not contain unused variables.*

### Rationale

Presence of unused variables indicates that the wrong variable name might be used in the source code. Removing these variables reduces the possibility of the wrong variable being used in further development. Keep padding bits in bitfields unnamed to reduce unused variables in your project.

### Polyspace Implementation

The checker flags local or global variables that are declared or defined but not read or written in any source files of the project. This specification also applies to members of structures and classes.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Use of Named Bit Field for Padding

```
#include <iostream>
struct S {
    unsigned char b1 : 3;
    unsigned char pad: 1;  //Noncompliant
    unsigned char b2 : 4;
};
void init(struct S S_obj)
{
    S_obj.b1 = 0;
    S_obj.b2 = 0;
}
```

In this example, the bit field `pad` is used for padding the structure. Therefore, the field is never read or written and causes a violation of this rule. To avoid the violation, use an unnamed field for padding.

```
#include <iostream>
struct S {
    unsigned char b1 : 3;
    unsigned char : 1;  //Compliant
    unsigned char b2 : 4;
};
void init(struct S S_obj)
{
    S_obj.b1 = 0;
    S_obj.b2 = 0;
}
```

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M0-1-4

A project shall not contain non-volatile POD variables having only one use

## Description

### Rule Definition

*A project shall not contain non-volatile POD variables having only one use.*

### Rationale

If you use a non-volatile variable with a Plain Old Data type (`int`, `double`, etc.) *only once*, you can replace the variable with a constant literal. Your use of a variable indicates that you intended more than one use for that variable and might have a programming error in the code. You might have omitted the other uses of the non-volatile variable or incorrectly used other variables at intended points of use.

### Polyspace Implementation

The checker flags local and static variables that have a function scope (locally static) and file scope, which are used only once. The checker considers `const`-qualified global variables without the `extern` specifier as static variables with file scope.

The checker counts these use cases as one use of the non-volatile variable:

- An explicit initialization using a constant literal or the return value of a function
- An assignment
- A reference to the variable such as a read operation
- An assignment of the variable address to a pointer

If the variable address is assigned to a pointer, the checker assumes that the pointer might be dereferenced later and does not flag the variable.

Some objects are designed to be used only once by their semantics. Polyspace does not flag a single use of these objects:

- `lock_guard`
- `scoped_lock`
- `shared_lock`
- `unique_lock`
- `thread`
- `future`
- `shared_future`

If you use nonstandard objects that provide similar functionality as the objects in the preceding list, Polyspace might flag single uses of the nonstandard objects. Justify their single uses by using comments.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Non-volatile Variable Used Only Once

```
#include <mutex>
int readStatus1();
int readStatus2();
void getReading(int*);
extern std::mutex m;
void foo()
{
    // Initiating lock 'lk'
    std::lock_guard<std::mutex> lk{m};
    int checkEngineStatus1 = readStatus1();
    int checkEngineStatus2 = readStatus2();//Noncompliant
    int sensorData;//Noncompliant
    getReading(&sensorData);
    if(checkEngineStatus1) {
        //Perform some actions if both statuses are valid
    }
    // Release lock when 'lk' is deleted at exit point of scope
}
```

In this example, the variable `checkEngineStatus2` is used only once. The single use of this variable might indicate a programming error. For instance, you might have intended to check both `checkEngineStatus1` and `checkEngineStatus2` in the `if` condition, but omitted the second check. The variable `sensorData` is also used only once when its address is passed to the function `getReading()`. Polyspace flags these single use variables.

The `lock_guard` object `lk` is used a single time. Because the semantics of a `lock_guard` object justifies its single use, Polyspace does not flag it.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M0-1-8

All functions with void return type shall have external side effect(s)

## Description

### Rule Definition

*All functions with void return type shall have external side effect(s).*

### Rationale

A function that has a `void` return type does not return anything. When such a function has no external side effects, it does not contribute to the output and consumes time. That these functions have no contribution to the output of the program might be contrary to developer expectation. Such a function might be unnecessary or indicate issues in the program design. Avoid such functions.

The MISRA C++:2008 standard considers these effects as external side effects:

- Reading or writing in resources such as a file or a stream.
- Changing the value of a nonlocal variable.
- Changing the value of a reference type argument.
- Using a `volatile` object.
- Raising an exception.

### Polyspace Implementation

Polyspace flags the definition of a `void` type function if the function has no side effects.

Polyspace considers a function to have side effects if the function performs any of these tasks:

- Calls an impure function other than itself.
- Changes the value or dereferences a reference or pointer type argument.
- Changes the value or deferences of a nonlocal variable.
- Contains assembly instructions.
- Accesses the `this` pointer of its parent class.
- Raises an exception. Raising exceptions is considered as a side effect even if the function does not exit with an exception.
- Writes into an absolute address by using a local pointer.
- Accesses a `volatile` object, class member, or `struct` member.
- Sets the value of a class or `struct` member.

This checker does not flag standard implementations of placement `new` and `delete` functions.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid void Functions That Have No Side Effects

```
#include<cmath>
volatile int flag;
struct reg2 {
    struct reg1 {
      unsigned int U;
    } REG1;
    unsigned int* P;
  };

void init ( int refToInt )          // Noncompliant
{
    refToInt = 0;
}

void transform(double theta) //Noncompliant
{
    theta = sin(theta)/(1-cos(theta));
}
void foo(int val){ //Noncompliant
    if(val){
        foo(val--);
    }
}

void rd(void){ //Compliant
    if(flag==0){
        //...
    }
}
void read_reg(void){ //Compliant
     reg2* reg = reinterpret_cast<reg2 *>((0x02008000));
     reg->REG1.U = 0;
     //...
}
```

In this example, Polyspace flags the `void` functions that have no side effects. For instance:

- The function `init()` initializes a local variable. This function returns no value and has no additional side effects. Perhaps the function is intended to initialize a reference and you missed an & in the declaration. Polyspace flags the function.
- The function `transform()` transforms a number to another number by calling the pure functions `sin()` and `cos()`. The function returns nothing and has no side effects. Perhaps the function is intended to return the transformed number and you missed a return statement. Polyspace flags the function.
- The function `foo()` sets up a recursion but has no effect on the output. Perhaps the recursion is set up improperly. Polyspace flags the function.
- The function `rd()` reads a `volatile` object `flag`. Polyspace does not raise a violation on this function.
- The function `read_reg()` writes into the absolute address `0x02008000` by using the local pointer `reg`. Polyspace assumes that the function might have a side effects and does not raise a violation on it.

## Check Information

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M0-1-9

There shall be no dead code

## Description

### Rule Definition

*There shall be no dead code.*

### Rationale

If an operation is reachable but removing the operation does not affect program behavior, the operation constitutes dead code. For instance, suppose that a variable is never read following a write operation. The write operation is redundant.

The presence of dead code can indicate an error in the program logic. Because a compiler can remove dead code, its presence can cause confusion for code reviewers.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Redundant Operations

```
#define ULIM 10000

int func(int arg) {
    int res;
    res = arg*arg + arg;
    if (res > ULIM)
        res = 0; //Noncompliant
    return arg;
}
```

In this example, the operations involving `res` are redundant because the function `func` returns its argument `arg`. All operations involving `res` can be removed without changing the effect of the function.

The checker flags the last write operation on `res` because the variable is never read after that point. The dead code can indicate an unintended coding error. For instance, you intended to return the value of `res` instead of `arg`.

## Check Information

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M0-1-10

Every defined function should be called at least once

## Description

### Rule Definition

*Every defined function should be called at least once.*

### Rationale

If a function with a definition is not called, it might indicate a serious coding error. For instance, the function call is unreachable or a different function is called unintentionally.

### Polyspace Implementation

The checker detects situations where a static function is defined but not called at all in its translation unit.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Uncalled Static Function

```
static void func1() {
}

static void func2() { //Noncompliant
}

void func3();

int main() {
    func1();
    return 0;
}
```

The `static` function `func2` is defined but not called.

The function `func3` is not called either, however, it is only declared and not defined. The absence of a call to `func3` does not violate the rule.

## Check Information

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M0-2-1

An object shall not be assigned to an overlapping object

## Description

### Rule Definition

*An object shall not be assigned to an overlapping object.*

### Rationale

When you assign an object to another object with overlapping memory, the behavior is undefined.

The exceptions are:

- You assign an object to another object with exactly overlapping memory and compatible type.
- You copy one object to another with `memmove`.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Assignment of Union Members

```
void func (void) {
    union {
        short i;
        int j;
    } a = {0}, b = {1};

    a.j = a.i;   //Noncompliant
    a = b;       //Compliant
}
```

In this example, the rule is violated when `a.i` is assigned to `a.j` because the two variables have overlapping regions of memory.

# AUTOSAR C++14 Rule M0-3-2

If a function generates error information, then that error information shall be tested

## Description

### Rule Definition

*If a function generates error information, then that error information shall be tested.*

### Rationale

If you do not check the return value of functions that indicate error information through their return values, your program can behave unexpectedly. Errors from these functions can propagate throughout the program causing incorrect output, security vulnerabilities, and possibly system failures.

For the `errno`-setting functions, to see if the function call completed without errors, check `errno` for error values. The return values of these `errno`-setting functions do not indicate errors. The return value can be one of the following:

- `void`
- Even if an error occurs, the return value can be the same as the value from a successful call. Such return values are called in-band error indicators. For instance, `strtol` converts a string to a long integer and returns the integer. If the result of conversion overflows, the function returns `LONG_MAX` and sets `errno` to `ERANGE`. However, the function can also return `LONG_MAX` from a successful conversion. Only by checking `errno` can you distinguish between an error and a successful conversion.

For the `errno`-setting functions, you can determine if an error occurred only by checking `errno`.

### Polyspace Implementation

The checker raises a violation when:

- You call sensitive functions that return information about possible errors and then you ignore the return value or use the output of the function without testing the return value.

  The checker covers function from the standard library and other well-known libraries such as the POSIX library or the WinAPI library. Polyspace considers a function as sensitive if the function call is prone to failure because of reasons such as:

  - Exhausted system resources (for example, when allocating resources).
  - Changed privileges or permissions.
  - Tainted sources when reading, writing, or converting data from external sources.
  - Unsupported features despite an existing API.

  Polyspace considers a function a critical sensitive when they perform critical tasks such as:

  - Set privileges (for example, `setuid`)
  - Create a jail (for example, `chroot`)

  - Create a process (for example, `fork`)
  - Create a thread (for example, `pthread_create`)
  - Lock or unlock mutex (for example, `pthread_mutex_lock`)
  - Lock or unlock memory segments (for example, `mlock`)

  For functions that are not critical, the checker is not flagged if you explicitly ignore the return value by casting it to `void`. Explicitly ignoring the return value of critical sensitive functions is flagged by Polyspace.

- You call a function that sets `errno` to indicate error conditions, but do not check `errno` after the call. For these functions, checking `errno` is the only reliable way to determine if an error occurred.

  Functions that set `errno` on errors include:

  - `fgetwc`, `strtol`, and `wcstol`.

    For a comprehensive list of functions, see documentation about errno.
  - POSIX `errno`-setting functions such as `encrypt` and `setkey`.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Sensitive Function Return Ignored

```
#include <pthread.h>
#include <string.h>
#include <stddef.h>
#include <stdio.h>
#include <cstdlib>
#define fatal_error() abort()

void initialize_1() {
    pthread_attr_t attr;
    pthread_attr_init(&attr); //Noncompliant
}

void initialize_2() {
    pthread_attr_t attr;
   (void)pthread_attr_init(&attr); //Compliant
}

void initialize_3() {
    pthread_attr_t attr;
    int result;
    result = pthread_attr_init(&attr); //Compliant
    if (result != 0) {
        /* Handle error */
        fatal_error();
    }
}
```

```
int read_file_1(int argc, char *argv[])
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  in = fmemopen (argv[1], strlen (argv[1]), "r");
  return 0; //Noncompliant

}
int read_file_2(int argc, char *argv[])
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  in = fmemopen (argv[1], strlen (argv[1]), "r"); //Compliant
  if (in==NULL){
      // Handle error
  }
  return 0;
}
```

This example shows a call to the sensitive functions `pthread_attr_init` and `fmemopen`. Polyspace raises a flag if:

- You implicitly ignore the return of the sensitive function. Explicitly ignoring the output of sensitive functions is not flagged.
- You obtain the return value of a sensitive function but do not test the value before exiting the relevant scope. The violation is raised on the exit statement.

To be compliant, you can explicitly cast their return value to `void` or test the return values to check for errors.

### Critical Function Return Ignored

```
#include <pthread.h>
#include <cstdlib>
#define fatal_error() abort()
extern void *start_routine(void *);

void returnnotchecked_1() {
    pthread_t thread_id;
    pthread_attr_t attr;
    void *res;

    (void)pthread_attr_init(&attr);
    (void)pthread_create(&thread_id, &attr, &start_routine, ((void *)0)); //Noncompliant
    pthread_join(thread_id,  &res); //Noncompliant
}

void returnnotchecked_2() {
    pthread_t thread_id;
    pthread_attr_t attr;
    void *res;
    int result;

    (void)pthread_attr_init(&attr);
    result = pthread_create(&thread_id, &attr, &start_routine, NULL); //Compliant
    if (result != 0) {
        /* Handle error */
        fatal_error();
    }

    result = pthread_join(thread_id,  &res); //Compliant
    if (result != 0) {
        /* Handle error */
        fatal_error();
    }
}
```

In this example, two critical functions are called: `pthread_create` and `pthread_join`. The return value of the `pthread_create` is ignored by casting to void, but because `pthread_create` is a critical function (not just a sensitive function), the rule checker still raises a violation. The other critical function, `pthread_join`, returns a value that is ignored implicitly.

To be compliant, check the return value of these critical functions to verify the function performed as expected.

### errno Not Checked After Call to strtol

```
#include<cstdlib>
#include<cerrno>
#include<climits>
#include<iostream>

int main(int argc, char *argv[]) {
    char *str, *endptr;
    int base;

    str = argv[1];
    base = 10;

    long val = strtol(str, &endptr, base); //Noncompliant
    std::cout<<"Return value of strtol() = %ld\n" << val;

    errno = 0;
    long val2 = strtol(str, &endptr, base); //Compliant
    if((val2 == LONG_MIN || val2 == LONG_MAX) && errno == ERANGE) {
         std::cout<<"strtol error";
         exit(EXIT_FAILURE);
    }
    std::cout<<"Return value of strtol() = %ld\n" << val2;
}
```

In the noncompliant example, the return value of `strtol` is used without checking `errno`.

To be compliant, before calling `strtol`, set `errno` to zero . After a call to `strtol`, check the return value for `LONG_MIN` or `LONG_MAX` and `errno` for `ERANGE`.

# AUTOSAR C++14 Rule M2-7-1

The character sequence /* shall not be used within a C-style comment

## Description

### Rule Definition

*The character sequence /* shall not be used within a C-style comment.*

### Rationale

If your code contains a `/*` in a `/* */` comment, it typically means that you have inadvertently commented out code. See the example that follows.

### Polyspace Implementation

You cannot justify a violation of this rule using source code annotations.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Use of `/*` in `/* */` Comment

```
void setup(void);
void foo() {
    /* Initializer functions
     setup();
    /* Step functions */  //Noncompliant
}
```

In this example, the call to `setup()` is commented out because the ending `*/` is omitted, perhaps inadvertently. The checker flags this issue by highlighting the `/*` in the `/* */` comment.

# AUTOSAR C++14 Rule M2-10-1

Different identifiers shall be typographically unambiguous

## Description

### Rule Definition

*Different identifiers shall be typographically unambiguous.*

### Rationale

When you use different identifiers that look typographically similar, you might inadvertently use the incorrect identifier later in your code. Such typographically ambiguous identifiers might lead to bugs that are difficult to diagnose.

Use identifiers that are unambiguously distinct. Avoid using identifiers that differ by a combination of these:

- The use of a lowercase letter instead of an uppercase one, and vice versa.
- The presence or absence of the underscore character.
- The interchange of the letter `O` and the digit `0`.
- The interchange of the letter `I` and the digit `1`.
- The interchange of the letter `I` and the letter `l`.
- The interchange of the letter `S` and the digit `5`.
- The interchange of the letter `Z` and the digit `2`.
- The interchange of the letter `n` and the letter `h`.
- The interchange of the letter `B` and the digit `8`.
- The interchange of the letters `rn` and the letter `m`.

Depending on the font you use, the preceding characters might look similar.

### Polyspace Implementation

Polyspace reports a defect if two identifiers differ by a combination of ambiguous characters mentioned in the preceding list. The rule checker does not consider the fully qualified names of variables when checking this rule.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Typographically Ambiguous Identifiers

```
void func(void) {
    int id1_numval;
    int id1_num_val;  //Non-compliant

    int id2_numval;
    int id2_numVal;   //Non-compliant

    int id3_lvalue;
    int id3_Ivalue;   //Non-compliant

    int id4_xyZ;
    int id4_xy2;      //Non-compliant

    int id5_zerO;
    int id5_zer0;     //Non-compliant

    int id6_rn;
    int id6_m;        //Non-compliant
}
```

In this example, the rule is violated when identifiers that can be confused for each other are used.

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M2-13-2

Octal constants (other than zero) and octal escape sequences (other than "\0" ) shall not be used

## Description

### Rule Definition

*Octal constants (other than zero) and octal escape sequences (other than "\0" ) shall not be used.*

### Rationale

Octal constants are denoted by a leading zero. A developer or code reviewer can mistake an octal constant as a decimal constant with a redundant leading zero.

Octal escape sequences beginning with \ can also cause confusion. Inadvertently introducing an 8 or 9 in the digit sequence after \ breaks the escape sequence and introduces a new digit. A developer or code reviewer can ignore this issue and continue to treat the escape sequence as one digit.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of Octal Constants and Octal Escape Sequences

```
void func(void) {
  int busData[6];

  busData[0] = 100;
  busData[1] = 108;
  busData[2] = 052;      //Noncompliant
  busData[3] = 071;      //Noncompliant
  busData[4] = '\109';   //Noncompliant
  busData[5] = '\100';   //Noncompliant

}
```

The checker flags all octal constants (other than zero) and all octal escape sequences (other than `\0`).

In this example:

- The octal escape sequence contains the digit 9, which is not an octal digit. This escape sequence has implementation-defined behavior.
- The octal escape sequence `\100` represents the number 64, but the rule checker forbids this use.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M2-13-3

A "U" suffix shall be applied to all octal or hexadecimal integer literals of unsigned type

## Description

### Rule Definition

*A "U" suffix shall be applied to all octal or hexadecimal integer literals of unsigned type.*

### Rationale

The signedness of a constant is determined from:

- Value of the constant.
- Base of the constant: octal, decimal or hexadecimal.
- Size of the various types.
- Any suffixes used.

Unless you use a suffix `u` or `U`, another developer looking at your code cannot determine easily whether a constant is signed or unsigned.

### Polyspace Implementation

Polyspace reports a violation of this rule if an unsigned octal or hexadecimal constant does not have the suffix `U`.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Check Information

**Group:** Lexical Conventions
**Category:** Required, Automated

# Version History

**Introduced in R2019a**

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M2-13-4

Literal suffixes shall be upper case

## Description

### Rule Definition

*Literal suffixes shall be upper case.*

### Rationale

Literal constants can end with the letter `l` (el). Enforcing literal suffixes to be upper case removes potential confusion between the letter `l` and the digit `1`.

For consistency, use upper case constants for other suffixes such as `U` (unsigned) and `F` (float).

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of Literal Constants with Lower Case Suffix

```
const int a = 0l; //Noncompliant
const int b = 0L; //Compliant
```

In this example, both `a` and `b` are assigned the same literal constant. However, from a quick glance, one can mistakenly assume that `a` is assigned the value `01` (octal one).

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M3-1-2

Functions shall not be declared at block scope

## Description

### Rule Definition

*Functions shall not be declared at block scope.*

### Rationale

It is a good practice to place all declarations at the namespace level.

Additionally, if you declare a function at block scope, it is often not clear if the statement is a function declaration or an object declaration with a call to the constructor.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Function Declarations at Block Scope

```
class A {
};

void b1() {
    void func(); //Noncompliant
    A a();   //Noncompliant
}
```

In this example, the declarations of `func` and `a` are in the block scope of `b1`.

The second function declaration can cause confusion because it is not clear if `a` is a function that returns an object of type `A` or `a` is itself an object of type `A`.

## Check Information

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M3-2-1

All declarations of an object or function shall have compatible types

## Description

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”*.

### Rule Definition

*All declarations of an object or function shall have compatible types.*

### Rationale

If the declarations of an object or function in two different translation units have incompatible types, the behavior is undefined.

### Polyspace Implementation

Polyspace considers two types to be compatible if they have the same size and signedness in the environment that you use. The checker is not raised on unused code such as

- Noninstantiated templates
- Uncalled `static` or `extern` functions
- Uncalled and undefined local functions
- Unused types and variables

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Compatible and Incompatible Definitions in Two Files

**file1.cpp**

```
typedef          char         char_t;
typedef signed   short        int16_t;
typedef signed   long         int64_t;

namespace bar {
    int64_t a;
    int16_t c;

};
```

**file2.cpp**

```
typedef          char         char_t;
typedef signed   int          int32_t;

namespace bar {
    extern char_t c;// Noncompliant
    extern int32_t a;
    void foo(void){
        ++a;
        ++c;
    }
};
```

In this example, the variable `bar::c` is defined as a `char` in `file2.cpp` and as a `signed short` in `file1.cpp`. In the target processor i386, the size of these types are not equal. Polyspace flags the definition of `bar::c`.

The variable `bar::a` is defined as a `long` in `file1.cpp` and as an `int` in `file2.cpp`. In the target processor i386, both `int` and `long` has a size of 32 bits. Because the definitions of `bar::a` is compatible in both files, Polyspace does not raise a flag.

## Check Information

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M3-2-2

The One Definition Rule shall not be violated

## Description

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”.*

### Rule Definition

*The One Definition Rule shall not be violated.*

### Rationale

Violations of the One Definition Rule leads to undefined behavior.

### Polyspace Implementation

The checker flags situations where the same function or object has multiple definitions and the definitions differ by some token. The checker is not raised on unused code such as

- Noninstantiated templates
- Uncalled `static` or `extern` functions
- Uncalled and undefined local functions
- Unused types and variables

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Different Tokens in Same Type Definition

This example uses two files:

- `file1.cpp`:

  ```
  typedef struct S //Noncompliant
  {
     int x;
     int y;
  }S;
  void foo(S& s){
  //...
  }
  ```
- `file2.cpp`:

  ```
  typedef struct S
  ```

```
{
   int y;
   int x;
}S ;
void bar(S& s){
//...
}
```

In this example, both `file1.cpp` and `file2.cpp` define the structure `S`. However, the definitions switch the order of the structure fields.

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M3-2-3

A type, object or function that is used in multiple translation units shall be declared in one and only one file

## Description

### Rule Definition

*A type, object or function that is used in multiple translation units shall be declared in one and only one file.*

### Rationale

If you declare an identifier in a header file, you can include the header file in any translation unit where the identifier is defined or used. In this way, you ensure consistency between:

- The declaration and the definition.
- The declarations in different translation units.

The rule enforces the practice of declaring external objects or functions in header files.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Check Information

**Group:** Basic Concepts
**Category:** Required, Automated

# Version History

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M3-2-4

An identifier with external linkage shall have exactly one definition

## Description

*This checker is deactivated in a default Polyspace* as You Code *analysis. See "Checkers Deactivated in Polyspace as You Code Analysis".*

### Rule Definition

*An identifier with external linkage shall have exactly one definition.*

### Rationale

If an identifier has multiple definitions or no definitions, it can lead to undefined behavior.

### Polyspace Implementation

The checker is not raised on unused code such as

- Noninstantiated templates
- Uncalled `static` functions or `extern` functions
- Uncalled and undefined local functions
- Unused types and variables

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Multiple Definitions of Identifier

This example uses two files:

- `file1.cpp`:

```
typedef signed   int          int32_t;

namespace NS {
    extern int32_t a;

    void foo(){
        a = 0;

    }
};
```
- `file2.cpp`:

```
typedef signed   int          int32_t;
typedef signed   long long         int64_t;

namespace NS {
    extern int64_t a; //Noncompliant
    void bar(){
        ++a;

    }
};
```

The same identifier `a` is defined in both files.

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M3-3-2

If a function has internal linkage then all re-declarations shall include the static storage class specifier

## Description

### Rule Definition

*If a function has internal linkage then all re-declarations shall include the static storage class specifier.*

### Rationale

If a function declaration has the `static` storage class specifier, it has internal linkage. Subsequent redeclarations of the function have internal linkage even without the `static` specifier.

However, if you do not specify the `static` keyword explicitly, it is not immediately clear from a declaration whether the function has internal linkage.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Missing `static` Specifier from Redeclaration

```
static void func1 ();
static void func2 ();

void func1() {}  //Noncompliant
static void func2() {}
```

In this example, the function `func1` is declared `static` but defined without the `static` specifier.

## Check Information

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M3-4-1

An identifier declared to be an object or type shall be defined in a block that minimizes its visibility

## Description

### Rule Definition

*An identifier declared to be an object or type shall be defined in a block that minimizes its visibility.*

### Rationale

Defining variables with the minimum possible block scope reduces the possibility that they might later be accessed unintentionally.

For instance, if an object is meant to be accessed in one function only, declare the object local to the function.

### Polyspace Implementation

The rule checker determines if an object is used in one block only. If the object is used in one block but defined outside the block, the checker raises a violation.

When you declare a variable outside a range-based `for` loop and use it only inside the loop block, Polyspace flags the variable. If you cannot declare the variable inside the loop block, justify this result using comments in your result or code. See “Address Results in Polyspace User Interface Through Bug Fixes or Justifications”.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of Global Variable in Single Function

```
static int countReset; //Noncompliant

volatile int check;

void increaseCount() {
    int count = countReset;
    while(check%2) {
     count++;
    }
}
```

In this example, the variable `countReset` is declared global used in one function only. A compliant solution declares the variable local to the function to reduce its visibility.

## Check Information

**Group:** Basic Concepts
**Category:** Required, Automated

# Version History

**Introduced in R2019a**

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M3-9-1

The types used for an object, a function return type, or a function parameter shall be token-for-token identical in all declarations and re-declarations

## Description

### Rule Definition

*The types used for an object, a function return type, or a function parameter shall be token-for-token identical in all declarations and re-declarations.*

### Rationale

If a redeclaration is not token-for-token identical to the previous declaration, it is not clear from visual inspection which object or function is being redeclared.

### Polyspace Implementation

The rule checker compares the current declaration with the last seen declaration.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Identical Declarations That Do Not Match Token for Token

```
typedef int* intptr;

int* map;
extern intptr map; //Noncompliant

intptr table;
extern intptr table; //Compliant
```

In this example, the variable `map` is declared twice. The second declaration uses a `typedef` which resolves to the type of the first declaration. Because of the `typedef`, the second declaration is not token-for-token identical to the first.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M3-9-3

The underlying bit representations of floating-point values shall not be used

## Description

### Rule Definition

*The underlying bit representations of floating-point values shall not be used.*

### Rationale

The underlying bit representations of floating point values vary across compilers. If you directly use the underlying representation of floating point values, your program is not portable across implementations.

### Polyspace Implementation

The rule checker flags conversions from pointers to floating point types into pointers to integer types, and vice versa.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Using Underlying Representation of Floating-Point Values

```
float fabs2(float f) {
    unsigned int* ptr = reinterpret_cast <unsigned int*> (&f); //Noncompliant
    *(ptr + 3) &= 0x7f;
    return f;
}
```

In this example, the `reinterpret_cast` attempts to cast a floating-point value to an integer and access the underlying bit representation of the floating point value.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M4-5-1

Expressions with type bool shall not be used as operands to built-in operators other than the assignment operator =, the logical operators &&, ||, !, the equality operators == and ! =, the unary & operator, and the conditional operator

## Description

### Rule Definition

*Expressions with type bool shall not be used as operands to built-in operators other than the assignment operator =, the logical operators &&, ||, !, the equality operators == and ! =, the unary & operator, and the conditional operator.*

### Rationale

Operators other than the ones mentioned in the rule do not produce meaningful results with `bool` operands. Use of `bool` operands with these operators can indicate programming errors. For instance, you intended to use the logical operator `||` but used the bitwise operator `|` instead.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Compliant and Noncompliant Uses of `bool` Operands

```
void boolOperations() {
    bool lhs = true;
    bool rhs = false;

    int res;

    if(lhs & rhs) {} //Noncompliant
    if(lhs < rhs) {} //Noncompliant
    if(~rhs) {}      //Noncompliant
    if(lhs ^ rhs) {} //Noncompliant
    if(lhs == rhs) {} //Compliant
    if(!rhs) {}       //Compliant
    res = lhs? -1:1;  //Compliant
}
```

In this example, `bool` operands do not violate the rule when used with the `==`, `!` and the `?` operators.

## Check Information

**Group:** Standard Conversions
**Category:** Required, Automated

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M4-5-3

Expressions with type (plain) char and wchar_t shall not be used as operands to built-in operators other than the assignment operator =, the equality operators == and ! =, and the unary & operator

## Description

### Rule Definition

*Expressions with type (plain) char and wchar_t shall not be used as operands to built-in operators other than the assignment operator =, the equality operators == and ! =, and the unary & operator.*

### Rationale

The C++03 Standard only requires that the characters `'0'` to `'9'` have consecutive values. Other characters do not have well-defined values. If you use these characters in operations other than the ones mentioned in the rule, you implicitly use their underlying values and might see unexpected results.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Compliant and Noncompliant Uses of Character Operands

```
void charManipulations (char ch) {

    char initChar = 'a'; //Compliant
    char finalChar = 'z'; //Compliant

    if(ch == initChar) {} //Compliant
    if( (ch >= initChar) && (ch <= finalChar)) {} //Noncompliant
    else if( (ch >= '0') && (ch <= '9') ) {} //Compliant by exception
}
```

In this example, character operands do not violate the rule when used with the = and == operators. Character operands can also be used with relational operators as long as the comparison is performed with the digits `'0'` to `'9'`.

# AUTOSAR C++14 Rule M4-10-1

NULL shall not be used as an integer value

## Description

### Rule Definition

*NULL shall not be used as an integer value.*

### Rationale

In C++, you can use the literals 0 and NULL as both an integer and a null pointer constant. However, use of 0 as a null pointer constant or NULL as an integer can cause developer confusion.

This rule restricts the use of NULL to null pointer constants. `AUTOSAR C++14 Rule M4-10-2` restricts the use of the literal 0 to integers.

### Polyspace Implementation

The checker flags assignment of NULL to an integer variable or binary operations involving NULL and an integer. Assignments can be direct or indirect such as passing NULL as integer argument to a function.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Compliant and Noncompliant Uses of `NULL`

```
#include <cstddef>

void checkInteger(int);
void checkPointer(int *);

void main() {
    checkInteger(NULL); //Noncompliant
    checkPointer(NULL); //Compliant
}
```

In this example, the use of `NULL` as argument to the `checkInteger` function is noncompliant because the function expects an `int` argument.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M4-10-2

Literal zero (0) shall not be used as the null-pointer-constant

## Description

### Rule Definition

*Literal zero (0) shall not be used as the null-pointer-constant.*

### Rationale

In C++, you can use the literals 0 and NULL as both an integer and a null pointer constant. However, use of 0 as a null pointer constant or NULL as an integer can cause developer confusion.

This rule restricts the use of the literal 0 to integers. `AUTOSAR C++14 Rule M4-10-1` restricts the use of NULL to null pointer constants.

### Polyspace Implementation

The checker flags assignment of 0 to a pointer variable or binary operations involving 0 and a pointer. Assignments can be direct or indirect such as passing 0 as pointer argument to a function.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Compliant and Noncompliant Uses of Literal 0

```
#include <cstddef>

void checkInteger(int);
void checkPointer(int *);

void main() {
    checkInteger(0); //Compliant
    checkPointer(0); //Noncompliant
}
```

In this example, the use of 0 as argument to the `checkPointer` function is noncompliant because the function expects an `int *` argument.

# AUTOSAR C++14 Rule M5-0-2

Limited dependence should be placed on C++ operator precedence rules in expressions

## Description

### Rule Definition

*Limited dependence should be placed on C++ operator precedence rules in expressions.*

### Rationale

Use parentheses to clearly indicate the order of evaluation.

Depending on operator precedence can cause the following issues:

- If you or another code reviewer reviews the code, the intended order of evaluation is not immediately clear.
- It is possible that the result of the evaluation does not meet your expectations. For instance:
  - In the operation `*p++`, it is possible that you expect the dereferenced value to be incremented. However, the pointer `p` is incremented before the dereference.
  - In the operation `(x == y | z)`, it is possible that you expect `x` to be compared with `y | z`. However, the `==` operation happens before the `|` operation.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Evaluation Order Dependent on Operator Precedence Rules

```
#include <cstdio>

void showbits(unsigned int x) {
    for(int i = (sizeof(int) * 8) - 1; i >= 0; i--) {
       (x & 1u << i) ? putchar('1') : putchar('0'); // Noncompliant
    }
    printf("\n");
}
```

In this example, the checker flags the operation `x & 1u << i` because the statement relies on operator precedence rules for the << operation to happen before the & operation. If this is the intended order, the operation can be rewritten as `x & (1u << i)`.

# AUTOSAR C++14 Rule M5-0-3

A cvalue expression shall not be implicitly converted to a different underlying type

## Description

### Rule Definition

*A cvalue expression shall not be implicitly converted to a different underlying type.*

### Rationale

This rule ensures that the result of the expression does not overflow when converted to a different type.

### Polyspace Implementation

Expressions flagged by this checker follow the detailed specifications for cvalue expressions from the MISRA C++ documentation.

The underlying data type of a cvalue expression is the widest of operand data types in the expression. For instance, if you add two variables, one of type `int8_t` (`typedef` for `char`) and another of type `int32_t` (`typedef` for `int`), the addition has underlying type `int32_t`. If you assign the sum to a variable of type `int8_t`, the rule is violated.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Implicit Conversion of Cvalue Expression

```
#include<cstdint>

void func ( )
  {
    int32_t s32;
    int8_t s8;
    s32 = s8 + s8; //Noncompliant
    s32 = s32 + s8; //Compliant
  }
```

In this example, the rule is violated when two variables of type `int8_t` are added and the result is assigned to a variable of type `int32_t`. The underlying type of the addition does not take into account the integer promotion involved and is simply the widest of operand data types, in this case, `int8_t`.

The rule is not violated if one of the operands has type `int32_t` and the result is assigned to a variable of type `int32_t`. In this case, the underlying data type of the addition is the same as the type of the variable to which the result is assigned.

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-0-4

An implicit integral conversion shall not change the signedness of the underlying type

## Description

### Rule Definition

*An implicit integral conversion shall not change the signedness of the underlying type.*

### Rationale

Some conversions from signed to unsigned data types can lead to implementation-defined behavior. You can see unexpected results from the conversion.

### Polyspace Implementation

The checker flags implicit conversions from a signed to an unsigned integer data type or vice versa.

The checker assumes that `ptrdiff_t` is a signed integer.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Implicit Conversions that Change Signedness

```
typedef char int8_t;
typedef unsigned char uint8_t;

void func()
  {
    int8_t s8;
    uint8_t u8;

    s8 = u8; //Noncompliant
    u8 = s8 + u8; //Noncompliant
    u8 = static_cast< uint8_t > ( s8 ) + u8; //Compliant
}
```

In this example, the rule is violated when a variable with a variable with signed data type is implicitly converted to a variable with unsigned data type or vice versa. If the conversion is explicit, as in the preceding example, the rule violation does not occur.

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M5-0-5

There shall be no implicit floating-integral conversions

## Description

### Rule Definition

*There shall be no implicit floating-integral conversions.*

### Rationale

If you convert from a floating point to an integer type, you lose information. Unless you explicitly cast from floating point to an integer type, it is not clear whether the loss of information is intended. Additionally, if the floating-point value cannot be represented in the integer type, the behavior is undefined.

Conversion from an integer to floating-point type can result in an inexact representation of the value. The error from conversion can accumulate over later operations and lead to unexpected results.

### Polyspace Implementation

The checker flags implicit conversions between floating-point types (`float` and `double`) and integer types (`short`, `int`, etc.).

This rule takes precedence over M5-0-4 and M5-0-6 if they apply at the same time.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Conversion Between Floating Point and Integer Types

```
typedef signed int int32_t;
typedef float float32_t;

void func ( )
  {
    float32_t f32;
    int32_t   s32;
    s32 = f32;   //Noncompliant
    f32 = s32;   //Noncompliant
    f32 = static_cast< float32_t > ( s32 ); //Compliant
  }
```

In this example, the rule is violated when a floating-point type is *implicitly* converted to an integer type. The violation does not occur if the conversion is explicit.

# AUTOSAR C++14 Rule M5-0-6

An implicit integral or floating-point conversion shall not reduce the size of the underlying type

## Description

### Rule Definition

*An implicit integral or floating-point conversion shall not reduce the size of the underlying type.*

### Rationale

A conversion that reduces the size of the underlying type can result in loss of information.

### Polyspace Implementation

If the conversion is to a narrower integer with a different sign, then rule M5-0-4 takes precedence over rule M5-0-6. Only rule M5-0-4 is shown.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M5-0-7

There shall be no explicit floating-integral conversions of a cvalue expression

## Description

### Rule Definition

*There shall be no explicit floating-integral conversions of a cvalue expression.*

### Rationale

If you evaluate an expression and later cast the result to a different type, the cast has no effect on the underlying type of the evaluation. For instance, in this example, the result of an integer division is then cast to a floating-point type.

```
short num;
short den;
float res;
res= static_cast<float> (num/den);
```

However, a developer or code reviewer can expect that the evaluation uses the data type to which the result is cast later. For instance, one can expect a floating-point division because of the later cast.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Conversion of Division Result from Integer to Floating Point

```
void func() {
     short num;
     short den;
     short res_short;
     float res_float;

     res_float = static_cast<float> (num/den); //Noncompliant

     res_short = num/den;
     res_float = static_cast<float> (res_short); //Compliant

}
```

In this example, the first cast on the division result violates the rule but the second cast does not.

- The first cast can lead to the incorrect expectation that the expression is evaluated with an underlying type `float`.
- The second cast makes it clear that the expression is evaluated with the underlying type `short`. The result is then cast to the type `float`.

## Check Information

# AUTOSAR C++14 Rule M5-0-8

An explicit integral or floating-point conversion shall not increase the size of the underlying type of a cvalue expression

## Description

### Rule Definition

*An explicit integral or floating-point conversion shall not increase the size of the underlying type of a cvalue expression.*

### Rationale

If you evaluate an expression and later cast the result to a different type, the cast has no effect on the underlying type of the evaluation. For instance, in this example, the sum of two `short` operands is cast to the wider type `int`.

```
short op1;
short op2;
int res;
res= static_cast<int> (op1 + op2);
```

However, a developer or code reviewer can expect that the evaluation uses the data type to which the result is cast later. For instance, one can expect a sum with the underlying type `int` because of the later cast.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Conversion of Sum to Wider Integer Type

```
void func() {
     short op1;
     short op2;
     int res;

     res = static_cast<int> (op1 + op2); //Noncompliant
     res = static_cast<int> (op1) + op2; //Compliant

}
```

In this example, the first cast on the sum violates the rule but the second cast does not.

- The first cast can lead to the incorrect expectation that the sum is evaluated with an underlying type `int`.
- The second cast first converts one of the operands to `int` so that the sum is actually evaluated with the underlying type `int`.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M5-0-9

An explicit integral conversion shall not change the signedness of the underlying type of a cvalue expression

## Description

### Rule Definition

*An explicit integral conversion shall not change the signedness of the underlying type of a cvalue expression.*

### Rationale

Expressions flagged by this checker follow the detailed specifications for cvalue expressions from the MISRA C++ documentation.

If you evaluate an expression and later cast the result to a different type, the cast has no effect on the underlying type of the evaluation (the widest of operand data types in the expression).. For instance, in this example, the sum of two `unsigned int` operands is cast to the type `int`.

```
unsigned int op1;
unsigned int op2;
int res;
res= static_cast<int> (op1 + op2);
```

However, a developer or code reviewer can expect that the evaluation uses the data type to which the result is cast later. For instance, one can expect a sum with the underlying type `int` because of the later cast.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Conversion of Sum to Wider Integer Type

```
typedef int int32_t;
typedef unsigned int uint32_t;

void func() {
     uint32_t op1;
     uint32_t op2;
     int32_t res;

     res = static_cast<int32_t> (op1 + op2); //Noncompliant
     res = static_cast<int32_t> (op1) +
           static_cast<int32_t> (op2); //Compliant

}
```

In this example, the first cast on the sum violates the rule but the second cast does not.

- The first cast can lead to the incorrect expectation that the sum is evaluated with an underlying type `int32_t`.
- The second cast first converts each of the operands to `int32_t` so that the sum is actually evaluated with the underlying type `int32_t`.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-0-10

If the bitwise operators ~and << are applied to an operand with an underlying type of unsigned char or unsigned short, the result shall be immediately cast to the underlying type of the operand

## Description

### Rule Definition

*If the bitwise operators ~and << are applied to an operand with an underlying type of unsigned char or unsigned short, the result shall be immediately cast to the underlying type of the operand.*

### Rationale

When the bitwise operators ~ and << are applied to small integer types, such as unsigned short and unsigned char, the operations are preceded by integral promotion. That is, the small integer types are first promoted to a larger integer type, and then the operation takes place. The result of these bitwise operation might contain unexpected higher order bits. For instance:

```
uint8_t var = 0x5aU;
uint8_t result = (~var)>>4;
```

The binary representation of `var` is `0101 1010` and that of `~var` is `1010 0101`. You might expect that `result` is `0000 1010`. Because `var` is promoted to a larger integer before `~var` is calculated, result becomes `1111 1010`. The higher order bits might be unexpected. The results of such operations might depend on the size of `int` in your implementation.

To avoid confusion and unexpected errors, cast the result of the bitwise ~ and >> operators back to the underlying type of the operands before using the results. For instance:

```
uint8_t var = 0x5aU;
uint8_t result = (static_cat<unit8_t>(~var))>>4;
```

The binary representation of `result` in this case is `0000 1010`, which is the expected value.

As an exception, casting is not required if you apply these bitwise operators on short integer types, and then immediately assign the result to an object of the same underlying type. For instance, the value of result in this case is `0000 1010` without requiring a cast.

```
uint8_t var = 0x5aU;
unit8_t result = ~var; // No higher order bits
                       // due to implicit conversion
uint8_t result = results>>4;
```

### Polyspace Implementation

Polyspace flags the use of the bitwise ~ and >> operators if all of these conditions are true:

- The operators are used on an `unsigned short` or `unsigned char` operand.
- The result of the operation is not immediately assigned to an object that has the same underlying type as the operand.
- The result is used without being cast to the underlying type of the operand.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Cast Results of ~ and << Operators to the Operand Type When the Operand Is Small Integer Type

```
#include<cstdint>
void foo(){
    uint8_t var = 0x5aU;
    uint8_t result;
    result = ( ~var ) >> 4; // Non-compliant
    result = static_cast<uint8_t>(( ~var )) >> 4; // Compliant
    uint8_t cbe = ~var;//Compliant by Exception
}
```

In this example, Polyspace flags the use of ~ on the small integer `var`. The ~ operator is flagged because:

- It operates on an unsigned short integer `var`.
- The result of the operator is used in an expression without casting ~`var` to `uint8_t`.

When the result of ~ operator is cast to `unit8_t`, the use is compliant with this rule. When the result of ~ is immediately assigned to a `unit8_t` variable, the use is compliant to this rule by exception.

The plain char type shall only be used for the storage and use of character values

## Description

### Rule Definition

*The plain char type shall only be used for the storage and use of character values.*

### Rationale

The signedness of plain `char` is implementation-defined. Because its sign is not well-defined, the plain `char` type is not suitable for use with numeric values. Use plain `char` for the storage and use of character values.

### Polyspace Implementation

The checker raises a violation when a value of signed or unsigned integer type is implicitly converted to the plain char type.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using Plain `char` For Numeric Data

```
#include<stdint.h>
typedef  char char_t;
void foo(){
char a = 'a'; // Compliant
char_t b = '\r'; // Compliant
char_t c = 10; // Noncompliant
char d = 'd'; // Compliant
}
```

In this example, Polyspace flags the use of plain `char` for numeric data.

## Check Information

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-0-12

Signed char and unsigned char type shall only be used for the storage and use of numeric values

## Description

### Rule Definition

*Signed char and unsigned char type shall only be used for the storage and use of numeric values.*

### Rationale

In C/C++, there are three types of `char`:

- Plain `char`
- `signed char`
- `unsigned char`

The signedness of plain `char` is implementation-defined. Plain `char` cannot be interchangeably used with the other types. For instance, you might assume `char` is unsigned and use `unsigned char` to store character. Your implementation might interpret characters as signed. In such a situation, your code might behave in unexpected manner, leading to bugs that are difficult to diagnose.

MISRA C++:2008 limits the use of these three types of `char` for different applications. The `signed` and `unsigned char` type is appropriate for numeric values and storage. The plain `char` is appropriate for character data. Avoid using `signed` or `unsigned char` when you intend to use the plain `char`.

This rule also applies to the different `typedef` of these `char` types, such as `uint8_t` and `int8_t`. See `MISRA C++:2008 Rule 3-9-2`.

### Polyspace Implementation

Polyspace raises a violation of this rule when a plain `char` is implicitly converted to either `signed char` or `unsigned char`.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use Plain char to Store Characters

```
typedef signed   char         int8_t;
typedef unsigned char         uint8_t;

namespace foo
{
    int8_t        ch_1   =   'a';     // Noncompliant
    uint8_t       ch_2  =   '\r';     // Noncompliant
    char          ch_3  =   'A';      // Compliant
    int8_t        num_1   =   10;     // Compliant
    uint8_t       num_2   =   12U;    // Compliant
    signed char   num_3   =   11;     // Compliant

};
```

In this example, Polyspace flags the use of `signed char` and `unsigned char` to store character data. The character literals are of plain `char` types, and Polyspace flags the implicit conversion of these plain `char` types to explicitly `signed` or `unsigned char` types.

# AUTOSAR C++14 Rule M5-0-15

Array indexing shall be the only form of pointer arithmetic

## Description

### Rule Definition

*Array indexing shall be the only form of pointer arithmetic.*

### Rationale

You can traverse an array in two ways:

- Increment or decrement an array index, and then use the array index to access an element.
- Increment or decrement a pointer to the array, and then dereference the pointer.

The first method is clearer and less error-prone. All other forms of explicit pointer arithmetic introduce the risk of accessing unintended memory locations.

As an exception, incrementing or decrementing pointer based iterators is compliant with this rule.

### Polyspace Implementation

The checker flags:

- Arithmetic operations on all pointers, for instance `p+I`, `I+p` and `p-I`, where `p` is a pointer and `I` an integer..
- Array indexing on nonarray pointers.

Polyspace does not flag incrementing or decrementing pointer based iterators, including these standard iterator types:

- `iterator`
- `cont_iterator`
- `reverse_iterator`
- `const_reverse_iterator`

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Explicitly Calculated Pointer Value When Indexing

```
#include<vector>
template < typename IterType >
int sumValues(IterType iter, IterType end)
{
    int result = 0;
    while (iter != end) {
        result += *iter;
        ++iter;  //Noncompliant
    }
    return result;
}
int sumVec(std::vector<int>& v)
{
    int res = 0;
    for (auto it = v.begin(); it != v.end(); ++it) //Compliant by exception
    res += *it;
    return res;
}
int sumVecModern(std::vector<int>& v)
{
    int res = 0;
    for(auto i:v){
        res+=i;
    }
    return res;
}
void foo(int* p_int, int arr_int[])
{
    p_int = p_int + 1; //Noncompliant
    arr_int[0] = arr_int[1];

    p_int[5] = 0; //Noncompliant
    *(p_int + 5) = 0; //Noncompliant
    arr_int[5] = 0.0;

    int a[100];
    std::vector<int> v(100);
    sumValues(&a[0],&a[99]);

}
```

In this example, indexing is done by using array indexing and by calculating the pointer values explicitly. In the function `foo()`:

- Polyspace flags the instances where a pointer value is explicitly calculated, such as `p_int+1` or `*(p_int+5)`.
- Polyspace flags the use of array indexing on the nonarray pointer `p_int`.

Polyspace does not flag uses of array indexing on an array that is compliant with this rule.

Incrementing and decrementing iterators to containers is compliant with this rule by exception. Because `sumVec()` increments an `iterator` object, Polyspace does not flag the increment operation. This exception does not apply to raw pointers. For instance, `sumValues` is instantiated in `foo()` with `int*`. Polyspace flags incrementing the raw pointer. In modern C++, the best practice is to use range-based for loops, as shown in the function `sumVecModern()`.

# AUTOSAR C++14 Rule M5-0-16

A pointer operand and any pointer resulting from pointer arithmetic using that operand shall both address elements of the same array

## Description

### Rule Definition

*A pointer operand and any pointer resulting from pointer arithmetic using that operand shall both address elements of the same array.*

### Rationale

It is undefined behavior when the result of a pointer arithmetic operation that uses a pointer to an array element does not point to either:

- An element of the array.
- One past the last element of the array. For instance:

  ```
  int arr[3];
  int* res;
  res = arr+3; // res points to one beyond arr
  ```

The rule applies to these operations. `ptr` is a pointer to an array element and `int_exp` is an integer expression.

- `ptr` + `int_exp`
- `int_exp` + `ptr`
- `ptr` - `int_exp`
- `ptr` + +
- ++`ptr`
- --`ptr`
- `ptr`--
- `ptr` [ `int_exp` ]

### Polyspace Implementation

- Single objects that are not part of an array are considered arrays of one element. For instance, in this code example, `arr_one` is equivalent to an array of one element. Polyspace does not flag the increment of pointer `ptr_to_one` because it points to one past the last element of `arr_one`.

  ```
  void f_incr(int* x){
      int* ptr_to_one = x;
      ++ptr_to_one;  // Compliant
  }

  void func(){
      int arr_one=1; // Equivalent to array of one element
      f_incr(&arr_one);
  }
  ```

- Polyspace does not flag the use of pointer parameters in pointer arithmetic operations when those pointers point to arrays. For instance, in this code snippet, the use of `&a1[2]` in `f1` is compliant when you pass an array to `f1`.

  ```
  void f1( int* const a1){
         int* b= &a1[2]; // Compliant
  }
  void f2(){
      int arr[3] {};
      f1(arr);
  }
  ```
- In structures with multiple elements, Polyspace does not flag the result of a pointer arithmetic operation on an element that results in a pointer that points to a different element if the pointer points within the allocated memory of the structure or to one past the last element of the structure.

  For instance, in this code snippet, the assignment to `ptr_to_struct` is compliant because it remains inside `myStruct`, even if it points outside `myStruct.elem1`. Using an index larger than the element dimension to access the content of that element is not compliant, even if the resulting address is within the allocated memory of the structure.

  ```
  void func(){
      struct {
          char elem1[10];
          char elem2[10];
      } myStruct;

      char* ptr_to_struct = &myStruct.elem1[11]; //Compliant
        // Address of myStruct.elem1[11] is inside myStruct
        char val_to_struct = myStruct.elem1[11]; // Non-compliant
  }
  ```
- In multidimensional arrays, Polyspace flags any use of indices that are larger than a subarray dimension to access an element of that subarray. Polyspace does not flag the assignment of the address of that same subarray element if the address is inside the allocated memory of the top-level array.

  For example, in this code snippet, the assignment to pointer `ptr_to_arr` is compliant because the pointer points to an address that is within the allocated memory of `multi_arr`. The assignment to variable `arr_val` is not compliant because the index used to access the subarray element (3) is larger than the dimension of the subarray (2).

  ```
  void func(){
      int multi_arr[5][2];

        // Assigned memory is inside top level array
      int* ptr_to_arr = &multi_arr[2][3]; //Compliant

      // Use of index 3 with subarray of size 2
      int arr_val = multi_arr[2][3]; // Non-compliant
  }
  ```
- Polyspace flags the dereference of a pointer when that pointer points to one past the last element of an array. For instance, in this code snippet, the assignment of `ptr` is compliant, but the dereference of `ptr` is not. `tab+3` is one past the last element of tab.

  ```
  void derefPtr(){
      int tab[3] {};
  ```

```
        int* ptr = tab+3; //Compliant
        int res = *(tab+3); // Non-compliant
    }
```

- Polyspace does not raise this checker when the result of a pointer arithmetic operation results in `nullptr`. For instance, consider this code:

  ```
  void g(int *p);

  void add(int* p, int n) {
      g(p + n); //Compliant
  }

  void foo() {
      add(nullptr, 0);

  }
  ```

  The pointer arithmetic in `add()` results in a `nullptr`. Polyspace does not flag this operation.

### Extend Checker

A default Bug Finder analysis might not raise a violation of this rule when the input values are unknown and only a subset of inputs can cause an issue. To check for violations caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Pointer Arithmetic by Using Pointers to Array Elements

```
void f_incr(int* x)
{
    int* ptr_to_one = x;
    ++ptr_to_one;  // Compliant
}

void f1(int* const a1)
{
    int* b = &a1[2]; // Compliant
}

int main()
{

    int arr_one = 1; // Equivalent to array of one element
    f_incr(&arr_one);

    int arr[3] {};
    f1(arr);

    struct {
```

```
        char elem1[10];
        char elem2[10];
    } myStruct;

    char* ptr_to_struct = &myStruct.elem1[11]; // Compliant
    ptr_to_struct = &myStruct.elem2[11]; //Non-compliant

    int tab[3] {1, 2, 3};
    int* ptr =  &tab[2];
    int res = tab[2];
    ++ptr; // Compliant
    res = *ptr; //Non-compliant

    return 0;
}
```

In this example:

- The increment of `ptr_to_one` inside `f_incr()` is compliant because the operation results in a pointer that points to one past the last element of array `x`. The integer that is passed to `f_incr()` is equivalent to an array of one element.
- The operation on pointer parameter `a1` inside `f1()` is compliant because the pointer points to array `arr`.
- The first assignment of `ptr_to_struct` is compliant because `elem1[11]` is still inside `myStruct`. The second assignment of `ptr_to_struct` is not compliant because the result of the operation does not point to either inside `myStruct` or to one past the last element of `myStruct`.
- The increment of `ptr` is compliant because the result of the operation points to one past the last element of `tab`. The dereference of `ptr` on the next line is not compliant.

# AUTOSAR C++14 Rule M5-0-17

Subtraction between pointers shall only be applied to pointers that address elements of the same array

## Description

### Rule Definition

*Subtraction between pointers shall only be applied to pointers that address elements of the same array.*

### Rationale

When you subtract between two pointers to elements in the same array, the result is the distance between the two array elements. If the pointers are null or point to different arrays, a subtraction operation is undefined. If you use the subtraction result as a buffer index, it can cause a buffer overflow.

Before you subtract between pointers to array elements, check that they are non-null and that they point to the same array.

### Polyspace Implementation

Polyspace flags subtraction between pointers to elements of different arrays.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Subtracting Pointers to Elements of Different Arrays

```
void foo(){
    int a[10];
    int b[10];
    int distance = a-b;//Noncompliant

}
```

In this example, Polyspace flags the subtraction between `a` and `b`, which are elements of different arrays.

# AUTOSAR C++14 Rule M5-0-18

>, >=, <, <= shall not be applied to objects of pointer type, except where they point to the same array

## Description

### Rule Definition

*>, >=, <, <= shall not be applied to objects of pointer type, except where they point to the same array.*

### Rationale

When you compare two pointers to array elements, the result is the positions of the pointers relative to each other. If the pointers are null or point to different arrays, a comparison operation is undefined.

Before you use >, >=, <, or <= between pointers to array elements, check that they are non-null and that they point to the same array.

### Polyspace Implementation

Polyspace flags the use of >, >=, <, or <= operators between pointers to elements of different arrays.

The checker ignores casts when showing the violation on relational operator use with pointers types.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

### Avoid Comparing Pointers to Elements of Different Arrays

```
bool foo(){
    int a[10];
    int b[10];
    return (a<b);

}
```

In this example, Polyspace flags the comparison between a and b, which are elements of different arrays.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M5-2-2

A pointer to a virtual base class shall only be cast to a pointer to a derived class by means of `dynamic_cast`

## Description

### Rule Definition

*A pointer to a virtual base class shall only be cast to a pointer to a derived class by means of `dynamic_cast`.*

### Rationale

A `virtual` base implies that multiple classes might be derived from it.

```
class Base{};
class childA: virtual public Base{};
class childB: virtual public Base{};
class childFinal: public childA, public childB{};;
```

In the preceding code, the derived classes `childA` and `childB` share the same instance of the class `Base`. The necessary pointer arithmetic is unknown at compile time when you cast from `Base*` to `childA*` or `childB*`. The offset of the child classes compared to `Base` is known only at run time.

Use `dynamic_cast` when downcasting a pointer to a virtual base class into a pointer to a child class. Using any other casting operation for this purpose results in an undefined behavior.

### Polyspace Implementation

Polyspace raises a violation if these conditions are met:

- A virtual base class is downcast.
- The casting operation is not done by using `dynamic_cast`

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use `dynamic_cast` to Downcast Pointers to `virtual` Base

```
class Base{};
class childA: virtual public Base{};
class childB: virtual public Base{};
class childFinal: public childA, public childB{};

void bar(){
    Base* pB;
    //...
    static_cast<childA*>(pB);//Noncompliant
}
```

In this example, the pointer to a `virtual` base `pB` is downcast to a pointer to a derived class. The information needed to cast `pB` to a `childA*` type is known at run time only. Using `static_cast` to perform these casts results in an undefined behavior. Polyspace raises a violation. This issue might also be reported as a compilation error.

## Check Information

**Group:** Expressions
**Category:** Required, Automated

# Version History

**Introduced in R2019a**

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-2-3

Casts from a base class to a derived class should not be performed on polymorphic types

## Description

### Rule Definition

*Casts from a base class to a derived class should not be performed on polymorphic types.*

### Rationale

Explicitly casting a polymorphic base class into a derived class bypasses the layers of abstraction in the implementation hierarchy, resulting in increased coupling and dependency between the classes.

When using a polymorphic class, avoid performing explicit downcasts. A pointer to the polymorphic base class does not require explicit casting into a pointer to a derived class.

### Polyspace Implementation

Polyspace raises a violation if a base class is cast to a derived class.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Downcasting In a Polymorphic Class Hierarchy

```
class Base{ //Abstract base class
    //...
public:
    virtual bool getStatus() const = 0;
};
class Derived: public Base{
    //...
public:
    virtual bool getStatus() const{ //Implementation of getStatus()
        //...
    }
};
void printStatus(const Base& B){
    const Derived* D = dynamic_cast<const Derived*>(&B);//Noncompliant
    D->getStatus();
}
void printStatus_compliant(const Base& B){
    B.getStatus();//Compliant
}
```

In this example, the `Base` class pointer `B` is cast to a `Derived` class pointer in `printStatus`. This cast is noncompliant and Polyspace raises a violation. The function `getStatus_compliant()` shows a compliant implementation of this functionality, where `virtual` functions invoke the `Derived` class member function through a pointer to the `Base` class.

## Check Information

**Group:** Expressions
**Category:** Advisory, Automated

# Version History

**Introduced in R2019a**

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-2-6

A cast shall not convert a pointer to a function to any other pointer type, including a pointer to function type

## Description

### Rule Definition

*A cast shall not convert a pointer to a function to any other pointer type, including a pointer to function type.*

### Rationale

Because calling a function through a pointer with incompatible type results in undefined behavior, the rule forbids these cast operations:

- Casting from a function pointer to any other type.
- Casting from a function pointer to another function pointer, if the function pointers have different arguments and return types.

### Polyspace Implementation

Polyspace raises a violation of this rule if the source type of a cast operation is a pointer to a function.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Casting Function Pointers

```
void* (*func1) (int);
void* (*func2)(float);
void bar(void* (*)(int));
void foo(){

    bar(reinterpret_cast<void* (*) (int)> (func2)); //Noncompliant
    bar(func1);
}
```

In this example, the function `bar` accepts a pointer to a function that takes an `int` as an input and returns a `void*` pointer. In `foo()`, the function pointer `func2` is converted so that it can be passed to `bar`. Polyspace flags the noncompliant conversion of function pointers.

## Check Information

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-2-8

An object with integer type or pointer to void type shall not be converted to an object with pointer type

## Description

### Rule Definition

*An object with integer type or pointer to void type shall not be converted to an object with pointer type.*

### Rationale

Converting between integral types or a `(void)*` type to other pointer types can result in unspecified behavior.

### Polyspace Implementation

The checker allows an exception on zero constants, such as `0x0`, `0`, or `0U`.

Objects with pointer type include objects with pointer-to-function type.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Converting to Pointers

In this example, Polyspace flags the conversion of integers to pointers. Polyspace does not flag converting zero constants such as `0`, `0x0`, or `0U` to pointers. Such conversions are equivalent to zero initialization of a pointer, which has a specified behavior.

```
void foo ()
{
  void *p1;
  void *p2;
  void *p3;

  p1 = static_cast < void *>(0x0);    //Compliant
  p2 = static_cast < void *>(0U);    //Compliant
  p3 = static_cast < void *>(0);    //Compliant

  p1 = (void *) 0xDEADBEEF;    //Noncompliant
  p2 = (void *) 03;       //Noncompliant
  p3 = (void *) 12345678U;    //Noncompliant
}
```

# AUTOSAR C++14 Rule M5-2-9

A cast shall not convert a pointer type to an integral type

## Description

### Rule Definition

*A cast shall not convert a pointer type to an integral type.*

### Rationale

The C++ standard specifies only the minimum size required for integral types. The implemented size of integral types and pointers depends on your hardware and development environment. In an environment where pointers have a larger size than integral types, casting a pointer type to an integral type results in an overflow. Avoid casting pointers to integral types.

### Polyspace Implementation

Polyspace flags a casting operation if it converts a pointer type variable to an integral type variable.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Avoid Casting Pointers to Integers

```
void foo(){
    int* pInt;
    //...
    int address = reinterpret_cast<int>(pInt);//Noncompliant
}
```

In this example, the pointer `pInt` is cast to an int. Depending on your environment, this operation might result in an overflow. For instance, in a 64-bit system, the size of `pInt` might be 64-bit and the size of `address` might be 32-bit. Polyspace flags this casting operation.

The increment (++) and decrement (--) operators shall not be mixed with other operators in an expression

## Description

### Rule Definition

*The increment (++) and decrement (--) operators shall not be mixed with other operators in an expression.*

### Rationale

Using the increment and decrement operators with other operators in an expressions results in code that is difficult to read. Such code might lead to undefined behavior.

### Polyspace Implementation

Polyspace flags an expression if it contains the increment or decrement operators mixed with other operators. If an expression contains multiple increment or decrement operators mixed with other operators, Polyspace flags the first increment or decrement operator.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Mixing Increment or Decrement Operators with Other Operators

```
void foo(int a, int b){
    int c = ++a + b--; //Noncompliant
    if(--c + --a - ++b){ //Noncompliant
        //...
    }
}
```

Polyspace flags the mixing of the ++ and `--` operators with other mathematical operators in an expression.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-2-11

The comma operator, && operator and the || operator shall not be overloaded

## Description

### Rule Definition

*The comma operator, && operator and the || operator shall not be overloaded.*

### Rationale

When you overload an operator, the overloaded operator behaves as a function call. The comma operator, the && operator, and the `||` operator have certain behaviors that cannot be replicated by their overloaded counterpart. For instance, a compiler might short circuit the built-in && or `||` operators. But such short circuiting is not possible when you use an overloaded version of these operators.

Overloading these operators creates confusion about how these operators behave. Avoid overloading the comma operator, the && operator, and the `||` operator.

### Polyspace Implementation

Polyspace flags the overloading of these operators:

- Comma operator
- && operator
- `||` operator

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Do Not Overload the && Operator

```
class flag{/**/};
class Util
{
public:
flag getValue ( );
flag setValue ( int const & );
};

bool operator && ( flag const &, flag const & ); // Noncompliant
void f2 ( Util & in3, Util & in4 )
{
in3.getValue ( ) && in4.setValue ( 0 ); // Both operands evaluated
}
```

In this example, the && operator is overloaded for the class `flag`. In `f2()`, the overloaded operator is used. The overloading prevent the short circuiting. The behavior of the overloaded operator might be unexpected. Polyspace flags the overloading of the && operator.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M5-2-12

An identifier with array type passed as a function argument shall not decay to a pointer

## Description

### Rule Definition

*An identifier with array type passed as a function argument shall not decay to a pointer.*

### Rationale

When you pass an array to a function as a pointer, the size information of the array becomes lost. Losing information about the array size might lead to confusion and unexpected behavior.

Avoid passing arrays as pointers to function. To pass arrays into a function, encapsulate the array into a class object and pass the object to functions. Starting in C++11, the standard template library implements several container classes that can be used to pass an array to a function. C++20 has the class `std::span`, which preserves the size information.

### Polyspace Implementation

Polyspace raises a violation when you use an array in a function interface.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using Arrays in Function Interfaces

```
void f1( int p[ 10 ] ); // Noncompliant

void f2( int ( &p )[ 10 ] );// Compliant
void foo ()
{
int a[ 10 ];
f1( a );

f2( a );
}
```

In this example,the interface of `f1()` uses an array. When you pass the array `a[10]` to `f1()` as a pointer, the size of the array `a` is lost. Polyspace flags the declaration of `f1()`. If you pass arrays to function while preserving the dimensionality information, as shown by `f2()`, Polyspace does not raise a violation.

# AUTOSAR C++14 Rule M5-3-1

Each operand of the ! operator, the logical && or the logical || operators shall have type bool

## Description

### Rule Definition

*Each operand of the ! operator, the logical && or the logical || operators shall have type bool.*

### Rationale

Use of non-`bool` operands with the logical operators `!`, && or `||`, is likely to indicate a programming error.

### Polyspace Implementation

The checker reports a violation if the operands of the logical operators `!`, && or `||`, are not effectively boolean. Allowed operands are:

- Variables of type `bool` or specified as effectively boolean using the option `Effective boolean types (-boolean-types)`.
- Expressions that compare two variables using operators such as == or < and return a boolean.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Logical && With Boolean and Non-Boolean Operands

In this example, both operands of the logical && in the `if` condition are effectively boolean and comply with the rule. The right operand of the logical && in the `else if` condition has a non-boolean type (`int32_t`) and violates the rule.

```
#include <cstdint>

class Pair
{
    int32_t leftVal;
    int32_t rightVal;
public:
    bool operator==(const Pair& anotherPair) {
        return(((*this).leftVal == anotherPair.leftVal)
             &&((*this).rightVal == anotherPair.rightVal));
    }
};

Pair getAPair();
int32_t checkPair(const Pair*);
```

```
void main() {
    Pair aPair = getAPair();
    Pair anotherPair = getAPair();
    Pair athirdPair = getAPair();

    if((aPair == anotherPair) &&
       (aPair == athirdPair)) //Compliant
       {}
    else if((aPair == anotherPair) && //Noncompliant
            (checkPair(&athirdPair)))
       {}
}
```

The right hand operand of a logical &&, || operators shall not contain side effects

## Description

### Rule Definition

*The right hand operand of a logical &&, || operators shall not contain side effects.*

### Rationale

When evaluated, an expression that has side effects modifies at least one of the variables in the expression. For instance, `n++` is an expression with side effect.

The right operand of a:

- Logical && operator is evaluated only if the left-hand operand evaluates to true.
- Logical `||` operator is evaluated only if the left-hand operand evaluates to false.

In other cases, the right operands are not evaluated. Side effects of the expression do not take place. If your program relies on such side effects, you might see unexpected results.

### Polyspace Implementation

The checker flags logical && or `||` operators whose right operands are expressions that have side effects. Polyspace assumes:

- Expressions that modifies at least one of its variables have side effects.
- Explicit constructors or conversion functions that are declared but not defined have no side effects. Defined conversion functions have side effects.
- Volatile accesses and function calls have no side effects.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Side Effects in Right Operand of Logical Operation

```
class real32_T {
public:
    real32_T() = default;

    /* Casting operations */
    explicit real32_T(float a) {
        // ...
    }
    /* Relational operators */
    bool operator==(real32_T a) const;
    bool operator>(real32_T a) const;
};

void bar() {
    real32_T d;

    if ((d == static_cast<real32_T>(0.0F))
    || (static_cast<real32_T>(0.0F) > d)) {//Noncompliant
        /**/
    }
}

void foo(int i, int j){
    if(i==0 && ++j==i){ //Noncompliant
        --i;
    }
}
```

In the function `foo`, the right operand of the && operator contains an increment operation, which has a side effect. Polyspace flags the operator. In the function `bar`, the right operand of the `||` operator contains a conversion function that is implemented in the class. Polyspace considers such constructor to have side effects. Because the right operator has side effects, the operator is flagged.

# AUTOSAR C++14 Rule M5-18-1

The comma operator shall not be used

## Description

### Rule Definition

*The comma operator shall not be used.*

### Rationale

The comma operator takes two operands. It evaluates the operators from left to right, discards the value of the left operand, and returns the value of the right operand. This operator has the lowest operator precedence. These properties can make the use of the comma operator nonintuitive. For instance, consider this code:

```
array[i++,j] = 1
```

At a glance, it might appear that the preceding code accesses a multidimensional array. In fact, this code is equivalent to:

```
i++;
array[j] = 1;
```

The use of the comma operator makes the code difficult to read and maintain. To avoid confusion, do not use the comma operator. Refactor the expression into multiple statements instead.

### Polyspace Implementation

Polyspace flags the use of comma operator. Violations are not raised when you use comma operator for function calls and initializations.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Comma Usage in C++ Code

```
typedef signed int abc, xyz, jkl;
static void func1 ( abc, xyz, jkl );       /* Compliant - case 1 */
int foo(void)
{
    volatile int rd = 1;                   /* Compliant - case 2*/
    int var=0, foo=0, k=0, n=2, p, t[10];  /* Compliant - case 3*/
    int abc = 0, xyz = abc + 1;            /* Compliant - case 4*/
    int jkl = ( abc + xyz, abc + xyz );    /* Noncompliant - case 1*/
    var = 1, foo += var, n = 3;          /* Noncompliant - case 2*/
    var = (n = 1, foo = 2);              /* Noncompliant - case 3*/
    for ( int *ptr = &t[ 0 ],var = 0 ;
          var < n; ++var, ++ptr){}    /* Noncompliant - case 4*/
    if ((abc,xyz)<0) { return 1; }        /* Noncompliant - case 5*/
}
```

In this example, the code shows various uses of commas in C code.

**Noncompliant Cases**

| Case | Reason for noncompliance |
|---|---|
| 1 | When reading the code, it is not immediately obvious what `jkl` is initialized to. |
| 2 | When reading the code, it is not immediately obvious whether `foo` has a value 0 or 1 after the statement. |
| 3 | When reading the code, it is not immediately obvious what value is assigned to `var`. |
| 4 | When reading the code, it is not immediately obvious which values control the `for` loop. |
| 5 | When reading the code, it is not immediately obvious whether the `if` statement depends on `abc`, `xyz`, or both. |

**Compliant Cases**

| Case | Reason for compliance |
|---|---|
| 1 | Using commas to call functions with variables is allowed. |
| 2 | Comma operator is not used. |
| 3 & 4 | When using the comma for initialization, the variables and their values are immediately obvious. |

# AUTOSAR C++14 Rule M6-2-1

Assignment operators shall not be used in sub-expressions

## Description

### Rule Definition

*Assignment operators shall not be used in sub-expressions.*

### Rationale

When used in a subexpression, assignment operators have side effects that are difficult to predict. These side effects might produce results contrary to developer expectations. This rule helps in avoiding confusion between the assignment operator (=) and the equal to operator (==). Do not use assignment operators in subexpressions.

### Polyspace Implementation

Polyspace raises this defect whenever a subexpression contains an assignment operator.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Assignment Operators in Sub-Expressions Are Noncompliant

```
#include <cstdint>

bool example(int x, int y)
{
    if (x == 10)         //Compliant
    {
        return true;
    }

       if ((x = y) == 0)            //Noncompliant
    {
        return false;
    }

    return false;
}
```

Because the assignment operator = is used in the subexpression `(x = y)`, Polyspace flags it as noncompliant.

# AUTOSAR C++14 Rule M6-2-2

Floating-point expressions shall not be directly or indirectly tested for equality or inequality

## Description

### Rule Definition

*Floating-point expressions shall not be directly or indirectly tested for equality or inequality.*

### Rationale

Due to the inherent rounding errors of floating-point numbers, there is no way to reliably compare floating-point numbers for equality. This includes both direct and indirect tests of equivalency. Comparisons of floating-point numbers can result in a false outcome when you expect equivalence. This behavior is unpredictable and can vary between implementations.

Avoid using floating-point numbers for equivalence comparisons. Alternatively, write a library that implements your comparison operations. Take into account the magnitude of numbers to compare as well as floating-point granularity during creation of this library.

### Polyspace Implementation

The rule checker detects the use of == or != with floating-point variables or expressions. Additionally, the rule checker detects indirect tests of equality or inequality of floating-point variables. For example:

```
float x, y = 0.0;
if ((x < y) || (x > y))           //Noncompliant
{
    //...
}
```

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Floating-Point Number Comparisons of Equivalence

This code contains different examples of floating-point number comparisons. Polyspace reports a violation for each of these floating-point tests of equality or inequality.

- `x == y`, due to the use of ==
- `x == 0.0f`, due to the use of `!=`
- `((x <= y) && (x >= y))`, due to an indirect comparison of equality
- `((x < y) || (x > y))`, due to an indirect comparison of inequality

```
#include <cmath>
#include <limits>
```

```
void main()
{
    float x, y = 0.0;
    if (x == y)          //Noncompliant
    {
        //...
    }
    if (x != 0.0f)       //Noncompliant
    {
        //...
    }
    if ((x <= y) && (x >= y))         //Noncompliant
    {
        //...
    }
    if ((x < y) || (x > y))           //Noncompliant
    {
        //...
    }
}
```

# AUTOSAR C++14 Rule M6-2-3

Before preprocessing, a null statement shall only occur on a line by itself; it may be followed by a comment, provided that the first character following the null statement is a white-space character

## Description

### Rule Definition

*Before preprocessing, a null statement shall only occur on a line by itself; it may be followed by a comment, provided that the first character following the null statement is a white-space character.*

### Rationale

A null statement:

```
;
```

used on a line with other code can indicate a programming error. If you want to enter a null statement, place the statement on a line by itself.

A comment can follow a null statement, but use a white space character between the null statement and the comment to provide a visual cue for reviewers.

### Polyspace Implementation

The rule checker considers a null statement as a line where the first character excluding comments is a semicolon. The rule checker reports violations for situations where:

- Comments appear before the null statement.

  For instance:

  ```
  /* wait for pin */ ;
  ```
- Comments appear immediately after the semicolon without a white space in between.

  For instance:

  ```
  ;// wait for pin
  ```

The rule checker also reports a violation when a second statement appears on the same line following the null statement.

For instance:

```
; count++;
```

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Proper Formatting for Null Statement

In this example, there are three different versions of comments after a null statement.

- The first option is compliant. The comment comes after the null statement, the null statement is the only statement on the line, and there is a white space separating the semicolon and the comment.
- The second option is noncompliant. The comment comes before the null statement.
- The third option is noncompliant. A white space does not separate the semicolon and comment.

```
#include <iostream>

void main()
{
    std::cout << "Hello World" << std::endl;
     ; // comment here - Compliant
     /* comment here */ ; // Noncompliant
     ;//comment here - Noncompliant

}
```

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-3-1

The statement forming the body of a switch, while, do ... while or for statement shall be a compound statement

## Description

### Rule Definition

*The statement forming the body of a switch, while, do ... while or for statement shall be a compound statement.*

### Rationale

A compound statement is included in braces.

If a block of code associated with an iteration or selection statement is not contained in braces, you can make mistakes about the association. For example:

- You can wrongly associate a line of code with an iteration or selection statement because of its indentation.
- You can accidentally place a semicolon following the iteration or selection statement. Because of the semicolon, the line following the statement is no longer associated with the statement even though you intended otherwise.

This checker enforces the practice of adding braces following a selection or iteration statement even for a single line in the body. Later, when more lines are added, the developer adding them does not need to note the absence of braces and include them.

### Polyspace Implementation

The checker flags `for` loops where the first token following a `for` statement is not a left brace, for instance:

```
for (i=init_val; i > 0; i--)
   if (arr[i] < 0)
      arr[i] = 0;
```

Similar checks are performed for `switch`, `for` and `do..while` statements.

The second line of the message on the **Result Details** pane indicates which statement is violating the rule. For instance, in the preceding example, the second line of the message states that the `for` loop is violating the rule.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M6-4-1

An if ( condition ) construct shall be followed by a compound statement. The else keyword shall be followed by either a compound statement, or another if statement

## Description

### Rule Definition

*An if ( condition ) construct shall be followed by a compound statement. The else keyword shall be followed by either a compound statement, or another if statement.*

### Rationale

If you use single statements as bodies of if or if...else constructs, then attempting to change the body into a compound statement might result in logic errors and unexpected results. This rule ensures that braces are not missed or forgotten when attempting to turn a single statement body into a compound statement body. Failure to use compound statements might provide unexpected results and cause developer confusion. Use `{ }` braces to create compound statements. Use braces even when the if statement is simple and contains only a single statement.

### Polyspace Implementation

Polyspace raises this defect whenever a compound statement does not immediately follow an if statement, else-if statement, or else statement.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Using Compound Statements in If...Else Conditionals

```
#include <cstdint>

int example(int test, int result)
{
    if (test > 5)
    {
        test--;
        result = test + result;   //Compliant
    }
    else if (test <= 5)
    {
        result = test - result;   //Compliant
    }
    else                          //Noncompliant
        result = test;

    return result;
}
```

Because the else statement does not use `{ }` braces to form a compound statement, Polyspace flags it as noncompliant.

## Check Information

**Group:** Statements
**Category:** Required, Automated

`Check AUTOSAR C++ 14 (-autosar-cpp14)`

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-4-2

All if ... else if constructs shall be terminated with an else clause

## Description

### Rule Definition

*All if ... else if constructs shall be terminated with an else clause.*

### Rationale

Ending an if... else if construct with an `else` statement is defensive programming. This final `else` statement acts as a fail-safe in case a unique situation occurs where the code progresses past the `if` and `else if` statements.

When an `if` statement is followed by one or more `else if` statements, follow the final `else if` statement with an `else` statement. Within the `else` statement provide an action. If no action is needed, provide a comment as to why no action is taken.

### Polyspace Implementation

Polyspace raises this defect whenever an `if … else if` construct does not end with an `else` statement.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### If Construct With No Else If Statements

```
#include <cstdint>

int example(int test, int result)
{
    if (test > 5)
    {
        test--;
        result = test + result;
    }

    return result;
}
```

Because no `else if` statement exists in this `if` construct, no final `else` statement is required within the construct.

### If Construct Containing Else-If Statements

```
#include <cstdint>
```

```
int example(int test, int result)
{
    if (test > 5)
    {
        test--;
        result = test + result;
    }
    else if (test <= 5)             //Noncompliant
    {
        result = test - result;
    }

    return result;
}
```

Because the final `else if` statement is not followed by a closing else statement, Polyspace marks it as noncompliant. Even though there should be no situation where a value of test progresses past both the `if` and `else if` statements, the additional else statement is required.

# AUTOSAR C++14 Rule M6-4-3

A switch statement shall be a well-formed switch statement

## Description

### Rule Definition

*A switch statement shall be a well-formed switch statement.*

### Rationale

In addition to the C++ standard syntax rules, MISRA defines their own syntax rules for creating well-formed switch statements. These additional syntax rules create a consistent structure for switch statements.

The additional MISRA syntax rules include:

| Rule | Syntax |
|---|---|
| switch-statement | `switch` (condition) {case-label-clause-list default-label-clause$_{opt}$} |
| case-label-clause-list | case-label case-clause$_{opt}$<br>case-label-clause-list case-label case-clause$_{opt}$ |
| case-label | `case` const-expression |
| case-clause | case-block-seq$_{opt}$ `break` ;<br>case-block-seq$_{opt}$ `throw` assignment-expression$_{opt}$ ;<br>{ statement-seq$_{opt}$ `break` ; }<br>{ statement-seq$_{opt}$ `throw` assignment-expression$_{opt}$ ; } |
| default-label-clause | default-label default-clause |
| default-label default-clause | `default` : case-clause |
| case-block | expression_statement<br>compound_statement<br>selection_statement<br>iteration_statement<br>try_block |
| case-block-seq | case-block<br>case-block-seq case-block |

These terms from the table are defined as such:

- `switch-label` — Either a `case-label` or `default-label`.
- `case-clause` — The code between any two `switch-labels`.
- `default-clause` — The code between the `default-label` and the end of the `switch` statement.
- `switch-clause` — Either a `case-clause` or a `default-clause`.

The MISRA C++ `switch` syntax rules do not include the following statements, but do permit them within the compound statements that form the body of a `switch-clause` statement.

- `labelled_statement`
- `jump_statement`
- `declaration_statement`

### Polyspace Implementation

The rule checker reports a violation in these situations:

- A statement occurs between the `switch` statement and the first `case` statement.

  For instance:

  ```
  switch(ch) {
    int temp;
    case 1:
      break;
    default:
      break;
  }
  ```
- A label or a jump statement such as `goto` or `return` occurs in the `switch` block.
- A variable is declared in a `case` statement that is outside any block.

  For instance:

  ```
  switch(ch) {
    case 1:
      int temp;
      break;
    default:
      break;
  }
  ```

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Adhere to MISRA Rules for Well-Formed Switch Statements

The example fails to follow two of the well-formed `switch` statement rules from MISRA.

- The statement `int temp;` occurs between the `switch` statement and the first `case` statement.

- `case 2` contains a return statement.

Polyspace reports a single violation for the entire `switch` statement despite multiple violations within the `switch` statement.

```
int example(int x)
{
    switch (x) {            //Noncompliant
        int temp;
        case 0:
            break;
        case 1:
        case 2:
            return x;
        default:
            break;
    }

    return x;
}
```

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-4-4

A switch-label shall only be used when the most closely-enclosing compound statement is the body of a switch statement

## Description

### Rule Definition

*A switch-label shall only be used when the most closely-enclosing compound statement is the body of a switch statement.*

### Rationale

Placing a case-label or default-label of a switch statement in different scopes might result in unstructured code. Unstructured code might lead to unexpected behavior resulting in developer confusion. To prevent this issue, all case-labels and the default-label must be at the same scope of the compound statement forming the body of the switch statement.

### Polyspace Implementation

Polyspace raises this defect whenever a case-label belongs to any scope other than the switch statement body.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Case-Label Nested Within Another Case-Label Is Noncompliant

```
#include <cstdint>

int y, sum;

int heresASum(int a, int b)
{
    sum = a + b;
    return sum;
}

int example(int x)
{
    switch (x) {
    case 1:                         //compliant
        if (y > 0) {
        case 2:                     //noncompliant
            y = heresASum(x, y);
            break;
        }
        break;
    case 3:
        break;

    default:
        break;
    }

    return x;
}
```

Because the case-label `case 2` in nested under the `case 1` case-label, it is considered in a different scope from the other case-label statements and the default-label statement. All of these other case-label statements are in the same scope of the body of the switch-label statement.

#### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-4-5

An unconditional throw or break statement shall terminate every non-empty switch-clause

## Description

### Rule Definition

*An unconditional throw or break statement shall terminate every non-empty switch-clause.*

### Rationale

If a throw or break statement is not used at the end of a switch-clause, control flow falls into the next switch-clause. If unintentional, this behavior might cause unexpected results. Using a throw or break statement helps to prevent unintentional fall-through behavior. Use a throw or break statement as the last statement of each case-clause and the default-clause.

Using an empty case-label is acceptable when utilizing fall-through to group together multiple clauses that otherwise require identical statements.

### Polyspace Implementation

Polyspace raises this defect whenever a case-label contains any statements and a throw or break statement is not the final statement of the case-label.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Noncompliant Unintentional Fall Through Case-Label

```
#include <cstdint>

int x, y = 2;

int example(int x)
{
    switch (x) {         //noncompliant error shows here
    case 0:              //compliant empty fall through
    case 1:
        break;           //compliant break
    case 2:
        x = y ^ 2;       //error: unintentional fall through
    case 3:              //compliant throw
        throw;

    default:             //compliant break
        break;
    }
    return x;
}
```

Because `case 2` does not contain a throw or break statement, it falls over into `case 3`. This type of fall through is noncompliant.

Because it is an empty case-label, `Case 0` will fall through to `case 1`. This is a compliant empty case-label fall through.

# AUTOSAR C++14 Rule M6-4-6

The final clause of a `switch` statement shall be the default-clause

## Description

### Rule Definition

*The final clause of a `switch` statement shall be the default-clause.*

### Rationale

It is a good defensive programming technique to always use a `default` clause as the final clause of a `switch` statement. The `default` clause must either take appropriate action or contain a comment as to why the `default` clause takes no action.

### Polyspace Implementation

The rule checker detects `switch` statements that do not have a final `default` clause.

The rule checker does not report a violation if the `switch` variable is an enumeration with finite number of values and you have a `case` clause for each value. For instance:

```
enum Colors { RED, BLUE, YELLOW } color;

switch (color) {
      case RED:
        break;
      case BLUE:
        break;
      case YELLOW:
        break;
}
```

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Example

### Use Default Clause as Final `Switch` Clause

Polyspace flags both `switch` statements in this example as noncompliant.

- `switch (i)` contains multiple `case` statements. However, there is no `default` clause to handle cases where `i` is any value other than 0, 1, or 2. Even if `i` can only be 0, 1, or 2, using a `default` clause is defensive programming to catch any circumstance where `i` is unexpectedly a different value.
- `switch (colors)` uses an enumeration for the `switch` variable. However, each value does not have an associated `case` clause. Adding the `case` clause for `case BLUE` makes this `switch` statement compliant.

```
#include <cstdint>

int main(){
    int i;

    switch (i)        //Noncompliant
    {
    case 0:
        break;
    case 1:
    case 2:
        break;
    }

    enum Colors { RED, BLUE, YELLOW } colors;

    switch (colors) {    //Noncompliant
    case RED:
        break;
    case YELLOW:
        break;
    }

    return 0;
}
```

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-4-7

The condition of a switch statement shall not have bool type

## Description

### Rule Definition

*The condition of a switch statement shall not have bool type.*

### Rationale

Switch statements that have a bool condition might cause confusion or mistakes not caught by the compiler. If statements are better suited to handling bool evaluations. Use If...else statements in place of switch statements that have a bool condition.

### Polyspace Implementation

Polyspace raises this defect whenever a switch-case conditional results in a bool.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Using Bools in Switch Conditions Is Noncompliant

```
#include <cstdint>

int x = 10;

int example(int x)
{
    switch (x > 0) { //noncompliant
    case true:
        x += 10;
        break;

    case false:
        x -= 10;
        break;

    default:
        x = 0;
        break;
    }

    return x;
}
```

Because the switch statement condition `x > 0` results in a bool, Polyspace marks it as noncompliant.

Use the following if statement in place of the above switch-case:

```
#include <cstdint>

int x = 10;

int example(int x)
{
    if (x > 0) {
        x += 10;
    } else if (x <= 0) {
        x -= 10;
    } else {
        x = 0;
    }

    return x;
}
```

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-5-2

If loop-counter is not modified by -- or ++, then, within condition, the loop-counter shall only be used as an operand to <=, <, > or >=

## Description

### Rule Definition

*If loop-counter is not modified by -- or ++, then, within condition, the loop-counter shall only be used as an operand to <=, <, > or >=.*

### Rationale

If the loop counter increments or decrements by more than one per iteration, avoid using == or != in the loop termination condition. It is unclear from visual inspection if such loop termination conditions are ever satisfied.

For instance, if a loop counter `ctr` increments by more than one per iteration, such as `ctr+=2`, and the termination condition is `ctr == someVal`, the counter might skip the value `someVal`, resulting in a nonterminating loop.

Nonterminating loops can result in developer confusion or unexpected values.

### Polyspace Implementation

Polyspace raises this defect whenever all the following are true:

- The loop-counter is not modified by `--` or `++`
- The loop-condition does not contain <=, <, > or >=

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Nonterminating Loops Created by Using Noncompliant Operand Pairings

```
#include <cstdint>

uint32_t row, col;

void example()
{
    for (row = 0; row <= 10; row++) {                 //Compliant
        for (col = 100; col != 10; col -= 4) {        //Noncompliant
            //...
        }
    }
    for (row = 0; row != 10; row++) {            //Compliant
        //...
    }
}
```

Because the second for loop-counter is not modified by `--` or `++`, `!=` becomes a noncompliant operand. Use one of the following operands instead: <=, <, > or >=.

# AUTOSAR C++14 Rule M6-5-3

The loop-counter shall not be modified within condition or statement

## Description

### Rule Definition

*The loop-counter shall not be modified within condition or statement.*

### Rationale

The `for` loop has a specific syntax for modifying the loop counter. A code reviewer expects modification using that syntax. Modifying the loop counter elsewhere can make the code harder to review.

### Polyspace Implementation

The checker flags modification of a `for` loop counter in the loop body or the loop condition (the condition that is checked to see if the loop must be terminated).

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-5-4

The loop-counter shall be modified by one of: --, ++, -=n, or +=n; where n remains constant for the duration of the loop

## Description

### Rule Definition

*The loop-counter shall be modified by one of: --, ++, -=n, or +=n; where n remains constant for the duration of the loop.*

### Rationale

If the loop-counter modifier of the loop is not constant, the loop might end unpredictably, causing results contrary to your expectations. Constant increments create predictable loop termination.

### Polyspace Implementation

Polyspace reports this defect whenever the modifier of a loop-counter is not constant. Polyspace also reports this defect when you modify a loop by -=*n* or +=*n* and modify *n* within the loop.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Noncompliant Nonconstant Loop-Counter Modifiers

```
#include <cstdint>

int i, x = 0;
int y, z = 1;

int ex2()
{
    return z;
}

void example()
{
    for (i = 0; i <= 10; i += x) {          //Noncompliant
        x += 1;
    }

    for (i = 0; i <= 10; i += y) {          //Compliant
        z += i;
    }

    for (i = 0; i >= 10; i -= ex2()) {      //Noncompliant
        z += i;
    }
}
```

Because the first `for` loop uses the loop-counter modifier of `+=x` and modifies the variable `x` within the `for` loop, Polyspace flags the `for` loop as noncompliant.

The second `for` loop shows a compliant case of using a loop-counter modifier of `+=y`, where `y` is not modified within the loop.

The third `for` loop modifies the loop counter by using the return value of a function, `ex2()`. Because the function returns a different value in each iteration, the loop-counter modifier is not constant. Polyspace flags the `for` loop as noncompliant.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-5-5

A loop-control-variable other than the loop-counter shall not be modified within condition or expression

## Description

### Rule Definition

*A loop-control-variable other than the loop-counter shall not be modified within condition or expression.*

### Rationale

Loops are easier to understand and predict if loop-control-variables, other than loop counters, are not modified within the condition or increment/decrement expression. A volatile typed loop-control-variable is an exception and you can modify it outside of the statement without triggering this violation.

Loop-control-variables are any variables that occur in the loop init-statement, condition, or expression. Loop-control-variables include loop-counters and flags used for early loop termination. A loop-counter is a loop-control-variable that is:

- Initialized prior to the `for` loop or in the init-statement of the `for` loop.
- An operand to a relational operator in the condition of the `for` loop.
- Modified in the expression of the `for` loop.

### Polyspace Implementation

Polyspace raises this defect whenever a loop-counter or flag used for early termination is modified within the condition or expression.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Modifying Loop-Control-Variables Within the Loop Condition

```
#include <cstdint>

bool tf_test, tf_test2 = false;
int32_t x = 0;

bool a_test(bool a)
{
    if (x % 2 == 0)
    {
        a = true;
    }
    else
    {
        a = false;
    }
    return a;
}

void example()
{

    for (x = 0; (x < 10) && (tf_test = a_test(tf_test)); x++)        //noncompliant
    {
        //...
    }

    for (x = 0; (x < 10) && tf_test2; x++)         //compliant
    {
             //...
        tf_test2 = a_test(tf_test2);
    }
}
```

In the first `for` loop, because `tf_test` is a flag used for early loop termination that is modified within the condition, Polyspace flags it as noncompliant.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-5-6

A loop-control-variable other than the loop-counter which is modified in statement shall have type bool

## Description

### Rule Definition

*A loop-control-variable other than the loop-counter which is modified in statement shall have type bool.*

### Rationale

Loops terminate when the loop-counter value meets a termination condition. You can use additional loop-control-variables if you want to end a loop early.

For instance:

`for(ctr = 0 ; ctr <= 10; ctr++) {…}` terminates when the value of `ctr` is greater than `10`.

`for(ctr = 0 ; ctr <= 10 && level > 0; ctr++) {…}` terminates when the value of `ctr` is greater than `10` or when the value of `level` is greater than `0`.

In the second instance, it is not clear why the condition `level >= 0` terminates the loop early. By using a Boolean variable as a loop-control-variable for early termination, you can use a more descriptive name that reflects the early termination state.

For example:

```
for(ctr = 0 ; ctr <= 10 && fuelTankNotEmpty; ctr++)
{
    /...
    fuelTankNotEmpty = (level >= 0);
}
```

This Boolean variable is called a flag. Boolean flags make loop control logic easier to understand.

### Polyspace Implementation

Polyspace raises this defect whenever a non-Boolean loop-control-variable is modified within the loop statement.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Modifying Non-Boolean Loop-Control-Variables Within the Loop Statement

```
#include <cstdint>
```

```
int32_t ctr, level = 1;
bool fuelTankNotEmpty = true;

void example()
{
    for(ctr = 0 ; ctr <= 10 && level >= 0; ctr++)        //Noncompliant
    {
        level--;
    }

    for (ctr = 0; ctr <= 10 && fuelTankNotEmpty; ctr++)    //Compliant
    {
        level--;
        fuelTankNotEmpty = (level >= 0);
    }

}
```

In the first `for` loop, because `level` is not a Boolean and is modified within the statement, Polyspace flags it as noncompliant.

The second loop shows how to use a Boolean flag to be compliant with this rule.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-6-1

Any label referenced by a goto statement shall be declared in the same block, or in a block enclosing the goto statement

## Description

### Rule Definition

*Any label referenced by a goto statement shall be declared in the same block, or in a block enclosing the goto statement.*

### Rationale

Using a goto statement to jump into nested blocks creates complex control flow, which might cause developer confusion or unexpected results. To avoid unexpected results, place the label the goto statement is referring to in the same block or in a block that encloses the goto statement.

### Polyspace Implementation

Polyspace raises this defect when the goto destination is in a different block than the goto statement. This defect is not raised if the goto destination is in a block enclosing the goto statement.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using goto Statements to Exit Out of a Block

```
#include <iostream>

int x, y = 0;

void foo1()
{
    int i = 0;
    if (x <= 10) {
        goto err;                    //Noncompliant
    }

    if(x > 10) {
    err:
        std::cout << "Error encountered in loop" << std::endl;
    }

}

void foo2()
{
    for (x = 0; x < 100; ++x) {
        for (y = 0; y < 100; ++y) {
            if (x > y) {
                goto stop;            //Compliant
            }
            //...
        }
    }
stop:
    std::cout << "Error encountered in loop" << std::endl;
}
```

Because the label `err` is located within a separate code block than `goto err`, and that code block does not enclose the code block where `goto err` resides, Polyspace flags the `goto` statement as noncompliant.

The label `stop` is not in the same block as `goto stop`, but is in a block enclosing the `goto stop` statement. This behavior is compliant behavior.

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M6-6-2

The goto statement shall jump to a label declared later in the same function body

## Description

### Rule Definition

*The goto statement shall jump to a label declared later in the same function body.*

### Rationale

Using a `goto` statement to jump to a label earlier in the same function body creates an iteration. Avoid creating iterations by using `goto` statements. Use iteration statements defined by the core language because they are easier to understand and maintain than goto statements.

### Polyspace Implementation

Polyspace raises this defect when an iteration is formed by using `goto` statements.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Creating Iterations by Using goto Statements

```
#include<iostream>
void foo(int x, int y)
{
test:
    x++;
    if (x <= y) {
        std::cout << x << std::endl;
        goto test;   //Noncompliant
    }
}
```

Because `goto test` sends the code back to the beginning of the function, the goto statement creates a loop. Use looping statements such as `while` or `for` instead.

```
#include<iostream>
void foo(int x, int y)
{
    while (x < y)
    {
        x++;
        std::cout << x << std::endl;
    }
}
```

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M6-6-3

The `continue` statement shall only be used within a well-formed `for` loop

## Description

### Rule Definition

*The `continue` statement shall only be used within a well-formed `for` loop.*

### Rationale

Using a `continue` statement can add unnecessary complexity to code, which can cause issues during testing due to the additional logic required.

### Polyspace Implementation

The rule checker reports a violation for the use of `continue` statements in:

- `for` loops that are not well-formed, that is, `for` loops that violate rules 6-5-x
- `while` loops

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Example

### Only Use `continue` Statement in Well-Formed `for` Loops

The `for` loop in this code is not well-formed as it breaks `MISRA C++:2008 Rule 6-5-2`. Because the `for` loop in the example is not well-formed and contains a `continue` statement, Polyspace raises this violation.

```
#include <cstdint>

uint32_t row, col;

void example()
{
    for (row = 0; row <= 10; row++) {
        for (col = 100; col != 10; col -= 4) {
            //...
            continue;        //Noncompliant
        }
    }
}
```

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M7-1-2

A pointer or reference parameter in a function shall be declared as pointer to const or reference to const if the corresponding object is not modified

## Description

### Rule Definition

*A pointer or reference parameter in a function shall be declared as pointer to const or reference to const if the corresponding object is not modified.*

### Polyspace Implementation

The checker flags pointers where the underlying object is not const-qualified but never modified in the function body.

If a variable is passed to another function by reference or pointers, the checker assumes that the variable can be modified. Pointers that point to these variables are not flagged.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M7-3-1

The global namespace shall only contain main, namespace declarations and extern "C" declarations

## Description

### Rule Definition

*The global namespace shall only contain main, namespace declarations and extern "C" declarations.*

### Rationale

The rule makes sure that all names found at global scope are part of a namespace. Adhering to this rule avoids name clashes and ensures that developers do not reuse a variable name, resulting in compilation/linking errors, or shadow a variable name, resulting in possibly unexpected issues later.

### Polyspace Implementation

Other than the `main` function, the checker flags all names used at global scope that are not part of a namespace.

The checker does not flag names at global scope if they are declared in `extern "C"` blocks (C code included within C++ code). However, if you use the option `Ignore link errors (-no-extern-c)`, these names are also flagged.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Check Information

The identifier main shall not be used for a function other than the global function main

## Description

### Rule Definition

*The identifier main shall not be used for a function other than the global function main.*

### Rationale

Typically, the `main` function lives in the global namespace and acts as the entry point to a program. The use of `main` in other contexts might defy developer expectations.

### Polyspace Implementation

The rule checker reports a violation if you use the identifier `main` in a namespace other than the global namespace.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Nonstandard Uses of `main`

```
#include <cstdint>

int32_t main() { //Compliant
    //...
    return 0;
}

namespace Backups {
    int32_t main() { //Noncompliant
        //...
        return 0;
    }
}
```

The use of `main` in a namespace other than the global namespace violates the rule.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M7-3-3

There shall be no unnamed namespaces in header files

## Description

### Rule Definition

*There shall be no unnamed namespaces in header files.*

### Rationale

According to the C++ standard, names in an unnamed namespace, for instance, `aVar`:

```
namespace {
   int aVar;
}
```

have internal linkage by default. If a header file contains an unnamed namespace, each translation unit with a source file that `#include`-s the header file defines its own instance of objects in the namespace. The multiple definitions are probably not what you intended and can lead to unexpected results, unwanted excess memory usage, or inadvertently violating the one-definition rule.

### Polyspace Implementation

The checker flags unnamed namespaces in header files.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Unexpected Results from Unnamed Namespaces in Header Files

Header File: `aHeader.h`

```
namespace { //Noncompliant
   int aVar;
}
```

First source file: `aSource.cpp`

```
#include "aHeader.h"
#include <iostream>

void setVar(int arg) {
    std::cout << "Current value: " << aVar << std::endl;
    aVar = arg;
    std::cout << "Value set at: " << aVar << std::endl;
}
```

Second source file: `anotherSource.cpp`

```
#include "aHeader.h"
#include <iostream>

extern void setVar(int);

void resetVar() {
    std::cout << "Current value: " << aVar << std::endl;
    aVar = 0;
    std::cout << "Value set at: 0" << std::endl;
}

void main() {
    setVar(1);
    resetVar();
}
```

In this example, the noncompliant unnamed namespace leads to two definitions of `aVar` in the translation unit from `aSource.cpp` and the translation unit from `anotherSource.cpp`. The two definitions can lead to possible unexpected output:

```
Current value: 0
Value set at: 1
Current value: 0
Value set at: 0
```

# AUTOSAR C++14 Rule M7-3-4

Using-directives shall not be used

## Description

### Rule Definition

*using-directives shall not be used.*

### Rationale

`using` directives can inadvertently expose more variables to name lookup than you intend. The wider scope for name lookup increases the likelihood of a variable being unintentionally used. For instance:

```
namespace NS {
    int i;
    int j;
}
using namespace NS;
```

exposes both `NS::i` and `NS::j` to name lookup, but you might have intended to use only one of the variables.

It is preferable to only expose variables that you intend to use or refer to variables by their fully qualified name when you use them. For instance, in the previous example, if you use the variable `NS::i`, expose only this variable to name lookup:

```
using NS::i;
```

or refer to `NS::i` instead of `i` in all instances.

### Polyspace Implementation

The rule checker reports a violation on `using` directives. These directives contain the keyword `using` followed by the keyword `namespace` and the name of a namespace. The `using` directives make all members of a namespace available to the current scope.

The checker does not flag `using` declarations. These declarations also contain the keyword `using` but not the keyword `namespace`. The `using` declarations only expose specific members of a namespace.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Namespace Exposed Through `using` Directive

```
namespace currentDataModel {
    int nodes;
    int count;
}
using namespace currentDataModel; //Noncompliant

namespace lastDataModel {
    int nodes;
    int count;
}
using lastDataModel::count; //Compliant
```

In this example, the `using` directive that exposes all members of the namespace `currentDataModel` violates the rule.

Using-directives and using-declarations (excluding class scope or function scope using-declarations) shall not be used in header files

## Description

### Rule Definition

*using-directives and using-declarations (excluding class scope or function scope using-declarations) shall not be used in header files.*

### Rationale

If `using` directives or declarations are present in a header file, the order in which the header is included might affect the final program results. It is a good practice to ensure that the program behavior does not depend on the order of inclusion of headers.

### Polyspace Implementation

The checker flags `using` directives or declarations in header files.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### `using` Directives in Headers Introduce Dependence on Order of Inclusion

Header File: `headerUnits.h`:

```
void checkValueForOverflows(int32_t);

namespace Units {
    void checkValueForOverflows(int8_t);
}

inline void convertToAcceptedUnit(int8_t originalValue) {
    checkValueForOverflows(originalValue);
}
```

Header File: `headerAcceptedUnits.h`:

```
namespace Units {

}

using namespace Units; //Noncompliant
```

Source file that includes previous two headers:

```
#include <cstdint>
#include "headerUnits.h"
```

```
#include "headerAcceptedUnits.h"

int8_t convert(int8_t meterReading) {
    convertToAcceptedUnit(meterReading);
}
```

In this example, the `using` directive in the header file `headerAcceptedUnits.h` exposes the namespace `Units`. This directive plus the inlined function in the header makes the order of inclusion of `headerUnits.h` and `headerAcceptedUnits.h` important for the final program execution.

- If `headerAcceptedUnits.h` is included before `headerUnits.h`, the function `convertToAcceptedUnit()` invokes the function `checkValueForOverflows(int32_t)`.
- If `headerAcceptedUnits.h` is included after `headerUnits.h`, as shown above, the function `convertToAcceptedUnit()` invokes the function `checkValueForOverflows(int8_t)`.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M7-4-2

Assembler instructions shall only be introduced using the asm declaration

## Description

### Rule Definition

*Assembler instructions shall only be introduced using the asm declaration.*

### Rationale

The `asm` declaration is available in all C++ implementations[23] but other ways of introducing assembler instructions might not be available. Using the `asm` declaration makes your code portable across implementations.

### Polyspace Implementation

The rule checker reports uses of methods other than `asm` declarations as rule violations.

For instance, the rule checker allows the `asm` declaration:

```
asm("ADD a0,1")
```

But if the same assembler instructions are introduced through a `#pragma asm`, the checker reports a violation:

```
#pragma asm
   "ADD a0,1"
#pragma endasm
```

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Introduction of Assembler Instructions Using Nonportable Methods

```
void Delay1 ( void ) {
#pragma asm             //Noncompliant
   "ADD a0,1"
#pragma endasm
     ;
}

void Delay2 ( void ) {
   asm("ADD a0,1");     //Compliant
}
```

The use of `#pragma asm` violates this rule.

[23] How the `asm` declaration is implemented might vary across compilers. See also `AUTOSAR C++14 Rule A7-4-1`.

# AUTOSAR C++14 Rule M7-4-3

Assembly language shall be encapsulated and isolated

## Description

### Rule Definition

*Assembly language shall be encapsulated and isolated.*

### Rationale

Assembler instructions can be difficult to port across implementations. Encapsulating and isolating them in a function helps to make your code portable. You can easily track down assembler instructions or provide alternative implementations without changing the rest of the code.

### Polyspace Implementation

The checker flags `asm` statements unless they are encapsulated in a function call.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Assembler Instructions Not Encapsulated in Function Call

```
void DoSomething(void);

void Delay ( void ) {
    asm( "NOP"); //Compliant
    asm( "NOP"); //Compliant
}
void DoSomethingAndDelay (void) {
    DoSomething();
    Delay();// Assembler is encapsulated
    DoSomething();
    asm("NOP"); //Noncompliant
    DoSomething();
}
```

The `asm` statement in the function `DoSomethingAndDelay()` is mixed with regular C code and violates the rule. The `asm` statements in the function `Delay()` are compliant because they form the only instructions in this function. The `Delay()` function thus effectively encapsulates the assembler instructions.

# AUTOSAR C++14 Rule M7-5-1

A function shall not return a reference or a pointer to an automatic variable (including parameters), defined within the function

## Description

### Rule Definition

*A function shall not return a reference or a pointer to an automatic variable (including parameters), defined within the function.*

### Rationale

Local objects of a function are destroyed at the end of a function call. If you return the address of such an object via a pointer, you might access a destroyed object. For instance:

```
int* foo(int a){
    int b = a^2;
    return &b;
}
```

The function `foo()` returns a pointer to `b`. The variable `b` goes out of scope at the end of the function call and the pointer returned by `foo()` points to a destroyed object. Accessing the pointer leads to undefined behavior.

### Polyspace Implementation

Polyspace raises a violation if a function returns a reference or pointer to a variable that goes out of scope at the end of the function call.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Returning Pointers to Local Variables

```
int gVal;
//...

int* foo(void){
    int val;
    //...
    return &val;//Noncompliant
}
```

In this example, the function `foo()` returns the address of `val`. This local variables goes out of scope at the end of the function call. Accessing the pointer returned by `foo()` results in undefined behavior. Polyspace raises a violation.

## Check Information

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M7-5-2

The address of an object with automatic storage shall not be assigned to another object that may persist after the first object has ceased to exist

## Description

### Rule Definition

*The address of an object with automatic storage shall not be assigned to another object that may persist after the first object has ceased to exist.*

### Rationale

If an object continues to point to another object *after* the latter object ceases to exist, dereferencing the first object leads to undefined behavior.

### Polyspace Implementation

The checker flags situations where the address of a local variable is assigned to a pointer defined at global scope.

The checker does not raise violations of this rule if:

- A function returns the address of a local variable. `AUTOSAR C++14 Rule M7-5-1` covers this situation.
- The address of a variable defined at block scope is assigned to a pointer that is defined with greater scope, but not global scope.

  For instance:

  ```
   void foobar ( void )
    {
      char * ptr;
      {
        char var;
        ptr = &var;
      }
    }
  ```

  Only if the pointer is defined at global scope is a rule violation raised. For instance, the rule checker flags the assignment here:

  ```
  char * ptr;
  void foobar ( void )
    {
        char var;
        ptr = &var;
    }
  ```

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Address of Local Variable Assigned to Global Pointer

```
char * ptr;

void foo (void) {
    char varInFoo;
    ptr = &varInFoo; //Noncompliant
}

void bar (void) {
    char varInBar = *ptr;
}

void main() {
    foo();
    bar();
}
```

The assignment `ptr = &varInFoo` is noncompliant because the global pointer `ptr` might be dereferenced outside the function `foo`, where the variable `varInFoo` is no longer in scope. For instance, in this example, `ptr` is dereferenced in the function `bar`, which is called after `foo` completes execution.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M8-0-1

An init-declarator-list or a member-declarator-list shall consist of a single init-declarator or member-declarator respectively

## Description

### Rule Definition

*An init-declarator-list or a member-declarator-list shall consist of a single init-declarator or member-declarator respectively.*

### Rationale

Init-declarator-lists that have multiple declarators might result in ambiguous type assignments and might cause a developer to assign unintended types to certain identifiers. Having a single init-declarator for each declaration clarifies the declaration type and reduces the risk of unwanted type assignments. Avoid multiple declarators in an init-declarator-list or a member-declarator-list.

### Polyspace Implementation

Polyspace flags declarators after the first declarator in an init-declarator-list or a member-declarator-list.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Multiple Declarators Within an Init-Declarator-List

```
#include <cstdint>
#include <string>

class exampleClass{};

void foo() {
    double a, b, c; //Noncompliant
    exampleClass objectOne, objectTwo; //Noncompliant
    int32_t d; int32_t e; //Compliant
    std::string f;  //Compliant
}
```

In this example, Polyspace flags init-declarator-lists that have multiple declarators. For instance:

- `double a, b, c` is noncompliant because the init-declarator-list consists of more than one init-declarator and the `b` and `c` declarators are flagged.
- `exampleClass objectOne, objectTwo` is noncompliant because the init-declarator-list consists of more than one init-declarator and the `objectTwo` declarator is flagged.

- `int32_t d, int32_t e` and `std::string f` are compliant because each init-declarator-list consists of a single init-declarator.

The identifiers used for the parameters in a re-declaration of a function shall be identical to those in the declaration

## Description

### Rule Definition

*The identifiers used for the parameters in a re-declaration of a function shall be identical to those in the declaration.*

### Polyspace Implementation

The checker detects mismatch in parameter names between:

- A function declaration and the corresponding definition.
- Two declarations of a function, provided they occur in the same file.

  If the declarations occur in different files, the checker does not raise a violation for mismatch in parameter names. Redeclarations in different files are forbidden by `AUTOSAR C++14 Rule M3-2-3`.

# AUTOSAR C++14 Rule M8-5-2

Braces shall be used to indicate and match the structure in the non-zero initialization of arrays and structures

## Description

### Rule Definition

*Braces shall be used to indicate and match the structure in the non-zero initialization of arrays and structures.*

### Rationale

The use of nested braces in initializer lists to match the structures of nested objects in arrays, unions, and structs encourages you to consider the order of initialization of complex data types and makes your code more readable. For example, the use of nested braces in the initialization of `ex1` makes it easier to see how the nested arrays `arr1` and `arr2` in struct `ex1` are initialized.

```
struct Example
{
    int num;
    int arr1[2];
    int arr2[3];
};

//....
struct Example ex1 {1, {2, 3}, {4, 5, 6}}; //Compliant
```

The rule does not require the use of nested braces if you zero initialize an array, a union, or a struct with nested structures are the top-level, for instance:

```
struct Example ex1 {}; //Compliant
```

### Polyspace Implementation

If you non-zero initialize an array, union, or struct that contains nested structures and you do not use nested braces to reflect the nested structure, Polyspace flags the first element of the first nested structure in the initializer list. For instance, in this code snippet, Polyspace flags the number `2` because it corresponds to the first element of nested structure `arr1` inside struct `ex1`.

```
struct Example
{
    int num;
    int arr1[2];
    int arr2[3];
};

//....
struct Example ex1 {1, 2, 3, 4, 5, 6}; // Non-compliant
```

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Missing Nested Braces in Initializer of Two-Dimensional Arrays

```
char arr1[2][3] {'a', 'b', 'c', 'd', 'e', 'f'}; //Non-compliant
char arr2[2][3] {{'a', 'b', 'c'}, {'d', 'e', 'f'}}; //Compliant
char arr_top_level[2][3] { }; //Compliant
char arr_sub_level[2][3] { {}, {'d', 'e', 'f'}}; //Non-compliant
```

In this example, two-dimensional array `arr1` is non-compliant because the initializer list does not reflect the nested structure of this array (two arrays of three elements each). The initialization of `arr2` uses nested braces to reflect the nested structure of the array and is compliant. Similarly, the initialization of `arr_top_level` is compliant because it zero initializes the array at the top level. Note that the initialization of `arr_sub_level` is non-compliant because zero-initializes only the first sub-array while explicitly initializing all the elements of the other sub-array.

# AUTOSAR C++14 Rule M9-3-1

`Const` member functions shall not return non-`const` pointers or references to class-data

## Description

### Rule Definition

*`const` member functions shall not return non-`const` pointers or references to class-data.*

### Rationale

A `const` object cannot be changed post initialization and can only invoke class member functions that are also declared as `const`. These member functions are not expected to change the state of the object.

If a `const` member function returns a non-`const` pointer or reference to a data member of the class, the function can modify the state of an object and violate developer expectations. To avoid this situation, when you define a `const` member function that returns a reference or a pointer to a class data member, specify the return type as `const`.

### Polyspace Implementation

Polyspace flags a violation of this rule only if a `const` member function returns a non-`const` pointer or reference to a non-`static` data member. The rule does not apply to `static` data members.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Specify Return Type of `const` Member Function as `const`

```
class A{

    private:

    int& rInt;
    public:

    int* getR() const{ //Noncompliant
        return &rInt;
    }

    const int* getConstR() const{ //Compliant
        return &rInt;
    }
};
```

In this example:

- The `const` member function `getR()` returns a non-`const` pointer and violates the rule.
- The `const` member function `getConstR()` returns a `const` pointer and is compliant with the rule.

### Check Information

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M9-3-3

If a member function can be made static then it shall be made static, otherwise if it can be made const then it shall be made const

## Description

### Rule Definition

*If a member function can be made static then it shall be made static, otherwise if it can be made const then it shall be made const.*

### Rationale

`const` member functions cannot modify the data members of the class. `static` member function cannot modify the nonstatic data members of the class. If a member function does not need to modify the nonstatic data members of the class, limit their access to data by declaring the member functions as `const` or `static`. Such declaration clearly expresses and enforces the design intent. That is, if you inadvertently attempt to modify a data member through a `const` member function, the compiler catches the error. Without the `const` declaration, this kind of inadvertent error might lead to bugs that are difficult to find or debug.

### Polyspace Implementation

The checker performs these checks in this order:

1. The checker first checks if a class member function accesses a data member of the class. Functions that do not access data members can be declared static.
2. The checker then checks functions that access data members to determine if the function modifies any of the data members. Functions that do not modify data members can be declared const.

A violation on a `const` member function means that the function does not access a data member of the class and can be declared static.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Explicitly Restrict Access for Member Functions that Do Not Modify Data Members

```
#include<cstdint>
void Connector(void);
class A
{
public:
    int16_t foo ( ) // Noncompliant
    {
        return m_i;
    }
    int16_t foo2 ( ) // Noncompliant
    {
        Connector();// Might have side-effect
        return m_i;
    }
    int16_t foo3 ( ) // Noncompliant
    {
        return m_s;
    }
    int16_t inc_m ( ) // Compliant
    {
        return ++m_i;
    }
    int16_t& getref()//Noncompliant
    {
        return m_i_ref;
    }
private:
    int16_t m_i;
    static int16_t m_s;
    int16_t& m_i_ref;
};
```

In this example, Polyspace flags the functions `foo`, `foo2`, `foo3`, and `getref` as noncompliant.

- The functions `foo` and `foo3` do not modify any nonstatic data members. Because their data access is not explicitly restricted by declaring them as `const`, Polyspace flags these functions. To fix these defects, declare `foo` and `foo3` as `const`.
- The function `foo2` does not explicitly modify any of the data members. Because it is not declared as `const`, Polyspace flags the function. `foo2` calls the global function `Connector`, which might have side effects. Do not declare `foo2` as a `const` function. In C++11 or later, `const` member functions are expected to be thread-safe, but `foo2` might not be thread-safe because of the side effects of `Connector`. To avoid data races, keep `foo2` as a nonconst function. Justify the defect by using review information or code comments.
- The function `getref` does not modify any data members. Because it is not declared as `const`, Polyspace flags it. Declaring `getref` as `const` resolves this defect, but that is not enough to restrict write access of `getref` because it returns a nonconst reference to `m_i_ref`. To restrict `getref` from modifying `m_i_ref`, the return type of `getref` must also be `const`.

# AUTOSAR C++14 Rule M9-6-4

Named bit-fields with signed integer type shall have a length of more than one bit

## Description

### Rule Definition

*Named bit-fields with signed integer type shall have a length of more than one bit.*

### Rationale

Variables that have signed integer bit-field types of length one bit might have values that do not meet developer expectations. For instance, signed integer types of a fixed width such as `std16_t` have a two's complement representation. In this representation, a single-bit variable has just the sign bit and the variable value might be 0 or -1.

### Polyspace Implementation

The checker flags declarations of named variables having signed integer bit-field types of length equal to one.

Bit-field types of length zero are not flagged.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Compliant and Noncompliant Bit-Field Types

```
#include <cstdint>

typedef struct
{
   std::uint16_t IOFlag :1;    //Compliant - unsigned type
   std::int16_t InterruptFlag :1; //Noncompliant
   std::int16_t Register1Flag :2; //Compliant - Length more than one bit
   std::int16_t : 1; //Compliant - Unnamed
   std::int16_t : 0; //Compliant - Unnamed
   std::uint16_t SetupFlag :1; //Compliant - unsigned type
} InterruptConfigbits_t;
```

In this example, only the second bit-field declaration is noncompliant. A named variable is declared with a signed type of length one bit.

# AUTOSAR C++14 Rule M10-1-1

Classes should not be derived from virtual bases

## Description

### Rule Definition

*Classes should not be derived from virtual bases.*

### Rationale

The use of virtual bases can lead to many confusing behaviors.

For instance, in an inheritance hierarchy involving a virtual base, the most derived class calls the constructor of the virtual base. Intermediate calls to the virtual base constructor are ignored.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of Virtual Bases

```
class Base {};
class Intermediate: public virtual Base {}; //Noncompliant
class Final: public Intermediate {};
```

In this example, the rule checker raises a violation when the `Intermediate` class is derived from the class `Base` with the `virtual` keyword.

The following behavior can be a potential source of confusion. When you create an object of type `Final`, the constructor of `Final` directly calls the constructor of `Base`. Any call to the `Base` constructor from the `Intermediate` constructor are ignored. You might see unexpected results if you do not take into account this behavior.

## Check Information

**Group:** Derived Classes

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M10-1-2

A base class shall only be declared virtual if it is used in a diamond hierarchy

## Description

### Rule Definition

*A base class shall only be declared virtual if it is used in a diamond hierarchy.*

### Rationale

This rule is less restrictive than `AUTOSAR C++14 Rule M10-1-1`. Rule M10-1-1 forbids the use of a virtual base anywhere in your code because a virtual base can lead to potentially confusing behavior.

Rule M10-1-2 allows the use of virtual bases in the one situation where they are useful, that is, as a common base class in diamond hierarchies.

For instance, the following diamond hierarchy violates rule M10-1-1 but not rule M10-1-2.

```
class Base {};
class Intermediate1: public virtual Base {};
class Intermediate2: public virtual Base {};
class Final: public Intermediate1, public Intermediate2 {};
```

### Polyspace Implementation

Polyspace flags a class if the class is used as a virtual base in a single and linear class hierarchy. In such a hierarchy, `virtual` bases are unnecessary.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using `virtual` Base Classes in Linear Hierarchy

```
class A{};
class B: public virtual A{};
class C: public virtual B{}; //Noncompliant

class alpha{};

class beta: public virtual alpha{};
class gamma: public virtual alpha{};
class omega: public beta, public gamma{}; //Compliant
```

In this example, the classes `B` and `C` in the linear hierarchy `A->B->C` uses virtual base classes. In this hierarchy, using virtual base classes is unnecessary and might cause confusion. Polyspace raises a violation. The class hierarchy `alpha->...->omega` is a diamond hierarchy and in this case, the use of virtual base classes is necessary. Polyspace does not flag this class hierarchy.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M10-1-3

An accessible base class shall not be both virtual and non-virtual in the same hierarchy

## Description

### Rule Definition

*An accessible base class shall not be both virtual and non-virtual in the same hierarchy.*

### Rationale

The checker flags situations where the same class is inherited as a virtual base class and a non-virtual base class in the same derived class. These situations defeat the purpose of virtual inheritance and causes multiple copies of the base class sub-object in the derived class object.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Base Class Both Virtual and Non-Virtual in Same Hierarchy

```
class Base {};
class Intermediate1: virtual public Base {};
class Intermediate2: virtual public Base {};
class Intermediate3: public Base {};
class Final: public Intermediate1, Intermediate2, Intermediate3 {}; //Noncompliant
```

In this example, the class `Base` is inherited in `Final` both as a virtual and non-virtual base class. The `Final` object contains at least two copies of a `Base` sub-object.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M10-2-1

All accessible entity names within a multiple inheritance hierarchy should be unique

## Description

### Rule Definition

*All accessible entity names within a multiple inheritance hierarchy should be unique.*

### Rationale

Data members and nonvirtual functions within the same inheritance hierarchy that have the same name might cause developer confusion. The entity the developer intended for use might not be the entity the compiler chooses. Avoid using nonunique names for accessible entities within a multiple inheritance hierarchy.

### Polyspace Implementation

This checker flags entities from separate classes that belong to the same derived class if they have an ambiguous name. The name of an entity is ambiguous if:

- Two variables share the same name, even if they are of different types.
- Two functions share the same name, same parameters, and the same return type.

If the data member accessed in the derived class is ambiguous, Polyspace reports this issue as a compilation issue, not a coding rule violation. The checker does not check for conflicts between entities of different kinds such as member functions against data members.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Noncompliant Data Members in a Multiple Inheritance Hierarchy

```
#include <iostream>
#include <cstdlib>
#include <cstdint>

using namespace std;

class A {
  public:
    int32_t num;
    int32_t total;
    int32_t sum(int32_t toSum)
    {
        total = toSum + num;
        return total;
    };
};

class B {
  public:
    int32_t num;   //Also in class A
    int32_t total();
    int32_t sum(int32_t toSum)   //Also in class A
    {
        num = toSum + num;
        return num;
    };
};

class C : public A, public B { //Noncompliant
  public:
    void foo() {
        num = total;
        sum(num);
    }
};
```

- Because `class A` and `class B` define their own local variable `int32_t num`, and because `class C` is a multiple inheritance hierarchy containing `class A` and `class B`, Polyspace flags both `int32_t num` variables as noncompliant.
- Because `int32_t sum()` in `class A` and `int32_t sum()` in `class B` share the same name, return type, arguments, and are members of the same multiple inheritance hierarchy, both functions are flagged by Polyspace as noncompliant.
- Because `int32_t total` and `int_32t total()` are different types of class members, Polyspace does not flag them even though they are part of the same multiple inheritance hierarchy.

The ambiguous data members might be reported as compilation issues.

### Nonunique Entity Names When Classes Derive From Templates

Because templates generate code, a class hierarchy deriving from a template might have nonunique names. In this example, the classes `Deriv1` and `Deriv2` derives from two separate instances of the template `myObj`. Then, the class `FinalDerived` derives from both `Deriv1` and `Deriv2`. The template `myObj` generates two version of the function `get()` in the `FinalDerived` class: one from the `myObj<int>` instance and one from the `myObj<short>` instance. The nonunique name might result in unexpected behavior. Polyspace reports a violation

```
template <typename T>
class myObj {
    //...
public:
    void get(void);
};

class Deriv1: public myObj<int> {
public:
    //...
};

class Deriv2: public myObj<short> {
public:
    //...
};

class FinalDerived: public Deriv1, public Deriv2 { //Noncompliant

public:
    //...
};
```

#### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M10-3-3

A virtual function shall only be overridden by a pure virtual function if it is itself declared as pure virtual

## Description

### Rule Definition

*A virtual function shall only be overridden by a pure virtual function if it is itself declared as pure virtual.*

### Rationale

In C++, an abstract class is the base of a polymorphic class hierarchy and the derived classes implement variation of the abstract class. When a virtual function is overridden in a derived class by a pure virtual function, the derived class becomes an abstract class. That a derived class is defined as an abstract class or an implemented function is overridden by a pure virtual function is unexpected behavior, which might confuse a developer.

### Polyspace Implementation

Polyspace flags a pure virtual function if it overrides a function that is not pure virtual.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Do Not Redeclare Functions as Pure Virtual

```
class Conic{
    //...
    public:
    double centerAbscissa;
    double centerOrdinate;
    //..
    virtual double  getArea()=0;
};
class Circle: public Conic{
    //...
    public:
    //...
    double getArea() override{
        //calculate area of circle
    }
};
class Ellipse: public Circle{
    //...
    public:
    //...
    virtual double getArea()=0; //Noncompliant
};
```

In this example, the base class `Conic` is an abstract class because the function `getArea()` is a pure virtual function. The derived class `Circle` implements the function `getArea`. The expectation from such a polymorphic hierarchy is that the virtual function `getArea` calculates the area correctly based on the derived class. When the derived class `Ellipse` redeclares `getArea` as a pure virtual function, the derived class `Ellipse` becomes abstract and the function `Ellipse.getArea()` cannot be invoked. Developers might expect `Ellipse.getArea()` to return the area of the ellipse. Because this redeclaration as a pure virtual function does not meet developer expectation, Polyspace flags the declaration.

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M11-0-1

Member data in non-POD class types shall be private

## Description

### Rule Definition

*Member data in non-POD class types shall be private.*

### Rationale

If classes have data members that are publicly accessible, other classes and functions might interact with the class data members directly. Any change in the class might require updating the clients that use the class. If a class is not a plain-old-data (POD) type, restricting access to its data members enables encapsulation of the class. In such an encapsulated class, the implementation details of the class are opaque to the clients that use it. The class retains control over its implementation and can be maintained independently without impacting the clients that use the class.

### Polyspace Implementation

Polyspace flags nonprivate data members in classes that are not POD types. Polyspace space uses the same definition of POD classes as the standard.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Declare Data Members in Non-POD Classes as `private`

```
class nonPOD{
    nonPOD(){
        //...
    }
    ~nonPOD(){
        //...
    }
    public:
    int getX();
    int setX(int&);
    int getY();
    int setY(int&);
    int getZ();
    int setZ(int&);
    int x; //Noncompliant
    protected:
    int y; //Noncompliant
    private:
    int z;
};
```

In this example, the data members `y` and `z` are not `private`. Polyspace flags them.

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M12-1-1

An object's dynamic type shall not be used from the body of its constructor or destructor

## Description

### Rule Definition

*An object's dynamic type shall not be used from the body of its constructor or destructor.*

### Rationale

The dynamic type of an object is the type of its most derived class. For instance:

```
struct B {
    virtual ~B() {}
};
struct D: B {};
D d;
B* ptr = &d;
```

The dynamic type of the object pointed to by `*ptr` is `D` because that is the most derived class in the polymorphic hierarchy.

When you invoke the dynamic type of a polymorphic object in its constructor or destructor, you might get the type of the constructed or destroyed object instead of the type of the most derived object. This is because when you invoke the dynamic type during construction or destructor, the derived classes might not be constructed yet. Using dynamic types in constructors and destructors might result in unexpected behavior. Calling pure virtual functions from constructors and destructors results in undefined behavior. Avoid using the dynamic type of an object in its constructors or destructors.

### Polyspace Implementation

Polyspace flags these items when they are used in a constructor or a destructor of a polymorphic class:

- The operator `typeid`
- Virtual or pure virtual functions
- The function `dynamic_cast` or implicit C-style casts

Polyspace assumes that a class is polymorphic if it has any virtual member.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using Dynamic Type in Constructors and Destructors

```
#include <cassert>
#include <typeinfo>
```

```
class PS
{
public:
    PS ( )
    {
        typeid ( PS );                // Compliant
    }
};

class PS_1
{
public:
    virtual ~PS_1 ( );
    virtual void bar ( );
    PS_1 ( )
    {
        typeid ( PS_1 );                // Noncompliant
        PS_1::bar ( );                  // Compliant
        bar ( );                      // Noncompliant
        dynamic_cast< PS_1* > ( this ); // Noncompliant
    }
};
```

In this example, class PS has no virtual member. Polyspace does not consider PS a polymorphic class. Because PS is not polymorphic, its dynamic type does not change at run time. Polyspace does not flag using the `typeid` operator in the constructor `PS::PS()`.

PS_1 is considered polymorphic because it has a `virtual` member function. Because it is polymorphic, its dynamic type changes during run time. Polyspace flags the invocation of its dynamic type in the constructor `PS_1::PS_1()`.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule A14-5-1

A template constructor shall not participate in overload resolution for a single argument of the enclosing class type

## Description

### Rule Definition

*A template constructor shall not participate in overload resolution for a single argument of the enclosing class type.*

### Rationale

A template constructor can lead to confusion about which copy or move constructor is being invoked in a copy or move. For instance:

- An implicit constructor might be invoked when you expect the template constructor to be used. An implicit copy or move constructor exists in the class because a template constructor does not prevent its definition.
- The template constructor might be invoked when you expect an explicit constructor to be used. A template constructor might a better match than the explicit constructor when an overload is resolved.

### Polyspace Implementation

The checker raises a violation when:

- A class contains a template copy or move constructor but at least one copy or move uses the implicit constructor in the class.

  The violation is shown on the template constructor. Events associated with the result show the copy or move where an implicit constructor is invoked.
- A class contains a template copy or move constructor and an explicit constructor but at least one copy or move uses the template constructor.

  The violation is shown on the template constructor. Events associated with the result show the copy or move where the template constructor is invoked and the explicit constructor definition.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Implicit Constructor Used Instead of Template Constructor

```
class record
{
  public:
    template<typename T>
    record(const T &);  /*Non-compliant*/
};

void lookup(record aRecord)
{
    record copyOfARecord {aRecord};
}
```

In this example, when creating the object `copyOfARecord` from the object `aRecord`, a copy constructor must be invoked. The template constructor specialization, that is, `record<record>(const record &)`, and the implicit constructor, that is, `record(const record &)` are equally good candidates for a copy constructor. When a function and a specialization are equally good matches in the overload resolution process, the function is preferred. In this case, the implicit constructor is called instead of the template constructor, but a developer or reviewer might expect otherwise.

#### Template Constructor Used Instead of Explicit Constructor

```
class record
{
  public:
    record(const record &);

    template<typename T>
    record(T &);  /*Non-compliant*/
};

void lookup(record aRecord)
{
    record copyOfARecord {aRecord};
}
```

In this example, when creating the object `copyOfARecord` from the object `aRecord`, a copy constructor must be invoked. The template constructor specialization, that is, `record<record>(record &)` is a better match compared to the explicit constructor, that is, `record(const record &)`. The template constructor is called instead of the explicit constructor, but a developer or reviewer might expect otherwise.

#### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M14-5-3

A copy assignment operator shall be declared when there is a template assignment operator with a parameter that is a generic parameter

## Description

### Rule Definition

*A copy assignment operator shall be declared when there is a template assignment operator with a parameter that is a generic parameter.*

### Rationale

When declaring a user-defined assignment operator, the corresponding implicit operator is suppressed. When declaring a template assignment operator that has a generic parameter, this behavior is not preserved. In that case, to suppress the implicit shallow-copying operator, explicitly instantiate a version of the copy assignment operator for the class.

If you do not declare the copy assignment operator for the class, the compiler-generated copy assignment operator might be used instead on implementation. Not declaring a copy assignment operator explicitly might result in an unexpected outcome, such as creating a shallow copy when a deep copy was intended.

### Polyspace Implementation

Polyspace flags this checker if a structure, class, or union contains a template assignment operator that has a generic parameter but no copy assignment operator is present within the structure, class, or union.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Noncompliant Template Assignment Operator That Has Generic Parameter

```
#include<cstdint>
namespace example
{
  class A          // Noncompliant
  {
    public:

      template <typename T>
      T & operator= ( T const & rhs )
      {
        if ( this != &rhs ) {
          delete i;
          i = new int32_t;
          *i = *rhs.i;
        }
        return *this;
      }
    private:
      int32_t * i;      // Member requires deep copy
  };

  void f ( A const & a1, A & a2 )
  {
    a2 = a1;
  }
};
```

Because no copy assignment operator is declared within the class, Polyspace flags `class A`. The implicitly defined copy assignment operator is not suppressed by the template assignment operator and results in a shallow copy of a1 to a2 when you might want a deep copy.

### Template Assignment Operator That Has a Generic Parameter and Copy Assignment Operator Declared

```
#include<cstdint>
namespace example
{
  class A
  {
    public:
      A & operator= (A const & rhs) {};    //Compliant

      template <typename T>
      T & operator= ( T const & rhs )      //Compliant
      {
        if ( this != &rhs ) {
          delete i;
          i = new int32_t;
          *i = *rhs.i;
        }
        return *this;
      }
    private:
      int32_t * i;
  };

  void f ( A const & a1, A & a2 )
  {
    a2 = a1;
  }
};
```

Because this class contains a copy assignment operation declaration, Polyspace does not flag `class A`.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M14-6-1

In a class template with a dependent base, any name that may be found in that dependent base shall be referred to using a qualified-id or this->

## Description

### Rule Definition

*In a class template with a dependent base, any name that may be found in that dependent base shall be referred to using a qualified-id or this->.*

### Rationale

When a class template derives from another class template, there might be confusion arising from the use of names that exist in both the base template and the current scope or namespace. When the same name exists in the base class template and a namespace that contains the classes, the scope resolution of these names is dependent on the compiler, which might be contrary to developer's expectation. To avoid confusion, use fully qualified id or `this->` to explicitly disambiguate the intended object when such a name conflict exists.

### Polyspace Implementation

Polyspace flags names for which all of these conditions are true:

- The name exists in the base class.
- The name exists in a namespace that contains the base class.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Use Fully Qualified Names in Class Templates That Have Dependent Base Classes

```
typedef signed   int          int32_t;
namespace NS0{
    typedef int32_t TYPE;

    void bar( );
    namespace NS1{
        namespace NS{

            template <typename T>
            class Base;
            template <typename T>
            class Derived : public Base<T>
            {
                void foo ( )
                {
                    TYPE t = 0;                           // Noncompliant
                    bar ( );                                // Noncompliant
                }
                void foo2 ( )
                {
                    NS0::TYPE t1 = 0;                       // Compliant
                    NS0::bar ( );                             // Compliant
                    typename Base<T>::TYPE t2 = 0; // Compliant
                    this->bar ( );                // Compliant
                }
            };
            template <typename T>
            class Base
            {
            public:
                typedef T TYPE;
                void bar ( );
            };
            template class Derived<int32_t>;
        }
    }
}
```

In this example, the names Type and bar are defined both in the namespace NS0 and within the class template Base. The class template Derived derives from Base. In Derived::foo1(), these names are used without using the fully qualified names or this->. It is not clear whether the TYPE in Base::foo1 resolves to NS0::TYPE or Base::TYPE. You might get different results depending on the implementation of the compiler. Polyspace flags these ambiguous statements.

In Derived::foo2(), TYPE and bar are invoked by using their fully qualified name or this->. By using qualified names or this->, the ambiguity in scope resolution is bypassed. Polyspace does not flag these uses.

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M15-0-3

Control shall not be transferred into a try or catch block using a goto or a switch statement

## Description

### Rule Definition

*Control shall not be transferred into a try or catch block using a goto or a switch statement.*

### Rationale

Transferring control into a `try` or `catch` block by using a `goto` or a `switch` statement results in ill-formed code that is difficult to understand. The intended behavior of such code is difficult to identify and the code might result in unexpected behavior. Abruptly entering into an exception handling block might cause compilation failure in some compilers while other compilers might not diagnose the issue. To improve code understanding and reduce unexpected behavior, avoid transferring control into a try or a catch block.

### Polyspace Implementation

Polyspace flags the `goto` and `switch` statements that jump into a `try` or a `catch` block.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Jumping into `try` or `catch` Blocks

```
#include<cstdint>
void foo ( int32_t input )
{
    if ( input==1 )
    {
        goto Label_1; // Noncompliant
    }
    if ( input==2 )
    {
        goto Label_2; // Noncompliant
    }
    switch ( input ) //Noncompliant
    {
    case 1:
        try
        {
            Label_1:
        case 2:
            break;
        }
        catch ( ... )
        {
            Label_2:
        case 3:
            break;
        }
        break;
    default:
        {
            //...
            break;
        }
    }
}
```

In this example, `goto` and `switch` statements are used to jump into a `try-catch` block. Jumping into a try-catch block makes the code difficult to understand. Abrupt transfer of control into a `try` block or a `catch` block might result in compilation failure. Polyspace flags the `goto` and `switch` statements. Such transfer of control into `try-catch` blocks might cause compilation failures.

# AUTOSAR C++14 Rule M15-1-1

The assignment-expression of a throw statement shall not itself cause an exception to be thrown

## Description

### Rule Definition

*The assignment-expression of a throw statement shall not itself cause an exception to be thrown.*

### Rationale

In C++, you can use a `throw` statement to raise exceptions explicitly. The compiler executes such a `throw` statement in two steps:

- First, it creates the argument for the `throw` statement. The compiler might call a constructor or evaluate an assignment expression to create the argument object.
- Then, it raises the created object as an exception. The compiler tries to match the exception object to a compatible handler.

If an unexpected exception is raised when the compiler is creating the expected exception in a `throw` statement, the unexpected exception is raised instead of the expected one. Consider this code where a `throw` statement raises an explicit exception of class `myException`.

```
class myException{
    myException(){
        msg = new char[10];
        //...
    }
    //...
};

foo(){
    try{
        //..
        throw myException();
    }
    catch(myException& e){
        //...
    }
}
```

During construction of the temporary `myException` object, the `new` operator can raise a `bad_alloc` exception. In such a case, the `throw` statement raises a `bad_alloc` exception instead of `myException`. Because `myException` was the expected exception, the catch block is incompatible with `bad_alloc`. The `bad_alloc` exception becomes an unhandled exception. It might cause the program to abort abnormally without unwinding the stack, leading to resource leak and security vulnerabilities.

Unexpected exceptions arising from the argument of a `throw` statement can cause resource leaks and security vulnerabilities. To prevent such unwanted outcome, avoid using expressions that might raise exceptions as argument in a `throw` statement.

### Polyspace Implementation

Polyspace flags the expressions in `throw` statements that can raise an exception. Expressions that can raise exceptions can include:

- Functions that are specified as `noexcept(false)`
- Functions that contain one or more explicit `throw` statements
- Constructors that perform memory allocation operations
- Expressions that involve dynamic casting

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Expressions That Can Raise Exceptions in `throw` Statements

This example shows how Polyspace flags the expressions in `throw` statements that can raise unexpected exceptions.

```
int f_throw() noexcept(false);

class WithDynamicAlloc {
public:
    WithDynamicAlloc(int n) {
        m_data = new int[n];
    }
    ~WithDynamicAlloc() {
        delete[] m_data;
    }
private:
    int* m_data;
};

class MightThrow {
public:
    MightThrow(bool b) {
        if (b) {
            throw 42;
        }
    }
};

class Base {
    virtual void bar() =0;
};
class Derived: public Base {
    void bar();
};
class UsingDerived {
public:
    UsingDerived(const Base& b) {
        m_d =
        dynamic_cast<const Derived&>(b);
    }
private:
    Derived m_d;
};
class CopyThrows {
public:
    CopyThrows() noexcept(true);
    CopyThrows(const CopyThrows& other) noexcept(false);
};
int foo(){
    try{
        //...
        throw WithDynamicAlloc(10); //Noncompliant
        //...
        throw MightThrow(false);//Noncompliant
        throw MightThrow(true);//Noncompliant
        //...
        Derived d;
        throw  UsingDerived(d);// Noncompliant
        //...
        throw f_throw(); //Noncompliant
        CopyThrows except;
        throw except;//Noncompliant
    }
    catch(WithDynamicAlloc& e){
        //...
    }
    catch(MightThrow& e){
        //...
    }
    catch(UsingDerived& e){
        //...
    }
}
```

- When constructing a `WithDyamicAlloc` object by calling the constructor `WithDynamicAlloc(10)`, exceptions can be raised during dynamic memory allocation. Because the expression `WithDynamicAlloc(10)` can raise an exception, Polyspace flags the `throw` statement `throw WithDynamicAlloc(10);`
- When constructing a `UsingDerived` object by calling the constructor `UsingDervide()`, exceptions can be raised during the dynamic casting operation. Because the expression `UsingDerived(d)` can raise exceptions, Polyspace flags the statement `throw UsingDerived(d)`.
- In the function `MightThrow()`, exceptions can be raised depending on the input to the function. Because Polyspace analyzes functions statically, it assumes that the function `MightThrow()` can raise exceptions. Polyspace flags the statements `throw MightThrow(false)` and `throw MightThrow(true)`.
- In the statement `throw except`, the object `except` is copied by implicitly calling the copy constructor of the class `CopyThrows`. Because the copy constructor is specified as `noexcept(false)`, Polyspace assumes that the copy operation might raise exceptions. Polyspace flags the statement `throw except`.
- Because the function `f_throw()` is specified as `noexcept(false)`, Polyspace assumes that it can raise exceptions. Polyspace flags the statement `throw f_throw()`.

# AUTOSAR C++14 Rule M15-1-2

NULL shall not be thrown explicitly

## Description

### Rule Definition

*NULL shall not be thrown explicitly.*

### Rationale

The macro `NULL` is commonly used to refer to null pointers. Compliers interpret `NULL` as an integer with value zero, instead of a pointer. When you use `NULL` explicitly in a `throw` statement, you might expect the statement to raise a pointer type exception. The `throw(NULL)` is equivalent to `throw(0)` and raises an integer exception. This behavior might be contrary to developer expectation and might result in bugs that are difficult to find. Avoid using `NULL` explicitly in a `throw` statement.

### Polyspace Implementation

Polyspace flags a `throw` statement that raises a `NULL` explicitly. Polyspace does not flag the statement when `NULL` is raised after casting to a specific type or assigning it to a pointer type.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Do Not Throw `NULL` Explicitly

```
typedef          char         char_t;
typedef signed   int          int32_t;

#include <cstddef>

void foo()
{
    try {
        char_t * p1 = NULL;
        throw ( NULL );            // Noncompliant
        throw(p1); //Compliant
        throw ( static_cast < const char_t * > ( NULL ) ); // Compliant
    } catch ( int32_t i ) {        // NULL exception handled here
        // /*...*/
    } catch ( const char_t * ) { // Other two exceptions are handled here
        // /*...*/
    }
}
```

In this example, three exceptions are raised directly by using `throw` statements.

- Polyspace flags the statement `throw(NULL)` because it explicitly raises `NULL` as exception. You might expect that this statement raises a pointer type exception that is handled in the second `catch` block. This statement actually raises an `int` exception that is handled in the first `catch` block.
- The other `throw` statements show the compliant method of using `NULL` in a `throw` statement. For instance, the second `throw` statement raises a `char*` that is assigned the value `NULL`. The third `throw` statement raises a `char*` by casting `NULL` to a `char*`. Because these statements do not raise `NULL` explicitly, Polyspace does not flag them.

# AUTOSAR C++14 Rule M15-1-3

An empty throw (throw;) shall only be used in the compound statement of a catch handler

## Description

### Rule Definition

*An empty throw (throw;) shall only be used in the compound statement of a catch handler.*

### Rationale

When you use an empty throw statement `(throw;)`, the compiler checks if an exception object is present in the current scope. If the current scope contains an exception object, the compiler raises a temporary object containing the current exception. If the current scope does not contain an exception objects, the compiler invokes `std::terminate()` implicitly. The function `std::terminate()` terminates the program execution in an implementation-defined manner. That is, the exact process of program termination depends on the software and hardware that you are using. For instance, `std:terminate()` might invoke `std::abort()` to abnormally abort the execution without unwinding the stack, leading to resource leak and security vulnerabilities.

The best practice is to use an empty throw statement only in the `catch` block of a `try-catch` construct, which enables you to spread the handling of an exception across multiple catch blocks. Avoid using empty throw statements in scopes that might not contain an exception.

### Polyspace Implementation

Polyspace flags an empty throw statement if it is not within a catch block.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using Empty `throw` Statements Outside `catch` Blocks

```
#include <iostream>
#include <typeinfo>
#include <exception>

void handleException()//function to handle all exception
{
    try {
        throw; // Noncompliant
    }
    catch (std::bad_cast& e) {
        //...Handle bad_cast...
    }
    catch (std::bad_alloc& e) {
        //...Handle bad_alloc...
    }
    catch(...){
        //...Handle other exceptions
    }
}

void f()
{
    try {
        //...something that might throw...
    }
    catch (...) {
        handleException();
    }
}
```

In this example, the function `handleException()` raises the current exception by using an empty throw statement, and then directs it to the appropriate `catch` block. This method of delegating the exception handling works as intended only when the function `handleException()` is called from within a `catch` block. The empty throw statement might cause abrupt termination of the program if the function is called in any other scope that does not contain an exception. Polyspace flags the empty throw statement.

#### Use Empty `throw` Statement to Handle Exceptions in Multiple Blocks

```
#include <iostream>
#include <typeinfo>
#include <exception>
void foo()//function to handle all exception
{
    try {
        //...
    }
    catch (std::bad_cast& e) {
        //...Handle bad_cast...
    }
    catch (std::bad_alloc& e) {
        //...Handle bad_alloc...
    }
    catch(std::exception& e){
        //...Handle std::exceptions
        // if exception cannot be handled
        // throw it again
        throw;//Compliant
    }
}

int main(){
    try{
        foo();
    }
    catch(...){

    }
}
```

This example shows a compliant use of an empty throw statement. The function `foo` contains a `try-catch` construct that handles specific exceptions. If the raised exception cannot be handled, `foo` raises the exception again as an unhandled exception by using an empty throw statement. In `main`, the function `foo` is invoked and any unhandled exception arising from `foo` is handled in a generic `catch(...)` block. By using the empty throw statement, the handling of the exception is spread across the catch blocks of `foo` and `main`. In this case, the empty throw statement is executed only when there is an exception in the same scope because it is within a `catch` block. Polyspace does not flag it.

# AUTOSAR C++14 Rule M15-3-1

Exceptions shall be raised only after start-up and before termination

## Description

### Rule Definition

*Exceptions shall be raised only after start-up and before termination.*

### Rationale

In C++, the process of exception handling runs during execution of `main()`, where exceptions arising in different scopes are handled by exception handlers in the same or adjacent scopes. Before starting the execution of `main()`, the compiler is in startup phase, and after finishing the execution of `main()`, the compiler is in termination phase. During these two phases, the compiler performs a set of predefined operations but does not execute any code.

If an exception is raised during either the startup phase or the termination phase, you cannot write an exception handler that the compiler can execute in those phases. For instance, you might implement `main()` as a `function-try-catch` block to handle exceptions. The `catch` blocks in `main()` can handle only the exceptions raised in `main()`. None of the `catch` blocks can handle exceptions raised during startup or termination phase. When such exceptions are raised, the compiler might abnormally terminate the code execution without unwinding the stack. Consider this code where the construction and destruction of the static object `obj` might cause an exception.

```
class A{
    A(){throw(0);}
    ~A(){throw(0)}
};

static A obj;

main(){
    //...
}
```

The static object `obj` is constructed by calling `A()` before `main()` starts, and it is destroyed by calling `~A()` after `main()` ends. When `A()` or `~A()` raises an exception, an exception handler cannot be matched with them. Based on the implementation, such an exception can result in program termination without stack unwinding, leading to memory leak and security vulnerabilities.

Avoid operations that might raise an exception in the parts of your code that might be executed before startup or after termination of the program. For instance, avoid operations that might raise exceptions in the constructor and destructor of static or global objects.

### Polyspace Implementation

Polyspace flags a global or a a static variable declaration that uses a callable entity that might raise an exception. For instance:

- Function: When you call an initializer function or constructor directly to initialize a global or static variable, Polyspace checks whether the function raises an exception and flags the variable declaration if the function might raise an exception. Polyspace deduces whether a function might raise an exception regardless of its exception specification. For instance, if a `noexcept` constructor raises an exception, Polyspace flags it. If the initializer or constructor calls another function, Polyspace assumes the called function might raise an exception only if it is specified as `noexcept(<false>)`. Some standard library functions, such as the constructor of `std::string`, use pointers to functions to perform memory allocation, which might raise exceptions. Polyspace does not flag the variable declaration when these functions are used.

- External function: When you call external functions to initialize a global or static variable, Polyspace flags the declaration if the external function is specified as `noexcept(<false>)`.
- Virtual function: When you call a virtual function to initialize a global or static variable, Polyspace flags it if the virtual function is specified as `noexcept(<false>)` in any derived class. For instance, if you use a virtual initializer function that is declared as `noexcept(<true>)` in the base class, and `noexcept(<false>)` in a subsequent derived class, Polyspace flags it.
- Pointers to function: When you use a pointer to a function to initialize a global or static variable, Polyspace assumes that pointer to a function do not raise exceptions.

Polyspace ignores:

- Exceptions raised in destructors
- Exceptions raised in `atexit()` operations

Polyspace also ignores the dynamic context when checking for exceptions. For instance, you might initialize a global or static variable by using a function that raises exceptions only in a certain dynamic context. Polyspace flags such a declaration even if the exception might never be raised. You can justify such a violation by using comments in Polyspace.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Exceptions Before `main()` Starts

This example shows how Polyspace flags construction or initialization of a global or static variable that might raise an exception. Consider this code where static and global objects are initialized by using various callable entities.

```
#include <stdexcept>
#include <string>
class C
{
public:
    C ( ){throw ( 0 );}
    ~C ( ){throw ( 0 );}
};
int LibraryFunc();
int LibraryFunc_noexcept_false() noexcept(false);
int LibraryFunc_noexcept_true() noexcept(true);
int  g() noexcept {
    throw std::runtime_error("dead code");
    return 0;
}
int f() noexcept {
    return g();
}
int init(int a) {
    if (a>10) {
        throw std::runtime_error("invalid case");
    }
    return a;
}
void* alloc(size_t s) noexcept {
    return new int[s];
}
int a = LibraryFunc() +
LibraryFunc_noexcept_true();            // Compliant
int global_int =
LibraryFunc_noexcept_false() +          // Noncompliant
LibraryFunc_noexcept_true();
static C static_c;                      //Noncompliant
static C static_d;                      //Compliant
C &get_static_c(){
    return static_c;
}
C global_c;                             //Noncompliant
int a3 = f();                           //Compliant
int b3 = g();                           //Noncompliant
int a4 = init(5);                       //Noncompliant
int b5 = init(20);                      //Noncompliant
int* arr = (int*)alloc(5);              //Noncompliant

int main(){
    //...
}
```

- The global pointer `arr` is initialized by using the function `alloc()`. Because `alloc()` uses `new` to allocate memory, it can raise an exception when initializing `arr` during the startup of the program. Polyspace flags the declaration of `arr` and highlights the use of `new` in the function `alloc()`.
- The integer variable `b3` is initialized by calling the function `g()`, which is specified as `noexcept`. Polyspace deduces that the correct exception specification of `g()` is `noexcept(false)` because it contains a `throw()` statement. Initializing the global variable `b3` by using `g()` might raise an exception when initializing `arr` during the startup of the program. Polyspace flags the declaration of `b3` and highlights the `throw` statement in `g()`. The declaration of `a3` by calling `f()` is not flagged. Because `f()` is a `noexcept` function that does not throw, and calls another `noexcept` function, Polyspace deduces that `f()` does not raise an exception.
- The global variables `a4` and `b5` are initialized by calling the function `init()`. The function `init()` might raise an exception in certain cases, depending on the context. Because Polyspace deduces the exception specification of a function statically, it assumes that `init()` might raise an exception regardless of context. Consequently, Polyspace flags the declarations of both `a4` and `b5`, even though `init()` raises an exception only when initializing `b5`.
- The global variable `global_int` is initialized by calling two external functions. The external function `LibraryFunc_noexcept_false()` is specified as `noexcept(false)` and Polyspace assumes that this external function might raise an exception. Polyspace flags the declaration of `global_int`. Polyspace does not flag the declaration of `a` because it is initialized by calling external functions that are not specified as `noexcept(false)`.

- The static variable `static_c` and the nonstatic global variable `global_c`is declared and initialized by using the constructor of the class `C`, which might raise an exception. Polyspace flags the declarations of these variables and highlights the `throw()` statement in the constructor of class `C`. Polyspace does not flag the declaration of the unused static variable `static_d`, even though its constructor might raise an exception. Because it is unused, `static_d` is not initialized and its constructor is not called. Its declaration does not raise any exception.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M15-3-3

Handlers of a function-try-block implementation of a class constructor or destructor shall not reference non-static members from this class or its bases

## Description

### Rule Definition

*Handlers of a function-try-block implementation of a class constructor or destructor shall not reference non-static members from this class or its bases.*

### Rationale

The handler `catch` blocks of a function `try` block handle exception that are raised from the body of the function and the initializer list. When used in class constructors and destructors, these `catch` blocks might handle exceptions that arise during the creation or destruction of the class nonstatic members. That is, the `catch` blocks might be executed before or after the lifetime of the nonstatic members of a class. If the nonstatic members of a class are accessed in such `catch` blocks, the compiler might attempt to access objects that are not created yet or already deleted, which is undefined behavior. For instance:

```
class C{

    private:
    int* inptr_x;
    public:
    C() try: inptr_x(new int){}
    catch(...){
        intptr_x = nullptr;
        //...
    }
};
```

Here, the constructor of `C` is implemented by using a function `try` block to handle any exception arising from the memory allocation operation in the initializer list. In the `catch` block of this function-`try` block, the class member `C.intptr_x` is accessed. The catch block executes when the memory allocation for `intptr_x` failed. That is, the catch block attempts to access the member before its lifetime, which is undefined behavior.

To avoid undefined behavior, avoid using the nonstatic data members or base classes of an object in the catch block of the function-try-block implementation of its constructors and destructor.

### Polyspace Implementation

If a statement in the catch block of a constructor or destructor function-`try` block accesses any of these, Polyspace flags the statement:

- The nonstatic members of the object
- The base classes of the object
- The nonstatic members of the base classes

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Accessing Nonstatic Members of Classes in `function-try` `catch` Blocks

```
#include<cstdint>
class B
{
public:
    B ( ) try: x(0){/*...*/}
    catch ( ... )
    {
        if ( 0 == x ){/*...*/}  //Noncompliant
        //...
    }
    ~B ( ) try{/*...*/}
    catch ( ... )
    {
        if ( 0 == x ){/*...*/} //Noncompliant
        //...
        else if (sb == 1){/*...*/} //Compliant
        //....
    }
public:
    static int32_t sb;
protected:
    int32_t x;
};

class D : public B
{
public:
    D ( ) try: B(),y{0}{/*...*/}
    catch ( ... )
    {
        if ( 0 == x ){/*...*/}  //Noncompliant
        //...
        else if (y == 1){/*...*/}   //Noncompliant
        //...
    }
    ~D ( )try {/*...*/}
    catch ( ... )
    {
        if ( 0 == x ) {/*...*/} //Noncompliant
        //...
    }
protected:
    int32_t y;
};
```

In this example, the constructors and destructors of `B` and `D` are implemented by using function-try blocks. The `catch` blocks of these function-`try` blocks access the nonstatic members of the class and its base class. Polyspace flags accessing these nonstatic members in the `catch` blocks. Because the lifetime of `static` members is greater than the lifetime of the object itself, Polyspace does not flag accessing `static` objects in these `catch` blocks.

# AUTOSAR C++14 Rule M15-3-4

Each exception explicitly thrown in the code shall have a handler of a compatible type in all call paths that could lead to that point

## Description

### Rule Definition

*Each exception explicitly thrown in the code shall have a handler of a compatible type in all call paths that could lead to that point.*

### Rationale

In C++, when an operation raises an exception, the compiler tries to match the exception with a compatible exception handler in the current and adjacent scopes. If no compatible exception handler for a raised exception exists, the compiler invokes the function `std::terminate()` implicitly. The function `std::terminate()` terminates the program execution in an implementation-defined manner. That is, the exact process of program termination depends on the particular set of software and hardware that you use. For instance, `std::terminate()` might invoke `std::abort()` to abnormally abort the execution without unwinding the stack. If the stack is not unwound before program termination, then the destructors of the variables in the stack are not invoked, leading to resource leak and security vulnerabilities.

Consider this code where multiple exceptions are raised in the try block of code.

```
class General{/*...  */};
class Specific : public General{/*...*/};
class Different{}
void foo() noexcept
{
    try{
        //...
        throw(General e);
        //..
        throw( Specific e);
        // ...
        throw(Different e);
    }
    catch (General& b){

    }
}
```

The catch block of code accepts references to the base class `General`. This catch block is compatible with exceptions of the base class `General` and the derived class `Specific`. The exception of class `Different` does not have a compatible handler. This unhandled exception violates this rule and might result in resource leaks and security vulnerabilities.

Because unhandled exceptions can lead to resource leak and security vulnerabilities, match the explicitly raised exceptions in your code with a compatible handler.

### Polyspace Implementation

- Polyspace flags a `throw` statement in a function if a compatible catch statement is absent in the call path of the function. If the function is not specified as `noexcept`, Polyspace ignores it if its call path lacks an entry point like `main()`.
- Polyspace flags a `throw` statement that uses a `catch(…)` statement to handle the raised exceptions.
- Polyspace does not flag rethrow statements, that is, `throw` statements within catch blocks.
- You might have compatible catch blocks for the `throw` statements in your function in a nested try-catch block Polyspace ignores nested try-catch blocks. Justify `throw` statements that have compatible catch blocks in a nested structure by using comments. Alternatively, use a single level of try-catch in your functions.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Match `throw` Statements with Compatible Catch Blocks

This example shows how Polyspace flags operations that raise exceptions without any compatible handler. Consider this code.

```
#include <stdexcept>

class MyException : public std::runtime_error {
public:
    MyException() : std::runtime_error("MyException") {}
};

void ThrowingFunc() {
    throw MyException(); //Noncompliant
}

void CompliantCaller() {
    try {
        ThrowingFunc();
    } catch (std::exception& e) {
        /* ... */
    }
}

void NoncompliantCaller() {
    ThrowingFunc();
}

int main(void) {
    CompliantCaller();
    NoncompliantCaller();
}

void GenericHandler() {
    try {
        throw MyException(); //Noncompliant
    } catch (...) {
        /* ... */
    }
}

void TrueNoexcept() noexcept {
    try {
        throw MyException();//Compliant
    } catch (std::exception& e) {
        /* ... */
    }
}

void NotNoexcept() noexcept {
    try {
        throw MyException(); //Noncompliant
    } catch (std::logic_error& e) {
        /* ... */
    }
}
```

- The function `ThrowingFunc()` raises an exception. This function has multiple call paths:

  - `main()->CompliantCaller()->ThrowingFunc()`: In this call path, the function `CompliantCaller()` has a catch block that is compatible with the exception raised by `ThrowingFunc()`. This call path is compliant with the rule.
  - `main()->NoncompliantCaller()->ThrowingFunc()`: In this call path, there are no compatible handlers for the exception raised by `ThrowingFunc()`. Polyspace flags the `throw` statement in `ThrowingFunc()` and highlights the call path in the code.

  The function `main()` is the entry point for both of these call paths. If `main()` is commented out, Polyspace ignores both of these call paths. If you want to analyze a call path that lacks an entry point, specify the top most calling function as `noexcept`.
- The function `GenericHandler()` raises an exception by using a `throw` statement and handles the raised exception by using a generic catch-all block. Because Polyspace considers such catch-all handler to be incompatible with exceptions that are raised by explicit `throw` statements, Polyspace flags the `throw` statement in `GenericHandler()`.
- The `noexcept` function `TrueNoexcept()` contains an explicit `throw`statement and a catch block of compatible type. Because this `throw` statement is matched with a compatible `catch` block, it is compliant with the rule.
- The `noexcept` function `NotNoexcept()` contains an explicit `throw` statement, but the catch block is not compatible with the raised exception. Because this `throw` statement is not matched with a compatible catch block, Polyspace flags the `throw` statement in `NotNoexcept()`.

# AUTOSAR C++14 Rule M15-3-6

Where multiple handlers are provided in a single try-catch statement or function-try-block for a derived class and some or all of its bases, the handlers shall be ordered most-derived to base class

## Description

### Rule Definition

*Where multiple handlers are provided in a single try-catch statement or function-try-block for a derived class and some or all of its bases, the handlers shall be ordered most-derived to base class.*

### Rationale

In a `try-catch` or `function-try` block, exception objects of a derived class match to handler `catch` blocks that accept the base class. If you place handlers of the base exception class before handlers of the derived exception class, the base class handler handles both base and derived class exceptions. The derived class handler becomes unreachable code, which is unexpected behavior. When using a class hierarchy to raise exceptions, make sure that the handler of a derived class precedes the handler of a base class.

### Polyspace Implementation

Polyspace flags a handler block if it follows a handler of a base class.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Order Handler Blocks from most Derived to Base Class

```
#include<exception>
// classes used for exception handling
class MathError { };
class NotANumber: public MathError { };
class DivideByZero: public NotANumber{};

void bar(void){
    try
    {
        // ...
    }
    catch ( MathError &e )
    {
        // ...
    }
    catch ( NotANumber &nan ) // Noncompliant
    {
        // Unreachable Code
    }
    catch (DivideByZero &dbz)//Noncompliant
    {
        //Unreachable Code
    }
}
```

In this example, three classes in a hierarchy might arise in the `try` block. The handler `catch` blocks handle the exceptions.

- The block `catch ( NotANumber &nan )` follows the handler of its base class `catch ( MathError &e )`. Because the exception of class `NotANumber` also matches to the handler `catch ( MathError &e )`, the handler block `catch ( NotANumber &nan )` becomes unreachable code. The order of this block is noncompliant with this rule. Polyspace flags the handler block.
- The block `catch ( DivideByZero &dbz )` becomes unreachable code because exceptions of the class `DivideByZero` match to the preceding handlers of its base classes. Polyspace flags the handler block `catch ( DivideByZero &dbz )`.

# AUTOSAR C++14 Rule M15-3-7

Where multiple handlers are provided in a single try-catch statement or function-try-block, any ellipsis (catch-all) handler shall occur last

## Description

### Rule Definition

*Where multiple handlers are provided in a single try-catch statement or function-try-block, any ellipsis (catch-all) handler shall occur last.*

### Rationale

In a try-catch statement or function-try block, the compiler matches the raised exception with a `catch()` handler. The `catch(…)` handler matches any exception. Handlers after the catch-all handler within the same try-catch statement or function try-block are ignored by the compiler during the exception handling process and are unreachable code.

Having a handler after the catch-all handler might result in developer confusion as to why certain intended handlers are not being executed. Likewise, the catch-all handler might not handle the exception in the way the developer intends, resulting in confusion.

### Polyspace Implementation

Polyspace raises this defect whenever a handler appears after the catch-all handler within the try-catch statement or function try-block.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Handlers After the Catch-All Handler Are Noncompliant

```
#include <iostream>
#include <exception>

using namespace std;

int main() {

    try {
        // some code
    } catch (exception& e1) { // Compliant

        //...

    } catch (...) { // Compliant

        //...
    } catch (exception& e2) { // Noncompliant

        //...
    }

    return 0;
}
```

Because the `catch (exception& e2)` handler comes after the `catch(…)` handler, Polyspace flags the handler before the catch-all handler as noncompliant. This issue might cause a compilation error.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M16-0-1

#include directives in a file shall only be preceded by other preprocessor directives or comments

## Description

### Rule Definition

*#include directives in a file shall only be preceded by other preprocessor directives or comments.*

### Rationale

Grouping all #include preprocessor directives at the beginning of the file makes the code more readable. #include directives might include header files where macros are defined. If you use such a macro before including its definition, you might encounter unexpected code behavior.

### Polyspace Implementation

Polyspace raises this defect when an `#include` directive comes after any code that is not a comment or preprocessor directive. Polyspace does not report a violation of this rule when an `#include` directive is located within an `extern "C"` block.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### #include Directive Preceded by Noncompliant Code

```
//this comment is compliant     //Compliant
/*
    This comment is compliant
*/

#ifndef TESTING_H               //Compliant
#define TESTING_H               //Compliant

#include <iostream>             //Compliant
using namespace std;            //Compliant
#include <exception>            //Noncompliant

#endif
```

Because an include directive follows a code statement that is neither a preprocessor directive nor a comment, `Polyspace` flags the include directive.

# AUTOSAR C++14 Rule M16-0-2

Macros shall only be #define'd or #undef'd in the global namespace

## Description

### Rule Definition

*Macros shall only be #define'd or #undef'd in the global namespace.*

### Rationale

If you define or undefine macros in a local namespace, you might expect the macro to be valid only in the local namespace. But macros do not follow the scoping mechanism. Instead, the compiler replaces all occurrences of a macro by its defined value beginning at the `#define` statement until the end of file or until the macro is redefined. This behavior of macros might be contrary to developer expectation and might cause logic errors that result in bugs.

### Polyspace Implementation

Polyspace flags a `#define` or `#undef` statement that is placed within a block instead of in the global namespace.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Macros in Local Namespaces

```
#include<cstdlib>
#define HCUT 1
namespace unnormalized{
    #define HCUT 6582 //Noncompliant
    void foo(){
        //...
    }
};
void bar(){
    int intEnergy = HCUT*10;
    //HCUT is 6582, you might expect HCUT=1;
}

namespace uniteV{
    const double hcut = 6582; //eV
    void foo(){

    }
};
```

In this example, different values of `HCUT` are defined, perhaps to accommodate code written by using different systems of unit. You might expect the definition of `HCUT` in the namespace `unnormalized` to remain limited to the namespace. But the value of HCUT remains 6582 until the end of file. For instance, in the function bar, you might expect that HCUT is one, but the value of HCUT remains 6582, which might cause logic error, unexpected results, and bugs. Polyspace flags the #define statement within the local namespace.

To implement constants that might have different values in different scopes, use const variables, as shown in the namespace uniteV. Avoid using macros to represent constants that might require different values in different scopes.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M16-0-5

Arguments to a function-like macro shall not contain tokens that look like pre-processing directives

## Description

### Rule Definition

*Arguments to a function-like macro shall not contain tokens that look like pre-processing directives.*

### Rationale

When a compiler encounters function-like macros, it replaces the argument of the macro into the replacement code. If the argument contains a token that looks like preprocessing directives, the replacement process during macro expansion is undefined. Depending on the environment, such a function-like macro might behave in unexpected ways, leading to errors and bugs.

### Polyspace Implementation

Polyspace flags calls to function-like macros if their argument starts with the character #.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Avoid Arguments That Start with # in Function-Like Macros

```
#include<cstdlib>
#include<iostream>
#define PRINT(ARG) std::cout<<#ARG
//....
#define Error1
//...

void foo(void){
    PRINT(
    #ifdef Error1  //Noncompliant
    "Error 1"
    #else    //Noncompliant
    "Error 2"
    #endif
    );

}
```

In this example, the function-like macro `PRINT` is invoked with an argument that chooses between two strings by using an `#ifdef` block. Depending on the environment, the output of this code might be `#ifdef Error1 //Noncompliant "Error 1" #else "Error 2" #endif // Noncompliant` or `Error 1`. Polyspace flags the arguments that start with the character #.

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M16-0-6

In the definition of a function-like macro, each instance of a parameter shall be enclosed in parentheses, unless it is used as the operand of # or ##

## Description

### Rule Definition

*In the definition of a function-like macro, each instance of a parameter shall be enclosed in parentheses, unless it is used as the operand of # or ##.*

### Rationale

When you invoke function-like macros, the compiler expands the macro by replacing its parameters with the tokens. Then the compiler substitutes the expanded macro into the code. This expansion and substitution process does not take precedence of operation into account. The function-like macros might produce unexpected results if their parameters are not enclosed in parenthesis. For instance, consider this function-like macro:

```
#define dustance_from_ten(x) x>10? x-10:10-x
```

The macro is intended to measure the distance of a number from ten. When you invoke the macro with the argument (a-b), the macro expands to:

```
a-b>10: a-b-10:10-a-b
```

The expression `10-a-b` is equivalent to `10-(a+b)` instead of the intended distance `10-(a-b)`. This unexpected behavior might result in errors and bugs. To avoid such unexpected behaviors, enclose parameters of a function-like macro in parentheses.

The exception to this rule is when a parameter is used as an operand of # or ##.

### Polyspace Implementation

Polyspace flags function-like macro definitions if the parameters are not enclosed in parenthesis. Polyspace does not flag unparenthesized parameters if they are preceded by the operators `.`, `->`, or the characters #, ##.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Enclose Parameters of Function-Like Macros in Parentheses

```
#include<iostream>
#include<cmath>
#define abs(x) (x>0) ? x:-x //Noncompliant

double foo(double num1, double num2){
    return log(abs(num1-num2));
}

int main(){
    std::cout<<foo(10,10.5);
}
```

In this example, when you invoke `foo(10,10.5)`, you might expect the output to be `log(0.5)` or `-0.69`. Because the parameters of `abs` are not enclosed in parentheses, the output becomes `log(-20.5)` or `NaN`, which is unexpected and might lead to bugs. Polyspace flags the function-like macro definition.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M16-0-7

Undefined macro identifiers shall not be used in #if or #elif pre-processor directives, except as operands to the defined operator

## Description

### Rule Definition

*Undefined macro identifiers shall not be used in #if or #elif pre-processor directives, except as operands to the defined operator.*

### Rationale

If you attempt to use a macro identifier in a preprocessing directive, and you have not defined that identifier, then the preprocessor assumes that it has a value of zero. This value might not meet developer expectations.

### Polyspace Implementation

Polyspace flags an `#if` or `#elif` statement if it uses an undefined macro identifier.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see "Diagnose Why Coding Standard Violations Do Not Appear as Expected".

## Examples

### Macro Identifiers

```
#if M == 0           //Noncompliant
#endif

#if defined (M)      //Complaint
#if M == 0           //Executes only when M is defined
#endif
#endif

#if defined (M) && (M == 0)  //Compliant
//...
#endif
```

This example shows various uses of `M` in preprocessing directives:

- The first `#if` clause uses the undefined identifier `M`. Because `M` is undefined when this preprocessor directive is evaluated, the compiler assumes that `M` is zero, which results in unexpected results. Such a use of undefined identifiers is not compliant with this rule. Polyspace flags the `#if` statement.
- The second and third `#if` statements use the undefined identifier `M` as the operand to the `defined` operator. These use of undefined identifiers are compliant with this rule.

### Topics

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M16-0-8

If the # token appears as the first token on a line, then it shall be immediately followed by a preprocessing token

## Description

### Rule Definition

*If the # token appears as the first token on a line, then it shall be immediately followed by a preprocessing token.*

### Rationale

The # character precedes a preprocessor directive when it is the first character on a line. If the # character is not immediately followed by a preprocessor directive, the preprocessor directive might be malformed.

Preprocessor directives might be used to exclude portions of code from compilation. The compiler excludes code until it encounters an #else, #elif, or #endif preprocessor directive. If one of those preprocessor directives is malformed, the compiler continues excluding code beyond the intended end point, resulting in bugs and unexpected behavior which can be difficult to diagnose.

Avoid malformed preprocessor directives by placing the preprocessor token directly after a # token. Specifically, do not place any characters other than white space between the # token and preprocessor token in #else and #endif directives.

### Polyspace Implementation

Polyspace raises this defect when the # character is followed by any character that is not part of a properly formed preprocessor token. A preprocessor token that is preceded or followed by any character other than white space causes Polyspace to raise this defect. Polyspace raises this defect when a preprocessor token is badly formed due to misspelling or improper capitalization.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Poorly Formed Preprocessor Tokens Following # Character

```
#define TESTING_H       //Compliant

namespace Example
{
#ifndef TESTING_H       //Compliant
    // code here
#elseX;                 //Noncompliant
    // code here
#else;                  //Compliant
```

```
    // code here
#endnif                 //Noncompliant
    // code here

};
```

Because `elseX` is not a preprocessor directive and follows directly after the # character, Polyspace flags it as noncompliant.

`#endnif` is not a properly formed preprocessor directive. Polyspace flags it as noncompliant.

`#define TESTING_H`, `#ifndef TESTING_H`, and `#else` are properly formed preprocessor conditionals and are compliant with this rule.

# AUTOSAR C++14 Rule M16-1-1

The defined pre-processor operator shall only be used in one of the two standard forms

## Description

### Rule Definition

*The defined pre-processor operator shall only be used in one of the two standard forms.*

### Rationale

The `defined` preprocessor operator checks whether an identifier is defined as a macro. In C, the only two permissible forms for this operator are:

- `defined (identifier)`
- `defined identifier`

Using any other form results in invalid code that compiler might not report. For instance, if you use expressions as arguments for the `defined` operator, the code is invalid. If the compiler does not report the invalid usage of `defined`, diagnosing the invalid code is difficult.

If your `#if` or similar preprocessor directives expand to create a `defined` statement, the code behavior is undefined. For instance:

```
#define DEFINED defined
#if DEFINED(X)
```

The `#if` preprocessor directive expands to form a `defined` operation. Depending on your environment, the code might behave in unexpected ways, leading to bugs that are difficult to diagnose.

To avoid invalid code, bugs, and undefined behavior, use only the permitted forms when using the `defined` operator.

### Polyspace Implementation

Polyspace flags incorrect usages of the `defined` operator, such as:

- The operator `defined` is used without an identifier.
- The operator `defined` appears after macro expansion.
- The operator `defined` is used with a complex expression.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use `defined` Operators With Identifiers

```
#if defined (X<Y)//Noncompliant
//...
#endif
#if defined (X) && defined (Y) &&(X<Y)//Compliant
//...
#endif
```

In this example, a block of code is conditionally executed only if the identifiers X and Y are defined and if X is smaller than Y. Constructing this condition by using an expression as the argument for the `defined` operator is not permissible and results in invalid code. Polyspace flags the impermissible `defined` statement. The permissible way to define such a condition is to use individual identifiers with `defined`.

### Topics

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M16-1-2

All #else, #elif and #endif pre-processor directives shall reside in the same file as the #if or #ifdef directive to which they are related

## Description

### Rule Definition

*All #else, #elif and #endif pre-processor directives shall reside in the same file as the #if or #ifdef directive to which they are related.*

### Rationale

You use preprocessor directives, such as `#if...#elif...#else...#endif`, to conditionally include or exclude blocks of code. If the different branches of such a directive reside in different source files, the code can be confusing. If all the branches are not included in a project, the code might behave in unexpected ways. To avoid confusion and unexpected behavior, keep the branches of a conditional preprocessor directive within the same source file.

### Polyspace Implementation

Polyspace raises a violation of this rule if either of these conditions are true:

- A corresponding `#if` directive cannot be found within a source file for every `#else`, `#elif`, or `#endif` directive.
- A corresponding `#endif` directive cannot be found within a source file for every `#if` directive.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Incomplete Conditional Preprocessor Directives

```
>//file1.h
#if !defined (FILE)
//.....
#elif //Noncompliant
//...///
```

```
//file2.h
#else //Noncompliant
//...
#endif //Noncompliant
///
```

In this example, a conditional directive is split across two source files.

- In `file1.h`, the `#if` directive has no corresponding `#endif` directive. Polyspace flags the block.

- In `file2.h`, the `#else` and `#endif` directives have no corresponding `#if` directive. Polyspace flags both directives.

### Check Information

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M16-2-3

Include guards shall be provided

## Description

### Rule Definition

*Include guards shall be provided.*

### Rationale

When a translation unit contains a complex hierarchy of nested header files, it is possible for a particular header file to be included more than once, leading to confusion. If this multiple inclusion produces multiple or conflicting definitions, then your program can have undefined or erroneous behavior.

For instance, suppose that a header file contains:

```
#ifdef _WIN64
   int env_var;
#elseif
   long int env_var;
#endif
```

If the header file is contained in two inclusion paths, one that defines the macro `_WIN64` and another that undefines it, you can have conflicting definitions of `env_var`.

To avoid multiple inclusion of the same file, add include guards to the beginning of header files. Use either of these formats:

-
  ```
  <start-of-file>
  // Comments allowed here
  #if !defined ( identifier )
  #define identifier
  // Contents of file
  #endif
  <end-of-file>
  ```

-
  ```
  <start-of-file>
  // Comments allowed here
  #ifndef identifier
  #define identifier
  // Contents of file
  #endif
  <end-of-file>
  ```

### Polyspace Implementation

The checker raises a violation if a header file does not contain an include guard.

For instance, this code uses an include guard for the `#define` and `#include` statements. This code does not violate the rule:

```
// Contents of a header file
#ifndef FILE_H
```

```
#define FILE_H
#include "libFile.h"
#endif
```

If you use include guards that do not adhere to the suggested format, Polyspace flags them. For instance:

- You might mistakenly use different identifiers in the `#ifndef` and `#define` statements:

  ```
  #ifndef MACRO
  #define MICRO
  //...
  #endif
  ```
- You might inadvertently use `#ifdef` instead of `#ifndef` or omit the `#define` statement.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Missing or Incorrectly Formatted Include Guard

| file1.h | file2.h | mainfile.cpp |
|---|---|---|
| `#ifndef MACRO`<br>`#define MICRO`<br>`//...`<br>`#endif` | `#ifdef DO_INCLUDE`<br>`#define DO_INCLUDE`<br>`void foo();`<br>`#endif` | `#include"file1.h"`<br>`#include"file2.h"`<br>`int main(){`<br>`    return 0;`<br>`}` |

In this example, two header files are included in the file `mainfile.cpp`.

- The include guard in `file1.h` queries the definition of `MACRO` but conditionally defines a different identifier `MICRO`, perhaps inadvertently. This include guard is incorrectly formatted. Polyspace flags the file.
- The include guard in `file2.h` uses `#ifdef` instead of `#ifndef`. This include guard is incorrect and Polyspace flags the file.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M16-3-1

There shall be at most one occurrence of the # or ## operators in a single macro definition

## Description

### Rule Definition

*There shall be at most one occurrence of the # or ## operators in a single macro definition.*

### Rationale

The evaluation of the # and ## preprocessor operators does not have a specified execution order. When more than one occurrence of the # or ## operators exists in a single macro definition, it is unclear which preprocessor operator is executed first by the compiler. The uncertainty of execution order might result in developer confusion or unexpected macro calculations. Use only one of the # or ## preprocessor operators for each macro definition.

### Polyspace Implementation

Polyspace raises this defect whenever more than one instance of the # or ## operators is used in a single macro definition.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Multiple # and ## Operators Used in a Single Macro Definition

```
#define STRING(X) { #X }                          //Compliant
#define CONCAT(X, Y) {X ## Y}                     //Compliant
#define STRING_CONCAT(x, y) {#x ## y}             //Noncompliant
#define MULTI_CONCAT(x, y, xy, z) {x ## y ## z}   //Noncompliant
```

Because the macro `STRING_CONCAT` uses both the # and ## operators, Polyspace flags the macro as noncompliant.

Polyspace flags the macro `MULTI_CONCAT` as noncompliant because it uses multiple ## operators.

## Check Information

**Group:** Preprocessing Directives

"Check for and Review Coding Standard Violations"

# AUTOSAR C++14 Rule M16-3-2

The # and ## operators should not be used

## Description

### Rule Definition

*The # and ## operators should not be used.*

### Rationale

The evaluation of the # and ## preprocessor operators does not have a specified execution order. Different compilers might evaluate these operators in different order of execution. The uncertainty of execution order might result in developer confusion or unexpected macro calculations. When possible, avoid using the # and ## preprocessor operators.

### Polyspace Implementation

Polyspace raises this advisory when the # or ## operators are used in a macro definition.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Avoid Using # and ## Operators in Macro Definition

```
#define STRING(X) { #X }                             //Noncompliant
#define CONCAT(X, Y) {X ## Y}                        //Noncompliant
```

Because the macro `STRING(X)` uses the # operator, Polyspace flags the macro as noncompliant.

Polyspace flags the macro `CONCAT(X, Y)` as noncompliant because it uses the ## operator.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M19-3-1

The error indicator errno shall not be used

## Description

### Rule Definition

*The error indicator errno shall not be used.*

### Rationale

Observing this rule encourages the good practice of not relying on errno to check error conditions.

Checking errno is not sufficient to guarantee absence of errors. Functions such as fopen might not set errno on error conditions. Often, you have to check the return value of such functions for error conditions.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of errno

```
#include <cstdlib>
#include <cerrno>

void func (const char* str) {
    errno = 0;  // Noncompliant
    int i = atoi(str);
    if(errno != 0) { // Noncompliant
        //Handle Error
    }
}
```

The use of errno violates this rule. The function atoi is not required to set errno if the input string cannot be converted to an integer. Checking errno later does not safeguard against possible failures in conversion.

“Check for and Review Coding Standard Violations”

# AUTOSAR C++14 Rule M27-0-1

The stream input/output library <cstdio> shall not be used

## Description

### Rule Definition

*The stream input/output library <cstdio> shall not be used.*

### Rationale

Functions in `cstdio` such as `gets`, `fgetpos`, `fopen`, `ftell`, etc. have unspecified, undefined and implementation-defined behavior.

For instance:

- The `gets` function:

  ```
  char * gets ( char * buf );
  ```

  does not check if the number of characters provided at the standard input exceeds the buffer `buf`. The function can have unexpected behavior when the input exceeds the buffer.
- The `fopen` function has implementation-specific behavior related to whether it sets `errno` on errors or whether it accepts additional characters following the standard mode specifiers.

### Polyspace Implementation

Polyspace reports a violation of this rule if you use the functions from the `cstdio` library. Polyspace detects the use of these `cstdio` functions:

- File operation functions such as `remove` and `rename`.
- File access functions such as `fclose`,`fflush`, and `fopen`.
- Formatted input/output functions such as `fprintf`, `fscanf`, `printf`, and `scanf`.
- Character input output functions such as `fgetc`, `fgets`, `fputc`, and `getc`.
- Direct input/output functions such as `fread` and `fwrite`.
- File positioning functions such as `fgetpos` and `fsetpos`.
- Error handling functions such as `clearerr`, `ferror`, and `perror`.

### Troubleshooting

If you expect a rule violation but Polyspace does not report it, see “Diagnose Why Coding Standard Violations Do Not Appear as Expected”.

## Examples

### Use of `gets`

```
#include <cstdio>
```

```
void func()
{
    char array[10];
    fgets(array, sizeof array, stdin); //Noncompliant
}
```

The use of `fgets` violates this rule.

# Common Weakness Enumeration (CWE)

# CWE Rule 14

Compiler Removal of Code to Clear Buffers

## Description

### Rule Description

*Sensitive memory is cleared according to the source code, but compiler optimizations leave the memory untouched when it is not read from again, aka "dead store removal."*

### Polyspace Implementation

The rule checker checks for **Uncertain memory cleaning**.

## Examples

### Uncertain memory cleaning

#### Issue

This issue occurs when you clean memory by writing `0` into it but the memory is not read after the cleaning operation. Because the memory is not read after the cleaning, a compiler might skip the cleaning operation when optimizing the code. For instance, consider this code:

```
void foo(){
    void* buffer = getSensitiveData();
    //...
    memset(buffer, 0, sizeof(buffer));
}
```

Here, `buffer` might contain sensitive data. The call to `memset()` is intended to scrub the data. Because buffer is not read after the scrubbing, the compiler optimization process might ignore the `memset()` command. The data in `buffer` might remain uncleaned. Polyspace flags such uncertain memory cleaning. Polyspace does not raise this defect if either of these conditions are true:

- The return value of the memory cleaning function is assigned to a variable.
- The memory cleaning function scrubs a global object.

#### Risk

When a variable is written with no further read, compilers might consider it as a deadstore. To optimize the code, the compiler might remove any assignments to deadstore variables.

If such code optimization removes code that scrubs sensitive information from memory, then sensitive information might remain uncleaned in your system. An attacker can then access the sensitive information and use it to further erode the protection mechanisms in your code.

#### Fix

When scrubbing memory, use code that the compiler cannot remove. For instance, instead of `memset`, use secure functions, such as `memset_s` or `fill_n`. If you use an older version of C or C++ where these functions are unavailable, consider updating your code to a more recent version. Alternatively, you might implement your own secure memory-scrubbing function. When using your own implementation, review the compiled code to make sure that the memory-cleaning operations are untouched by the compiler.

#### Example — Avoid Uncertainty in Cleaning Sensitive Memory

```
#include <string.h>

extern int getSensitiveData(char*, size_t);
extern int writeDB(char*, char*);
char Gbuffer[64];
void Job(char *key) {
    char buffer[64];
    if (getSensitiveData(buffer, sizeof(buffer))) {
        if (writeDB(key, buffer)) {
            // Record data
        }
    }
    (void) memset(buffer, 0, sizeof(buffer)); // Defect
}

void manageGBuffer(char *key) {
    //...
    memset(Gbuffer, 0, sizeof(Gbuffer)); // No Defect
}
```

In this example, the command `memset()` is used in `Job()` to clean the memory in `buffer`. Because `buffer` is not read after the cleaning, the compiler might remove this code when optimizing the code. Polyspace flags the uncertain cleaning. In the function `manage()`, `memset()` is used to clean the global array `Gbuffer`. Polyspace does not flag this cleaning operation.

#### Correction — Use Secure Functions to Clean Sensitive Memory

To fix this defect, use secure functions, such as `memset_s()`, to clean uncertain memory.

```
#include <string.h>

extern int getSensitiveData(char*, size_t);
extern int writeDB(char*, char*);

void Job(char *key) {
    char buffer[64];
    if (getSensitiveData(buffer, sizeof(buffer))) {
        if (writeDB(key, buffer)) {
            // Record data
        }
    }
    memset_s(buffer, 0, sizeof(buffer)); // No Defect
}
```

CWE-14

# CWE Rule 119

Improper Restriction of Operations within the Bounds of a Memory Buffer

## Description

### Rule Description

*The software performs operations on a memory buffer, but it can read from or write to a memory location that is outside of the intended boundary of the buffer.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access out of bounds**
- **Array access with tainted index**
- **Buffer overflow from incorrect string format specifier**
- **Cast to pointer pointing to object of different type**
- **Destination buffer overflow in string manipulation**
- **Destination buffer underflow in string manipulation**
- **Invalid use of standard library memory routine**
- **Invalid use of standard library routine**
- **Invalid use of standard library string routine**
- **Mismatch between data length and size**
- **Missing null in string array**
- **Pointer access out of bounds**
- **Pointer dereference with tainted offset**
- **Possible misuse of sizeof**
- **Reading memory reallocated from object of another type without reinitializing first**
- **Tainted NULL or non-null-terminated string**
- **Use of dangerous standard function**
- **Use of indeterminate string**

## Examples

### Array access out of bounds

#### Issue

This issue occurs when an array index falls outside the range `[0...array_size-1]` during array access.

#### Risk

Accessing an array outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you accessed an array inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used an array index that is the same as the loop index instead of being one less than the loop index.

To fix the issue, you have to modify the loop bound or the array index.

Another reason why an array index can exceed array bounds is a prior conversion from signed to unsigned integers. The conversion can result in a wrap around of the index value, eventually causing the array index to exceed the array bounds.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Array Access Out of Bounds Error

```
#include <stdio.h>

void fibonacci(void)
{
    int i;
    int fib[10];

    for (i = 0; i < 10; i++)
       {
        if (i < 2)
            fib[i] = 1;
         else
            fib[i] = fib[i-1] + fib[i-2];
       }
    printf("The 10-th Fibonacci number is %i .\n", fib[i]);
    /* Defect: Value of i is greater than allowed value of 9 */
}
```

The array `fib` is assigned a size of 10. An array index for `fib` has allowed values of `[0,1,2,...,9]`. The variable `i` has a value 10 when it comes out of the `for`-loop. Therefore, the `printf` statement attempts to access `fib[10]` through `i`.

**Correction — Keep Array Index Within Array Bounds**

One possible correction is to print `fib[i-1]` instead of `fib[i]` after the `for`-loop.

```
#include <stdio.h>

void fibonacci(void)
{
   int i;
   int fib[10];

   for (i = 0; i < 10; i++)
    {
        if (i < 2)
            fib[i] = 1;
        else
            fib[i] = fib[i-1] + fib[i-2];
    }

    /* Fix: Print fib[9] instead of fib[10] */
    printf("The 10-th Fibonacci number is %i .\n", fib[i-1]);
}
```

The `printf` statement accesses `fib[9]` instead of `fib[10]`.

### Array access with tainted index

**Issue**

This issue occurs when you access an array by using an index that is obtained from unsecure sources and which has not been validated.

**Risk**

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite — writing to memory before the beginning of the buffer.
- Buffer overflow — writing to memory after the end of a buffer.
- Over-reading a buffer — accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write operation create to problems in your program.

**Fix**

Before using the index to access the array, validate the index value to make sure that it is inside the array range.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Use Index to Return Buffer Value

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
  return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    return tab[num];//Noncompliant
}
```

In this example, the index `num` accesses the array `tab`. The index `num` is obtained from an unsecure source and the function `taintedarrayindex` does not check to see if `num` is inside the range of `tab`.

#### Correction — Check Range Before Use

One possible correction is to check that `num` is in range before using it.

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
    return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    if (num >= 0 && num < SIZE100) {
        return tab[num];
    } else {
        return -1;
    }
}
```

### Buffer overflow from incorrect string format specifier

#### Issue

This issue occurs when the format specifier argument for functions such as `sscanf` leads to an overflow or underflow in the memory buffer argument.

#### Risk

If the format specifier specifies a precision that is greater than the memory buffer size, an overflow occurs. Overflows can cause unexpected behavior such as memory corruption.

#### Fix

Use a format specifier that is compatible with the memory buffer size.

**Example — Memory Buffer Overflow**

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%33c", buf);
}
```

In this example, `buf` can contain 32 `char` elements. Therefore, the format specifier `%33c` causes a buffer overflow.

**Correction — Use Smaller Precision in Format Specifier**

One possible correction is to read a smaller number of elements into the buffer.

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%32c", buf);
}
```

### Cast to pointer pointing to object of different type

**Issue**

The issue occurs when you perform a cast between a pointer to an object type and a pointer to a different object type.

**Risk**

If a pointer to an object is cast into a pointer to a different object, the resulting pointer can be incorrectly aligned. The incorrect alignment causes undefined behavior.

Even if the conversion produces a pointer that is correctly aligned, the behavior can be undefined if the pointer is used to access an object.

Exception: You can convert a pointer to object type into a pointer to one of these types:

- `char`
- `signed char`
- `unsigned char`

**Example - Cast to Pointer Pointing to Object of Wider Type**

```
signed   char *p1;
unsigned int *p2;

void foo(void){
  p2 = ( unsigned int * ) p1;     /* Non-compliant */
}
```

In this example, `p1` can point to a `signed char` object. However, `p1` is cast to a pointer that points to an object of wider type, `unsigned int`.

**Example - Cast to Pointer Pointing to Object of Narrower Type**

```
extern unsigned int read_value ( void );
extern void display ( unsigned int n );
```

```
void foo ( void ){
  unsigned int u = read_value ( );
  unsigned short *hi_p = ( unsigned short * ) &u;    /* Non-compliant  */
  *hi_p = 0;
  display ( u );
}
```

In this example, u is an unsigned int variable. &u is cast to a pointer that points to an object of narrower type, unsigned short.

On a big-endian machine, the statement *hi_p = 0 attempts to clear the high bits of the memory location that &u points to. But, from the result of display(u), you might find that the high bits have not been cleared.

**Example - Cast Adding a Type Qualifier**

```
const short *p;
const volatile short *q;
void foo (void){
  q = ( const volatile short * ) p;  /* Compliant */
}
```

In this example, both p and q can point to short objects. The cast between them adds a volatile qualifier only and is therefore compliant.

### Destination buffer overflow in string manipulation

**Issue**

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function sprintf(char* buffer, const char* format), you use a constant string format of greater size than buffer.

**Risk**

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

**Fix**

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use sprintf to write formatted data to a string, use snprintf, _snprintf or sprintf_s instead to enforce length control. Alternatively, use asprintf to automatically allocate the memory required for the destination buffer.
- If you use vsprintf to write formatted data from a variable argument list to a string, use vsnprintf or vsprintf_s instead to enforce length control.
- If you use wcscpy to copy a wide string, use wcsncpy, wcslcpy, or wcscpy_s instead to enforce length control.

Another possible solution is to increase the buffer size.

#### Example — Buffer Overflow in sprintf Use

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

#### Correction — Use `snprintf` Instead of `sprintf`

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Destination buffer underflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at a negative offset from the beginning of the buffer.

For instance, for the function `sprintf(char* buffer, const char* format)`, you obtain the `buffer` from an operation `buffer = (char*)arr; ... buffer += offset;`. `arr` is an array and `offset` is a negative value.

#### Risk

Buffer underflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer underflow also introduces the risk of code injection.

#### Fix

If the destination buffer argument results from pointer arithmetic, see if you are decrementing a pointer. Fix the pointer decrement by modifying either the original value before decrement or the decrement value.

#### Example — Buffer Underflow in sprintf Use

```
#include <stdio.h>
#define offset -2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

In this example, &buffer[offset] is at a negative offset from the memory allocated to buffer.

#### Correction — Change Pointer Decrementer

One possible correction is to change the value of offset.

```
#include <stdio.h>
#define offset 2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

### Invalid use of standard library memory routine

#### Issue

This issue occurs when a memory library function is called with invalid arguments. For instance, the memcpy function copies to an array that cannot accommodate the number of bytes copied.

#### Risk

Use of a memory library function with invalid arguments can result in issues such as buffer overflow.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Invalid Use of Standard Library Memory Routine Error

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  char str1[10],str2[5];

  printf("Enter string:\n");
  scanf("%s",str1);
  memcpy(str2,str1,6);
  /* Defect: Arguments of memcpy invalid: str2 has size < 6 */

  return str2;
 }
```

The size of string `str2` is 5, but six characters of string `str1` are copied into `str2` using the `memcpy` function.

**Correction — Call Function with Valid Arguments**

One possible correction is to adjust the size of `str2` so that it accommodates the characters copied with the `memcpy` function.

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  /* Fix: Declare str2 with size 6 */
  char str1[10],str2[6];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  return str2;
 }
```

### Invalid use of standard library routine

**Issue**

This issue occurs when you use invalid arguments with a function from the standard library. This defect picks up errors related to other functions not covered by float, integer, memory, or string standard library routines.

**Risk**

Invalid arguments to a standard library function result in undefined behavior.

**Fix**

The fix depends on the root cause of the defect. For instance, the argument to a `printf` function can be `NULL` because a pointer was initialized with `NULL` and the initialization value was not overwritten along a specific execution path.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Calling printf Without a String

```
#include <stdio.h>
#include <stdlib.h>

void print_null(void) {

  printf(NULL);
}
```

The function `printf` takes only string input arguments or format specifiers. In this function, the input value is NULL, which is not a valid string.

#### Correction — Use Compatible Input Arguments

One possible correction is to change the input arguments to fit the requirements of the standard library routine. In this example, the input argument was changed to a character.

```
#include <stdio.h>

void print_null(void) {
    char zero_val = '0';
    printf((const char*)zero_val);
}
```

### Invalid use of standard library string routine

#### Issue

This issue occurs when a string library function is called with invalid arguments.

#### Risk

The risk depends on the type of invalid arguments. For instance, using the `strcpy` function with a source argument larger than the destination argument can result in buffer overflows.

#### Fix

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the `strcpy` function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to `strcpy`. In some cases, you can use an alternative function to avoid the error. For instance, instead of `strcpy`, you can use `strncpy` to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Invalid Use of Standard Library String Routine Error**

```
 #include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  char gbuffer[5],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);
  /* Error: Size of text is less than gbuffer */

  return(res);
 }
```

The string `text` is larger in size than `gbuffer`. Therefore, the function `strcpy` cannot copy `text` into `gbuffer`.

**Correction — Use Valid Arguments**

One possible correction is to declare the destination string `gbuffer` with equal or larger size than the source string `text`.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

### Mismatch between data length and size

**Issue**

This issue occurs when you do not check the length argument and data buffer argument of memory copying functions such as `memcpy`, `memset`, or `memmove`, to protect against buffer overflows.

**Risk**

If an attacker can manipulate the data buffer or length argument, the attacker can cause buffer overflow by making the actual data size smaller than the length.

This mismatch in length allows the attacker to copy memory past the data buffer to a new location. If the extra memory contains sensitive information, the attacker can now access that data.

This defect is similar to the SSL Heartbleed bug.

**Fix**

When copying or manipulating memory, compute the length argument directly from the data so that the sizes match.

**Example — Copy Buffer of Data**

```
#include <stdlib.h>
#include <string.h>

typedef struct buf_mem_st {
    char *data;
    size_t max;     /* size of buffer */
} BUF_MEM;

extern BUF_MEM beta;

int cpy_data(BUF_MEM *alpha)
{
    BUF_MEM *os = alpha;
    int num, length;

    if (alpha == 0x0) return 0;
    num = 0;

    length = *(unsigned short *)os->data;
    memcpy(&(beta.data[num]), os->data + 2, length);

    return(1);
}
```

This function copies the buffer `alpha` into a buffer `beta`. However, the `length` variable is not related to `data+2`.

**Correction — Check Buffer Length**

One possible correction is to check the length of your buffer against the maximum value minus 2. This check ensures that you have enough space to copy the data to the `beta` structure.

```
#include <stdlib.h>
#include <string.h>

typedef struct buf_mem_st {
    char *data;
    size_t max;     /* size of buffer */
} BUF_MEM;

extern BUF_MEM beta;

int cpy_data(BUF_MEM *alpha)
{
    BUF_MEM *os = alpha;
    int num, length;

    if (alpha == 0x0) return 0;
    num = 0;

    length = *(unsigned short *)os->data;
    if (length<(os->max -2)) {
        memcpy(&(beta.data[num]), os->data + 2, length);
    }

    return(1);
}
```

### Missing null in string array

#### Issue

This issue occurs when a string does not have enough space to terminate with a null character `'\0'`.

This defect applies only for projects in C.

#### Risk

A buffer overflow can occur if you copy a string to an array without assuming the implicit null terminator.

#### Fix

If you initialize a character array with a literal, avoid specifying the array bounds.

```
char three[]  = "THREE";
```

The compiler automatically allocates space for a null terminator. In the preceding example, the compiler allocates sufficient space for five characters and a null terminator.

If the issue occurs after initialization, you might have to increase the size of the array by one to account for the null terminator.

In certain circumstances, you might want to initialize the character array with a sequence of characters instead of a string. In this situation, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Array size is too small

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[5] = "THREE";
}
```

The character array `three` has a size of 5 and 5 characters `'T'`, `'H'`, `'R'`, `'E'`, and `'E'`. There is no room for the null character at the end because `three` is only five bytes large.

#### Correction — Increase Array Size

One possible correction is to change the array size to allow for the five characters plus a null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[6] = "THREE";
}
```

#### Correction — Change Initialization Method

One possible correction is to initialize the string by leaving the array size blank. This initialization method allocates enough memory for the five characters and a terminating-null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[]  = "THREE";
}
```

### Pointer access out of bounds

#### Issue

This issue occurs when a pointer is dereferenced outside its bounds.

When a pointer is assigned an address, a block of memory is associated with the pointer. You cannot access memory beyond that block using the pointer.

#### Risk

Dereferencing a pointer outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you dereferenced a pointer inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used pointer arithmetic to advance the pointer with an incorrect value for the pointer increment.

To fix the issue, you have to modify the loop bound or the pointer increment value.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.

- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Pointer access out of bounds error**

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
   {
    ptr++;
    *ptr=i;
    /* Defect: ptr out of bounds for i=9 */
   }

 return(arr);
}
```

`ptr` is assigned the address `arr` that points to a memory block of size `10*sizeof(int)`. In the `for`-loop, `ptr` is incremented 10 times. In the last iteration of the loop, `ptr` points outside the memory block assigned to it. Therefore, it cannot be dereferenced.

**Correction — Check Pointer Stays Within Bounds**

One possible correction is to reverse the order of increment and dereference of `ptr`.

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
     {
      /* Fix: Dereference pointer before increment */
      *ptr=i;
      ptr++;
     }

 return(arr);
}
```

After the last increment, even though `ptr` points outside the memory block assigned to it, it is not dereferenced more.

### Pointer dereference with tainted offset

**Issue**

This issue occurs when a pointer dereference uses an offset variable from an unknown or unsecure source.

This check focuses on dynamically allocated buffers. For static buffer offsets, see `Array access with tainted index`.

**Risk**

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite, or writing to memory before the beginning of the buffer.
- Buffer overflow, or writing to memory after the end of a buffer.
- Over reading a buffer, or accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write to compromise your program.

#### Fix

Validate the index before you use the variable to access the pointer. Check to make sure that the variable is inside the valid range and does not overflow.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Dereference Pointer Array

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

#### Correction — Check Index Before Dereference

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

### Possible misuse of sizeof

#### Issue

This issue occurs when Polyspace Bug Finder detects possibly unintended results from the use of `sizeof` operator. For instance:

- You use the `sizeof` operator on an array parameter name, expecting the array size. However, the array parameter name by itself is a pointer. The `sizeof` operator returns the size of that pointer.
- You use the `sizeof` operator on an array element, expecting the array size. However, the operator returns the size of the array element.
- The size argument of certain functions such as `strncmp` or `wcsncpy` is incorrect because you used the `sizeof` operator earlier with possibly incorrect expectations. For instance:

  - In a function call `strncmp(string1, string2, num)`, `num` is obtained from an incorrect use of the `sizeof` operator on a pointer.
  - In a function call `wcsncpy(destination, source, num)`, `num` is the not the number of wide characters but a size in bytes obtained by using the `sizeof` operator. For instance, you use `wcsncpy(destination, source, sizeof(destination) - 1)` instead of `wcsncpy(destination, source, (sizeof(desintation)/sizeof(wchar_t)) - 1)`.

#### Risk

Incorrect use of the `sizeof` operator can cause the following issues:

- If you expect the `sizeof` operator to return array size and use the return value to constrain a loop, the number of loop runs are smaller than what you expect.
- If you use the return value of `sizeof` operator to allocate a buffer, the buffer size is smaller than what you require. Insufficient buffer can lead to resultant weaknesses such as buffer overflows.
- If you use the return value of `sizeof` operator incorrectly in a function call, the function does not behave as you expect.

#### Fix

Possible fixes are:

- Do not use the sizeof operator on an array parameter name or array element to determine array size.

  The best practice is to pass the array size as a separate function parameter and use that parameter in the function body.
- Use the sizeof operator carefully to determine the number argument of functions such as strncmp or wcsncpy. For instance, for wide string functions such as wcsncpy, use the number of wide characters as argument instead of the number of bytes.

#### Example — sizeof Used Incorrectly to Determine Array Size

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < sizeof(a)/sizeof(int); i++)    {
        a[i] = i + 1;
    }
}
```

In this example, sizeof(a) returns the size of the pointer a and not the array size.

#### Correction — Determine Array Size in Another Way

One possible correction is to use another means to determine the array size.

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < MAX_SIZE; i++)    {
        a[i] = i + 1;
    }
}
```

### Reading memory reallocated from object of another type without reinitializing first

#### Issue

This issue occurs when you do the following in sequence:

1. Reallocate memory to an object with a type that is different from the original allocation.

   For instance, in this code snippet, a memory originally allocated to a pointer with type struct A* is reallocated to a pointer with type struct B*:

   ```
   struct A;
   struct B;

   struct A *Aptr = (struct A*) malloc(sizeof(struct A));
   struct B *Bptr = (struct B*) realloc(Aptr, sizeof(struct B));
   ```

**2** Read from this reallocated memory without reinitializing the memory first.

Read accesses on the pointer to the reallocated memory can happen through pointer dereference or array indexing. Passing the pointer to a function that takes a pointer to a `const`-qualified object as the corresponding parameter also counts as a read access.

#### Risk

Reading from reallocated memory that has not been reinitialized leads to undefined behavior.

#### Fix

Reinitialize memory after reallocation and before the first read access.

The checker considers any write access on the pointer to the reallocated memory as satisfying the reinitialization requirement (even if the object might only be partially reinitialized). Write accesses on the pointer to the reallocated memory can happen through pointer dereference or array indexing. Passing the pointer to a function that takes a pointer to a non-`const`-qualified object as the corresponding parameter also counts as a write access.

#### Example – Noncompliant: Reading from Reallocated Memory Without Reinitializing First

```
#include<stdlib.h>

struct group {
    char *groupFirst;
    int groupSize;
};

struct groupWithID {
    int groupID;
    char *groupFirst;
    int groupSize;
};

char* readName();
int readSize();

void createGroup(int nextAvailableID) {
    struct group *aGroup;
    struct groupWithID *aGroupWithID;

    aGroup = (struct group*) malloc(sizeof(struct group));

    if(!aGroup) {
        /*Handle error*/
    }

    aGroup->groupFirst = readName();
    aGroup->groupSize  = readSize();

    /* Reassign to group with ID */
    aGroupWithID = (struct groupWithID*) realloc(aGroup, sizeof(struct groupWithID));
    if(!aGroupWithID) {
        free(aGroup);
        /*Handle error*/
    }
    if(aGroupWithID -> groupSize > 0) { /* Noncompliant */
        /* ... */
    }

    /* ...*/
    free(aGroupWithID);
}
```

In this example, the memory allocated to a `group*` pointer using the `malloc` function is reallocated to a `groupWithID*` pointer using the `realloc` function. There is a read access on the reallocated memory before the memory is reinitialized.

**Correction – Reinitialize Memory After Reallocation and Before First Read**

Reinitialize the memory assigned to the `groupWithID*` pointer before the first read access. All bits of the memory can be reinitialized using the `memset` function.

```
#include<stdlib.h>
#include<string.h>

struct group {
    char *groupFirst;
    int groupSize;
};

struct groupWithID {
    int groupID;
    char *groupFirst;
    int groupSize;
};

char* readName();
int readSize();

void createGroup(int nextAvailableID) {
    struct group *aGroup;
    struct groupWithID *aGroupWithID;

    aGroup = (struct group*) malloc(sizeof(struct group));

    if(!aGroup) {
        /*Handle error*/
    }

    aGroup->groupFirst = readName();
    aGroup->groupSize  = readSize();

    /* Reassign to group with ID */
    aGroupWithID = (struct groupWithID*) realloc(aGroup, sizeof(struct groupWithID));
    if(!aGroupWithID) {
        free(aGroup);
        /*Handle error*/
    }

    memset(aGroupWithID, 0 , sizeof(struct groupWithID));
    /* Reinitialize group */
    if(aGroupWithID -> groupSize > 0) {
        /* ... */
    }

    /* ...*/
    free(aGroupWithID);
}
```

### Tainted NULL or non-null-terminated string

#### Issue

This issue occurs when strings from unsecure sources are used in string manipulation routines that implicitly dereference the string buffer, for instance, `strcpy` or `sprintf`.

**Tainted NULL or non-null-terminated string** raises no defect for a string returned from a call to `scanf`-family variadic functions. Similarly, no defect is raised when you pass the string with a `%s` specifier to `printf`-family variadic functions.

#### Risk

If a string is from an unsecure source, it is possible that an attacker manipulated the string or pointed the string pointer to a different memory location.

If the string is NULL, the string routine cannot dereference the string, causing the program to crash. If the string is not null-terminated, the string routine might not know when the string ends. This error can cause you to write out of bounds, causing a buffer overflow.

#### Fix

Validate the string before you use it. Check that:

- The string is not NULL.
- The string is null-terminated
- The size of the string matches the expected size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Getting String from Input

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));//Noncompliant
    print_str(str);
}
```

In this example, the string `str` is concatenated with the argument `userstr`. The value of `userstr` is unknown. If the size of `userstr` is greater than the space available, the concatenation overflows.

**Correction — Validate the Data**

One possible correction is to check the size of `userstr` and make sure that the string is null-terminated before using it in `strncat`. This example uses a helper function, `sansitize_str`, to validate the string. The defects are concentrated in this function.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
int sanitize_str(char* s) {
    int res = 0;
    if (s && (strlen(s) > 0)) { // Noncompliant-TAINTED_STRING only flagged here
        // - string is not null
        // - string has a positive and limited size
        // - TAINTED_STRING on strlen used as a firewall
        res = 1;
    }
    return res;
}
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    if (sanitize_str(userstr))
        strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

**Correction — Validate the Data**

Another possible correction is to call function `errorMsg` and `warningMsg` with specific strings.

```
#include <stdio.h>
#include <string.h>
#include <stdlib.h>

#define SIZE128 128

extern void print_str(const char*);

void warningMsg(char* userstr)
{
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

```
void errorMsg(char* userstr)
{
  char str[SIZE128] = "Error: ";
  strncat(str, userstr, SIZE128-(strlen(str)+1));
  print_str(str);
}

int manageSensorValue(int sensorValue) {
  int ret = sensorValue;
  if ( sensorValue < 0 ) {
    errorMsg("sensor value should be positive");
    exit(1);
  } else if ( sensorValue > 50 ) {
    warningMsg("sensor value greater than 50 (applying threshold)...");
    sensorValue = 50;
  }

  return sensorValue;
}
```

### Use of dangerous standard function

#### Issue

This issue occurs when your code uses standard functions that write data to a buffer in a way that can result in buffer overflows.

The following table lists dangerous standard functions, the risks of using each function, and what function to use instead. The checker flags:

- Any use of an inherently dangerous function.
- An use of a possibly dangerous function only if the size of the buffer to which data is written can be determined at compile time. The checker does not flag an use of such a function with a dynamically allocated buffer.

| Dangerous Function | Risk Level | Safer Function |
|---|---|---|
| `gets` | Inherently dangerous — You cannot control the length of input from the console. | `fgets` |
| `std::cin::operator>>` and `std::wcin::operator>>` | Inherently dangerous — You cannot control the length of input from the console. | Preface calls to `cin` by `cin.width` to control the input length. This method can result in truncated input.<br>To avoid potential buffer overflow and truncated input, use `std::string` objects as destinations for >> operator. |

| Dangerous Function | Risk Level | Safer Function |
|---|---|---|
| `strcpy` | Possibly dangerous — If the size of the destination buffer is too small to accommodate the source buffer and a null terminator, a buffer overflow might occur. | Use the function `strlen()` to determine the size of the source buffer, and allocate sufficient memory so that the destination buffer can accommodate the source buffer and a null terminator. Instead of `strcpy`, use the function `strncpy`. |
| `stpcpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `stpncpy` |
| `lstrcpy` or `StrCpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `StringCbCopy`, `StringCchCopy`, `strncpy`, `strcpy_s`, or `strlcpy` |
| `strcat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `strncat`, `strlcat`, or `strcat_s` |
| `lstrcat` or `StrCat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `StringCbCat`, `StringCchCat`, `strncay`, `strcat_s`, or `strlcat` |
| `wcpcpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `wcpncpy` |
| `wcscat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `wcsncat`, `wcslcat`, or `wcncat_s` |
| `wcscpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `wcsncpy` |
| `sprintf` | Possibly dangerous — If the output length depends on unknown lengths or values, buffer overflow can occur. | `snprintf` |
| `vsprintf` | Possibly dangerous — If the output length depends on unknown lengths or values, buffer overflow can occur. | `vsnprintf` |

**Risk**

These functions can cause buffer overflow, which attackers can use to infiltrate your program.

**Fix**

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.

- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

### Example — Using sprintf

```
#include <stdio.h>
#include <string.h>
#include <iostream>

#define BUFF_SIZE 128

int dangerous_func(char *str)
{
    char dst[BUFF_SIZE];
    int r = 0;

    if (sprintf(dst, "%s", str) == 1)
    {
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}
```

This example function uses `sprintf` to copy the string `str` to `dst`. However, if `str` is larger than the buffer, `sprintf` can cause buffer overflow.

### Correction — Use `snprintf` with Buffer Size

One possible correction is to use `snprintf` instead and specify a buffer size.

```
#include <stdio.h>
#include <string.h>
#include <iostream>

#define BUFF_SIZE 128

int dangerous_func(char *str)
{
    char dst[BUFF_SIZE];
    int r = 0;

    if (snprintf(dst, sizeof(dst), "%s", str) == 1)
    {
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}
```

### Use of indeterminate string

#### Issue

This issue occurs when you do not check if a write operation using an fgets-family function such as:

```
char * fgets(char* buf, int n, FILE *stream)
```

succeeded and the buffer written has valid content, or you do not reset the buffer on failure. You then perform an operation that assumes a buffer with valid content. For instance, if the buffer with possibly indeterminate content is buf (as shown above), the checker raises a defect if:

- You pass buf as argument to standard functions that print or manipulate strings or wide strings.
- You return buf from a function.
- You pass buf as argument to external functions with parameter type const char * or const wchar_t *.
- You read buf as buf[index] or *(buf + offset), where index or offset is a numerical value representing the distance from the beginning of the buffer.

#### Risk

If an fgets-family function fails, the content of its output buffer is indeterminate. Use of such a buffer has undefined behavior and can result in a program that stops working or other security vulnerabilities.

#### Fix

Reset the output buffer of an fgets-family function to a known string value when the function fails.

#### Example — Output of fgets() Passed to External Function

```
#include <stdio.h>
#include <wchar.h>
#include <string.h>
#include <stdlib.h>

#define SIZE20 20

extern void display_text(const char *txt);

void func(void) {
    char buf[SIZE20];

    /* Check fgets() error */
    if (fgets (buf, sizeof (buf), stdin) == NULL)
    {
        /* 'buf' may contain an indeterminate string.  */
        ;
    }
    /* 'buf passed to external function */
    display_text(buf);
}
```

In this example, the output buf is passed to the external function display_text(), but its value is not reset if fgets() fails.

#### Correction — Reset `fgets()` Output on Failure

If `fgets()` fails, reset `buf` to a known value before you pass it to an external function.

```
#include <stdio.h>
#include <wchar.h>
#include <string.h>
#include <stdlib.h>

#define SIZE20 20

extern void display_text(const char *txt);

void func1(void) {
    char buf[SIZE20];
    /* Check fgets() error */
    if (fgets (buf, sizeof (buf), stdin) == NULL)
    {
        /* value of 'buf' reset after fgets() failure. */
        buf[0] = '\0';
    }
    /* 'buf' passed to external function */
    display_text(buf);
}
```

CWE-119

# CWE Rule 120

Buffer Copy without Checking Size of Input ('Classic Buffer Overflow')

## Description

### Rule Description

*The program copies an input buffer to an output buffer without verifying that the size of the input buffer is less than the size of the output buffer, leading to a buffer overflow.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Destination buffer overflow in string manipulation**
- **Invalid use of standard library memory routine**
- **Invalid use of standard library string routine**
- **Tainted NULL or non-null-terminated string**

## Examples

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

**Example — Buffer Overflow in sprintf Use**

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

**Correction — Use `snprintf` Instead of `sprintf`**

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Invalid use of standard library memory routine

**Issue**

This issue occurs when a memory library function is called with invalid arguments. For instance, the `memcpy` function copies to an array that cannot accommodate the number of bytes copied.

**Risk**

Use of a memory library function with invalid arguments can result in issues such as buffer overflow.

**Fix**

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Invalid Use of Standard Library Memory Routine Error**

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  char str1[10],str2[5];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  /* Defect: Arguments of memcpy invalid: str2 has size < 6 */

  return str2;
 }
```

The size of string `str2` is 5, but six characters of string `str1` are copied into `str2` using the `memcpy` function.

**Correction — Call Function with Valid Arguments**

One possible correction is to adjust the size of `str2` so that it accommodates the characters copied with the `memcpy` function.

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  /* Fix: Declare str2 with size 6 */
  char str1[10],str2[6];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  return str2;
 }
```

### Invalid use of standard library string routine

**Issue**

This issue occurs when a string library function is called with invalid arguments.

**Risk**

The risk depends on the type of invalid arguments. For instance, using the `strcpy` function with a source argument larger than the destination argument can result in buffer overflows.

**Fix**

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the `strcpy` function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to `strcpy`. In some cases, you can use an alternative function to avoid the error. For instance, instead of `strcpy`, you can use `strncpy` to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Invalid Use of Standard Library String Routine Error

```
 #include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  char gbuffer[5],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);
  /* Error: Size of text is less than gbuffer */

  return(res);
 }
```

The string `text` is larger in size than `gbuffer`. Therefore, the function `strcpy` cannot copy `text` into `gbuffer`.

#### Correction — Use Valid Arguments

One possible correction is to declare the destination string `gbuffer` with equal or larger size than the source string `text`.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

### Tainted NULL or non-null-terminated string

#### Issue

This issue occurs when strings from unsecure sources are used in string manipulation routines that implicitly dereference the string buffer, for instance, `strcpy` or `sprintf`.

**Tainted NULL or non-null-terminated string** raises no defect for a string returned from a call to `scanf`-family variadic functions. Similarly, no defect is raised when you pass the string with a `%s` specifier to `printf`-family variadic functions.

#### Risk

If a string is from an unsecure source, it is possible that an attacker manipulated the string or pointed the string pointer to a different memory location.

If the string is NULL, the string routine cannot dereference the string, causing the program to crash. If the string is not null-terminated, the string routine might not know when the string ends. This error can cause you to write out of bounds, causing a buffer overflow.

#### Fix

Validate the string before you use it. Check that:

- The string is not NULL.
- The string is null-terminated
- The size of the string matches the expected size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Getting String from Input

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));//Noncompliant
    print_str(str);
}
```

In this example, the string `str` is concatenated with the argument `userstr`. The value of `userstr` is unknown. If the size of `userstr` is greater than the space available, the concatenation overflows.

### Correction — Validate the Data

One possible correction is to check the size of `userstr` and make sure that the string is null-terminated before using it in `strncat`. This example uses a helper function, `sansitize_str`, to validate the string. The defects are concentrated in this function.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
int sanitize_str(char* s) {
    int res = 0;
    if (s && (strlen(s) > 0)) { // Noncompliant-TAINTED_STRING only flagged here
        // - string is not null
        // - string has a positive and limited size
        // - TAINTED_STRING on strlen used as a firewall
        res = 1;
    }
    return res;
}
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    if (sanitize_str(userstr))
        strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

### Correction — Validate the Data

Another possible correction is to call function `errorMsg` and `warningMsg` with specific strings.

```
#include <stdio.h>
#include <string.h>
#include <stdlib.h>

#define SIZE128 128

extern void print_str(const char*);

void warningMsg(char* userstr)
{
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}

void errorMsg(char* userstr)
{
  char str[SIZE128] = "Error: ";
  strncat(str, userstr, SIZE128-(strlen(str)+1));
  print_str(str);
}
```

```
int manageSensorValue(int sensorValue) {
  int ret = sensorValue;
  if ( sensorValue < 0 ) {
    errorMsg("sensor value should be positive");
    exit(1);
  } else if ( sensorValue > 50 ) {
    warningMsg("sensor value greater than 50 (applying threshold)...");
    sensorValue = 50;
  }

  return sensorValue;
}
```

## Check Information

CWE-120

# CWE Rule 121

Stack-based Buffer Overflow

## Description

### Rule Description

*A stack-based buffer overflow condition is a condition where the buffer being overwritten is allocated on the stack (i.e., is a local variable or, rarely, a parameter to a function).*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access with tainted index**
- **Destination buffer overflow in string manipulation**
- **Invalid use of standard library memory routine**
- **Invalid use of standard library string routine**

## Examples

### Array access with tainted index

#### Issue

This issue occurs when you access an array by using an index that is obtained from unsecure sources and which has not been validated.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite — writing to memory before the beginning of the buffer.
- Buffer overflow — writing to memory after the end of a buffer.
- Over-reading a buffer — accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write operation create to problems in your program.

#### Fix

Before using the index to access the array, validate the index value to make sure that it is inside the array range.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Use Index to Return Buffer Value

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
  return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    return tab[num];//Noncompliant
}
```

In this example, the index `num` accesses the array `tab`. The index `num` is obtained from an unsecure source and the function `taintedarrayindex` does not check to see if `num` is inside the range of `tab`.

#### Correction — Check Range Before Use

One possible correction is to check that `num` is in range before using it.

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
    return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    if (num >= 0 && num < SIZE100) {
        return tab[num];
    } else {
        return -1;
    }
}
```

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

**Example — Buffer Overflow in sprintf Use**

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

**Correction — Use `snprintf` Instead of `sprintf`**

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Invalid use of standard library memory routine

**Issue**

This issue occurs when a memory library function is called with invalid arguments. For instance, the `memcpy` function copies to an array that cannot accommodate the number of bytes copied.

**Risk**

Use of a memory library function with invalid arguments can result in issues such as buffer overflow.

**Fix**

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Invalid Use of Standard Library Memory Routine Error**

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  char str1[10],str2[5];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  /* Defect: Arguments of memcpy invalid: str2 has size < 6 */

  return str2;
 }
```

The size of string `str2` is 5, but six characters of string `str1` are copied into `str2` using the `memcpy` function.

**Correction — Call Function with Valid Arguments**

One possible correction is to adjust the size of `str2` so that it accommodates the characters copied with the `memcpy` function.

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  /* Fix: Declare str2 with size 6 */
  char str1[10],str2[6];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  return str2;
 }
```

### Invalid use of standard library string routine

**Issue**

This issue occurs when a string library function is called with invalid arguments.

#### Risk

The risk depends on the type of invalid arguments. For instance, using the `strcpy` function with a source argument larger than the destination argument can result in buffer overflows.

#### Fix

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the `strcpy` function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to `strcpy`. In some cases, you can use an alternative function to avoid the error. For instance, instead of `strcpy`, you can use `strncpy` to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Invalid Use of Standard Library String Routine Error

```
 #include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  char gbuffer[5],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);
  /* Error: Size of text is less than gbuffer */

  return(res);
 }
```

The string `text` is larger in size than `gbuffer`. Therefore, the function `strcpy` cannot copy `text` into `gbuffer`.

#### Correction — Use Valid Arguments

One possible correction is to declare the destination string `gbuffer` with equal or larger size than the source string `text`.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

CWE-121

# CWE Rule 122

Heap-based Buffer Overflow

## Description

### Rule Description

*A heap overflow condition is a buffer overflow, where the buffer that can be overwritten is allocated in the heap portion of memory, generally meaning that the buffer was allocated using a routine such as malloc().*

### Polyspace Implementation

The rule checker checks for these issues:

- **Destination buffer overflow in string manipulation**
- **Pointer dereference with tainted offset**

## Examples

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

**Example — Buffer Overflow in sprintf Use**

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

**Correction — Use `snprintf` Instead of `sprintf`**

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Pointer dereference with tainted offset

**Issue**

This issue occurs when a pointer dereference uses an offset variable from an unknown or unsecure source.

This check focuses on dynamically allocated buffers. For static buffer offsets, see `Array access with tainted index`.

**Risk**

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite, or writing to memory before the beginning of the buffer.
- Buffer overflow, or writing to memory after the end of a buffer.
- Over reading a buffer, or accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write to compromise your program.

**Fix**

Validate the index before you use the variable to access the pointer. Check to make sure that the variable is inside the valid range and does not overflow.

**Extend Checker**

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of

Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Dereference Pointer Array

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

#### Correction — Check Index Before Dereference

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

"Check for and Review Coding Standard Violations"

### External Websites

CWE-122

# CWE Rule 123

Write-what-where Condition

## Description

### Rule Description

*Any condition where the attacker has the ability to write an arbitrary value to an arbitrary location, often as the result of a buffer overflow.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access with tainted index**
- **Invalid use of standard library memory routine**
- **Pointer dereference with tainted offset**
- **Tainted NULL or non-null-terminated string**

## Examples

### Array access with tainted index

#### Issue

This issue occurs when you access an array by using an index that is obtained from unsecure sources and which has not been validated.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite — writing to memory before the beginning of the buffer.
- Buffer overflow — writing to memory after the end of a buffer.
- Over-reading a buffer — accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write operation create to problems in your program.

#### Fix

Before using the index to access the array, validate the index value to make sure that it is inside the array range.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Use Index to Return Buffer Value**

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
  return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    return tab[num];//Noncompliant
}
```

In this example, the index `num` accesses the array `tab`. The index `num` is obtained from an unsecure source and the function `taintedarrayindex` does not check to see if `num` is inside the range of `tab`.

**Correction — Check Range Before Use**

One possible correction is to check that `num` is in range before using it.

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
    return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    if (num >= 0 && num < SIZE100) {
        return tab[num];
    } else {
        return -1;
    }
}
```

### Invalid use of standard library memory routine

**Issue**

This issue occurs when a memory library function is called with invalid arguments. For instance, the `memcpy` function copies to an array that cannot accommodate the number of bytes copied.

**Risk**

Use of a memory library function with invalid arguments can result in issues such as buffer overflow.

**Fix**

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Invalid Use of Standard Library Memory Routine Error**

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  char str1[10],str2[5];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  /* Defect: Arguments of memcpy invalid: str2 has size < 6 */

  return str2;
 }
```

The size of string `str2` is 5, but six characters of string `str1` are copied into `str2` using the `memcpy` function.

**Correction — Call Function with Valid Arguments**

One possible correction is to adjust the size of `str2` so that it accommodates the characters copied with the `memcpy` function.

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  /* Fix: Declare str2 with size 6 */
  char str1[10],str2[6];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  return str2;
 }
```

### Pointer dereference with tainted offset

**Issue**

This issue occurs when a pointer dereference uses an offset variable from an unknown or unsecure source.

This check focuses on dynamically allocated buffers. For static buffer offsets, see `Array access with tainted index`.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite, or writing to memory before the beginning of the buffer.
- Buffer overflow, or writing to memory after the end of a buffer.
- Over reading a buffer, or accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write to compromise your program.

#### Fix

Validate the index before you use the variable to access the pointer. Check to make sure that the variable is inside the valid range and does not overflow.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See "Sources of Tainting in a Polyspace Analysis". To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Dereference Pointer Array

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

#### Correction — Check Index Before Dereference

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

### Tainted NULL or non-null-terminated string

#### Issue

This issue occurs when strings from unsecure sources are used in string manipulation routines that implicitly dereference the string buffer, for instance, `strcpy` or `sprintf`.

**Tainted NULL or non-null-terminated string** raises no defect for a string returned from a call to `scanf`-family variadic functions. Similarly, no defect is raised when you pass the string with a `%s` specifier to `printf`-family variadic functions.

#### Risk

If a string is from an unsecure source, it is possible that an attacker manipulated the string or pointed the string pointer to a different memory location.

If the string is NULL, the string routine cannot dereference the string, causing the program to crash. If the string is not null-terminated, the string routine might not know when the string ends. This error can cause you to write out of bounds, causing a buffer overflow.

#### Fix

Validate the string before you use it. Check that:

- The string is not NULL.
- The string is null-terminated
- The size of the string matches the expected size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of

Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Getting String from Input**

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));//Noncompliant
    print_str(str);
}
```

In this example, the string `str` is concatenated with the argument `userstr`. The value of `userstr` is unknown. If the size of `userstr` is greater than the space available, the concatenation overflows.

**Correction — Validate the Data**

One possible correction is to check the size of `userstr` and make sure that the string is null-terminated before using it in `strncat`. This example uses a helper function, `sansitize_str`, to validate the string. The defects are concentrated in this function.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
int sanitize_str(char* s) {
    int res = 0;
    if (s && (strlen(s) > 0)) { // Noncompliant-TAINTED_STRING only flagged here
        // - string is not null
        // - string has a positive and limited size
        // - TAINTED_STRING on strlen used as a firewall
        res = 1;
    }
    return res;
}
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    if (sanitize_str(userstr))
        strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

#### Correction — Validate the Data

Another possible correction is to call function `errorMsg` and `warningMsg` with specific strings.

```
#include <stdio.h>
#include <string.h>
#include <stdlib.h>

#define SIZE128 128

extern void print_str(const char*);

void warningMsg(char* userstr)
{
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}

void errorMsg(char* userstr)
{
  char str[SIZE128] = "Error: ";
  strncat(str, userstr, SIZE128-(strlen(str)+1));
  print_str(str);
}

int manageSensorValue(int sensorValue) {
  int ret = sensorValue;
  if ( sensorValue < 0 ) {
    errorMsg("sensor value should be positive");
    exit(1);
  } else if ( sensorValue > 50 ) {
    warningMsg("sensor value greater than 50 (applying threshold)...");
    sensorValue = 50;
  }

  return sensorValue;
}
```

## Check Information

CWE-123

# CWE Rule 124

Buffer Underwrite ('Buffer Underflow')

## Description

### Rule Description

*The software writes to a buffer using an index or pointer that references a memory location prior to the beginning of the buffer.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access with tainted index**
- **Destination buffer underflow in string manipulation**
- **Pointer dereference with tainted offset**

## Examples

### Array access with tainted index

#### Issue

This issue occurs when you access an array by using an index that is obtained from unsecure sources and which has not been validated.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite — writing to memory before the beginning of the buffer.
- Buffer overflow — writing to memory after the end of a buffer.
- Over-reading a buffer — accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write operation create to problems in your program.

#### Fix

Before using the index to access the array, validate the index value to make sure that it is inside the array range.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Use Index to Return Buffer Value

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
  return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    return tab[num];//Noncompliant
}
```

In this example, the index `num` accesses the array `tab`. The index `num` is obtained from an unsecure source and the function `taintedarrayindex` does not check to see if `num` is inside the range of `tab`.

#### Correction — Check Range Before Use

One possible correction is to check that `num` is in range before using it.

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
    return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    if (num >= 0 && num < SIZE100) {
        return tab[num];
    } else {
        return -1;
    }
}
```

### Destination buffer underflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at a negative offset from the beginning of the buffer.

For instance, for the function `sprintf(char* buffer, const char* format)`, you obtain the `buffer` from an operation `buffer = (char*)arr; ... buffer += offset;`. `arr` is an array and `offset` is a negative value.

#### Risk

Buffer underflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer underflow also introduces the risk of code injection.

#### Fix

If the destination buffer argument results from pointer arithmetic, see if you are decrementing a pointer. Fix the pointer decrement by modifying either the original value before decrement or the decrement value.

**Example — Buffer Underflow in sprintf Use**

```
#include <stdio.h>
#define offset -2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

In this example, `&buffer[offset]` is at a negative offset from the memory allocated to `buffer`.

**Correction — Change Pointer Decrementer**

One possible correction is to change the value of `offset`.

```
#include <stdio.h>
#define offset 2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

### Pointer dereference with tainted offset

**Issue**

This issue occurs when a pointer dereference uses an offset variable from an unknown or unsecure source.

This check focuses on dynamically allocated buffers. For static buffer offsets, see `Array access with tainted index`.

**Risk**

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite, or writing to memory before the beginning of the buffer.
- Buffer overflow, or writing to memory after the end of a buffer.
- Over reading a buffer, or accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write to compromise your program.

**Fix**

Validate the index before you use the variable to access the pointer. Check to make sure that the variable is inside the valid range and does not overflow.

**Extend Checker**

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of

Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Dereference Pointer Array

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

#### Correction — Check Index Before Dereference

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

## Check Information

**Category:** Memory Buffer Errors

# Version History

**Introduced in R2023a**

## See Also

Check CWE (-cwe)

### Topics

"Check for and Review Coding Standard Violations"

### External Websites

CWE-124

# CWE Rule 125

Out-of-bounds Read

## Description

### Rule Description

*The software reads data past the end, or before the beginning, of the intended buffer.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access out of bounds**
- **Array access with tainted index**
- **Buffer overflow from incorrect string format specifier**
- **Destination buffer overflow in string manipulation**
- **Destination buffer underflow in string manipulation**
- **Invalid use of standard library memory routine**
- **Invalid use of standard library string routine**
- **Missing null in string array**
- **Pointer access out of bounds**
- **Pointer dereference with tainted offset**
- **Possible misuse of sizeof**
- **Tainted NULL or non-null-terminated string**

## Examples

### Array access out of bounds

#### Issue

This issue occurs when an array index falls outside the range `[0...array_size-1]` during array access.

#### Risk

Accessing an array outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you accessed an array inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used an array index that is the same as the loop index instead of being one less than the loop index.

To fix the issue, you have to modify the loop bound or the array index.

Another reason why an array index can exceed array bounds is a prior conversion from signed to unsigned integers. The conversion can result in a wrap around of the index value, eventually causing the array index to exceed the array bounds.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Extend Checker**

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

**Example — Array Access Out of Bounds Error**

```
#include <stdio.h>

void fibonacci(void)
{
    int i;
    int fib[10];

    for (i = 0; i < 10; i++)
       {
        if (i < 2)
            fib[i] = 1;
         else
            fib[i] = fib[i-1] + fib[i-2];
       }

    printf("The 10-th Fibonacci number is %i .\n", fib[i]);
    /* Defect: Value of i is greater than allowed value of 9 */
}
```

The array `fib` is assigned a size of 10. An array index for `fib` has allowed values of `[0,1,2,...,9]`. The variable `i` has a value 10 when it comes out of the `for`-loop. Therefore, the `printf` statement attempts to access `fib[10]` through `i`.

#### Correction — Keep Array Index Within Array Bounds

One possible correction is to print `fib[i-1]` instead of `fib[i]` after the `for`-loop.

```
#include <stdio.h>

void fibonacci(void)
{
   int i;
   int fib[10];

   for (i = 0; i < 10; i++)
    {
        if (i < 2)
            fib[i] = 1;
        else
            fib[i] = fib[i-1] + fib[i-2];
    }

    /* Fix: Print fib[9] instead of fib[10] */
    printf("The 10-th Fibonacci number is %i .\n", fib[i-1]);
}
```

The `printf` statement accesses `fib[9]` instead of `fib[10]`.

### Array access with tainted index

#### Issue

This issue occurs when you access an array by using an index that is obtained from unsecure sources and which has not been validated.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite — writing to memory before the beginning of the buffer.
- Buffer overflow — writing to memory after the end of a buffer.
- Over-reading a buffer — accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write operation create to problems in your program.

#### Fix

Before using the index to access the array, validate the index value to make sure that it is inside the array range.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Use Index to Return Buffer Value**

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
  return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    return tab[num];//Noncompliant
}
```

In this example, the index `num` accesses the array `tab`. The index `num` is obtained from an unsecure source and the function `taintedarrayindex` does not check to see if `num` is inside the range of `tab`.

**Correction — Check Range Before Use**

One possible correction is to check that `num` is in range before using it.

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
    return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    if (num >= 0 && num < SIZE100) {
        return tab[num];
    } else {
        return -1;
    }
}
```

### Buffer overflow from incorrect string format specifier

**Issue**

This issue occurs when the format specifier argument for functions such as `sscanf` leads to an overflow or underflow in the memory buffer argument.

**Risk**

If the format specifier specifies a precision that is greater than the memory buffer size, an overflow occurs. Overflows can cause unexpected behavior such as memory corruption.

**Fix**

Use a format specifier that is compatible with the memory buffer size.

**Example — Memory Buffer Overflow**

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%33c", buf);
}
```

In this example, `buf` can contain 32 `char` elements. Therefore, the format specifier `%33c` causes a buffer overflow.

#### Correction — Use Smaller Precision in Format Specifier

One possible correction is to read a smaller number of elements into the buffer.

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%32c", buf);
}
```

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

#### Example — Buffer Overflow in sprintf Use

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, buffer can contain 20 char elements but fmt_string has a greater size.

#### Correction — Use snprintf Instead of sprintf

One possible correction is to use the snprintf function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Destination buffer underflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at a negative offset from the beginning of the buffer.

For instance, for the function sprintf(char* buffer, const char* format), you obtain the buffer from an operation buffer = (char*)arr; ... buffer += offset;. arr is an array and offset is a negative value.

#### Risk

Buffer underflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer underflow also introduces the risk of code injection.

#### Fix

If the destination buffer argument results from pointer arithmetic, see if you are decrementing a pointer. Fix the pointer decrement by modifying either the original value before decrement or the decrement value.

#### Example — Buffer Underflow in sprintf Use

```
#include <stdio.h>
#define offset -2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

In this example, &buffer[offset] is at a negative offset from the memory allocated to buffer.

#### Correction — Change Pointer Decrementer

One possible correction is to change the value of offset.

```
#include <stdio.h>
#define offset 2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

### Invalid use of standard library memory routine

**Issue**

This issue occurs when a memory library function is called with invalid arguments. For instance, the `memcpy` function copies to an array that cannot accommodate the number of bytes copied.

**Risk**

Use of a memory library function with invalid arguments can result in issues such as buffer overflow.

**Fix**

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Invalid Use of Standard Library Memory Routine Error**

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  char str1[10],str2[5];

  printf("Enter string:\n");
  scanf("%9s",str1);

  memcpy(str2,str1,6);
  /* Defect: Arguments of memcpy invalid: str2 has size < 6 */

  return str2;
 }
```

The size of string `str2` is 5, but six characters of string `str1` are copied into `str2` using the `memcpy` function.

#### Correction — Call Function with Valid Arguments

One possible correction is to adjust the size of `str2` so that it accommodates the characters copied with the `memcpy` function.

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  /* Fix: Declare str2 with size 6 */
  char str1[10],str2[6];

  printf("Enter string:\n");
  scanf("%9s",str1);

  memcpy(str2,str1,6);
  return str2;
 }
```

### Invalid use of standard library string routine

#### Issue

This issue occurs when a string library function is called with invalid arguments.

#### Risk

The risk depends on the type of invalid arguments. For instance, using the `strcpy` function with a source argument larger than the destination argument can result in buffer overflows.

#### Fix

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the `strcpy` function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to `strcpy`. In some cases, you can use an alternative function to avoid the error. For instance, instead of `strcpy`, you can use `strncpy` to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Invalid Use of Standard Library String Routine Error

```
 #include <string.h>
 #include <stdio.h>
  char* Copy_String(void)
  {
   char *res;
   char gbuffer[5],text[20]="ABCDEFGHIJKL";

   res=strcpy(gbuffer,text);
   /* Error: Size of text is less than gbuffer */

   return(res);
  }
```

The string `text` is larger in size than `gbuffer`. Therefore, the function `strcpy` cannot copy `text` into `gbuffer`.

**Correction — Use Valid Arguments**

One possible correction is to declare the destination string `gbuffer` with equal or larger size than the source string `text`.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

### Missing null in string array

**Issue**

This issue occurs when a string does not have enough space to terminate with a null character `'\0'`.

This defect applies only for projects in C.

**Risk**

A buffer overflow can occur if you copy a string to an array without assuming the implicit null terminator.

**Fix**

If you initialize a character array with a literal, avoid specifying the array bounds.

```
char three[]  = "THREE";
```

The compiler automatically allocates space for a null terminator. In the preceding example, the compiler allocates sufficient space for five characters and a null terminator.

If the issue occurs after initialization, you might have to increase the size of the array by one to account for the null terminator.

In certain circumstances, you might want to initialize the character array with a sequence of characters instead of a string. In this situation, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Array size is too small

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[5] = "THREE";
}
```

The character array `three` has a size of 5 and 5 characters `'T'`, `'H'`, `'R'`, `'E'`, and `'E'`. There is no room for the null character at the end because `three` is only five bytes large.

#### Correction — Increase Array Size

One possible correction is to change the array size to allow for the five characters plus a null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[6] = "THREE";
}
```

#### Correction — Change Initialization Method

One possible correction is to initialize the string by leaving the array size blank. This initialization method allocates enough memory for the five characters and a terminating-null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[]  = "THREE";
}
```

### Pointer access out of bounds

#### Issue

This issue occurs when a pointer is dereferenced outside its bounds.

When a pointer is assigned an address, a block of memory is associated with the pointer. You cannot access memory beyond that block using the pointer.

**Risk**

Dereferencing a pointer outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

**Fix**

The fix depends on the root cause of the defect. For instance, you dereferenced a pointer inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used pointer arithmetic to advance the pointer with an incorrect value for the pointer increment.

To fix the issue, you have to modify the loop bound or the pointer increment value.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Pointer access out of bounds error**

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
   {
    ptr++;
    *ptr=i;
    /* Defect: ptr out of bounds for i=9 */
   }

 return(arr);
}
```

`ptr` is assigned the address `arr` that points to a memory block of size `10*sizeof(int)`. In the `for`-loop, `ptr` is incremented 10 times. In the last iteration of the loop, `ptr` points outside the memory block assigned to it. Therefore, it cannot be dereferenced.

**Correction — Check Pointer Stays Within Bounds**

One possible correction is to reverse the order of increment and dereference of `ptr`.

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
     {
      /* Fix: Dereference pointer before increment */
      *ptr=i;
      ptr++;
     }

 return(arr);
}
```

After the last increment, even though `ptr` points outside the memory block assigned to it, it is not dereferenced more.

### Pointer dereference with tainted offset

#### Issue

This issue occurs when a pointer dereference uses an offset variable from an unknown or unsecure source.

This check focuses on dynamically allocated buffers. For static buffer offsets, see `Array access with tainted index`.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite, or writing to memory before the beginning of the buffer.
- Buffer overflow, or writing to memory after the end of a buffer.
- Over reading a buffer, or accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write to compromise your program.

#### Fix

Validate the index before you use the variable to access the pointer. Check to make sure that the variable is inside the valid range and does not overflow.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Dereference Pointer Array

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

#### Correction — Check Index Before Dereference

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

### Possible misuse of sizeof

#### Issue

This issue occurs when Polyspace Bug Finder detects possibly unintended results from the use of `sizeof` operator. For instance:

- You use the `sizeof` operator on an array parameter name, expecting the array size. However, the array parameter name by itself is a pointer. The `sizeof` operator returns the size of that pointer.
- You use the `sizeof` operator on an array element, expecting the array size. However, the operator returns the size of the array element.
- The size argument of certain functions such as `strncmp` or `wcsncpy` is incorrect because you used the `sizeof` operator earlier with possibly incorrect expectations. For instance:
  - In a function call `strncmp(string1, string2, num)`, `num` is obtained from an incorrect use of the `sizeof` operator on a pointer.
  - In a function call `wcsncpy(destination, source, num)`, `num` is the not the number of wide characters but a size in bytes obtained by using the `sizeof` operator. For instance, you use `wcsncpy(destination, source, sizeof(destination) - 1)` instead of `wcsncpy(destination, source, (sizeof(desintation)/sizeof(wchar_t)) - 1)`.

#### Risk

Incorrect use of the `sizeof` operator can cause the following issues:

- If you expect the `sizeof` operator to return array size and use the return value to constrain a loop, the number of loop runs are smaller than what you expect.
- If you use the return value of `sizeof` operator to allocate a buffer, the buffer size is smaller than what you require. Insufficient buffer can lead to resultant weaknesses such as buffer overflows.
- If you use the return value of `sizeof` operator incorrectly in a function call, the function does not behave as you expect.

#### Fix

Possible fixes are:

- Do not use the `sizeof` operator on an array parameter name or array element to determine array size.

  The best practice is to pass the array size as a separate function parameter and use that parameter in the function body.
- Use the `sizeof` operator carefully to determine the number argument of functions such as `strncmp` or `wcsncpy`. For instance, for wide string functions such as `wcsncpy`, use the number of wide characters as argument instead of the number of bytes.

#### Example — sizeof Used Incorrectly to Determine Array Size

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < sizeof(a)/sizeof(int); i++)    {
        a[i] = i + 1;
    }
}
```

In this example, `sizeof(a)` returns the size of the pointer `a` and not the array size.

#### Correction — Determine Array Size in Another Way

One possible correction is to use another means to determine the array size.

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < MAX_SIZE; i++)    {
        a[i] = i + 1;
    }
}
```

### Tainted NULL or non-null-terminated string

#### Issue

This issue occurs when strings from unsecure sources are used in string manipulation routines that implicitly dereference the string buffer, for instance, `strcpy` or `sprintf`.

**Tainted NULL or non-null-terminated string** raises no defect for a string returned from a call to `scanf`-family variadic functions. Similarly, no defect is raised when you pass the string with a `%s` specifier to `printf`-family variadic functions.

#### Risk

If a string is from an unsecure source, it is possible that an attacker manipulated the string or pointed the string pointer to a different memory location.

If the string is NULL, the string routine cannot dereference the string, causing the program to crash. If the string is not null-terminated, the string routine might not know when the string ends. This error can cause you to write out of bounds, causing a buffer overflow.

#### Fix

Validate the string before you use it. Check that:

- The string is not NULL.
- The string is null-terminated
- The size of the string matches the expected size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Getting String from Input

```
#include <stdio.h>
#include <stdlib.h>
```

```
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));//Noncompliant
    print_str(str);
}
```

In this example, the string `str` is concatenated with the argument `userstr`. The value of `userstr` is unknown. If the size of `userstr` is greater than the space available, the concatenation overflows.

#### Correction — Validate the Data

One possible correction is to check the size of `userstr` and make sure that the string is null-terminated before using it in `strncat`. This example uses a helper function, `sansitize_str`, to validate the string. The defects are concentrated in this function.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
int sanitize_str(char* s) {
    int res = 0;
    if (s && (strlen(s) > 0)) { // Noncompliant-TAINTED_STRING only flagged here
        // - string is not null
        // - string has a positive and limited size
        // - TAINTED_STRING on strlen used as a firewall
        res = 1;
    }
    return res;
}
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    if (sanitize_str(userstr))
        strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

#### Correction — Validate the Data

Another possible correction is to call function `errorMsg` and `warningMsg` with specific strings.

```
#include <stdio.h>
#include <string.h>
```

```
#include <stdlib.h>

#define SIZE128 128

extern void print_str(const char*);

void warningMsg(char* userstr)
{
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}

void errorMsg(char* userstr)
{
  char str[SIZE128] = "Error: ";
  strncat(str, userstr, SIZE128-(strlen(str)+1));
  print_str(str);
}

int manageSensorValue(int sensorValue) {
  int ret = sensorValue;
  if ( sensorValue < 0 ) {
    errorMsg("sensor value should be positive");
    exit(1);
  } else if ( sensorValue > 50 ) {
    warningMsg("sensor value greater than 50 (applying threshold)...");
    sensorValue = 50;
  }

  return sensorValue;
}
```

Buffer Over-read

## Description

### Rule Description

*The software reads from a buffer using buffer access mechanisms such as indexes or pointers that reference memory locations after the targeted buffer.*

### Polyspace Implementation

The rule checker checks for **Buffer overflow from incorrect string format specifier**.

## Examples

### Buffer overflow from incorrect string format specifier

#### Issue

This issue occurs when the format specifier argument for functions such as `sscanf` leads to an overflow or underflow in the memory buffer argument.

#### Risk

If the format specifier specifies a precision that is greater than the memory buffer size, an overflow occurs. Overflows can cause unexpected behavior such as memory corruption.

#### Fix

Use a format specifier that is compatible with the memory buffer size.

#### Example — Memory Buffer Overflow

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%33c", buf);
}
```

In this example, `buf` can contain 32 `char` elements. Therefore, the format specifier `%33c` causes a buffer overflow.

#### Correction — Use Smaller Precision in Format Specifier

One possible correction is to read a smaller number of elements into the buffer.

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%32c", buf);
}
```

Buffer Under-read

## Description

### Rule Description

*The software reads from a buffer using buffer access mechanisms such as indexes or pointers that reference memory locations prior to the targeted buffer.*

### Polyspace Implementation

The rule checker checks for **Buffer overflow from incorrect string format specifier**.

## Examples

### Buffer overflow from incorrect string format specifier

**Issue**

This issue occurs when the format specifier argument for functions such as `sscanf` leads to an overflow or underflow in the memory buffer argument.

**Risk**

If the format specifier specifies a precision that is greater than the memory buffer size, an overflow occurs. Overflows can cause unexpected behavior such as memory corruption.

**Fix**

Use a format specifier that is compatible with the memory buffer size.

**Example — Memory Buffer Overflow**

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%33c", buf);
}
```

In this example, `buf` can contain 32 `char` elements. Therefore, the format specifier `%33c` causes a buffer overflow.

**Correction — Use Smaller Precision in Format Specifier**

One possible correction is to read a smaller number of elements into the buffer.

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%32c", buf);
}

Wrap-around Error

## Description

### Rule Description

*Wrap around errors occur whenever a value is incremented past the maximum value for its type and therefore "wraps around" to a very small, negative, or undefined value.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Integer constant overflow**
- **Integer conversion overflow**
- **Integer overflow**
- **Tainted sign change conversion**
- **Unsigned integer constant overflow**
- **Unsigned integer conversion overflow**
- **Unsigned integer overflow**

## Examples

### Integer constant overflow

#### Issue

This issue occurs in the following cases:

- You assign a compile-time integer constant to a signed integer variable whose data type cannot accommodate the value.

  See “Constant Overflows from Assignments” on page 7-17.
- You use an `enum` value that cannot be accommodated by the underlying type of the `enum` (and the underlying type is signed). For most C compilers, the default underlying type is `signed int` (based on the C standard).

  See “Constant Overflows from enum Values” on page 7-17.
- You perform a binary operation involving two integer constants that results in an overflow, that is, a value outside the range allowed by the data type that the operation uses. A binary operation with integer constants uses the `signed int` data type (unless you use modifiers such as `u` or `L`).

  See “Constant Overflows from Binary Operations” on page 7-18.

An `n`-bit signed integer holds values in the range [$-2^{n-1}$, $2^{n-1}-1$]. For instance, `c` is an 8-bit signed `char` variable that cannot hold the value 255.

```
signed char c = 255;
```

This defect checker depends on the following options:

- `Target processor type (-target)`: Determines the sizes of fundamental types.
- `Enum type definition (-enum-type-definition)`: Determines the underlying types of enumerations.
- `Compiler (-compiler)`: Impacts the interpretation of code.

You do not see the defect in these situations:

- Creation of new constants from `const` variables (for specific compilers only).

  Different compilers might define compile-time constants differently. In the following code, `c+1` is considered a compile-time constant by GCC compilers, but not by the standard C compiler:

  ```
  const int16_t c = 32767;
  int16_t y = c + 1;
  ```

  Whether you see a violation of this check on `y` might depend on your compiler.
- Bitwise `NOT` operation.

  Polyspace does not raise this violation when you perform a bitwise `NOT` operation.

**Risk**

The default behavior for constant overflows can vary between compilers and platforms. Retaining constant overflows can reduce the portability of your code.

Even if your compilers wraps around overflowing constants with a warning, the wrap-around behavior can be unintended and cause unexpected results.

**Fix**

Check if the constant value is what you intended. If the value is correct, use a different, possibly wider, data type for the variable.

**Example — Constant Overflows from Assignments**

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_SIGNED_CHAR 127

void main() {
    char c1 = MAX_UNSIGNED_CHAR;
    char c2 = MAX_SIGNED_CHAR+1;
}
```

In this example, the defect appears on the macros because at least one use of the macro causes an overflow. To reproduce these defects, use a `Target processor type (-target)` where `char` is signed by default.

**Correction — Use Different Data Type**

One possible correction is to use a different data type for the variables that overflow.

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_SIGNED_CHAR 127

void main() {
```

```
    unsigned char c1 = MAX_UNSIGNED_CHAR;
    unsigned char c2 = MAX_SIGNED_CHAR+1;
}
```

**Example — Constant Overflows from enum Values**

```
enum {
  a=0x7fffffff,
  b,
  c=0xffffffff
} MyEnumA;
```

In this example, the `enum` has an underlying type `int`. The `int` type can accommodate values in the range [-$2^{31}$, $2^{31}$-1]. However, the value of the enumerator `b` is 0x80000000 or $2^{31}$ (one more than the previous value `a`). This value falls outside the allowed range of `int`.

The value of `c`, that is 0xffffffff or $2^{32}$-1, is even larger and also causes an overflow.

To see this defect:

- Specify `Compiler (-compiler)` as `generic`.
- Specify `Source code language (-lang)` as `c`.

**Example — Constant Overflows from Binary Operations**

```
const unsigned int K_ATM_Label_Ram_init_value [] = {
     0x06 | ( 3 << 29) ,
     0x80 | ( 9 << 29) ,
     ( 2 << 31 )        ,
};
```

In this example, two of the shift operations result in values that cannot be accommodated by the `signed int` data type. The `signed int` data type can accommodate values in the range [-$2^{31}$, $2^{31}$-1]. The operation:

- `9 << 29` results in the value $2^{32}$+536870912.
- `2 << 31` results in the value $2^{32}$.

Note that even though the result is assigned to an `unsigned int` variable, the overflow detection uses the underlying type of the binary operation, that is, `signed int`.

### Integer conversion overflow

#### Issue

This issue occurs when converting an integer to a smaller integer type. If the variable does not have enough bytes to represent the original value, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Converting from int to char

```
char convert(void) {

    int num = 1000000;

    return (char)num;
}
```

In the return statement, the integer variable `num` is converted to a `char`. However, an 8-bit or 16-bit character cannot represent 1000000 because it requires at least 20 bits. So the conversion operation overflows.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number.

```
long convert(void) {

    int num = 1000000;

    return (long)num;
}
```

### Integer overflow

#### Issue

This issue occurs when an operation on integer variables results in values that cannot be represented by the data type that the operation uses. This data type depends on the operand types and determines the number of bytes allocated for storing the result, thus constraining the range of allowed values.

Note that:

- The data type used to determine an overflow is based on the operand data types. If you then assign the result of an operation to another variable, a different checker, `Integer conversion overflow`, determines if the value assigned also overflows the variable assigned to. For instance, in an operation such as:

  ```
  res = x + y;
  ```

  This checker checks for an overflow based on the types of `x` and `y`, and not on the type of `res`. The checker for integer conversion overflows then checks for an overflow based on the type of `res`.
- The two operands in a binary operation might undergo promotion before the operation occurs. See also “Code Prover Assumptions About Implicit Data Type Conversions” (Polyspace Code Prover).

The exact storage allocation for different data types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer overflows on signed integers result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the operation so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

To avoid overflows in general, try one of these techniques:

- Keep integer variable values restricted to within half the range of signed integers.
- In operations that might overflow, check for conditions that can lead to the overflow and implement wrap around or saturation behavior depending on how the result of the operation is used. The result then becomes predictable and can be safely used in subsequent computations.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Addition of Maximum Integer

```
#include <limits.h>

int plusplus(void) {

    int var = INT_MAX;
    var++;
    return var;
}
```

In the third statement of this function, the variable `var` is increased by one. But the value of `var` is the maximum integer value, so an `int` cannot represent one plus the maximum integer value.

#### Correction — Different Storage Type

One possible correction is to change data types. Store the result of the operation in a larger data type (Note that on a 32-bit machine, `int` and `long` has the same size). In this example, on a 32-bit machine, by returning a `long long` instead of an `int`, the overflow error is fixed.

```
#include <limits.h>

long long plusplus(void) {

    long long lvar = INT_MAX;
    lvar++;
    return lvar;
}
```

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
memmove
strncmp
strncpy
```

```
calloc
malloc
memalign
```

**Risk**

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

**Fix**

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

**Extend Checker**

By default, Polyspace assumes that data from external sources are tainted. See "Sources of Tainting in a Polyspace Analysis". To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Set Memory Value with Size Argument**

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

**Correction — Check Value of `size`**

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

### Unsigned integer constant overflow

#### Issue

This issue occurs in the following cases:

- You assign a compile-time constant to an unsigned integer variable whose data type cannot accommodate the value.
- You use an `enum` value that cannot be accommodated by the underlying type of the `enum` (and the underlying type is unsigned).

An `n`-bit unsigned integer holds values in the range [0, $2^n$-1]. For instance, `c` is an 8-bit unsigned `char` variable that cannot hold the value 256.

```
unsigned char c = 256;
```

This defect checker depends on the following options:

- To determine the sizes of fundamental types, Bug Finder uses your specification for `Target processor type (-target)`.
- To determine the underlying types of enumerations, Bug Finder uses your specification for `Enum type definition (-enum-type-definition)`.

You do not see the defect in these situations:

- Creation of new constants from `const` variables (for specific compilers only).

  Different compilers might define compile-time constants differently. In the following code, `c+1u` is considered a compile time-constant by GCC compilers, but not by the standard C compiler:

  ```
  const uint16_t c = 0xffffu;
  uint16_t y = c + 1u;
  ```

  Whether you see a violation of this check on `y` might depend on your compiler.
- Bitwise `NOT` operation.

  Polyspace does not raise this violation when you perform a bitwise `NOT` operation.

#### Risk

The C standard states that overflowing unsigned integers must be wrapped around (see, for instance, the C11 standard, section 6.2.5). However, the wrap-around behavior can be unintended and cause unexpected results.

#### Fix

Check if the constant value is what you intended. If the value is correct, use a wider data type for the variable.

#### Example — Overflows from Assignments

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_UNSIGNED_SHORT 65535

void main() {
    unsigned char c1 = MAX_UNSIGNED_CHAR + 1;
    unsigned short c2 = MAX_UNSIGNED_SHORT + 1;
}
```

In this example, the defect appears on the macros because at least one use of the macro causes an overflow.

#### Correction — Use Wider Data Type

One possible correction is to use a wider data type for the variables that overflow.

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_UNSIGNED_SHORT 65535

void main() {
    unsigned short c1 = MAX_UNSIGNED_CHAR + 1;
    unsigned int c2 = MAX_UNSIGNED_SHORT + 1;
}
```

### Unsigned integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a smaller unsigned integer type. If the variable does not have enough bytes to represent the original constant, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Converting from int to char

```
unsigned char convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned char)unum;
}
```

In the return statement, the unsigned integer variable `unum` is converted to an unsigned character type. However, the conversion overflows because 1000000 requires at least 20 bits. The C programming language standard does not view unsigned overflow as an error because the program automatically reduces the result by modulo the maximum value plus 1. In this example, `unum` is reduced by modulo `2^8` because a character data type can only represent `2^8-1`.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number. For example, `long`.

```
unsigned long convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned long)unum;
}
```

### Unsigned integer overflow

#### Issue

This issue occurs when an operation on unsigned integer variables can result in values that cannot be represented by the result data type. The data type of a variable determines the number of bytes allocated for the variable storage and constrains the range of allowed values.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

The C11 standard states that unsigned integer overflows result in wrap-around behavior. However, a wrap around behavior might not always be desirable. For instance, if the result of a computation is used as an array size and the computation overflows, the array size is much smaller than expected.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the operation so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling. In the error handling code, you can override the default wrap-around behavior for overflows and implement saturation behavior, for instance.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Add One to Maximum Unsigned Integer

```
#include <limits.h>

unsigned int plusplus(void) {

    unsigned uvar = UINT_MAX;
    uvar++;
    return uvar;
}
```

In the third statement of this function, the variable `uvar` is increased by 1. However, the value of `uvar` is the maximum unsigned integer value, so 1 plus the maximum integer value cannot be represented by an `unsigned int`. The C programming language standard does not view unsigned overflow as an error because the program automatically reduces the result by modulo the maximum value plus 1. In this example, `uvar` is reduced by modulo `UINT_MAX`. The result is `uvar = 1`.

**Correction — Different Storage Type**

One possible correction is to store the operation result in a larger data type. In this example, by returning an `unsigned long long` instead of an `unsigned int`, the overflow error is fixed.

```
#include <limits.h>

unsigned long long plusplus(void) {

    unsigned long long ullvar = UINT_MAX;
    ullvar++;
    return ullvar;
}
```

## Check Information

CWE-128

# CWE Rule 129

Improper Validation of Array Index

## Description

### Rule Description

*The product uses untrusted input when calculating or using an array index, but the product does not validate or incorrectly validates the index to ensure the index references a valid position within the array.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access with tainted index**
- **Invalid use of standard library string routine**
- **Pointer dereference with tainted offset**
- **Tainted division operand**
- **Tainted modulo operand**

## Examples

### Array access with tainted index

#### Issue

This issue occurs when you access an array by using an index that is obtained from unsecure sources and which has not been validated.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite — writing to memory before the beginning of the buffer.
- Buffer overflow — writing to memory after the end of a buffer.
- Over-reading a buffer — accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write operation create to problems in your program.

#### Fix

Before using the index to access the array, validate the index value to make sure that it is inside the array range.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of

Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Use Index to Return Buffer Value

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
  return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    return tab[num];//Noncompliant
}
```

In this example, the index `num` accesses the array `tab`. The index `num` is obtained from an unsecure source and the function `taintedarrayindex` does not check to see if `num` is inside the range of `tab`.

#### Correction — Check Range Before Use

One possible correction is to check that `num` is in range before using it.

```
#include <stdlib.h>
#include <stdio.h>
#define SIZE100 100
extern int tab[SIZE100];
static int tainted_int_source(void) {
    return strtol(getenv("INDEX"),NULL,10);
}
int taintedarrayindex(void) {
    int num = tainted_int_source();
    if (num >= 0 && num < SIZE100) {
        return tab[num];
    } else {
        return -1;
    }
}
```

### Invalid use of standard library string routine

#### Issue

This issue occurs when a string library function is called with invalid arguments.

#### Risk

The risk depends on the type of invalid arguments. For instance, using the `strcpy` function with a source argument larger than the destination argument can result in buffer overflows.

#### Fix

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the `strcpy` function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to strcpy. In some cases, you can use an alternative function to avoid the error. For instance, instead of strcpy, you can use strncpy to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Invalid Use of Standard Library String Routine Error

```
 #include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  char gbuffer[5],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);
  /* Error: Size of text is less than gbuffer */

  return(res);
 }
```

The string text is larger in size than gbuffer. Therefore, the function strcpy cannot copy text into gbuffer.

#### Correction — Use Valid Arguments

One possible correction is to declare the destination string gbuffer with equal or larger size than the source string text.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

### Pointer dereference with tainted offset

#### Issue

This issue occurs when a pointer dereference uses an offset variable from an unknown or unsecure source.

This check focuses on dynamically allocated buffers. For static buffer offsets, see `Array access with tainted index`.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite, or writing to memory before the beginning of the buffer.
- Buffer overflow, or writing to memory after the end of a buffer.
- Over reading a buffer, or accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write to compromise your program.

#### Fix

Validate the index before you use the variable to access the pointer. Check to make sure that the variable is inside the valid range and does not overflow.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Dereference Pointer Array

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

#### Correction — Check Index Before Dereference

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

### Tainted division operand

#### Issue

This issue occurs when one or both integer operands in a division operation comes from unsecure sources.

#### Risk

- If the numerator is the minimum possible value and the denominator is `-1`, your division operation overflows because the result cannot be represented by the current variable size.
- If the denominator is zero, your division operation fails possibly causing your program to crash.

These risks can be used to execute arbitrary code. This code is usually outside the scope of a program's implicit security policy.

#### Fix

Before performing the division, validate the values of the operands. Check for denominators of `0` or `-1`, and numerators of the minimum integer value.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See "Sources of Tainting in a Polyspace Analysis". To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Division of Function Arguments

```
#include <limits.h>
#include <stdio.h>

extern void print_int(int);

int taintedintdivision(void) {
    long num, denum;
    scanf("%lf %lf", &num, &denum);
    int r =  num/denum; //Noncompliant
    print_int(r);
    return r;
}
```

This example function divides two argument variables, then prints and returns the result. The argument values are unknown and can cause division by zero or integer overflow.

#### Correction — Check Values

One possible correction is to check the values of the numerator and denominator before performing the division.

```
#include <limits.h>
#include <stdio.h>

extern void print_long(long);

int taintedintdivision(void) {
    long num, denum;
    scanf("%lf %lf", &num, &denum);
    long res= 0;
    if (denum!=0 && !(num==INT_MIN && denum==-1)) {
        res = num/denum;
    }
    print_long(res);
    return res;
}
```

### Tainted modulo operand

#### Issue

This issue occurs when one or both integer operands in a remainder operation (%) comes from unsecure sources.

#### Risk

- If the second remainder operand is zero, your remainder operation fails, causing your program to crash.
- If the second remainder operand is `-1`, your remainder operation can overflow if the remainder operation is implemented based on the division operation that can overflow.

- If one of the operands is negative, the operation result is uncertain. For C89, the modulo operation is not standardized, so the result from negative operands is implementation-defined.

These risks can be exploited by attackers to gain access to your program or the target in general.

#### Fix

Before performing the modulo operation, validate the values of the operands. Check the second operand for values of `0` and `-1`. Check both operands for negative values.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Modulo with User Input

```
#include <stdio.h>
extern void print_int(int);

int taintedintmod(void) {
    int userden;
    scanf("%d", &userden);
    int rem =  128%userden; //Noncompliant
    print_int(rem);
    return rem;
}
```

In this example, the function performs a modulo operation by using a user input. The input is not checked before calculating the remainder for values that can crash the program, such as 0 and -1.

#### Correction — Check Operand Values

One possible correction is to check the values of the operands before performing the modulo operation. In this corrected example, the modulo operation continues only if the second operand is greater than zero.

```
#include<stdio.h>
extern void print_int(int);

int taintedintmod(void) {
    int userden;
    scanf("%d", &userden);
    int rem = 0;
    if (userden > 0 ) {
        rem = 128 % userden;
    }
    print_int(rem);
    return rem;
}
```

CWE-129

# CWE Rule 130

Improper Handling of Length Parameter Inconsistency

## Description

### Rule Description

*The software parses a formatted message or structure, but it does not handle or incorrectly handles a length field that is inconsistent with the actual length of the associated data.*

### Polyspace Implementation

The rule checker checks for **Mismatch between data length and size**.

## Examples

### Mismatch between data length and size

**Issue**

This issue occurs when you do not check the length argument and data buffer argument of memory copying functions such as `memcpy`, `memset`, or `memmove`, to protect against buffer overflows.

**Risk**

If an attacker can manipulate the data buffer or length argument, the attacker can cause buffer overflow by making the actual data size smaller than the length.

This mismatch in length allows the attacker to copy memory past the data buffer to a new location. If the extra memory contains sensitive information, the attacker can now access that data.

This defect is similar to the SSL Heartbleed bug.

**Fix**

When copying or manipulating memory, compute the length argument directly from the data so that the sizes match.

**Example — Copy Buffer of Data**

```
#include <stdlib.h>
#include <string.h>

typedef struct buf_mem_st {
    char *data;
    size_t max;     /* size of buffer */
} BUF_MEM;

extern BUF_MEM beta;

int cpy_data(BUF_MEM *alpha)
{
    BUF_MEM *os = alpha;
    int num, length;
    if (alpha == 0x0) return 0;
    num = 0;

    length = *(unsigned short *)os->data;
    memcpy(&(beta.data[num]), os->data + 2, length);

    return(1);
}
```

This function copies the buffer `alpha` into a buffer `beta`. However, the `length` variable is not related to `data+2`.

#### Correction — Check Buffer Length

One possible correction is to check the length of your buffer against the maximum value minus 2. This check ensures that you have enough space to copy the data to the `beta` structure.

```
#include <stdlib.h>
#include <string.h>

typedef struct buf_mem_st {
    char *data;
    size_t max;     /* size of buffer */
} BUF_MEM;

extern BUF_MEM beta;

int cpy_data(BUF_MEM *alpha)
{
    BUF_MEM *os = alpha;
    int num, length;

    if (alpha == 0x0) return 0;
    num = 0;

    length = *(unsigned short *)os->data;
    if (length<(os->max -2)) {
        memcpy(&(beta.data[num]), os->data + 2, length);
    }

    return(1);

}
```

CWE-130

# CWE Rule 131

Incorrect Calculation of Buffer Size

## Description

### Rule Description

*The software does not correctly calculate the size to be used when allocating a buffer, which could lead to a buffer overflow.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access out of bounds**
- **Memory allocation with tainted size**
- **Pointer access out of bounds**
- **Tainted sign change conversion**
- **Tainted size of variable length array**
- **Wrong type used in sizeof**

## Examples

### Array access out of bounds

#### Issue

This issue occurs when an array index falls outside the range `[0...array_size-1]` during array access.

#### Risk

Accessing an array outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you accessed an array inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used an array index that is the same as the loop index instead of being one less than the loop index.

To fix the issue, you have to modify the loop bound or the array index.

Another reason why an array index can exceed array bounds is a prior conversion from signed to unsigned integers. The conversion can result in a wrap around of the index value, eventually causing the array index to exceed the array bounds.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Extend Checker**

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

**Example — Array Access Out of Bounds Error**

```
#include <stdio.h>

void fibonacci(void)
{
    int i;
    int fib[10];

    for (i = 0; i < 10; i++)
       {
        if (i < 2)
            fib[i] = 1;
         else
            fib[i] = fib[i-1] + fib[i-2];
       }

    printf("The 10-th Fibonacci number is %i .\n", fib[i]);
    /* Defect: Value of i is greater than allowed value of 9 */
}
```

The array `fib` is assigned a size of 10. An array index for `fib` has allowed values of `[0,1,2,...,9]`. The variable `i` has a value 10 when it comes out of the `for`-loop. Therefore, the `printf` statement attempts to access `fib[10]` through `i`.

**Correction — Keep Array Index Within Array Bounds**

One possible correction is to print `fib[i-1]` instead of `fib[i]` after the `for`-loop.

```
#include <stdio.h>

void fibonacci(void)
{
   int i;
   int fib[10];

   for (i = 0; i < 10; i++)
    {
        if (i < 2)
            fib[i] = 1;
        else
            fib[i] = fib[i-1] + fib[i-2];
    }

    /* Fix: Print fib[9] instead of fib[10] */
    printf("The 10-th Fibonacci number is %i .\n", fib[i-1]);
}
```

The `printf` statement accesses `fib[9]` instead of `fib[10]`.

### Memory allocation with tainted size

#### Issue

This issue occurs when a memory allocation function, such as `calloc` or `malloc`, uses a size argument from an unsecure source.

#### Risk

Uncontrolled memory allocation can cause your program to request too much system memory. This consequence can lead to a crash due to an out-of-memory condition, or assigning too many resources.

#### Fix

Before allocating memory, check the value of your arguments to check that they do not exceed the bounds.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Allocate Memory Using Input From User

```
#include<stdio.h>
#include <stdlib.h>

int* bug_taintedmemoryallocsize(void) {
    size_t size;
    scanf("%zu", &size);
    int* p = (int*)malloc(size);//Noncompliant
    return p;
}
```

In this example, `malloc` allocates `size` bytes of memory for the pointer `p`. The variable `size` comes from the user of the program. Its value is not checked, and it could be larger than the amount of available memory. If `size` is larger than the number of available bytes, your program could crash.

#### Correction — Check Size of Memory to be Allocated

One possible correction is to check the size of the memory that you want to allocate before performing the `malloc` operation. This example checks to see if `size` is positive and less than the maximum size.

```
#include<stdio.h>
#include <stdlib.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

int* corrected_taintedmemoryallocsize(void) {
    size_t size;
    scanf("%zu", &size);
    int* p = NULL;
    if (size>0 && size<SIZE128) {          /* Fix: Check entry range before use */
        p = (int*)malloc((unsigned int)size);
    }
    return p;
}
```

### Pointer access out of bounds

#### Issue

This issue occurs when a pointer is dereferenced outside its bounds.

When a pointer is assigned an address, a block of memory is associated with the pointer. You cannot access memory beyond that block using the pointer.

#### Risk

Dereferencing a pointer outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you dereferenced a pointer inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used pointer arithmetic to advance the pointer with an incorrect value for the pointer increment.

To fix the issue, you have to modify the loop bound or the pointer increment value.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Pointer access out of bounds error

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
   {
    ptr++;
    *ptr=i;
    /* Defect: ptr out of bounds for i=9 */
   }

 return(arr);
}
```

`ptr` is assigned the address `arr` that points to a memory block of size `10*sizeof(int)`. In the `for`-loop, `ptr` is incremented 10 times. In the last iteration of the loop, `ptr` points outside the memory block assigned to it. Therefore, it cannot be dereferenced.

#### Correction — Check Pointer Stays Within Bounds

One possible correction is to reverse the order of increment and dereference of `ptr`.

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
     {
      /* Fix: Dereference pointer before increment */
      *ptr=i;
      ptr++;
     }

 return(arr);
}
```

After the last increment, even though `ptr` points outside the memory block assigned to it, it is not dereferenced more.

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
memmove
strncmp
strncpy
calloc
malloc
memalign
```

**Risk**

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

**Fix**

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

**Extend Checker**

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Set Memory Value with Size Argument**

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

#### Correction — Check Value of `size`

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

### Tainted size of variable length array

#### Issue

This issue occurs when the size of a variable length array (VLA) is obtained from an unsecure source.

#### Risk

If an attacker changed the size of your VLA to an unexpected value, it can cause your program to crash or behave unexpectedly.

If the size is non-positive, the behavior of the VLA is undefined. Your program does not perform as expected.

If the size is unbounded, the VLA can cause memory exhaustion or stack overflow.

#### Fix

Validate your VLA size to make sure that it is positive and less than a maximum value.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Example — User Input Argument Used as Size of VLA

```
#include<stdio.h>
#inclule<stdlib.h>
#define LIM 40
```

```
long squaredSum(int size) {

    int tabvla[size];
    long res = 0;
    for (int i=0 ; i<LIM-1 ; ++i) {
        tabvla[i] = i*i;
        res += tabvla[i];
    }
    return res;
}
int main(){
    int size;
    scanf("%d",&size);
    //...
    long result = squaredSum(size);
    //...
    return 0;
}
```

In this example, a variable length array size is based on an input argument. Because this input argument value is not checked, the size may be negative or too large.

#### Correction — Check VLA Size

One possible correction is to check the size variable before creating the variable length array. This example checks if the size is larger than 0 and less than 40, before creating the VLA

```
#include <stdio.h>
#include <stdlib.h>
#define LIM 40

long squaredSum(int size) {
    long res = 0;
    if (size>0 && size<LIM){
        int tabvla[size];
        for (int i=0 ; i<size || i<LIM-1 ; ++i) {
            tabvla[i] = i*i;
            res += tabvla[i];
        }
    }else{
        res = -1;
    }
    return res;
}
int main(){
    int size;
    scanf("%d",&size);
    //...
    long result = squaredSum(size);
    //...
    return 0;
}
```

### Wrong type used in sizeof

#### Issue

This issue occurs when both of the following conditions hold:

1 You assign the address of a block of memory to a pointer, or transfer data between two blocks of memory. The assignment or copy uses the `sizeof` operator.

   For instance, you initialize a pointer using `malloc(sizeof(`*`type`*`))` or copy data between two addresses using `memcpy(`*`destination_ptr`*`, `*`source_ptr`*`, sizeof(`*`type`*`))`.

2 You use an incorrect type as argument of the `sizeof` operator. For instance:

   - You might be using the pointer type instead of the type that the pointer points to. For example, to initialize a *`type`*`*` pointer, you might be using `malloc(sizeof(`*`type`*`*))` instead of `malloc(sizeof(`*`type`*`))`.
   - You might be using a completely unrelated type as `sizeof` argument. For example, to initialize a *`type`*`*` pointer, you might be using `malloc(sizeof(`*`anotherType`*`))`.

#### Risk

Irrespective of what *`type`* stands for, the expression `sizeof(`*`type`*`*)` always returns a fixed size. The size returned is the pointer size on your platform in bytes. The appearance of `sizeof(`*`type`*`*)` often indicates an unintended usage. The error can cause allocation of a memory block that is much smaller than what you need and lead to weaknesses such as buffer overflows.

For instance, assume that `structType` is a structure with ten `int` variables. If you initialize a `structType*` pointer using `malloc(sizeof(structType*))` on a 32-bit platform, the pointer is assigned a memory block of four bytes. However, to be allocated completely for one `structType` variable, the `structType*` pointer must point to a memory block of `sizeof(structType) = 10 * sizeof(int)` bytes. The required size is much greater than the actual allocated size of four bytes.

#### Fix

To initialize a *`type`*`*` pointer, replace `sizeof(`*`type`*`*)` in your pointer initialization expression with `sizeof(`*`type`*`)`.

#### Example — Allocate a Char Array With sizeof

```
#include <stdlib.h>

void test_case_1(void) {
    char* str;

    str = (char*)malloc(sizeof(char*) * 5);
    free(str);

}
```

In this example, memory is allocated for the character pointer `str` using a `malloc` of five char pointers. However, `str` is a pointer to a character, not a pointer to a character pointer. Therefore the `sizeof` argument, `char*`, is incorrect.

#### Correction — Match Pointer Type to `sizeof` Argument

One possible correction is to match the argument to the pointer type. In this example, `str` is a character pointer, therefore the argument must also be a character.

```
#include <stdlib.h>

void test_case_1(void) {
    char* str;
    str = (char*)malloc(sizeof(char) * 5);
    free(str);

}
```

CWE-131

# CWE Rule 134

Use of Externally-Controlled Format String

## Description

### Rule Description

*The software uses a function that accepts a format string as an argument, but the format string originates from an external source.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Format string specifiers and arguments mismatch**
- **Tainted string format**

## Examples

### Format string specifiers and arguments mismatch

#### Issue

This issue occurs when the format specifiers in the formatted output functions such as `printf` do not match their corresponding arguments. For example, an argument of type `unsigned long` must have a format specification of `%lu`.

#### Risk

Mismatch between format specifiers and the corresponding arguments result in undefined behavior.

#### Fix

Make sure that the format specifiers match the corresponding arguments. For instance, in this example, the `%d` specifier does not match the string argument `message` and the `%s` specifier does not match the integer argument `err_number`.

```
const char *message = "License not available";
int err_number = ;-4
printf("Error: %d (error type %s)\n", message, err_number);
```

Switching the two format specifiers fixes the issue. See the specifications for the printf function for more information about format specifiers.

In cases where integer promotion modifies the perceived data type of an argument, the analysis result shows both the original type and the type after promotion. The format specifier has to match the type after integer promotion.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.

- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Printing a Float**

```
#include <stdio.h>

void string_format(void) {

    unsigned long fst = 1;

    printf("%d\n", fst);
}
```

In the `printf` statement, the format specifier, `%d`, does not match the data type of `fst`.

**Correction — Use an Unsigned Long Format Specifier**

One possible correction is to use the `%lu` format specifier. This specifier matches the `unsigned` integer type and `long` size of `fst`.

```
#include <stdio.h>

void string_format(void) {

    unsigned long fst = 1;

    printf("%lu\n", fst);
}
```

**Correction — Use an Integer Argument**

One possible correction is to change the argument to match the format specifier. Convert `fst` to an integer to match the format specifier and print the value `1`.

```
#include <stdio.h>

void string_format(void) {

    unsigned long fst = 1;

    printf("%d\n", (int)fst);
}
```

### Tainted string format

**Issue**

This issue occurs when `printf`-style functions use a format specifier constructed from unsecure sources.

**Risk**

If you use externally controlled elements to format a string, you can cause buffer overflow or data-representation problems. An attacker can use these string formatting elements to view the contents of a stack using `%x` or write to a stack using `%n`.

#### Fix

Pass a static string to format string functions. This fix ensures that an external actor cannot control the string.

Another possible fix is to allow only the expected number of arguments. If possible, use functions that do not support the vulnerable `%n` operator in format strings.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See "Sources of Tainting in a Polyspace Analysis". To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Get Elements from User Input

```
#include <stdio.h>
#include <unistd.h>
#define MAX 40
void taintedstringformat(void) {
    char userstr[MAX];
    read(0,userstr,MAX);
    printf(userstr);//Noncompliant
}
```

This example prints the input argument `userstr`. The string is unknown. If it contains elements such as `%`, `printf` can interpret `userstr` as a string format instead of a string, causing your program to crash.

#### Correction — Print as String

One possible correction is to print `userstr` explicitly as a string so that there is no ambiguity.

```
#include "stdio.h"
#include <unistd.h>
#define MAX 40

void taintedstringformat(void) {
    char userstr[MAX];
    read(0,userstr,MAX);
    printf("%.20s", userstr);
}
```

CWE-134

# CWE Rule 135

Incorrect Calculation of Multi-Byte String Length

## Description

### Rule Description

*The software does not correctly calculate the length of strings that can contain wide or multi-byte characters.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Destination buffer overflow in string manipulation**
- **Misuse of narrow or wide character string**
- **Unreliable cast of pointer**

## Examples

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

**Example — Buffer Overflow in sprintf Use**

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

**Correction — Use `snprintf` Instead of `sprintf`**

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Misuse of narrow or wide character string

**Issue**

This issue occurs when you pass a narrow character string to a wide string function, or a wide character string to a narrow string function.

**Misuse of narrow or wide character string** raises no defect on operating systems where narrow and wide character strings have the same size.

**Risk**

Using a narrow character string with a wide string function, or vice versa, can result in unexpected or undefined behavior.

If you pass a wide character string to a narrow string function, you can encounter these issues:

- Data truncation. If the string contains null bytes, a copy operation using `strncpy()` can terminate early.
- Incorrect string length. `strlen()` returns the number of characters of a string up to the first null byte. A wide string can have additional characters after its first null byte.

If you pass a narrow character string to a wide string function, you can encounter this issue:

- Buffer overflow. In a copy operation using `wcsncpy()`, the destination string might have insufficient memory to store the result of the copy.

**Fix**

Use the narrow string functions with narrow character strings. Use the wide string functions with wide character strings.

#### Example — Passing Wide Character Strings to strncpy()

```
#include <string.h>
#include <wchar.h>

void func(void)
{
    wchar_t wide_str1[]  = L"0123456789";
    wchar_t wide_str2[] =  L"0000000000";
    strncpy(wide_str2, wide_str1, 10);
}
```

In this example, `strncpy()` copies 10 wide characters from `wide_strt1` to `wide_str2`. If `wide_str1` contains null bytes, the copy operation can end prematurely and truncate the wide character string.

#### Correction — Use `wcsncpy()` to Copy Wide Character Strings

One possible correction is to use `wcsncpy()` to copy `wide_str1` to `wide_str2`.

```
#include <string.h>
#include <wchar.h>

void func(void)
{
    wchar_t wide_str1[]  = L"0123456789";
    wchar_t wide_str2[] =  L"0000000000";
    wcsncpy(wide_str2, wide_str1, 10);
}
```

### Unreliable cast of pointer

#### Issue

This issue occurs when a pointer is implicitly cast to a data type different from its declaration type. Such an implicit casting can take place, for instance, when a pointer to data type `char` is assigned the address of an integer.

This defect applies only if the code language for the project is C.

#### Risk

Casting a pointer to data type different from its declaration type can result in issues such as buffer overflow. If the cast is implicit, it can indicate a coding error.

#### Fix

Avoid *implicit* cast of a pointer to a data type different from its declaration type.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.

- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Unreliable cast of pointer error

```
#include <string.h>

void Copy_Integer_To_String()
{
 int src[]={1,2,3,4,5,6,7,8,9,10};
 char buffer[]="Buffer_Text";
 strcpy(buffer,src);
 /* Defect: Implicit cast of (int*) to (char*) */
}
```

`src` is declared as an `int*` pointer. The `strcpy` statement, while copying to `buffer`, implicitly casts `src` to `char*`.

#### Correction — Avoid Pointer Cast

One possible correction is to declare the pointer `src` with the same data type as `buffer`.

```
#include <string.h>
 void Copy_Integer_To_String()
{
 /* Fix: Declare src with same type as buffer */
 char *src[10]={"1","2","3","4","5","6","7","8","9","10"};
 char *buffer[10];

 for(int i=0;i<10;i++)
   buffer[i]="Buffer_Text";

 for(int i=0;i<10;i++)
   buffer[i]= src[i];
 }
```

Improper Null Termination

## Description

### Rule Description

*The software does not terminate or incorrectly terminates a string or array with a null character or equivalent terminator.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Invalid use of standard library string routine**
- **Missing null in string array**
- **Misuse of readlink()**
- **Tainted NULL or non-null-terminated string**

## Examples

### Invalid use of standard library string routine

#### Issue

This issue occurs when a string library function is called with invalid arguments.

#### Risk

The risk depends on the type of invalid arguments. For instance, using the `strcpy` function with a source argument larger than the destination argument can result in buffer overflows.

#### Fix

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the `strcpy` function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to `strcpy`. In some cases, you can use an alternative function to avoid the error. For instance, instead of `strcpy`, you can use `strncpy` to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.

- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Invalid Use of Standard Library String Routine Error**

```
 #include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  char gbuffer[5],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);
  /* Error: Size of text is less than gbuffer */

  return(res);
 }
```

The string `text` is larger in size than `gbuffer`. Therefore, the function `strcpy` cannot copy `text` into `gbuffer`.

**Correction — Use Valid Arguments**

One possible correction is to declare the destination string `gbuffer` with equal or larger size than the source string `text`.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

### Missing null in string array

**Issue**

This issue occurs when a string does not have enough space to terminate with a null character `'\0'`.

This defect applies only for projects in C.

**Risk**

A buffer overflow can occur if you copy a string to an array without assuming the implicit null terminator.

**Fix**

If you initialize a character array with a literal, avoid specifying the array bounds.

```
char three[]  = "THREE";
```

The compiler automatically allocates space for a null terminator. In the preceding example, the compiler allocates sufficient space for five characters and a null terminator.

If the issue occurs after initialization, you might have to increase the size of the array by one to account for the null terminator.

In certain circumstances, you might want to initialize the character array with a sequence of characters instead of a string. In this situation, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Array size is too small**

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[5] = "THREE";
}
```

The character array `three` has a size of 5 and 5 characters `'T'`, `'H'`, `'R'`, `'E'`, and `'E'`. There is no room for the null character at the end because `three` is only five bytes large.

**Correction — Increase Array Size**

One possible correction is to change the array size to allow for the five characters plus a null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[6] = "THREE";
}
```

**Correction — Change Initialization Method**

One possible correction is to initialize the string by leaving the array size blank. This initialization method allocates enough memory for the five characters and a terminating-null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[]  = "THREE";
}
```

### Misuse of readlink()

**Issue**

This issue occurs when you pass a buffer size argument to `readlink()` that does not leave space for a null terminator in the buffer.

For instance:

```
ssize_t len = readlink("/usr/bin/perl", buf, sizeof(buf));
```

The third argument is exactly equal to the size of the second argument. For large enough symbolic links, this use of `readlink()` does not leave space to enter a null terminator.

**Risk**

The `readlink()` function copies the content of a symbolic link (first argument) to a buffer (second argument). However, the function does not append a null terminator to the copied content. After using `readlink()`, you must explicitly add a null terminator to the buffer.

If you fill the entire buffer when using `readlink`, you do not leave space for this null terminator.

**Fix**

When using the `readlink()` function, make sure that the third argument is one less than the buffer size.

Then, append a null terminator to the buffer. To determine where to add the null terminator, check the return value of `readlink()`. If the return value is -1, an error has occurred. Otherwise, the return value is the number of characters (bytes) copied.

**Example — Incorrect Size Argument of readlink**

```
#include <unistd.h>

#define SIZE1024 1024

extern void display_path(const char *);

void func() {
    char buf[SIZE1024];
    ssize_t len = readlink("/usr/bin/perl", buf, sizeof(buf));
    if (len > 0) {
        buf[len - 1] = '\0';
    }
    display_path(buf);
}
```

In this example, the third argument of `readlink` is exactly the size of the buffer (second argument). If the first argument is long enough, this use of `readlink` does not leave space for the null terminator.

Also, if no characters are copied, the return value of `readlink` is 0. The following statement leads to a buffer underflow when `len` is 0.

```
buf[len - 1] = '\0';
```

**Correction — Make Sure Size Argument is One Less Than Buffer Size**

One possible correction is to make sure that the third argument of `readlink` is one less than size of the second argument.

The following corrected code also accounts for `readlink` returning 0.

```
#include <stdlib.h>
#include <unistd.h>
```

```
#define fatal_error() abort()
#define SIZE1024 1024

extern void display_path(const char *);

void func() {
    char buf[SIZE1024];
    ssize_t len = readlink("/usr/bin/perl", buf, sizeof(buf) - 1);
    if (len != -1) {
        buf[len] = '\0';
        display_path(buf);
    }
    else {
        /* Handle error */
        fatal_error();
    }
}
```

### Tainted NULL or non-null-terminated string

#### Issue

This issue occurs when strings from unsecure sources are used in string manipulation routines that implicitly dereference the string buffer, for instance, `strcpy` or `sprintf`.

**Tainted NULL or non-null-terminated string** raises no defect for a string returned from a call to `scanf`-family variadic functions. Similarly, no defect is raised when you pass the string with a `%s` specifier to `printf`-family variadic functions.

#### Risk

If a string is from an unsecure source, it is possible that an attacker manipulated the string or pointed the string pointer to a different memory location.

If the string is NULL, the string routine cannot dereference the string, causing the program to crash. If the string is not null-terminated, the string routine might not know when the string ends. This error can cause you to write out of bounds, causing a buffer overflow.

#### Fix

Validate the string before you use it. Check that:

- The string is not NULL.
- The string is null-terminated
- The size of the string matches the expected size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Getting String from Input

```
#include <stdio.h>
#include <stdlib.h>
```

```
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));//Noncompliant
    print_str(str);
}
```

In this example, the string `str` is concatenated with the argument `userstr`. The value of `userstr` is unknown. If the size of `userstr` is greater than the space available, the concatenation overflows.

**Correction — Validate the Data**

One possible correction is to check the size of `userstr` and make sure that the string is null-terminated before using it in `strncat`. This example uses a helper function, `sansitize_str`, to validate the string. The defects are concentrated in this function.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
int sanitize_str(char* s) {
    int res = 0;
    if (s && (strlen(s) > 0)) { // Noncompliant-TAINTED_STRING only flagged here
        // - string is not null
        // - string has a positive and limited size
        // - TAINTED_STRING on strlen used as a firewall
        res = 1;
    }
    return res;
}
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    if (sanitize_str(userstr))
        strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

**Correction — Validate the Data**

Another possible correction is to call function `errorMsg` and `warningMsg` with specific strings.

```
#include <stdio.h>
#include <string.h>
```

```
#include <stdlib.h>

#define SIZE128 128

extern void print_str(const char*);

void warningMsg(char* userstr)
{
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}

void errorMsg(char* userstr)
{
  char str[SIZE128] = "Error: ";
  strncat(str, userstr, SIZE128-(strlen(str)+1));
  print_str(str);
}

int manageSensorValue(int sensorValue) {
  int ret = sensorValue;
  if ( sensorValue < 0 ) {
    errorMsg("sensor value should be positive");
    exit(1);
  } else if ( sensorValue > 50 ) {
    warningMsg("sensor value greater than 50 (applying threshold)...");
    sensorValue = 50;
  }

  return sensorValue;
}
```

Reliance on Data/Memory Layout

## Description

### Rule Description

*The software makes invalid assumptions about how protocol data or memory is organized at a lower level, resulting in unintended program behavior.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Invalid assumptions about memory organization**
- **Memory comparison of padding data**
- **Missing byte reordering when transferring data**

## Examples

### Invalid assumptions about memory organization

#### Issue

This issue occurs when you compute the address of a variable in the stack by adding or subtracting from the address of another non-array variable.

#### Risk

When you compute the address of a variable in the stack by adding or subtracting from the address of another variable, you assume a certain memory organization. If your assumption is incorrect, accessing the computed address can be invalid.

#### Fix

Do not perform an access that relies on assumptions about memory organization.

#### Example — Reliance on Memory Organization

```
void func(void) {
    int var1 = 0x00000011, var2;
    *(&var1 + 1) = 0;
}
```

In this example, the programmer relies on the assumption that `&var1 + 1` provides the address of `var2`. Therefore, an **Invalid assumptions about memory organization** appears on the `+` operation. In addition, a **Pointer access out of bounds** error also appears on the dereference.

#### Correction — Do Not Rely on Memory Organization

One possible correction is not perform direct computation on addresses to access separately declared variables.

### Memory comparison of padding data

#### Issue

This issue occurs when you use the `memcmp` function to compare two structures as a whole. In the process, you compare meaningless data stored in the structure padding.

For instance:

```
struct structType {
    char member1;
    int member2;
    .
    .
};

structType var1;
structType var2;
.
.
if(memcmp(&var1,&var2,sizeof(var1)))
{...}
```

#### Risk

If members of a structure have different data types, your compiler introduces additional padding for data alignment in memory. For an example of padding, see `Higher Estimate of Size of Local Variables`.

The content of these extra padding bytes is meaningless. The C Standard allows the content of these bytes to be indeterminate, giving different compilers latitude to implement their own padding. If you perform a byte-by-byte comparison of structures with `memcmp`, you compare even the meaningless data stored in the padding. You might reach the false conclusion that two data structures are not equal, even if their corresponding members have the same value.

#### Fix

Instead of comparing two structures in one attempt, compare the structures member by member.

For efficient code, write a function that does the comparison member by member. Use this function for comparing two structures.

You can use `memcmp` for byte-by-byte comparison of structures only if you know that the structures do not contain padding. Typically, to prevent padding, you use specific attributes or pragmas such as `#pragma pack`. However, these attributes or pragmas are not supported by all compilers and make your code implementation-dependent. If your structures contain bit-fields, using these attributes or pragmas cannot prevent padding.

#### Example — Structures Compared with memcmp

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define fatal_error() abort()

typedef struct s_padding
{
    char c;
    int i;
    unsigned int bf1:1;
    unsigned int bf2:2;
    unsigned char buffer[20];
} S_Padding ;

/* Function that guarantees safe access to the input memory */
extern int trusted_memory_zone(void *ptr, size_t sz);

int func(const S_Padding *left, const S_Padding *right)
{

    if (!trusted_memory_zone((void *)left, sizeof(S_Padding)) ||
        !trusted_memory_zone((void *)right, sizeof(S_Padding))) {
        fatal_error();
    }

    if (0 == memcmp(left, right, sizeof(S_Padding)))
    {
        return 1;
    }
    else
        return 0;
}
```

In this example, `memcmp` compares byte-by-byte the two structures that `left` and `right` point to. Even if the values stored in the structure members are the same, the comparison can show an inequality if the meaningless values in the padding bytes are not the same.

**Correction — Compare Structures Member by Member**

One possible correction is to compare individual structure members.

**Note** You can compare entire arrays by using `memcmp`. All members of an array have the same data type. Padding bytes are not required to store arrays.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define fatal_error() abort()

typedef struct s_padding
{
    char c;
    int i;
    unsigned int bf1:1;
    unsigned int bf2:2;
    unsigned char buffer[20];
} S_Padding ;

/* Function that guarantees safe access to the input memory */
extern int trusted_memory_zone(void *ptr, size_t sz);

int func(const S_Padding *left, const S_Padding *right)
```

```
{
    if (!trusted_memory_zone((void *)left, sizeof(S_Padding)) ||
        !trusted_memory_zone((void *)right, sizeof(S_Padding))) {
        fatal_error();
    }

    return ((left->c == right->c) &&
            (left->i == right->i) &&
            (left->bf1 == right->bf1) &&
            (left->bf2 == right->bf2) &&
            (memcmp(left->buffer, right->buffer, 20) == 0));
}
```

### Missing byte reordering when transferring data

#### Issue

This issue occurs when you do not use a byte ordering function:

- Before sending data to a network socket.
- After receiving data from a network socket.

#### Risk

Some system architectures implement little endian byte ordering (least significant byte first), and other systems implement big endian (most significant byte first). If the endianness of the sent data does not match the endianness of the receiving system, the value returned when reading the data is incorrect.

#### Fix

After receiving data from a socket, use a byte ordering function such as `ntohl()`. Before sending data to a socket, use a byte ordering function such as `htonl()` .

#### Example — Data Transferred Without Byte Reordering

```
#include <stdio.h>
#include <stdlib.h>
#include <stdint.h>
#include <sys/types.h>
#include <sys/socket.h>
#include <arpa/inet.h>
#include <byteswap.h>
#include <unistd.h>
#include <string.h>

unsigned int func(int sock, int server)
{
    unsigned int num;   /* assume int is 32-bits */
    if (server)
    {
        /* Server side */
        num = 0x17;
        /* Endianness of server host may not match endianness of network. */
        if (send(sock, (void *)&num, sizeof(num), 0) < (int)sizeof(num))
        {
            /* Handle error */
        }
        return 0;
    }
    else {
        /* Endianness of client host may not match endianness of network. */
        if (recv (sock, (void *)&num, sizeof(num), 0) < (int) sizeof(num))
        {
            /* Handle error */
        }

        /* Comparison may be inaccurate */
        if (num> 255)
        {
            return 255;
        }
        else
        {
            return num;
        }
    }
}
```

In this example, variable `num` is assigned hexadecimal value `0x17` and is sent over a network to the client from the server. If the server host is little endian and the network is big endian, `num` is transferred as `0x17000000`. The client then reads an incorrect value for `num` and compares it to a local numeric value.

**Correction — Use Byte Ordering Function**

Before sending `num` from the server host, use `htonl()` to convert from host to network byte ordering. Similarly, before reading `num` on the client host, use `ntohl()` to convert from network to host byte ordering.

```
#include <stdio.h>
#include <stdlib.h>
#include <stdint.h>
#include <sys/types.h>
#include <sys/socket.h>
#include <arpa/inet.h>
#include <byteswap.h>
#include <unistd.h>
#include <string.h>

unsigned int func(int sock, int server)
{
    unsigned int num;   /* assume int is 32-bits */
    if (server)
    {
        /* Server side */
        num = 0x17;

        /* Convert to network byte order. */
        num = htonl(num);
        if (send(sock, (void *)&num, sizeof(num), 0) < (int)sizeof(num))
        {
            /* Handle error */
        }
        return 0;
    }
    else {
        if (recv (sock, (void *)&num, sizeof(num), 0) < (int) sizeof(num))
        {
            /* Handle error */
        }

        /* Convert to host byte order. */
        num = ntohl(num);
        if (num > 255)
        {
            return 255;
        }
        else
        {
            return num;
        }
    }
}
```

CWE-188

# CWE Rule 191

Integer Underflow (Wrap or Wraparound)

## Description

### Rule Description

*The product subtracts one value from another, such that the result is less than the minimum allowable integer value, which produces a value that is not equal to the correct result.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Integer constant overflow**
- **Integer overflow**
- **Unsigned integer constant overflow**
- **Unsigned integer conversion overflow**
- **Unsigned integer overflow**

## Examples

### Integer constant overflow

#### Issue

This issue occurs in the following cases:

- You assign a compile-time integer constant to a signed integer variable whose data type cannot accommodate the value.

  See “Constant Overflows from Assignments” on page 7-17.
- You use an `enum` value that cannot be accommodated by the underlying type of the `enum` (and the underlying type is signed). For most C compilers, the default underlying type is `signed int` (based on the C standard).

  See “Constant Overflows from enum Values” on page 7-17.
- You perform a binary operation involving two integer constants that results in an overflow, that is, a value outside the range allowed by the data type that the operation uses. A binary operation with integer constants uses the `signed int` data type (unless you use modifiers such as `u` or `L`).

  See “Constant Overflows from Binary Operations” on page 7-18.

An `n`-bit signed integer holds values in the range [-$2^{n-1}$, $2^{n-1}$-1]. For instance, `c` is an 8-bit signed `char` variable that cannot hold the value 255.

```
signed char c = 255;
```

This defect checker depends on the following options:

- `Target processor type (-target)`: Determines the sizes of fundamental types.
- `Enum type definition (-enum-type-definition)`: Determines the underlying types of enumerations.
- `Compiler (-compiler)`: Impacts the interpretation of code.

You do not see the defect in these situations:

- Creation of new constants from `const` variables (for specific compilers only).

  Different compilers might define compile-time constants differently. In the following code, `c+1` is considered a compile-time constant by GCC compilers, but not by the standard C compiler:

  ```
  const int16_t c = 32767;
  int16_t y = c + 1;
  ```

  Whether you see a violation of this check on `y` might depend on your compiler.
- Bitwise `NOT` operation.

  Polyspace does not raise this violation when you perform a bitwise `NOT` operation.

#### Risk

The default behavior for constant overflows can vary between compilers and platforms. Retaining constant overflows can reduce the portability of your code.

Even if your compilers wraps around overflowing constants with a warning, the wrap-around behavior can be unintended and cause unexpected results.

#### Fix

Check if the constant value is what you intended. If the value is correct, use a different, possibly wider, data type for the variable.

#### Example — Constant Overflows from Assignments

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_SIGNED_CHAR 127

void main() {
    char c1 = MAX_UNSIGNED_CHAR;
    char c2 = MAX_SIGNED_CHAR+1;
}
```

In this example, the defect appears on the macros because at least one use of the macro causes an overflow. To reproduce these defects, use a `Target processor type (-target)` where `char` is signed by default.

#### Correction — Use Different Data Type

One possible correction is to use a different data type for the variables that overflow.

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_SIGNED_CHAR 127

void main() {
    unsigned char c1 = MAX_UNSIGNED_CHAR;
    unsigned char c2 = MAX_SIGNED_CHAR+1;
}
```

#### Example — Constant Overflows from enum Values

```
enum {
  a=0x7fffffff,
  b,
  c=0xffffffff
} MyEnumA;
```

In this example, the `enum` has an underlying type `int`. The `int` type can accommodate values in the range [-$2^{31}$, $2^{31}$-1]. However, the value of the enumerator `b` is 0x80000000 or $2^{31}$ (one more than the previous value `a`). This value falls outside the allowed range of `int`.

The value of `c`, that is 0xffffffff or $2^{32}$-1, is even larger and also causes an overflow.

To see this defect:

- Specify `Compiler (-compiler)` as `generic`.
- Specify `Source code language (-lang)` as `c`.

#### Example — Constant Overflows from Binary Operations

```
const unsigned int K_ATM_Label_Ram_init_value [] = {
     0x06 | ( 3 << 29) ,
     0x80 | ( 9 << 29) ,
     ( 2 << 31 )        ,
};
```

In this example, two of the shift operations result in values that cannot be accommodated by the `signed int` data type. The `signed int` data type can accommodate values in the range [-$2^{31}$, $2^{31}$-1]. The operation:

- `9 << 29` results in the value $2^{32}$+536870912.
- `2 << 31` results in the value $2^{32}$.

Note that even though the result is assigned to an `unsigned int` variable, the overflow detection uses the underlying type of the binary operation, that is, `signed int`.

### Integer overflow

#### Issue

This issue occurs when an operation on integer variables results in values that cannot be represented by the data type that the operation uses. This data type depends on the operand types and determines the number of bytes allocated for storing the result, thus constraining the range of allowed values.

Note that:

- The data type used to determine an overflow is based on the operand data types. If you then assign the result of an operation to another variable, a different checker, `Integer conversion overflow`, determines if the value assigned also overflows the variable assigned to. For instance, in an operation such as:

  ```
  res = x + y;
  ```

This checker checks for an overflow based on the types of `x` and `y`, and not on the type of `res`. The checker for integer conversion overflows then checks for an overflow based on the type of `res`.
- The two operands in a binary operation might undergo promotion before the operation occurs. See also “Code Prover Assumptions About Implicit Data Type Conversions” (Polyspace Code Prover).

The exact storage allocation for different data types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer overflows on signed integers result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the operation so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

To avoid overflows in general, try one of these techniques:

- Keep integer variable values restricted to within half the range of signed integers.
- In operations that might overflow, check for conditions that can lead to the overflow and implement wrap around or saturation behavior depending on how the result of the operation is used. The result then becomes predictable and can be safely used in subsequent computations.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Addition of Maximum Integer

```
#include <limits.h>

int plusplus(void) {
    int var = INT_MAX;
    var++;
    return var;
}
```

In the third statement of this function, the variable `var` is increased by one. But the value of `var` is the maximum integer value, so an `int` cannot represent one plus the maximum integer value.

**Correction — Different Storage Type**

One possible correction is to change data types. Store the result of the operation in a larger data type (Note that on a 32-bit machine, `int` and `long` has the same size). In this example, on a 32-bit machine, by returning a `long long` instead of an `int`, the overflow error is fixed.

```
#include <limits.h>

long long plusplus(void) {

    long long lvar = INT_MAX;
    lvar++;
    return lvar;
}
```

### Unsigned integer constant overflow

**Issue**

This issue occurs in the following cases:

- You assign a compile-time constant to an unsigned integer variable whose data type cannot accommodate the value.
- You use an `enum` value that cannot be accommodated by the underlying type of the `enum` (and the underlying type is unsigned).

An `n`-bit unsigned integer holds values in the range [0, $2^n$-1]. For instance, `c` is an 8-bit unsigned `char` variable that cannot hold the value 256.

```
unsigned char c = 256;
```

This defect checker depends on the following options:

- To determine the sizes of fundamental types, Bug Finder uses your specification for `Target processor type (-target)`.
- To determine the underlying types of enumerations, Bug Finder uses your specification for `Enum type definition (-enum-type-definition)`.

You do not see the defect in these situations:

- Creation of new constants from `const` variables (for specific compilers only).

  Different compilers might define compile-time constants differently. In the following code, `c+1u` is considered a compile time-constant by GCC compilers, but not by the standard C compiler:

  ```
  const uint16_t c = 0xffffu;
  uint16_t y = c + 1u;
  ```

  Whether you see a violation of this check on `y` might depend on your compiler.

- Bitwise NOT operation.

  Polyspace does not raise this violation when you perform a bitwise NOT operation.

#### Risk

The C standard states that overflowing unsigned integers must be wrapped around (see, for instance, the C11 standard, section 6.2.5). However, the wrap-around behavior can be unintended and cause unexpected results.

#### Fix

Check if the constant value is what you intended. If the value is correct, use a wider data type for the variable.

#### Example — Overflows from Assignments

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_UNSIGNED_SHORT 65535

void main() {
    unsigned char c1 = MAX_UNSIGNED_CHAR + 1;
    unsigned short c2 = MAX_UNSIGNED_SHORT + 1;
}
```

In this example, the defect appears on the macros because at least one use of the macro causes an overflow.

#### Correction — Use Wider Data Type

One possible correction is to use a wider data type for the variables that overflow.

```
#define MAX_UNSIGNED_CHAR 255
#define MAX_UNSIGNED_SHORT 65535

void main() {
    unsigned short c1 = MAX_UNSIGNED_CHAR + 1;
    unsigned int c2 = MAX_UNSIGNED_SHORT + 1;
}
```

### Unsigned integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a smaller unsigned integer type. If the variable does not have enough bytes to represent the original constant, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Converting from int to char

```
unsigned char convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned char)unum;
}
```

In the return statement, the unsigned integer variable `unum` is converted to an unsigned character type. However, the conversion overflows because 1000000 requires at least 20 bits. The C programming language standard does not view unsigned overflow as an error because the program automatically reduces the result by modulo the maximum value plus 1. In this example, `unum` is reduced by modulo `2^8` because a character data type can only represent `2^8-1`.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number. For example, `long`.

```
unsigned long convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned long)unum;
}
```

### Unsigned integer overflow

#### Issue

This issue occurs when an operation on unsigned integer variables can result in values that cannot be represented by the result data type. The data type of a variable determines the number of bytes allocated for the variable storage and constrains the range of allowed values.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

The C11 standard states that unsigned integer overflows result in wrap-around behavior. However, a wrap around behavior might not always be desirable. For instance, if the result of a computation is used as an array size and the computation overflows, the array size is much smaller than expected.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the operation so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling. In the error handling code, you can override the default wrap-around behavior for overflows and implement saturation behavior, for instance.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Add One to Maximum Unsigned Integer

```
#include <limits.h>

unsigned int plusplus(void) {
    unsigned uvar = UINT_MAX;
    uvar++;
    return uvar;
}
```

In the third statement of this function, the variable `uvar` is increased by 1. However, the value of `uvar` is the maximum unsigned integer value, so 1 plus the maximum integer value cannot be represented by an `unsigned int`. The C programming language standard does not view unsigned overflow as an error because the program automatically reduces the result by modulo the maximum value plus 1. In this example, `uvar` is reduced by modulo `UINT_MAX`. The result is `uvar = 1`.

#### Correction — Different Storage Type

One possible correction is to store the operation result in a larger data type. In this example, by returning an `unsigned long long` instead of an `unsigned int`, the overflow error is fixed.

```
#include <limits.h>

unsigned long long plusplus(void) {

    unsigned long long ullvar = UINT_MAX;
    ullvar++;
    return ullvar;
}
```

## Check Information

CWE-191

# CWE Rule 192

Integer Coercion Error

## Description

### Rule Description

*Integer coercion refers to a set of flaws pertaining to the type casting, extension, or truncation of primitive data types.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Integer conversion overflow**
- **Sign change integer conversion overflow**
- **Tainted sign change conversion**
- **Unsigned integer conversion overflow**

## Examples

### Integer conversion overflow

#### Issue

This issue occurs when converting an integer to a smaller integer type. If the variable does not have enough bytes to represent the original value, the conversion overflows. For instance, if you perform a comparison between implementation-defined type `time_t` and a signed integer, Polyspace reports a violation because `time_t` might be implemented as an unsigned integer.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Converting from int to char

```
char convert(void) {

    int num = 1000000;

    return (char)num;
}
```

In the return statement, the integer variable `num` is converted to a `char`. However, an 8-bit or 16-bit character cannot represent 1000000 because it requires at least 20 bits. So the conversion operation overflows.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number.

```
long convert(void) {

    int num = 1000000;

    return (long)num;
}
```

### Sign change integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a signed integer. If the variable does not have enough bytes to represent both the original constant and the sign bit, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Convert from unsigned char to char

```
char sign_change(void) {
    unsigned char count = 255;

    return (char)count;
}
```

In the return statement, the unsigned character variable `count` is converted to a signed character. However, `char` has 8 bits, 1 for the sign of the constant and 7 to represent the number. The conversion operation overflows because 255 uses 8 bits.

#### Correction — Change conversion types

One possible correction is using a larger integer type. By using an `int`, there are enough bits to represent the sign and the number value.

```
int sign_change(void) {
    unsigned char count = 255;

    return (int)count;
}
```

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
```

```
memmove
strncmp
strncpy
calloc
malloc
memalign
```

**Risk**

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

**Fix**

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

**Extend Checker**

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Set Memory Value with Size Argument**

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

#### Correction — Check Value of size

One possible correction is to check if size is inside the valid range. This correction checks if size is greater than zero and less than the buffer size before calling memset.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

### Unsigned integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a smaller unsigned integer type. If the variable does not have enough bytes to represent the original constant, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See Target processor type (-target).

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Converting from int to char

```
unsigned char convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned char)unum;
}
```

In the return statement, the unsigned integer variable `unum` is converted to an unsigned character type. However, the conversion overflows because 1000000 requires at least 20 bits. The C programming language standard does not view unsigned overflow as an error because the program automatically reduces the result by modulo the maximum value plus 1. In this example, `unum` is reduced by modulo `2^8` because a character data type can only represent `2^8-1`.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number. For example, `long`.

```
unsigned long convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned long)unum;
}
```

Unexpected Sign Extension

## Description

### Rule Description

*The software performs an operation on a number that causes it to be sign extended when it is transformed into a larger data type. When the original number is negative, this can produce unexpected values that lead to resultant weaknesses.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Sign change integer conversion overflow**
- **Tainted sign change conversion**

## Examples

### Sign change integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a signed integer. If the variable does not have enough bytes to represent both the original constant and the sign bit, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Convert from unsigned char to char

```
char sign_change(void) {
    unsigned char count = 255;

    return (char)count;
}
```

In the return statement, the unsigned character variable `count` is converted to a signed character. However, `char` has 8 bits, 1 for the sign of the constant and 7 to represent the number. The conversion operation overflows because 255 uses 8 bits.

#### Correction — Change conversion types

One possible correction is using a larger integer type. By using an `int`, there are enough bits to represent the sign and the number value.

```
int sign_change(void) {
    unsigned char count = 255;

    return (int)count;
}
```

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
memmove
strncmp
strncpy
calloc
malloc
memalign
```

#### Risk

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

#### Fix

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Set Memory Value with Size Argument

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

#### Correction — Check Value of `size`

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

CWE-194

# CWE Rule 195

Signed to Unsigned Conversion Error

## Description

### Rule Description

*The software uses a signed primitive and performs a cast to an unsigned primitive, which can produce an unexpected value if the value of the signed primitive can not be represented using an unsigned primitive.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Sign change integer conversion overflow**
- **Tainted sign change conversion**

## Examples

### Sign change integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a signed integer. If the variable does not have enough bytes to represent both the original constant and the sign bit, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Convert from unsigned char to char

```
char sign_change(void) {
    unsigned char count = 255;

    return (char)count;
}
```

In the return statement, the unsigned character variable `count` is converted to a signed character. However, `char` has 8 bits, 1 for the sign of the constant and 7 to represent the number. The conversion operation overflows because 255 uses 8 bits.

#### Correction — Change conversion types

One possible correction is using a larger integer type. By using an `int`, there are enough bits to represent the sign and the number value.

```
int sign_change(void) {
    unsigned char count = 255;

    return (int)count;
}
```

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
memmove
strncmp
strncpy
calloc
malloc
memalign
```

#### Risk

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

#### Fix

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Set Memory Value with Size Argument

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

#### Correction — Check Value of `size`

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

Unsigned to Signed Conversion Error

## Description

### Rule Description

*The software uses an unsigned primitive and performs a cast to a signed primitive, which can produce an unexpected value if the value of the unsigned primitive can not be represented using a signed primitive.*

### Polyspace Implementation

The rule checker checks for **Sign change integer conversion overflow**.

## Examples

### Sign change integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a signed integer. If the variable does not have enough bytes to represent both the original constant and the sign bit, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Convert from unsigned char to char

```
char sign_change(void) {
    unsigned char count = 255;

    return (char)count;
}
```

In the return statement, the unsigned character variable `count` is converted to a signed character. However, `char` has 8 bits, 1 for the sign of the constant and 7 to represent the number. The conversion operation overflows because 255 uses 8 bits.

#### Correction — Change conversion types

One possible correction is using a larger integer type. By using an `int`, there are enough bits to represent the sign and the number value.

```
int sign_change(void) {
    unsigned char count = 255;

    return (int)count;
}
```

### External Websites

CWE-196

# CWE Rule 197

Numeric Truncation Error

## Description

### Rule Description

*Truncation errors occur when a primitive is cast to a primitive of a smaller size and data is lost in the conversion.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Call to memset family with unintended value**
- **Float conversion overflow**
- **Integer conversion overflow**
- **Sign change integer conversion overflow**
- **Tainted sign change conversion**
- **Unsigned integer conversion overflow**

## Examples

### Call to memset family with unintended value

#### Issue

This issue occurs when Polyspace Bug Finder detects a use of the `memset` or `wmemset` function with possibly incorrect arguments.

`void *memset (void *ptr, int value, size_t num)` fills the first `num` bytes of the memory block that `ptr` points to with the specified `value`. If the argument `value` is incorrect, the memory block is initialized with an unintended value.

The unintended initialization can occur in the following cases.

| Issue | Risk | Possible Fix |
|---|---|---|
| The second argument is `'0'` instead of `0` or `'\0'`. | The ASCII value of character `'0'` is `48` (decimal), `0x30` (hexadecimal), `069` (octal) but not `0` (or `'\0'`) . | If you want to initialize with `'0'`, use one of the ASCII values. Otherwise, use `0` or `'\0'`. |
| The second and third arguments are probably reversed. For instance, the third argument is a literal and the second argument is not a literal. | If the order is reversed, a memory block of unintended size is initialized with incorrect arguments. | Reverse the order of the arguments. |

| Issue | Risk | Possible Fix |
|---|---|---|
| The second argument cannot be represented in a byte. | If the second argument cannot be represented in a byte, and you expect each byte of a memory block to be filled with that argument, the initialization does not occur as intended. | Apply a bit mask to the argument to produce a wrapped or truncated result that can be represented in a byte. When you apply a bit mask, make sure that it produces an expected result.<br>For instance, replace `memset(a, -13, sizeof(a))` with `memset(a, (-13) & 0xFF, sizeof(a))`. |

**Fix**

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Value Cannot Be Represented in a Byte**

```
#include <string.h>

#define SIZE 32
void func(void) {
    char buf[SIZE];
    int c = -2;
    memset(buf, (char)c, sizeof(buf));
}
```

In this example, `(char)c` cannot be represented in a byte.

**Correction — Apply Cast**

One possible correction is to apply a cast so that the result can be represented in a byte. Check that the result of the cast is an acceptable initialization value. In this correction, Polyspace does not raise this defect. The cast from signed `int` to `unsigned char` is contrary to best practices and Polyspace raises the defect `Sign change integer conversion overflow`.

```
#include <string.h>

#define SIZE 32
void func(void) {
    char buf[SIZE   ];
    int c = -2;
    memset(buf, (unsigned char)c, sizeof(buf));// Might Overflow
}
```

#### Correction — Avoid Using `memset`

One possible correction is to reserve the use of `memset` only for setting or clearing all bits in a buffer. For instance, in this code, `memset` is called to clear the bits of the character array `buf`.

```
#include <string.h>

#define SIZE 32
void func(void) {
    char buf[SIZE   ];
    int c = -2;
    memset(buf, 0, sizeof(buf));//Compliant
    /* After clearing buf, use it in operations*/
}
```

### Float conversion overflow

#### Issue

This issue occurs when converting a floating point number to a smaller floating point data type. If the variable does not have enough memory to represent the original number, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Overflows can result in unpredictable values from computations. The result can be infinity or the maximum finite value depending on the rounding mode used in the implementation. If you use the result of an overflowing conversion in subsequent computations and do not account for the overflow, you can see unexpected results.

#### Fix

The fix depends on the root cause of the defect. Often the result details show a sequence of events that led to the defect. Use this event list to determine how the variable being converted acquires its current value You can implement the fix on any event in the sequence. If the result details do not show the event history, you can trace back using right-click options in the source code and see previous related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller floating point types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.

- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

By default, a Bug Finder analysis does not recognize infinities and `NaNs`. Operations that results in infinities and `NaNs` might be flagged as defects. To handle infinities and `NaN` values in your code, use the option `Consider non finite floats (-allow-non-finite-floats).`

**Extend Checker**

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

**Example — Converting from double to float**

```
float convert(void) {

    double diam = 1e100;
    return (float)diam;
}
```

In the return statement, the variable `diam` of type double (64 bits) is converted to a variable of type float (32 bits). However, the value 1^100 requires more than 32 bits to be precisely represented.

### Integer conversion overflow

**Issue**

This issue occurs when converting an integer to a smaller integer type. If the variable does not have enough bytes to represent the original value, the conversion overflows. For instance, if you perform a comparison between implementation-defined type `time_t` and a signed integer, Polyspace reports a violation because `time_t` might be implemented as an unsigned integer.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

**Risk**

Integer conversion overflows result in undefined behavior.

**Fix**

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Converting from int to char

```
char convert(void) {

    int num = 1000000;

    return (char)num;
}
```

In the return statement, the integer variable `num` is converted to a `char`. However, an 8-bit or 16-bit character cannot represent 1000000 because it requires at least 20 bits. So the conversion operation overflows.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number.

```
long convert(void) {

    int num = 1000000;

    return (long)num;
}
```

### Sign change integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a signed integer. If the variable does not have enough bytes to represent both the original constant and the sign bit, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Convert from unsigned char to char

```
char sign_change(void) {
    unsigned char count = 255;

    return (char)count;
}
```

In the return statement, the unsigned character variable `count` is converted to a signed character. However, `char` has 8 bits, 1 for the sign of the constant and 7 to represent the number. The conversion operation overflows because 255 uses 8 bits.

#### Correction — Change conversion types

One possible correction is using a larger integer type. By using an `int`, there are enough bits to represent the sign and the number value.

```
int sign_change(void) {
    unsigned char count = 255;

    return (int)count;
}
```

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
memmove
strncmp
strncpy
calloc
malloc
memalign
```

#### Risk

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

#### Fix

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See "Sources of Tainting in a Polyspace Analysis". To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Set Memory Value with Size Argument

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

#### Correction — Check Value of `size`

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>
```

```
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

### Unsigned integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a smaller unsigned integer type. If the variable does not have enough bytes to represent the original constant, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Converting from int to char

```
unsigned char convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned char)unum;
}
```

In the return statement, the unsigned integer variable `unum` is converted to an unsigned character type. However, the conversion overflows because 1000000 requires at least 20 bits. The C programming language standard does not view unsigned overflow as an error because the program automatically reduces the result by modulo the maximum value plus 1. In this example, `unum` is reduced by modulo `2^8` because a character data type can only represent `2^8-1`.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number. For example, `long`.

```
unsigned long convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned long)unum;
}
```

# CWE Rule 242

Use of Inherently Dangerous Function

## Description

### Rule Description

*The program calls a function that can never be guaranteed to work safely.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Use of dangerous standard function**
- **Use of obsolete standard function**

## Examples

### Use of dangerous standard function

#### Issue

This issue occurs when your code uses standard functions that write data to a buffer in a way that can result in buffer overflows.

The following table lists dangerous standard functions, the risks of using each function, and what function to use instead. The checker flags:

- Any use of an inherently dangerous function.
- An use of a possibly dangerous function only if the size of the buffer to which data is written can be determined at compile time. The checker does not flag an use of such a function with a dynamically allocated buffer.

| Dangerous Function | Risk Level | Safer Function |
|---|---|---|
| `gets` | Inherently dangerous — You cannot control the length of input from the console. | `fgets` |
| `std::cin::operator>>` and `std::wcin::operator>>` | Inherently dangerous — You cannot control the length of input from the console. | Preface calls to `cin` by `cin.width` to control the input length. This method can result in truncated input.<br>To avoid potential buffer overflow and truncated input, use `std::string` objects as destinations for >> operator. |

| Dangerous Function | Risk Level | Safer Function |
|---|---|---|
| `strcpy` | Possibly dangerous — If the size of the destination buffer is too small to accommodate the source buffer and a null terminator, a buffer overflow might occur. | Use the function `strlen()` to determine the size of the source buffer, and allocate sufficient memory so that the destination buffer can accommodate the source buffer and a null terminator. Instead of `strcpy`, use the function `strncpy`. |
| `stpcpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `stpncpy` |
| `lstrcpy` or `StrCpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `StringCbCopy`, `StringCchCopy`, `strncpy`, `strcpy_s`, or `strlcpy` |
| `strcat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `strncat`, `strlcat`, or `strcat_s` |
| `lstrcat` or `StrCat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `StringCbCat`, `StringCchCat`, `strncay`, `strcat_s`, or `strlcat` |
| `wcpcpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `wcpncpy` |
| `wcscat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `wcsncat`, `wcslcat`, or `wcncat_s` |
| `wcscpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `wcsncpy` |
| `sprintf` | Possibly dangerous — If the output length depends on unknown lengths or values, buffer overflow can occur. | `snprintf` |
| `vsprintf` | Possibly dangerous — If the output length depends on unknown lengths or values, buffer overflow can occur. | `vsnprintf` |

#### Risk

These functions can cause buffer overflow, which attackers can use to infiltrate your program.

#### Fix

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.

- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

### Example — Using sprintf

```
#include <stdio.h>
#include <string.h>
#include <iostream>

#define BUFF_SIZE 128

int dangerous_func(char *str)
{
    char dst[BUFF_SIZE];
    int r = 0;

    if (sprintf(dst, "%s", str) == 1)
    {
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}
```

This example function uses `sprintf` to copy the string `str` to `dst`. However, if `str` is larger than the buffer, `sprintf` can cause buffer overflow.

### Correction — Use `snprintf` with Buffer Size

One possible correction is to use `snprintf` instead and specify a buffer size.

```
#include <stdio.h>
#include <string.h>
#include <iostream>

#define BUFF_SIZE 128

int dangerous_func(char *str)
{
    char dst[BUFF_SIZE];
    int r = 0;

    if (snprintf(dst, sizeof(dst), "%s", str) == 1)
    {
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}
```

### Use of obsolete standard function

#### Issue

This issue occurs when you use standard function routines that are considered legacy, removed, deprecated, or obsolete by C/C++ coding standards.

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| `asctime` | Deprecated in POSIX.1-2008 | Not thread-safe. | `strftime` or `asctime_s` |
| `asctime_r` | Deprecated in POSIX.1-2008 | Implementation based on unsafe function `sprintf`. | `strftime` or `asctime_s` |
| `bcmp` | Deprecated in 4.3BSD<br>Marked as legacy in POSIX.1-2001. | Returns from function after finding the first differing byte, making it vulnerable to timing attacks. | `memcmp` |
| `bcopy` | Deprecated in 4.3BSD<br>Marked as legacy in POSIX.1-2001. | Returns from function after finding the first differing byte, making it vulnerable to timing attacks. | `memcpy` or `memmove` |
| `brk` and `sbrk` | Marked as legacy in SUSv2 and POSIX.1-2001. | | `malloc` |
| `bsd_signal` | Removed in POSIX.1-2008 | | `sigaction` |
| `bzero` | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | `memset` |
| `ctime` | Deprecated in POSIX.1-2008 | Not thread-safe. | `strftime` or `asctime_s` |
| `ctime_r` | Deprecated in POSIX.1-2008 | Implementation based on unsafe function `sprintf`. | `strftime` or `asctime_s` |
| `cuserid` | Removed in POSIX.1-2001. | Not reentrant. Precise functionality not standardized causing portability issues. | `getpwuid` |
| `ecvt` and `fcvt` | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008 | Not reentrant | `snprintf` |
| `ecvt_r` and `fcvt_r` | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008 | | `snprintf` |
| `ftime` | Removed in POSIX.1-2008 | | `time`, `gettimeofday`, `clock_gettime` |
| `gamma`, `gammaf`, `gammal` | Function not specified in any standard because of historical variations | Portability issues. | `tgamma`, `lgamma` |

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| gcvt | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | snprintf |
| getcontext | Removed in POSIX.1-2008. | Portability issues. | Use POSIX thread instead. |
| getdtablesize | BSD API function not included in POSIX.1-2001 | Portability issues. | sysconf( _SC_OPEN _MAX ) |
| gethostbyaddr | Removed in POSIX.1-2008 | Not reentrant | getaddrinfo |
| gethostbyname | Removed in POSIX.1-2008 | Not reentrant | getnameinfo |
| getpagesize | BSD API function not included in POSIX.1-2001 | Portability issues. | sysconf( _SC_PAGE SIZE ) |
| getpass | Removed in POSIX.1-2001. | Not reentrant. | getpwuid |
| getw | Not present in POSIX.1-2001. | | fread |
| getwd | Marked legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | getcwd |
| index | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | strchr |
| makecontext | Removed in POSIX.1-2008. | Portability issues. | Use POSIX thread instead. |
| memalign | Appears in SunOS 4.1.3. Not in 4.4 BSD or POSIX.1-2001 | | posix_memalign |
| mktemp | Removed in POSIX.1-2008. | Generated names are predictable and can cause a race condition. | mkstemp removes race risk |
| pthread_attr_ getstackaddr and pthread_attr_ setstackaddr | | Ambiguities in the specification of the stackaddr attribute cause portability issues | pthread_attr_ getstack and pthread_attr_ setstack |
| putw | Not present in POSIX.1-2001. | Portability issues. | fwrite |
| qecvt and qfcvt | Marked as legacy in POSIX.1-2001, removed in POSIX.1-2008 | | snprintf |
| qecvt_r and qfcvt_r | Marked as legacy in POSIX.1-2001, removed in POSIX.1-2008 | | snprintf |
| rand_r | Marked as obsolete in POSIX.1-2008 | | |
| re_comp | BSD API function | Portability issues | regcomp |
| re_exes | BSD API function | Portability issues | regexec |
| rindex | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | strrchr |
| scalb | Removed in POSIX.1-2008 | | scalbln, scalblnf, or scalblnl |

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| sigblock | 4.3BSD signal API whose origin is unclear | | sigprocmask |
| sigmask | 4.3BSD signal API whose origin is unclear | | sigprocmask |
| sigsetmask | 4.3BSD signal API whose origin is unclear | | sigprocmask |
| sigstack | Interface is obsolete and not implemented on most platforms. | Portability issues. | sigaltstack |
| sigvec | 4.3BSD signal API whose origin is unclear | | sigaction |
| swapcontext | Removed in POSIX.1-2008 | Portability issues. | Use POSIX threads. |
| tmpnam and tmpnam_r | Marked as obsolete in POSIX.1-2008. | This function generates a different string each time it is called, up to TMP_MAX times. If it is called more than TMP_MAX times, the behavior is implementation-defined. | mkstemp, tmpfile |
| ttyslot | Removed in POSIX.1-2001. | | |
| ualarm | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | Errors are under-specified | setitimer or POSIX timer_create |
| usleep | Removed in POSIX.1-2008. | | nanosleep |
| utime | SVr4, POSIX.1-2001. POSIX.1-2008 marks as obsolete. | | |
| valloc | Marked as obsolete in 4.3BSD.<br>Marked as legacy in SUSv2.<br>Removed from POSIX.1-2001 | | posix_memalign |
| vfork | Removed from POSIX.1-2008 | Under-specified in previous standards. | fork |
| wcswcs | This function was not included in the final ISO/IEC 9899:1990/ Amendment 1:1995 (E). | | wcsstr |
| WinExec | WinAPI provides this function only for 16-bit Windows compatibility. | | CreateProcess |
| LoadModule | WinAPI provides this function only for 16-bit Windows compatibility. | | CreateProcess |

#### Fix

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Printing Out Time**

```
#include <stdio.h>
#include <time.h>

void timecheck_bad(int argc, char *argv[])
{
    time_t ticks;

    ticks = time(NULL);
    printf("%.24s\r\n", ctime(&ticks));
}
```

In this example, the function `ctime` formats the current time and prints it out. However, `ctime` was removed after C99 because it does not work on multithreaded programs.

**Correction — Different Time Function**

One possible correction is to use `strftime` instead because this function uses a set buffer size.

```
#include <stdio.h>
#include <string.h>
#include <time.h>

void timecheck_good(int argc, char *argv[])
{
    char outBuff[1025];
    time_t ticks;
    struct tm * timeinfo;

    memset(outBuff, 0, sizeof(outBuff));

    ticks = time(NULL);
    timeinfo = localtime(&ticks);
    strftime(outBuff,sizeof(outBuff),"%I:%M%p.",timeinfo);
    fprintf(stdout, outBuff);
}
```

Creation of chroot Jail Without Changing Working Directory

## Description

### Rule Description

*The program uses the chroot() system call to create a jail, but does not change the working directory afterward. This does not prevent access to files outside of the jail.*

### Polyspace Implementation

The rule checker checks for **File manipulation after chroot() without chdir("/")**.

## Examples

### File manipulation after chroot() without chdir("/")

**Issue**

This issue occurs when you have access to a file system outside of the jail created by `chroot`. By calling `chroot`, you create a file system jail that confines access to a specific file subsystem. However, this jail is ineffective if you do not call `chdir("/")`.

**Risk**

If you do not call `chdir("/")` after creating a `chroot` jail, file manipulation functions that takes a path as an argument can access files outside of the jail. An attacker can still manipulate files outside the subsystem that you specified, making the chroot jail ineffective.

**Fix**

After calling `chroot`, call `chdir("/")` to make your `chroot` jail more secure.

**Example — Open File in chroot-jail**

```
#include <unistd.h>
#include <stdio.h>

const char root_path[] = "/var/ftproot";
const char log_path[] = "file.log";
FILE* chrootmisuse() {
    FILE* res;
    chroot(root_path);
    chdir("base");
    res = fopen(log_path, "r");
    return res;
}
```

This example uses `chroot` to create a chroot-jail. However, to use the `chroot` jail securely, you must call `chdir("\")` afterward. This example calls `chdir("base")`, which is not equivalent. Bug Finder also flags `fopen` because `fopen` opens a file in the vulnerable `chroot`-jail.

#### Correction — Call `chdir("/")`

Before opening files, call `chdir("/")`.

```
#include <unistd.h>
#include <stdio.h>

const char root_path[] = "/var/ftproot";
const char log_path[] = "file.log";
FILE* chrootmisuse() {
    FILE* res;
    chroot(root_path);
    chdir("/");
    res = fopen(log_path, "r");
    return res;
}
```

Improper Clearing of Heap Memory Before Release ('Heap Inspection')

## Description

### Rule Description

*Using realloc() to resize buffers that store sensitive information can leave the sensitive information exposed to attack, because it is not removed from memory.*

### Polyspace Implementation

The rule checker checks for **Sensitive heap memory not cleared before release**.

## Examples

### Sensitive heap memory not cleared before release

**Issue**

This issue occurs when dynamically allocated memory contains sensitive data and you do not clear the data before you free the memory.

**Risk**

If the memory zone is reallocated, an attacker can still inspect the sensitive data in the old memory zone.

**Fix**

Before calling `free`, clear out the sensitive data using `memset` or `SecureZeroMemory`.

**Example — Sensitive Buffer Freed, Not Cleared**

```
#include <unistd.h>
#include <stdlib.h>
#include <string.h>
#include <sys/types.h>
#include <pwd.h>

void sensitiveheapnotcleared(const char * my_user) {
    struct passwd* result, pwd;
    long bufsize = sysconf(_SC_GETPW_R_SIZE_MAX);
    char* buf = (char*) malloc(1024);
    getpwnam_r(my_user, &pwd, buf, bufsize, &result);
    free(buf);
}
```

In this example, the function uses a buffer of passwords and frees the memory before the end of the function. However, the data in the memory is not cleared by using the `free` command.

**Correction — Nullify Data**

One possible correction is to write over the data to clear out the sensitive information. This example uses `memset` to write over the data with zeros.

```
#include <unistd.h>
#include <stdlib.h>
#include <string.h>
#include <sys/types.h>
#include <pwd.h>
#include <assert.h>

#define isNull(arr) for(int i=0;i<(sizeof(arr)/sizeof(arr[0]));i++) assert(arr[i]==0)

void sensitiveheapnotcleared(const char * my_user) {
    struct passwd* result, pwd;
    long bufsize = sysconf(_SC_GETPW_R_SIZE_MAX);
    char* buf = (char*) malloc(1024);

    if (buf) {
        getpwnam_r(my_user, &pwd, buf, bufsize, &result);
        memset(buf, 0, (size_t)1024);
        isNull(buf);
        free(buf);
    }
}
```

CWE-244

# CWE Rule 248

Uncaught Exception

## Description

### Rule Description

*An exception is thrown from a function, but it is not caught.*

### Polyspace Implementation

The rule checker checks for **Uncaught exception**.

## Examples

### Uncaught exception

#### Issue

This issue occurs when a function that is called in `main()` raises an exception and the exception is not handled. Polyspace highlights the location in the function body where the unhandled exception is raised and flags the call to the function in `main()`. For instance:

```
void foo(){
    throw std::exception(); //Uncaught exception
}
int main(){
    foo(); //Defect
    return 1;
}
```

Polyspace does not raise this defect when an `std::bad_alloc` raised by a `new` operator remains unhandled.

#### Risk

When an exception remains unhandled, the compiler might invoke the function `std::terminate()`, which terminates the program abruptly. The abrupt termination does not invoke any exit handlers, does not call the destructors of the constructed objects, and does not unwind the stack.

Exceptions that are unhandled might result in issues such as memory leaks, security vulnerability, and other unintended behaviors. Poorly designed exception handling process might make your program vulnerable to denial-of-service attacks.

#### Fix

To fix this defect, design the exception handling in your code to handle expected and unexpected exceptions. Call functions that are not `noexcept` in `try` blocks. Handle the exceptions that these functions might raise by using matching `catch()` blocks. Include a `catch-all` block to handle unexpected exceptions.

#### Example — Avoid Unhandled Exceptions

```
#include <exception>
#include <stdexcept>
```

```
int flag();

void foo() {
    if (flag()==0) {
        //....
        throw std::exception();
    }
}

void bar() {
    if (flag()!=0 & flag()!=1) {
        throw std::logic_error("Error");
    }
}

void fubar() {
    foo();
}

int main() {
    foo(); // Defect
    bar(); // Defect
    fubar(); // Defect

}
```

In this exception, the functions `foo()` and `bar()` raise exceptions that are not handled. The function `fubar()` raises an unhandled exception by calling `foo()`. These functions are invoked in `main()`. Because these functions raise exceptions that are unhandled and are called from the `main()` function, Polyspace flags the calls to these functions in `main`.

**Correction — Handle the exceptions**

To resolve this defect, handle the exceptions in your code. For instance, in the `main()` function, call the exception raising function in a `try` block and handle the exception by using a series of `catch()` blocks, including a `catch(...)` block.

```
#include <exception>
#include <stdexcept>

int flag();

void foo() {
    if (flag()==0) {
        //....
        throw std::exception();
    }
}

void bar() {
    if (flag()!=0 & flag()!=1) {
        throw std::logic_error("bla");
    }
}
```

```
void fubar() {
    foo();
}

int main() {
    try{
    foo(); // Defect
    bar(); // Defect
    fubar(); // Defect
    }catch(std::logic_error& e){
        //...
    }catch(std::exception& e){
        //...
    }catch(...){
        //..
    }

}
```

## Check Information

Unchecked Return Value

## Description

### Rule Description

*The software does not check the return value from a method or function, which can prevent it from detecting unexpected states and conditions.*

### Polyspace Implementation

The rule checker checks for **Returned value of a sensitive function not checked**.

## Examples

### Returned value of a sensitive function not checked

#### Issue

This issue occurs when you call sensitive standard functions that return information about possible errors and you do one of the following:

- Ignore the return value.

  You simply do not assign the return value to a variable, or explicitly cast the return value to `void`.
- Use an output from the function (return value or argument passed by reference) without testing the return value for errors.

The checker considers a function as sensitive if the function call is prone to failure because of reasons such as:

- Exhausted system resources (for example, when allocating resources).
- Changed privileges or permissions.
- Tainted sources when reading, writing, or converting data from external sources.
- Unsupported features despite an existing API.

The checker only considers functions where the *return value* indicates if the function completed without errors.

Some of these functions can perform critical tasks such as:

- Set privileges (for example, `setuid`)
- Create a jail (for example, `chroot`)
- Create a process (for example, `fork`)
- Create a thread (for example, `pthread_create`)
- Lock or unlock mutex (for example, `pthread_mutex_lock`)
- Lock or unlock memory segments (for example, `mlock`)

#### Risk

If you do not check the return value of functions that perform sensitive tasks and indicate error information through their return values, your program can behave unexpectedly. Errors from these functions can propagate throughout the program causing incorrect output, security vulnerabilities, and possibly system failures.

#### Fix

Before continuing with the program, test the return value of critical sensitive functions.

For sensitive functions that are not critical, you can explicitly ignore a return value by casting the function to `void`. Polyspace does not raise this defect for sensitive functions cast to void. This resolution is not accepted for *critical sensitive functions* because they perform more vulnerable tasks.

#### Example — Sensitive Function Return Ignored

```
#include <pthread.h>
#include <string.h>
#include <stddef.h>
#include <stdio.h>

void initialize() {
    pthread_attr_t attr;

    pthread_attr_init(&attr);//Noncompliant
}
int read_file(int argc, char *argv[])
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  in = fmemopen (argv[1], strlen (argv[1]), "r");
  return 0; //Noncompliant

}
```

This example shows calls to the sensitive POSIX functions `pthread_attr_init` and `fmemopen`. Their return values are ignored, causing defect.

#### Correction — Cast Function to (void)

One possible correction is to cast the function to void. This fix informs Polyspace and any reviewers that you are explicitly ignoring the return value of the sensitive function.

```
#include <pthread.h>
#include <string.h>
#include <stddef.h>
#include <stdio.h>

void initialize() {
    pthread_attr_t attr;

    (void)pthread_attr_init(&attr);//Compliant
}
int read_file(int argc, char *argv[])
```

```
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  (void)fmemopen (argv[1], strlen (argv[1]), "r"); //Compliant

  return 0;
}
```

**Correction — Test Return Value**

One possible correction is to test the return value of `pthread_attr_init` and `fmemopen` to check for errors.

```
#include <pthread.h>
#include <string.h>
#include <stddef.h>
#include <stdio.h>

void initialize() {
    pthread_attr_t attr;

    int result = pthread_attr_init(&attr);//Compliant
    if(result != 0){
        //Handle fatal error
    }
}
int read_file(int argc, char *argv[])
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  in = fmemopen (argv[1], strlen (argv[1]), "r");
  if (in==NULL){
      // Handle error
  }
  return 0;//Compliant
}
```

**Example — Critical Function Return Ignored**

```
#include <pthread.h>
extern void *start_routine(void *);

void returnnotchecked() {
    pthread_t thread_id;
    pthread_attr_t attr;
    void *res;

    (void)pthread_attr_init(&attr);
    (void)pthread_create(&thread_id, &attr, &start_routine, ((void *)0));
    pthread_join(thread_id,  &res);
}
```

In this example, two critical functions are called: `pthread_create` and `pthread_join`. The return value of the `pthread_create` is ignored by casting to void, but because `pthread_create` is a critical function (not just a sensitive function), Polyspace does not ignore this *Return value of a sensitive function not checked* defect. The other critical function, `pthread_join`, returns value that is ignored implicitly. `pthread_join` uses the return value of `pthread_create`, which was not checked.

**Correction — Test the Return Value of Critical Functions**

The correction for this defect is to check the return value of these critical functions to verify the function performed as expected.

```
#include <pthread.h>
#include <stdlib.h>
#define fatal_error() abort()

extern void *start_routine(void *);

void returnnotchecked() {
    pthread_t thread_id;
    pthread_attr_t attr;
    void *res;
    int result;

    (void)pthread_attr_init(&attr);
    result = pthread_create(&thread_id, &attr, &start_routine, NULL);
    if (result != 0) {
        /* Handle error */
        fatal_error();
    }

    result = pthread_join(thread_id,  &res);
    if (result != 0) {
        /* Handle error */
        fatal_error();
    }
}
```

CWE-252

# CWE Rule 253

Incorrect Check of Function Return Value

## Description

### Rule Description

*The software incorrectly checks a return value from a function, which prevents the software from detecting errors or exceptional conditions.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Errno not reset**
- **Unprotected dynamic memory allocation**

## Examples

### Errno not reset

#### Issue

This issue occurs when you do not reset errno before calling a function that sets errno to indicate error conditions. However, you check errno for those error conditions after the function call.

#### Risk

The errno is not clean and can contain values from a previous call. Checking errno for errors can give the false impression that an error occurred.

errno is set to zero at program startup but subsequently, errno is not reset by a C standard library function. You must explicitly set errno to zero when required.

#### Fix

Before calling a function that sets errno to indicate error conditions, reset errno to zero explicitly.

#### Example — errno Not Reset Before Call to strtod

```
#include <stdio.h>
#include <stdlib.h>
#include <errno.h>
#include <float.h>

#define fatal_error() abort()

double func(const char *s1, const char *s2)
{
    double f1;
    f1 = strtod (s1, NULL);
    if (0 == errno) {
      double f2 = strtod (s2, NULL);
```

```
        if (0 == errno) {
            long double result = (long double)f1 + f2;
            if ((result <= (long double)DBL_MAX) && (result >= (long double)-DBL_MAX))
                  {
                return (double)result;
            }
        }
    }
    fatal_error();
    return 0.0;
}
```

In this example, `errno` is not reset to 0 before the first call to `strtod`. Checking `errno` for 0 later can lead to a false positive.

#### Correction — Reset `errno` Before Call

One possible correction is to reset `errno` to 0 before calling `strtod`.

```
#include <stdio.h>
#include <stdlib.h>
#include <errno.h>
#include <float.h>

#define fatal_error() abort()

double func(const char *s1, const char *s2)
{
    double f1;
    errno = 0;
    f1 = strtod (s1, NULL);
    if (0 == errno) {
      double f2 = strtod (s2, NULL);
        if (0 == errno) {
            long double result = (long double)f1 + f2;
            if ((result <= (long double)DBL_MAX) && (result >= (long double)-DBL_MAX))
              {
                return (double)result;
            }
        }
    }
    fatal_error();
    return 0.0;
}
```

### Unprotected dynamic memory allocation

#### Issue

This issue occurs when you access dynamically allocated memory without first checking if the prior memory allocation succeeded.

#### Risk

When memory is dynamically allocated using `malloc`, `calloc`, or `realloc`, it returns a value `NULL` if the requested memory is not available. If the code following the allocation accesses the memory block without checking for this `NULL` value, this access is not protected from failures.

**Fix**

Check the return value of malloc, calloc, or realloc for NULL before accessing the allocated memory location.

```
int *ptr = malloc(size * sizeof(int));

if(ptr) /* Check for NULL */
{
   /* Memory access through ptr */
}
```

**Example — Unprotected dynamic memory allocation error**

```
#include <stdlib.h>

void Assign_Value(void)
{
  int* p = (int*)calloc(5, sizeof(int));

  *p = 2;
  /* Defect: p is not checked for NULL value */

  free(p);
}
```

If the memory allocation fails, the function calloc returns NULL to p. Before accessing the memory through p, the code does not check whether p is NULL

**Correction — Check for NULL Value**

One possible correction is to check whether p has value NULL before dereference.

```
#include <stdlib.h>

void Assign_Value(void)
 {
   int* p = (int*)calloc(5, sizeof(int));

   /* Fix: Check if p is NULL */
   if(p!=NULL) *p = 2;

   free(p);
 }
```

**Example — Unprotected dynamic memory allocation error only on dereference**

```
#include <stdlib.h>
#include<string.h>
typedef struct recordType {
    const char* id;
    const char* data;
} RECORD;

RECORD* MakerecordType(const char *id,unsigned int size){
    RECORD *rec = (RECORD *)calloc(1, sizeof(RECORD));
    rec->id = strdup(id);

    const char *newData = (char *)calloc(1, size);
    rec->data = newData;
    return rec;
}
```

In this example, the checker raises a defect when you dereference the pointer `rec` without checking for a `NULL` value from the prior dynamic memory allocation.

A similar issue happens with the pointer `newData`. However, a defect is not raised because the pointer is not dereferenced but simply copied over to `rec->data`. Simply copying over a possibly null pointer is not an issue by itself. For instance, callers of the `recordType_new` function might check for `NULL` value of `rec->data` before dereferencing, thereby avoiding a null pointer dereference.

# CWE Rule 256

Plaintext storage of a password

## Description

### Rule Definition

*Storing a password in plaintext may result in a system compromise.*

### Polyspace Implementation

This rule checker checks for the issue **Plain Text Password Stored in File System**.

## Examples

### Plain Text Password Stored in File System

#### Issue

**Plain Text Password Stored in File System** occurs when data read from a file is used in functions that expect plain-text passwords. The checker for this issue detects the flow of data from file read functions to the password parameter of functions that take user credentials.

Functions flagged by this checker include the following:

- Windows functions such as `LogonUserW()`, `LogonUserA()` and `CreateProcessWithLogonW()`. The third parameter is the password.
- MySQL functions such as `mysql_real_connect()` and `mysql_real_connect_nonblocking()`. The fourth parameter is the password.

#### Risk

Storing a password in plain-text form in a configuration file is a security risk. Anyone with access to the file can read the passwords and gain access to the password-protected resource.

#### Fix

Instead of reading passwords from a file system, accept passwords on the fly from standard input.

If passwords have to be stored on the file system, store them in encrypted form. After reading an encrypted password from a file, decrypt the password before use in functions that take user credentials. You can use standard encryption and decryption functions from cryptographic libraries, or write your own functions.

#### Extend Checker

You can extend this checker by specifying your own password functions or decryption functions.

Suppose you want to specify the following:

- Function `logOnToServer()` requires an user name and password.

```
void logOnToServer(const char* user,
                 const char*passwd);
```

Suppose the *n_pass*-th argument of this function is the password. For instance, the second argument in the above signature could be the password.

- Function `decrypt()` converts an encrypted password to plain-text form.

  ```
  void decrypt(const char* cipher_text,
               char* plain_text,
               size_t plain_text_size);
  ```

  Suppose the *n_decrypted*-th argument of this function is the decrypted password. For instance, the second argument in the above signature could be the decrypted password.

To make the checker aware of these functions:

1. In a file with extension `.dl`, add the following:

   ```
   .include "models/interfaces/plain_text_password.dl"

   PlainTextPassword.Basic.sensitive("logOnToServer", $InParameterDeref(n_pass-1)).
   PlainTextPassword.Basic.sanitizing("decrypt", $OutParameterDeref(n_decrypted-1)).
   ```

   If *n_pass* and *n_decrypted* are both 2 (that is, the second parameters of each function are the passwords), then the statements become:

   ```
   .include "models/interfaces/plain_text_password.dl"

   PlainTextPassword.Basic.sensitive("logOnToServer", $InParameterDeref(1)).
   PlainTextPassword.Basic.sanitizing("decrypt", $OutParameterDeref(1)).
   ```
2. Specify this file using the option `-code-behavior-specifications`. For instance, if the file is named `passwordFunctions.dl`, use the analysis option:

   ```
   -code-behavior-specifications passwordFunctions.dl
   ```

**Example – Password Read From File**

In this example, the string `plain_passwd` used as a password with `mysql_real_connect()` is previously read from a file `foo.cfg`. If an attacker or malicious user gains access to this file, they can easily access the password-protected resource.

```
#include <mysql/mysql.h>

#define CONNECT_TO_MYSQL_WITH_PASSWORD(passwd) \
        mysql_real_connect( \
        sql, \
        host, \
        user, \
        passwd, \
        db, \
        0, 0x0, 0)

extern MYSQL *sql;
extern const char *host;
extern char *user;
extern char *domain;
extern wchar_t *wuser;
```

```
extern wchar_t *wdomain;
extern char *db;

int non_compliant_from_file_to_mysql() {
    FILE* fp = fopen("foo.cfg", "r");
    if (fp == NULL) {
        return -1;
    }

    char plain_passwd[64];
    if (fgets(plain_passwd, sizeof(plain_passwd), fp) == NULL) {
        fclose(fp);
        return -1;
    }

    CONNECT_TO_MYSQL_WITH_PASSWORD(plain_passwd); //Noncompliant

    memset(plain_passwd, 'X', sizeof(plain_passwd));

    fclose(fp);

    return 0;
}
```

**Correction – Store Encrypted Password in File**

Instead of storing passwords in the clear, you can store passwords in an encrypted form. After reading the encrypted password from a file, you can use a decryption function to decrypt the password on the fly. The example below uses a function `decrypt()` to convert the encrypted password to a plain-text password before using the password with `mysql_real_connect()`.

```
#include <mysql/mysql.h>

#define CONNECT_TO_MYSQL_WITH_PASSWORD(passwd) \
        mysql_real_connect( \
        sql, \
        host, \
        user, \
        passwd, \
        db, \
        0, 0x0, 0)

extern MYSQL *sql;
extern const char *host;
extern char *user;
extern char *domain;
extern wchar_t *wuser;
extern wchar_t *wdomain;
extern char *db;

void decrypt(const char* cipher_text, char* plain_text, size_t plain_text_size);

int non_compliant_from_file_to_mysql() {
    FILE* fp = fopen("foo.cfg", "r");
    if (fp == NULL) {
        return -1;
    }
    char plain_passwd[64], cipher_passwd[64];
    if (fgets(cipher_passwd, sizeof(cipher_passwd), fp) == NULL) {
        fclose(fp);
        return -1;
    }

    decrypt(cipher_passwd, plain_passwd, sizeof(plain_passwd));

    CONNECT_TO_MYSQL_WITH_PASSWORD(plain_passwd);

    memset(plain_passwd, 'X', sizeof(plain_passwd));

    fclose(fp);

    return 0;
}
```

To make the Polyspace analysis aware of the nature of your decryption function:

1. Specify the following in a file with extension `.dl` (for instance, `decryptFunctions.dl`):

   ```
   .include "models/interfaces/plain_text_password.dl"

   PlainTextPassword.Basic.sanitizing("decrypt", $OutParameterDeref(1))..
   ```
2. Specify the following option with the analysis:

   ```
   -code-behavior-specifications decryptFunctions.dl
   ```

   See also `-code-behavior-specifications`.

Cleartext Storage of Sensitive Information

## Description

### Rule Description

*The product stores sensitive information in cleartext within a resource that might be accessible to another control sphere.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Sensitive heap memory not cleared before release**
- **Uncleared sensitive data in stack**

## Examples

### Sensitive heap memory not cleared before release

#### Issue

This issue occurs when dynamically allocated memory contains sensitive data and you do not clear the data before you free the memory.

#### Risk

If the memory zone is reallocated, an attacker can still inspect the sensitive data in the old memory zone.

#### Fix

Before calling `free`, clear out the sensitive data using `memset` or `SecureZeroMemory`.

#### Example — Sensitive Buffer Freed, Not Cleared

```
#include <unistd.h>
#include <stdlib.h>
#include <string.h>
#include <sys/types.h>
#include <pwd.h>

void sensitiveheapnotcleared(const char * my_user) {
    struct passwd* result, pwd;
    long bufsize = sysconf(_SC_GETPW_R_SIZE_MAX);
    char* buf = (char*) malloc(1024);
    getpwnam_r(my_user, &pwd, buf, bufsize, &result);
    free(buf);
}
```

In this example, the function uses a buffer of passwords and frees the memory before the end of the function. However, the data in the memory is not cleared by using the `free` command.

#### Correction — Nullify Data

One possible correction is to write over the data to clear out the sensitive information. This example uses `memset` to write over the data with zeros.

```
#include <unistd.h>
#include <stdlib.h>
#include <string.h>
#include <sys/types.h>
#include <pwd.h>
#include <assert.h>

#define isNull(arr) for(int i=0;i<(sizeof(arr)/sizeof(arr[0]));i++) assert(arr[i]==0)

void sensitiveheapnotcleared(const char * my_user) {
    struct passwd* result, pwd;
    long bufsize = sysconf(_SC_GETPW_R_SIZE_MAX);
    char* buf = (char*) malloc(1024);

    if (buf) {
        getpwnam_r(my_user, &pwd, buf, bufsize, &result);
        memset(buf, 0, (size_t)1024);
        isNull(buf);
        free(buf);
    }
}
```

### Uncleared sensitive data in stack

#### Issue

This issue occurs when statically allocated memory contains sensitive data and you do not clear the data before exiting a function or program.

#### Risk

Leaving sensitive information in your stack, such as passwords or user information, allows an attacker additional access to the information after your program has ended.

#### Fix

Before exiting a function or program, clear out the memory zones that contain sensitive data by using `memset` or `SecureZeroMemory`.

#### Example — Static Buffer of Password Information

```
#include <unistd.h>
#include <sys/types.h>
#include <pwd.h>

void bug_sensitivestacknotcleared(const char * my_user) {
    struct passwd* result, pwd;
    long bufsize = sysconf(_SC_GETPW_R_SIZE_MAX);
    char buf[1024] = "";
    getpwnam_r(my_user, &pwd, buf, bufsize, &result);
}
```

In this example, a static buffer is filled with password information. The program frees the stack memory at the end of the program. However, the data is still accessible from the memory.

#### Correction — Clear Memory

One possible correction is to write over the memory before exiting the function. This example uses `memset` to clear the data from the buffer memory.

```
#include <unistd.h>
#include <string.h>
#include <sys/types.h>
#include <pwd.h>
#include <assert.h>

#define isNull(arr) for(int i=0;i<(sizeof(arr)/sizeof(arr[0]));i++) assert(arr[i]==0)

void corrected_sensitivestacknotcleared(const char * my_user) {
    struct passwd* result, pwd;
    long bufsize = sysconf(_SC_GETPW_R_SIZE_MAX);
    char buf[1024] = "";
    getpwnam_r(my_user, &pwd, buf, bufsize, &result);
    memset(buf, 0, (size_t)1024);
    isNull(buf);
}
```

Incorrect Usage of Seeds in Pseudo-Random Number Generator (PRNG)

## Description

### Rule Description

*The software uses a Pseudo-Random Number Generator (PRNG) but does not correctly manage seeds.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Deterministic random output from constant seed**
- **Hard-coded sensitive data**
- **Predictable random output from predictable seed**

## Examples

### Deterministic random output from constant seed

**Issue**

This issue occurs when you use standard random number generator functions that have deterministic output given a constant seed.

The checker detects this issue with the following random number generator functions:

- C Standard Library functions such as `srand`, `srandom` and `initstate`
- OpenSSL functions such as `RAND_seed` and `RAND_add`
- C++ Standard Library functions such as `std::linear_congruential_engine<>::seed()` and `std::mersenne_twister_engine<>::seed()` (and also the constructors of these class templates)

**Risk**

With constant seeds, random number generator functions produce the same output every time your program is run. A hacker can disrupt your program if they know how your program behaves.

**Fix**

Use a different random standard function or use a nonconstant seed.

Some standard random routines are inherently cryptographically weak on page 13-97, and should not be used for security purposes.

**Example — Random Number Generator Initialization**

```
#include <stdlib.h>

void random_num(void)
```

```
{
    srand(12345U);
    /* ... */
}
```

This example initializes a random number generator using `srand` with a constant seed. The random number generation is deterministic, making this function cryptographically weak.

#### Correction — Use Different Random Number Generator

One possible correction is to use a random number generator that does not require a seed. This example uses `rand_s`.

```
#define _CRT_RAND_S
#include <stdlib.h>
#include <stdio.h>

unsigned int random_num_time(void)
{

    unsigned int number;
    errno_t err;
    err = rand_s(&number);

    if(err != 0)
    {
        return number;
    }
    else
    {
        return err;
    }
}
```

### Hard-coded sensitive data

#### Issue

This issue occurs when data that is potentially sensitive is directly exposed in the code, for instance, as string literals. The checker identifies certain data as sensitive from their use in certain functions such as password encryption functions.

Following data can be potentially sensitive.

| Type of Data | Functions That Indicate Sensitive Nature of Information |
|---|---|
| Host name | • sethostname, setdomainname, gethostbyname, gethostbyname2, getaddrinfo, gethostbyname_r, gethostbyname2_r (string argument)<br>• inet_aton, inet_pton, inet_net_pton, inet_addr, inet_network (string argument)<br>• mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (2nd argument) |
| Password | • CreateProcessWithLogonW, LogonUser (1st argument)<br>• mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (3rd argument) |
| Database | • MySQL: mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (4th argument)<br>• SQLite: sqlite3_open, sqlite3_open16, sqlite3_open_v2 (1st argument)<br>• PostgreSQL: PQconnectdb<br>• Microsoft SQL: SQLDriverConnect (3rd argument) |
| User name | • getpw, getpwnam, getpwnam_r, getpwuid, getpwuid_r |
| Salt | crypt, crypt_r (2nd argument) |
| Cryptography keys and initialization vectors | OpenSSL:<br>• EVP_CipherInit, EVP_EncryptInit, EVP_DecryptInit (3rd argument)<br>• EVP_CipherInit_ex, EVP_EncryptInit_ex, EVP_DecryptInit_ex (4th argument) |
| Seed | • srand, srandom, initstate (1st argument)<br>• OpenSSL: RAND_seed, RAND_add |

**Risk**

Information that is hardcoded can be queried from binaries generated from the code.

**Fix**

Avoid hard coding sensitive information.

**Example — Sensitive Data Exposed Through String Literals**

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

MYSQL *mysql_real_connect(MYSQL *mysql,
                          const char *host, const char *user, const char *passwd,
                          const char *db, unsigned int port, const char *unix_socket,
                          unsigned long client_flag);

typedef void * DbHandle;
extern MYSQL *sql;

// File that uses functions from "mysql.h"
const char *host = "localhost";
char *user = "guest";
char *passwd;

DbHandle connect_to_database_server(const char *db)
{
    passwd = (char*)"guest";
    return (DbHandle)
        mysql_real_connect (sql, host, user, passwd, db, 0, 0x0, 0);
}
```

In this example, the arguments `host` (host name), `user` (user name), and `passwd` (password) are string literals and directly exposed in the code.

Querying the generated binary for ASCII strings can reveal this information.

**Correction – Read Sensitive Data from Secured Configuration Files**

One possible correction is to read the data from a configuration file. In the following corrected example, the call to function `connect_to_database_server_init` presumably reads the host name, user name, and password into its arguments from a secured configuration file.

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

MYSQL *mysql_real_connect(MYSQL *mysql,
                          const char *host, const char *user, const char *passwd,
                          const char *db, unsigned int port, const char *unix_socket,
                          unsigned long client_flag);

typedef void * DbHandle;
extern MYSQL *sql;

// File that uses functions from "mysql.h"

int connect_to_database_server_init(const char **host,
                                    const char **user,
                                    const char **passwd,
                                    const char **db);
```

```
DbHandle connect_to_database_server(const char *db)
{
    const char *host_from_cfg;
    const char *user_from_cfg;
    const char *passwd_from_cfg;
    const char *db_from_cfg;
    if (connect_to_database_server_init(&host_from_cfg,
                                        &user_from_cfg,
                                        &passwd_from_cfg,
                                        &db_from_cfg))
    {
        return (DbHandle)
            mysql_real_connect (sql, host_from_cfg, user_from_cfg,
                        passwd_from_cfg, db_from_cfg,  0, 0x0, 0);
    }
    else
        return (DbHandle)0x0;
}
```

### Predictable random output from predictable seed

**Issue**

This issue occurs when you use standard random number generator functions with a nonconstant but predictable seed. Examples of predictable seed generators are `time`, `gettimeofday`, and `getpid`.

The checker detects this issue with the following random number generator functions:

- C Standard Library functions such as `srand`, `srandom` and `initstate`
- C++ Standard Library functions such as `std::linear_congruential_engine<>::seed()` and `std::mersenne_twister_engine<>::seed()` (and also the constructors of these class templates)

**Risk**

When you use predictable seed values for random number generation, your random numbers are also predictable. A hacker can disrupt your program if they know how your program behaves.

**Fix**

You can use a different function to generate less predictable seeds.

You can also use a different random number generator that does not require a seed. For example, the Windows API function `rand_s` seeds itself by default. It uses information from the entire system, for example, system time, thread ids, system counter, and memory clusters. This information is more random and a user cannot access this information.

Some standard random routines are inherently cryptographically weak on page 13-97, and should not be used for security purposes.

**Example — Seed as an Argument**

```
#include <stdlib.h>
#include <time.h>

void seed_rng(int seed)
{
    srand(seed);
}

int generate_num(void)
{
    seed_rng(time(NULL) + 3);
    /* ... */
}
```

This example uses `srand` to start the random number generator with `seed` as the seed. However, `seed` is predictable because the function `time` generates it. So, an attacker can predict the random numbers generated by `srand`.

#### Correction — Use Different Random Number Generator

One possible correction is to use a random number generator that does not require a seed. This example uses `rand_s`.

```
#define _CRT_RAND_S

#include <stdlib.h>
#include <stdio.h>
#include <errno.h>

int generate_num(void)
{
    unsigned int number;
    errno_t err;
    err = rand_s(&number);

    if(err != 0)
    {
        return number;
    }
    else
    {
        return err;
    }
}
```

# CWE Rule 338

Use of Cryptographically Weak Pseudo-Random Number Generator (PRNG)

## Description

### Rule Description

*The product uses a Pseudo-Random Number Generator (PRNG) in a security context, but the PRNG's algorithm is not cryptographically strong.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Predictable block cipher initialization vector**
- **Predictable cipher key**
- **Vulnerable pseudo-random number generator**

## Examples

### Predictable block cipher initialization vector

#### Issue

This issue occurs when you use a weak random number generator for the block cipher initialization vector.

#### Risk

If you use a weak random number generator for the initiation vector, your data is vulnerable to dictionary attacks.

Block ciphers break your data into blocks of fixed size. Block cipher modes such as CBC (Cipher Block Chaining) protect against dictionary attacks by XOR-ing each block with the encrypted output from the previous block. To protect the first block, these modes use a random initialization vector (IV). If you use a weak random number generator for your IV, your data becomes vulnerable to dictionary attacks.

#### Fix

Use a strong pseudo-random number generator (PRNG) for the initialization vector. For instance, use:

- OS-level PRNG such as `/dev/random` on UNIX or `CryptGenRandom()` on Windows
- Application-level PRNG such as Advanced Encryption Standard (AES) in Counter (CTR) mode, HMAC-SHA1, etc.

For a list of random number generators that are cryptographically weak, see `Vulnerable pseudo-random number generator`.

#### Example — Predictable Initialization Vector

```
#include <openssl/evp.h>
#include <openssl/rand.h>
```

```
#include <stdlib.h>
#define SIZE16 16

int func(EVP_CIPHER_CTX *ctx, unsigned char *key){
    unsigned char iv[SIZE16];
    RAND_pseudo_bytes(iv, 16);
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

In this example, the function `RAND_pseudo_bytes` declared in `openssl/rand.h` produces the initialization vector. The byte sequences that `RAND_pseudo_bytes` generates are not necessarily unpredictable.

**Correction — Use Strong Random Number Generator**

Use a strong random number generator to produce the initialization vector. The corrected code here uses the function `RAND_bytes` declared in `openssl/rand.h`.

```
#include <openssl/evp.h>
#include <openssl/rand.h>
#include <stdlib.h>
#define SIZE16 16

int func(EVP_CIPHER_CTX *ctx, unsigned char *key){
    unsigned char iv[SIZE16];
    RAND_bytes(iv, 16);
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

## Predictable cipher key

### Issue

This issue occurs when you use a weak random number generator for the encryption or decryption key.

### Risk

If you use a weak random number generator for the encryption or decryption key, an attacker can retrieve your key easily.

You use a key to encrypt and later decrypt your data. If a key is easily retrieved, data encrypted using that key is not secure.

### Fix

Use a strong pseudo-random number generator (PRNG) for the key. For instance:

- Use an OS-level PRNG such as `/dev/random` on UNIX or `CryptGenRandom()` on Windows
- Use an application-level PRNG such as Advanced Encryption Standard (AES) in Counter (CTR) mode, HMAC-SHA1, etc.

For a list of random number generators that are cryptographically weak, see `Vulnerable pseudo-random number generator`.

#### Example — Predictable Cipher Key

```
#include <openssl/evp.h>
#include <openssl/rand.h>
#include <stdlib.h>
#define SIZE16 16

int func(EVP_CIPHER_CTX *ctx, unsigned char *iv){
    unsigned char key[SIZE16];
    RAND_pseudo_bytes(key, 16);
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

In this example, the function `RAND_pseudo_bytes` declared in `openssl/rand.h` produces the cipher key. However, the byte sequences that `RAND_pseudo_bytes` generates are not necessarily unpredictable.

#### Correction — Use Strong Random Number Generator

One possible correction is to use a strong random number generator to produce the cipher key. The corrected code here uses the function `RAND_bytes` declared in `openssl/rand.h`.

```
#include <openssl/evp.h>
#include <openssl/rand.h>
#include <stdlib.h>
#define SIZE16 16

int func(EVP_CIPHER_CTX *ctx, unsigned char *iv){
    unsigned char key[SIZE16];
    RAND_bytes(key, 16);
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

### Vulnerable pseudo-random number generator

#### Issue

This issue occurs when you use cryptographically weak pseudo-random number generator (PRNG) routines.

The list of cryptographically weak routines flagged by this checker include:

- `rand`, `random`
- `drand48`, `lrand48`, `mrand48`, `erand48`, `nrand48`, `jrand48`, and their `_r` equivalents such as `drand48_r`
- `RAND_pseudo_bytes`

#### Risk

These cryptographically weak routines are predictable and must not be used for security purposes. When a predictable random value controls the execution flow, your program is vulnerable to malicious attacks.

**Fix**

Use more cryptographically sound random number generators, such as `CryptGenRandom` (Windows), `OpenSSL/RAND_bytes`(Linux/UNIX).

**Example — Random Loop Numbers**

```
#include <stdio.h>
#include <stdlib.h>

volatile int rd = 1;
int main(int argc, char *argv[])
{
    int j, r, nloops;
    struct random_data buf;
    int i = 0;

    nloops = rand();

    for (j = 0; j < nloops; j++) {
        if (random_r(&buf, &i))
            exit(1);
        printf("random_r: %ld\n", (long)i);
    }
    return 0;
}
```

This example uses `rand` and `random_r` to generate random numbers. If you use these functions for security purposes, these PRNGs can be the source of malicious attacks.

**Correction — Use Stronger PRNG**

One possible correction is to replace the vulnerable PRNG with a stronger random number generator.

```
#include <stdio.h>
#include <stdlib.h>
#include <openssl/rand.h>

volatile int rd = 1;
int main(int argc, char* argv[])
{
    int j, r, nloops;
    unsigned char buf;
    unsigned int seed;
    int i = 0;

    if (argc != 3)
    {
        fprintf(stderr, "Usage: %s <seed> <nloops>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    seed = atoi(argv[1]);
    nloops = atoi(argv[2]);

    for (j = 0; j < nloops; j++) {
        if (RAND_bytes(&buf, i) != 1)
```

```
            exit(1);
        printf("RAND_bytes: %u\n", (unsigned)buf);
    }
    return 0;
}
```

# CWE Rule 353

Missing Support for Integrity Check

## Description

### Rule Description

*The software uses a transmission protocol that does not include a mechanism for verifying the integrity of the data during transmission, such as a checksum.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Context initialized incorrectly for digest operation**
- **Nonsecure hash algorithm**

## Examples

### Context initialized incorrectly for digest operation

#### Issue

This issue occurs when you initialize an `EVP_MD_CTX` context object for a specific digest operation but use the context for a different operation.

For instance, you initialize the context for creating a message digest only.

```
ret = EVP_DigestInit(ctx, EVP_sha256())
```

However, you perform a final step for signing:

```
ret = EVP_SignFinal(&ctx, out, &out_len, pkey);
```

The error is shown only if the final step is not consistent with the initialization of the context. If the intermediate update steps are inconsistent, it does not trigger an error because the intermediate steps do not depend on the nature of the operation. For instance, `EVP_DigestUpdate` works identically to `EVP_SignUpdate`.

#### Risk

Mixing up different operations on the same context can lead to obscure code. It is difficult to determine at a glance whether the current object is used for message digest creation, signing, or verification. The mixup can also lead to a failure in the operation or unexpected message digest.

#### Fix

After you set up a context for a certain family of operations, use the context for only that family of operations. For instance, use these pairs of functions for initialization and final steps.

- `EVP_DigestInit` : `EVP_DigestFinal`
- `EVP_DigestInit_ex` : `EVP_DigestFinal_ex`

- EVP_DigestSignInit : EVP_DigestSignFinal

If you want to reuse an existing context object for a different family of operations, reinitialize the context.

**Example — Inconsistent Initial and Final Digest Operation**

```
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
unsigned char *out_buf16;
unsigned int out_len16;

void func(unsigned char *src, size_t len){
  EVP_MD_CTX* ctx = EVP_MD_CTX_create();

  ret = EVP_SignInit_ex(ctx, EVP_sha256(), NULL);
  if (ret != 1) fatal_error();

  ret = EVP_SignUpdate(ctx, src, len);
  if (ret != 1) fatal_error();

  ret = EVP_DigestSignFinal(ctx, out_buf16, (size_t*) out_len16);

  if (ret != 1) fatal_error();
}
```

In this example, the context object is initialized for signing only with EVP_SignInit but the final step attempts to create a signed digest with EVP_DigestSignFinal.

**Correction — Use One Family of Operations**

One possible correction is to use the context object for signing only. Change the final step to EVP_SignFinal in keeping with the initialization step.

```
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
unsigned char *out_buf16;
unsigned int out_len16;

void corrected_cryptomdbadfunction(unsigned char *src, size_t len, EVP_PKEY* pkey){
  EVP_MD_CTX* ctx = EVP_MD_CTX_create();

  ret = EVP_SignInit_ex(ctx, EVP_sha256(), NULL);
  if (ret != 1) fatal_error();

  ret = EVP_SignUpdate(ctx, src, len);
  if (ret != 1) fatal_error();

  ret = EVP_SignFinal(ctx, out_buf16, &out_len16, pkey);
  if (ret != 1) fatal_error();
}
```

### Nonsecure hash algorithm

**Issue**

This issue occurs when you use a cryptographic hash function that is proven to be weak against certain forms of attack.

The hash functions flagged by this checker include SHA-0, SHA-1, MD4, MD5, and RIPEMD-160. The checker detects the use of these hash functions in:

- Functions from the EVP API such as `EVP_DigestUpdate` or `EVP_SignUpdate`.
- Functions from the low level API such as `SHA1_Update` or `MD5_Update`.

**Risk**

You use a hash function to create a message digest from input data and thereby ensure integrity of your data. The hash functions flagged by this checker use algorithms with known weaknesses that an attacker can exploit. The attacks can comprise the integrity of your data.

**Fix**

Use a more secure hash function. For instance, use the later SHA functions such as SHA-224, SHA-256, SHA-384, and SHA-512.

**Example — Use of MD5 Algorithm**

```
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
unsigned char *out_buf;
unsigned int out_len;

void func(unsigned char *src, size_t len, EVP_PKEY* pkey){
  EVP_MD_CTX* ctx = EVP_MD_CTX_create();

  ret = EVP_SignInit_ex(ctx, EVP_md5(), NULL);
  if (ret != 1) fatal_error();

  ret = EVP_DigestUpdate(ctx,src,len);

  if (ret != 1) fatal_error();

  ret = EVP_SignFinal(ctx, out_buf, &out_len, pkey);
  if (ret != 1) fatal_error();
}
```

In this example, during initialization with `EVP_SignInit_ex`, the context object is associated with the weak hash function MD5. The checker flags the usage of this context in the update step with `EVP_DigestUpdate`.

**Correction — Use SHA-2 Family Function**

One possible correction is to use a hash function from the SHA-2 family, such as SHA-256.

```
#include <openssl/evp.h>
```

```
#define fatal_error() exit(-1)

int ret;
unsigned char *out_buf;
unsigned int out_len;

void func(unsigned char *src, size_t len, EVP_PKEY* pkey){
  EVP_MD_CTX* ctx = EVP_MD_CTX_create();

  ret = EVP_SignInit_ex(ctx, EVP_sha256(), NULL);
  if (ret != 1) fatal_error();

  ret = EVP_SignUpdate(ctx, src, len);
  if (ret != 1) fatal_error();

  ret = EVP_SignFinal(ctx, out_buf, &out_len, pkey);
  if (ret != 1) fatal_error();
}
```

CWE-353

# CWE Rule 362

Concurrent Execution using Shared Resource with Improper Synchronization ('Race Condition')

## Description

### Rule Description

*The program contains a code sequence that can run concurrently with other code, and the code sequence requires temporary, exclusive access to a shared resource, but a timing window exists in which the shared resource can be modified by another code sequence that is operating concurrently.*

### Polyspace Implementation

The rule checker checks for **File descriptor exposure to child process**.

## Examples

### File descriptor exposure to child process

**Issue**

This issue occurs when a process is forked and the child process uses file descriptors inherited from the parent process.

**Risk**

When you fork a child process, file descriptors are copied from the parent process, which means that you can have concurrent operations on the same file. Use of the same file descriptor in the parent and child processes can lead to race conditions that may not be caught during standard debugging. If you do not properly manage the file descriptor permissions and privileges, the file content is vulnerable to attacks targeting the child process.

**Fix**

Check that the file has not been modified before forking the process. Close all inherited file descriptors and reopen them with stricter permissions and privileges, such as read-only permission.

**Example — File Descriptor Accessed from Forked Process**

```
# include <stdio.h>
# include <stdlib.h>
# include <string.h>
# include <unistd.h>
# include <fcntl.h>
# include <sys/types.h>
# include <sys/stat.h>

const char *test_file="/home/user/test.txt";

void func(void)
{
    char c;
    pid_t pid;
    /* create file descriptor in read and write mode */
    int fd = open(test_file, O_RDWR);
    if (fd == -1)
    {
        /* Handle error */
        abort();
    }
    /* fork process */
    pid = fork();
    if (pid == -1)
    {
        /* Handle error */
        abort();
    }
    else if (pid == 0)
    {   /* Child process accesses file descriptor inherited
        from parent process */
        (void)read(fd, &c, 1);
    }
    else
    {   /* Parent process access same file descriptor as
        child process */
        (void)read(fd, &c, 1);
    }
}
```

In this example, a file descriptor `fd` is created in read and write mode. The process is then forked. The child process inherits and accesses `fd` with the same permissions as the parent process. A race condition exists between the parent and child processes. The contents of the file is vulnerable to attacks through the child process.

#### Correction — Close and Reopen Inherited File Descriptor

After you create the file descriptor, check the file for tampering. Then, close the inherited file descriptor in the child process and reopen it in read-only mode.

```
# include <stdio.h>
# include <stdlib.h>
# include <string.h>
# include <unistd.h>
# include <fcntl.h>
# include <sys/types.h>
# include <sys/stat.h>

const char *test_file="/home/user/test.txt";

void func(void)
{
    char c;
    pid_t pid;

    /* Get the state of file for further file tampering checking */

    /* create file descriptor in read and write mode */
    int fd = open(test_file, O_RDWR);
    if (fd == -1)
    {
        /* Handle error */
        abort();
    }

    /* Be sure the file was not tampered with while opening */

    /* fork process */

    pid = fork();
    if (pid == -1)
    {
        /* Handle error */
        (void)close(fd);
        abort();
    }
    else if (pid == 0)
    {  /* Close file descriptor in child process and repoen
        it in read only mode */

        (void)close(fd);
        fd = open(test_file, O_RDONLY);
        if (fd == -1)
        {
            /* Handle error */
            abort();
        }

        (void)read(fd, &c, 1);
        (void)close(fd);
    }
    else
    {  /* Parent acceses original file descriptor */
        (void)read(fd, &c, 1);
        (void)close(fd);
    }
}
```

Signal Handler Race Condition

## Description

### Rule Description

*The software uses a signal handler that introduces a race condition.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Function called from signal handler not asynchronous-safe**
- **Function called from signal handler not asynchronous-safe (strict ISO C)**
- **Shared data access within signal handler**

## Examples

### Function called from signal handler not asynchronous-safe

#### Issue

This issue occurs when a signal handler calls a function that is not asynchronous-safe according to the POSIX standard. An asynchronous-safe function can be interrupted at any point in its execution, then called again without causing an inconsistent state. It can also correctly handle global data that might be in an inconsistent state.

If a signal handler calls another function that calls an asynchronous-unsafe function, the defect appears on the function call in the signal handler. The defect traceback shows the full path from the signal handler to the asynchronous-unsafe function.

#### Risk

When a signal handler is invoked, the execution of the program is interrupted. After the handler is finished, program execution resumes at the point of interruption. If a function is executing at the time of the interruption, calling it from within the signal handler is undefined behavior, unless it is asynchronous-safe.

#### Fix

The POSIX standard defines these functions as asynchronous-safe. You can call these functions from a signal handler.

| | | |
|---|---|---|
| `_exit()` | `getpgrp()` | `setsockopt()` |
| `_Exit()` | `getpid()` | `setuid()` |
| `abort()` | `getppid()` | `shutdown()` |

| fchdir() | pthread_sigmask() | tcgetpgrp() |
| fchmod() | quick_exit() | tcsendbreak() |
| fchmodat() | raise() | tcsetattr() |
| fchown() | read() | tcsetpgrp() |
| fchownat() | readlink() | time() |
| fcntl() | readlinkat() | timer_getoverrun() |
| fdatasync() | recv() | timer_gettime() |
| fexecve() | recvfrom() | timer_settime() |
| fork() | recvmsg() | times() |
| fpathconf() | rename() | umask() |
| fstat() | renameat() | uname() |
| fstatat() | rmdir() | unlink() |
| fsync() | select() | unlinkat() |
| ftruncate() | sem_post() | utime() |

| | | |
|---|---|---|
| futimens() | send() | utimensat() |
| getegid() | sendmsg() | utimes() |
| geteuid() | sendto() | wait() |
| getgid() | setgid() | waitpid() |
| getgroups() | setpgid() | write() |
| getpeername() | setsid() | |

Functions not in the previous table are not asynchronous-safe, and should not be called from a signal hander.

**Example — Call to printf() Inside Signal Handler**

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
#include <unistd.h>

#define SIZE20 20

extern volatile sig_atomic_t e_flag;

void display_info(const char *info)
{
    if (info)
    {
        (void)fputs(info, stderr);
    }
}

void sig_handler(int signum)
{
    /* Call function printf() that is not
    asynchronous-safe */
    printf("signal %d received.", signum);
    e_flag = 1;
}

int main(void)
{
    e_flag = 0;
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    char *info = (char *)calloc(SIZE20, sizeof(char));
    if (info == NULL)
    {
        /* Handle Error */
    }
    while (!e_flag)
    {
        /* Main loop program code */
        display_info(info);
        /* More program code */
    }
    free(info);
    info = NULL;
    return 0;
}
```

In this example, `sig_handler` calls `printf()` when catching a signal. If the handler catches another signal while `printf()` is executing, the behavior of the program is undefined.

**Correction — Set Flag Only in Signal Handler**

Use your signal handler to set only the value of a flag. `e_flag` is of type volatile `sig_atomic_t`. `sig_handler` can safely access it asynchronously.

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
#include <unistd.h>

#define SIZE20 20

extern volatile sig_atomic_t e_flag;

void display_info(const char *info)
{
    if (info)
    {
        (void)fputs(info, stderr);
    }
}

void sig_handler1(int signum)
{
    int s0 = signum;
    e_flag = 1;
}

int func(void)
{
    e_flag = 0;
    if (signal(SIGINT, sig_handler1) == SIG_ERR)
    {
        /* Handle error */
    }
    char *info = (char *)calloc(SIZE20, 1);
    if (info == NULL)
    {
        /* Handle error */
    }
    while (!e_flag)
    {
        /* Main loop program code */
        display_info(info);
        /* More program code */
    }
    free(info);
    info = NULL;
    return 0;
}
```

### Function called from signal handler not asynchronous-safe (strict ISO C)

#### Issue

This issue occurs when a signal handler calls a function that is not asynchronous-safe according to the C standard. An asynchronous-safe function can be interrupted at any point in its execution, then called again without causing an inconsistent state. It can also correctly handle global data that might be in an inconsistent state.

The C standard defines a stricter subset of functions as asynchronous-safe compared to the set of functions that are asynchronous-safe according to the POSIX standard. **Function called from signal handler not asynchronous-safe (strict ISO C)** reports a defect when a signal handler calls any function that is not part of that subset, even if the function is asynchronous-safe according to the POSIX standard.

To check for calls to functions that are not asynchronous-safe according to the POSIX standard, enable checker **Function called from signal handler not asynchronous-safe**.

If a signal handler calls another function that calls an asynchronous-unsafe function, the defect appears on the function call in the signal handler. The defect traceback shows the full path from the signal handler to the asynchronous-unsafe function.

#### Risk

When a signal handler is invoked, the execution of the program is interrupted. After the handler is finished, program execution resumes at the point of interruption. If a function is executing at the time of the interruption, calling it from within the signal handler is undefined behavior, unless it is asynchronous-safe.

#### Fix

The C standard defines the following functions as asynchronous-safe. You can call these functions from a signal handler:

- `abort()`
- `_Exit()`
- `quick_exit()`
- `signal()`

#### Example — Call to raise() Inside Signal Handler

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
```

```
#include <unistd.h>

void SIG_ERR_handler(int signum)
{
    int s0 = signum;
    /* SIGTERM specific handling */
}

void sig_handler(int signum)
{
    int s0 = signum;
    /* Call raise() */
    if (raise(SIGTERM) != 0) {
        /* Handle error */
    }
}

int finc(void)
{
    if (signal(SIGTERM, SIG_ERR_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
    }
    /* More code */
    return 0;
}
```

In this example, `sig_handler` calls `raise()` when catching a signal. If the handler catches another signal while `raise()` is executing, the behavior of the program is undefined.

**Correction — Remove Call to `raise()` in Signal Handler**

According to the C standard, the only functions that you can safely call from a signal handler are `abort()`, `_Exit()`, `quick_exit()`, and `signal()`.

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
#include <unistd.h>

void SIG_ERR_handler(int signum)
{
    int s0 = signum;
    /* SIGTERM specific handling */
}
void sig_handler(int signum)
{
    int s0 = signum;

}

int func(void)
{
    if (signal(SIGTERM, SIG_ERR_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
    }
    /* More code */
    return 0;
}
```

## Shared data access within signal handler

### Issue

This issue occurs when you access or modify a shared object inside a signal handler.

### Risk

When you define a signal handler function to access or modify a shared object, the handler accesses or modifies the shared object when it receives a signal. If another function is already accessing the shared object, that function causes a race condition and can leave the data in an inconsistent state.

### Fix

To access or modify shared objects inside a signal handler, check that the objects are lock-free atomic, or, if they are integers, declare them as `volatile sig_atomic_t`.

### Example — int Variable Access in Signal Handler

```
#include <signal.h>
#include <stdlib.h>
#include <string.h>

/* declare global variable. */
int e_flag;

void sig_handler(int signum)
{
    /* Signal handler accesses variable that is not
    of type volatile sig_atomic_t. */
    e_flag = signum;
}
```

```
int func(void)
{
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
        abort();
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
        abort();
    }
    /* More code */
    return 0;
}
```

In this example, `sig_handler` accesses `e_flag`, a variable of type `int`. A concurrent access by another function can leave `e_flag` in an inconsistent state.

**Correction — Declare Variable of Type `volatile sig_atomic_t`**

Before you access a shared variable from a signal handler, declare the variable with type `volatile sig_atomic_t` instead of `int`. You can safely access variables of this type asynchronously.

```
#include <signal.h>
#include <stdlib.h>
#include <string.h>

/* Declare variable of type volatile sig_atomic_t. */
volatile sig_atomic_t e_flag;
void sig_handler(int signum)
{
    /* Use variable of proper type inside signal handler. */
    e_flag = signum;

}

int func(void)
{
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
        abort();
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
        abort();
    }
    /* More code */
    return 0;
}
```

CWE-364

# CWE Rule 366

Race Condition within a Thread

## Description

### Rule Description

*If two threads of execution use a resource simultaneously, there exists the possibility that resources may be used while invalid, in turn making the state of execution undefined.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Atomic load and store sequence not atomic**
- **Atomic variable accessed twice in an expression**
- **Data race**
- **Data race on adjacent bit fields**
- **Data race through standard library function call**

## Examples

### Atomic load and store sequence not atomic

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See "Checkers Deactivated in Polyspace as You Code Analysis".*

This issue occurs when you use these functions to load, and then store an atomic variable.

- C functions:
  - `atomic_load()`
  - `atomic_load_explicit()`
  - `atomic_store()`
  - `atomic_store_explicit()`
- C++ functions:
  - `std::atomic_load()`
  - `std::atomic_load_explicit()`
  - `std::atomic_store()`
  - `std::atomic_store_explicit()`
  - `std::atomic::load()`
  - `std::atomic::store()`

A thread cannot interrupt an atomic load or an atomic store operation on a variable, but a thread can interrupt a store, and then load sequence.

**Risk**

A thread can modify a variable between the load and store operations, resulting in a data race condition.

**Fix**

To read, modify, and store a variable atomically, use a compound assignment operator such as +=, `atomic_compare_exchange()` or `atomic_fetch_*`-family functions.

**Example — Loading Then Storing an Atomic Variable**

```
#include <stdatomic.h>
#include <stdbool.h>

static atomic_bool flag = ATOMIC_VAR_INIT(false);

void init_flag(void)
{
    atomic_init(&flag, false);
}

void toggle_flag(void)
{
    bool temp_flag = atomic_load(&flag);
    temp_flag = !temp_flag;
    atomic_store(&flag, temp_flag);
}

bool get_flag(void)
{
    return atomic_load(&flag);
}
```

In this example, variable `flag` of type `atomic_bool` is referenced twice inside the `toggle_flag()` function. The function loads the variable, negates its value, then stores the new value back to the variable. If two threads call `toggle_flag()`, the second thread can access `flag` between the load and store operations of the first thread. `flag` can end up in an incorrect state.

**Correction — Use Compound Assignment to Modify Variable**

One possible correction is to use a compound assignment operator to toggle the value of `flag`. The C standard defines the operation by using ^= as atomic.

```
#include <stdatomic.h>
#include <stdbool.h>

static atomic_bool flag = ATOMIC_VAR_INIT(false);

void toggle_flag(void)
{
    flag ^= 1;
}

bool get_flag(void)
{
    return flag;
}
```

### Atomic variable accessed twice in an expression

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”.*

This issue occurs when C atomic types or C++ `std::atomic` class variables appear twice in an expression and there are:

- Two atomic read operations on the variable.
- An atomic read and a distinct atomic write operation on the variable.

The C standard defines certain operations on atomic variables that are thread safe and do not cause data race conditions. Unlike individual operations, a pair of operations on the same atomic variable in an expression is not thread safe.

#### Risk

A thread can modify the atomic variable between the pair of atomic operations, which can result in a data race condition.

#### Fix

Do not reference an atomic variable twice in the same expression.

#### Example — Referencing Atomic Variable Twice in an Expression

```
#include <stdatomic.h>

atomic_int n = ATOMIC_VAR_INIT(0);

int compute_sum(void)
{
    return n * (n + 1) / 2;
}
```

In this example, the global variable `n` is referenced twice in the return statement of `compute_sum()`. The value of `n` can change between the two distinct read operations. `compute_sum()` can return an incorrect value.

#### Correction — Pass Variable as Function Argument

One possible correction is to pass the variable as a function argument `n`. The variable is copied to memory and the read operations on the copy guarantee that `compute_sum()` returns a correct result. If you pass a variable of type `int` instead of type `atomic_int`, the correction is still valid.

```
#include <stdatomic.h>

int compute_sum(atomic_int n)
{
    return n * (n + 1) / 2;
}
```

### Data race

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”.*

This issue occurs when:

1. Multiple tasks perform unprotected operations on a shared variable.
2. At least one task performs a write operation.
3. At least one operation is nonatomic. To detect data race on both atomic and nonatomic operations, use the options `-detect-atomic-data-race`. See “Extend Data Race Checkers to Atomic Operations”.

   See “Define Atomic Operations in Multitasking Code”.

If you activate this checker without specifying the multitasking options first, you see a warning in the log:To find this defect, specify the multitasking options before analysis.

To specify these options, on the **Configuration** pane, select **Multitasking**. For more information, see “Configuring Polyspace Multitasking Analysis Manually”.

#### Risk

Data race can result in unpredictable values of the shared variable because you do not control the order of the operations in different tasks.

Data races between two write operations are more serious than data races between a write and read operation. Two write operations can interfere with each other and result in indeterminate values. To identify write-write conflicts, use the filters on the **Detail** column of the **Results List** pane. For these conflicts, the **Detail** column shows the additional line:

```
 Variable value may be altered by write-write concurrent access.
```

See also “Filter and Group Results in Polyspace Desktop User Interface” or “Filter and Sort Results in Polyspace Access Web Interface”.

#### Fix

To fix this defect, protect the operations on the shared variable using critical sections, temporal exclusion or another means. See “Protections for Shared Variables in Multitasking Code”.

To identify existing protections that you can reuse, see the table and graphs associated with the result. The table shows each pair of conflicting calls. The **Access Protections** column shows existing protections on the calls. To see the function call sequence leading to the conflicts, click the icon. For an example, see below.

#### Extend Checker

Extend this checker to check for data races in operations that Bug Finder might not detect by default. For instance:

- You might be using multithreading functions that are not supported by Polyspace. Extend this checker by mapping the functions of your multithreading functions to their known POSIX equivalent. See “Extend Concurrency Defect Checkers to Unsupported Multithreading Environments”.
- Polyspace assumes that certain operations are atomic and excludes them from data race checks. See “Define Atomic Operations in Multitasking Code”. These assumptions might not apply to your environment. To extend the data race checkers to include these operations, use the option `-detect-atomic-data-race`. See “Extend Data Race Checkers to Atomic Operations”.

#### Example — Unprotected Operation on Global Variable from Multiple Tasks

```
int var;
void begin_critical_section(void);
void end_critical_section(void);

void increment(void) {
    var++;
}

void task1(void)  {
      increment();
}

void task2(void)  {
      increment();
}

void task3(void)  {
     begin_critical_section();
     increment();
     end_critical_section();
}
```

In this example, to emulate multitasking behavior, specify the following options:

| Option | Specification | |
|---|---|---|
| Configure multitasking manually | ☑ | |
| Tasks (-entry-points) | task1<br>task2<br>task3 | |
| Critical section details (-critical-section-begin -critical-section-end) | **Starting routine** | **Ending routine** |
| | begin_critical_section | end_critical_section |

On the command-line, you can use the following:

```
polyspace-bug-finder
  -entry-points task1,task2,task3
  -critical-section-begin begin_critical_section:cs1
  -critical-section-end end_critical_section:cs1
```

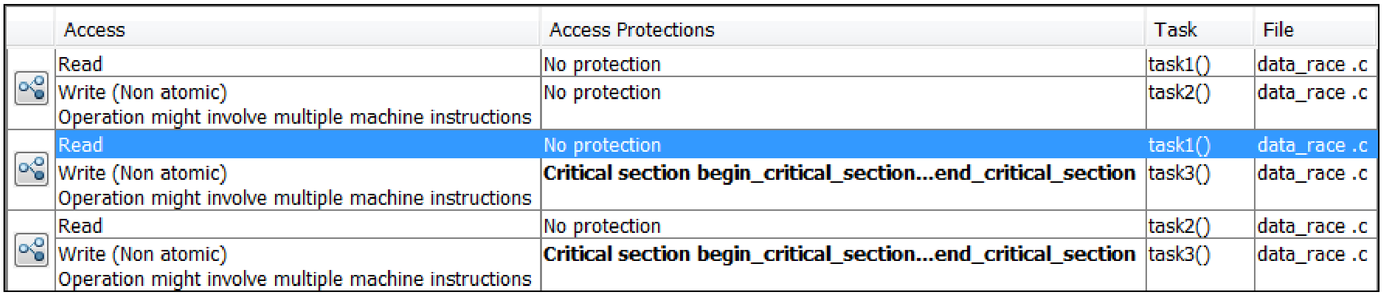
In this example, the tasks `task1`, `task2`, and `task3` call the function `increment`. `increment` contains the operation `var++` that can involve multiple machine instructions including:

- Reading `var`.
- Writing an increased value to `var`.

These machine instructions, when executed from `task1` and `task2`, can occur concurrently in an unpredictable sequence. For example, reading `var` from `task1` can occur either before or after writing to `var` from `task2`. Therefore the value of `var` can be unpredictable.

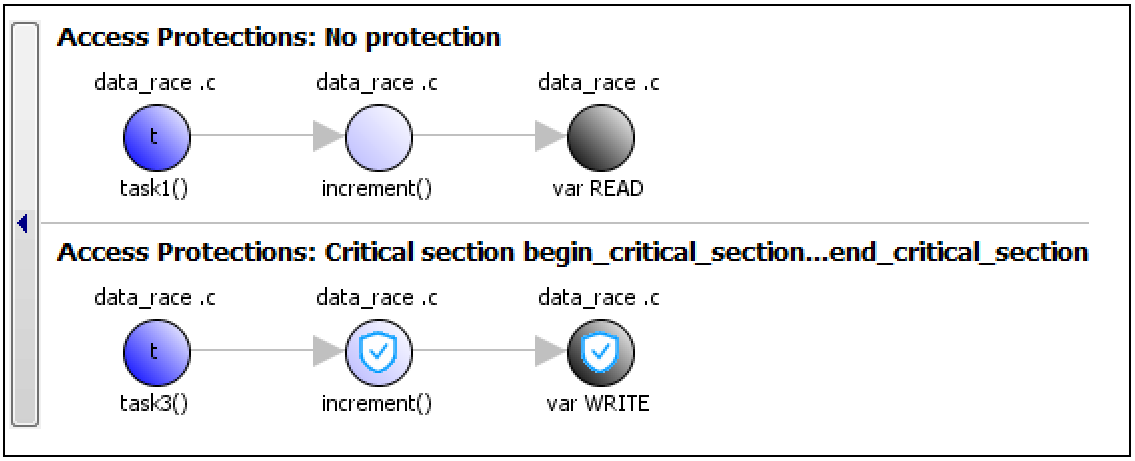
Though `task3` calls `increment` inside a critical section, other tasks do not use the same critical section. The operations in the critical section of `task3` are not mutually exclusive with operations in other tasks.

Therefore, the three tasks are operating on a shared variable without common protection. In your result details, you see each pair of conflicting function calls.



| | Access | Access Protections | Task | File |
|---|---|---|---|---|
| | Read | No protection | task1() | data_race .c |
| | Write (Non atomic)<br>Operation might involve multiple machine instructions | No protection | task2() | data_race .c |
| | Read | No protection | task1() | data_race .c |
| | Write (Non atomic)<br>Operation might involve multiple machine instructions | **Critical section begin_critical_section...end_critical_section** | task3() | data_race .c |
| | Read | No protection | task2() | data_race .c |
| | Write (Non atomic)<br>Operation might involve multiple machine instructions | **Critical section begin_critical_section...end_critical_section** | task3() | data_race .c |

If you click the icon, you see the function call sequence starting from the entry point to the read or write operation. You also see that the operation starting from `task3` is in a critical section. The **Access Protections** entry shows the lock and unlock function that begin and end the critical section. In this example, you see the functions `begin_critical_section` and `end_critical_section`.



#### Correction — Place Operation in Critical Section

One possible correction is to place the operation in critical section. You can implement the critical section in multiple ways. For instance:

- You can place `var++` in a critical section. When `task1` enters its critical section, the other tasks cannot enter their critical sections until `task1` leaves its critical section. The operation `var++` from the three tasks cannot interfere with each other.

  To implement the critical section, in the function `increment`, place the operation `var++` between calls to `begin_critical_section` and `end_critical_section`.

  ```
  int var;

  void begin_critical_section(void);
  void end_critical_section(void);

  void increment(void) {
        begin_critical_section();
        var++;
        end_critical_section();
  }

  void task1(void)  {
        increment();
  }

  void task2(void)  {
        increment();
  }

  void task3(void)  {
        increment();
  }
  ```
- You can place the call to `increment` in the same critical section in the three tasks. When `task1` enters its critical section, the other tasks cannot enter their critical sections until `task1` leaves its critical section. The calls to `increment` from the three tasks cannot interfere with each other.

  To implement the critical section, in each of the three tasks, call `increment` between calls to `begin_critical_section` and `end_critical_section`.

  ```
  int var;

  void begin_critical_section(void);
  void end_critical_section(void);

  void increment(void) {
        var++;
  }

  void task1(void)  {
  ```

```
        begin_critical_section();
        increment();
        end_critical_section();
   }

   void task2(void)  {
        begin_critical_section();
        increment();
        end_critical_section();
   }

   void task3(void)  {
        begin_critical_section();
        increment();
        end_critical_section();
   }
```

#### Correction — Make Tasks Temporally Exclusive

Another possible correction is to make the tasks, `task1`, `task2` and `task3`, temporally exclusive. Temporally exclusive tasks cannot execute concurrently.

On the **Configuration** pane, specify the following additional options:

| Option | Value |
|---|---|
| Temporally exclusive tasks (-temporal-exclusions-file) | task1 task2 task3 |

On the command-line, you can use the following:

```
 polyspace-bug-finder
     -temporal-exclusions-file "C:\exclusions_file.txt"
```

where the file `C:\exclusions_file.txt` has the following line:

```
task1 task2 task3
```

#### Example — Unprotected Operation in Threads Created with pthread_create

```
#include <pthread.h>

pthread_mutex_t count_mutex;
long long count;

void* increment_count(void* args)
{
    count = count + 1;
    return NULL;
}

void* set_count(void *args)
{
    long long c;
    c = count;
    return NULL;
}
```

```
int main(void)
{
    pthread_t thread_increment;
    pthread_t thread_get;

    pthread_create(&thread_increment, NULL, increment_count, NULL);
    pthread_create(&thread_get, NULL, set_count, NULL);

    pthread_join(thread_get, NULL);
    pthread_join(thread_increment, NULL);

    return 1;
}
```

In this example, Bug Finder detects the creation of separate threads with `pthread_create`. The **Data race** defect is raised because the operation `count = count + 1` in the thread with id `thread_increment` conflicts with the operation `c = count` in the thread with id `thread_get`. The variable `count` is accessed in multiple threads without a common protection.

The two conflicting operations are nonatomic. The operation `c = count` is nonatomic on 32-bit targets. See “Define Atomic Operations in Multitasking Code”.

#### Correction — Protect Operations with `pthread_mutex_lock` and `pthread_mutex_unlock` Pair

To prevent concurrent access on the variable `count`, protect operations on `count` with a critical section. Use the functions `pthread_mutex_lock` and `pthread_mutex_unlock` to implement the critical section.

```
#include <pthread.h>

pthread_mutex_t count_mutex;
long long count;

void* increment_count(void* args)
{
    pthread_mutex_lock(&count_mutex);
    count = count + 1;
    pthread_mutex_unlock(&count_mutex);
    return NULL;
}

void* set_count(void *args)
{
    long long c;
    pthread_mutex_lock(&count_mutex);
    c = count;
    pthread_mutex_unlock(&count_mutex);
    return NULL;
}

int main(void)
{
    pthread_t thread_increment;
    pthread_t thread_get;

    pthread_create(&thread_increment, NULL, increment_count, NULL);
    pthread_create(&thread_get, NULL, set_count, NULL);

    pthread_join(thread_get, NULL);
    pthread_join(thread_increment, NULL);

    return 1;
}
```

### Data race on adjacent bit fields

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See "Checkers Deactivated in Polyspace as You Code Analysis".*

This issue occurs when:

1. Multiple tasks perform unprotected operations on bit fields that are part of the same structure.

   For instance, a task operates on field `errorFlag1` and another task on field `errorFlag2` in a variable of this type:

   ```
   struct errorFlags {
      unsigned int errorFlag1 : 1;
      unsigned int errorFlag2 : 1;
      ...
   }
   ```

   Suppose that the operations are not atomic with respect to each other. In other words, you have not implemented protection mechanisms to ensure that one operation is completed before another operation begins.
2. At least one of the unprotected operations is a write operation.

To find this defect, before analysis, you must specify the multitasking options. To specify these options, on the **Configuration** pane, select **Multitasking**. For more information, see "Configuring Polyspace Multitasking Analysis Manually".

#### Risk

Adjacent bit fields that are part of the same structure might be stored in one byte in the same memory location. Read or write operations on all variables including bit fields occur one byte or word at a time. To modify only specific bits in a byte, steps similar to these steps occur in sequence:

1. The byte is loaded into RAM.
2. A mask is created so that only specific bits are modified to the intended value and the remaining bits remain unchanged.
3. A bitwise OR operation is performed between the copy of the byte in RAM and the mask.
4. The byte with specific bits modified is copied back from RAM.

When you access two different bit fields, these four steps have to be performed for each bit field. If the accesses are not protected, all four steps for one bit field might not be completed before the four steps for the other bit field begin. As a result, the modification of one bit field might undo the modification of an adjacent bit field. For instance, in the preceding example, the modification of `errorFlag1` and `errorFlag2` can occur in the following sequence. Steps 1,2 and 5 relate to modification of `errorFlag1` and while steps 3,4 and 6 relate to that of `errorFlag2`.

1. The byte with both `errorFlag1` and `errorFlag2` unmodified is copied into RAM, for purposes of modifying `errorFlag1`.
2. A mask that modifies only `errorFlag1` is bitwise OR-ed with this copy.
3. The byte containing both `errorFlag1` and `errorFlag2` unmodified is copied into RAM a second time, for purposes of modifying `errorFlag2`.
4. A mask that modifies only `errorFlag2` is bitwise OR-ed with this second copy.
5. The version with `errorFlag1` modified is copied back. This version has `errorFlag2` unmodified.
6. The version with `errorFlag2` modified is copied back. This version has `errorFlag1` unmodified and overwrites the previous modification.

#### Fix

To fix this defect, protect the operations on bit fields that are part of the same structure by using critical sections, temporal exclusion, or another means. See “Protections for Shared Variables in Multitasking Code”.

To identify existing protections that you can reuse, see the table and graphs associated with the result. The table shows each pair of conflicting calls. The **Access Protections** column shows existing protections on the calls. To see the function call sequence leading to the conflicts, click the icon.

#### Example — Unprotected Operation on Global Variable from Multiple Tasks

```
typedef struct
{
   unsigned int IOFlag :1;
   unsigned int InterruptFlag :1;
   unsigned int Register1Flag :1;
   unsigned int SignFlag :1;
   unsigned int SetupFlag :1;
   unsigned int Register2Flag :1;
   unsigned int ProcessorFlag :1;
   unsigned int GeneralFlag :1;
} InterruptConfigbits_t;

InterruptConfigbits_t InterruptConfigbitsProc12;

void task1 (void) {
    InterruptConfigbitsProc12.IOFlag = 0;
}

void task2 (void) {
    InterruptConfigbitsProc12.SetupFlag = 0;
}
```

In this example, `task1` and `task2` access different bit fields `IOFlag` and `SetupFlag`, which belong to the same structured variable `InterruptConfigbitsProc12`.

To emulate multitasking behavior, specify the options listed in this table.

| Option | Specification |
|---|---|
| **Configure multitasking manually** on page 2-117 | ☑ |

| Option | Specification |
|---|---|
| **Tasks** on page 2-121 | task1<br>task2 |

At the command-line, use:

```
 polyspace-bug-finder
   -entry-points task1,task2
```

**Correction – Use Critical Sections**

One possible correction is to wrap the bit field access in a critical section. A critical section lies between a call to a lock function and an unlock function. In this correction, the critical section lies between the calls to functions `begin_critical_section` and `end_critical_section`.

```
typedef struct
{
   unsigned int IOFlag :1;
   unsigned int InterruptFlag :1;
   unsigned int Register1Flag :1;
   unsigned int SignFlag :1;
   unsigned int SetupFlag :1;
   unsigned int Register2Flag :1;
   unsigned int ProcessorFlag :1;
   unsigned int GeneralFlag :1;
} InterruptConfigbits_t;

InterruptConfigbits_t InterruptConfigbitsProc12;

void begin_critical_section(void);
void end_critical_section(void);

void task1 (void) {
    begin_critical_section();
    InterruptConfigbitsProc12.IOFlag = 0;
    end_critical_section();
}

void task2 (void) {
    begin_critical_section();
    InterruptConfigbitsProc12.SetupFlag = 0;
    end_critical_section();
}
```

In this example, to emulate multitasking behavior, specify options listed in this table.

| Option | Specification | |
|---|---|---|
| **Configure multitasking manually** on page 2-117 | ☑ | |
| **Tasks** on page 2-121 | task1<br>task2 | |
| **Critical section details** on page 2-133 | **Starting routine** | **Ending routine** |

| Option | Specification | |
|---|---|---|
| | begin_critical_section | end_critical_section |

At the command-line, use:

```
polyspace-bug-finder
  -entry-points task1,task2
  -critical-section-begin begin_critical_section:cs1
  -critical-section-end end_critical_section:cs1
```

#### Correction – Avoid Bit Fields

If you do not have memory constraints, use the `char` data type instead of bit fields. The `char` variables in a structure occupy at least one byte and do not have the thread-safety issues that come from bit manipulations in a byte-sized operation. Data races do not result from unprotected operations on different `char` variables that are part of the same structure.

```
typedef struct
{
   unsigned char IOFlag;
   unsigned char InterruptFlag;
   unsigned char Register1Flag;
   unsigned char SignFlag;
   unsigned char SetupFlag;
   unsigned char Register2Flag;
   unsigned char ProcessorFlag;
   unsigned char GeneralFlag;
} InterruptConfigbits_t;

InterruptConfigbits_t InterruptConfigbitsProc12;

void task1 (void) {
    InterruptConfigbitsProc12.IOFlag = 0;
}

void task2 (void) {
    InterruptConfigbitsProc12.SetupFlag = 0;
}
```

Though the checker does not flag this correction, do not use this correction for C99 or earlier. Only from C11 and later does the C Standard mandate that distinct `char` variables cannot be accessed using the same word.

#### Correction – Insert Bit Field of Size 0

You can enter a non-bit field member or an unnamed bit field member of size 0 between two adjacent bit fields that might be accessed concurrently. A non-bit field member or size 0 bit field member ensures that the subsequent bit field starts from a new memory location. In this corrected example, the size 0 bit field member ensures that `IOFlag` and `SetupFlag` are stored in distinct memory locations.

```
typedef struct
{
   unsigned int IOFlag :1;
   unsigned int InterruptFlag :1;
   unsigned int Register1Flag :1;
   unsigned int SignFlag :1;
   unsigned int : 0;
   unsigned int SetupFlag :1;
   unsigned int Register2Flag :1;
   unsigned int ProcessorFlag :1;
   unsigned int GeneralFlag :1;
} InterruptConfigbits_t;

InterruptConfigbits_t InterruptConfigbitsProc12;

void task1 (void) {
    InterruptConfigbitsProc12.IOFlag = 0;
}

void task2 (void) {
    InterruptConfigbitsProc12.SetupFlag = 0;
}
```

### Data race through standard library function call

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See "Checkers Deactivated in Polyspace as You Code Analysis".*

This issue occurs when:

1. Multiple tasks call the same standard library function.

   For instance, multiple tasks call the `strerror` function.
2. The calls are not protected using a common protection.

   For instance, the calls are not protected by the same critical section.

Functions flagged by this defect are not guaranteed to be reentrant. A function is reentrant if it can be interrupted and safely called again before its previous invocation completes execution. If a function is not reentrant, multiple tasks calling the function without protection can cause concurrency issues. For the list of functions that are flagged, see CON33-C: Avoid race conditions when using library functions.

To find this defect, you must specify the multitasking options before analysis. To specify these options, on the **Configuration** pane, select **Multitasking**. For more information, see "Configuring Polyspace Multitasking Analysis Manually".

#### Risk

The functions flagged by this defect are nonreentrant because their implementations can use global or static variables. When multiple tasks call the function without protection, the function call from one task can interfere with the call from another task. The two invocations of the function can concurrently access the global or static variables and cause unpredictable results.

The calls can also cause more serious security vulnerabilities, such as abnormal termination, denial-of-service attack, and data integrity violations.

#### Fix

To fix this defect, do one of the following:

- Use a reentrant version of the standard library function if it exists.

  For instance, instead of `strerror()`, use `strerror_r()` or `strerror_s()`. For alternatives to functions flagged by this defect, see the documentation for CON33-C.
- Protect the function calls using common critical sections or temporal exclusion.

  See `Critical section details (-critical-section-begin -critical-section-end)` and `Temporally exclusive tasks (-temporal-exclusions-file)`.

  To identify existing protections that you can reuse, see the table and graphs associated with the result. The table shows each pair of conflicting calls. The **Access Protections** column shows existing protections on the calls. To see the function call sequence leading to the conflicts, click the icon. For an example, see below.

**Example — Unprotected Call to Standard Library Function from Multiple Tasks**

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char *errmsg = strerror(errno);
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    func(fptr1);
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     func(fptr2);
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

In this example, to emulate multitasking behavior, specify the following options:

| Option | Specification | |
|---|---|---|
| `Configure multitasking manually` | ☑ | |
| `Tasks (-entry-points)` | `task1`<br>`task2`<br>`task3` | |
| `Critical section details (-critical-section-begin -critical-section-end)` | **Starting routine** | **Ending routine** |
| | `begin_critical_section` | `end_critical_section` |

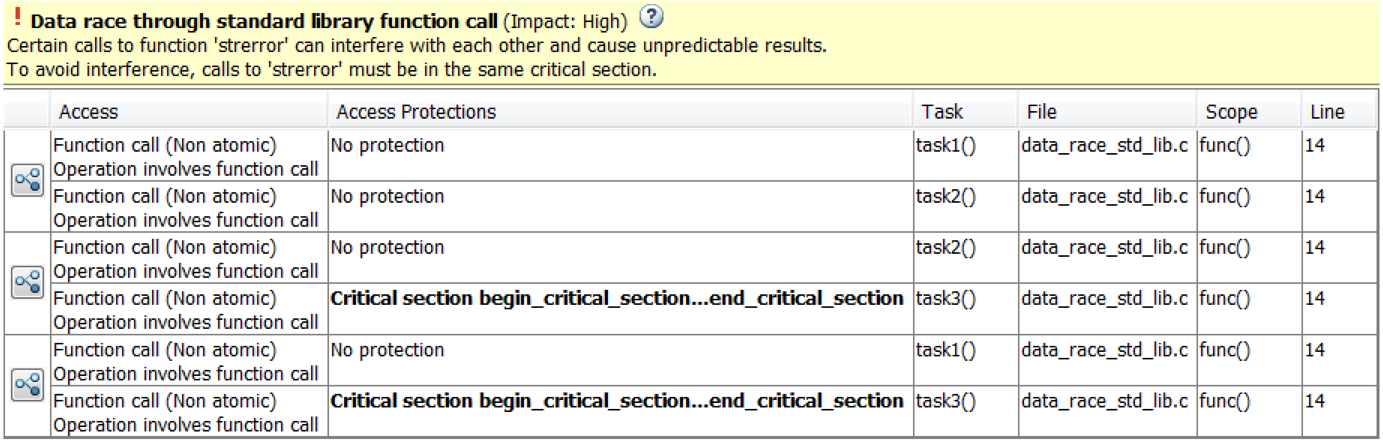
On the command-line, you can use the following:

```
 polyspace-bug-finder
   -entry-points task1,task2,task3
   -critical-section-begin begin_critical_section:cs1
   -critical-section-end end_critical_section:cs1
```

In this example, the tasks, `task1`, `task2` and `task3`, call the function `func`. `func` calls the nonreentrant standard library function, `strerror`.

Though `task3` calls `func` inside a critical section, other tasks do not use the same critical section. Operations in the critical section of `task3` are not mutually exclusive with operations in other tasks.

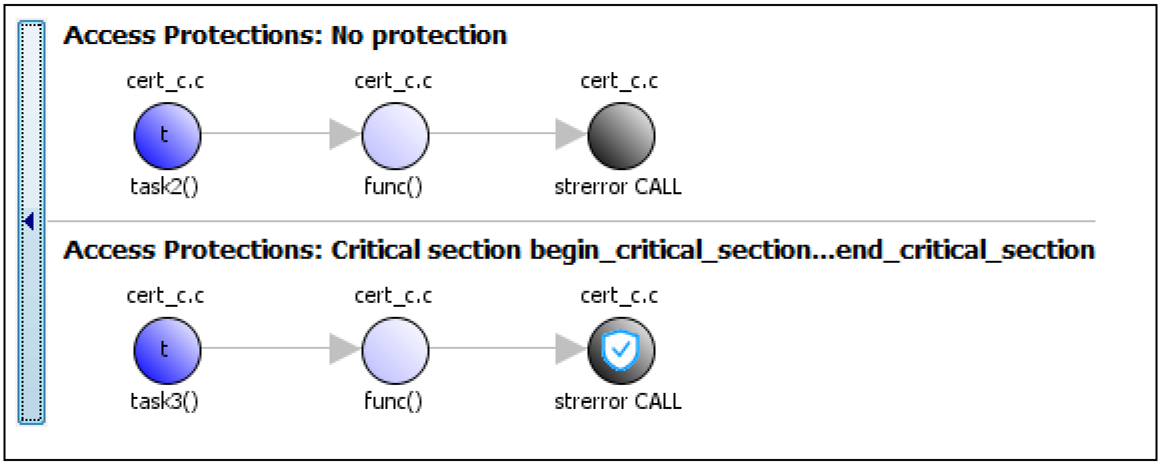
These three tasks are calling a nonreentrant standard library function without common protection. In your result details, you see each pair of conflicting function calls.



**! Data race through standard library function call** (Impact: High)
Certain calls to function 'strerror' can interfere with each other and cause unpredictable results.
To avoid interference, calls to 'strerror' must be in the same critical section.

| | Access | Access Protections | Task | File | Scope | Line |
|---|---|---|---|---|---|---|
| | Function call (Non atomic)<br>Operation involves function call | No protection | task1() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task2() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task2() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | **Critical section begin_critical_section...end_critical_section** | task3() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task1() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | **Critical section begin_critical_section...end_critical_section** | task3() | data_race_std_lib.c | func() | 14 |

If you click the icon, you see the function call sequence starting from the entry point to the standard library function call. You also see that the call starting from `task3` is in a critical section. The **Access Protections** entry shows the lock and unlock function that begin and end the critical section. In this example, you see the functions `begin_critical_section` and `end_critical_section`.



Access Protections: No protection
cert_c.c
t
task2()
cert_c.c
func()
cert_c.c
strerror CALL
Access Protections: Critical section begin_critical_section...end_critical_section
cert_c.c
t
task3()
cert_c.c
func()
cert_c.c
strerror CALL

**Correction — Use Reentrant Version of Standard Library Function**

One possible correction is to use a reentrant version of the standard library function `strerror`. You can use the POSIX version `strerror_r` which has the same functionality but also guarantees thread-safety.

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);
enum { BUFFERSIZE = 64 };

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char errmsg[BUFFERSIZE];
    if (strerror_r(errno, errmsg, BUFFERSIZE) != 0) {
      /* Handle error */
    }
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    func(fptr1);
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     func(fptr2);
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

**Correction — Place Function Call in Critical Section**

One possible correction is to place the call to `strerror` in critical section. You can implement the critical section in multiple ways.

For instance, you can place the call to the intermediate function `func` in the same critical section in the three tasks. When `task1` enters its critical section, the other tasks cannot enter their critical sections until `task1` leaves its critical section. The calls to `func` and therefore the calls to `strerror` from the three tasks cannot interfere with each other.

To implement the critical section, in each of the three tasks, call `func` between calls to `begin_critical_section` and `end_critical_section`.

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char *errmsg = strerror(errno);
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    begin_critical_section();
    func(fptr1);
    end_critical_section();
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     begin_critical_section();
     func(fptr2);
     end_critical_section();
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

#### Correction — Make Tasks Temporally Exclusive

Another possible correction is to make the tasks, `task1`, `task2` and `task3`, temporally exclusive. Temporally exclusive tasks cannot execute concurrently.

On the **Configuration** pane, specify the following additional options:

| Option | Value |
|---|---|
| `Temporally exclusive tasks (-temporal-exclusions-file)` | `task1 task2 task3` |

On the command-line, you can use the following:

```
polyspace-bug-finder
    -temporal-exclusions-file "C:\exclusions_file.txt"
```

where the file `C:\exclusions_file.txt` has the following line:

```
task1 task2 task3
```

CWE-366

# CWE Rule 369

Divide By Zero

## Description

### Rule Description

*The product divides a value by zero.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Float division by zero**
- **Integer division by zero**
- **Tainted division operand**
- **Tainted modulo operand**

## Examples

### Float division by zero

#### Issue

This issue occurs when the denominator of a division operation can be a zero-valued floating point number.

#### Risk

A division by zero can result in a program crash.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

It is a good practice to check for zero values of a denominator before division and handle the error. Instead of performing the division directly:

```
res = num/den;
```

use a library function that handles zero values of the denominator before performing the division:

```
res = div(num, den);
```

See examples of fixes below.

If you do not want to fix the issue, for instance, when you handle infinities in your code, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

By default, a Bug Finder analysis does not recognize infinities and `NaNs`. Operations that results in infinities and `NaNs` might be flagged as defects. To handle infinities and `NaN` values in your code, use the option `Consider non finite floats (-allow-non-finite-floats).`

**Extend Checker**

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

**Example — Dividing a Floating Point Number by Zero**

```
float fraction(float num)
{
    float denom = 0.0;
    float result = 0.0;

    result = num/denom;

    return result;
}
```

A division by zero error occurs at `num/denom` because `denom` is zero.

**Correction — Check Before Division**

```
float fraction(float num)
{
    float denom = 0.0;
    float result = 0.0;

    if( ((int)denom) != 0)
        result = num/denom;

    return result;
}
```

Before dividing, add a test to see if the denominator is zero, checking before division occurs. If `denom` is always zero, this correction can produce a dead code defect in your Polyspace results.

**Correction — Change Denominator**

One possible correction is to change the denominator value so that `denom` is not zero.

```
float fraction(float num)
{
    float denom = 2.0;
    float result = 0.0;
    result = num/denom;

    return result;
}
```

### Integer division by zero

#### Issue

This issue occurs when the denominator of a division or modulo operation can be a zero-valued integer.

#### Risk

A division by zero can result in a program crash.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

It is a good practice to check for zero values of a denominator before division and handle the error. Instead of performing the division directly:

```
res = num/den;
```

use a library function that handles zero values of the denominator before performing the division:

```
res = div(num, den);
```

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Dividing an Integer by Zero

```
int fraction(int num)
{
    int denom = 0;
    int result = 0;
    result = num/denom;

    return result;
}
```

A division by zero error occurs at `num/denom` because `denom` is zero.

#### Correction — Check Before Division

```
int fraction(int num)
{
    int denom = 0;
    int result = 0;

    if (denom != 0)
        result = num/denom;

    return result;
}
```

Before dividing, add a test to see if the denominator is zero, checking before division occurs. If `denom` is always zero, this correction can produce a dead code defect in your Polyspace results.

#### Correction — Change Denominator

One possible correction is to change the denominator value so that `denom` is not zero.

```
int fraction(int num)
{
    int denom = 2;
    int result = 0;

    result = num/denom;

    return result;
}
```

#### Example — Modulo Operation with Zero

```
int mod_arr(int input)
{
    int arr[5];
    for(int i = 0; i < 5; i++)
    {
        arr[i] = input % i;
    }

    return arr[0]+arr[1]+arr[2]+arr[3]+arr[4];
}
```

In this example, Polyspace flags the modulo operation as a division by zero. Because modulo is inherently a division operation, the divisor (right hand argument) cannot be zero. The modulo operation uses the `for` loop index as the divisor. However, the `for` loop starts at zero, which cannot be an iterator.

#### Correction — Check Divisor Before Operation

One possible correction is checking the divisor before the modulo operation. In this example, see if the index `i` is zero before the modulo operation.

```
int mod_arr(int input)
{
    int arr[5];
    for(int i = 0; i < 5; i++)
    {
        if(i != 0)
        {
             arr[i] = input % i;
        }
        else
        {
             arr[i] = input;
        }
    }

    return arr[0]+arr[1]+arr[2]+arr[3]+arr[4];
}
```

**Correction — Change Divisor**

Another possible correction is changing the divisor to a nonzero integer. In this example, add one to the index before the % operation to avoid dividing by zero.

```
int mod_arr(int input)
{
    int arr[5];
    for(int i = 0; i < 5; i++)
    {
         arr[i] = input % (i+1);
    }

    return arr[0]+arr[1]+arr[2]+arr[3]+arr[4];
}
```

### Tainted division operand

**Issue**

This issue occurs when one or both integer operands in a division operation comes from unsecure sources.

**Risk**

- If the numerator is the minimum possible value and the denominator is `-1`, your division operation overflows because the result cannot be represented by the current variable size.
- If the denominator is zero, your division operation fails possibly causing your program to crash.

These risks can be used to execute arbitrary code. This code is usually outside the scope of a program's implicit security policy.

**Fix**

Before performing the division, validate the values of the operands. Check for denominators of `0` or `-1`, and numerators of the minimum integer value.

**Extend Checker**

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of

Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Division of Function Arguments

```
#include <limits.h>
#include <stdio.h>

extern void print_int(int);

int taintedintdivision(void) {
    long num, denum;
    scanf("%lf %lf", &num, &denum);
    int r =  num/denum; //Noncompliant
    print_int(r);
    return r;
}
```

This example function divides two argument variables, then prints and returns the result. The argument values are unknown and can cause division by zero or integer overflow.

#### Correction — Check Values

One possible correction is to check the values of the numerator and denominator before performing the division.

```
#include <limits.h>
#include <stdio.h>

extern void print_long(long);

int taintedintdivision(void) {
    long num, denum;
    scanf("%lf %lf", &num, &denum);
    long res= 0;
    if (denum!=0 && !(num==INT_MIN && denum==-1)) {
        res = num/denum;
    }
    print_long(res);
    return res;
}
```

### Tainted modulo operand

#### Issue

This issue occurs when one or both integer operands in a remainder operation (`%`) comes from unsecure sources.

#### Risk

- If the second remainder operand is zero, your remainder operation fails, causing your program to crash.
- If the second remainder operand is `-1`, your remainder operation can overflow if the remainder operation is implemented based on the division operation that can overflow.
- If one of the operands is negative, the operation result is uncertain. For C89, the modulo operation is not standardized, so the result from negative operands is implementation-defined.

These risks can be exploited by attackers to gain access to your program or the target in general.

#### Fix

Before performing the modulo operation, validate the values of the operands. Check the second operand for values of `0` and `-1`. Check both operands for negative values.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Modulo with User Input

```
#include <stdio.h>
extern void print_int(int);

int taintedintmod(void) {
    int userden;
    scanf("%d", &userden);
    int rem =  128%userden; //Noncompliant
    print_int(rem);
    return rem;
}
```

In this example, the function performs a modulo operation by using a user input. The input is not checked before calculating the remainder for values that can crash the program, such as 0 and -1.

#### Correction — Check Operand Values

One possible correction is to check the values of the operands before performing the modulo operation. In this corrected example, the modulo operation continues only if the second operand is greater than zero.

```
#include<stdio.h>
extern void print_int(int);

int taintedintmod(void) {
    int userden;
    scanf("%d", &userden);
    int rem = 0;
    if (userden > 0 ) {
        rem = 128 % userden;
    }
    print_int(rem);
    return rem;
}
```

CWE-369

# CWE Rule 375

Returning a Mutable Object to an Untrusted Caller

## Description

### Rule Description

*Sending non-cloned mutable data as a return value may result in that data being altered or deleted by the calling function.*

### Polyspace Implementation

The rule checker checks for **Return of non-const handle to encapsulated data member**.

## Examples

### Return of non-const handle to encapsulated data member

#### Issue

This issue occurs when:

- A class method returns a handle to a data member. Handles include pointers and references.
- The method is more accessible than the data member. For instance, the method has access specifier `public`, but the data member is `private` or `protected`.

#### Risk

The access specifier determines the accessibility of a class member. For instance, a class member declared with the `private` access specifier cannot be accessed outside a class. Therefore, nonmember, nonfriend functions cannot modify the member.

When a class method returns a handle to a less accessible data member, the member accessibility changes. For instance, if a `public` method returns a pointer to a `private` data member, the data member is effectively not `private` anymore. A nonmember, nonfriend function calling the `public` method can use the returned pointer to view and modify the data member.

Also, if you assign the pointer to a data member of an object to another pointer, when you delete the object, the second pointer can be left dangling. The second pointer points to the part of an object that does not exist anymore.

#### Fix

One possible fix is to avoid returning a handle to a data member from a class method. Return a data member by value so that a copy of the member is returned. Modifying the copy does not change the data member.

If you must return a handle, use a `const` qualifier with the method return type so that the handle allows viewing, but not modifying, the data member.

#### Example — Return of Pointer to private Data Member

```
#include <string>
#define NUM_RECORDS 100
```

```
struct Date {
    int dd;
    int mm;
    int yyyy;
};

struct Period {
    Date startDate;
    Date endDate;
};

class DataBaseEntry {
private:
    std::string employeeName;
    Period employmentPeriod;
public:
    Period* getPeriod(void);
};

Period* DataBaseEntry::getPeriod(void) {
    return &employmentPeriod;
}

void use(Period*);
void reset(Period*);

int main() {
    DataBaseEntry dataBase[NUM_RECORDS];
    Period* tempPeriod;
    for(int i=0;i < NUM_RECORDS;i++) {
        tempPeriod = dataBase[i].getPeriod();
        use(tempPeriod);
        reset(tempPeriod);
    }
    return 0;
}

void reset(Period* aPeriod) {
       aPeriod->startDate.dd = 1;
       aPeriod->startDate.mm = 1;
       aPeriod->startDate.yyyy = 2000;
}
```

In this example, `employmentPeriod` is `private` to the class `DataBaseEntry`. It is therefore immune from modification by nonmember, nonfriend functions. However, returning a pointer to `employmentPeriod` breaks this encapsulation. For instance, the nonmember function `reset` modifies the member `startDate` of `employmentPeriod`.

#### Correction: Return Member by Value

One possible correction is to return the data member `employmentPeriod` by value instead of pointer. Modifying the return value does not change the data member because the return value is a copy of the data member.

```
#include <string>
#define NUM_RECORDS 100

struct Date {
    int dd;
    int mm;
    int yyyy;
};

struct Period {
    Date startDate;
    Date endDate;
};

class DataBaseEntry {
private:
    std::string employeeName;
    Period employmentPeriod;
public:
    Period getPeriod(void);
};

Period DataBaseEntry::getPeriod(void) {
    return employmentPeriod;
}

void use(Period*);
void reset(Period*);

int main() {
    DataBaseEntry dataBase[NUM_RECORDS];
    Period tempPeriodVal;
    Period* tempPeriod;
    for(int i=0;i < NUM_RECORDS;i++) {
        tempPeriodVal = dataBase[i].getPeriod();
        tempPeriod = &tempPeriodVal;
        use(tempPeriod);
        reset(tempPeriod);
    }
    return 0;
}

void reset(Period* aPeriod) {
       aPeriod->startDate.dd = 1;
       aPeriod->startDate.mm = 1;
       aPeriod->startDate.yyyy = 2000;
}
```

CWE-375

# CWE Rule 396

Declaration of Catch for Generic Exception

## Description

### Rule Description

*Catching overly broad exceptions promotes complex error handling code that is more likely to contain security vulnerabilities.*

### Polyspace Implementation

The rule checker checks for **Declaration of catch for generic exception**.

## Examples

### Declaration of catch for generic exception

#### Issue

This issue occurs when you design `catch` blocks to handle generic high level exceptions. Polyspace checks the exception specifications of a function and raises a violation if a catch block handles:

- All exceptions by using a catch-all block.
- Exception of the class `std::exception`. Because `std::exception` is the base class for all standard C++ exceptions, a catch block that handles `std::exception` type matches all derived exceptions.

#### Risk

Using generic catch blocks hides the emergence of unexpected new exceptions and hinders their proper handling. Such generic catch blocks makes the code vulnerable to security issues. For instance:

```
void foo(void){
    try{
        //..
    }catch(std::exception& e){
        //Log error
    }
}
```

Because the `catch` block handles the generic `std::exception` class, this code hides unexpected exceptions or those that need to be handled differently. For instance, If an unexpected `std::invalid_argument` exception is raised in `foo()`, it might remain undetected by the developer because it is matched with the catch block. Because the catch block is not programmed to handle `std::invalid_argument` properly, the poorly handled exception becomes a vulnerability for the code.

#### Fix

To fix this defect, avoid catching high-level generic exceptions. Write catch blocks that handle specific exceptions to enable handling different exceptions in different ways. Unexpected or new exceptions are also easily detected when catch blocks are specific.

#### Example — Avoid Generic Catch Blocks

```
#include<string>
#include<exception>
#include<stdexcept>

extern void logger(std::string s, std::exception& e);
void foo(void){
    try{
        //..
    }catch(std::exception& e){
         logger("foo failed", e);
    }
}
```

In this example, Polyspace flags the use of the generic `catch` block.

#### Correction — Use Specific Catch Blocks

To resolve this defect, use specific catch blocks. When you use specific catch blocks, new and unexpected exceptions become unhandled exceptions that are easily detected.

```
#include<string>
#include<exception>
extern void logger(std::string s, std::exception& e);
void foo(void){
    try{
        //..
    }catch(std::domain_error& e){
         logger("Domain Error in foo", e);
    }catch(std::invalid_argument& e){
        logger("Invalid Argument in foo", e);
    }
}
```

CWE-396

# CWE Rule 397

Declaration of Throws for Generic Exception

## Description

### Rule Description

*Throwing overly broad exceptions promotes complex error handling code that is more likely to contain security vulnerabilities.*

### Polyspace Implementation

The rule checker checks for **Declaration of throw for generic exception**.

## Examples

### Declaration of throw for generic exception

#### Issue

This issue occurs when a function throws a generic exception. Polyspace checks the throw statements, dynamic exception specifications, or the documentation of a function and raises this defect if any of these conditions is true:

- The function contains `throw` statements that raise generic exceptions.
- The dynamic exception specification contains generic exceptions.
- The function is documented with a `@throw` comment that contains generic exceptions.

Polyspace considers exceptions of the class `std::exception` as generic.These are base exception classes that have many derived exception classes.

#### Risk

Raising generic exceptions hinders proper error handling and error recovery. For instance:

```
void foo(void) throw(std::exception){
    //...
}

void caller(void){
    try{
        //...
        foo();
    }catch(std::exception& e){
        // Need to figure out what the error is.
    }
}
```

When handling the exceptions raised by `foo()`, determining what errors might happen in `foo()` is handled by `caller()`. Because the exception specification of `foo()` is broad, the emergence of new or unexpected exceptions might not be detected. Handling and recovering from errors in `foo()` becomes more complicated for `caller()`.

### Fix

To resolve this defect, use specific exceptions when documenting the exception in a function. Caller functions are then able to address specific exceptions by using specific error-handling code. Unexpected exceptions are easily detected.

#### Example — Avoid Generic Exception Specification

```
#include<exception>
#include<stdexcept>
#include<iostream>

void foo(void) throw(std::exception){
    //...
}
// @throw std::exception
void bar() {  //Noncompliant
    //...
    throw std::exception();
}

void foo1(){
    //...
    throw std::exception();
}
int main(void){
    try{
        //...
        foo();
    }catch(std::exception& e){
        // Need to figure out what the error is.

    }
    try{
        //...
        bar();
    }catch(std::exception& e){
        // Need to figure out what the error is.

    }
    try{
        //...
        foo1();
    }catch(std::exception& e){
        // Need to figure out what the error is.

    }
}
```

In this example, Polyspace flags the generic `throw` specifications. For instance:

- Polyspace flags the dynamic exception specification of `foo()` because it uses `std::exception`.
- Polyspace flags the function `bar()` because it is documented to raise the generic exception `std::exception`. Polyspace also flags the generic `throw` statement in this function.
- Polyspace flags the generic `throw` statement in `foo1()`.

Because these functions raise generic exceptions, identifying the exceptions is handled by the caller function `main()`. Because the caller does not know which specific exception are expected, it might fail to detect unexpected exceptions.

**Correction — Use Specific Exceptions**

To fix this issue, document specific exceptions that might arise from a function. This specific documentation enables the caller function to address specific exceptions. Unexpected exceptions become unhandled exceptions and are easily detected.

```
#include<exception>
#include<stdexcept>
#include<iostream>

void foo(void) throw(std::overflow_error){
    //...
}
// @throw std::invalid_argument
void bar() {
    //...
}

void foo1(){
    //...
    throw std::range_error("MSG");
}
int main(void){
    try{
        //...
        foo();
    }catch(std::overflow_error& e){
        // Expecting an overflow.

    }
    try{
        //...
        bar();
    }catch(std::invalid_argument& e){
        // Expecting an invalid argument.

    }
    try{
        //...
        foo1();
    }catch(std::range_error& e){
        // Expecting a range error.

    }
}
```

CWE-397

# CWE Rule 401

Missing Release of Memory after Effective Lifetime

## Description

### Rule Description

*The software does not sufficiently track and release allocated memory after it has been used, which slowly consumes remaining memory.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Memory leak**
- **Thread-specific memory leak**

## Examples

### Memory leak

#### Issue

This issue occurs when you do not free a block of memory allocated through `malloc`, `calloc`, `realloc`, or `new`. If the memory is allocated in a function, the defect does not occur if:

- Within the function, you free the memory using `free` or `delete`.
- The function returns the pointer assigned by `malloc`, `calloc`, `realloc`, or `new`.
- The function stores the pointer in a global variable or in a parameter.

#### Risk

Dynamic memory allocation functions such as `malloc` allocate memory on the heap. If you do not release the memory after use, you reduce the amount of memory available for another allocation. On embedded systems with limited memory, you might end up exhausting available heap memory even during program execution.

#### Fix

Determine the scope where the dynamically allocated memory is accessed. Free the memory block at the end of this scope.

To free a block of memory, use the `free` function on the pointer that was used during memory allocation. For instance:

```
ptr = (int*)malloc(sizeof(int));
...
free(ptr);
```

It is a good practice to allocate and free memory in the same module at the same level of abstraction. For instance, in this example, `func` allocates and frees memory at the same level but `func2` does not.

```
void func() {
  ptr = (int*)malloc(sizeof(int));
  {
    ...
  }
  free(ptr);
}

void func2() {
  {
   ptr = (int*)malloc(sizeof(int));
   ...
  }
  free(ptr);
}
```

See CERT-C Rule MEM00-C.

**Example — Dynamic Memory Not Released Before End of Function**

```
#include<stdlib.h>
#include<stdio.h>

void assign_memory(void)
{
    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL)
        {
         printf("Memory allocation failed");
         return;
        }

    *pi = 42;
    /* Defect: pi is not freed */
}
```

In this example, `pi` is dynamically allocated by `malloc`. The function `assign_memory` does not free the memory, nor does it return `pi`.

**Correction — Free Memory**

One possible correction is to free the memory referenced by `pi` using the `free` function. The `free` function must be called before the function `assign_memory` terminates

```
#include<stdlib.h>
#include<stdio.h>

void assign_memory(void)
{
    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL)
        {
         printf("Memory allocation failed");
         return;
        }
    *pi = 42;

    /* Fix: Free the pointer pi*/
    free(pi);
}
```

**Correction — Return Pointer from Dynamic Allocation**

Another possible correction is to return the pointer `pi`. Returning `pi` allows the function calling `assign_memory` to free the memory block using `pi`.

```
#include<stdlib.h>
#include<stdio.h>

int* assign_memory(void)
{
    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL)
        {
            printf("Memory allocation failed");
            return(pi);
        }
    *pi = 42;

    /* Fix: Return the pointer pi*/
    return(pi);
}
```

**Example — Memory Leak with New/Delete**

```
#define NULL '\0'

void initialize_arr1(void)
{
    int *p_scalar = new int(5);
}

void initialize_arr2(void)
{
    int *p_array = new int[5];
}
```

In this example, the functions create two variables, `p_scalar` and `p_array`, using the `new` keyword. However, the functions end without cleaning up the memory for these pointers. Because the functions used `new` to create these variables, you must clean up their memory by calling `delete` at the end of each function.

**Correction — Add Delete**

To correct this error, add a `delete` statement for every `new` initialization. If you used brackets `[]` to instantiate a variable, you must call delete with brackets as well.

```
#define NULL '\0'

void initialize_arrs(void)
{
    int *p_scalar = new int(5);
    int *p_array = new int[5];

    delete p_scalar;
    p_scalar = NULL;

    delete[] p_array;
    p_scalar = NULL;
}
```

### Thread-specific memory leak

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”.*

This issue occurs when you do not free thread-specific dynamically allocated memory before the end of a thread.

To create thread-specific storage, you generally do these steps:

1. You create a key for thread-specific storage.
2. You create the threads.
3. In each thread, you allocate storage dynamically and then associate the key with this storage.

   After the association, you can read the stored data later using the key.
4. Before the end of the thread, you free the thread-specific memory using the key.

The checker flags execution paths in the thread where the last step is missing.

The checker works on these families of functions:

- `tss_get` and `tss_set` (C11)
- `pthread_getspecific` and `pthread_setspecific` (POSIX)

#### Risk

The data stored in the memory is available to other processes even after the threads end (memory leak). Besides security vulnerabilities, memory leaks can shrink the amount of available memory and reduce performance.

#### Fix

Free dynamically allocated memory before the end of a thread.

You can explicitly free dynamically allocated memory with functions such as `free`.

Alternatively, when you create a key, you can associate a destructor function with the key. The destructor function is called with the key value as argument at the end of a thread. In the body of the destructor function, you can free any memory associated with the key. If you use this method, Bug Finder still flags a defect. Ignore this defect with appropriate comments. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Memory Not Freed at End of Thread**

```
#include <threads.h>
#include <stdlib.h>

/* Global key to the thread-specific storage */
tss_t key;
enum { MAX_THREADS = 3 };

int add_data(void) {
  int *data = (int *)malloc(2 * sizeof(int));
  if (data == NULL) {
    return -1;  /* Report error  */
  }
  data[0] = 0;
  data[1] = 1;

  if (thrd_success != tss_set(key, (void *)data)) {
    /* Handle error */
  }
  return 0;
}

void print_data(void) {
  /* Get this thread's global data from key */
  int *data = tss_get(key);

  if (data != NULL) {
    /* Print data */
  }
}

int func(void *dummy) {
  if (add_data() != 0) {
    return -1;  /* Report error */
  }
  print_data();
  return 0;
}

int main(void) {
  thrd_t thread_id[MAX_THREADS];

  /* Create the key before creating the threads */
  if (thrd_success != tss_create(&key, NULL)) {
    /* Handle error */
  }

  /* Create threads that would store specific storage */
  for (size_t i = 0; i < MAX_THREADS; i++) {
    if (thrd_success != thrd_create(&thread_id[i], func, NULL)) {
      /* Handle error */
    }
  }

  for (size_t i = 0; i < MAX_THREADS; i++) {
    if (thrd_success != thrd_join(thread_id[i], NULL)) {
      /* Handle error */
    }
  }

  tss_delete(key);
  return 0;
}
```

In this example, the start function of each thread `func` calls two functions:

- `add_data`: This function allocates storage dynamically and associates the storage with a key using the `tss_set` function.
- `print_data`: This function reads the stored data using the `tss_get` function.

At the points where `func` returns, the dynamically allocated storage has not been freed.

**Correction — Free Dynamically Allocated Memory Explicitly**

One possible correction is to free dynamically allocated memory explicitly before leaving the start function of a thread. See the highlighted change in the corrected version.

In this corrected version, a defect still appears on the `return` statement in the error handling section of `func`. The defect cannot occur in practice because the error handling section is entered only if dynamic memory allocation fails. Ignore this remaining defect with appropriate comments. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

```
#include <threads.h>
#include <stdlib.h>

/* Global key to the thread-specific storage */
tss_t key;
enum { MAX_THREADS = 3 };

int add_data(void) {
  int *data = (int *)malloc(2 * sizeof(int));
  if (data == NULL) {
    return -1;  /* Report error  */
  }
  data[0] = 0;
  data[1] = 1;

  if (thrd_success != tss_set(key, (void *)data)) {
    /* Handle error */
  }
  return 0;
}

void print_data(void) {
  /* Get this thread's global data from key */
  int *data = tss_get(key);
  if (data != NULL) {
    /* Print data */
  }
}

int func(void *dummy) {
  if (add_data() != 0) {
    return -1;  /* Report error */
  }
  print_data();
  free(tss_get(key));
  return 0;
}

int main(void) {
  thrd_t thread_id[MAX_THREADS];

  /* Create the key before creating the threads */
  if (thrd_success != tss_create(&key, NULL)) {
    /* Handle error */
  }

  /* Create threads that would store specific storage */
  for (size_t i = 0; i < MAX_THREADS; i++) {
    if (thrd_success != thrd_create(&thread_id[i], func, NULL)) {
      /* Handle error */
    }
  }

  for (size_t i = 0; i < MAX_THREADS; i++) {
    if (thrd_success != thrd_join(thread_id[i], NULL)) {
      /* Handle error */
    }
  }

  tss_delete(key);
  return 0;
}
```

Improper Resource Locking

## Description

### Rule Description

*The software does not lock or does not correctly lock a resource when the software must have exclusive access to the resource.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Data race**
- **Data race through standard library function call**
- **Shared data access within signal handler**

## Examples

### Data race

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See "Checkers Deactivated in Polyspace as You Code Analysis"*.

This issue occurs when:

1. Multiple tasks perform unprotected operations on a shared variable.
2. At least one task performs a write operation.
3. At least one operation is nonatomic. To detect data race on both atomic and nonatomic operations, use the options `-detect-atomic-data-race`. See "Extend Data Race Checkers to Atomic Operations".

   See "Define Atomic Operations in Multitasking Code".

If you activate this checker without specifying the multitasking options first, you see a warning in the log:To find this defect, specify the multitasking options before analysis.

To specify these options, on the **Configuration** pane, select **Multitasking**. For more information, see "Configuring Polyspace Multitasking Analysis Manually".

#### Risk

Data race can result in unpredictable values of the shared variable because you do not control the order of the operations in different tasks.

Data races between two write operations are more serious than data races between a write and read operation. Two write operations can interfere with each other and result in indeterminate values. To identify write-write conflicts, use the filters on the **Detail** column of the **Results List** pane. For these conflicts, the **Detail** column shows the additional line:

```
 Variable value may be altered by write-write concurrent access.
```

See also “Filter and Group Results in Polyspace Desktop User Interface” or “Filter and Sort Results in Polyspace Access Web Interface”.

#### Fix

To fix this defect, protect the operations on the shared variable using critical sections, temporal exclusion or another means. See “Protections for Shared Variables in Multitasking Code”.

To identify existing protections that you can reuse, see the table and graphs associated with the result. The table shows each pair of conflicting calls. The **Access Protections** column shows existing protections on the calls. To see the function call sequence leading to the conflicts, click the icon. For an example, see below.

#### Extend Checker

Extend this checker to check for data races in operations that Bug Finder might not detect by default. For instance:

- You might be using multithreading functions that are not supported by Polyspace. Extend this checker by mapping the functions of your multithreading functions to their known POSIX equivalent. See “Extend Concurrency Defect Checkers to Unsupported Multithreading Environments”.
- Polyspace assumes that certain operations are atomic and excludes them from data race checks. See “Define Atomic Operations in Multitasking Code”. These assumptions might not apply to your environment. To extend the data race checkers to include these operations, use the option `-detect-atomic-data-race`. See “Extend Data Race Checkers to Atomic Operations”.

#### Example — Unprotected Operation on Global Variable from Multiple Tasks

```
int var;
void begin_critical_section(void);
void end_critical_section(void);

void increment(void) {
    var++;
}

void task1(void)  {
      increment();
}

void task2(void)  {
      increment();
}

void task3(void)  {
     begin_critical_section();
     increment();
    end_critical_section();
}
```

In this example, to emulate multitasking behavior, specify the following options:

| Option | Specification | |
|---|---|---|
| `Configure multitasking manually` | ☑ | |
| `Tasks (-entry-points)` | `task1`<br>`task2`<br>`task3` | |
| `Critical section details (-critical-section-begin -critical-section-end)` | **Starting routine** | **Ending routine** |
| | `begin_critical_section` | `end_critical_section` |

On the command-line, you can use the following:

```
 polyspace-bug-finder
   -entry-points task1,task2,task3
   -critical-section-begin begin_critical_section:cs1
   -critical-section-end end_critical_section:cs1
```

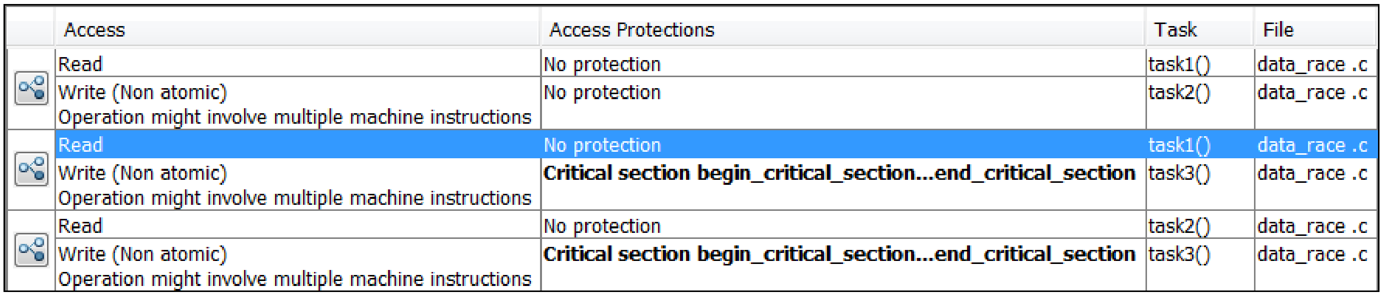
In this example, the tasks `task1`, `task2`, and `task3` call the function `increment`. `increment` contains the operation `var++` that can involve multiple machine instructions including:

- Reading `var`.
- Writing an increased value to `var`.

These machine instructions, when executed from `task1` and `task2`, can occur concurrently in an unpredictable sequence. For example, reading `var` from `task1` can occur either before or after writing to `var` from `task2`. Therefore the value of `var` can be unpredictable.

Though `task3` calls `increment` inside a critical section, other tasks do not use the same critical section. The operations in the critical section of `task3` are not mutually exclusive with operations in other tasks.

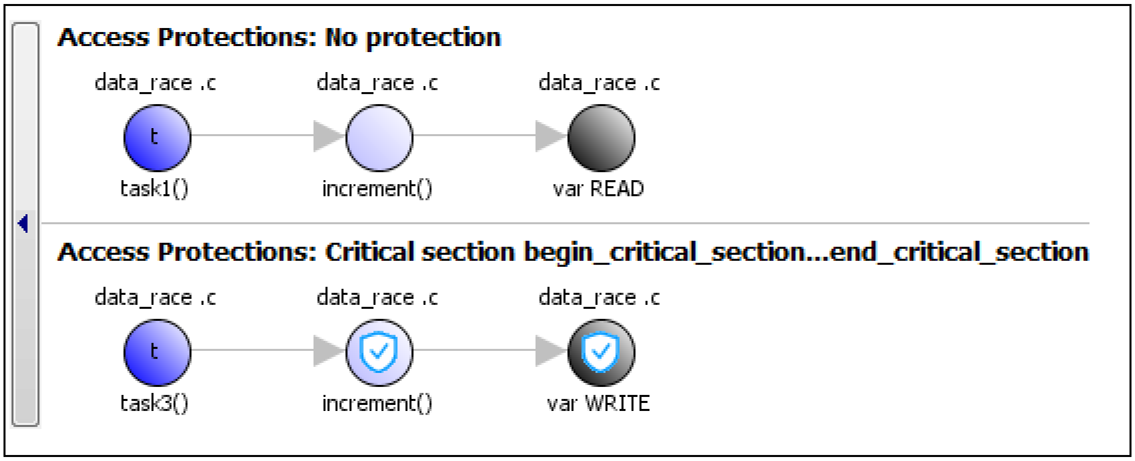
Therefore, the three tasks are operating on a shared variable without common protection. In your result details, you see each pair of conflicting function calls.



| | Access | Access Protections | Task | File |
|---|---|---|---|---|
| | Read | No protection | task1() | data_race .c |
| | Write (Non atomic)<br>Operation might involve multiple machine instructions | No protection | task2() | data_race .c |
| | Read | No protection | task1() | data_race .c |
| | Write (Non atomic)<br>Operation might involve multiple machine instructions | **Critical section begin_critical_section...end_critical_section** | task3() | data_race .c |
| | Read | No protection | task2() | data_race .c |
| | Write (Non atomic)<br>Operation might involve multiple machine instructions | **Critical section begin_critical_section...end_critical_section** | task3() | data_race .c |

If you click the icon, you see the function call sequence starting from the entry point to the read or write operation. You also see that the operation starting from `task3` is in a critical section. The

**Access Protections** entry shows the lock and unlock function that begin and end the critical section. In this example, you see the functions `begin_critical_section` and `end_critical_section`.



Access Protections: No protection

Access Protections: Critical section begin_critical_section...end_critical_section

**Correction — Place Operation in Critical Section**

One possible correction is to place the operation in critical section. You can implement the critical section in multiple ways. For instance:

- You can place `var++` in a critical section. When `task1` enters its critical section, the other tasks cannot enter their critical sections until `task1` leaves its critical section. The operation `var++` from the three tasks cannot interfere with each other.

  To implement the critical section, in the function `increment`, place the operation `var++` between calls to `begin_critical_section` and `end_critical_section`.

```
int var;

void begin_critical_section(void);
void end_critical_section(void);

void increment(void) {
      begin_critical_section();
      var++;
      end_critical_section();
}

void task1(void)  {
      increment();
}

void task2(void)  {
      increment();
}

void task3(void)  {
      increment();
}
```

- You can place the call to `increment` in the same critical section in the three tasks. When `task1` enters its critical section, the other tasks cannot enter their critical sections until `task1` leaves its critical section. The calls to `increment` from the three tasks cannot interfere with each other.

  To implement the critical section, in each of the three tasks, call `increment` between calls to `begin_critical_section` and `end_critical_section`.

```
int var;

void begin_critical_section(void);
void end_critical_section(void);

void increment(void) {
      var++;
}

void task1(void)  {
     begin_critical_section();
     increment();
     end_critical_section();
}

void task2(void)  {
     begin_critical_section();
     increment();
     end_critical_section();
}

void task3(void)  {
     begin_critical_section();
     increment();
     end_critical_section();
}
```

**Correction — Make Tasks Temporally Exclusive**

Another possible correction is to make the tasks, `task1`, `task2` and `task3`, temporally exclusive. Temporally exclusive tasks cannot execute concurrently.

On the **Configuration** pane, specify the following additional options:

| Option | Value |
|---|---|
| Temporally exclusive tasks (-temporal-exclusions-file) | task1 task2 task3 |

On the command-line, you can use the following:

```
 polyspace-bug-finder
     -temporal-exclusions-file "C:\exclusions_file.txt"
```

where the file `C:\exclusions_file.txt` has the following line:

```
task1 task2 task3
```

#### Example — Unprotected Operation in Threads Created with pthread_create

```
#include <pthread.h>

pthread_mutex_t count_mutex;
long long count;

void* increment_count(void* args)
{
    count = count + 1;
    return NULL;
}

void* set_count(void *args)
{
    long long c;
    c = count;
    return NULL;
}

int main(void)
{
    pthread_t thread_increment;
    pthread_t thread_get;

    pthread_create(&thread_increment, NULL, increment_count, NULL);
    pthread_create(&thread_get, NULL, set_count, NULL);

    pthread_join(thread_get, NULL);
    pthread_join(thread_increment, NULL);

    return 1;
}
```

In this example, Bug Finder detects the creation of separate threads with `pthread_create`. The **Data race** defect is raised because the operation `count = count + 1` in the thread with id `thread_increment` conflicts with the operation `c = count` in the thread with id `thread_get`. The variable `count` is accessed in multiple threads without a common protection.

The two conflicting operations are nonatomic. The operation `c = count` is nonatomic on 32-bit targets. See “Define Atomic Operations in Multitasking Code”.

#### Correction — Protect Operations with `pthread_mutex_lock` and `pthread_mutex_unlock` Pair

To prevent concurrent access on the variable `count`, protect operations on `count` with a critical section. Use the functions `pthread_mutex_lock` and `pthread_mutex_unlock` to implement the critical section.

```
#include <pthread.h>

pthread_mutex_t count_mutex;
long long count;

void* increment_count(void* args)
{
    pthread_mutex_lock(&count_mutex);
    count = count + 1;
    pthread_mutex_unlock(&count_mutex);
    return NULL;
}

void* set_count(void *args)
{
    long long c;
    pthread_mutex_lock(&count_mutex);
    c = count;
    pthread_mutex_unlock(&count_mutex);
    return NULL;
}

int main(void)
{
    pthread_t thread_increment;
    pthread_t thread_get;

    pthread_create(&thread_increment, NULL, increment_count, NULL);
    pthread_create(&thread_get, NULL, set_count, NULL);

    pthread_join(thread_get, NULL);
    pthread_join(thread_increment, NULL);

    return 1;
}
```

### Data race through standard library function call

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”.*

This issue occurs when:

1. Multiple tasks call the same standard library function.

   For instance, multiple tasks call the `strerror` function.
2. The calls are not protected using a common protection.

   For instance, the calls are not protected by the same critical section.

Functions flagged by this defect are not guaranteed to be reentrant. A function is reentrant if it can be interrupted and safely called again before its previous invocation completes execution. If a function is not reentrant, multiple tasks calling the function without protection can cause concurrency issues. For the list of functions that are flagged, see CON33-C: Avoid race conditions when using library functions.

To find this defect, you must specify the multitasking options before analysis. To specify these options, on the **Configuration** pane, select **Multitasking**. For more information, see “Configuring Polyspace Multitasking Analysis Manually”.

#### Risk

The functions flagged by this defect are nonreentrant because their implementations can use global or static variables. When multiple tasks call the function without protection, the function call from one task can interfere with the call from another task. The two invocations of the function can concurrently access the global or static variables and cause unpredictable results.

The calls can also cause more serious security vulnerabilities, such as abnormal termination, denial-of-service attack, and data integrity violations.

**Fix**

To fix this defect, do one of the following:

- Use a reentrant version of the standard library function if it exists.

  For instance, instead of `strerror()`, use `strerror_r()` or `strerror_s()`. For alternatives to functions flagged by this defect, see the documentation for CON33-C.
- Protect the function calls using common critical sections or temporal exclusion.

  See `Critical section details (-critical-section-begin -critical-section-end)` and `Temporally exclusive tasks (-temporal-exclusions-file)`.

  To identify existing protections that you can reuse, see the table and graphs associated with the result. The table shows each pair of conflicting calls. The **Access Protections** column shows existing protections on the calls. To see the function call sequence leading to the conflicts, click the icon. For an example, see below.

**Example — Unprotected Call to Standard Library Function from Multiple Tasks**

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char *errmsg = strerror(errno);
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    func(fptr1);
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     func(fptr2);
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

In this example, to emulate multitasking behavior, specify the following options:

| Option | Specification | |
|---|---|---|
| `Configure multitasking manually` | ☑ | |
| `Tasks (-entry-points)` | `task1`<br>`task2`<br>`task3` | |
| `Critical section details (-critical-section-begin -critical-section-end)` | **Starting routine** | **Ending routine** |
| | `begin_critical_section` | `end_critical_section` |

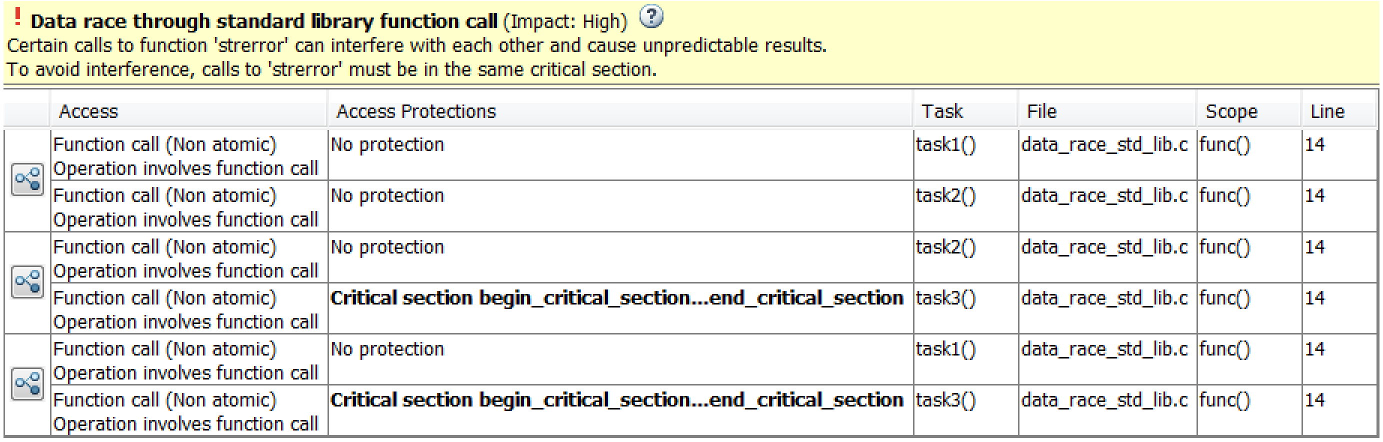
On the command-line, you can use the following:

```
 polyspace-bug-finder
   -entry-points task1,task2,task3
   -critical-section-begin begin_critical_section:cs1
   -critical-section-end end_critical_section:cs1
```

In this example, the tasks, `task1`, `task2` and `task3`, call the function `func`. `func` calls the nonreentrant standard library function, `strerror`.

Though `task3` calls `func` inside a critical section, other tasks do not use the same critical section. Operations in the critical section of `task3` are not mutually exclusive with operations in other tasks.

These three tasks are calling a nonreentrant standard library function without common protection. In your result details, you see each pair of conflicting function calls.

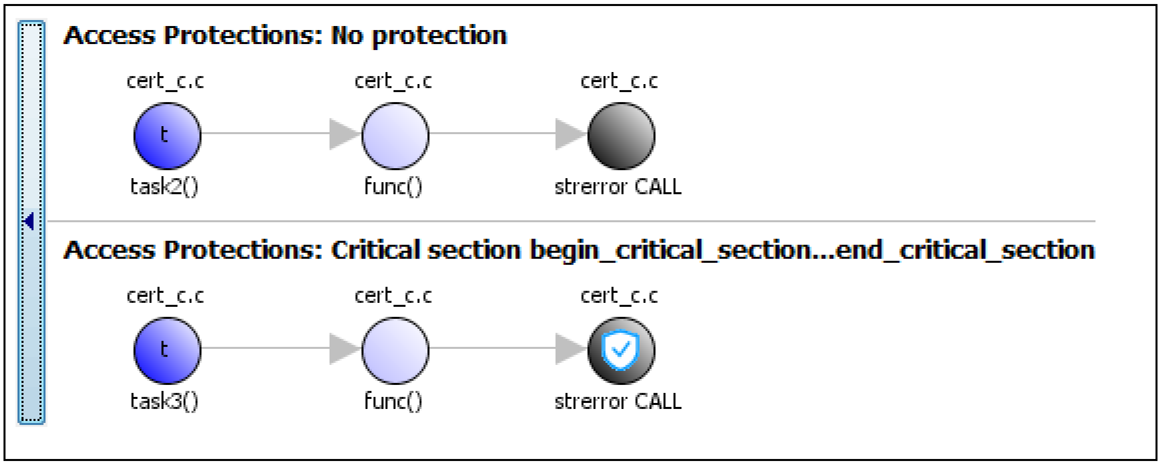


! **Data race through standard library function call** (Impact: High)
Certain calls to function 'strerror' can interfere with each other and cause unpredictable results.
To avoid interference, calls to 'strerror' must be in the same critical section.

| | Access | Access Protections | Task | File | Scope | Line |
|---|---|---|---|---|---|---|
| | Function call (Non atomic)<br>Operation involves function call | No protection | task1() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task2() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task2() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | **Critical section begin_critical_section...end_critical_section** | task3() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task1() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | **Critical section begin_critical_section...end_critical_section** | task3() | data_race_std_lib.c | func() | 14 |

If you click the icon, you see the function call sequence starting from the entry point to the standard library function call. You also see that the call starting from `task3` is in a critical section.

The **Access Protections** entry shows the lock and unlock function that begin and end the critical section. In this example, you see the functions `begin_critical_section` and `end_critical_section`.



Access Protections: No protection
cert_c.c
cert_c.c
cert_c.c
t
task2()
func()
strerror CALL
Access Protections: Critical section begin_critical_section...end_critical_section
cert_c.c
cert_c.c
cert_c.c
t
task3()
func()
strerror CALL

**Correction — Use Reentrant Version of Standard Library Function**

One possible correction is to use a reentrant version of the standard library function `strerror`. You can use the POSIX version `strerror_r` which has the same functionality but also guarantees thread-safety.

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);
enum { BUFFERSIZE = 64 };

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char errmsg[BUFFERSIZE];
    if (strerror_r(errno, errmsg, BUFFERSIZE) != 0) {
      /* Handle error */
    }
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    func(fptr1);
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     func(fptr2);
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

#### Correction — Place Function Call in Critical Section

One possible correction is to place the call to `strerror` in critical section. You can implement the critical section in multiple ways.

For instance, you can place the call to the intermediate function `func` in the same critical section in the three tasks. When `task1` enters its critical section, the other tasks cannot enter their critical sections until `task1` leaves its critical section. The calls to `func` and therefore the calls to `strerror` from the three tasks cannot interfere with each other.

To implement the critical section, in each of the three tasks, call `func` between calls to `begin_critical_section` and `end_critical_section`.

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char *errmsg = strerror(errno);
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    begin_critical_section();
    func(fptr1);
    end_critical_section();
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     begin_critical_section();
     func(fptr2);
     end_critical_section();
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

#### Correction — Make Tasks Temporally Exclusive

Another possible correction is to make the tasks, `task1`, `task2` and `task3`, temporally exclusive. Temporally exclusive tasks cannot execute concurrently.

On the **Configuration** pane, specify the following additional options:

| Option | Value |
|---|---|
| Temporally exclusive tasks (-temporal-exclusions-file) | task1 task2 task3 |

On the command-line, you can use the following:

```
 polyspace-bug-finder
     -temporal-exclusions-file "C:\exclusions_file.txt"
```

where the file `C:\exclusions_file.txt` has the following line:

```
task1 task2 task3
```

### Shared data access within signal handler

#### Issue

This issue occurs when you access or modify a shared object inside a signal handler.

#### Risk

When you define a signal handler function to access or modify a shared object, the handler accesses or modifies the shared object when it receives a signal. If another function is already accessing the shared object, that function causes a race condition and can leave the data in an inconsistent state.

#### Fix

To access or modify shared objects inside a signal handler, check that the objects are lock-free atomic, or, if they are integers, declare them as `volatile sig_atomic_t`.

#### Example — int Variable Access in Signal Handler

```
#include <signal.h>
#include <stdlib.h>
#include <string.h>

/* declare global variable. */
int e_flag;

void sig_handler(int signum)
{
    /* Signal handler accesses variable that is not
    of type volatile sig_atomic_t. */
    e_flag = signum;
}
```

```
int func(void)
{
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
        abort();
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
        abort();
    }
    /* More code */
    return 0;
}
```

In this example, `sig_handler` accesses `e_flag`, a variable of type `int`. A concurrent access by another function can leave `e_flag` in an inconsistent state.

**Correction — Declare Variable of Type `volatile sig_atomic_t`**

Before you access a shared variable from a signal handler, declare the variable with type `volatile sig_atomic_t` instead of `int`. You can safely access variables of this type asynchronously.

```
#include <signal.h>
#include <stdlib.h>
#include <string.h>

/* Declare variable of type volatile sig_atomic_t. */
volatile sig_atomic_t e_flag;
void sig_handler(int signum)
{
    /* Use variable of proper type inside signal handler. */
    e_flag = signum;

}

int func(void)
{
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
        abort();
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
        abort();
    }
    /* More code */
    return 0;
}
```

CWE-413

# CWE Rule 415

Double Free

## Description

### Rule Description

*The product calls free() twice on the same memory address, potentially leading to modification of unexpected memory locations.*

### Polyspace Implementation

The rule checker checks for **Deallocation of previously deallocated pointer**.

## Examples

### Deallocation of previously deallocated pointer

#### Issue

This issue occurs when a block of memory is freed more than once using the `free` function without an intermediate allocation.

#### Risk

When a pointer is allocated dynamic memory with `malloc`, `calloc` or `realloc`, it points to a memory location on the heap. When you use the `free` function on this pointer, the associated block of memory is freed for reallocation. Trying to free this block of memory can result in a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. See if you intended to allocate a memory block to the pointer between the first deallocation and the second. Otherwise, remove the second `free` statement.

As a good practice, after you free a memory block, assign the corresponding pointer to NULL. Before freeing pointers, check them for NULL values and handle the error. In this way, you are protected against freeing an already freed block.

#### Example — Deallocation of Previously Deallocated Pointer Error

```
#include <stdlib.h>

void allocate_and_free(void)
{

    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return;

    *pi = 2;
    free(pi);
    free (pi);
    /* Defect: pi has already been freed */
}
```

The first `free` statement releases the block of memory that `pi` refers to. The second `free` statement on `pi` releases a block of memory that has been freed already.

**Correction — Remove Duplicate Deallocation**

One possible correction is to remove the second `free` statement.

```
#include <stdlib.h>

void allocate_and_free(void)
{

    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return;

    *pi = 2;
    free(pi);
    /* Fix: remove second deallocation */
 }
```

**Example — Freeing Pointer Previously Reallocated With Possibly Zero Size**

```
#include <stdlib.h>

void reshape(char *buf, size_t size) {
  char *reshaped_buf = (char *)realloc(buf, size);
  if (reshaped_buf == NULL) {
    free(buf);
  }
}
```

In this example, the argument `size` of the `reshape()` function can be zero and result in a zero-size reallocation with `realloc()`. In some implementations such as the GNU library, zero-size reallocations free the memory leading to a double free defect.

**Correction – Guard Against Zero-Size Reallocations**

One possible correction is to check size argument of `realloc()` for zero values before use. If the size argument is zero, you can simply free the memory instead of reallocating it.

```
#include <stdlib.h>

void reshape(char *buf, size_t size) {
  if (size != 0) {
    char *reshaped_buf = (char *)realloc(buf, size);
    if (reshaped_buf == NULL) {
      free(buf);
    }
  }
  else {
    free(buf);
  }

}
```

CWE-415

# CWE Rule 416

Use After Free

## Description

### Rule Description

*Referencing memory after it has been freed can cause a program to crash, use unexpected values, or execute code.*

### Polyspace Implementation

The rule checker checks for **Use of previously freed pointer**.

## Examples

### Use of previously freed pointer

#### Issue

This issue occurs when you access a block of memory after freeing the block using the `free` function.

#### Risk

When a pointer is allocated dynamic memory with `malloc`, `calloc` or `realloc`, it points to a memory location on the heap. When you use the `free` function on this pointer, the associated block of memory is freed for reallocation. Trying to access this block of memory can result in unpredictable behavior or even a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. See if you intended to free the memory later or allocate another memory block to the pointer before access.

As a good practice, after you free a memory block, assign the corresponding pointer to NULL. Before dereferencing pointers, check them for NULL values and handle the error. In this way, you are protected against accessing a freed block.

#### Example — Use of Previously Freed Pointer Error

```
#include <stdlib.h>
#include <stdio.h>
 int increment_content_of_address(int base_val, int shift)
   {
    int j;
    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return 0;

    *pi = base_val;
    free(pi);

    j = *pi + shift;
    /* Defect: Reading a freed pointer */
    return j;
   }
```

The `free` statement releases the block of memory that `pi` refers to. Therefore, dereferencing`pi` after the `free` statement is not valid.

#### Correction — Free Pointer After Use

One possible correction is to free the pointer `pi` only after the last instance where it is accessed.

```
#include <stdlib.h>

int increment_content_of_address(int base_val, int shift)
{
    int j;
    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return 0;

    *pi = base_val;

    j = *pi + shift;
    *pi = 0;

    /* Fix: The pointer is freed after its last use */
    free(pi);
    return j;
}
```

# CWE Rule 457

Use of Uninitialized Variable

## Description

### Rule Description

*The code uses a variable that has not been initialized, leading to unpredictable or unintended results.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Member not initialized in constructor**
- **Non-initialized pointer**
- **Non-initialized variable**

## Examples

### Member not initialized in constructor

#### Issue

This issue occurs when a class constructor has at least one execution path on which it does not initialize some data members of the class.

The defect does not appear in the following cases:

- Empty constructors.
- The non-initialized member is not used in the code.

#### Risk

The members that the constructor does not initialize can have unintended values when you read them later.

Initializing all members in the constructor makes it easier to use your class. If you call a separate method to initialize your members and then read them, you can avoid uninitialized values. However, someone else using your class can read a class member *before* calling your initialization method. Because a constructor is called when you create an object of the class, if you initialize all members in the constructor, they cannot have uninitialized values later on.

#### Fix

The best practice is to initialize all members in your constructor, preferably in an initialization list.

#### Example — Non-Initialized Member

```
class MyClass {
public:
    explicit MyClass(int);
private:
    int _i;
    char _c;
};

MyClass::MyClass(int flag) {
    if(flag == 0) {
        _i = 0;
        _c = 'a';
    }
    else {
        _i = 1;
    }
}
```

In this example, if `flag` is not 0, the member `_c` is not initialized.

The defect appears on the closing brace of the constructor. Following are some tips for navigating in the source code:

- On the **Result Details** pane, see which members are not initialized.
- To navigate to the class definition, right-click a member that is initialized in the constructor. Select **Go To Definition**. In the class definition, you can see all the members, including those members that are not initialized in the constructor.

#### Correction — Initialize All Members on All Execution Paths

One possible correction is to initialize all members of the class `MyClass` for all values of `flag`.

```
class MyClass {
public:
    explicit MyClass(int);
private:
    int _i;
    char _c;
};

MyClass::MyClass(int flag) {
    if(flag == 0) {
        _i = 0;
        _c = 'a';
    }
    else {
        _i = 1;
        _c = 'b';
    }
}
```

### Non-initialized pointer

#### Issue

This issue occurs when a pointer is not assigned an address before dereference.

#### Risk

Unless a pointer is explicitly assigned an address, it points to an unpredictable location.

#### Fix

The fix depends on the root cause of the defect. For instance, you assigned an address to the pointer but the assignment is unreachable.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

See examples of fixes below. It is a good practice to initialize a pointer to NULL when declaring the pointer.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

If a pointer in your code is non-initialized only for certain system input values, you can see one possible combination of input values causing the defect. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Non-initialized pointer error

```
#include <stdlib.h>

int* assign_pointer(int* prev)
{
    int j = 42;
    int* pi;

    if (prev == NULL)
      {
        pi = (int*)malloc(sizeof(int));
        if (pi == NULL) return NULL;
      }

    *pi = j;
    /* Defect: Writing to uninitialized pointer */

    return pi;
}
```

If `prev` is not `NULL`, the pointer `pi` is not assigned an address. However, `pi` is dereferenced on every execution paths, irrespective of whether `prev` is `NULL` or not.

#### Correction — Initialize Pointer on Every Execution Path

One possible correction is to assign an address to `pi` when `prev` is not `NULL`.

```
#include <stdlib.h>

int* assign_pointer(int* prev)
{
    int j = 42;
    int* pi;

    if (prev == NULL)
       {
        pi = (int*)malloc(sizeof(int));
        if (pi == NULL) return NULL;
       }
    /* Fix: Initialize pi in branches of if statement  */
    else
        pi = prev;

    *pi = j;

    return pi;
}
```

### Non-initialized variable

#### Issue

This issue occurs when a variable is not initialized before its value is read.

#### Risk

Unless a variable is explicitly initialized, the variable value is unpredictable. You cannot rely on the variable having a specific value.

#### Fix

The fix depends on the root cause of the defect. For instance, you assigned a value to the variable but the assignment is unreachable or you assigned a value to the variable in one of two branches of a conditional statement. Fix the unreachable code or missing assignment.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below. It is a good practice to initialize a variable at declaration.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

You can extend the checker in the following ways:

- Polyspace does not flag passing pointers to noninitialized variables to functions. To detect noninitialized variables that are passed to functions by pointers, extend the checker by using the option `-code-behavior-specification`. See “Extend Checkers for Initialization to Check Function Arguments Passed by Pointers”.
- If a variable in your code is non-initialized only for certain system input values, you can see one possible combination of input values causing the defect. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Non-initialized variable error

```
int get_sensor_value(void)
{
    extern int getsensor(void);
    int command;
    int val;

    command = getsensor();
    if (command == 2)
      {
        val = getsensor();
      }

    return val;
    /* Defect: val does not have a value if command is not 2 */
}
```

If `command` is not 2, the variable `val` is unassigned. In this case, the return value of function `get_sensor_value` is undetermined.

#### Correction — Initialize During Declaration

One possible correction is to initialize `val` during declaration so that the initialization is not bypassed on some execution paths.

```
int get_sensor_value(void)
{
    extern int getsensor(void);
    int command;
    /* Fix: Initialize val */
    int val=0;

    command = getsensor();
    if (command == 2)
      {
        val = getsensor();
      }

    return val;
 }
```

`val` is assigned an initial value of 0. When `command` is not equal to 2, the function `get_sensor_value` returns this value.

Improper Cleanup on Thrown Exception

## Description

### Rule Description

*The product does not clean up its state or incorrectly cleans up its state when an exception is thrown, leading to unexpected state or control flow.*

### Polyspace Implementation

The rule checker checks for **Exception violating class invariant**.

## Examples

### Exception violating class invariant

#### Issue

This issue occurs when a non-`noexcept` member function attempts to raise an exception after modifying any of the fields of the class. For instance, Polyspace flags a `throw()` statement or a `new` statement if they are used after modifying the internal state of a class.

#### Risk

To facilitate recovery from an exception while preserving the invariant of the relevant objects, design programs that have exception safety. The C++ standard allows these levels of exception safety:

- Basic Exception Safety: This level of exception safety requires that after raising an exception, the basic invariants of all objects are maintained in a valid state and no memory is leaked. If an operation has basic exception safety, then you can destroy or assign to an object after the operations, even if an exception has been raised. The operations in the standard library offer at least basic exception safety.
- Strong Exception Safety: This level of exception safety requires that after raising an exception, the state of the program remains as it was before the exception. Operations with strong exception safety either succeed or exit with an exception and have no effects on the program.
- `nothrow`: This level of safety requires that an exception cannot occur in an operation.

Without at least the basic exception safety, exceptions might corrupt the state of a program, leave the program in an invalid state, or create memory leaks. Code that does not provide at least the basic exception safety guarantee is unsafe and defective.

#### Fix

To provide at least the basic exception safety in a function, modify the class invariant only when there can be no exceptions. When performing actions that might raise exceptions, use temporary objects that do not modify the original objects invariant.

#### Example

```
#include <cstdint>
#include <cstring>
```

```
template<typename T=int>
class myArray
{
public:
    myArray(){/*...*/}
    myArray(const myArray& rhs)
    {
        DeepCopyNC(rhs);
    }
    ~myArray()
    {
        delete[] array;
    }
    void DeepCopyNC(const myArray& rhs) // Noncompliant
    {
        if (this != &rhs) {
            delete[] array;
            array = nullptr;
            len = rhs.len;

            if (len > 0) {

                array = new T[len];
                std::memcpy(array, rhs.array, len * sizeof(T));
            }
        }
    }

private:
    T* array;
    std::size_t len;
};
extern     myArray<> c1{};
void foo(){

    myArray<> c2{c1};

}
```

This example shows a generic class template `myArray` that manages a raw array. The copy constructor of this class shows two implementation of deep copy. In the function `DeepCopyNC()`, the memory operations are performed after modifying the `this->array` and `this->len` fields. If the memory operation exits with an exception, the invariant of the original class is violated. Because the class invariant is violated by an exception, the function `DeepCopyNC()` cannot guarantee basic exception safety. Polyspace flags it.

**Correction**

To guarantee basic exception safety, modify the class invariant only when the memory operation succeeds with no exceptions, as shown in `DeepCopy`.

```
#include <cstdint>
#include <cstring>
template<typename T=int>
class myArray
{
public:
    myArray(){/*...*/}
    myArray(const myArray& rhs)
    {
        DeepCopy(rhs);
    }
    ~myArray()
    {
        delete[] array;
    }
    void DeepCopy(const myArray& rhs) // Compliant
    {
        T* eTmp = nullptr;

        if (rhs.len > 0) {
            eTmp = new T[rhs.len];
            std::memcpy(eTmp, rhs.array, rhs.len * sizeof(T));
        }

        delete[] array;
        array = eTmp;
        len = rhs.len;
    }

private:
    T* array;
    std::size_t len;
};
extern     myArray<> c1{};
void foo(){

    myArray<> c2{c1};

}
```

Deletion of Data Structure Sentinel

## Description

### Rule Description

*The accidental deletion of a data-structure sentinel can cause serious programming logic problems.*

### Polyspace Implementation

The rule checker checks for **Missing null in string array**.

## Examples

### Missing null in string array

**Issue**

This issue occurs when a string does not have enough space to terminate with a null character `'\0'`.

This defect applies only for projects in C.

**Risk**

A buffer overflow can occur if you copy a string to an array without assuming the implicit null terminator.

**Fix**

If you initialize a character array with a literal, avoid specifying the array bounds.

```
char three[]  = "THREE";
```

The compiler automatically allocates space for a null terminator. In the preceding example, the compiler allocates sufficient space for five characters and a null terminator.

If the issue occurs after initialization, you might have to increase the size of the array by one to account for the null terminator.

In certain circumstances, you might want to initialize the character array with a sequence of characters instead of a string. In this situation, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Array size is too small**

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[5] = "THREE";
}
```

The character array `three` has a size of 5 and 5 characters `'T'`, `'H'`, `'R'`, `'E'`, and `'E'`. There is no room for the null character at the end because `three` is only five bytes large.

#### Correction — Increase Array Size

One possible correction is to change the array size to allow for the five characters plus a null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[6] = "THREE";
}
```

#### Correction — Change Initialization Method

One possible correction is to initialize the string by leaving the array size blank. This initialization method allocates enough memory for the five characters and a terminating-null character.

```
void countdown(int i)
{
    static char one[5]   = "ONE";
    static char two[5]   = "TWO";
    static char three[]  = "THREE";
}
```

Return of Pointer Value Outside of Expected Range

## Description

### Rule Description

*A function can return a pointer to memory that is outside of the buffer that the pointer is expected to reference.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access out of bounds**
- **Pointer access out of bounds**

## Examples

### Array access out of bounds

#### Issue

This issue occurs when an array index falls outside the range `[0...array_size-1]` during array access.

#### Risk

Accessing an array outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you accessed an array inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used an array index that is the same as the loop index instead of being one less than the loop index.

To fix the issue, you have to modify the loop bound or the array index.

Another reason why an array index can exceed array bounds is a prior conversion from signed to unsigned integers. The conversion can result in a wrap around of the index value, eventually causing the array index to exceed the array bounds.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

### Example — Array Access Out of Bounds Error

```
#include <stdio.h>

void fibonacci(void)
{
    int i;
    int fib[10];

    for (i = 0; i < 10; i++)
       {
        if (i < 2)
            fib[i] = 1;
         else
            fib[i] = fib[i-1] + fib[i-2];
       }

    printf("The 10-th Fibonacci number is %i .\n", fib[i]);
    /* Defect: Value of i is greater than allowed value of 9 */
}
```

The array `fib` is assigned a size of 10. An array index for `fib` has allowed values of `[0,1,2,...,9]`. The variable `i` has a value 10 when it comes out of the `for`-loop. Therefore, the `printf` statement attempts to access `fib[10]` through `i`.

### Correction — Keep Array Index Within Array Bounds

One possible correction is to print `fib[i-1]` instead of `fib[i]` after the `for`-loop.

```
#include <stdio.h>

void fibonacci(void)
{
   int i;
   int fib[10];

   for (i = 0; i < 10; i++)
    {
        if (i < 2)
            fib[i] = 1;
        else
            fib[i] = fib[i-1] + fib[i-2];
    }

    /* Fix: Print fib[9] instead of fib[10] */
    printf("The 10-th Fibonacci number is %i .\n", fib[i-1]);
}
```

The `printf` statement accesses `fib[9]` instead of `fib[10]`.

### Pointer access out of bounds

#### Issue

This issue occurs when a pointer is dereferenced outside its bounds.

When a pointer is assigned an address, a block of memory is associated with the pointer. You cannot access memory beyond that block using the pointer.

#### Risk

Dereferencing a pointer outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you dereferenced a pointer inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used pointer arithmetic to advance the pointer with an incorrect value for the pointer increment.

To fix the issue, you have to modify the loop bound or the pointer increment value.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Pointer access out of bounds error

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
   {
    ptr++;
    *ptr=i;
    /* Defect: ptr out of bounds for i=9 */
   }

 return(arr);
}
```

`ptr` is assigned the address `arr` that points to a memory block of size `10*sizeof(int)`. In the `for`-loop, `ptr` is incremented 10 times. In the last iteration of the loop, `ptr` points outside the memory block assigned to it. Therefore, it cannot be dereferenced.

#### Correction — Check Pointer Stays Within Bounds

One possible correction is to reverse the order of increment and dereference of `ptr`.

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
     {
      /* Fix: Dereference pointer before increment */
      *ptr=i;
      ptr++;
     }

 return(arr);
}
```

After the last increment, even though `ptr` points outside the memory block assigned to it, it is not dereferenced more.

Use of sizeof() on a Pointer Type

## Description

### Rule Description

*The code calls sizeof() on a malloced pointer type, which always returns the wordsize/8. This can produce an unexpected result if the programmer intended to determine how much memory has been allocated.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Possible misuse of sizeof**
- **Wrong type used in sizeof**

## Examples

### Possible misuse of sizeof

#### Issue

This issue occurs when Polyspace Bug Finder detects possibly unintended results from the use of `sizeof` operator. For instance:

- You use the `sizeof` operator on an array parameter name, expecting the array size. However, the array parameter name by itself is a pointer. The `sizeof` operator returns the size of that pointer.
- You use the `sizeof` operator on an array element, expecting the array size. However, the operator returns the size of the array element.
- The size argument of certain functions such as `strncmp` or `wcsncpy` is incorrect because you used the `sizeof` operator earlier with possibly incorrect expectations. For instance:
  - In a function call `strncmp(string1, string2, num)`, `num` is obtained from an incorrect use of the `sizeof` operator on a pointer.
  - In a function call `wcsncpy(destination, source, num)`, `num` is the not the number of wide characters but a size in bytes obtained by using the `sizeof` operator. For instance, you use `wcsncpy(destination, source, sizeof(destination) - 1)` instead of `wcsncpy(destination, source, (sizeof(desintation)/sizeof(wchar_t)) - 1)`.

#### Risk

Incorrect use of the `sizeof` operator can cause the following issues:

- If you expect the `sizeof` operator to return array size and use the return value to constrain a loop, the number of loop runs are smaller than what you expect.
- If you use the return value of `sizeof` operator to allocate a buffer, the buffer size is smaller than what you require. Insufficient buffer can lead to resultant weaknesses such as buffer overflows.

- If you use the return value of `sizeof` operator incorrectly in a function call, the function does not behave as you expect.

#### Fix

Possible fixes are:

- Do not use the `sizeof` operator on an array parameter name or array element to determine array size.

  The best practice is to pass the array size as a separate function parameter and use that parameter in the function body.
- Use the `sizeof` operator carefully to determine the number argument of functions such as `strncmp` or `wcsncpy`. For instance, for wide string functions such as `wcsncpy`, use the number of wide characters as argument instead of the number of bytes.

#### Example — sizeof Used Incorrectly to Determine Array Size

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < sizeof(a)/sizeof(int); i++)    {
        a[i] = i + 1;
    }
}
```

In this example, `sizeof(a)` returns the size of the pointer `a` and not the array size.

#### Correction — Determine Array Size in Another Way

One possible correction is to use another means to determine the array size.

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < MAX_SIZE; i++)    {
        a[i] = i + 1;
    }
}
```

### Wrong type used in sizeof

#### Issue

This issue occurs when both of the following conditions hold:

1. You assign the address of a block of memory to a pointer, or transfer data between two blocks of memory. The assignment or copy uses the `sizeof` operator.

   For instance, you initialize a pointer using `malloc(sizeof(`*`type`*`))` or copy data between two addresses using `memcpy(`*`destination_ptr`*`, `*`source_ptr`*`, sizeof(`*`type`*`))`.
2. You use an incorrect type as argument of the `sizeof` operator. For instance:

- You might be using the pointer type instead of the type that the pointer points to. For example, to initialize a *type** pointer, you might be using `malloc(sizeof(`*type*`*))` instead of `malloc(sizeof(`*type*`))`.
- You might be using a completely unrelated type as `sizeof` argument. For example, to initialize a *type** pointer, you might be using `malloc(sizeof(`*anotherType*`))`.

**Risk**

Irrespective of what *type* stands for, the expression `sizeof(`*type*`*)` always returns a fixed size. The size returned is the pointer size on your platform in bytes. The appearance of `sizeof(`*type*`*)` often indicates an unintended usage. The error can cause allocation of a memory block that is much smaller than what you need and lead to weaknesses such as buffer overflows.

For instance, assume that `structType` is a structure with ten `int` variables. If you initialize a `structType*` pointer using `malloc(sizeof(structType*))` on a 32-bit platform, the pointer is assigned a memory block of four bytes. However, to be allocated completely for one `structType` variable, the `structType*` pointer must point to a memory block of `sizeof(structType) = 10 * sizeof(int)` bytes. The required size is much greater than the actual allocated size of four bytes.

**Fix**

To initialize a *type** pointer, replace `sizeof(`*type*`*)` in your pointer initialization expression with `sizeof(`*type*`)`.

**Example — Allocate a Char Array With sizeof**

```
#include <stdlib.h>

void test_case_1(void) {
    char* str;

    str = (char*)malloc(sizeof(char*) * 5);
    free(str);

}
```

In this example, memory is allocated for the character pointer `str` using a `malloc` of five char pointers. However, `str` is a pointer to a character, not a pointer to a character pointer. Therefore the `sizeof` argument, `char*`, is incorrect.

**Correction — Match Pointer Type to `sizeof` Argument**

One possible correction is to match the argument to the pointer type. In this example, `str` is a character pointer, therefore the argument must also be a character.

```
#include <stdlib.h>

void test_case_1(void) {
    char* str;

    str = (char*)malloc(sizeof(char) * 5);
    free(str);

}
```

Incorrect Pointer Scaling

## Description

### Rule Description

*In C and C++, one may often accidentally refer to the wrong memory due to the semantics of when math operations are implicitly scaled.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Array access out of bounds**
- **Incorrect pointer scaling**
- **Pointer access out of bounds**
- **Subtraction or comparison between pointers to different arrays**

## Examples

### Array access out of bounds

#### Issue

This issue occurs when an array index falls outside the range `[0...array_size-1]` during array access.

#### Risk

Accessing an array outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you accessed an array inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used an array index that is the same as the loop index instead of being one less than the loop index.

To fix the issue, you have to modify the loop bound or the array index.

Another reason why an array index can exceed array bounds is a prior conversion from signed to unsigned integers. The conversion can result in a wrap around of the index value, eventually causing the array index to exceed the array bounds.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Array Access Out of Bounds Error

```
#include <stdio.h>

void fibonacci(void)
{
    int i;
    int fib[10];

    for (i = 0; i < 10; i++)
       {
        if (i < 2)
            fib[i] = 1;
         else
            fib[i] = fib[i-1] + fib[i-2];
       }

    printf("The 10-th Fibonacci number is %i .\n", fib[i]);
    /* Defect: Value of i is greater than allowed value of 9 */
}
```

The array `fib` is assigned a size of 10. An array index for `fib` has allowed values of `[0,1,2,...,9]`. The variable `i` has a value 10 when it comes out of the `for`-loop. Therefore, the `printf` statement attempts to access `fib[10]` through `i`.

#### Correction — Keep Array Index Within Array Bounds

One possible correction is to print `fib[i-1]` instead of `fib[i]` after the `for`-loop.

```
#include <stdio.h>

void fibonacci(void)
{
   int i;
   int fib[10];
  for (i = 0; i < 10; i++)
   {
       if (i < 2)
           fib[i] = 1;
       else
           fib[i] = fib[i-1] + fib[i-2];
   }

   /* Fix: Print fib[9] instead of fib[10] */
   printf("The 10-th Fibonacci number is %i .\n", fib[i-1]);
}
```

The `printf` statement accesses `fib[9]` instead of `fib[10]`.

### Incorrect pointer scaling

#### Issue

This issue occurs when Polyspace Bug Finder considers that you are ignoring the implicit scaling in pointer arithmetic.

For instance, the defect can occur in the following situations.

| Situation | Risk | Possible Fix |
|---|---|---|
| You use the `sizeof` operator in arithmetic operations on a pointer. | The `sizeof` operator returns the size of a data type in number of bytes.<br>Pointer arithmetic is already implicitly scaled by the size of the data type of the pointed variable. Therefore, the use of `sizeof` in pointer arithmetic produces unintended results. | Do not use `sizeof` operator in pointer arithmetic. |
| You perform arithmetic operations on a pointer, and then apply a cast. | Pointer arithmetic is implicitly scaled. If you do not consider this implicit scaling, casting the result of a pointer arithmetic produces unintended results. | Apply the cast before the pointer arithmetic. |

#### Fix

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

### Example — Use of sizeof Operator

```
void func(void) {
    int arr[5] = {1,2,3,4,5};
    int *ptr = arr;

    int value_in_position_2 = *(ptr + 2*(sizeof(int)));
}
```

In this example, the operation `2*(sizeof(int))` returns twice the size of an `int` variable in bytes. However, because pointer arithmetic is implicitly scaled, the number of bytes by which `ptr` is offset is `2*(sizeof(int))*(sizeof(int))`.

In this example, the incorrect scaling shifts `ptr` outside the bounds of the array. Therefore, a **Pointer access out of bounds** error appears on the * operation.

### Correction — Remove `sizeof` Operator

One possible correction is to remove the `sizeof` operator.

```
void func(void) {
    int arr[5] = {1,2,3,4,5};
    int *ptr = arr;

    int value_in_position_2 = *(ptr + 2);
}
```

### Example — Cast Following Pointer Arithmetic

```
int func(void) {
    int x = 0;
    char r = *(char *)(&x + 1);
    return r;
}
```

In this example, the operation `&x + 1` offsets `&x` by `sizeof(int)`. Following the operation, the resulting pointer points outside the allowed buffer. When you dereference the pointer, a **Pointer access out of bounds** error appears on the * operation.

### Correction — Apply Cast Before Pointer Arithmetic

If you want to access the second byte of `x`, first cast `&x` to a `char*` pointer and then perform the pointer arithmetic. The resulting pointer is offset by `sizeof(char)` bytes and still points within the allowed buffer, whose size is `sizeof(int)` bytes.

```
int func(void) {
    int x = 0;
    char r = *((char *)(&x )+ 1);
    return r;
}
```

## Pointer access out of bounds

### Issue

This issue occurs when a pointer is dereferenced outside its bounds.

When a pointer is assigned an address, a block of memory is associated with the pointer. You cannot access memory beyond that block using the pointer.

#### Risk

Dereferencing a pointer outside its bounds is undefined behavior. You can read an unpredictable value or try to access a location that is not allowed and encounter a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. For instance, you dereferenced a pointer inside a loop and one of these situations happened:

- The upper bound of the loop is too large.
- You used pointer arithmetic to advance the pointer with an incorrect value for the pointer increment.

To fix the issue, you have to modify the loop bound or the pointer increment value.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Pointer access out of bounds error

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
   {
    ptr++;
    *ptr=i;
    /* Defect: ptr out of bounds for i=9 */
   }

 return(arr);
}
```

`ptr` is assigned the address `arr` that points to a memory block of size `10*sizeof(int)`. In the `for`-loop, `ptr` is incremented 10 times. In the last iteration of the loop, `ptr` points outside the memory block assigned to it. Therefore, it cannot be dereferenced.

#### Correction — Check Pointer Stays Within Bounds

One possible correction is to reverse the order of increment and dereference of `ptr`.

```
int* Initialize(void)
{
 int arr[10];
 int *ptr=arr;

 for (int i=0; i<=9;i++)
     {
      /* Fix: Dereference pointer before increment */
      *ptr=i;
      ptr++;
     }

 return(arr);
}
```

After the last increment, even though `ptr` points outside the memory block assigned to it, it is not dereferenced more.

### Subtraction or comparison between pointers to different arrays

#### Issue

This issue occurs when you subtract or compare pointers that are null or that point to elements in different arrays. The relational operators for the comparison are >, <, >=, and <=.

#### Risk

When you subtract two pointers to elements in the same array, the result is the difference between the subscripts of the two array elements. Similarly, when you compare two pointers to array elements, the result is the positions of the pointers relative to each other. If the pointers are null or point to different arrays, a subtraction or comparison operation is undefined. If you use the subtraction result as a buffer index, it can cause a buffer overflow.

#### Fix

Before you subtract or use relational operators to compare pointers to array elements, check that they are non-null and that they point to the same array.

#### Example — Subtraction Between Pointers to Elements in Different Arrays

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define SIZE20 20

size_t func(void)
{
    int nums[SIZE20];
    int end;
    int *next_num_ptr = nums;
    size_t free_elements;
    /* Increment next_num_ptr as array fills */

    /* Subtraction operation is undefined unless array nums
    is adjacent to variable end in memory. */
    free_elements = &end - next_num_ptr;
    return free_elements;
}
```

In this example, the array nums is incrementally filled. Pointer subtraction is then used to determine how many free elements remain. Unless end points to a memory location one past the last element of nums, the subtraction operation is undefined.

#### Correction — Subtract Pointers to the Same Array

Subtract the pointer to the last element that was filled from the pointer to the last element in the array.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define SIZE20 20

size_t func(void)
{
    int nums[SIZE20];
    int *next_num_ptr = nums;
    size_t free_elements;
    /* Increment next_num_ptr as array fills */

    /* Subtraction operation involves pointers to the same array. */
    free_elements = &(nums[SIZE20 - 1]) - next_num_ptr;

    return free_elements + 1;
}
```

CWE-468

# CWE Rule 469

Use of Pointer Subtraction to Determine Size

## Description

### Rule Description

*The application subtracts one pointer from another in order to determine size, but this calculation can be incorrect if the pointers do not exist in the same memory chunk.*

### Polyspace Implementation

The rule checker checks for **Subtraction or comparison between pointers to different arrays**.

## Examples

### Subtraction or comparison between pointers to different arrays

**Issue**

This issue occurs when you subtract or compare pointers that are null or that point to elements in different arrays. The relational operators for the comparison are >, <, >=, and <=.

**Risk**

When you subtract two pointers to elements in the same array, the result is the difference between the subscripts of the two array elements. Similarly, when you compare two pointers to array elements, the result is the positions of the pointers relative to each other. If the pointers are null or point to different arrays, a subtraction or comparison operation is undefined. If you use the subtraction result as a buffer index, it can cause a buffer overflow.

**Fix**

Before you subtract or use relational operators to compare pointers to array elements, check that they are non-null and that they point to the same array.

**Example — Subtraction Between Pointers to Elements in Different Arrays**

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define SIZE20 20

size_t func(void)
{
    int nums[SIZE20];
    int end;
    int *next_num_ptr = nums;
    size_t free_elements;
    /* Increment next_num_ptr as array fills */

    /* Subtraction operation is undefined unless array nums
    is adjacent to variable end in memory. */
    free_elements = &end - next_num_ptr;
    return free_elements;
}
```

In this example, the array `nums` is incrementally filled. Pointer subtraction is then used to determine how many free elements remain. Unless `end` points to a memory location one past the last element of `nums`, the subtraction operation is undefined.

#### Correction — Subtract Pointers to the Same Array

Subtract the pointer to the last element that was filled from the pointer to the last element in the array.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define SIZE20 20

size_t func(void)
{
    int nums[SIZE20];
    int *next_num_ptr = nums;
    size_t free_elements;
    /* Increment next_num_ptr as array fills */

    /* Subtraction operation involves pointers to the same array. */
    free_elements = &(nums[SIZE20 - 1]) - next_num_ptr;

    return free_elements + 1;
}
```

CWE-469

# CWE Rule 474

Use of Function with Inconsistent Implementations

## Description

### Rule Description

*The code uses a function that has inconsistent implementations across operating systems and versions.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Signal call from within signal handler**
- **Use of obsolete standard function**

## Examples

### Signal call from within signal handler

**Issue**

This issue occurs when you call the function `signal()` from a signal handler on Windows platforms.

The defect is detected only if you specify a Visual Studio compiler. See `Compiler (-compiler)`.

**Risk**

The function `signal()` associates a signal with a signal handler function. On platforms such as Windows, which removes this association after receiving the signal, you might call the function `signal()` again *within the signal handler* to re-establish the association.

However, this attempt to make a signal handler persistent is prone to race conditions. On Windows platforms, from the time the signal handler begins execution to when the `signal` function is called again, it is the default signal handling, `SIG_DFL`, that is active. If a second signal is received within this time window, you see the default signal handling and not the custom signal handler, but you might expect otherwise.

**Fix**

Do not call `signal()` from a signal handler on Windows platforms.

**Example — signal() Called from Signal Handler**

```
#include <stdio.h>
#include <stdlib.h>
#include <signal.h>
#include <unistd.h>

volatile sig_atomic_t e_flag = 0;
```

```
void sig_handler(int signum)
{
    int s0 = signum;
    e_flag = 1;

    /* Call signal() to reestablish sig_handler
    upon receiving SIG_ERR. */

    if (signal(s0, sig_handler) == SIG_ERR)
    {
        /* Handle error */
    }
}

void func(void)
{
        if (signal(SIGINT, sig_handler) == SIG_ERR)
        {
            /* Handle error */

        }
  /* more code */
}
```

In this example, the definition of `sig_handler()` includes a call to `signal()` when the handler catches `SIG_ERR`. On Windows platforms, signal handlers are nonpersistent. This code can result in a race condition.

The issue is detected only if you specify a compiler such as `visual15.x` for the analysis.

#### Correction — Do Not Call `signal()` from Signal Handler

Avoid attempting to make a signal handler persistent on Windows. If your code requires the use of a persistent signal handler on a Windows platform, use a persistent signal handler after performing a thorough risk analysis.

```
#include <stdio.h>
#include <stdlib.h>
#include <signal.h>
#include <unistd.h>

volatile sig_atomic_t e_flag = 0;

void sig_handler(int signum)
{
    int s0 = signum;
    e_flag = 1;
    /* No call to signal() */
}

int main(void)
{
        if (signal(SIGINT, sig_handler) == SIG_ERR)
        {
            /* Handle error */

        }
}
```

### Use of obsolete standard function

#### Issue

This issue occurs when you use standard function routines that are considered legacy, removed, deprecated, or obsolete by C/C++ coding standards.

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| `asctime` | Deprecated in POSIX.1-2008 | Not thread-safe. | `strftime` or `asctime_s` |
| `asctime_r` | Deprecated in POSIX.1-2008 | Implementation based on unsafe function `sprintf`. | `strftime` or `asctime_s` |
| `bcmp` | Deprecated in 4.3BSD<br>Marked as legacy in POSIX.1-2001. | Returns from function after finding the first differing byte, making it vulnerable to timing attacks. | `memcmp` |
| `bcopy` | Deprecated in 4.3BSD<br>Marked as legacy in POSIX.1-2001. | Returns from function after finding the first differing byte, making it vulnerable to timing attacks. | `memcpy` or `memmove` |
| `brk` and `sbrk` | Marked as legacy in SUSv2 and POSIX.1-2001. | | `malloc` |
| `bsd_signal` | Removed in POSIX.1-2008 | | `sigaction` |
| `bzero` | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | `memset` |
| `ctime` | Deprecated in POSIX.1-2008 | Not thread-safe. | `strftime` or `asctime_s` |
| `ctime_r` | Deprecated in POSIX.1-2008 | Implementation based on unsafe function `sprintf`. | `strftime` or `asctime_s` |
| `cuserid` | Removed in POSIX.1-2001. | Not reentrant. Precise functionality not standardized causing portability issues. | `getpwuid` |
| `ecvt` and `fcvt` | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008 | Not reentrant | `snprintf` |
| `ecvt_r` and `fcvt_r` | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008 | | `snprintf` |

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| ftime | Removed in POSIX.1-2008 | | time, gettimeofday, clock_gettime |
| gamma, gammaf, gammal | Function not specified in any standard because of historical variations | Portability issues. | tgamma, lgamma |
| gcvt | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | snprintf |
| getcontext | Removed in POSIX.1-2008. | Portability issues. | Use POSIX thread instead. |
| getdtablesize | BSD API function not included in POSIX.1-2001 | Portability issues. | sysconf( _SC_OPEN _MAX ) |
| gethostbyaddr | Removed in POSIX.1-2008 | Not reentrant | getaddrinfo |
| gethostbyname | Removed in POSIX.1-2008 | Not reentrant | getnameinfo |
| getpagesize | BSD API function not included in POSIX.1-2001 | Portability issues. | sysconf( _SC_PAGE SIZE ) |
| getpass | Removed in POSIX.1-2001. | Not reentrant. | getpwuid |
| getw | Not present in POSIX.1-2001. | | fread |
| getwd | Marked legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | getcwd |
| index | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | strchr |
| makecontext | Removed in POSIX.1-2008. | Portability issues. | Use POSIX thread instead. |
| memalign | Appears in SunOS 4.1.3. Not in 4.4 BSD or POSIX.1-2001 | | posix_memalign |
| mktemp | Removed in POSIX.1-2008. | Generated names are predictable and can cause a race condition. | mkstemp removes race risk |
| pthread_attr_ getstackaddr and pthread_attr_ setstackaddr | | Ambiguities in the specification of the stackaddr attribute cause portability issues | pthread_attr_ getstack and pthread_attr_ setstack |
| putw | Not present in POSIX.1-2001. | Portability issues. | fwrite |
| qecvt and qfcvt | Marked as legacy in POSIX.1-2001, removed in POSIX.1-2008 | | snprintf |
| qecvt_r and qfcvt_r | Marked as legacy in POSIX.1-2001, removed in POSIX.1-2008 | | snprintf |
| rand_r | Marked as obsolete in POSIX.1-2008 | | |
| re_comp | BSD API function | Portability issues | regcomp |

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| re_exes | BSD API function | Portability issues | regexec |
| rindex | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | | strrchr |
| scalb | Removed in POSIX.1-2008 | | scalbln, scalblnf, or scalblnl |
| sigblock | 4.3BSD signal API whose origin is unclear | | sigprocmask |
| sigmask | 4.3BSD signal API whose origin is unclear | | sigprocmask |
| sigsetmask | 4.3BSD signal API whose origin is unclear | | sigprocmask |
| sigstack | Interface is obsolete and not implemented on most platforms. | Portability issues. | sigaltstack |
| sigvec | 4.3BSD signal API whose origin is unclear | | sigaction |
| swapcontext | Removed in POSIX.1-2008 | Portability issues. | Use POSIX threads. |
| tmpnam and tmpnam_r | Marked as obsolete in POSIX.1-2008. | This function generates a different string each time it is called, up to TMP_MAX times. If it is called more than TMP_MAX times, the behavior is implementation-defined. | mkstemp, tmpfile |
| ttyslot | Removed in POSIX.1-2001. | | |
| ualarm | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | Errors are under-specified | setitimer or POSIX timer_create |
| usleep | Removed in POSIX.1-2008. | | nanosleep |
| utime | SVr4, POSIX.1-2001. POSIX.1-2008 marks as obsolete. | | |
| valloc | Marked as obsolete in 4.3BSD.<br>Marked as legacy in SUSv2.<br>Removed from POSIX.1-2001 | | posix_memalign |
| vfork | Removed from POSIX.1-2008 | Under-specified in previous standards. | fork |
| wcswcs | This function was not included in the final ISO/IEC 9899:1990/ Amendment 1:1995 (E). | | wcsstr |
| WinExec | WinAPI provides this function only for 16-bit Windows compatibility. | | CreateProcess |

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| `LoadModule` | WinAPI provides this function only for 16-bit Windows compatibility. | | `CreateProcess` |

#### Fix

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Printing Out Time

```
#include <stdio.h>
#include <time.h>

void timecheck_bad(int argc, char *argv[])
{
    time_t ticks;

    ticks = time(NULL);
    printf("%.24s\r\n", ctime(&ticks));
}
```

In this example, the function `ctime` formats the current time and prints it out. However, `ctime` was removed after C99 because it does not work on multithreaded programs.

#### Correction — Different Time Function

One possible correction is to use `strftime` instead because this function uses a set buffer size.

```
#include <stdio.h>
#include <string.h>
#include <time.h>

void timecheck_good(int argc, char *argv[])
{
    char outBuff[1025];
    time_t ticks;
    struct tm * timeinfo;

    memset(outBuff, 0, sizeof(outBuff));

    ticks = time(NULL);
    timeinfo = localtime(&ticks);
    strftime(outBuff,sizeof(outBuff),"%I:%M%p.",timeinfo);
    fprintf(stdout, outBuff);
}
```

NULL Pointer Dereference

## Description

### Rule Description

*A NULL pointer dereference occurs when the application dereferences a pointer that it expects to be valid, but is NULL, typically causing a crash or exit.*

### Polyspace Implementation

The rule checker checks for **Dereference of a null pointer**.

## Examples

### Dereference of a null pointer

#### Issue

This issue occurs when you use a pointer with a value of `NULL` as if it points to a valid memory location. If you dereference the zero address, such as 0x00, Polyspace considers the null address as equivalent to `NULL` and raises this defect.

#### Risk

Dereferencing a null pointer is undefined behavior. In most implementations, the dereference can cause your program to crash.

#### Fix

Check a pointer for `NULL` before dereference.

If the issue occurs despite an earlier check for `NULL`, look for intermediate events between the check and the subsequent dereference. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Null pointer error

```
#include <stdlib.h>
```

```
int FindMax(int *arr, int Size)
{
 int* p=NULL;

 *p=arr[0];
 /* Defect: Null pointer dereference */

 for(int i=0;i<Size;i++)
  {
   if(arr[i] > (*p))
     *p=arr[i];
  }

 return *p;
}
```

The pointer p is initialized with value of NULL. However, when the value arr[0] is written to *p, p is assumed to point to a valid memory location.

#### Correction — Assign Address to Null Pointer Before Dereference

One possible correction is to initialize p with a valid memory address before dereference.

```
#include <stdlib.h>

int FindMax(int *arr, int Size)
{
 /* Fix: Assign address to null pointer */
 int* p=&arr[0];

 for(int i=0;i<Size;i++)
  {
   if(arr[i] > (*p))
     *p=arr[i];
  }

 return *p;
}
```

| tmpnam and tmpnam_r | Marked as obsolete in POSIX.1-2008. | This function generates a different string each time it is called, up to TMP_MAX times. If it is called more than TMP_MAX times, the behavior is implementation-defined. | mkstemp, tmpfile |
| ttyslot | Removed in POSIX.1-2001. | | |
| ualarm | Marked as legacy in POSIX.1-2001. Removed in POSIX.1-2008. | Errors are under-specified | setitimer or POSIX timer_create |
| usleep | Removed in POSIX.1-2008. | | nanosleep |
| utime | SVr4, POSIX.1-2001. POSIX.1-2008 marks as obsolete. | | |

| Obsolete Function | Standards | Risk | Replacement Function |
|---|---|---|---|
| `valloc` | Marked as obsolete in 4.3BSD.<br>Marked as legacy in SUSv2.<br>Removed from POSIX.1-2001 | | `posix_memalign` |
| `vfork` | Removed from POSIX.1-2008 | Under-specified in previous standards. | `fork` |
| `wcswcs` | This function was not included in the final ISO/IEC 9899:1990/ Amendment 1:1995 (E). | | `wcsstr` |
| `WinExec` | WinAPI provides this function only for 16-bit Windows compatibility. | | `CreateProcess` |
| `LoadModule` | WinAPI provides this function only for 16-bit Windows compatibility. | | `CreateProcess` |

**Fix**

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Printing Out Time**

```
#include <stdio.h>
#include <time.h>

void timecheck_bad(int argc, char *argv[])
{
    time_t ticks;

    ticks = time(NULL);
    printf("%.24s\r\n", ctime(&ticks));
}
```

In this example, the function `ctime` formats the current time and prints it out. However, `ctime` was removed after C99 because it does not work on multithreaded programs.

**Correction — Different Time Function**

One possible correction is to use `strftime` instead because this function uses a set buffer size.

```
#include <stdio.h>
#include <string.h>
#include <time.h>
```

```
void timecheck_good(int argc, char *argv[])
{
    char outBuff[1025];
    time_t ticks;
    struct tm * timeinfo;

    memset(outBuff, 0, sizeof(outBuff));

    ticks = time(NULL);
    timeinfo = localtime(&ticks);
    strftime(outBuff,sizeof(outBuff),"%I:%M%p.",timeinfo);
    fprintf(stdout, outBuff);
}
```

Missing Default Case in Multiple Condition Expression

## Description

### Rule Description

*The code does not have a default case in an expression with multiple conditions, such as a switch statement.*

### Polyspace Implementation

The rule checker checks for **Missing case for switch condition**.

## Examples

### Missing case for switch condition

#### Issue

This issue occurs when the `switch` variable can take values that are not covered by a `case` statement.

**Note** Bug Finder only raises a defect if the switch variable is not full range.

#### Risk

If the `switch` variable takes a value that is not covered by a `case` statement, your program can have unintended behavior.

A switch-statement that makes a security decision is particularly vulnerable when all possible values are not explicitly handled. An attacker can use this situation to deviate the normal execution flow.

#### Fix

It is good practice to use a `default` statement as a catch-all for values that are not covered by a `case` statement. Even if the `switch` variable takes an unintended value, the resulting behavior can be anticipated.

#### Example — Missing Default Condition

```
#include <stdio.h>
#include <string.h>

typedef enum E
{
    ADMIN=1,
    GUEST,
    UNKNOWN = 0
} LOGIN;
```

```
static LOGIN system_access(const char *username) {
  LOGIN user = UNKNOWN;

  if ( strcmp(username, "root") == 0 )
    user = ADMIN;

  if ( strcmp(username, "friend") == 0 )
    user = GUEST;

  return user;
}

int identify_bad_user(const char * username)
{
    int r=0;

    switch( system_access(username) )
    {
    case ADMIN:
        r = 1;
        break;
    case GUEST:
        r = 2;
    }

    printf("Welcome!\n");
    return r;
}
```

In this example, the `enum` parameter `User` can take a value `UNKNOWN` that is not covered by a `case` statement.

**Correction — Add a Default Condition**

One possible correction is to add a default condition for possible values that are not covered by a `case` statement.

```
#include <stdio.h>
#include <string.h>

typedef enum E
{
    ADMIN=1,
    GUEST,
    UNKNOWN = 0
} LOGIN;

static LOGIN system_access(const char *username) {
  LOGIN user = UNKNOWN;

  if ( strcmp(username, "root") == 0 )
    user = ADMIN;

  if ( strcmp(username, "friend") == 0 )
    user = GUEST;

  return user;
}
```

```
int identify_bad_user(const char * username)
{
    int r=0;

    switch( system_access(username) )
    {
    case ADMIN:
        r = 1;
        break;
    case GUEST:
        r = 2;
    break;
    default:
        printf("Invalid login credentials!\n");
    }

    printf("Welcome!\n");
    return r;
}
```

Signal Handler Use of a Non-reentrant Function

## Description

### Rule Description

*The program defines a signal handler that calls a non-reentrant function.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Function called from signal handler not asynchronous-safe**
- **Function called from signal handler not asynchronous-safe (strict ISO C)**

## Examples

### Function called from signal handler not asynchronous-safe

**Issue**

This issue occurs when a signal handler calls a function that is not asynchronous-safe according to the POSIX standard. An asynchronous-safe function can be interrupted at any point in its execution, then called again without causing an inconsistent state. It can also correctly handle global data that might be in an inconsistent state.

If a signal handler calls another function that calls an asynchronous-unsafe function, the defect appears on the function call in the signal handler. The defect traceback shows the full path from the signal handler to the asynchronous-unsafe function.

**Risk**

When a signal handler is invoked, the execution of the program is interrupted. After the handler is finished, program execution resumes at the point of interruption. If a function is executing at the time of the interruption, calling it from within the signal handler is undefined behavior, unless it is asynchronous-safe.

**Fix**

The POSIX standard defines these functions as asynchronous-safe. You can call these functions from a signal handler.

| | | |
|---|---|---|
| `_exit()` | `getpgrp()` | `setsockopt()` |
| `_Exit()` | `getpid()` | `setuid()` |
| `abort()` | `getppid()` | `shutdown()` |
| `accept()` | `getsockname()` | `sigaction()` |
| `access()` | `getsockopt()` | `sigaddset()` |
| `aio_error()` | `getuid()` | `sigdelset()` |

| | | |
|---|---|---|
| aio_return() | kill() | sigemptyset() |
| aio_suspend() | link() | sigfillset() |
| alarm() | linkat() | sigismember() |
| bind() | listen() | signal() |
| cfgetispeed() | lseek() | sigpause() |
| cfgetospeed() | lstat() | sigpending() |
| cfsetispeed() | mkdir() | sigprocmask() |
| cfsetospeed() | mkdirat() | sigqueue() |
| chdir() | mkfifo() | sigset() |
| chmod() | mkfifoat() | sigsuspend() |
| chown() | mknod() | sleep() |
| clock_gettime() | mknodat() | sockatmark() |
| close() | open() | socket() |
| connect() | openat() | socketpair() |
| creat() | pathconf() | stat() |
| dup() | pause() | symlink() |
| dup2() | pipe() | symlinkat() |
| execl() | poll() | sysconf() |
| execle() | posix_trace_event() | tcdrain() |
| execv() | pselect() | tcflow() |
| execve() | pthread_kill() | tcflush() |
| faccessat() | pthread_self() | tcgetattr() |
| fchdir() | pthread_sigmask() | tcgetpgrp() |
| fchmod() | quick_exit() | tcsendbreak() |
| fchmodat() | raise() | tcsetattr() |
| fchown() | read() | tcsetpgrp() |
| fchownat() | readlink() | time() |
| fcntl() | readlinkat() | timer_getoverrun() |
| fdatasync() | recv() | timer_gettime() |
| fexecve() | recvfrom() | timer_settime() |
| fork() | recvmsg() | times() |
| fpathconf() | rename() | umask() |
| fstat() | renameat() | uname() |
| fstatat() | rmdir() | unlink() |
| fsync() | select() | unlinkat() |
| ftruncate() | sem_post() | utime() |
| futimens() | send() | utimensat() |

| | | |
|---|---|---|
| getegid() | sendmsg() | utimes() |
| geteuid() | sendto() | wait() |
| getgid() | setgid() | waitpid() |
| getgroups() | setpgid() | write() |
| getpeername() | setsid() | |

Functions not in the previous table are not asynchronous-safe, and should not be called from a signal hander.

**Example — Call to printf() Inside Signal Handler**

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
#include <unistd.h>

#define SIZE20 20

extern volatile sig_atomic_t e_flag;

void display_info(const char *info)
{
    if (info)
    {
        (void)fputs(info, stderr);
    }
}

void sig_handler(int signum)
{
    /* Call function printf() that is not
    asynchronous-safe */
    printf("signal %d received.", signum);
    e_flag = 1;
}

int main(void)
{
    e_flag = 0;
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    char *info = (char *)calloc(SIZE20, sizeof(char));
    if (info == NULL)
    {
        /* Handle Error */
    }
    while (!e_flag)
    {
        /* Main loop program code */
        display_info(info);
        /* More program code */
    }
    free(info);
    info = NULL;
    return 0;
}
```

In this example, `sig_handler` calls `printf()` when catching a signal. If the handler catches another signal while `printf()` is executing, the behavior of the program is undefined.

**Correction — Set Flag Only in Signal Handler**

Use your signal handler to set only the value of a flag. `e_flag` is of type volatile `sig_atomic_t`. `sig_handler` can safely access it asynchronously.

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
#include <unistd.h>

#define SIZE20 20

extern volatile sig_atomic_t e_flag;

void display_info(const char *info)
{
    if (info)
    {
        (void)fputs(info, stderr);
    }
}

void sig_handler1(int signum)
{
    int s0 = signum;
    e_flag = 1;
}

int func(void)
{
    e_flag = 0;
    if (signal(SIGINT, sig_handler1) == SIG_ERR)
    {
        /* Handle error */
    }
    char *info = (char *)calloc(SIZE20, 1);
    if (info == NULL)
    {
        /* Handle error */
    }
    while (!e_flag)
    {
        /* Main loop program code */
        display_info(info);
        /* More program code */
    }
    free(info);
    info = NULL;
    return 0;
}
```

### Function called from signal handler not asynchronous-safe (strict ISO C)

#### Issue

This issue occurs when a signal handler calls a function that is not asynchronous-safe according to the C standard. An asynchronous-safe function can be interrupted at any point in its execution, then called again without causing an inconsistent state. It can also correctly handle global data that might be in an inconsistent state.

The C standard defines a stricter subset of functions as asynchronous-safe compared to the set of functions that are asynchronous-safe according to the POSIX standard. **Function called from signal handler not asynchronous-safe (strict ISO C)** reports a defect when a signal handler calls any function that is not part of that subset, even if the function is asynchronous-safe according to the POSIX standard.

To check for calls to functions that are not asynchronous-safe according to the POSIX standard, enable checker **Function called from signal handler not asynchronous-safe**.

If a signal handler calls another function that calls an asynchronous-unsafe function, the defect appears on the function call in the signal handler. The defect traceback shows the full path from the signal handler to the asynchronous-unsafe function.

#### Risk

When a signal handler is invoked, the execution of the program is interrupted. After the handler is finished, program execution resumes at the point of interruption. If a function is executing at the time of the interruption, calling it from within the signal handler is undefined behavior, unless it is asynchronous-safe.

#### Fix

The C standard defines the following functions as asynchronous-safe. You can call these functions from a signal handler:

- `abort()`
- `_Exit()`
- `quick_exit()`
- `signal()`

#### Example — Call to raise() Inside Signal Handler

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
#include <unistd.h>
```

```
void SIG_ERR_handler(int signum)
{
    int s0 = signum;
    /* SIGTERM specific handling */
}

void sig_handler(int signum)
{
    int s0 = signum;
    /* Call raise() */
    if (raise(SIGTERM) != 0) {
        /* Handle error */
    }
}

int finc(void)
{
    if (signal(SIGTERM, SIG_ERR_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
    }
    /* More code */
    return 0;
}
```

In this example, `sig_handler` calls `raise()` when catching a signal. If the handler catches another signal while `raise()` is executing, the behavior of the program is undefined.

**Correction — Remove Call to `raise()` in Signal Handler**

According to the C standard, the only functions that you can safely call from a signal handler are `abort()`, `_Exit()`, `quick_exit()`, and `signal()`.

```
#include <signal.h>
#include <stdio.h>
#include <string.h>
#include <stdlib.h>
#include <setjmp.h>
#include <syslog.h>
#include <unistd.h>

void SIG_ERR_handler(int signum)
{
    int s0 = signum;
    /* SIGTERM specific handling */
}
void sig_handler(int signum)
```

```
{
    int s0 = signum;

}

int func(void)
{
    if (signal(SIGTERM, SIG_ERR_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    if (signal(SIGINT, sig_handler) == SIG_ERR)
    {
        /* Handle error */
    }
    /* Program code */
    if (raise(SIGINT) != 0)
    {
        /* Handle error */
    }
    /* More code */
    return 0;
}
```

Use of Incorrect Operator

## Description

### Rule Description

*The programmer accidentally uses the wrong operator, which changes the application logic in security-relevant ways.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Invalid use of = (assignment) operator**
- **Invalid use of == (equality) operator**
- **Use of bitwise operator with a Boolean-like operand**

## Examples

### Invalid use of = (assignment) operator

#### Issue

This issue occurs when an assignment is made inside the predicate of a conditional, such as `if` or `while`.

In C and C++, a single equal sign is an assignment not a comparison. Using a single equal sign in a conditional statement can indicate a typo or a mistake.

#### Risk

- Conditional statement tests the wrong values— The single equal sign operation assigns the value of the right operand to the left operand. Then, because this assignment is inside the predicate of a conditional, the program checks whether the new value of the left operand is nonzero or not NULL.
- Maintenance and readability issues — Even if the assignment is intended, someone reading or updating the code can misinterpret the assignment as an equality comparison instead of an assignment.

#### Fix

- If the assignment is a bug, to check for equality, add a second equal sign (==).
- If the assignment inside the conditional statement was intentional, to improve readability, separate the assignment and the test. Move the assignment outside the control statement. In the control statement, simply test the result of the assignment.

  If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Single Equal Sign Inside an if Condition

```
#include <stdio.h>

void bad_equals_ex(int alpha, int beta)
{
    if(alpha = beta)
    {
        printf("Equal\n");
    }
}
```

The equal sign is flagged as a defect because the assignment operator is used within the predicate of the if-statement. The predicate assigns the value `beta` to `alpha`, then implicitly tests whether `alpha` is true or false.

#### Correction — Change Expression to Comparison

One possible correction is adding an additional equal sign. This correction changes the assignment to a comparison. The if condition compares whether `alpha` and `beta` are equal.

```
#include <stdio.h>

void equality_test(int alpha, int beta)
{
    if(alpha == beta)
    {
        printf("Equal\n");
    }
}
```

#### Correction — Assignment and Comparison Inside the `if` Condition

If an assignment must be made inside the predicate, a possible correction is adding an explicit comparison. This correction assigns the value of `beta` to `alpha`, then explicitly checks whether `alpha` is nonzero. The code is clearer.

```
#include <stdio.h>

int assignment_not_zero(int alpha, int beta)
{
    if((alpha = beta) != 0)
    {
        return alpha;
    }
    else
    {
        return 0;
    }
}
```

#### Correction — Move Assignment Outside the `if` Statement

If the assignment can be made outside the control statement, one possible correction is to separate the assignment and comparison. This correction assigns the value of `beta` to `alpha` before the if. Inside the if-condition, only `alpha` is given to test if `alpha` is nonzero or not NULL.

```
#include <stdio.h>

void assign_and_print(int alpha, int beta)
{
    alpha = beta;
    if(alpha)
    {
        printf("%d", alpha);
    }
}
```

### Invalid use of == (equality) operator

#### Issue

This issue occurs when you use an equality operator instead of an assignment operator in a simple statement.

#### Risk

The use of == operator instead of an = operator can silently produce incorrect results. If you intended to assign a value to a variable, the assignment does not occur. The variable retains its previous value or if not initialized previously, stays uninitialized.

#### Fix

Use the = (assignment) operator instead of the == (equality) operator.

The check appears on chained assignment and equality operators such as:

```
compFlag = val1 == val2;
```

For better readability of your code, place the equality check in parenthesis.

```
compFlag = (val1 == val2);
```

If the use of == operator is intended, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Equality Evaluation in for-Loop

```
void populate_array(void)
{
    int i = 0;
    int j = 0;
    int array[4];
    for (j == 5; j < 9; j++) {
        array[i] = j;
        i++;
    }
}
```

Inside the `for`-loop, the statement `j == 5` tests whether `j` is equal to 5 instead of setting `j` to 5. The `for`-loop iterates from 0 to 8 because `j` starts with a value of 0, not 5. A by-product of the invalid equality operator is an out-of-bounds array access in the next line.

#### Correction — Change to Assignment Operator

One possible correction is to change the == operator to a single equal sign (=). Changing the == sign resolves both defects because the `for`-loop iterates the intended number of times.

```
void populate_array(void)
{
    int i = 0;
    int j = 0;
    int array[4];

    for (j = 5; j < 9; j++) {
        array[i] = j;
        i++;
    }
}
```

### Use of bitwise operator with a Boolean-like operand

#### Issue

This issue occurs when you use bitwise operators, such as:

- Bitwise AND (&, &=)
- Bitwise OR (`|`, `|=`)
- Bitwise XOR (^, ^=)
- Bitwise NOT(~)

with:

- Boolean type variables
- Outputs of relational or equality expressions

Using Boolean type variables as array indices, in Boolean arithmetic expression, and in shifting operations does not raise this defect.

#### Risk

Boolean-like operands, such as variables of type `bool` and outputs of relational operators typically appear in logical expressions. Using a bitwise operator in an expression containing Boolean variables and relational operators might be a sign of logic error. Because bitwise operators and logical operators look similar, you might inadvertently use a bitwise operator instead of a logical operator. Such logic errors do not raise any compilation error and can introduce bugs in your code that are difficult to find.

#### Fix

Use logical operators in expressions that contain Boolean variables and relational operator. To indicate that you intend to use a bitwise operator in such an expression, use parentheses.

#### Example — Possible Bug Due to Using Bitwise Operator

```
class User{
    //...
    int uid;
    int euid;
public:
    int getuid();
    int geteuid();
};
void Noncompliant ()
{
    User nU;
    if (nU.getuid () & nU.geteuid () == 0) {   //Noncompliant
        //...
    }else{
        //...
    }
}
```

In this example, the `if-else` block is executed conditionally. The conditional statement uses the bitwise AND (&) instead of the logical AND (&&), perhaps by mistake. Consider when the function `nU.geteuid()` evaluates to 0, and `nU.getuid()` evaluates to 2. In this case, the `else` block of code executes if you use & because `2&1` evaluates to `false`. Conversely, the `if` block of code executes when you use && because `2&&1` evaluates to `true`. Using & instead of && might introduce logic errors and bugs in your code that are difficult to find. Polyspace flags the use of bitwise operators in these kinds of expressions where relational operators are also used.

#### Correction — Use Logical Operators with Boolean-Like Operands

One possible correction is to use logical operators in expressions that contain relational operators and Boolean variables.

```
class User{
    //...
    int uid;
    int euid;
public:
    int getuid();
    int geteuid();
};
void Noncompliant ()
{
    User nU;
    if (nU.getuid () && nU.geteuid () == 0) {   //Compliant
        //...
    }else{
        //...
    }
}
```

Assigning instead of Comparing

## Description

### Rule Description

*The code uses an operator for assignment when the intention was to perform a comparison.*

### Polyspace Implementation

The rule checker checks for **Invalid use of = (assignment) operator**.

## Examples

### Invalid use of = (assignment) operator

#### Issue

This issue occurs when an assignment is made inside the predicate of a conditional, such as `if` or `while`.

In C and C++, a single equal sign is an assignment not a comparison. Using a single equal sign in a conditional statement can indicate a typo or a mistake.

#### Risk

- Conditional statement tests the wrong values— The single equal sign operation assigns the value of the right operand to the left operand. Then, because this assignment is inside the predicate of a conditional, the program checks whether the new value of the left operand is nonzero or not NULL.
- Maintenance and readability issues — Even if the assignment is intended, someone reading or updating the code can misinterpret the assignment as an equality comparison instead of an assignment.

#### Fix

- If the assignment is a bug, to check for equality, add a second equal sign (==).
- If the assignment inside the conditional statement was intentional, to improve readability, separate the assignment and the test. Move the assignment outside the control statement. In the control statement, simply test the result of the assignment.

  If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

  - “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
  - “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
  - “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Single Equal Sign Inside an if Condition

```
#include <stdio.h>

void bad_equals_ex(int alpha, int beta)
{
    if(alpha = beta)
    {
        printf("Equal\n");
    }
}
```

The equal sign is flagged as a defect because the assignment operator is used within the predicate of the if-statement. The predicate assigns the value `beta` to `alpha`, then implicitly tests whether `alpha` is true or false.

#### Correction — Change Expression to Comparison

One possible correction is adding an additional equal sign. This correction changes the assignment to a comparison. The if condition compares whether `alpha` and `beta` are equal.

```
#include <stdio.h>

void equality_test(int alpha, int beta)
{
    if(alpha == beta)
    {
        printf("Equal\n");
    }
}
```

#### Correction — Assignment and Comparison Inside the `if` Condition

If an assignment must be made inside the predicate, a possible correction is adding an explicit comparison. This correction assigns the value of `beta` to `alpha`, then explicitly checks whether `alpha` is nonzero. The code is clearer.

```
#include <stdio.h>

int assignment_not_zero(int alpha, int beta)
{
    if((alpha = beta) != 0)
    {
        return alpha;
    }
    else
    {
        return 0;
    }
}
```

#### Correction — Move Assignment Outside the `if` Statement

If the assignment can be made outside the control statement, one possible correction is to separate the assignment and comparison. This correction assigns the value of `beta` to `alpha` before the if. Inside the if-condition, only `alpha` is given to test if `alpha` is nonzero or not NULL.

```
#include <stdio.h>
```

```
void assign_and_print(int alpha, int beta)
{
    alpha = beta;
    if(alpha)
    {
        printf("%d", alpha);
    }
}
```

Comparing instead of Assigning

## Description

### Rule Description

*The code uses an operator for comparison when the intention was to perform an assignment.*

### Polyspace Implementation

The rule checker checks for **Invalid use of == (equality) operator**.

## Examples

### Invalid use of == (equality) operator

#### Issue

This issue occurs when you use an equality operator instead of an assignment operator in a simple statement.

#### Risk

The use of == operator instead of an = operator can silently produce incorrect results. If you intended to assign a value to a variable, the assignment does not occur. The variable retains its previous value or if not initialized previously, stays uninitialized.

#### Fix

Use the = (assignment) operator instead of the == (equality) operator.

The check appears on chained assignment and equality operators such as:

```
compFlag = val1 == val2;
```

For better readability of your code, place the equality check in parenthesis.

```
compFlag = (val1 == val2);
```

If the use of == operator is intended, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Equality Evaluation in for-Loop

```
void populate_array(void)
{
    int i = 0;
    int j = 0;
    int array[4];

    for (j == 5; j < 9; j++) {
        array[i] = j;
        i++;
    }
}
```

Inside the `for`-loop, the statement `j == 5` tests whether `j` is equal to 5 instead of setting `j` to 5. The `for`-loop iterates from 0 to 8 because `j` starts with a value of 0, not 5. A by-product of the invalid equality operator is an out-of-bounds array access in the next line.

#### Correction — Change to Assignment Operator

One possible correction is to change the == operator to a single equal sign (=). Changing the == sign resolves both defects because the `for`-loop iterates the intended number of times.

```
void populate_array(void)
{
    int i = 0;
    int j = 0;
    int array[4];

    for (j = 5; j < 9; j++) {
        array[i] = j;
        i++;
    }
}
```

CWE-482

# CWE Rule 483

Incorrect Block Delimitation

## Description

### Rule Description

*The code does not explicitly delimit a block that is intended to contain 2 or more statements, creating a logic error.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Incorrectly indented statement**
- **Semicolon on the same line as an if, for or while statement**

## Examples

### Incorrectly indented statement

#### Issue

This issue occurs when the indentation of a statement makes it appear as part of an `if`, `else` or another block but the arrangement or lack of braces actually keeps the statement outside the block.

#### Risk

A developer or reviewer might incorrectly associate the statement with a block based on its indentation, leading to an incorrect assumption about the program logic.

For instance, in this example:

```
if(credentialsOK())
   login=1;
   setCookies();
```

the line `setCookies();` is not part of the `if` block, but the indentation suggests otherwise.

#### Fix

If you want a statement to be part of a block, make sure that the statement is within the braces associated with the block. To identify the extent of a block, on the **Source** pane, click the opening brace.

If an `if`, `else` or `while` statement has no braces following the condition, only the next line on an execution path up to a semicolon is considered part of the `if`, `else` or `while` block. If you want subsequent lines to be included in the block, wrap the lines in braces.

For instance, in the preceding example, to include both statements in the `if` block, use:

```
if(credentialsOK()) {
   login=1;
   setCookies();
}
```

**Example — else Statement Incorrectly Indented**

```
int switch1, switch2;

void doSomething(void);
void doSomethingElse(void);

void func() {
    if(switch1)
        if(switch2)
            doSomething();
    else
        doSomethingElse();
}
```

In this example, the `else` is indented as if it is associated with the first `if`. However, the `else` is actually associated with the second `if`. The indentation does not match the actual association and might lead to incorrect assumptions about the program logic.

**Correction – Use Braces Appropriately**

If you want the `else` to be associated with the first `if`, use braces to mark the boundaries of the first `if` block.

```
int switch1, switch2;

void doSomething(void);
void doSomethingElse(void);

void func() {
    if(switch1) {
        if(switch2)
            doSomething();
    }
    else
        doSomethingElse();
}
```

### Semicolon on the same line as an if, for or while statement

**Issue**

This issue occurs when a semicolon on the same line as the last token of an `if`, `for` or `while` statement results in an empty body.

The checker makes an exception for the case where the `if` statement is immediately followed by an `else` statement:

```
if(condition);
else {
  ...
}
```

#### Risk

The semicolon following the if, for or while statement often indicates a programming error. The spurious semicolon changes the execution flow and leads to unintended results.

#### Fix

If you want an empty body for the `if`, `for` or `while` statement, wrap the semicolon in a block and place the block on a new line to explicitly indicate your intent:

```
if(condition)
   {;}
```

Otherwise, remove the spurious semicolon.

#### Example — Spurious Semicolon

```
int credentialsOK(void);

void login () {
    int loggedIn = 0;
    if(credentialsOK());
      loggedIn = 1;
}
```

In this example, the spurious semicolon results in an empty `if` body. The assignment `loggedIn=1` is always performed. However, the assignment was probably to be performed only under a condition.

#### Correction – Remove Spurious Semicolon

If the semicolon was unintended, remove the semicolon.

```
int credentialsOK(void);

void login () {
    int loggedIn = 0;
    if(credentialsOK())
      loggedIn = 1;
}
```

CWE-483

# CWE Rule 484

Omitted Break Statement in Switch

## Description

### Rule Description

*The program omits a break statement within a switch or similar construct, causing code associated with multiple conditions to execute. This can cause problems when the programmer only intended to execute code associated with one condition.*

### Polyspace Implementation

The rule checker checks for **Missing break of switch case**.

## Examples

### Missing break of switch case

#### Issue

This issue occurs when a `case` block of `switch` statement does not end in a `break`, a `[[fallthrough]]`, or a code comment.

If the last entry in the case block is a code comment, for instance:

```
switch (wt)
    {
      case WE_W:
        do_something_for_WE_W();
        do_something_else_for_WE_W();
        /* fall through to WE_X*/
      case WE_X:
        ...
    }
```

Polyspace assumes that the missing break is intentional and does not raise a defect.

#### Risk

Switch cases without break statements fall through to the next switch case. If this fall-through is not intended, the switch case can unintentionally execute code and end the switch with unexpected results.

#### Fix

If you forgot the break statement, add it before the end of the switch case.

If you do not want a break for the highlighted switch case, add a comment to your code to document why this case falls through to the next case. This comment removes the defect from your results and makes your code more maintainable.

In some cases, such as in template functions, the defect checker might ignore the comment at the end of a case statement. A cleaner way to indicate a deliberate fall through to the next case is to use one of these `fallthrough` attributes if possible:

- `[[fallthrough]]`: Available since C++17.
- `[[gnu::fallthrough]]` and `[[clang::fallthrough]]`: Available with GCC and Clang compilers.
- `__attribute__((fallthrough))`: Available with GCC compilers.

**Example — Switch Without Break Statements**

```
enum WidgetEnum { WE_W, WE_X, WE_Y, WE_Z } widget_type;

extern void demo_do_something_for_WE_W(void);
extern void demo_do_something_for_WE_X(void);
extern void demo_report_error(void);

void bug_missingswitchbreak(enum WidgetEnum wt)
{
    /*
      In this non-compliant code example, the case where widget_type is WE_W lacks a
      break statement. Consequently, statements that should be executed only when
      widget_type is WE_X are executed even when widget_type is WE_W.
    */
    switch (wt)
    {
      case WE_W:
        demo_do_something_for_WE_W();
      case WE_X:
        demo_do_something_for_WE_X();
      default:
        /* Handle error condition */
        demo_report_error();
    }
}
```

In this example, there are two cases without `break` statements. When `wt` is `WE_W`, the statements for `WE_W`, `WE_X`, and the `default` case execute because the program falls through the two cases without a break. No defect is raised on the `default` case or last case because it does not need a break statement.

**Correction — Add a Comment or break**

To fix this example, either add a comment after the last statement in the case block and before the next case block to mark and document the acceptable fall-through or add a break statement to avoid fall-through. In this example, case `WE_W` is supposed to fall through, so a comment is added to explicitly state this action. For the second case, a break statement is added to avoid falling through to the `default` case.

```
enum WidgetEnum { WE_W, WE_X, WE_Y, WE_Z } widget_type;

extern void demo_do_something_for_WE_W(void);
extern void demo_do_something_for_WE_X(void);
extern void demo_report_error(void);

void corrected_missingswitchbreak(enum WidgetEnum wt)
{
    switch (wt)
    {
      case WE_W:
        demo_do_something_for_WE_W();
        /* fall through to WE_X*/
      case WE_X:
        demo_do_something_for_WE_X();
        break;
      default:
        /* Handle error condition */
        demo_report_error();
    }
}
```

Active Debug Code

## Description

### Rule Description

*The application is deployed to unauthorized actors with debugging code still enabled or active, which can create unintended entry points or expose sensitive information.*

### Polyspace Implementation

The rule checker checks for **Use of a forbidden function**.

## Examples

### Use of a forbidden function

#### Issue

This issue occurs when you use a function that appears in a blocklist of forbidden functions. To create the blocklist:

- List functions in an XML file in a specific syntax.

  Copy the template file `code-behavior-specifications-template.xml` from the folder *`polyspaceroot`*`\polyspace\verifier\cxx` to a writable location and modify the file. Enter each function in the file using the following syntax after existing similar entries:

  ```
  <function name="funcname">
     <behavior name="FORBIDDEN_FUNC"/>
  </function>
  ```

  where *`funcname`* is the name of the function you want to block.
- Specify this XML file as argument for the option `-code-behavior-specifications`. See “Flag Deprecated or Unsafe Functions, Keywords, or Macros Using Bug Finder Checkers”.

#### Risk

A function might be blocked for one of these reasons:

- The function can lead to many situations where the behavior is undefined leading to security vulnerabilities, and a more secure function exists.

  You can forbid functions that are not explicitly checked by existing checkers such as `Use of dangerous standard function` or `Use of obsolete standard function`.
- The function is being deprecated as part of a migration, for instance, from C++98 to C++11.

  As part of a migration, you can make a list of functions that need to be replaced and use this checker to identify their use.

#### Fix

Replace the blocked function with an allowed function.

When rolling out this checker to a group, project or organization, create a list of blocked functions and their replacements so that results reviewers can consult the list and make appropriate replacements.

#### Extend Checker

This defect checker requires a blocklist of functions to be specified. Even if you specify the checker using the option `Find defects (-checkers)`, it is not enabled unless you also specify the blocklist. See “Flag Deprecated or Unsafe Functions, Keywords, or Macros Using Bug Finder Checkers”.

#### Example — Use of Forbidden Function std::signal

```
#include <csignal>
#include <iostream>

namespace
{
  volatile std::sig_atomic_t gSignalStatus;
}

void signal_handler(int signal)
{
  gSignalStatus = signal;
}

int main()
{
  // Install a signal handler
  std::signal(SIGINT, signal_handler);

  std::cout << "SignalValue: " << gSignalStatus << '\n';
  std::cout << "Sending signal " << SIGINT << '\n';
  std::raise(SIGINT);
  std::cout << "SignalValue: " << gSignalStatus << '\n';
}
```

Suppose you want to deprecate the `std::signal` function. Add the following to the template XML file after similar existing entries:

```
<specifications>
  <functions>
     <function name="std::signal">
        <behavior name="FORBIDDEN_FUNC"/>
     </function>
   </functions>
</specifications>
```

and specify the XML file with the option `-code-behavior-specifications`.

In the analysis results, all uses of the `std::signal` function are flagged by this checker.

**Example — Blocking C++ Overloaded Operators**

```
class orderedPair {
        int var1;
        int var2;
    public:
        orderedPair() {
            var1 = 0;
            var2 = 0;
        }
        orderedPair(int arg1, int arg2) {
            var1 = arg1;
            var2 = arg2;
        }
        orderedPair& operator=(const orderedPair& rhs) {
            var1 = rhs.var1;
            var2 = rhs.var2;
            return *this;
        }
        orderedPair& operator+(orderedPair& rhs) {
            var1 += rhs.var1;
            var2 += rhs.var2;
            return *this;
        }
};

void main() {
    int one=1, zero=0, sum;
    orderedPair firstOrderedPair(one, one);
    orderedPair secondOrderedPair(zero, one);
    orderedPair sumPair;

    sum = zero + one;
    sumPair = firstOrderedPair + secondOrderedPair;
}
```

Suppose you want to identify all the locations where operator overloads in the `orderedPair` class are used. Add the overloaded operators to the template XML file:

```
<specifications>
  <functions>
     <function name="orderedPair::operator=">
        <behavior name="FORBIDDEN_FUNC"/>
     </function>
     <function name="orderedPair::operator+">
        <behavior name="FORBIDDEN_FUNC"/>
     </function>
   </functions>
</specifications>
```

and specify the XML file with the option `-code-behavior-specifications`.

The analysis identifies all calls to the overloaded operators and flags their use. Using this method, you can distinguish specific overloads of an operator instead of searching for and browsing through all instances of the operator.

Private Data Structure Returned From A Public Method

## Description

### Rule Description

*The product has a method that is declared public, but returns a reference to a private data structure, which could then be modified in unexpected ways.*

### Polyspace Implementation

The rule checker checks for **Return of non-const pointer or reference to private or protected data owned by the class**.

## Examples

### Return of non-const pointer or reference to private or protected data owned by the class

**Issue**

The issue occurs if a member function returns a non-`const` pointer or reference to a nonstatic data member. The rule does not apply to static data members.

**Risk**

Returning a nonconstant pointer or reference to private or protected class-owned data enables clients to externally access and modify the state of the object without an interface. Such access without an explicit interface might bypass the private/protected data access hierarchy of the class, which might result in unexpected behavior and lead to bugs.

This rule applies to data that is owned by the class. Nonconstant handles to objects that are shared between different classes might be returned. Classes that mimic smart pointers and containers do not violate this rule.

**Fix**

Do not return a non-`const` pointer or reference to class-owned data that is private or protected.

**Example — Avoid Returning Non-Constant Raw Pointers to Private Data**

```
#include <cstdint>
#include <memory>
#include <utility>

class A
{
  public:
    explicit A(std::int32_t number) : x(number) {}
    std::int32_t&
    GetX() noexcept // Noncompliant
    {
      return x;
    }

  private:
    std::int32_t x;
};

void Fn1() noexcept
{
  A a{10};
  std::int32_t& number = a.GetX();
  number = 15; // External modification of private class data
}
```

In this example, the `class A` member function `GetX()` returns a non-constant raw pointer to `x`, which is private data owned by `class A`. Polyspace flags this implementation as noncompliant. `Fn1()` demonstrates the issues of `a.GetX()` returning a non-constant raw pointer to private class data, which is then stored and modified by number. The class has no control over changes to its own private data member, which might lead to unexpected behavior.

**Example — Return Shared Smart Pointer Variables**

```
#include <cstdint>
#include <memory>
#include <utility>
class B
{
  public:
    explicit B(std::shared_ptr<std::int32_t> ptr) : sharedptr(std::move(ptr)) {}
    std::shared_ptr<std::int32_t> GetSharedPtr() const noexcept // Compliant
    {
      return sharedptr;
    }

  private:
    std::shared_ptr<std::int32_t> sharedptr;
};

void Fn2() noexcept
{
  std::shared_ptr<std::int32_t> ptr = std::make_shared<std::int32_t>(10);
  B b1{ptr};
  B b2{ptr};
  *ptr = 50; // External modification of ptr which shared between b1 and b2
  // instances
  auto shared = b1.GetSharedPtr();

  *shared = 100;   // External modification of ptr which shared between b1 and
  // b2 instances
}
```

In this example, the `class B` function `GetSharedPtr()` returns a smart pointer variable that is shared between the instances `b1` and `b2`. Polyspace does not flag this implementation as noncompliant.

**Example — Return Constant References**

```
#include <cstdint>
#include <memory>
#include <utility>
class C
{
  public:
    explicit C(std::int32_t number)
      : ownedptr{std::make_unique<std::int32_t>(number)}
    {
    }
    const std::int32_t& GetData() const noexcept // Compliant
    {
      return *ownedptr;
    }

  private:
    std::unique_ptr<std::int32_t> ownedptr;
};
void Fn3() noexcept
{
  C c{10};
  const std::int32_t& data = c.GetData();
  // data = 20; // Cannot modify data, it is a const reference
}
```

In this example, `GetData()` returns a constant reference. You cannot modify private class-data by using this member function. Polyspace does not flag this implementation as noncompliant.

Public Static Field Not Marked Final

## Description

### Rule Description

*An object contains a public static field that is not marked final, which might allow it to be modified in unexpected ways.*

### Polyspace Implementation

The rule checker checks for **Public static field not const**.

## Examples

### Public static field not const

#### Issue

This issue occurs when all of these conditions are true:

- A class contains a data member that is both `static` and `public`
- The `static` and `public` data member is not `const`

#### Risk

The `public static` data members of a class can be modified by any of class in the program. Unless `public static` data members are specified as `const`, they might be modified in unexpected ways and result in bugs that are difficult to diagnose.

#### Fix

To resolve this defect, specify the `public static` data members as `const` or `constexpr`.

#### Example — Avoid Nonconst public static Data Members

```
#include<string>
class SomeAppClass {

private:
    static std::string appPropertiesConfigFilep2;

protected:
    static std::string appPropertiesConfigFilepr2;

public:
    static std::string appPropertiesConfigFile2; //Defect

    static void foo() {}
    int bar() {
        static int v = 3;
        return v;
    }
};
```

In this example, the data member `appPropertiesConfigFile2` is `static` and `public`, but not `const`. Polyspace flags the member. The `static` data members that are `private` and `protected` are not flagged. This rule does not apply to `static` objects that are in the scope of `public` member functions of a class.

#### Correction — Declare `public static` Data Members as `const`

To resolve this defect, declare the `public static` data members of a class as `const`.

```
#include<string>
class SomeAppClass {

private:
    static std::string appPropertiesConfigFilep2;

protected:
    static std::string appPropertiesConfigFilepr2;

public:
    static const std::string appPropertiesConfigFile2; //No Defect

    static void foo() {}
    int bar() {
        static int v = 3;
        return v;
    }
};
```

Insufficiently Protected Credentials

## Description

### Rule Description

*The product transmits or stores authentication credentials, but it uses an insecure method that is susceptible to unauthorized interception and/or retrieval.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Constant cipher key**
- **Hard-coded sensitive data**
- **Nonsecure hash algorithm**
- **Nonsecure parameters for key generation**
- **Nonsecure RSA public exponent**
- **Nonsecure SSL/TLS protocol**
- **Unsafe standard encryption function**

## Examples

### Constant cipher key

#### Issue

This issue occurs when you use a constant for the encryption or decryption key.

#### Risk

If you use a constant for the encryption or decryption key, an attacker can retrieve your key easily.

You use a key to encrypt and later decrypt your data. If a key is easily retrieved, data encrypted using that key is not secure.

#### Fix

Produce a random key by using a strong random number generator.

For a list of random number generators that are cryptographically weak, see `Vulnerable pseudo-random number generator`.

#### Example — Constants Used for Key

```
#include <openssl/evp.h>
#include <stdlib.h>
#define SIZE16 16
```

```
int func(EVP_CIPHER_CTX *ctx, unsigned char *iv){
    unsigned char key[SIZE16] = {'1', '2', '3', '4','5','6','b','8','9',
                                 '1','2','3','4','5','6','7'};
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

In this example, the cipher key, `key`, has constants only. An attacker can easily retrieve a constant key.

#### Correction — Use Random Key

Use a strong random number generator to produce the cipher key. The corrected code here uses the function `RAND_bytes` declared in `openssl/rand.h`.

```
#include <openssl/evp.h>
#include <openssl/rand.h>
#include <stdlib.h>
#define SIZE16 16

int func(EVP_CIPHER_CTX *ctx, unsigned char *iv){
    unsigned char key[SIZE16];
    RAND_bytes(key, 16);
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

### Hard-coded sensitive data

#### Issue

This issue occurs when data that is potentially sensitive is directly exposed in the code, for instance, as string literals. The checker identifies certain data as sensitive from their use in certain functions such as password encryption functions.

Following data can be potentially sensitive.

| Type of Data | Functions That Indicate Sensitive Nature of Information |
|---|---|
| Host name | • `sethostname`, `setdomainname`, `gethostbyname`, `gethostbyname2`, `getaddrinfo`, `gethostbyname_r`, `gethostbyname2_r` (string argument)<br>• `inet_aton`, `inet_pton`, `inet_net_pton`, `inet_addr`, `inet_network` (string argument)<br>• `mysql_real_connect`, `mysql_real_connect_nonblocking`, `mysql_connect` (2nd argument) |

| Type of Data | Functions That Indicate Sensitive Nature of Information |
|---|---|
| Password | • `CreateProcessWithLogonW`, `LogonUser` (1st argument)<br>• `mysql_real_connect`, `mysql_real_connect_nonblocking`, `mysql_connect` (3rd argument) |
| Database | • MySQL: `mysql_real_connect`, `mysql_real_connect_nonblocking`, `mysql_connect` (4th argument)<br>• SQLite: `sqlite3_open`, `sqlite3_open16`, `sqlite3_open_v2` (1st argument)<br>• PostgreSQL: `PQconnectdb`<br>• Microsoft SQL: `SQLDriverConnect` (3rd argument) |
| User name | • `getpw`, `getpwnam`, `getpwnam_r`, `getpwuid`, `getpwuid_r` |
| Salt | `crypt`, `crypt_r` (2nd argument) |
| Cryptography keys and initialization vectors | OpenSSL:<br>• `EVP_CipherInit`, `EVP_EncryptInit`, `EVP_DecryptInit` (3rd argument)<br>• `EVP_CipherInit_ex`, `EVP_EncryptInit_ex`, `EVP_DecryptInit_ex` (4th argument) |
| Seed | • `srand`, `srandom`, `initstate` (1st argument)<br>• OpenSSL: `RAND_seed`, `RAND_add` |

**Risk**

Information that is hardcoded can be queried from binaries generated from the code.

**Fix**

Avoid hard coding sensitive information.

**Example — Sensitive Data Exposed Through String Literals**

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

MYSQL *mysql_real_connect(MYSQL *mysql,
                          const char *host, const char *user, const char *passwd,
                          const char *db, unsigned int port, const char *unix_socket,
                          unsigned long client_flag);

typedef void * DbHandle;
extern MYSQL *sql;
```

```
// File that uses functions from "mysql.h"
const char *host = "localhost";
char *user = "guest";
char *passwd;

DbHandle connect_to_database_server(const char *db)
{
    passwd = (char*)"guest";
    return (DbHandle)
        mysql_real_connect (sql, host, user, passwd, db, 0, 0x0, 0);
}
```

In this example, the arguments `host` (host name), `user` (user name), and `passwd` (password) are string literals and directly exposed in the code.

Querying the generated binary for ASCII strings can reveal this information.

**Correction – Read Sensitive Data from Secured Configuration Files**

One possible correction is to read the data from a configuration file. In the following corrected example, the call to function `connect_to_database_server_init` presumably reads the host name, user name, and password into its arguments from a secured configuration file.

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

MYSQL *mysql_real_connect(MYSQL *mysql,
                          const char *host, const char *user, const char *passwd,
                          const char *db, unsigned int port, const char *unix_socket,
                          unsigned long client_flag);

typedef void * DbHandle;
extern MYSQL *sql;

// File that uses functions from "mysql.h"

int connect_to_database_server_init(const char **host,
                                    const char **user,
                                    const char **passwd,
                                    const char **db);

DbHandle connect_to_database_server(const char *db)
{
    const char *host_from_cfg;
    const char *user_from_cfg;
    const char *passwd_from_cfg;
    const char *db_from_cfg;
    if (connect_to_database_server_init(&host_from_cfg,
                                        &user_from_cfg,
                                        &passwd_from_cfg,
                                        &db_from_cfg))
    {
        return (DbHandle)
            mysql_real_connect (sql, host_from_cfg, user_from_cfg,
                        passwd_from_cfg, db_from_cfg,  0, 0x0, 0);
    }
    else
        return (DbHandle)0x0;
}
```

### Nonsecure hash algorithm

#### Issue

This issue occurs when you use a cryptographic hash function that is proven to be weak against certain forms of attack.

The hash functions flagged by this checker include SHA-0, SHA-1, MD4, MD5, and RIPEMD-160. The checker detects the use of these hash functions in:

- Functions from the EVP API such as `EVP_DigestUpdate` or `EVP_SignUpdate`.
- Functions from the low level API such as `SHA1_Update` or `MD5_Update`.

#### Risk

You use a hash function to create a message digest from input data and thereby ensure integrity of your data. The hash functions flagged by this checker use algorithms with known weaknesses that an attacker can exploit. The attacks can comprise the integrity of your data.

#### Fix

Use a more secure hash function. For instance, use the later SHA functions such as SHA-224, SHA-256, SHA-384, and SHA-512.

#### Example — Use of MD5 Algorithm

```
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
unsigned char *out_buf;
unsigned int out_len;

void func(unsigned char *src, size_t len, EVP_PKEY* pkey){
  EVP_MD_CTX* ctx = EVP_MD_CTX_create();

  ret = EVP_SignInit_ex(ctx, EVP_md5(), NULL);
  if (ret != 1) fatal_error();

  ret = EVP_DigestUpdate(ctx,src,len);

  if (ret != 1) fatal_error();

  ret = EVP_SignFinal(ctx, out_buf, &out_len, pkey);
  if (ret != 1) fatal_error();
}
```

In this example, during initialization with `EVP_SignInit_ex`, the context object is associated with the weak hash function MD5. The checker flags the usage of this context in the update step with `EVP_DigestUpdate`.

#### Correction — Use SHA-2 Family Function

One possible correction is to use a hash function from the SHA-2 family, such as SHA-256.

```
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
unsigned char *out_buf;
unsigned int out_len;

void func(unsigned char *src, size_t len, EVP_PKEY* pkey){
  EVP_MD_CTX* ctx = EVP_MD_CTX_create();

  ret = EVP_SignInit_ex(ctx, EVP_sha256(), NULL);
  if (ret != 1) fatal_error();

  ret = EVP_SignUpdate(ctx, src, len);
  if (ret != 1) fatal_error();

  ret = EVP_SignFinal(ctx, out_buf, &out_len, pkey);
  if (ret != 1) fatal_error();
}
```

### Nonsecure parameters for key generation

#### Issue

This issue occurs when you attempt key generation by using an EVP_PKEY_CTX context object that is associated with weak parameters. What constitutes a weak parameter depends on the public key algorithm used. In the DSA algorithm, a weak parameter can be the result of setting an insufficient parameter length.

For instance, you set the number of bits used for DSA parameter generation to 512 bits, and then use the parameters for key generation:

```
EVP_PKEY_CTX *pctx,*kctx;
EVP_PKEY *params, *pkey;

/* Initializations for parameter generation */
pctx = EVP_PKEY_CTX_new_id(EVP_PKEY_DSA, NULL);
params = EVP_PKEY_new();

/* Parameter generation */
ret = EVP_PKEY_paramgen_init(pctx);
ret = EVP_PKEY_CTX_set_dsa_paramgen_bits(pctx, KEYLEN_512BITS);
ret = EVP_PKEY_paramgen(pctx, &params);

/* Initializations for key generation */
kctx = EVP_PKEY_CTX_new(params, NULL);
pkey = EVP_PKEY_new();

/* Key generation */
ret = EVP_PKEY_keygen_init(kctx);
ret = EVP_PKEY_keygen(kctx, &pkey);
```

#### Risk

Weak parameters lead to keys that are not sufficiently strong for encryption and expose sensitive information to known ways of attack.

#### Fix

Depending on the algorithm, use these parameters:

- Diffie-Hellman (DH): Set the length of the DH prime parameter to 2048 bits.

  ```
  ret = EVP_PKEY_CTX_set_dh_paramgen_prime_len(pctx, 2048);
  ```

  Set the DH generator to 2 or 5.

  ```
  ret = EVP_PKEY_CTX_set_dh_paramgen_generator(pctx, 2);
  ```
- Digital Signature Algorithm (DSA): Set the number of bits used for DSA parameter generation to 2048 bits.

  ```
  ret = EVP_PKEY_CTX_set_dsa_paramgen_bits(pctx, 2048);
  ```
- RSA: Set the RSA key length to 2048 bits.

  ```
  ret = EVP_PKEY_CTX_set_rsa_keygen_bits(kctx, 2048);
  ```
- Elliptic curve (EC): Avoid using curves that are known to be broken, for instance, `X9_62_prime256v1`. Use, for instance, `sect239k1`.

  ```
  ret = EVP_PKEY_CTX_set_ec_paramgen_curve_nid(pctx, NID_sect239k1);
  ```

#### Example — Insufficient Bits for RSA Key Generation

```
#include <stddef.h>
#include <openssl/rsa.h>
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
int func(EVP_PKEY *pkey){
  EVP_PKEY_CTX * ctx = EVP_PKEY_CTX_new_id(EVP_PKEY_RSA, NULL);
  if (ctx == NULL) fatal_error();

  ret = EVP_PKEY_keygen_init(ctx);
  if (ret <= 0) fatal_error();
  ret = EVP_PKEY_CTX_set_rsa_keygen_bits(ctx, 512);
  if (ret <= 0) fatal_error();
  return EVP_PKEY_keygen(ctx, &pkey);
}
```

In this example, the RSA key generation uses 512 bits, which makes the generated key vulnerable to attacks.

#### Correction — Use 2048 bits

Use 2048 bits for RSA key generation.

```
#include <stddef.h>
```

```
#include <openssl/rsa.h>
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
int func(EVP_PKEY *pkey){
  EVP_PKEY_CTX * ctx = EVP_PKEY_CTX_new_id(EVP_PKEY_RSA, NULL);
  if (ctx == NULL) fatal_error();

  ret = EVP_PKEY_keygen_init(ctx);
  if (ret <= 0) fatal_error();
  ret = EVP_PKEY_CTX_set_rsa_keygen_bits(ctx, 2048);
  if (ret <= 0) fatal_error();
  return EVP_PKEY_keygen(ctx, &pkey);
}
```

### Nonsecure RSA public exponent

#### Issue

This issue occurs when you attempt RSA key generation by using a context object that is associated with a low public exponent.

For instance, you set a public exponent of 3 in the context object, and then use it for key generation.

```
/* Set public exponent */
ret = BN_dec2bn(&pubexp, "3");

/* Initialize context */
ctx = EVP_PKEY_CTX_new_id(EVP_PKEY_RSA, NULL);
pkey = EVP_PKEY_new();
ret = EVP_PKEY_keygen_init(kctx);

/* Set public exponent in context */
ret = EVP_PKEY_CTX_set_rsa_keygen_pubexp(ctx, pubexp);

/* Generate key */
ret = EVP_PKEY_keygen(kctx, &pkey);
```

#### Risk

A low RSA public exponent makes certain kinds of attacks more damaging, especially when a weak padding scheme is used or padding is not used at all.

#### Fix

It is recommended to use a public exponent of 65537. Using a higher public exponent can make the operations slower.

#### Example — Using RSA Public Exponent of 3

```
#include <stddef.h>
#include <openssl/rsa.h>
#include <openssl/evp.h>

#define fatal_error() exit(-1)
```

```
int ret;
int func(EVP_PKEY *pkey){
  BIGNUM* pubexp;
  EVP_PKEY_CTX* ctx;

  pubexp = BN_new();
  if (pubexp == NULL) fatal_error();
  ret = BN_set_word(pubexp, 3);
  if (ret <= 0) fatal_error();

  ctx = EVP_PKEY_CTX_new_id(EVP_PKEY_RSA, NULL);
  if (ctx == NULL) fatal_error();

  ret = EVP_PKEY_keygen_init(ctx);
  if (ret <= 0) fatal_error();
  ret = EVP_PKEY_CTX_set_rsa_keygen_bits(ctx, 2048);
  if (ret <= 0) fatal_error();
  ret = EVP_PKEY_CTX_set_rsa_keygen_pubexp(ctx, pubexp);
  if (ret <= 0) fatal_error();
  return EVP_PKEY_keygen(ctx, &pkey);
}
```

In this example, an RSA public exponent of 3 is associated with the context object `ctx`. The low exponent makes operations that use the generated key vulnerable to certain attacks.

**Correction — Use Public Exponent of 65537**

One possible correction is to use the recommended public exponent 65537.

```
#include <stddef.h>
#include <openssl/rsa.h>
#include <openssl/evp.h>

#define fatal_error() exit(-1)

int ret;
int func(EVP_PKEY *pkey){
  BIGNUM* pubexp;
  EVP_PKEY_CTX* ctx;

  pubexp = BN_new();
  if (pubexp == NULL) fatal_error();
  ret = BN_set_word(pubexp, 65537);
  if (ret <= 0) fatal_error();

  ctx = EVP_PKEY_CTX_new_id(EVP_PKEY_RSA, NULL);
  if (ctx == NULL) fatal_error();

  ret = EVP_PKEY_keygen_init(ctx);
  if (ret <= 0) fatal_error();
  ret = EVP_PKEY_CTX_set_rsa_keygen_bits(ctx, 2048);
  if (ret <= 0) fatal_error();
  ret = EVP_PKEY_CTX_set_rsa_keygen_pubexp(ctx, pubexp);
  if (ret <= 0) fatal_error();
  return EVP_PKEY_keygen(ctx, &pkey);
}
```

## Nonsecure SSL/TLS protocol

#### Issue

This issue occurs when you do not disable nonsecure protocols in an `SSL_CTX` or `SSL` context object before using the object for handling SSL/TLS connections.

For instance, you disable the protocols SSL2.0 and TLS1.0 but forget to disable the protocol SSL3.0, which is also considered weak.

```
/* Create and configure context */
ctx = SSL_CTX_new(SSLv23_method());
SSL_CTX_set_options(ctx, SSL_OP_NO_SSLv2|SSL_OP_NO_TLSv1);

/* Use context to handle connection */
ssl = SSL_new(ctx);
SSL_set_fd(ssl, NULL);
ret = SSL_connect(ssl);
```

#### Risk

The protocols SSL2.0, SSL3.0, and TLS1.0 are considered weak in the cryptographic community. Using one of these protocols can expose your connections to cross-protocol attacks. The attacker can decrypt an RSA ciphertext without knowing the RSA private key.

#### Fix

Disable the nonsecure protocols in the context object before using the object to handle connections.

```
/* Create and configure context */
ctx = SSL_CTX_new(SSLv23_method());
SSL_CTX_set_options(ctx, SSL_OP_NO_SSLv2|SSL_OP_NO_SSLv3|SSL_OP_NO_TLSv1);
```

#### Example — Nonsecure Protocols Not Disabled

```
#include <stdlib.h>
#include <stdio.h>
#include <unistd.h>
#include <sys/socket.h>
#include <arpa/inet.h>
#include <openssl/ssl.h>
#include <openssl/err.h>

#define fatal_error() exit(-1)

int ret;
int func(){
  SSL_CTX *ctx;
  SSL *ssl;

  SSL_library_init();

  /* context configuration */
  ctx = SSL_CTX_new(SSLv23_client_method());
  if (ctx==NULL) fatal_error();

  ret = SSL_CTX_use_certificate_file(ctx, "cert.pem", SSL_FILETYPE_PEM);
  if (ret <= 0) fatal_error();

  ret = SSL_CTX_load_verify_locations(ctx, NULL, "ca/path");
  if (ret <= 0) fatal_error();

  /* Handle connection */
  ssl = SSL_new(ctx);
  if (ssl==NULL) fatal_error();
  SSL_set_fd(ssl, NULL);

  return SSL_connect(ssl);
}
```

In this example, the protocols SSL2.0, SSL3.0, and TLS1.0 are not disabled in the context object before the object is used for a new connection.

**Correction — Disable Nonsecure Protocols**

Disable nonsecure protocols before using the objects for a new connection. Use the function `SSL_CTX_set_options` to disable the protocols SSL2.0, SSL3.0, and TLS1.0.

```
#include <stdlib.h>
#include <stdio.h>
#include <unistd.h>
#include <sys/socket.h>
#include <arpa/inet.h>
#include <openssl/ssl.h>
#include <openssl/err.h>

#define fatal_error() exit(-1)

int ret;
int func(){
  SSL_CTX *ctx;
  SSL *ssl;

  SSL_library_init();

  /* context configuration */
  ctx = SSL_CTX_new(SSLv23_client_method());
  if (ctx==NULL) fatal_error();

  SSL_CTX_set_options(ctx, SSL_OP_NO_SSLv2|SSL_OP_NO_SSLv3|SSL_OP_NO_TLSv1);

  ret = SSL_CTX_use_certificate_file(ctx, "cert.pem", SSL_FILETYPE_PEM);
  if (ret <= 0) fatal_error();

  ret = SSL_CTX_load_verify_locations(ctx, NULL, "ca/path");
  if (ret <= 0) fatal_error();

  /* Handle connection */
  ssl = SSL_new(ctx);
  if (ssl==NULL) fatal_error();
  SSL_set_fd(ssl, NULL);
  return SSL_connect(ssl);
}
```

### Unsafe standard encryption function

#### Issue

This issue occurs when a standard encryption function uses a broken or weak cryptographic algorithm. For example, `crypt` is not reentrant and is based on the risky Data Encryption Standard (DES).

#### Risk

The use of a broken, weak, or nonstandard algorithm can expose sensitive information to an attacker. A determined hacker can access the protected data using various techniques.

If the weak function is nonreentrant, when you use the function in concurrent programs, there is an additional race condition risk.

#### Fix

Avoid functions that use these encryption algorithms. Instead, use a reentrant function that uses a stronger encryption algorithm.

**Note** Some implementations of `crypt` support additional, possibly more secure, encryption algorithms.

#### Example — Decrypting Password Using crypt

```
#define _GNU_SOURCE
#include <pwd.h>
#include <string.h>
#include <crypt.h>

volatile int rd = 1;

const char *salt = NULL;
struct crypt_data input, output;

int verif_pwd(const char *pwd, const char *cipher_pwd, int safe)
{
    int r = 0;
    char *decrypted_pwd = NULL;

    switch(safe)
    {
      case 1:
        decrypted_pwd = crypt_r(pwd, cipher_pwd, &output);
        break;

      case 2:
        decrypted_pwd = crypt_r(pwd, cipher_pwd, &output);
        break;

      default:
        decrypted_pwd = crypt(pwd, cipher_pwd);
```

```
            break;
    }

    r = (strcmp(cipher_pwd, decrypted_pwd) == 0);

    return r;
}
```

In this example, crypt_r and crypt decrypt a password. However, crypt is nonreentrant and uses the unsafe Data Encryption Standard algorithm.

**Correction — Use crypt_r**

One possible correction is to replace crypt with crypt_r.

```
#define _GNU_SOURCE
#include <pwd.h>
#include <string.h>
#include <crypt.h>

volatile int rd = 1;

const char *salt = NULL;
struct crypt_data input, output;

int verif_pwd(const char *pwd, const char *cipher_pwd, int safe)
{
    int r = 0;
    char *decrypted_pwd = NULL;

    switch(safe)
    {
      case 1:
        decrypted_pwd = crypt_r(pwd, cipher_pwd, &output);
        break;

      case 2:
        decrypted_pwd = crypt_r(pwd, cipher_pwd, &output);
        break;

      default:
        decrypted_pwd = crypt_r(pwd, cipher_pwd, &output);
        break;
    }

    r = (strcmp(cipher_pwd, decrypted_pwd) == 0);

    return r;
}
```

CWE-522

# CWE Rule 547

Use of Hard-coded, Security-relevant Constants

## Description

### Rule Description

*The program uses hard-coded constants instead of symbolic names for security-critical values, which increases the likelihood of mistakes during code maintenance or security policy change.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Hard-coded buffer size**
- **Hard-coded loop boundary**
- **Hard-coded object size used to manipulate memory**
- **Hard-coded sensitive data**

## Examples

### Hard-coded buffer size

#### Issue

This issue occurs when you use a numerical value instead of a symbolic constant when declaring a memory buffer such as an array.

#### Risk

Hard-coded buffer size causes the following issues:

- Hard-coded buffer size increases the likelihood of mistakes and therefore maintenance costs. If a policy change requires developers to change the buffer size, they must change every occurrence of the buffer size in the code.
- Hard-constant constants can be exposed to attack if the code is disclosed.

#### Fix

Use a symbolic name instead of a hard-coded constant for buffer size. Symbolic names include `const`-qualified variables, `enum` constants, or macros.

`enum` constants are recommended.

- Macros are replaced by their constant values after preprocessing. Therefore, they can expose the loop boundary.
- `enum` constants are known at compilation time. Therefore, compilers can optimize the loops more efficiently.

  `const`-qualified variables are usually known at run time.

#### Example — Hard-Coded Buffer Size

```
int table[100];

void read(int);

void func(void) {
    for (int i=0; i<100; i++)
        read(table[i]);
}
```

In this example, the size of the array `table` is hard-coded.

#### Correction — Use Symbolic Name

One possible correction is to replace the hard-coded size with a symbolic name.

```
const int MAX_1 = 100;
#define MAX_2 100
enum { MAX_3 = 100 };

int table_1[MAX_1];
int table_2[MAX_2];
int table_3[MAX_3];

void read(int);

void func(void) {
    for (int i=0; i < MAX_1; i++)
        read(table_1[i]);
    for (int i=0; i < MAX_2; i++)
        read(table_2[i]);
    for (int i=0; i < MAX_3; i++)
        read(table_3[i]);
}
```

### Hard-coded loop boundary

#### Issue

This issue occurs when you use a numerical value instead of symbolic constant for the boundary of a `for`, `while` or `do-while` loop.

#### Risk

Hard-coded loop boundary causes the following issues:

- Hard-coded loop boundary makes the code vulnerable to denial of service attacks when the loop involves time-consuming computation or resource allocation.
- Hard-coded loop boundary increases the likelihood of mistakes and maintenance costs. If a policy change requires developers to change the loop boundary, they must change every occurrence of the boundary in the code.

  For instance, the loop boundary is 10000 and represents the maximum number of client connections supported in a network server application. If the server supports more clients, you must change all instances of the loop boundary in your code. Even if the loop boundary occurs once, you have to search for a numerical value of `10000` in your code. The numerical value can occur in places other than the loop boundary. You must browse through those places before you find the loop boundary.

#### Fix

Use a symbolic name instead of a hard-coded constant for loop boundary. Symbolic names include `const`-qualified variables, `enum` constants or macros.`enum` constants are recommended because:

- Macros are replaced by their constant values after preprocessing. Therefore, they can expose the buffer size.
- `enum` constants are known at compilation time. Therefore, compilers can allocate storage for them more efficiently.

  `const`-qualified variables are usually known at run time.

#### Example — Hard-Coded Loop Boundary

```
void performOperation(int);

void func(void) {
    for (int i=0; i<100; i++)
        performOperation(i);
}
```

In this example, the boundary of the `for` loop is hard-coded.

#### Correction — Use Symbolic Name

One possible correction is to replace the hard-coded loop boundary with a symbolic name.

```
const int MAX_1 = 100;
#define MAX_2 100
enum { MAX_3 = 100 };

void performOperation_1(int);
void performOperation_2(int);
void performOperation_3(int);

void func(void) {
    for (int i=0; i<MAX_1; i++)
        performOperation_1(i);
    for (int i=0; i<MAX_2; i++)
        performOperation_2(i);
    for (int i=0; i<MAX_3; i++)
        performOperation_3(i);
}
```

### Hard-coded object size used to manipulate memory

#### Issue

This issue occurs when you use hard-coded constants as memory size arguments for these memory functions:

- Dynamic memory allocation function such as `malloc` or `calloc`.
- Memory manipulation functions such as `memcpy`, `memmove`, `memcmp`, or `memset`.

When performing memory operations with a string literal, Polyspace does not report a defect if you hard code the memory size.

#### Risk

If you hard code object size, your code is not portable to architectures with different type sizes. If the constant value is not the same as the object size, the buffer might or might not overflow.

#### Fix

For the size argument of memory functions, use `sizeof(`*`object`*`)`.

#### Example — Assume 4-Byte Integer Pointers

```
#include <stddef.h>
#include <stdlib.h>
enum {
    SIZE3   = 3,
    SIZE20  = 20
};
extern void fill_ints(int **matrix, size_t nb, size_t s);

void bug_hardcodedmemsize()
{
    size_t i, s;

    s = 4;
    int **matrix = (int **)calloc(SIZE20, s);
    if (matrix == NULL) {
        return; /* Indicate calloc() failure */
    }
    fill_ints(matrix, SIZE20, s);
    free(matrix);
}
```

In this example, the memory allocation function `calloc` is called with a memory size of 4. The memory is allocated for an integer pointer, which can be a more or less than 4 bytes depending on your target. If the integer pointer is not 4 bytes, your program can fail.

#### Correction — Use `sizeof(int *)`

When calling `calloc`, replace the hard-coded size with a call to `sizeof`. This change makes your code more portable.

```
#include <stddef.h>
#include <stdlib.h>
enum {
    SIZE3   = 3,
    SIZE20  = 20
};
extern void fill_ints(int **matrix, size_t nb, size_t s);

void corrected_hardcodedmemsize()
{
    size_t i, s;

    s = sizeof(int *);
    int **matrix = (int **)calloc(SIZE20, s);
    if (matrix == NULL) {
        return; /* Indicate calloc() failure */
    }
    fill_ints(matrix, SIZE20, s);
    free(matrix);
}
```

### Hard-coded sensitive data

#### Issue

This issue occurs when data that is potentially sensitive is directly exposed in the code, for instance, as string literals. The checker identifies certain data as sensitive from their use in certain functions such as password encryption functions.

Following data can be potentially sensitive.

| Type of Data | Functions That Indicate Sensitive Nature of Information |
|---|---|
| Host name | • sethostname, setdomainname, gethostbyname, gethostbyname2, getaddrinfo, gethostbyname_r, gethostbyname2_r (string argument)<br>• inet_aton, inet_pton, inet_net_pton, inet_addr, inet_network (string argument)<br>• mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (2nd argument) |
| Password | • CreateProcessWithLogonW, LogonUser (1st argument)<br>• mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (3rd argument) |
| Database | • MySQL: mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (4th argument)<br>• SQLite: sqlite3_open, sqlite3_open16, sqlite3_open_v2 (1st argument)<br>• PostgreSQL: PQconnectdb<br>• Microsoft SQL: SQLDriverConnect (3rd argument) |
| User name | • getpw, getpwnam, getpwnam_r, getpwuid, getpwuid_r |
| Salt | crypt, crypt_r (2nd argument) |

| Type of Data | Functions That Indicate Sensitive Nature of Information |
|---|---|
| Cryptography keys and initialization vectors | OpenSSL:<br>• EVP_CipherInit, EVP_EncryptInit, EVP_DecryptInit (3rd argument)<br>• EVP_CipherInit_ex, EVP_EncryptInit_ex, EVP_DecryptInit_ex (4th argument) |
| Seed | • srand, srandom, initstate (1st argument)<br>• OpenSSL: RAND_seed, RAND_add |

**Risk**

Information that is hardcoded can be queried from binaries generated from the code.

**Fix**

Avoid hard coding sensitive information.

**Example — Sensitive Data Exposed Through String Literals**

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

MYSQL *mysql_real_connect(MYSQL *mysql,
                          const char *host, const char *user, const char *passwd,
                          const char *db, unsigned int port, const char *unix_socket,
                          unsigned long client_flag);

typedef void * DbHandle;
extern MYSQL *sql;

// File that uses functions from "mysql.h"
const char *host = "localhost";
char *user = "guest";
char *passwd;

DbHandle connect_to_database_server(const char *db)
{
    passwd = (char*)"guest";
    return (DbHandle)
        mysql_real_connect (sql, host, user, passwd, db, 0, 0x0, 0);
}
```

In this example, the arguments host (host name), user (user name), and passwd (password) are string literals and directly exposed in the code.

Querying the generated binary for ASCII strings can reveal this information.

### Correction – Read Sensitive Data from Secured Configuration Files

One possible correction is to read the data from a configuration file. In the following corrected example, the call to function `connect_to_database_server_init` presumably reads the host name, user name, and password into its arguments from a secured configuration file.

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

MYSQL *mysql_real_connect(MYSQL *mysql,
                          const char *host, const char *user, const char *passwd,
                          const char *db, unsigned int port, const char *unix_socket,
                          unsigned long client_flag);

typedef void * DbHandle;
extern MYSQL *sql;

// File that uses functions from "mysql.h"

int connect_to_database_server_init(const char **host,
                                    const char **user,
                                    const char **passwd,
                                    const char **db);

DbHandle connect_to_database_server(const char *db)
{
    const char *host_from_cfg;
    const char *user_from_cfg;
    const char *passwd_from_cfg;
    const char *db_from_cfg;
    if (connect_to_database_server_init(&host_from_cfg,
                                        &user_from_cfg,
                                        &passwd_from_cfg,
                                        &db_from_cfg))
    {
        return (DbHandle)
            mysql_real_connect (sql, host_from_cfg, user_from_cfg,
                        passwd_from_cfg, db_from_cfg,  0, 0x0, 0);
    }
    else
        return (DbHandle)0x0;
}
```

Use of getlogin() in Multithreaded Application

## Description

### Rule Description

*The application uses the getlogin() function in a multithreaded context, potentially causing it to return incorrect values.*

### Polyspace Implementation

The rule checker checks for **Unsafe standard function**.

## Examples

### Unsafe standard function

**Issue**

This issue occurs when you use standard functions that are unsafe and must not be used for security-related programming. Functions can be unsafe for many reasons. Some functions are unsafe because they are nonreentrant. Other functions change behavior depending on the target or platform, making some implementations unsafe.

**Risk**

Some unsafe functions are not reentrant, meaning that the contents of the function are not locked during a call. So, an attacker can change the values midstream.

`getlogin` specifically can be unsafe depending on the implementation. Some implementations of `getlogin` return only the first eight characters of a log-in name. An attacker can use a different login with the same first eight characters to gain entry and manipulate the program.

**Fix**

Avoid unsafe functions for security-related purposes. If you cannot avoid unsafe functions, use a safer version of the function instead. For `getlogin`, use `getlogin_r`.

**Example — Using getlogin**

```
#include <stdio.h>
#include <unistd.h>
#include <sys/types.h>
#include <pwd.h>
#include <string.h>
#include <stdlib.h>

volatile int rd = 1;

int login_name_check(char *user)
{
    int r = -2;
    char *name = getlogin();
    if (name != NULL)
    {
        if (strcmp(name, user) == 0)
        {
            r = 0;
        }
        else
            r = -1;
    }

    return r;
}
```

This example uses `getlogin` to compare the user name of the current user to the given user name . However, `getlogin` can return something other than the current user name because a parallel process can change the string.

**Correction — Use `getlogin_r`**

One possible correction is to use `getlogin_r` instead of `getlogin`. `getlogin_r` is reentrant, so you can trust the result.

```
#define _POSIX_C_SOURCE 199506L // use of getlogin_r
#include <stdio.h>
#include <unistd.h>
#include <sys/types.h>
#include <pwd.h>
#include <string.h>
#include <stdlib.h>

volatile int rd = 1;

enum {  NAME_MAX_SIZE=64  };

int login_name_check(char *user)
{
    int r;
    char name[NAME_MAX_SIZE];

    if (getlogin_r(name, sizeof(name)) == 0)
    {
        if ((strlen(user) < sizeof(name)) &&
                     (strncmp(name, user, strlen(user)) == 0))
        {
            r = 0;
        }
        else
            r = -1;
    }
    else
        r = -2;
    return r;
}
```

CWE-558

# CWE Rule 560

Use of umask() with chmod-style Argument

## Description

### Rule Description

*The product calls umask() with an incorrect argument that is specified as if it is an argument to chmod().*

### Polyspace Implementation

The rule checker checks for **Umask used with chmod-style arguments**.

## Examples

### Umask used with chmod-style arguments

#### Issue

This issue occurs when `umask` commands have arguments specified in the style of arguments to `chmod` and provide possibly unintended permissions. For instance:

- The `umask` command provides more permissions to the group than the current user.
- The `umask` command provides more permissions to other users than the group.

For new files, the `umask` argument or the mask value specifies which permissions *not* to set, in other words, which permissions to remove. The mask is bitwise-negated and then applied to new file permissions. In contrast, `chmod` sets the permissions as you specify them.

#### Risk

If you use `chmod`-style arguments, you specify opposite permissions of what you want. This mistake can give external users unintended read/write access to new files and folders.

#### Fix

To fix this defect, perform both of these tasks:

- Enable read permission for the user.
- Set the mask value so that the user (`u`) has equal or fewer permissions turned off than the group (`g`) and the group has equal or fewer permissions turned off than other users (`o`), or `u <= g <= o`.

You can see the umask value by calling,

```
umask
```

or the symbolic value by calling,

```
umask -S
```

**Example — Setting the Default Mask**

```
#include <stdio.h>
#include <assert.h>
#include <sys/types.h>
#include <sys/stat.h>

typedef mode_t (*umask_func)(mode_t);

const mode_t default_mode = (
    S_IRUSR    /* 00400 */
    | S_IWUSR  /* 00200 */
    | S_IRGRP  /* 00040 */
    | S_IWGRP  /* 00020 */
    | S_IROTH  /* 00004 */
    | S_IWOTH  /* 00002 */
    );         /* 00666 (i.e. -rw-rw-rw-) */

static void my_umask(mode_t mode)
{
    umask(mode);
}

int umask_use(mode_t m)
{
    my_umask(default_mode);
    return 0;
}
```

This example uses a function called `my_umask` to set the default mask mode. However, the `default_mode` variable gives the permissions 666 or `-rw-rw-rw`. `umask` negates this value. However, this negation means the default mask mode turns off read/write permissions for the user, group users, and other outside users.

**Correction — Negate Preferred Permissions**

One possible correction is to negate the `default_mode` argument to `my_umask`. This correction nullifies the negation `umask` for new files.

```
#include <stdio.h>
#include <assert.h>
#include <sys/types.h>
#include <sys/stat.h>

typedef mode_t (*umask_func)(mode_t);

const mode_t default_mode = (
    S_IRUSR    /* 00400 */
    | S_IWUSR  /* 00200 */
    | S_IRGRP  /* 00040 */
    | S_IWGRP  /* 00020 */
    | S_IROTH  /* 00004 */
    | S_IWOTH  /* 00002 */
    );         /* 00666 (i.e. -rw-rw-rw-) */

static void my_umask(mode_t mode)
{
    umask(mode);
}

int umask_use(mode_t m)
{
    my_umask(~default_mode);
    return 0;
}
```

Dead Code

## Description

### Rule Description

*The software contains dead code, which can never be executed.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Dead code**
- **Static uncalled function**
- **Unreachable code**

## Examples

### Dead code

#### Issue

This issue occurs when a block of code cannot be reached because of a condition that is always true or false. This defect excludes:

- `Code deactivated by constant false condition`, which checks for directives with compile-time constants such as `#if 0` or `if(0)`.
- `Unreachable code`, which checks for code after a control escape such as `goto`, `break`, or `return`.
- `Useless if`, which checks for if statements that are always true.

#### Risk

Dead code wastes development time, memory and execution cycles. Developers have to maintain code that is not being executed. Instructions that are not executed still have to be stored and cached.

Dead code often represents legacy code that is no longer used. Cleaning up dead code periodically reduces future maintenance.

#### Fix

The fix depends on the root cause of the defect. For instance, the root cause can be an error condition that is checked twice on the same execution path, making the second check redundant and the corresponding block dead code.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder

Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you see dead code from use of functions such as `isinf` and `isnan`, enable an analysis mode that takes into account non-finite values. See `Consider non finite floats (-allow-non-finite-floats)`.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Dead Code from if-Statement**

```
#include <stdio.h>

int Return_From_Table(int ch){

    int table[5];

    /* Create a table */
    for(int i=0;i<=4;i++){
        table[i]=i^2+i+1;
    }

    if(table[ch]>100){ /* Defect: Condition always false */
         return 0;
    }
    return table[ch];
}
```

The maximum value in the array `table` is `4^2+4+1=21`, so the test expression `table[ch]>100` always evaluates to false. The `return 0` in the `if` statement is not executed.

**Correction — Remove Dead Code**

One possible correction is to remove the `if` condition from the code.

```
#include <stdio.h>

int Return_From_Table(int ch){

    int table[5];

    /* Create a table */
    for(int i=0;i<=4;i++){
        table[i]=i^2+i+1;
    }

    return table[ch];
}
```

#### Example — Dead Code for if with Enumerated Type

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS))
        card = UNKNOWN_SUIT;

    if (card > 7) {
        do_something(card);
    }
}
```

The type `suit` is enumerated with five options. However, the conditional expression `card > 7` always evaluates to false because `card` can be at most 5. The content in the `if` statement is not executed.

#### Correction — Change Condition

One possible correction is to change the if-condition in the code. In this correction, the 7 is changed to `HEART` to relate directly to the type of `card`.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS))
        card = UNKNOWN_SUIT;

    if (card > HEARTS) {
        do_something(card);
    }
}
```

### Static uncalled function

#### Issue

This issue occurs when a `static` function is not called in the same file where it is defined.

#### Risk

Uncalled functions often result from legacy code and cause unnecessary maintenance.

#### Fix

If the function is not meant to be called, remove the function. If the function is meant for debugging purposes only, wrap the function definition in a debug macro.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Uncalled function error**

Save the following code in the file `Initialize_Value.c`

```
#include <stdlib.h>
#include <stdio.h>

static int Initialize(void)
/* Defect: Function not called */
  {
   int input;
   printf("Enter an integer:");
   scanf("%d",&input);
   return(input);
  }

 void main()
  {
   int num;

   num=0;

   printf("The value of num is %d",num);
  }
```

The `static` function `Initialize` is not called in the file `Initialize_Value.c`.

**Correction — Call Function at Least Once**

One possible correction is to call `Initialize` at least once in the file `Initialize_Value.c`.

```
#include <stdlib.h>
#include <stdio.h>

static int Initialize(void)
  {
   int input;
   printf("Enter an integer:");
   scanf("%d",&input);
   return(input);
  }

 void main()
  {
   int num;

   /* Fix: Call static function Initialize */
   num=Initialize();

   printf("The value of num is %d",num);
  }
```

## Unreachable code

### Issue

This issue occurs when a section of code cannot be reached because of a previous break in control flow.

Statements such as `break`, `goto`, and `return`, move the flow of the program to another section or function. Because of this flow escape, the statements following the control-flow code, statistically, do not execute, and therefore the statements are unreachable.

This check also finds code following trivial infinite loops, such as `while(1)`. These types of loops only release the flow of the program by exiting the program. This type of exit causes code after the infinite loop to be unreachable.

### Risk

Unreachable code wastes development time, memory and execution cycles. Developers have to maintain code that is not being executed. Instructions that are not executed still have to be stored and cached.

### Fix

The fix depends on the intended functionality of the unreachable code. If you want the code to be executed, check the placement of the code or the prior statement that diverts the control flow. For instance, if the unreachable code follows a `return` statement, you might have to switch their order or remove the `return` statement altogether.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

### Example — Unreachable Code After Return

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void guess(suit s);

suit deal(void){
    suit card = nextcard();
    if( (card < SPADES) || (card > CLUBS) )
        card = UNKNOWN_SUIT;
        return card;

    if (card < HEARTS) {
        guess(card);
    }
    return card;
}
```

In this example, there are missing braces and misleading indentation. The first `return` statement changes the flow of code back to where the function was called. Because of this return statement, the `if`-block and second `return` statement do not execute.

If you correct the indentation and the braces, the error becomes clearer.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void guess(suit s);

suit deal(void){
    suit card = nextcard();
    if( (card < SPADES) || (card > CLUBS) ){
        card = UNKNOWN_SUIT;
    }
    return card;

    if (card < HEARTS) {
        guess(card);
    }
    return card;
}
```

#### Correction — Remove Return

One possible correction is to remove the escape statement. In this example, remove the first `return` statement to reach the final `if` statement.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void guess(suit s);

suit deal(void){
    suit card = nextcard();
    if( (card < SPADES) || (card > CLUBS) )
    {
        card = UNKNOWN_SUIT;
    }

    if(card < HEARTS)
    {
        guess(card);
    }
    return card;
}
```

#### Correction — Remove Unreachable Code

Another possible correction is to remove the unreachable code if you do not need it. Because the function does not reach the second `if`-statement, removing it simplifies the code and does not change the program behavior.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void guess(suit s);

suit deal(void){
    suit card = nextcard();
    if( (card < SPADES) || (card > CLUBS) )
    {
        card = UNKNOWN_SUIT;
    }
    return card;
}
```

**Example — Infinite Loop Causing Unreachable Code**

```
int add_apples(int apple) {
    int count = 1;
    while(1) {
        if(apple < 99){
            apple++;
            count++;
        }else{
            count--;
        }
    }
    return count;
}
```

In this example, the `while(1)` statement creates an infinite loop. The `return count` statement following this infinite loop is unreachable because the only way to exit this infinite loop is to exit the program.

**Correction — Rewrite Loop Condition**

One possible correction is to change the loop condition to make the `while` loop finite. In the example correction here, the loop uses the statement from the `if` condition: `apple < 99`.

```
int add_apples1(int apple) {
    int count = 0;
    while(apple < 99) {
        apple++;
        count++;
    }
    if(count == 0)
        count = -1;
    return count;
}
```

**Correction — Add a Break Statement**

Another possible correction is to add a break from the infinite loop, so there is a possibility of reaching code after the infinite loop. In this example, a `break` is added to the `else` block making the `return count` statement reachable.

```
int add_apples(int apple) {
    int count = 1;
    while(1) {
        if(apple < 99)
        {
            apple++;
            count++;
        }else{
            count--;
            break;
        }
    }
    return count;
}
```

#### Correction — Remove Unreachable Code

Another possible correction is to remove the unreachable code. This correction cleans up the code and makes it easier to review and maintain. In this example, remove the return statement and change the function return type to `void`.

```
void add_apples(int apple) {
    int count = 1;
    while(1) {
        if(apple < 99)
        {
            apple++;
            count++;
        }else{
            count--;
        }
    }
}
```

Return of Stack Variable Address

## Description

### Rule Description

*A function returns the address of a stack variable, which will cause unintended program behavior, typically in the form of a crash.*

### Polyspace Implementation

The rule checker checks for **Pointer or reference to stack variable leaving scope**.

## Examples

### Pointer or reference to stack variable leaving scope

#### Issue

This issue occurs when a pointer or reference to a local variable leaves the scope of the variable. For instance:

- A function returns a pointer to a local variable.
- A function performs the assignment `globPtr = &locVar`. `globPtr` is a global pointer variable and `locVar` is a local variable.
- A function performs the assignment `*paramPtr = &locVar`. `paramPtr` is a function parameter that is, for instance, an `int**` pointer and `locVar` is a local `int` variable.
- A C++ method performs the assignment `memPtr = &locVar`. `memPtr` is a pointer data member of the class the method belongs to. `locVar` is a variable local to the method.
- (C++11 and later) A function returns a lambda expression object that captures local variables of the function by reference.

The defect also applies to memory allocated using the `alloca` function. The defect does not apply to static, local variables. Polyspace assumes that the local objects within a function definition are in the same scope.

#### Risk

Local variables are allocated an address on the stack. Once the scope of a local variable ends, this address is available for reuse. Using this address to access the local variable value outside the variable scope can cause unexpected behavior.

If a pointer to a local variable leaves the scope of the variable, Polyspace Bug Finder highlights the defect. The defect appears even if you do not use the address stored in the pointer. For maintainable code, it is a good practice to not allow the pointer to leave the variable scope. Even if you do not use the address in the pointer now, someone else using your function can use the address, causing undefined behavior.

### Fix

Do not allow a pointer or reference to a local variable to leave the variable scope.

### Example — Pointer to Local Variable Returned from Function

```
void func2(int *ptr) {
    *ptr = 0;
}

int* func1(void) {
    int ret = 0;
    return &ret ;
}
void main(void) {
    int* ptr = func1() ;
    func2(ptr) ;
}
```

In this example, `func1` returns a pointer to local variable `ret`.

In `main`, `ptr` points to the address of the local variable. When `ptr` is accessed in `func2`, the access is illegal because the scope of `ret` is limited to `func1`,

### Example — Pointer to Local Variable Escapes Through Lambda Expression

```
auto createAdder(int amountToAdd) {
  int addThis = amountToAdd;
  auto adder = [&] (int initialAmount) {
      return (initialAmount + addThis);
  };
  return adder;
}

void func() {
  auto AddByTwo = createAdder(2);
  int res = AddByTwo(10);
}
```

In this example, the `createAdder` function defines a lambda expression `adder` that captures the local variable `addThis` by reference. The scope of `addThis` is limited to the `createAdder` function. When the object returned by `createAdder` is called, a reference to the variable `addThis` is accessed outside its scope. When accessed in this way, the value of `addThis` is undefined.

### Correction – Capture Local Variables by Copy in Lambda Expression Instead of Reference

If a function returns a lambda expression object, avoid capturing local variables by reference in the lambda object. Capture the variables by copy instead.

Variables captured by copy have the same lifetime as the lambda object, but variables captured by reference often have a smaller lifetime than the lambda object itself. When the lambda object is used, these variables accessed outside scope have undefined values.

```
auto createAdder(int amountToAdd) {
  int addThis = amountToAdd;
  auto adder = [=] (int initialAmount) {
      return (initialAmount + addThis);
  };
  return adder;
}

void func() {
  auto AddByTwo = createAdder(2);
  int res = AddByTwo(10);
}
```

Assignment to Variable without Use

## Description

### Rule Description

*The variable's value is assigned but never used, making it a dead store.*

### Polyspace Implementation

The rule checker checks for **Write without a further read**.

## Examples

### Write without a further read

#### Issue

This issue occurs when a value assigned to a variable is never read.

For instance, you write a value to a variable and then write a second value before reading the previous value. The first write operation is redundant.

#### Risk

Redundant write operations often indicate programming errors. For instance, you forgot to read the variable between two successive write operations or unintentionally read a different variable.

#### Fix

Identify the reason why you write to the variable but do not read it later. Look for common programming errors such as accidentally reading a different variable with a similar name.

If you determine that the write operation is redundant, remove the operation.

#### Example — Write Without Further Read Error

```
void sensor_amplification(void)
{
    extern int getsensor(void);
    int level;

    level = 4 * getsensor();
    /* Defect: Useless write */
}
```

After the variable `level` gets assigned the value `4 * getsensor()`, it is not read.

#### Correction — Use Value After Assignment

One possible correction is to use the variable `level` after the assignment.

```
#include <stdio.h>

void sensor_amplification(void)
{
    extern int getsensor(void);
    int level;

    level = 4 * getsensor();

    /* Fix: Use level after assignment */
    printf("The value is %d", level);

}
```

The variable `level` is printed, reading the new value.

### External Websites

CWE-563

# CWE Rule 570

Expression is Always False

## Description

### Rule Description

*The software contains an expression that will always evaluate to false.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Code deactivated by constant false condition**
- **Dead code**

## Examples

### Code deactivated by constant false condition

#### Issue

This issue occurs when a block of code is deactivated using a `#if 0` directive or `if(0)` condition.

#### Risk

A `#if 0` directive or `if(0)` condition is used to temporarily deactivate segments of code. If your production code contains these directives, it means that the deactivation has not been lifted before shipping the code.

#### Fix

If the segment of code is present for debugging purposes only, remove the segment from production code. If the deactivation occurred by accident, remove the `#if 0` and `#endif` statements.

Often, a segment of code is deactivated for specific conditions, for instance, a specific operating system. Use macros with the `#if` directive to indicate these conditions instead of deactivating the code completely with a `#if 0` directive. For instance, GCC provides macros to detect the Windows operating system:

```
#ifdef _WIN32
   //Code deactivated for all operating systems
   //Other than 32-bit Windows
#endif
```

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.

- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Code Deactivated by Constant False Condition Error**

```
#include<stdio.h>
int Trim_Value(int* Arr,int Size,int Cutoff)
{
    int Count=0;

    for(int i=0;i < Size;i++){
        if(Arr[i]>Cutoff){
            Arr[i]=Cutoff;
            Count++;
        }
    }

    #if 0
    /* Defect: Code Segment Deactivated */

    if(Count==0){
        printf("Values less than cutoff.");
    }
     #endif

    return Count;
}
```

In the preceding code, the `printf` statement is placed within a `#if #endif` directive. The software treats the portion within the directive as code comments and not compiled.

**Correction — Change `#if 0` to `#if 1`**

Unless you intended to deactivate the `printf` statement, one possible correction is to reactivate the block of code in the `#if #endif` directive. To reactivate the block, change `#if 0` to `#if 1`.

```
#include<stdio.h>
int Trim_Value(int* Arr,int Size,int Cutoff)
{
 int Count=0;

 for(int i=0;i < Size;i++)
     {
      if(Arr[i]>Cutoff)
           {
            Arr[i]=Cutoff;
            Count++;
           }
     }

 /* Fix: Replace #if 0 by #if 1 */
 #if 1
      if(Count==0)
           {
            printf("Values less than cutoff.");
           }
 #endif
 return Count;
}
```

### Dead code

#### Issue

This issue occurs when a block of code cannot be reached because of a condition that is always true or false. This defect excludes:

- `Code deactivated by constant false condition`, which checks for directives with compile-time constants such as `#if 0` or `if(0)`.
- `Unreachable code`, which checks for code after a control escape such as `goto`, `break`, or `return`.
- `Useless if`, which checks for if statements that are always true.

#### Risk

Dead code wastes development time, memory and execution cycles. Developers have to maintain code that is not being executed. Instructions that are not executed still have to be stored and cached.

Dead code often represents legacy code that is no longer used. Cleaning up dead code periodically reduces future maintenance.

#### Fix

The fix depends on the root cause of the defect. For instance, the root cause can be an error condition that is checked twice on the same execution path, making the second check redundant and the corresponding block dead code.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you see dead code from use of functions such as `isinf` and `isnan`, enable an analysis mode that takes into account non-finite values. See `Consider non finite floats (-allow-non-finite-floats)`.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Dead Code from if-Statement

```
#include <stdio.h>
```

```
int Return_From_Table(int ch){

    int table[5];

    /* Create a table */
    for(int i=0;i<=4;i++){
        table[i]=i^2+i+1;
    }

    if(table[ch]>100){ /* Defect: Condition always false */
         return 0;
    }
    return table[ch];
}
```

The maximum value in the array `table` is `4^2+4+1=21`, so the test expression `table[ch]>100` always evaluates to false. The `return 0` in the `if` statement is not executed.

**Correction — Remove Dead Code**

One possible correction is to remove the `if` condition from the code.

```
#include <stdio.h>

int Return_From_Table(int ch){

    int table[5];

    /* Create a table */
    for(int i=0;i<=4;i++){
        table[i]=i^2+i+1;
    }

    return table[ch];
}
```

**Example — Dead Code for if with Enumerated Type**

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS))
        card = UNKNOWN_SUIT;

    if (card > 7) {
        do_something(card);
    }
}
```

The type `suit` is enumerated with five options. However, the conditional expression `card > 7` always evaluates to false because `card` can be at most 5. The content in the `if` statement is not executed.

#### Correction — Change Condition

One possible correction is to change the if-condition in the code. In this correction, the 7 is changed to HEART to relate directly to the type of `card`.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS))
        card = UNKNOWN_SUIT;

    if (card > HEARTS) {
        do_something(card);
    }
}
```

Expression is Always True

## Description

### Rule Description

*The software contains an expression that will always evaluate to true.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Dead code**
- **Useless if**

## Examples

### Dead code

#### Issue

This issue occurs when a block of code cannot be reached because of a condition that is always true or false. This defect excludes:

- `Code deactivated by constant false condition`, which checks for directives with compile-time constants such as `#if 0` or `if(0)`.
- `Unreachable code`, which checks for code after a control escape such as `goto`, `break`, or `return`.
- `Useless if`, which checks for if statements that are always true.

#### Risk

Dead code wastes development time, memory and execution cycles. Developers have to maintain code that is not being executed. Instructions that are not executed still have to be stored and cached.

Dead code often represents legacy code that is no longer used. Cleaning up dead code periodically reduces future maintenance.

#### Fix

The fix depends on the root cause of the defect. For instance, the root cause can be an error condition that is checked twice on the same execution path, making the second check redundant and the corresponding block dead code.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you see dead code from use of functions such as `isinf` and `isnan`, enable an analysis mode that takes into account non-finite values. See `Consider non finite floats (-allow-non-finite-floats)`.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

**Example — Dead Code from if-Statement**

```
#include <stdio.h>

int Return_From_Table(int ch){

    int table[5];

    /* Create a table */
    for(int i=0;i<=4;i++){
        table[i]=i^2+i+1;
    }

    if(table[ch]>100){ /* Defect: Condition always false */
         return 0;
    }
    return table[ch];
}
```

The maximum value in the array `table` is `4^2+4+1=21`, so the test expression `table[ch]>100` always evaluates to false. The `return 0` in the `if` statement is not executed.

**Correction — Remove Dead Code**

One possible correction is to remove the `if` condition from the code.

```
#include <stdio.h>

int Return_From_Table(int ch){

    int table[5];

    /* Create a table */
    for(int i=0;i<=4;i++){
        table[i]=i^2+i+1;
    }

    return table[ch];
}
```

**Example — Dead Code for if with Enumerated Type**

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
```

```
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS))
        card = UNKNOWN_SUIT;

    if (card > 7) {
        do_something(card);
    }
}
```

The type `suit` is enumerated with five options. However, the conditional expression `card > 7` always evaluates to false because `card` can be at most 5. The content in the `if` statement is not executed.

**Correction — Change Condition**

One possible correction is to change the if-condition in the code. In this correction, the 7 is changed to `HEART` to relate directly to the type of `card`.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS))
        card = UNKNOWN_SUIT;

    if (card > HEARTS) {
        do_something(card);
    }
}
```

## Useless if

**Issue**

This issue occurs on `if`-statements where the condition is always true. This issue occurs only on if-statements that do not have an else-statement.

This defect shows unnecessary `if`-statements when there is no difference in code execution if the `if`-statement is removed.

**Risk**

Unnecessary `if` statements often indicate a coding error. Perhaps the `if` condition is coded incorrectly or the `if` statement is not required at all.

**Fix**

The fix depends on the root cause of the defect. For instance, the root cause can be an error condition that is checked twice on the same execution path, making the second check redundant.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If the redundant condition represents defensive coding practices and you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — if with Enumerated Type

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS)){
        card = UNKNOWN_SUIT;
    }

    if (card < 7) {
        do_something(card);
    }
}
```

The type `suit` is enumerated with five options. However, the conditional expression `card < 7` always evaluates to true because `card` can be at most 5. The `if` statement is unnecessary.

#### Correction — Change Condition

One possible correction is to change the if-condition in the code. In this correction, the 7 is changed to `UNKNOWN_SUIT` to relate directly to the type of `card`.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS)){
        card = UNKNOWN_SUIT;
    }

    if (card > UNKNOWN_SUIT) {
        do_something(card);
    }
}
```

#### Correction — Remove If

Another possible correction is to remove the if-condition in the code. Because the condition is always true, you can remove the condition to simplify your code.

```
typedef enum _suit {UNKNOWN_SUIT, SPADES, HEARTS, DIAMONDS, CLUBS} suit;
suit nextcard(void);
void do_something(suit s);

void bridge(void)
{
    suit card = nextcard();
    if ((card < SPADES) || (card > CLUBS)){
        card = UNKNOWN_SUIT;
    }

    do_something(card);
}
```

### External Websites

CWE-571

# CWE Rule 587

Assignment of a Fixed Address to a Pointer

## Description

### Rule Description

*The software sets a pointer to a specific address other than NULL or 0.*

### Polyspace Implementation

The rule checker checks for **Function pointer assigned with absolute address**.

## Examples

### Function pointer assigned with absolute address

**Issue**

This issue occurs when a function pointer is assigned an absolute address.

Bug Finder considers expressions with any combination of literal constants as an absolute address. The one exception is when the value of the expression is zero.

**Risk**

Using a fixed address is not portable because it is possible that the address is invalid on other platforms.

An attacker can inject code at the absolute address, causing your program to execute arbitrary, possibly malicious, code.

**Fix**

Do not use an absolute address with function pointers.

**Example — Function Pointer Address Assignment**

```
extern int func0(int i, char c);
typedef int (*FuncPtr) (int, char);

FuncPtr funcptrabsoluteaddr() {
    return (FuncPtr)0x08040000;
}
```

In this example, the function returns a function pointer to the address `0x08040000`. If an attacker knows this absolute address, an attacker can compromise your program.

**Correction — Function Address**

One possible correction is to use the address of an existing function instead.

```
extern int func0(int i, char c);
typedef int (*FuncPtr) (int, char);
```

```
FuncPtr funcptrabsoluteaddr() {
    return &func0;
}
```

CWE-587

# CWE Rule 617

Reachable Assertion

## Description

### Rule Description

*The product contains an assert() or similar statement that can be triggered by an attacker, which leads to an application exit or other behavior that is more severe than necessary.*

### Polyspace Implementation

The rule checker checks for **Assertion**.

## Examples

### Assertion

**Issue**

This issue occurs when you use an `assert`, and the asserted expression is or could be false.

**Note** Polyspace does not flag `assert(0)` as an assertion defect because these statements are commonly used to disable certain sections of code.

**Risk**

Typically you use `assert` statements for functional testing in debug mode. An assertion failure found using static analysis indicates that the corresponding functional test would fail at run time.

**Fix**

The fix depends on the root cause of the defect. For instance, the root cause can be unconstrained input from an external source that eventually led to the assertion failure.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.

- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Check Assertion on Unsigned Integer

```
#include <assert.h>

void asserting_x(unsigned int theta) {
    theta =+ 5;
    assert(theta < 0);
}
```

In this example, the `assert` function checks if the input variable, `theta`, is less than or equal to zero. The assertion fails because `theta` is an unsigned integer, so the value at the beginning of the function is at least zero. The += statement increases this positive value by five. Therefore, the range of `theta` is `[5..MAX_INT]`. `theta` is always greater than zero.

#### Correction — Change Assert Expression

One possible correction is to change the assertion expression. By changing the *less-than-or-equal-to* sign to a *greater-than-or-equal-to* sign, the assertion does not fail.

```
#include <assert.h>

void asserting_x(unsigned int theta) {
    theta =+ 5;
    assert(theta > 0);
}
```

#### Correction — Fix Code

One possible correction is to fix the code related to the assertion expression. If the assertion expression is true, fix your code so the assertion passes.

```
#include <assert.h>
#include <stdlib.h>

void asserting_x(int theta) {
    theta = -abs(theta);
    assert(theta < 0);
}
```

#### Example — Asserting Zero

```
#include <assert.h>

#define FLAG 0

int main(void){
    int i_test_z = 0;
    float f_test_z = (float)i_test_z;

    assert(i_test_z);
    assert(f_test_z);
    assert(FLAG);

    return 0;
}
```

In this example, Polyspace does not flag `assert(FLAG)` as a violation because a macro defines `FLAG` as `0`. The Polyspace Bug Finder assertion checker does not flag assertions with a constant zero parameter, `assert(0)`. These types of assertions are commonly used as dynamic checks during runtime. By inserting `assert(0)`, you indicate that the program must not reach this statement during run time, otherwise the program crashes.

However, the assertion checker does flag failed assertions caused by a variable value equal to zero, as seen in the example with `assert(i_test_z)` and `assert(f_test_z)`.

## Check Information

**Category:** Error Conditions, Return Values, Status Codes

# Version History

**Introduced in R2023a**

### External Websites

CWE-617

# CWE Rule 676

Use of Potentially Dangerous Function

## Description

### Rule Description

*The program invokes a potentially dangerous function that could introduce a vulnerability if it is used incorrectly, but the function can also be used safely.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Buffer overflow from incorrect string format specifier**
- **Data race through standard library function call**
- **Destination buffer overflow in string manipulation**
- **Unsafe call to a system function**
- **Unsafe conversion from string to numerical value**
- **Use of dangerous standard function**
- **Use of rand() for generating pseudorandom number**

## Examples

### Buffer overflow from incorrect string format specifier

**Issue**

This issue occurs when the format specifier argument for functions such as `sscanf` leads to an overflow or underflow in the memory buffer argument.

**Risk**

If the format specifier specifies a precision that is greater than the memory buffer size, an overflow occurs. Overflows can cause unexpected behavior such as memory corruption.

**Fix**

Use a format specifier that is compatible with the memory buffer size.

**Example — Memory Buffer Overflow**

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%33c", buf);
}
```

In this example, `buf` can contain 32 `char` elements. Therefore, the format specifier `%33c` causes a buffer overflow.

#### Correction — Use Smaller Precision in Format Specifier

One possible correction is to read a smaller number of elements into the buffer.

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%32c", buf);
}
```

### Data race through standard library function call

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”.*

This issue occurs when:

1. Multiple tasks call the same standard library function.

   For instance, multiple tasks call the `strerror` function.
2. The calls are not protected using a common protection.

   For instance, the calls are not protected by the same critical section.

Functions flagged by this defect are not guaranteed to be reentrant. A function is reentrant if it can be interrupted and safely called again before its previous invocation completes execution. If a function is not reentrant, multiple tasks calling the function without protection can cause concurrency issues. For the list of functions that are flagged, see CON33-C: Avoid race conditions when using library functions.

To find this defect, you must specify the multitasking options before analysis. To specify these options, on the **Configuration** pane, select **Multitasking**. For more information, see “Configuring Polyspace Multitasking Analysis Manually”.

#### Risk

The functions flagged by this defect are nonreentrant because their implementations can use global or static variables. When multiple tasks call the function without protection, the function call from one task can interfere with the call from another task. The two invocations of the function can concurrently access the global or static variables and cause unpredictable results.

The calls can also cause more serious security vulnerabilities, such as abnormal termination, denial-of-service attack, and data integrity violations.

#### Fix

To fix this defect, do one of the following:

- Use a reentrant version of the standard library function if it exists.

  For instance, instead of `strerror()`, use `strerror_r()` or `strerror_s()`. For alternatives to functions flagged by this defect, see the documentation for CON33-C.
- Protect the function calls using common critical sections or temporal exclusion.

See `Critical section details (-critical-section-begin -critical-section-end)` and `Temporally exclusive tasks (-temporal-exclusions-file)`.

To identify existing protections that you can reuse, see the table and graphs associated with the result. The table shows each pair of conflicting calls. The **Access Protections** column shows existing protections on the calls. To see the function call sequence leading to the conflicts, click the icon. For an example, see below.

**Example — Unprotected Call to Standard Library Function from Multiple Tasks**

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char *errmsg = strerror(errno);
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    func(fptr1);
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     func(fptr2);
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

In this example, to emulate multitasking behavior, specify the following options:

| Option | Specification |
|---|---|
| `Configure multitasking manually` | ☑ |

| Option | Specification | |
|---|---|---|
| `Tasks (-entry-points)` | `task1`<br>`task2`<br>`task3` | |
| `Critical section details (-critical-section-begin -critical-section-end)` | **Starting routine** | **Ending routine** |
| | `begin_critical_section` | `end_critical_section` |

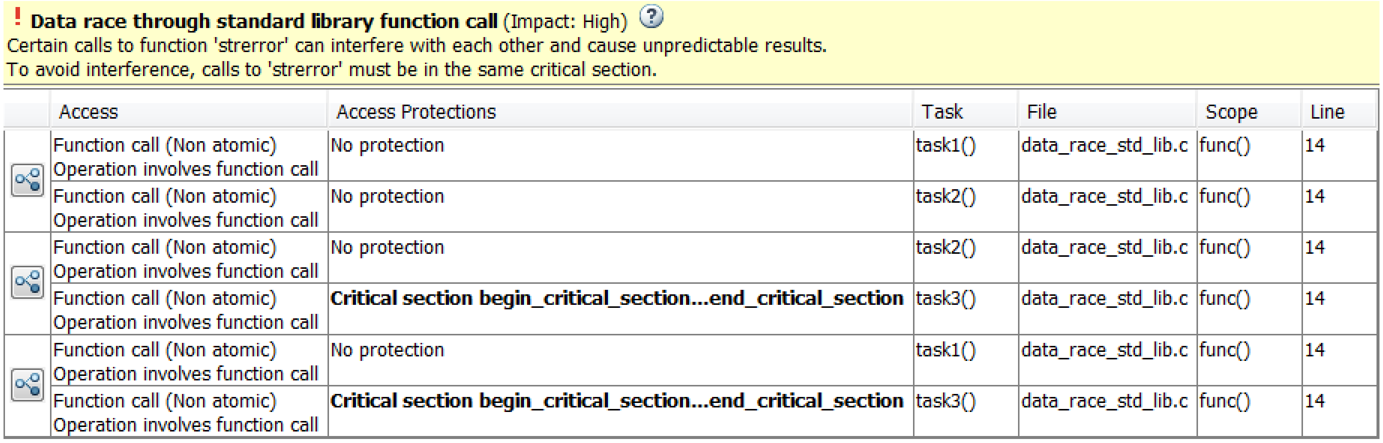
On the command-line, you can use the following:

```
polyspace-bug-finder
  -entry-points task1,task2,task3
  -critical-section-begin begin_critical_section:cs1
  -critical-section-end end_critical_section:cs1
```

In this example, the tasks, `task1`, `task2` and `task3`, call the function `func`. `func` calls the nonreentrant standard library function, `strerror`.

Though `task3` calls `func` inside a critical section, other tasks do not use the same critical section. Operations in the critical section of `task3` are not mutually exclusive with operations in other tasks.

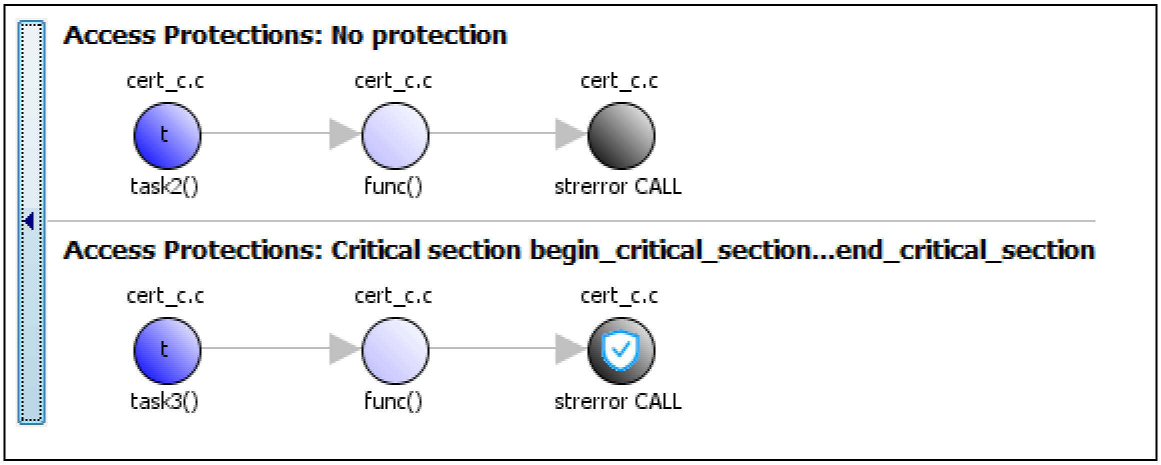
These three tasks are calling a nonreentrant standard library function without common protection. In your result details, you see each pair of conflicting function calls.



! **Data race through standard library function call** (Impact: High)
Certain calls to function 'strerror' can interfere with each other and cause unpredictable results.
To avoid interference, calls to 'strerror' must be in the same critical section.

| | Access | Access Protections | Task | File | Scope | Line |
|---|---|---|---|---|---|---|
| | Function call (Non atomic)<br>Operation involves function call | No protection | task1() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task2() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task2() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | **Critical section begin_critical_section...end_critical_section** | task3() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | No protection | task1() | data_race_std_lib.c | func() | 14 |
| | Function call (Non atomic)<br>Operation involves function call | **Critical section begin_critical_section...end_critical_section** | task3() | data_race_std_lib.c | func() | 14 |

If you click the icon, you see the function call sequence starting from the entry point to the standard library function call. You also see that the call starting from `task3` is in a critical section. The **Access Protections** entry shows the lock and unlock function that begin and end the critical section. In this example, you see the functions `begin_critical_section` and `end_critical_section`.



Access Protections: No protection
cert_c.c
t
task2()
cert_c.c
func()
cert_c.c
strerror CALL
Access Protections: Critical section begin_critical_section...end_critical_section
cert_c.c
t
task3()
cert_c.c
func()
cert_c.c
strerror CALL

**Correction — Use Reentrant Version of Standard Library Function**

One possible correction is to use a reentrant version of the standard library function `strerror`. You can use the POSIX version `strerror_r` which has the same functionality but also guarantees thread-safety.

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);
enum { BUFFERSIZE = 64 };

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char errmsg[BUFFERSIZE];
    if (strerror_r(errno, errmsg, BUFFERSIZE) != 0) {
      /* Handle error */
    }
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    func(fptr1);
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     func(fptr2);
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

**Correction — Place Function Call in Critical Section**

One possible correction is to place the call to `strerror` in critical section. You can implement the critical section in multiple ways.

For instance, you can place the call to the intermediate function `func` in the same critical section in the three tasks. When `task1` enters its critical section, the other tasks cannot enter their critical sections until `task1` leaves its critical section. The calls to `func` and therefore the calls to `strerror` from the three tasks cannot interfere with each other.

To implement the critical section, in each of the three tasks, call `func` between calls to `begin_critical_section` and `end_critical_section`.

```
#include <errno.h>
#include <stdio.h>
#include <string.h>

void begin_critical_section(void);
void end_critical_section(void);

FILE *getFilePointer(void);

void func(FILE *fp) {
  fpos_t pos;
  errno = 0;
  if (0 != fgetpos(fp, &pos)) {
    char *errmsg = strerror(errno);
    printf("Could not get the file position: %s\n", errmsg);
  }
}

void task1(void) {
    FILE* fptr1 = getFilePointer();
    begin_critical_section();
    func(fptr1);
    end_critical_section();
}

void task2(void) {
     FILE* fptr2 = getFilePointer();
     begin_critical_section();
     func(fptr2);
     end_critical_section();
}

void task3(void) {
     FILE* fptr3 = getFilePointer();
     begin_critical_section();
     func(fptr3);
     end_critical_section();
}
```

#### Correction — Make Tasks Temporally Exclusive

Another possible correction is to make the tasks, `task1`, `task2` and `task3`, temporally exclusive. Temporally exclusive tasks cannot execute concurrently.

On the **Configuration** pane, specify the following additional options:

| Option | Value |
|---|---|
| Temporally exclusive tasks (-temporal-exclusions-file) | task1 task2 task3 |

On the command-line, you can use the following:

```
 polyspace-bug-finder
     -temporal-exclusions-file "C:\exclusions_file.txt"
```

where the file `C:\exclusions_file.txt` has the following line:

```
task1 task2 task3
```

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

#### Example — Buffer Overflow in sprintf Use

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

**Correction — Use `snprintf` Instead of `sprintf`**

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Unsafe call to a system function

**Issue**

This issue occurs when you use a function that invokes an implementation-defined command processor. These functions include:

- The C standard `system()` function.
- The POSIX `popen()` function.
- The Windows `_popen()` and `_wpopen()` functions.

**Risk**

If the argument of a function that invokes a command processor is not sanitized, it can cause exploitable vulnerabilities. An attacker can execute arbitrary commands or read and modify data anywhere on the system.

**Fix**

Do not use a `system`-family function to invoke a command processor. Instead, use safer functions such as POSIX `execve()` and WinAPI `CreateProcess()`.

**Example — system() Called**

```
# include <string.h>
# include <stdlib.h>
# include <stdio.h>
# include <unistd.h>

enum {
SIZE512=512,
SIZE3=3};

void func(char *arg)
{
    char buf[SIZE512];
    int retval=sprintf(buf, "/usr/bin/any_cmd %s", arg);
    if (retval<=0 || retval>SIZE512){
        /* Handle error */
        abort();
    }
    /* Use of system() to pass any_cmd with
    unsanitized argument to command processor */

    if (system(buf) == -1) {
    /* Handle error */
  }
}
```

In this example, `system()` passes its argument to the host environment for the command processor to execute. This code is vulnerable to an attack by command-injection.

**Correction — Sanitize Argument and Use execve()**

In the following code, the argument of `any_cmd` is sanitized, and then passed to `execve()` for execution. `exec`-family functions are not vulnerable to command-injection attacks.

```
# include <string.h>
# include <stdlib.h>
# include <stdio.h>
# include <unistd.h>

enum {
SIZE512=512,
SIZE3=3};

void func(char *arg)
{
  char *const args[SIZE3] = {"any_cmd", arg, NULL};
  char  *const env[] = {NULL};

  /* Sanitize argument */

  /* Use execve() to execute any_cmd. */

  if (execve("/usr/bin/time", args, env) == -1) {
    /* Handle error */
  }
}
```

### Unsafe conversion from string to numerical value

**Issue**

This issue occurs when you perform conversions from strings to integer or floating-point values and your conversion method does not include robust error handling.

**Risk**

Converting a string to numerical value can cause data loss or misinterpretation. Without validation of the conversion or error handling, your program continues with invalid values.

#### Fix

- Add additional checks to validate the numerical value.
- Use a more robust string-to-numeric conversion function such as `strtol`, `strtoll`, `strtoul`, or `strtoull`.

#### Example — Conversion With atoi

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

static int demo_check_string_not_empty(char *s)
{
    if (s != NULL)
        return strlen(s) > 0; /* check string null-terminated and not empty */
    else
        return 0;
}

int unsafestrtonumeric(char* argv1)
{
    int s = 0;
    if (demo_check_string_not_empty(argv1))
    {
        s = atoi(argv1);
    }
    return s;
}
```

In this example, `argv1` is converted to an integer with `atoi`. `atoi` does not provide errors for an invalid integer string. The conversion can fail unexpectedly.

#### Correction — Use `strtol` instead

One possible correction is to use `strtol` to validate the input string and the converted integer.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <limits.h>
#include <errno.h>

static int demo_check_string_not_empty(char *s)
{
    if (s != NULL)
        return strlen(s) > 0; /* check string null-terminated and not empty */
    else
        return 0;
}

int unsafestrtonumeric(char *argv1)
{
    char *c_str = argv1;
    char *end;
    long sl;

    if (demo_check_string_not_empty(c_str))
    {
        errno = 0; /* set errno for error check */
        sl = strtol(c_str, &end, 10);
        if (end == c_str)
        {
            (void)fprintf(stderr, "%s: not a decimal number\n", c_str);
        }
        else if ('\0' != *end)
        {
            (void)fprintf(stderr, "%s: extra characters: %s\n", c_str, end);
        }
        else if ((LONG_MIN == sl || LONG_MAX == sl) && ERANGE == errno)
        {
            (void)fprintf(stderr, "%s out of range of type long\n", c_str);
        }
        else if (sl > INT_MAX)
        {
            (void)fprintf(stderr, "%ld greater than INT_MAX\n", sl);
        }
        else if (sl < INT_MIN)
        {
            (void)fprintf(stderr, "%ld less than INT_MIN\n", sl);
        }
        else
        {
            return (int)sl;
        }
    }
    return 0;
}
```

### Use of dangerous standard function

#### Issue

This issue occurs when your code uses standard functions that write data to a buffer in a way that can result in buffer overflows.

The following table lists dangerous standard functions, the risks of using each function, and what function to use instead. The checker flags:

- Any use of an inherently dangerous function.
- An use of a possibly dangerous function only if the size of the buffer to which data is written can be determined at compile time. The checker does not flag an use of such a function with a dynamically allocated buffer.

| Dangerous Function | Risk Level | Safer Function |
|---|---|---|
| `gets` | Inherently dangerous — You cannot control the length of input from the console. | `fgets` |

| Dangerous Function | Risk Level | Safer Function |
|---|---|---|
| `std::cin::operator>>` and `std::wcin::operator>>` | Inherently dangerous — You cannot control the length of input from the console. | Preface calls to `cin` by `cin.width` to control the input length. This method can result in truncated input.<br>To avoid potential buffer overflow and truncated input, use `std::string` objects as destinations for >> operator. |
| `strcpy` | Possibly dangerous — If the size of the destination buffer is too small to accommodate the source buffer and a null terminator, a buffer overflow might occur. | Use the function `strlen()` to determine the size of the source buffer, and allocate sufficient memory so that the destination buffer can accommodate the source buffer and a null terminator. Instead of `strcpy`, use the function `strncpy`. |
| `stpcpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `stpncpy` |
| `lstrcpy` or `StrCpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `StringCbCopy`, `StringCchCopy`, `strncpy`, `strcpy_s`, or `strlcpy` |
| `strcat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `strncat`, `strlcat`, or `strcat_s` |
| `lstrcat` or `StrCat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `StringCbCat`, `StringCchCat`, `strncay`, `strcat_s`, or `strlcat` |
| `wcpcpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `wcpncpy` |
| `wcscat` | Possibly dangerous — If the concatenated result is greater than the destination, buffer overflow can occur. | `wcsncat`, `wcslcat`, or `wcncat_s` |
| `wcscpy` | Possibly dangerous — If the source length is greater than the destination, buffer overflow can occur. | `wcsncpy` |
| `sprintf` | Possibly dangerous — If the output length depends on unknown lengths or values, buffer overflow can occur. | `snprintf` |
| `vsprintf` | Possibly dangerous — If the output length depends on unknown lengths or values, buffer overflow can occur. | `vsnprintf` |

#### Risk

These functions can cause buffer overflow, which attackers can use to infiltrate your program.

#### Fix

The fix depends on the root cause of the defect. See fixes in the table above and code examples with fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Using sprintf

```
#include <stdio.h>
#include <string.h>
#include <iostream>

#define BUFF_SIZE 128

int dangerous_func(char *str)
{
    char dst[BUFF_SIZE];
    int r = 0;

    if (sprintf(dst, "%s", str) == 1)
    {
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}
```

This example function uses `sprintf` to copy the string `str` to `dst`. However, if `str` is larger than the buffer, `sprintf` can cause buffer overflow.

#### Correction — Use `snprintf` with Buffer Size

One possible correction is to use `snprintf` instead and specify a buffer size.

```
#include <stdio.h>
#include <string.h>
#include <iostream>

#define BUFF_SIZE 128

int dangerous_func(char *str)
{
    char dst[BUFF_SIZE];
    int r = 0;

    if (snprintf(dst, sizeof(dst), "%s", str) == 1)
    {
        r += 1;
        dst[BUFF_SIZE-1] = '\0';
    }

    return r;
}
```

### Use of rand() for Generating Pseudorandom Number

#### Issue

This issue occurs when you use the function `rand` for generating pseudorandom numbers.

#### Risk

The function `rand` is cryptographically weak. That is, the numbers generated by `rand` can be predictable. Do not use pseudorandom numbers generated from `rand` for security purposes. When a predictable random value controls the execution flow, your program is vulnerable to attacks.

#### Fix

Use more cryptographically sound pseudorandom number generators (PRNG), such as `CryptGenRandom` (Windows), `OpenSSL/RAND_bytes`(Linux/UNIX), or `random` (POSIX).

#### Example — Random Loop Numbers

```
#include <stdio.h>
#include <stdlib.h>

volatile int rd = 1;
int main(int argc, char *argv[])
{
    int j, r, nloops;
    struct random_data buf;
    int i = 0;

    nloops = rand(); //Noncompliant

    for (j = 0; j < nloops; j++) {
        i = rand(); //Noncompliant
        printf("random_r: %ld\n", (long)i);
    }
    return 0;
}
```

This example uses `rand` to generate random numbers `nloops` and `i`. The predictability of these variables makes these function vulnerable to attacks.

#### Correction — Use Stronger PRNG

One possible correction is to replace the vulnerable PRNG with a stronger random number generator. For instance, this code uses the PRNG `random()` from POSIX library. `random` is a much stronger PRNG because it can be seeded by a different number every time it is called.

```
#include <stdio.h>
#include <stdlib.h>
```

```
#include <time.h>
#define TIME_UTC 1
volatile int rd = 1;
int randomWrapper(){
    struct timespec ts;
  if (timespec_get(&ts, TIME_UTC) == 0) {
    /* Handle error */
  }
  srandom(ts.tv_nsec ^ ts.tv_sec);  /* Seed the PRNG */
    return random();
}
int main(int argc, char *argv[])
{
    int j, r, nloops;
    struct random_data buf;
    int i = 0;

    nloops = randomWrapper();

    for (j = 0; j < nloops; j++) {
        i = randomWrapper();
        printf("random_r: %ld\n", (long)i);
    }
    return 0;
}
```

# CWE Rule 685

Function Call With Incorrect Number of Arguments

## Description

### Rule Description

*The software calls a function, procedure, or routine, but the caller specifies too many arguments, or too few arguments, which may lead to undefined behavior and resultant weaknesses.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Format string specifiers and arguments mismatch**
- **Too many va_arg calls for current argument list**
- **Unreliable cast of function pointer**

## Examples

### Format string specifiers and arguments mismatch

#### Issue

This issue occurs when the format specifiers in the formatted output functions such as `printf` do not match their corresponding arguments. For example, an argument of type `unsigned long` must have a format specification of `%lu`.

#### Risk

Mismatch between format specifiers and the corresponding arguments result in undefined behavior.

#### Fix

Make sure that the format specifiers match the corresponding arguments. For instance, in this example, the `%d` specifier does not match the string argument `message` and the `%s` specifier does not match the integer argument `err_number`.

```
const char *message = "License not available";
int err_number = -4;
printf("Error: %d (error type %s)\n", message, err_number);
```

Switching the two format specifiers fixes the issue. See the specifications for the printf function for more information about format specifiers.

In cases where integer promotion modifies the perceived data type of an argument, the analysis result shows both the original type and the type after promotion. The format specifier has to match the type after integer promotion.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.

- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Printing a Float

```
#include <stdio.h>

void string_format(void) {

    unsigned long fst = 1;

    printf("%d\n", fst);
}
```

In the `printf` statement, the format specifier, `%d`, does not match the data type of `fst`.

#### Correction — Use an Unsigned Long Format Specifier

One possible correction is to use the `%lu` format specifier. This specifier matches the `unsigned` integer type and `long` size of `fst`.

```
#include <stdio.h>

void string_format(void) {

    unsigned long fst = 1;

    printf("%lu\n", fst);
}
```

#### Correction — Use an Integer Argument

One possible correction is to change the argument to match the format specifier. Convert `fst` to an integer to match the format specifier and print the value `1`.

```
#include <stdio.h>

void string_format(void) {

    unsigned long fst = 1;

    printf("%d\n", (int)fst);
}
```

### Too many va_arg calls for current argument list

#### Issue

This issue occurs when the number of calls to `va_arg` exceeds the number of arguments passed to the corresponding variadic function. The analysis raises a defect only when the variadic function is called.

**Too many va_arg calls for current argument list** does not raise a defect when:

- The number of calls to `va_arg` inside the variadic function is indeterminate. For example, if the calls are from an external source.

- The va_list used in va_arg is invalid.

**Risk**

When you call va_arg and there is no next argument available in va_list, the behavior is undefined. The call to va_arg might corrupt data or return an unexpected result.

**Fix**

Ensure that you pass the correct number of arguments to the variadic function.

**Example — No Argument Available When Calling va_arg**

```
#include <stdarg.h>
#include <stddef.h>
#include <math.h>

/* variadic function defined with
* one named argument 'count'
*/
int variadic_func(int count, ...) {
    int result = -1;
    va_list ap;
    va_start(ap, count);
    if (count > 0) {
        result = va_arg(ap, int);
        count --;
        if (count > 0) {
/* No further argument available
* in va_list when calling va_arg
*/

            result += va_arg(ap, int);
        }
    }
    va_end(ap);
    return result;
}

void func(void) {

    (void)variadic_func(2, 100);

}
```

In this example, the named argument and only one variadic argument are passed to variadic_func() when it is called inside func(). On the second call to va_arg, no further variadic argument is available in ap and the behavior is undefined.

**Correction — Pass Correct Number of Arguments to Variadic Function**

One possible correction is to ensure that you pass the correct number of arguments to the variadic function.

```
#include <stdarg.h>
#include <stddef.h>
#include <math.h>

/* variadic function defined with
```

```
* one named argument 'count'
*/

int variadic_func(int count, ...) {
    int result = -1;
    va_list ap;
    va_start(ap, count);
    if (count > 0) {
        result = va_arg(ap, int);
        count --;
        if (count > 0) {

/* The correct number of arguments is
* passed to va_list when variadic_func()
* is called inside func()
*/
            result += va_arg(ap, int);
        }
    }
    va_end(ap);
    return result;
}

void func(void) {

    (void)variadic_func(2, 100, 200);

}
```

### Unreliable cast of function pointer

#### Issue

This issue occurs when a function pointer is cast to another function pointer that has different argument or return type.

#### Risk

If you cast a function pointer to another function pointer with different argument or return type and then use the latter function pointer to call a function, the behavior is undefined.

#### Fix

Avoid a cast between two function pointers with mismatch in argument or return types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Unreliable cast of function pointer error

```
#include <stdio.h>
#include <math.h>
```

```
#define PI 3.142

double Calculate_Sum(int (*fptr)(double))
{
    double  sum = 0.0;
    double  y;

    for (int i = 0;  i <= 100;  i++)
    {
        y = (*fptr)(i*PI/100);
        sum += y;
    }
    return sum / 100;
}

int main(void)
{
    double  (*fp)(double);
    double  sum;

    fp = sin;
    sum = Calculate_Sum(fp);
    /* Defect: fp implicitly cast to int(*) (double) */

    printf("sum(sin): %f\n", sum);
    return 0;
}
```

The function pointer `fp` is declared as `double (*)(double)`. However in passing it to function `Calculate_Sum`, `fp` is implicitly cast to `int (*)(double)`.

#### Correction — Avoid Function Pointer Cast

One possible correction is to check that the function pointer in the definition of `Calculate_Sum` has the same argument and return type as `fp`. This step makes sure that `fp` is not implicitly cast to a different argument or return type.

```
#include <stdio.h>
#include <math.h>
# define PI 3.142

/*Fix: fptr has same argument and return type everywhere*/
double Calculate_Sum(double (*fptr)(double))
{
    double  sum = 0.0;
    double y;

    for (int i = 0;  i <= 100;  i++)
    {
        y = (*fptr)(i*PI/100);
        sum += y;
    }
    return sum / 100;
}

int main(void)
{
    double  (*fp)(double);
    double  sum;

    fp = sin;
    sum = Calculate_Sum(fp);
    printf("sum(sin): %f\n", sum);

    return 0;
}
```

# CWE Rule 690

Unchecked Return Value to NULL Pointer Dereference

## Description

### Rule Description

*The product does not check for an error after calling a function that can return with a NULL pointer if the function fails, which leads to a resultant NULL pointer dereference.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Returned value of a sensitive function not checked**
- **Tainted NULL or non-null-terminated string**
- **Unprotected dynamic memory allocation**

## Examples

### Returned value of a sensitive function not checked

#### Issue

This issue occurs when you call sensitive standard functions that return information about possible errors and you do one of the following:

- Ignore the return value.

  You simply do not assign the return value to a variable, or explicitly cast the return value to `void`.
- Use an output from the function (return value or argument passed by reference) without testing the return value for errors.

The checker considers a function as sensitive if the function call is prone to failure because of reasons such as:

- Exhausted system resources (for example, when allocating resources).
- Changed privileges or permissions.
- Tainted sources when reading, writing, or converting data from external sources.
- Unsupported features despite an existing API.

The checker only considers functions where the *return value* indicates if the function completed without errors.

Some of these functions can perform critical tasks such as:

- Set privileges (for example, `setuid`)
- Create a jail (for example, `chroot`)

- Create a process (for example, `fork`)
- Create a thread (for example, `pthread_create`)
- Lock or unlock mutex (for example, `pthread_mutex_lock`)
- Lock or unlock memory segments (for example, `mlock`)

**Risk**

If you do not check the return value of functions that perform sensitive tasks and indicate error information through their return values, your program can behave unexpectedly. Errors from these functions can propagate throughout the program causing incorrect output, security vulnerabilities, and possibly system failures.

**Fix**

Before continuing with the program, test the return value of critical sensitive functions.

For sensitive functions that are not critical, you can explicitly ignore a return value by casting the function to `void`. Polyspace does not raise this defect for sensitive functions cast to void. This resolution is not accepted for *critical sensitive functions* because they perform more vulnerable tasks.

**Example — Sensitive Function Return Ignored**

```
#include <pthread.h>
#include <string.h>
#include <stddef.h>
#include <stdio.h>

void initialize() {
    pthread_attr_t attr;

    pthread_attr_init(&attr);//Noncompliant
}
int read_file(int argc, char *argv[])
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  in = fmemopen (argv[1], strlen (argv[1]), "r");
  return 0; //Noncompliant

}
```

This example shows calls to the sensitive POSIX functions `pthread_attr_init` and `fmemopen`. Their return values are ignored, causing defect.

**Correction — Cast Function to `(void)`**

One possible correction is to cast the function to void. This fix informs Polyspace and any reviewers that you are explicitly ignoring the return value of the sensitive function.

```
#include <pthread.h>
#include <string.h>
#include <stddef.h>
#include <stdio.h>
```

```
void initialize() {
    pthread_attr_t attr;

    (void)pthread_attr_init(&attr);//Compliant
}
int read_file(int argc, char *argv[])
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  (void)fmemopen (argv[1], strlen (argv[1]), "r"); //Compliant

  return 0;
}
```

**Correction — Test Return Value**

One possible correction is to test the return value of `pthread_attr_init` and `fmemopen` to check for errors.

```
#include <pthread.h>
#include <string.h>
#include <stddef.h>
#include <stdio.h>

void initialize() {
    pthread_attr_t attr;

    int result = pthread_attr_init(&attr);//Compliant
    if(result != 0){
        //Handle fatal error
    }
}
int read_file(int argc, char *argv[])
{
  FILE *in;
  if (argc != 2) {
    /* Handle error */
  }

  in = fmemopen (argv[1], strlen (argv[1]), "r");
  if (in==NULL){
      // Handle error
  }
  return 0;//Compliant
}
```

**Example — Critical Function Return Ignored**

```
#include <pthread.h>
extern void *start_routine(void *);

void returnnotchecked() {
    pthread_t thread_id;
    pthread_attr_t attr;
    void *res;
    (void)pthread_attr_init(&attr);
    (void)pthread_create(&thread_id, &attr, &start_routine, ((void *)0));
    pthread_join(thread_id,  &res);
}
```

In this example, two critical functions are called: `pthread_create` and `pthread_join`. The return value of the `pthread_create` is ignored by casting to void, but because `pthread_create` is a critical function (not just a sensitive function), Polyspace does not ignore this *Return value of a sensitive function not checked* defect. The other critical function, `pthread_join`, returns value that is ignored implicitly. `pthread_join` uses the return value of `pthread_create`, which was not checked.

#### Correction — Test the Return Value of Critical Functions

The correction for this defect is to check the return value of these critical functions to verify the function performed as expected.

```
#include <pthread.h>
#include <stdlib.h>
#define fatal_error() abort()

extern void *start_routine(void *);

void returnnotchecked() {
    pthread_t thread_id;
    pthread_attr_t attr;
    void *res;
    int result;

    (void)pthread_attr_init(&attr);
    result = pthread_create(&thread_id, &attr, &start_routine, NULL);
    if (result != 0) {
        /* Handle error */
        fatal_error();
    }

    result = pthread_join(thread_id,  &res);
    if (result != 0) {
        /* Handle error */
        fatal_error();
    }
}
```

### Tainted NULL or non-null-terminated string

#### Issue

This issue occurs when strings from unsecure sources are used in string manipulation routines that implicitly dereference the string buffer, for instance, `strcpy` or `sprintf`.

**Tainted NULL or non-null-terminated string** raises no defect for a string returned from a call to `scanf`-family variadic functions. Similarly, no defect is raised when you pass the string with a `%s` specifier to `printf`-family variadic functions.

#### Risk

If a string is from an unsecure source, it is possible that an attacker manipulated the string or pointed the string pointer to a different memory location.

If the string is NULL, the string routine cannot dereference the string, causing the program to crash. If the string is not null-terminated, the string routine might not know when the string ends. This error can cause you to write out of bounds, causing a buffer overflow.

**Fix**

Validate the string before you use it. Check that:

- The string is not NULL.
- The string is null-terminated
- The size of the string matches the expected size.

**Extend Checker**

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Getting String from Input**

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));//Noncompliant
    print_str(str);
}
```

In this example, the string `str` is concatenated with the argument `userstr`. The value of `userstr` is unknown. If the size of `userstr` is greater than the space available, the concatenation overflows.

**Correction — Validate the Data**

One possible correction is to check the size of `userstr` and make sure that the string is null-terminated before using it in `strncat`. This example uses a helper function, `sansitize_str`, to validate the string. The defects are concentrated in this function.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>
#define SIZE128 128
#define MAX 40
extern void print_str(const char*);
int sanitize_str(char* s) {
    int res = 0;
    if (s && (strlen(s) > 0)) { // Noncompliant-TAINTED_STRING only flagged here
        // - string is not null
        // - string has a positive and limited size
        // - TAINTED_STRING on strlen used as a firewall
        res = 1;
    }
    return res;
}
void warningMsg(void)
{
    char userstr[MAX];
    read(0,userstr,MAX);
    char str[SIZE128] = "Warning: ";
    if (sanitize_str(userstr))
        strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}
```

**Correction — Validate the Data**

Another possible correction is to call function `errorMsg` and `warningMsg` with specific strings.

```
#include <stdio.h>
#include <string.h>
#include <stdlib.h>

#define SIZE128 128

extern void print_str(const char*);

void warningMsg(char* userstr)
{
    char str[SIZE128] = "Warning: ";
    strncat(str, userstr, SIZE128-(strlen(str)+1));
    print_str(str);
}

void errorMsg(char* userstr)
{
  char str[SIZE128] = "Error: ";
  strncat(str, userstr, SIZE128-(strlen(str)+1));
  print_str(str);
}

int manageSensorValue(int sensorValue) {
  int ret = sensorValue;
  if ( sensorValue < 0 ) {
    errorMsg("sensor value should be positive");
    exit(1);
  } else if ( sensorValue > 50 ) {
    warningMsg("sensor value greater than 50 (applying threshold)...");
    sensorValue = 50;
  }

  return sensorValue;
}
```

### Unprotected dynamic memory allocation

#### Issue

This issue occurs when you access dynamically allocated memory without first checking if the prior memory allocation succeeded.

#### Risk

When memory is dynamically allocated using `malloc`, `calloc`, or `realloc`, it returns a value `NULL` if the requested memory is not available. If the code following the allocation accesses the memory block without checking for this `NULL` value, this access is not protected from failures.

#### Fix

Check the return value of `malloc`, `calloc`, or `realloc` for NULL before accessing the allocated memory location.

```
int *ptr = malloc(size * sizeof(int));

if(ptr) /* Check for NULL */
{
   /* Memory access through ptr */
}
```

#### Example — Unprotected dynamic memory allocation error

```
#include <stdlib.h>

void Assign_Value(void)
{
  int* p = (int*)calloc(5, sizeof(int));

  *p = 2;
  /* Defect: p is not checked for NULL value */

  free(p);
}
```

If the memory allocation fails, the function `calloc` returns `NULL` to `p`. Before accessing the memory through `p`, the code does not check whether `p` is `NULL`

#### Correction — Check for NULL Value

One possible correction is to check whether `p` has value `NULL` before dereference.

```
#include <stdlib.h>

void Assign_Value(void)
 {
   int* p = (int*)calloc(5, sizeof(int));

   /* Fix: Check if p is NULL */
   if(p!=NULL) *p = 2;

   free(p);
 }
```

**Example — Unprotected dynamic memory allocation error only on dereference**

```
#include <stdlib.h>
#include<string.h>
typedef struct recordType {
    const char* id;
    const char* data;
} RECORD;

RECORD* MakerecordType(const char *id,unsigned int size){
    RECORD *rec = (RECORD *)calloc(1, sizeof(RECORD));
    rec->id = strdup(id);

    const char *newData = (char *)calloc(1, size);
    rec->data = newData;
    return rec;
}
```

In this example, the checker raises a defect when you dereference the pointer `rec` without checking for a `NULL` value from the prior dynamic memory allocation.

A similar issue happens with the pointer `newData`. However, a defect is not raised because the pointer is not dereferenced but simply copied over to `rec->data`. Simply copying over a possibly null pointer is not an issue by itself. For instance, callers of the `recordType_new` function might check for `NULL` value of `rec->data` before dereferencing, thereby avoiding a null pointer dereference.

CWE-690

# CWE Rule 704

Incorrect Type Conversion or Cast

## Description

### Rule Description

*The software does not correctly convert an object, resource, or structure from one type to a different type.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Cast to pointer pointing to object of different type**
- **Character value absorbed into EOF**
- **Conversion between pointer and integer**
- **Integer conversion overflow**
- **Misuse of sign-extended character value**
- **Precision loss in integer to float conversion**
- **Qualifier removed in conversion**
- **Reading memory reallocated from object of another type without reinitializing first**
- **Sign change integer conversion overflow**
- **Tainted sign change conversion**
- **Unreliable cast of pointer**
- **Unsafe conversion between pointer and integer**
- **Unsigned integer conversion overflow**
- **Wrong allocated object size for cast**

## Examples

### Cast to pointer pointing to object of different type

#### Issue

The issue occurs when you perform a cast between a pointer to an object type and a pointer to a different object type.

#### Risk

If a pointer to an object is cast into a pointer to a different object, the resulting pointer can be incorrectly aligned. The incorrect alignment causes undefined behavior.

Even if the conversion produces a pointer that is correctly aligned, the behavior can be undefined if the pointer is used to access an object.

Exception: You can convert a pointer to object type into a pointer to one of these types:

- `char`
- `signed char`
- `unsigned char`

**Example - Cast to Pointer Pointing to Object of Wider Type**

```
signed   char *p1;
unsigned int *p2;

void foo(void){
  p2 = ( unsigned int * ) p1;     /* Non-compliant */
}
```

In this example, `p1` can point to a `signed char` object. However, `p1` is cast to a pointer that points to an object of wider type, `unsigned int`.

**Example - Cast to Pointer Pointing to Object of Narrower Type**

```
extern unsigned int read_value ( void );
extern void display ( unsigned int n );

void foo ( void ){
  unsigned int u = read_value ( );
  unsigned short *hi_p = ( unsigned short * ) &u;    /* Non-compliant  */
  *hi_p = 0;
  display ( u );
}
```

In this example, `u` is an `unsigned int` variable. `&u` is cast to a pointer that points to an object of narrower type, `unsigned short`.

On a big-endian machine, the statement `*hi_p = 0` attempts to clear the high bits of the memory location that `&u` points to. But, from the result of `display(u)`, you might find that the high bits have not been cleared.

**Example - Cast Adding a Type Qualifier**

```
const short *p;
const volatile short *q;
void foo (void){
  q = ( const volatile short * ) p;  /* Compliant */
}
```

In this example, both `p` and `q` can point to `short` objects. The cast between them adds a `volatile` qualifier only and is therefore compliant.

### Character value absorbed into EOF

**Issue**

This issue occurs when you perform a data type conversion that makes a valid character value indistinguishable from `EOF` (End-of-File). Bug Finder flags the defect in one of the following situations:

- *End-of-File*: You perform a data type conversion such as from `int` to `char` that converts a non-EOF character value into `EOF`.

  ```
  char ch = (char)getchar()
  ```

You then compare the result with EOF.

```
if((int)ch == EOF)
```

The conversion can be explicit or implicit.

- *Wide End-of-File*: You perform a data type conversion that can convert a non-WEOF wide character value into WEOF, and then compare the result with WEOF.

**Risk**

The data type `char` cannot hold the value `EOF` that indicates the end of a file. Functions such as `getchar` have return type `int` to accommodate `EOF`. If you convert from `int` to `char`, the values `UCHAR_MAX` (a valid character value) and `EOF` get converted to the same value -1 and become indistinguishable from each other. When you compare the result of this conversion with `EOF`, the comparison can lead to false detection of `EOF`. This rationale also applies to wide character values and `WEOF`.

**Fix**

Perform the comparison with `EOF` or `WEOF` before conversion.

**Example — Return Value of getchar Converted to char**

```
#include <stdio.h>
#include <stdlib.h>
#define fatal_error() abort()

char func(void)
{
    char ch;
    ch = getchar();
    if (EOF == (int)ch) {
        fatal_error();
    }
    return ch;
}
```

In this example, the return value of `getchar` is implicitly converted to `char`. If `getchar` returns `UCHAR_MAX`, it is converted to -1, which is indistinguishable from EOF. When you compare with EOF later, it can lead to a false positive.

**Correction — Perform Comparison with EOF Before Conversion**

One possible correction is to first perform the comparison with EOF, and then convert from `int` to `char`.

```
#include <stdio.h>
#include <stdlib.h>
#define fatal_error() abort()

char func(void)
{
    int i;
    i = getchar();
    if (EOF == i) {
        fatal_error();
    }
    else {
        return (char)i;
    }
}
```

### Conversion between pointer and integer

#### Issue

The issue occurs when you convert an integral type into a raw pointer type. Polyspace reports the conversion as a violation of the rule regardless of the sizes of the integral and raw pointer types. For instance, if an integer originates from a pointer and then later, is cast into a pointer, Polyspace flags the conversion from integer to pointer. In this case, the integer and the pointer have the same size.

#### Risk

The mapping between pointers and integers is not always consistent with the addressing structure of the environment.

Converting from integers to pointers can create:

- Misaligned pointers or misaligned objects.
- Invalid pointer addresses.

#### Fix

Where possible, avoid integer-to-pointer conversions. If you want to convert a `void` pointer to an integer, so that you do not change the value, use types:

- C99 — `intptr_t` or `uintptr_t`
- C90 — `size_t` or `ssize_t`

#### Example — Integer to Pointer Conversions

```
unsigned int* badintptrcast(void)
{
    int* ptr;
    unsigned long long int_same_as_ptr ;
    unsigned int int_smaller_than_ptr;

    unsigned int* ptr0 = (unsigned int*)0xdeadbeef; //Noncompliant

    /*int to ptr of same size*/
    ptr = (int*)int_same_as_ptr;  //Noncompliant

    /*int to ptr of different size*/
    ptr = (int*)int_smaller_than_ptr;  //Noncompliant

    return (unsigned int*)(ptr0 - (unsigned int*)ptr);  //Noncompliant
}
```

In this example, Polyspace flags the conversions that might be unsafe. For instance:

- The conversion of `0xdeadbeef` to `unsigned int*` causes alignment issues for the pointer. Polyspace flags the conversion.
- The conversion of the `int_same_as_ptr` and `int_smaller_than_ptr` to `int*` pointers might result in invalid pointer address. Polyspace flags these conversion.

- The `return` statement casts `ptrdiff_t` to a pointer. This pointer might not point to an invalid address. Polyspace flags the conversion.

#### Correction — Use `intptr_t`

One possible correction is to use `intptr_t` types to store addresses. When storing the result of subtracting two pointers, use the type `ptrdiff_t`.

```
#include<stdint.h>
#include<stddef.h>
ptrdiff_t badintptrcast(void)
{
    intptr_t ptr;
    unsigned long long int_same_as_ptr ;
    unsigned int int_smaller_than_ptr;

    intptr_t ptr0 = (intptr_t)0xdeadbeef; //Compliant

    /*int to ptr of same size*/
    ptr = (intptr_t)int_same_as_ptr;  //Compliant

    /*int to ptr of different size*/
    ptr = (intptr_t)int_smaller_than_ptr;  //Compliant

    int offset = 0;
    return (ptrdiff_t)(ptr0 - offset);//Compliant

}
```

### Integer conversion overflow

#### Issue

This issue occurs when converting an integer to a smaller integer type. If the variable does not have enough bytes to represent the original value, the conversion overflows. For instance, if you perform a comparison between implementation-defined type `time_t` and a signed integer, Polyspace reports a violation because `time_t` might be implemented as an unsigned integer.

The checker also detects comparison

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Converting from int to char

```
char convert(void) {

    int num = 1000000;

    return (char)num;
}
```

In the return statement, the integer variable `num` is converted to a `char`. However, an 8-bit or 16-bit character cannot represent 1000000 because it requires at least 20 bits. So the conversion operation overflows.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number.

```
long convert(void) {

    int num = 1000000;

    return (long)num;
}
```

### Misuse of sign-extended character value

#### Issue

This issue occurs when you convert a signed or plain `char` variable containing possible negative values to a wider integer data type (or perform an arithmetic operation that does the conversion) and then use the resulting value in one of these ways:

- For comparison with `EOF` (using == or `!=`)
- As array index

- As argument to a character-handling function in `ctype.h`, for instance, `isalpha()` or `isdigit()`

If you convert a signed `char` variable with a negative value to a wider type such as `int`, the sign bit is preserved (sign extension). This can lead to specific problems even in situations where you think you have accounted for the sign bit.

For instance, the signed `char` value of -1 can represent the character `EOF` (end-of-file), which is an invalid character. Suppose a `char` variable `var` acquires this value. If you treat `var` as a `char` variable, you might want to write special code to account for this invalid character value. However, if you perform an operation such as `var++` (involving integer promotion), it leads to the value 0, which represents a valid value `'\0'` by accident. You transitioned from an invalid to a valid value through the arithmetic operation.

Even for negative values other than -1, a conversion from signed `char` to signed `int` can lead to other issues. For instance, the signed `char` value -126 is equivalent to the `unsigned char` value 130 (corresponding to an extended character `'\202'`). If you convert the value from `char` to `int`, the sign bit is preserved. If you then cast the resulting value to `unsigned int`, you get an unexpectedly large value, 4294967170 (assuming 32-bit `int`). If your code expects the `unsigned char` value of 130 in the final `unsigned int` variable, you can see unexpected results.

The underlying cause of this issue is the sign extension during conversion to a wider type. Most architectures use two's complement representation for storing values. In this representation, the most significant bit indicates the sign of the value. When converted to a wider type, the conversion is done by copying this sign bit to all the leading bits of the wider type, so that the sign is preserved. For instance, the `char` value of -3 is represented as `11111101` (assuming 8-bit `char`). When converted to `int`, the representation is:

```
11111111 11111111 11111111  11111101
```

The value -3 is preserved in the wider type `int`. However, when converted to `unsigned int`, the value (4294967293) is no longer the same as the `unsigned char` equivalent of the original `char` value. If you are not aware of this issue, you can see unexpected results in your code.

**Risk**

In the following cases, Bug Finder flags use of variables after a conversion from `char` to a wider data type or an arithmetic operation that implicitly converts the variable to a wider data type:

- *If you compare the variable value with EOF*:

  A `char` value of -1 can represent the invalid character `EOF` or the valid extended character value `'\377'` (corresponding to the `unsigned char` equivalent, 255). After a `char` variable is cast to a wider type such as `int`, because of sign extension, the `char` value -1, representing one of `EOF` or `'\377'` becomes the `int` value -1, representing only `EOF`. The `unsigned char` value 255 can no longer be recovered from the `int` variable. Bug Finder flags this situation so that you can cast the variable to `unsigned char` first (or avoid the `char`-to-`int` conversion or converting operation before comparison with `EOF`). Only then, a comparison with `EOF` is meaningful. See “Sign-Extended Character Value Compared with EOF” on page 11-125.
- *If you use the variable value as an array index*:

  After a `char` variable is cast to a wider type such as `int`, because of sign extension, all negative values retain their sign. If you use the negative values directly to access an array, you cause buffer overflow/underflow. Even when you account for the negative values, the way you account for them might result in incorrect elements being read from the array. See “Sign-Extended Character Value Used as Array Index” on page 11-126.

- *If you pass the variable value as argument to a character-handling function*:

  According to the C11 standard (Section 7.4), if you supply an integer argument that cannot be represented as unsigned char or EOF, the resulting behavior is undefined. Bug Finder flags this situation because negative char values after conversion can no longer be represented as unsigned char or EOF. For instance, the signed char value -126 is equivalent to the unsigned char value 130, but the signed int value -126 cannot be represented as unsigned char or EOF.

**Fix**

Before conversion to a wider integer data type, cast the signed or plain char value explicitly to unsigned char.

If you use the char data type to not represent characters but simply as a smaller data type to save memory, your use of sign-extended char values might avoid the risks mentioned earlier. If so, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Sign-Extended Character Value Compared with EOF**

```
#include <stdio.h>
#include <stdlib.h>
#define fatal_error() abort()

extern char parsed_token_buffer[20];

static int parser(char *buf)
{
    int c = EOF;
    if (buf && *buf) {
        c = *buf++;
    }
    return c;
}

void func()
{
    if (parser(parsed_token_buffer) == EOF) {
        /* Handle error */
        fatal_error();
    }
}
```

In this example, the function parser can traverse a string input buf. If a character in the string has the value -1, it can represent either EOF or the valid character value '\377' (corresponding to the unsigned char equivalent 255). When converted to the int variable c, its value becomes the integer value -1, which is always EOF. The later comparison with EOF will not detect if the value returned from parser is actually EOF.

### Correction — Cast to `unsigned char` Before Conversion

One possible correction is to cast the plain `char` value to `unsigned char` before conversion to the wider `int` type. Only then can you test if the return value of `parser` is really `EOF`.

```
#include <stdio.h>
#include <stdlib.h>
#define fatal_error() abort()

extern char parsed_token_buffer[20];

static int parser(char *buf)
{
    int c = EOF;
    if (buf && *buf) {
        c = (unsigned char)*buf++;
    }
    return c;
}

void func()
{
    if (parser(parsed_token_buffer) == EOF) {
        /* Handle error */
        fatal_error();
    }
}
```

### Example — Sign-Extended Character Value Used as Array Index

```
#include <limits.h>
#include <stddef.h>
#include <stdio.h>

#define NUL '\0'
#define SOH 1    /* start of heading */
#define STX 2    /* start of text */
#define ETX 3    /* end of text */
#define EOT 4    /* end of transmission */
#define ENQ 5    /* enquiry */
#define ACK 6    /* acknowledge */

static const int ascii_table[UCHAR_MAX + 1] =
{
      [0]=NUL,[1]=SOH, [2]=STX, [3]=ETX, [4]=EOT, [5]=ENQ,[6]=ACK,
      /* ... */
      [126] = '~',
      /* ... */
      [130/*-126*/]='\202',
      /* ... */
      [255 /*-1*/]='\377'
};

int lookup_ascii_table(char c)
{
    int i;
    i = (c < 0 ? -c : c);
    return ascii_table[i];
}
```

In this example, the `char` variable `c` is converted to the `int` variable `i`. If `c` has negative values, they are converted to positive values before assignment to `i`. However, this conversion can lead to unexpected values when `i` is used as array index. For instance:

- If `c` has the value -1 representing the invalid character `EOF`, you want to probably treat this value separately. However, in this example, a value of `c` equal to -1 leads to a value of `i` equal to 1. The function `lookup_ascii_table` returns the value `ascii_table[1]` (or `SOH`) without the invalid character value `EOF` being accounted for.

  If you use the `char` data type to not represent characters but simply as a smaller data type to save memory, you need not worry about this issue.
- If `c` has a negative value, when assigned to `i`, its sign is reversed. However, if you access the elements of `ascii_table` through `i`, this sign reversal can result in unexpected values being read.

  For instance, if `c` has the value -126, `i` has the value 126. The function `lookup_ascii_table` returns the value `ascii_table[126]` (or `'~'`) but you probably expected the value `ascii_table[130]` (or `'\202'`).

#### Correction – Cast to `unsigned char`

To correct the issues, avoid the conversion from `char` to `int`. First, check `c` for the value `EOF`. Then, cast the value of the `char` variable `c` to `unsigned char` and use the result as array index.

```
#include <limits.h>
#include <stddef.h>
#include <stdio.h>

#define NUL '\0'
#define SOH 1    /* start of heading */
#define STX 2    /* start of text */
#define ETX 3    /* end of text */
#define EOT 4    /* end of transmission */
#define ENQ 5    /* enquiry */
#define ACK 6    /* acknowledge */

static const int ascii_table[UCHAR_MAX + 1] =
{
      [0]=NUL,[1]=SOH, [2]=STX, [3]=ETX, [4]=EOT, [5]=ENQ,[6]=ACK,
      /* ... */
      [126] = '~',
      /* ... */
      [130/*-126*/]='\202',
      /* ... */
      [255 /*-1*/]='\377'
};

int lookup_ascii_table(char c)
{
    int r = EOF;
    if (c != EOF) /* specific handling EOF, invalid character */
        r = ascii_table[(unsigned char)c]; /* cast to 'unsigned char' */
    return r;
}
```

### Precision loss in integer to float conversion

#### Issue

This issue occurs when you cast an integer value to a floating-point type that cannot represent the original integer value.

For instance, the `long int` value `1234567890L` is too large for a variable of type `float` .

#### Risk

If the floating-point type cannot represent the integer value, the behavior is undefined (see C11 standard, 6.3.1.4, paragraph 2). For instance, least significant bits of the variable value can be dropped leading to unexpected results.

#### Fix

Convert to a floating-point type that can represent the integer value.

For instance, if the `float` data type cannot represent the integer value, use the `double` data type instead.

When writing a function that converts an integer to floating point type, before the conversion, check if the integer value can be represented in the floating-point type. For instance, `DBL_MANT_DIG * log2(FLT_RADIX)` represents the number of base-2 digits in the type `double`. Before conversion to the type `double`, check if this number is greater than or equal to the precision of the integer that you are converting. To determine the precision of an integer `num`, use this code:

```
 size_t precision = 0;
 while (num != 0) {
    if (num % 2 == 1) {
      precision++;
    }
    num >>= 1;
 }
```

Some implementations provide a builtin function to determine the precision of an integer. For instance, GCC provides the function `__builtin_popcount`.

#### Example — Conversion of Large Integer to Floating-Point Type

```
#include <stdio.h>

int main(void) {
  long int big = 1234567890L;
  float approx = big;
  printf("%ld\n", (big - (long int)approx));
  return 0;
}
```

In this C code, the `long int` variable `big` is converted to `float`.

#### Correction — Use a Wider Floating-Point Type

One possible correction is to convert to the `double` data type instead of `float`.

```
#include <stdio.h>

int main(void) {
  long int big = 1234567890L;
  double approx = big;
  printf("%ld\n", (big - (long int)approx));
  return 0;
}
```

### Qualifier removed in conversion

#### Issue

*This checker is deactivated in a default Polyspace* as You Code *analysis. See “Checkers Deactivated in Polyspace as You Code Analysis”.*

This issue occurs during a pointer conversion when one pointer has a qualifier and the other does not. For example, when converting from a `const int*` to an `int*`, the conversion removes the `const` qualifier.

This defect applies only for projects in C.

#### Risk

Qualifiers such as `const` or `volatile` in a pointer declaration:

```
const int* ptr;
```

imply that the underlying object is `const` or `volatile`. These qualifiers act as instructions to the compiler. For instance, a `const` object is not supposed to be modified in the code and a `volatile` object is not supposed to be optimized away by the compiler.

If a second pointer points to the same object but does not use the same qualifier, the qualifier on the first pointer is no longer valid. For instance, if a `const int*` pointer and an `int*` pointer point to the same object, you can modify the object through the second pointer and violate the contract implied by the `const` qualifier in the first pointer.

#### Fix

If you intend to convert from one pointer to another, declare both pointers with the same qualifiers.

#### Example — Cast of Character Pointers

```
void read(char *);

void implicit_cast(void) {
    const char  cc, *pcc = &cc;
    char * quo;

    quo = &cc;
    quo = pcc;

    read(quo);
}
```

During the assignment to the character `q`, the variables, `cc` and `pcc`, are converted from `const char` to `char`. The `const` qualifier is removed during the conversion causing a defect.

#### Correction — Add Qualifiers

One possible correction is to add the same qualifiers to the new variables. In this example, changing `q` to a `const char` fixes the defect.

```
void read(char *);

void implicit_cast(void) {
    const char  cc, *pcc = &cc;
    const char * quo;

    quo = &cc;
    quo = pcc;

    read(quo);
}
```

#### Correction — Remove Qualifiers

One possible correction is to remove the qualifiers in the converted variable. In this example, removing the `const` qualifier from the `cc` and `pcc` initialization fixes the defect.

```
void read(char *);

void implicit_basic_cast(void) {
    char  cc, *pcc = &cc;
    char * quo;

    quo = &cc;
    quo = pcc;

    read(quo);
}
```

### Reading memory reallocated from object of another type without reinitializing first

#### Issue

This issue occurs when you do the following in sequence:

1. Reallocate memory to an object with a type that is different from the original allocation.

   For instance, in this code snippet, a memory originally allocated to a pointer with type `struct A*` is reallocated to a pointer with type `struct B*`:

   ```
   struct A;
   struct B;

   struct A *Aptr = (struct A*) malloc(sizeof(struct A));
   struct B *Bptr = (struct B*) realloc(Aptr, sizeof(struct B));
   ```
2. Read from this reallocated memory without reinitializing the memory first.

   Read accesses on the pointer to the reallocated memory can happen through pointer dereference or array indexing. Passing the pointer to a function that takes a pointer to a `const`-qualified object as the corresponding parameter also counts as a read access.

#### Risk

Reading from reallocated memory that has not been reinitialized leads to undefined behavior.

#### Fix

Reinitialize memory after reallocation and before the first read access.

The checker considers any write access on the pointer to the reallocated memory as satisfying the reinitialization requirement (even if the object might only be partially reinitialized). Write accesses on the pointer to the reallocated memory can happen through pointer dereference or array indexing. Passing the pointer to a function that takes a pointer to a non-`const`-qualified object as the corresponding parameter also counts as a write access.

**Example – Noncompliant: Reading from Reallocated Memory Without Reinitializing First**

```
#include<stdlib.h>

struct group {
    char *groupFirst;
    int groupSize;
};

struct groupWithID {
    int groupID;
    char *groupFirst;
    int groupSize;
};

char* readName();
int readSize();

void createGroup(int nextAvailableID) {
    struct group *aGroup;
    struct groupWithID *aGroupWithID;

    aGroup = (struct group*) malloc(sizeof(struct group));

    if(!aGroup) {
        /*Handle error*/
    }

    aGroup->groupFirst = readName();
    aGroup->groupSize  = readSize();

    /* Reassign to group with ID */
    aGroupWithID = (struct groupWithID*) realloc(aGroup, sizeof(struct groupWithID));
    if(!aGroupWithID) {
        free(aGroup);
        /*Handle error*/
    }

    if(aGroupWithID -> groupSize > 0) { /* Noncompliant */
        /* ... */
    }

    /* ...*/
    free(aGroupWithID);
}
```

In this example, the memory allocated to a `group*` pointer using the `malloc` function is reallocated to a `groupWithID*` pointer using the `realloc` function. There is a read access on the reallocated memory before the memory is reinitialized.

#### Correction – Reinitialize Memory After Reallocation and Before First Read

Reinitialize the memory assigned to the `groupWithID*` pointer before the first read access. All bits of the memory can be reinitialized using the `memset` function.

```
#include<stdlib.h>
#include<string.h>

struct group {
    char *groupFirst;
    int groupSize;
};

struct groupWithID {
    int groupID;
    char *groupFirst;
    int groupSize;
};

char* readName();
int readSize();

void createGroup(int nextAvailableID) {
    struct group *aGroup;
    struct groupWithID *aGroupWithID;

    aGroup = (struct group*) malloc(sizeof(struct group));

    if(!aGroup) {
        /*Handle error*/
    }

    aGroup->groupFirst = readName();
    aGroup->groupSize  = readSize();

    /* Reassign to group with ID */
    aGroupWithID = (struct groupWithID*) realloc(aGroup, sizeof(struct groupWithID));
    if(!aGroupWithID) {
        free(aGroup);
        /*Handle error*/
    }

    memset(aGroupWithID, 0 , sizeof(struct groupWithID));
    /* Reinitialize group */
    if(aGroupWithID -> groupSize > 0) {
        /* ... */
    }

    /* ...*/
    free(aGroupWithID);
}
```

### Sign change integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a signed integer. If the variable does not have enough bytes to represent both the original constant and the sign bit, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Convert from unsigned char to char

```
char sign_change(void) {
    unsigned char count = 255;

    return (char)count;
}
```

In the return statement, the unsigned character variable `count` is converted to a signed character. However, `char` has 8 bits, 1 for the sign of the constant and 7 to represent the number. The conversion operation overflows because 255 uses 8 bits.

#### Correction — Change conversion types

One possible correction is using a larger integer type. By using an `int`, there are enough bits to represent the sign and the number value.

```
int sign_change(void) {
    unsigned char count = 255;

    return (int)count;
}
```

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
memmove
strncmp
strncpy
calloc
malloc
memalign
```

#### Risk

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

#### Fix

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Set Memory Value with Size Argument

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

**Correction — Check Value of size**

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

### Unreliable cast of pointer

**Issue**

This issue occurs when a pointer is implicitly cast to a data type different from its declaration type. Such an implicit casting can take place, for instance, when a pointer to data type `char` is assigned the address of an integer.

This defect applies only if the code language for the project is C.

**Risk**

Casting a pointer to data type different from its declaration type can result in issues such as buffer overflow. If the cast is implicit, it can indicate a coding error.

**Fix**

Avoid *implicit* cast of a pointer to a data type different from its declaration type.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.

- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

**Example — Unreliable cast of pointer error**

```
#include <string.h>

void Copy_Integer_To_String()
{
 int src[]={1,2,3,4,5,6,7,8,9,10};
 char buffer[]="Buffer_Text";
 strcpy(buffer,src);
 /* Defect: Implicit cast of (int*) to (char*) */
}
```

`src` is declared as an `int*` pointer. The `strcpy` statement, while copying to `buffer`, implicitly casts `src` to `char*`.

**Correction — Avoid Pointer Cast**

One possible correction is to declare the pointer `src` with the same data type as `buffer`.

```
#include <string.h>
 void Copy_Integer_To_String()
{
 /* Fix: Declare src with same type as buffer */
 char *src[10]={"1","2","3","4","5","6","7","8","9","10"};
 char *buffer[10];

 for(int i=0;i<10;i++)
   buffer[i]="Buffer_Text";

 for(int i=0;i<10;i++)
   buffer[i]= src[i];
 }
```

### Unsafe conversion between pointer and integer

**Issue**

This issue occurs when you convert between a pointer type, such as `intptr_t`, or `uintprt_t`, and an integer type, such as `enum`, `ptrdiff_t`, or `pid_t`, or vice versa.

**Risk**

The mapping between pointers and integers is not always consistent with the addressing structure of the environment.

Converting from pointers to integers can create:

- Truncated or out of range integer values.
- Invalid integer types.

Converting from integers to pointers can create:

- Misaligned pointers or misaligned objects.

- Invalid pointer addresses.

#### Fix

Where possible, avoid pointer-to-integer or integer-to-pointer conversions. If you want to convert a `void` pointer to an integer, so that you do not change the value, use types:

- C99 — `intptr_t` or `uintptr_t`
- C90 — `size_t` or `ssize_t`

#### Example — Integer to Pointer Conversions

```
 unsigned int *badintptrcast(void)
{
    unsigned int *ptr0 = (unsigned int *)0xdeadbeef;
    char *ptr1 = (char *)0xdeadbeef;
    unsigned int *explicit_ptr = reinterpret_cast<unsigned int*>(0xdeadbeef);
    return (unsigned int *)(ptr0 - (unsigned int *)ptr1);
}
```

In this example, there are four conversions, three unsafe conversions and one safe conversion.

- The conversion of `0xdeadbeef` to an `unsigned int*` causes alignment issues for the pointer. Polyspace flags this conversion.
- The conversion of `0xdeadbeef` to a `char *` is not flagged because there are no alignment issues for `char`.
- The explicit `reinterpret_cast` of `0xdeadbeef` to an `unsigned int*` causes alignment issues for the pointer. Polyspace flags this conversion.
- The conversion in the return casts `ptrdiff_t` to a pointer. This pointer might point to an invalid address. Polyspace flags this conversion.

#### Correction — Use `intptr_t`

One possible correction is to use `intptr_t` types to store the pointer address `0xdeadbeef`. Also, you can change the second pointer to an integer offset so that there is no longer a conversion from `ptrdiff_t` to a pointer.

```
#include <stdint.h>

unsigned int *badintptrcast(void)
{
    intptr_t iptr0 = (intptr_t)0xdeadbeef;
    int offset = 0;
    return (unsigned int *)(iptr0 - offset);
}
```

### Unsigned integer conversion overflow

#### Issue

This issue occurs when converting an unsigned integer to a smaller unsigned integer type. If the variable does not have enough bytes to represent the original constant, the conversion overflows.

The exact storage allocation for different floating point types depends on your processor. See `Target processor type (-target)`.

#### Risk

Integer conversion overflows result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the conversion so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

In general, avoid conversions to smaller integer types.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Converting from int to char

```
unsigned char convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned char)unum;
}
```

In the return statement, the unsigned integer variable `unum` is converted to an unsigned character type. However, the conversion overflows because 1000000 requires at least 20 bits. The C programming language standard does not view unsigned overflow as an error because the program automatically reduces the result by modulo the maximum value plus 1. In this example, `unum` is reduced by modulo `2^8` because a character data type can only represent `2^8-1`.

#### Correction — Change Conversion Type

One possible correction is to convert to a different integer type that can represent the entire number. For example, `long`.

```
unsigned long convert(void) {
    unsigned int unum = 1000000U;

    return (unsigned long)unum;
}
```

### Wrong allocated object size for cast

#### Issue

This issue occurs during pointer conversion when the pointer's address is misaligned. If a pointer is converted to a different pointer type, the size of the allocated memory must be a multiple of the size of the destination pointer.

#### Risk

Dereferencing a misaligned pointer has undefined behavior and can cause your program to crash.

#### Fix

Suppose you convert a pointer `ptr1` to `ptr2`. If `ptr1` points to a buffer of `N` bytes and `ptr2` is a *`type`* `*` pointer where `sizeof(`*`type`*`)` is `n` bytes, make sure that `N` is an integer multiple of `n`.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Dynamic Allocation of Pointers

```
#include <stdlib.h>

void dyn_non_align(void){
    void *ptr = malloc(13);
    long *dest;

    dest = (long*)ptr; //defect
}
```

In this example, the software raises a defect on the conversion of `ptr` to a `long*`. The dynamically allocated memory of `ptr`, 13 bytes, is not a multiple of the size of `dest`, 4 bytes. This misalignment causes the **Wrong allocated object size for cast** defect.

#### Correction — Change the Size of the Pointer

One possible correction is to use a pointer size that is a multiple of the destination size. In this example, resolve the defect by changing the allocated memory to 12 instead of 13.

```
#include <stdlib.h>

void dyn_non_align(void){
    void *ptr = malloc(12);
    long *dest;
    dest = (long*)ptr;
}
```

#### Example — Static Allocation of Pointers

```
void static_non_align(void){
    char arr[13], *ptr;
    int *dest;

    ptr = &arr[0];
    dest = (int*)ptr; //defect
}
```

In this example, the software raises a defect on the conversion of `ptr` to an `int*` in line 6. `ptr` has a memory size of 13 bytes because the array `arr` has a size of 13 bytes. The size of `dest` is 4 bytes, which is not a multiple of 13. This misalignment causes the **Wrong allocated object size for cast** defect.

#### Correction — Change the Size of the Pointer

One possible correction is to use a pointer size that is a multiple of the destination size. In this example, resolve the defect by changing the size of the array `arr` to a multiple of 4.

```
void static_non_align(void){
    char arr[12], *ptr;
    int *dest;

    ptr = &arr[0];
    dest = (int*)ptr;
}
```

#### Example — Allocation with a Function

```
#include <stdlib.h>

void *my_alloc(int size) {
    void *ptr_func = malloc(size);
    if(ptr_func == NULL) exit(-1);
    return ptr_func;
}

void fun_non_align(void){
    int *dest1;
    char *dest2;

    dest1 = (int*)my_alloc(13);  //defect
    dest2 = (char*)my_alloc(13); //not a defect
}
```

In this example, the software raises a defect on the conversion of the pointer returned by `my_alloc(13)` to an `int*` in line 11. `my_alloc(13)` returns a pointer with a dynamically allocated size of 13 bytes. The size of `dest1` is 4 bytes, which is not a divisor of 13. This misalignment causes the **Wrong allocated object size for cast** defect. In line 12, the same function call, `my_alloc(13)`, does not call a defect for the conversion to `dest2` because the size of `char*`, 1 byte, a divisor of 13.

#### Correction — Change the Size of the Pointer

One possible correction is to use a pointer size that is a multiple of the destination size. In this example, resolve the defect by changing the argument for `my_alloc` to a multiple of 4.

```
#include <stdlib.h>

void *my_alloc(int size) {
    void *ptr_func = malloc(size);
    if(ptr_func == NULL) exit(-1);
    return ptr_func;
}

void fun_non_align(void){
    int *dest1;
    char *dest2;

    dest1 = (int*)my_alloc(12);
    dest2 = (char*)my_alloc(13);
}
```

Compiler Optimization Removal or Modification of Security-critical Code

## Description

### Rule Description

*The developer builds a security-critical protection mechanism into the software, but the compiler optimizes the program such that the mechanism is removed or modified.*

### Polyspace Implementation

The rule checker checks for **Uncertain memory cleaning**.

## Examples

### Uncertain memory cleaning

#### Issue

This issue occurs when you clean memory by writing `0` into it but the memory is not read after the cleaning operation. Because the memory is not read after the cleaning, a compiler might skip the cleaning operation when optimizing the code. For instance, consider this code:

```
void foo(){
    void* buffer = getSensitiveData();
    //...
    memset(buffer, 0, sizeof(buffer));
}
```

Here, `buffer` might contain sensitive data. The call to `memset()` is intended to scrub the data. Because buffer is not read after the scrubbing, the compiler optimization process might ignore the `memset()` command. The data in `buffer` might remain uncleaned. Polyspace flags such uncertain memory cleaning. Polyspace does not raise this defect if either of these conditions are true:

- The return value of the memory cleaning function is assigned to a variable.
- The memory cleaning function scrubs a global object.

#### Risk

When a variable is written with no further read, compilers might consider it as a deadstore. To optimize the code, the compiler might remove any assignments to deadstore variables.

If such code optimization removes code that scrubs sensitive information from memory, then sensitive information might remain uncleaned in your system. An attacker can then access the sensitive information and use it to further erode the protection mechanisms in your code.

#### Fix

When scrubbing memory, use code that the compiler cannot remove. For instance, instead of `memset`, use secure functions, such as `memset_s` or `fill_n`. If you use an older version of C or C++ where these functions are unavailable, consider updating your code to a more recent version. Alternatively, you might implement your own secure memory-scrubbing function. When using your own implementation, review the compiled code to make sure that the memory-cleaning operations are untouched by the compiler.

**Example — Avoid Uncertainty in Cleaning Sensitive Memory**

```
#include <string.h>

extern int getSensitiveData(char*, size_t);
extern int writeDB(char*, char*);
char Gbuffer[64];
void Job(char *key) {
    char buffer[64];
    if (getSensitiveData(buffer, sizeof(buffer))) {
        if (writeDB(key, buffer)) {
            // Record data
        }
    }
    (void) memset(buffer, 0, sizeof(buffer)); // Defect
}

void manageGBuffer(char *key) {
    //...
    memset(Gbuffer, 0, sizeof(Gbuffer)); // No Defect
}
```

In this example, the command `memset()` is used in `Job()` to clean the memory in `buffer`. Because `buffer` is not read after the cleaning, the compiler might remove this code when optimizing the code. Polyspace flags the uncertain cleaning. In the function `manage()`, `memset()` is used to clean the global array `Gbuffer`. Polyspace does not flag this cleaning operation.

**Correction — Use Secure Functions to Clean Sensitive Memory**

To fix this defect, use secure functions, such as `memset_s()`, to clean uncertain memory.

```
#include <string.h>

extern int getSensitiveData(char*, size_t);
extern int writeDB(char*, char*);

void Job(char *key) {
    char buffer[64];
    if (getSensitiveData(buffer, sizeof(buffer))) {
        if (writeDB(key, buffer)) {
            // Record data
        }
    }
    memset_s(buffer, 0, sizeof(buffer)); // No Defect
}
```

Mismatched Memory Management Routines

## Description

### Rule Description

*The application attempts to return a memory resource to the system, but it calls a release function that is not compatible with the function that was originally used to allocate that resource.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Invalid free of pointer**
- **Mismatched alloc/dealloc functions on Windows**

## Examples

### Invalid free of pointer

**Issue**

This issue occurs when a block of memory released using the `free` function was not previously allocated using `malloc`, `calloc`, or `realloc`.

**Risk**

The `free` function releases a block of memory allocated on the heap. If you try to access a location on the heap that you did not allocate previously, a segmentation fault can occur.

The issue can highlight coding errors. For instance, you perhaps wanted to use the `free` function or a previous `malloc` function on a different pointer.

**Fix**

In most cases, you can fix the issue by removing the `free` statement. If the pointer is not allocated memory from the heap with `malloc` or `calloc`, you do not need to free the pointer. You can simply reuse the pointer as required.

If the issue highlights a coding error such as use of `free` or `malloc` on the wrong pointer, correct the error.

If the issue occurs because you use the `free` function to free memory allocated with the `new` operator, replace the `free` function with the `delete` operator.

**Example — Invalid Free of Pointer Error**

```
#include <stdlib.h>

void Assign_Ones(void)
{
  int p[10];
  for(int i=0;i<10;i++)
     *(p+i)=1;

  free(p);
  /* Defect: p does not point to dynamically allocated memory */
}
```

The pointer `p` is deallocated using the `free` function. However, `p` points to a memory location that was not dynamically allocated.

#### Correction — Remove Pointer Deallocation

If the number of elements of the array `p` is known at compile time, one possible correction is to remove the deallocation of the pointer `p`.

```
#include <stdlib.h>

void Assign_Ones(void)
 {
  int p[10];
  for(int i=0;i<10;i++)
     *(p+i)=1;
  /* Fix: Remove deallocation of p */
 }
```

#### Correction — Introduce Pointer Allocation

If the number of elements of the array `p` is not known at compile time, one possible correction is to dynamically allocate memory to the array `p`.

```
#include <stdlib.h>

void Assign_Ones(int num)
{
  int *p;
  /* Fix: Allocate memory dynamically to p */
  p=(int*) calloc(10,sizeof(int));
  for(int i=0;i<10;i++)
     *(p+i)=1;
  free(p);
}
```

### Mismatched alloc/dealloc functions on Windows

#### Issue

This issue occurs when you use a Windows deallocation function that is not properly paired to its corresponding allocation function.

#### Risk

Deallocating memory with a function that does not match the allocation function can cause memory corruption or undefined behavior. If you are using an older version of Windows, the improper function can also cause compatibility issues with newer versions.

#### Fix

Properly pair your allocation and deallocation functions according to the functions listed in this table.

| Allocation Function | Deallocation Function |
|---|---|
| malloc() | free() |
| realloc() | free() |
| calloc() | free() |
| _aligned_malloc() | _aligned_free() |
| _aligned_offset_malloc() | _aligned_free() |
| _aligned_realloc() | _aligned_free() |
| _aligned_offset_realloc() | _aligned_free() |
| _aligned_recalloc() | _aligned_free() |
| _aligned_offset_recalloc() | _aligned_free() |
| _malloca() | _freea() |
| LocalAlloc() | LocalFree() |
| LocalReAlloc() | LocalFree() |
| GlobalAlloc() | GlobalFree() |
| GlobalReAlloc() | GlobalFree() |
| VirtualAlloc() | VirtualFree() |
| VirtualAllocEx() | VirtualFreeEx() |
| VirtualAllocExNuma() | VirtualFreeEx() |
| HeapAlloc() | HeapFree() |
| HeapReAlloc() | HeapFree() |

**Example — Memory Deallocated with Incorrect Function**

```
#ifdef _WIN32_
#include <windows.h>
#else
#define _WIN32_
typedef void *HANDLE;
typedef HANDLE HGLOBAL;
typedef HANDLE HLOCAL;
typedef unsigned int UINT;
extern HLOCAL LocalAlloc(UINT uFlags, UINT uBytes);
extern HLOCAL LocalFree(HLOCAL hMem);
extern HGLOBAL GlobalFree(HGLOBAL hMem);
#endif

#define SIZE9 9

void func(void)
{
    /* Memory allocation */
    HLOCAL p = LocalAlloc(0x0000, SIZE9);

    if (p) {
        /* Memory deallocation. */
        GlobalFree(p);
    }
}
```

In this example, memory is allocated with `LocallAlloc()`. The program then erroneously uses `GlobalFree()` to deallocate the memory.

**Correction — Properly Pair Windows Allocation and Deallocation Functions**

When you allocate memory with `LocalAllocate()`, use `LocalFree()` to deallocate the memory.

```
#ifdef _WIN32_
#include <windows.h>
#else
#define _WIN32_
typedef void *HANDLE;
typedef HANDLE HGLOBAL;
typedef HANDLE HLOCAL;
typedef unsigned int UINT;
extern HLOCAL LocalAlloc(UINT uFlags, UINT uBytes);
extern HLOCAL LocalFree(HLOCAL hMem);
extern HGLOBAL GlobalFree(HGLOBAL hMem);
#endif

#define SIZE9 9
void func(void)
{
    /* Memory allocation */
    HLOCAL p = LocalAlloc(0x0000, SIZE9);
    if (p) {
        /* Memory deallocation. */
        LocalFree(p);
    }
}
```

CWE-762

# CWE Rule 763

Release of Invalid Pointer or Reference

## Description

### Rule Description

*The application attempts to return a memory resource to the system, but calls the wrong release function or calls the appropriate release function incorrectly.*

### Polyspace Implementation

The rule checker checks for **Invalid free of pointer**.

## Examples

### Invalid free of pointer

#### Issue

This issue occurs when a block of memory released using the `free` function was not previously allocated using `malloc`, `calloc`, or `realloc`.

#### Risk

The `free` function releases a block of memory allocated on the heap. If you try to access a location on the heap that you did not allocate previously, a segmentation fault can occur.

The issue can highlight coding errors. For instance, you perhaps wanted to use the `free` function or a previous `malloc` function on a different pointer.

#### Fix

In most cases, you can fix the issue by removing the `free` statement. If the pointer is not allocated memory from the heap with `malloc` or `calloc`, you do not need to free the pointer. You can simply reuse the pointer as required.

If the issue highlights a coding error such as use of `free` or `malloc` on the wrong pointer, correct the error.

If the issue occurs because you use the `free` function to free memory allocated with the `new` operator, replace the `free` function with the `delete` operator.

#### Example — Invalid Free of Pointer Error

```
#include <stdlib.h>

void Assign_Ones(void)
{
  int p[10];
  for(int i=0;i<10;i++)
     *(p+i)=1;
  free(p);
  /* Defect: p does not point to dynamically allocated memory */
}
```

The pointer `p` is deallocated using the `free` function. However, `p` points to a memory location that was not dynamically allocated.

#### Correction — Remove Pointer Deallocation

If the number of elements of the array `p` is known at compile time, one possible correction is to remove the deallocation of the pointer `p`.

```
#include <stdlib.h>

void Assign_Ones(void)
 {
  int p[10];
  for(int i=0;i<10;i++)
     *(p+i)=1;
  /* Fix: Remove deallocation of p */
 }
```

#### Correction — Introduce Pointer Allocation

If the number of elements of the array `p` is not known at compile time, one possible correction is to dynamically allocate memory to the array `p`.

```
#include <stdlib.h>

void Assign_Ones(int num)
{
  int *p;
  /* Fix: Allocate memory dynamically to p */
  p=(int*) calloc(10,sizeof(int));
  for(int i=0;i<10;i++)
     *(p+i)=1;
  free(p);
}
```

CWE-763

# CWE Rule 766

Critical Data Element Declared Public

## Description

### Rule Description

*The software declares a critical variable, field, or member to be public when intended security policy requires it to be private.*

### Polyspace Implementation

The rule checker checks for **Critical data member is not private**.

## Examples

### Critical data member is not private

#### Issue

This issue occurs when you declare a critical nonstatic data member of a class to be `public`. By default, Polyspace assumes that no data member is critical. Specify the critical data members in your code by using the code behavior `CRITICAL_DATA`. See “Specifying Critical Data Members”. If you do not specify any critical data members, Polyspace raises a warning during the analysis.

#### Risk

Declaring the critical data members as `public` allows the clients of a class to modify critical data members. You can inadvertently introduce vulnerabilities when critical data members are public. The vulnerabilities of such code are difficult to find and time-consuming to fix.

#### Fix

To fix this defect, determine which data members are critical and declare them as `private` or `protected`.

#### Example — Declare Critical Data Members as Private

```
#include <string.h>
#define MAX_PASSWORD_LENGTH 15
#define MAX_USERNAME_LENGTH 15

class UserAccount
{
public:
  UserAccount(char *username, char *password)
  {
    //...
  }

  int authorizeAccess(char *username, char *password)
  {
    //...
  }
  char username[MAX_USERNAME_LENGTH+1];
  char password[MAX_PASSWORD_LENGTH+1];
};
```

In this example, the data members `username` and `password` are declared as `public`. Specify these variables as critical in a code behavior XML file:

```
<specifications>
   <members>
    <member name="password" kind="variable">
        <behavior name="CRITICAL_DATA"/>
    </member>
    <member name="username" kind="variable">
        <behavior name="CRITICAL_DATA"/>
    </member>
   </members>
</specifications>
```

After you specify the variables as critical, Polyspace flags the public critical data members. If you do not specify the critical data members, Polyspace assumes that no data members are critical and the defect is not raised.

#### Correction — Declare Critical Variables as Private

To fix this defect, declare the critical variables as `private`

```
#include <string.h>

#define MAX_PASSWORD_LENGTH 15
#define MAX_USERNAME_LENGTH 15

class UserAccount
{
public:
  UserAccount(char *username, char *password)
  {
    //...
  }

  int authorizeAccess(char *username, char *password)
  {
    //...
  }
private:
  char username[MAX_USERNAME_LENGTH+1];
  char password[MAX_PASSWORD_LENGTH+1];
};
```

Access to Critical Private Variable via Public Method

## Description

### Rule Description

*The software defines a public method that reads or modifies a private variable.*

### Polyspace Implementation

The rule checker checks for **Return of non-const handle to encapsulated data member**.

## Examples

### Return of non-const handle to encapsulated data member

#### Issue

This issue occurs when:

- A class method returns a handle to a data member. Handles include pointers and references.
- The method is more accessible than the data member. For instance, the method has access specifier `public`, but the data member is `private` or `protected`.

#### Risk

The access specifier determines the accessibility of a class member. For instance, a class member declared with the `private` access specifier cannot be accessed outside a class. Therefore, nonmember, nonfriend functions cannot modify the member.

When a class method returns a handle to a less accessible data member, the member accessibility changes. For instance, if a `public` method returns a pointer to a `private` data member, the data member is effectively not `private` anymore. A nonmember, nonfriend function calling the `public` method can use the returned pointer to view and modify the data member.

Also, if you assign the pointer to a data member of an object to another pointer, when you delete the object, the second pointer can be left dangling. The second pointer points to the part of an object that does not exist anymore.

#### Fix

One possible fix is to avoid returning a handle to a data member from a class method. Return a data member by value so that a copy of the member is returned. Modifying the copy does not change the data member.

If you must return a handle, use a `const` qualifier with the method return type so that the handle allows viewing, but not modifying, the data member.

#### Example — Return of Pointer to private Data Member

```
#include <string>
#define NUM_RECORDS 100
```

```
struct Date {
    int dd;
    int mm;
    int yyyy;
};

struct Period {
    Date startDate;
    Date endDate;
};

class DataBaseEntry {
private:
    std::string employeeName;
    Period employmentPeriod;
public:
    Period* getPeriod(void);
};

Period* DataBaseEntry::getPeriod(void) {
    return &employmentPeriod;
}

void use(Period*);
void reset(Period*);

int main() {
    DataBaseEntry dataBase[NUM_RECORDS];
    Period* tempPeriod;
    for(int i=0;i < NUM_RECORDS;i++) {
        tempPeriod = dataBase[i].getPeriod();
        use(tempPeriod);
        reset(tempPeriod);
    }
    return 0;
}

void reset(Period* aPeriod) {
       aPeriod->startDate.dd = 1;
       aPeriod->startDate.mm = 1;
       aPeriod->startDate.yyyy = 2000;
}
```

In this example, `employmentPeriod` is `private` to the class `DataBaseEntry`. It is therefore immune from modification by nonmember, nonfriend functions. However, returning a pointer to `employmentPeriod` breaks this encapsulation. For instance, the nonmember function `reset` modifies the member `startDate` of `employmentPeriod`.

**Correction: Return Member by Value**

One possible correction is to return the data member `employmentPeriod` by value instead of pointer. Modifying the return value does not change the data member because the return value is a copy of the data member.

```
#include <string>
#define NUM_RECORDS 100

struct Date {
    int dd;
    int mm;
    int yyyy;
};

struct Period {
    Date startDate;
    Date endDate;
};

class DataBaseEntry {
private:
    std::string employeeName;
    Period employmentPeriod;
public:
    Period getPeriod(void);
};

Period DataBaseEntry::getPeriod(void) {
    return employmentPeriod;
}

void use(Period*);
void reset(Period*);

int main() {
    DataBaseEntry dataBase[NUM_RECORDS];
    Period tempPeriodVal;
    Period* tempPeriod;
    for(int i=0;i < NUM_RECORDS;i++) {
        tempPeriodVal = dataBase[i].getPeriod();
        tempPeriod = &tempPeriodVal;
        use(tempPeriod);
        reset(tempPeriod);
    }
    return 0;
}

void reset(Period* aPeriod) {
       aPeriod->startDate.dd = 1;
       aPeriod->startDate.mm = 1;
       aPeriod->startDate.yyyy = 2000;
}
```

Operator Precedence Logic Error

## Description

### Rule Description

*The program uses an expression in which operator precedence causes incorrect logic to be used.*

### Polyspace Implementation

The rule checker checks for **Possibly unintended evaluation of expression because of operator precedence rules**.

## Examples

### Possibly unintended evaluation of expression because of operator precedence rules

#### Issue

This issue occurs when an arithmetic expression result is possibly unintended because operator precedence rules dictate an evaluation order that you do not expect.

The defect highlights expressions of the form `x` *`op_1`* `y` *`op_2`* `z`. Here, *`op_1`* and *`op_2`* are operator combinations that commonly induce this error. For instance, `x == y | z`.

The checker does not flag all operator combinations. For instance, `x == y || z` is not flagged because you most likely intended to perform a logical OR between `x == y` and `z`. Specifically, the checker flags these combinations:

- && and `||`: For instance, `x || y && z` or `x && y || z`.
- Assignment and bitwise operations: For instance, `x = y | z`.
- Assignment and comparison operations: For instance, `x = y != z` or `x = y > z`.
- Comparison operations: For instance, `x > y > z` (except when one of the comparisons is an equality `x == y > z`).
- Shift and numerical operation: For instance, `x << y + 2`.
- Pointer dereference and arithmetic: For instance, `*p++`.

#### Risk

The defect can cause the following issues:

- If you or another code reviewer reviews the code, the intended order of evaluation is not immediately clear.
- It is possible that the result of the evaluation does not meet your expectations. For instance:
  - In the operation `*p++`, it is possible that you expect the dereferenced value to be incremented. However, the pointer `p` is incremented before the dereference.
  - In the operation `(x == y | z)`, it is possible that you expect `x` to be compared with `y | z`. However, the == operation happens before the `|` operation.

#### Fix

See if the order of evaluation is what you intend. If not, apply parentheses to implement the evaluation order that you want.

For better readability of your code, it is good practice to apply parenthesis to implement an evaluation order even when operator precedence rules impose that order.

#### Example — Expressions with Possibly Unintended Evaluation Order

```
int test(int a, int b, int c) {
    return(a & b == c);
}
```

In this example, the == operation happens first, followed by the & operation. If you intended the reverse order of operations, the result is not what you expect.

#### Correction — Parenthesis For Intended Order

One possible correction is to apply parenthesis to implement the intended evaluation order.

```
int test(int a, int b, int c) {
    return((a & b) == c);
}
```

Use of Path Manipulation Function without Maximum-sized Buffer

## Description

### Rule Description

*The software invokes a function for normalizing paths or file names, but it provides an output buffer that is smaller than the maximum possible size, such as PATH_MAX.*

### Polyspace Implementation

The rule checker checks for **Use of path manipulation function without maximum-sized buffer checking**.

## Examples

### Use of path manipulation function without maximum-sized buffer checking

**Issue**

This issue occurs when the destination argument of a path manipulation function such as `realpath` or `getwd` has a buffer size less than `PATH_MAX` bytes.

**Risk**

A buffer smaller than `PATH_MAX` bytes can overflow but you cannot test the function return value to determine if an overflow occurred. If an overflow occurs, following the function call, the content of the buffer is undefined.

For instance, `char *getwd(char *buf)` copies an absolute path name of the current folder to its argument. If the length of the absolute path name is greater than `PATH_MAX` bytes, `getwd` returns `NULL` and the content of `*buf` is undefined. You can test the return value of `getwd` for `NULL` to see if the function call succeeded.

However, if the allowed buffer for `buf` is less than `PATH_MAX` bytes, a failure can occur for a smaller absolute path name. In this case, `getwd` does not return `NULL` even though a failure occurred. Therefore, the allowed buffer for `buf` must be `PATH_MAX` bytes long.

**Fix**

Possible fixes are:

- Use a buffer size of `PATH_MAX` bytes. If you obtain the buffer from an unknown source, before using the buffer as argument of `getwd` or `realpath` function, make sure that the size is less than `PATH_MAX` bytes.
- Use a path manipulation function that allows you to specify a buffer size.

  For instance, if you are using `getwd` to get the absolute path name of the current folder, use `char *getcwd(char *buf, size_t size);` instead. The additional argument `size` allows you to specify a size greater than or equal to `PATH_MAX`.

- Allow the function to allocate additional memory dynamically, if possible.

  For instance, `char *realpath(const char *path, char *resolved_path);` dynamically allocates memory if `resolved_path` is `NULL`. However, you have to deallocate this memory later using the `free` function.

**Example — Possible Buffer Overflow in Use of getwd Function**

```
#include <unistd.h>
#include <linux/limits.h>
#include <stdio.h>

void func(void) {
    char buf[PATH_MAX];
    if (getwd(buf+1)!= NULL)         {
        printf("cwd is %s\n", buf);
    }
}
```

In this example, although the array `buf` has `PATH_MAX` bytes, the argument of `getwd` is `buf + 1`, whose allowed buffer is less than `PATH_MAX` bytes.

**Correction — Use Array of Size PATH_MAX Bytes**

One possible correction is to use an array argument with size equal to `PATH_MAX` bytes.

```
#include <unistd.h>
#include <linux/limits.h>
#include <stdio.h>

void func(void) {
    char buf[PATH_MAX];
    if (getwd(buf)!= NULL)         {
        printf("cwd is %s\n", buf);
    }
}
```

Out-of-bounds Write

## Description

### Rule Description

*The software writes data past the end, or before the beginning, of the intended buffer.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Destination buffer overflow in string manipulation**
- **Destination buffer underflow in string manipulation**

## Examples

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

#### Example — Buffer Overflow in sprintf Use

```
#include <stdio.h>
```

```
void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

**Correction — Use `snprintf` Instead of `sprintf`**

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Destination buffer underflow in string manipulation

**Issue**

This issue occurs when certain string manipulation functions write to their destination buffer argument at a negative offset from the beginning of the buffer.

For instance, for the function `sprintf(char* buffer, const char* format)`, you obtain the `buffer` from an operation `buffer = (char*)arr; ... buffer += offset;`. `arr` is an array and `offset` is a negative value.

**Risk**

Buffer underflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer underflow also introduces the risk of code injection.

**Fix**

If the destination buffer argument results from pointer arithmetic, see if you are decrementing a pointer. Fix the pointer decrement by modifying either the original value before decrement or the decrement value.

**Example — Buffer Underflow in sprintf Use**

```
#include <stdio.h>
#define offset -2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

In this example, `&buffer[offset]` is at a negative offset from the memory allocated to `buffer`.

#### Correction — Change Pointer Decrementer

One possible correction is to change the value of `offset`.

```
#include <stdio.h>
#define offset 2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

Memory Allocation with Excessive Size Value

## Description

### Rule Description

*The product allocates memory based on an untrusted, large size value, but it does not ensure that the size is within expected limits, allowing arbitrary amounts of memory to be allocated.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Memory allocation with tainted size**
- **Tainted size of variable length array**
- **Wrong type used in sizeof**

## Examples

### Memory allocation with tainted size

#### Issue

This issue occurs when a memory allocation function, such as `calloc` or `malloc`, uses a size argument from an unsecure source.

#### Risk

Uncontrolled memory allocation can cause your program to request too much system memory. This consequence can lead to a crash due to an out-of-memory condition, or assigning too many resources.

#### Fix

Before allocating memory, check the value of your arguments to check that they do not exceed the bounds.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Allocate Memory Using Input From User

```
#include<stdio.h>
#include <stdlib.h>

int* bug_taintedmemoryallocsize(void) {
    size_t size;
    scanf("%zu", &size);
    int* p = (int*)malloc(size);//Noncompliant
    return p;
}
```

In this example, `malloc` allocates `size` bytes of memory for the pointer `p`. The variable `size` comes from the user of the program. Its value is not checked, and it could be larger than the amount of available memory. If `size` is larger than the number of available bytes, your program could crash.

#### Correction — Check Size of Memory to be Allocated

One possible correction is to check the size of the memory that you want to allocate before performing the `malloc` operation. This example checks to see if `size` is positive and less than the maximum size.

```
#include<stdio.h>
#include <stdlib.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

int* corrected_taintedmemoryallocsize(void) {
    size_t size;
    scanf("%zu", &size);
    int* p = NULL;
    if (size>0 && size<SIZE128) {          /* Fix: Check entry range before use */
        p = (int*)malloc((unsigned int)size);
    }
    return p;
}
```

### Tainted size of variable length array

#### Issue

This issue occurs when the size of a variable length array (VLA) is obtained from an unsecure source.

#### Risk

If an attacker changed the size of your VLA to an unexpected value, it can cause your program to crash or behave unexpectedly.

If the size is non-positive, the behavior of the VLA is undefined. Your program does not perform as expected.

If the size is unbounded, the VLA can cause memory exhaustion or stack overflow.

#### Fix

Validate your VLA size to make sure that it is positive and less than a maximum value.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

### Example — Example — User Input Argument Used as Size of VLA

```
#include<stdio.h>
#inclule<stdlib.h>
#define LIM 40

long squaredSum(int size) {

    int tabvla[size];
    long res = 0;
    for (int i=0 ; i<LIM-1 ; ++i) {
        tabvla[i] = i*i;
        res += tabvla[i];
    }
    return res;
}
int main(){
    int size;
    scanf("%d",&size);
    //...
    long result = squaredSum(size);
    //...
    return 0;
}
```

In this example, a variable length array size is based on an input argument. Because this input argument value is not checked, the size may be negative or too large.

### Correction — Check VLA Size

One possible correction is to check the size variable before creating the variable length array. This example checks if the size is larger than 0 and less than 40, before creating the VLA

```
#include <stdio.h>
#include <stdlib.h>
#define LIM 40

long squaredSum(int size) {
    long res = 0;
    if (size>0 && size<LIM){
        int tabvla[size];
        for (int i=0 ; i<size || i<LIM-1 ; ++i) {
            tabvla[i] = i*i;
            res += tabvla[i];
        }
    }else{
        res = -1;
    }
    return res;
}
int main(){
    int size;
    scanf("%d",&size);
    //...
    long result = squaredSum(size);
    //...
    return 0;
}
```

## Wrong type used in sizeof

### Issue

This issue occurs when both of the following conditions hold:

1. You assign the address of a block of memory to a pointer, or transfer data between two blocks of memory. The assignment or copy uses the `sizeof` operator.

   For instance, you initialize a pointer using `malloc(sizeof(`*`type`*`))` or copy data between two addresses using `memcpy(`*`destination_ptr`*`, `*`source_ptr`*`, sizeof(`*`type`*`))`.
2. You use an incorrect type as argument of the `sizeof` operator. For instance:

   - You might be using the pointer type instead of the type that the pointer points to. For example, to initialize a *`type`*`*` pointer, you might be using `malloc(sizeof(`*`type`*`*))` instead of `malloc(sizeof(`*`type`*`))`.
   - You might be using a completely unrelated type as `sizeof` argument. For example, to initialize a *`type`*`*` pointer, you might be using `malloc(sizeof(`*`anotherType`*`))`.

### Risk

Irrespective of what *`type`* stands for, the expression `sizeof(`*`type`*`*)` always returns a fixed size. The size returned is the pointer size on your platform in bytes. The appearance of `sizeof(`*`type`*`*)` often indicates an unintended usage. The error can cause allocation of a memory block that is much smaller than what you need and lead to weaknesses such as buffer overflows.

For instance, assume that `structType` is a structure with ten `int` variables. If you initialize a `structType*` pointer using `malloc(sizeof(structType*))` on a 32-bit platform, the pointer is assigned a memory block of four bytes. However, to be allocated completely for one `structType` variable, the `structType*` pointer must point to a memory block of `sizeof(structType) = 10 * sizeof(int)` bytes. The required size is much greater than the actual allocated size of four bytes.

### Fix

To initialize a *`type`*`*` pointer, replace `sizeof(`*`type`*`*)` in your pointer initialization expression with `sizeof(`*`type`*`)`.

### Example — Allocate a Char Array With sizeof

```
#include <stdlib.h>

void test_case_1(void) {
    char* str;

    str = (char*)malloc(sizeof(char*) * 5);
    free(str);

}
```

In this example, memory is allocated for the character pointer `str` using a `malloc` of five char pointers. However, `str` is a pointer to a character, not a pointer to a character pointer. Therefore the `sizeof` argument, `char*`, is incorrect.

### Correction — Match Pointer Type to `sizeof` Argument

One possible correction is to match the argument to the pointer type. In this example, `str` is a character pointer, therefore the argument must also be a character.

```
#include <stdlib.h>

void test_case_1(void) {
    char* str;

    str = (char*)malloc(sizeof(char) * 5);
    free(str);

}
```

Use of Hard-coded Credentials

## Description

### Rule Description

*The software contains hard-coded credentials, such as a password or cryptographic key, which it uses for its own inbound authentication, outbound communication to external components, or encryption of internal data.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Constant cipher key**
- **Hard-coded sensitive data**

## Examples

### Constant cipher key

**Issue**

This issue occurs when you use a constant for the encryption or decryption key.

**Risk**

If you use a constant for the encryption or decryption key, an attacker can retrieve your key easily.

You use a key to encrypt and later decrypt your data. If a key is easily retrieved, data encrypted using that key is not secure.

**Fix**

Produce a random key by using a strong random number generator.

For a list of random number generators that are cryptographically weak, see `Vulnerable pseudo-random number generator`.

**Example — Constants Used for Key**

```
#include <openssl/evp.h>
#include <stdlib.h>
#define SIZE16 16

int func(EVP_CIPHER_CTX *ctx, unsigned char *iv){
    unsigned char key[SIZE16] = {'1', '2', '3', '4','5','6','b','8','9',
                                 '1','2','3','4','5','6','7'};
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

In this example, the cipher key, key, has constants only. An attacker can easily retrieve a constant key.

#### Correction — Use Random Key

Use a strong random number generator to produce the cipher key. The corrected code here uses the function RAND_bytes declared in openssl/rand.h.

```
#include <openssl/evp.h>
#include <openssl/rand.h>
#include <stdlib.h>
#define SIZE16 16

int func(EVP_CIPHER_CTX *ctx, unsigned char *iv){
    unsigned char key[SIZE16];
    RAND_bytes(key, 16);
    return EVP_CipherInit_ex(ctx, EVP_aes_128_cbc(), NULL, key, iv, 1);
}
```

### Hard-coded sensitive data

#### Issue

This issue occurs when data that is potentially sensitive is directly exposed in the code, for instance, as string literals. The checker identifies certain data as sensitive from their use in certain functions such as password encryption functions.

Following data can be potentially sensitive.

| Type of Data | Functions That Indicate Sensitive Nature of Information |
|---|---|
| Host name | • sethostname, setdomainname, gethostbyname, gethostbyname2, getaddrinfo, gethostbyname_r, gethostbyname2_r (string argument)<br>• inet_aton, inet_pton, inet_net_pton, inet_addr, inet_network (string argument)<br>• mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (2nd argument) |
| Password | • CreateProcessWithLogonW, LogonUser (1st argument)<br>• mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (3rd argument) |

| Type of Data | Functions That Indicate Sensitive Nature of Information |
|---|---|
| Database | • MySQL: mysql_real_connect, mysql_real_connect_nonblocking, mysql_connect (4th argument)<br>• SQLite: sqlite3_open, sqlite3_open16, sqlite3_open_v2 (1st argument)<br>• PostgreSQL: PQconnectdb<br>• Microsoft SQL: SQLDriverConnect (3rd argument) |
| User name | • getpw, getpwnam, getpwnam_r, getpwuid, getpwuid_r |
| Salt | crypt, crypt_r (2nd argument) |
| Cryptography keys and initialization vectors | OpenSSL:<br>• EVP_CipherInit, EVP_EncryptInit, EVP_DecryptInit (3rd argument)<br>• EVP_CipherInit_ex, EVP_EncryptInit_ex, EVP_DecryptInit_ex (4th argument) |
| Seed | • srand, srandom, initstate (1st argument)<br>• OpenSSL: RAND_seed, RAND_add |

**Risk**

Information that is hardcoded can be queried from binaries generated from the code.

**Fix**

Avoid hard coding sensitive information.

**Example — Sensitive Data Exposed Through String Literals**

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

MYSQL *mysql_real_connect(MYSQL *mysql,
                          const char *host, const char *user, const char *passwd,
                          const char *db, unsigned int port, const char *unix_socket,
                          unsigned long client_flag);

typedef void * DbHandle;
extern MYSQL *sql;

// File that uses functions from "mysql.h"
const char *host = "localhost";
char *user = "guest";
char *passwd;

DbHandle connect_to_database_server(const char *db)
```

```
{
    passwd = (char*)"guest";
    return (DbHandle)
        mysql_real_connect (sql, host, user, passwd, db, 0, 0x0, 0);
}
```

In this example, the arguments `host` (host name), `user` (user name), and `passwd` (password) are string literals and directly exposed in the code.

Querying the generated binary for ASCII strings can reveal this information.

**Correction – Read Sensitive Data from Secured Configuration Files**

One possible correction is to read the data from a configuration file. In the following corrected example, the call to function `connect_to_database_server_init` presumably reads the host name, user name, and password into its arguments from a secured configuration file.

```
// Typically, you include the header "mysql.h" with function and type declarations.
// In this example, only the required lines from the header are quoted.

typedef struct _MYSQL MYSQL;

# CWE Rule 805

Buffer Access with Incorrect Length Value

## Description

### Rule Description

*The software uses a sequential operation to read or write a buffer, but it uses an incorrect length value that causes it to access memory that is outside of the bounds of the buffer.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Buffer overflow from incorrect string format specifier**
- **Destination buffer overflow in string manipulation**
- **Destination buffer underflow in string manipulation**
- **Invalid use of standard library memory routine**
- **Invalid use of standard library routine**
- **Invalid use of standard library string routine**
- **Mismatch between data length and size**
- **Possible misuse of sizeof**

## Examples

### Buffer overflow from incorrect string format specifier

**Issue**

This issue occurs when the format specifier argument for functions such as `sscanf` leads to an overflow or underflow in the memory buffer argument.

**Risk**

If the format specifier specifies a precision that is greater than the memory buffer size, an overflow occurs. Overflows can cause unexpected behavior such as memory corruption.

**Fix**

Use a format specifier that is compatible with the memory buffer size.

**Example — Memory Buffer Overflow**

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%33c", buf);
}
```

In this example, buf can contain 32 char elements. Therefore, the format specifier %33c causes a buffer overflow.

**Correction — Use Smaller Precision in Format Specifier**

One possible correction is to read a smaller number of elements into the buffer.

```
#include <stdio.h>

void func (char *str[]) {
    char buf[32];
    sscanf(str[1], "%32c", buf);
}
```

### Destination buffer overflow in string manipulation

**Issue**

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function sprintf(char* buffer, const char* format), you use a constant string format of greater size than buffer.

**Risk**

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

**Fix**

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use sprintf to write formatted data to a string, use snprintf, _snprintf or sprintf_s instead to enforce length control. Alternatively, use asprintf to automatically allocate the memory required for the destination buffer.
- If you use vsprintf to write formatted data from a variable argument list to a string, use vsnprintf or vsprintf_s instead to enforce length control.
- If you use wcscpy to copy a wide string, use wcsncpy, wcslcpy, or wcscpy_s instead to enforce length control.

Another possible solution is to increase the buffer size.

**Example — Buffer Overflow in sprintf Use**

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, buffer can contain 20 char elements but fmt_string has a greater size.

#### Correction — Use `snprintf` Instead of `sprintf`

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Destination buffer underflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at a negative offset from the beginning of the buffer.

For instance, for the function `sprintf(char* buffer, const char* format)`, you obtain the `buffer` from an operation `buffer = (char*)arr; ... buffer += offset;`. `arr` is an array and `offset` is a negative value.

#### Risk

Buffer underflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer underflow also introduces the risk of code injection.

#### Fix

If the destination buffer argument results from pointer arithmetic, see if you are decrementing a pointer. Fix the pointer decrement by modifying either the original value before decrement or the decrement value.

#### Example — Buffer Underflow in sprintf Use

```
#include <stdio.h>
#define offset -2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";

    sprintf(&buffer[offset], fmt_string);
}
```

In this example, `&buffer[offset]` is at a negative offset from the memory allocated to `buffer`.

#### Correction — Change Pointer Decrementer

One possible correction is to change the value of `offset`.

```
#include <stdio.h>
#define offset 2

void func(void) {
    char buffer[20];
    char *fmt_string ="Text";
    sprintf(&buffer[offset], fmt_string);
}
```

### Invalid use of standard library memory routine

#### Issue

This issue occurs when a memory library function is called with invalid arguments. For instance, the `memcpy` function copies to an array that cannot accommodate the number of bytes copied.

#### Risk

Use of a memory library function with invalid arguments can result in issues such as buffer overflow.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Example — Invalid Use of Standard Library Memory Routine Error

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  char str1[10],str2[5];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  /* Defect: Arguments of memcpy invalid: str2 has size < 6 */

  return str2;
 }
```

The size of string `str2` is 5, but six characters of string `str1` are copied into `str2` using the `memcpy` function.

#### Correction — Call Function with Valid Arguments

One possible correction is to adjust the size of str2 so that it accommodates the characters copied with the memcpy function.

```
#include <string.h>
#include <stdio.h>

char* Copy_First_Six_Letters(void)
 {
  /* Fix: Declare str2 with size 6 */
  char str1[10],str2[6];

  printf("Enter string:\n");
  scanf("%s",str1);

  memcpy(str2,str1,6);
  return str2;
 }
```

### Invalid use of standard library routine

#### Issue

This issue occurs when you use invalid arguments with a function from the standard library. This defect picks up errors related to other functions not covered by float, integer, memory, or string standard library routines.

#### Risk

Invalid arguments to a standard library function result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. For instance, the argument to a printf function can be NULL because a pointer was initialized with NULL and the initialization value was not overwritten along a specific execution path.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Calling printf Without a String

```
#include <stdio.h>
#include <stdlib.h>

void print_null(void) {

  printf(NULL);
}
```

The function printf takes only string input arguments or format specifiers. In this function, the input value is NULL, which is not a valid string.

#### Correction — Use Compatible Input Arguments

One possible correction is to change the input arguments to fit the requirements of the standard library routine. In this example, the input argument was changed to a character.

```
#include <stdio.h>

void print_null(void) {
    char zero_val = '0';
    printf((const char*)zero_val);
}
```

### Invalid use of standard library string routine

#### Issue

This issue occurs when a string library function is called with invalid arguments.

#### Risk

The risk depends on the type of invalid arguments. For instance, using the strcpy function with a source argument larger than the destination argument can result in buffer overflows.

#### Fix

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the strcpy function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to strcpy. In some cases, you can use an alternative function to avoid the error. For instance, instead of strcpy, you can use strncpy to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Invalid Use of Standard Library String Routine Error

```
 #include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  char gbuffer[5],text[20]="ABCDEFGHIJKL";
  res=strcpy(gbuffer,text);
  /* Error: Size of text is less than gbuffer */

  return(res);
 }
```

The string `text` is larger in size than `gbuffer`. Therefore, the function `strcpy` cannot copy `text` into `gbuffer`.

**Correction — Use Valid Arguments**

One possible correction is to declare the destination string `gbuffer` with equal or larger size than the source string `text`.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

### Mismatch between data length and size

**Issue**

This issue occurs when you do not check the length argument and data buffer argument of memory copying functions such as `memcpy`, `memset`, or `memmove`, to protect against buffer overflows.

**Risk**

If an attacker can manipulate the data buffer or length argument, the attacker can cause buffer overflow by making the actual data size smaller than the length.

This mismatch in length allows the attacker to copy memory past the data buffer to a new location. If the extra memory contains sensitive information, the attacker can now access that data.

This defect is similar to the SSL Heartbleed bug.

**Fix**

When copying or manipulating memory, compute the length argument directly from the data so that the sizes match.

**Example — Copy Buffer of Data**

```
#include <stdlib.h>
#include <string.h>

typedef struct buf_mem_st {
    char *data;
    size_t max;     /* size of buffer */
} BUF_MEM;
```

```
extern BUF_MEM beta;

int cpy_data(BUF_MEM *alpha)
{
    BUF_MEM *os = alpha;
    int num, length;

    if (alpha == 0x0) return 0;
    num = 0;

    length = *(unsigned short *)os->data;
    memcpy(&(beta.data[num]), os->data + 2, length);

    return(1);
}
```

This function copies the buffer `alpha` into a buffer `beta`. However, the `length` variable is not related to `data+2`.

#### Correction — Check Buffer Length

One possible correction is to check the length of your buffer against the maximum value minus 2. This check ensures that you have enough space to copy the data to the `beta` structure.

```
#include <stdlib.h>
#include <string.h>

typedef struct buf_mem_st {
    char *data;
    size_t max;     /* size of buffer */
} BUF_MEM;

extern BUF_MEM beta;

int cpy_data(BUF_MEM *alpha)
{
    BUF_MEM *os = alpha;
    int num, length;

    if (alpha == 0x0) return 0;
    num = 0;

    length = *(unsigned short *)os->data;
    if (length<(os->max -2)) {
        memcpy(&(beta.data[num]), os->data + 2, length);
    }

    return(1);

}
```

### Possible misuse of sizeof

#### Issue

This issue occurs when Polyspace Bug Finder detects possibly unintended results from the use of `sizeof` operator. For instance:

- You use the sizeof operator on an array parameter name, expecting the array size. However, the array parameter name by itself is a pointer. The sizeof operator returns the size of that pointer.
- You use the sizeof operator on an array element, expecting the array size. However, the operator returns the size of the array element.
- The size argument of certain functions such as strncmp or wcsncpy is incorrect because you used the sizeof operator earlier with possibly incorrect expectations. For instance:
  - In a function call strncmp(string1, string2, num), num is obtained from an incorrect use of the sizeof operator on a pointer.
  - In a function call wcsncpy(destination, source, num), num is the not the number of wide characters but a size in bytes obtained by using the sizeof operator. For instance, you use wcsncpy(destination, source, sizeof(destination) - 1) instead of wcsncpy(destination, source, (sizeof(desintation)/sizeof(wchar_t)) - 1).

**Risk**

Incorrect use of the sizeof operator can cause the following issues:

- If you expect the sizeof operator to return array size and use the return value to constrain a loop, the number of loop runs are smaller than what you expect.
- If you use the return value of sizeof operator to allocate a buffer, the buffer size is smaller than what you require. Insufficient buffer can lead to resultant weaknesses such as buffer overflows.
- If you use the return value of sizeof operator incorrectly in a function call, the function does not behave as you expect.

**Fix**

Possible fixes are:

- Do not use the sizeof operator on an array parameter name or array element to determine array size.

  The best practice is to pass the array size as a separate function parameter and use that parameter in the function body.
- Use the sizeof operator carefully to determine the number argument of functions such as strncmp or wcsncpy. For instance, for wide string functions such as wcsncpy, use the number of wide characters as argument instead of the number of bytes.

**Example — sizeof Used Incorrectly to Determine Array Size**

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < sizeof(a)/sizeof(int); i++)    {
        a[i] = i + 1;
    }
}
```

In this example, sizeof(a) returns the size of the pointer a and not the array size.

**Correction — Determine Array Size in Another Way**

One possible correction is to use another means to determine the array size.

```
#define MAX_SIZE 1024

void func(int a[MAX_SIZE]) {
    int i;

    for (i = 0; i < MAX_SIZE; i++)    {
        a[i] = i + 1;
    }
}
```

Buffer Access Using Size of Source Buffer

## Description

### Rule Description

*The software uses the size of a source buffer when reading from or writing to a destination buffer, which may cause it to access memory that is outside of the bounds of the buffer.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Destination buffer overflow in string manipulation**
- **Invalid use of standard library string routine**

## Examples

### Destination buffer overflow in string manipulation

#### Issue

This issue occurs when certain string manipulation functions write to their destination buffer argument at an offset greater than the buffer size.

For instance, when calling the function `sprintf(char* buffer, const char* format)`, you use a constant string `format` of greater size than `buffer`.

#### Risk

Buffer overflow can cause unexpected behavior such as memory corruption or stopping your system. Buffer overflow also introduces the risk of code injection.

#### Fix

One possible solution is to use alternative functions to constrain the number of characters written. For instance:

- If you use `sprintf` to write formatted data to a string, use `snprintf`, `_snprintf` or `sprintf_s` instead to enforce length control. Alternatively, use `asprintf` to automatically allocate the memory required for the destination buffer.
- If you use `vsprintf` to write formatted data from a variable argument list to a string, use `vsnprintf` or `vsprintf_s` instead to enforce length control.
- If you use `wcscpy` to copy a wide string, use `wcsncpy`, `wcslcpy`, or `wcscpy_s` instead to enforce length control.

Another possible solution is to increase the buffer size.

#### Example — Buffer Overflow in sprintf Use

```
#include <stdio.h>
```

```
void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    sprintf(buffer, fmt_string);
}
```

In this example, `buffer` can contain 20 `char` elements but `fmt_string` has a greater size.

#### Correction — Use `snprintf` Instead of `sprintf`

One possible correction is to use the `snprintf` function to enforce length control.

```
#include <stdio.h>

void func(void) {
    char buffer[20];
    char *fmt_string = "This is a very long string, it does not fit in the buffer";

    snprintf(buffer, 20, fmt_string);
}
```

### Invalid use of standard library string routine

#### Issue

This issue occurs when a string library function is called with invalid arguments.

#### Risk

The risk depends on the type of invalid arguments. For instance, using the `strcpy` function with a source argument larger than the destination argument can result in buffer overflows.

#### Fix

The fix depends on the standard library function involved in the defect. In some cases, you can constrain the function arguments before the function call. For instance, if the `strcpy` function:

```
char * strcpy(char * destination, const char* source)
```

tries to copy too many bytes into the destination argument compared to the available buffer, constrain the source argument before the call to `strcpy`. In some cases, you can use an alternative function to avoid the error. For instance, instead of `strcpy`, you can use `strncpy` to control the number of bytes copied.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Example — Invalid Use of Standard Library String Routine Error

```
 #include <string.h>
 #include <stdio.h>
 char* Copy_String(void)
 {
  char *res;
  char gbuffer[5],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);
  /* Error: Size of text is less than gbuffer */

  return(res);
 }
```

The string `text` is larger in size than `gbuffer`. Therefore, the function `strcpy` cannot copy `text` into `gbuffer`.

#### Correction — Use Valid Arguments

One possible correction is to declare the destination string `gbuffer` with equal or larger size than the source string `text`.

```
#include <string.h>
 #include <stdio.h>

 char* Copy_String(void)
 {
  char *res;
  /*Fix: gbuffer has equal or larger size than text */
  char gbuffer[20],text[20]="ABCDEFGHIJKL";

  res=strcpy(gbuffer,text);

  return(res);
 }
```

Access of Uninitialized Pointer

## Description

### Rule Description

*The program accesses or uses a pointer that has not been initialized.*

### Polyspace Implementation

The rule checker checks for **Non-initialized pointer**.

## Examples

### Non-initialized pointer

#### Issue

This issue occurs when a pointer is not assigned an address before dereference.

#### Risk

Unless a pointer is explicitly assigned an address, it points to an unpredictable location.

#### Fix

The fix depends on the root cause of the defect. For instance, you assigned an address to the pointer but the assignment is unreachable.

Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

See examples of fixes below. It is a good practice to initialize a pointer to NULL when declaring the pointer.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- “Address Results in Polyspace User Interface Through Bug Fixes or Justifications” if you review results in the Polyspace user interface.
- “Address Results in Polyspace Access Through Bug Fixes or Justifications” if you review results in a web browser.
- “Annotate Code and Hide Known or Acceptable Results” if you review results in an IDE.

#### Extend Checker

If a pointer in your code is non-initialized only for certain system input values, you can see one possible combination of input values causing the defect. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

#### Example — Non-initialized pointer error

```
#include <stdlib.h>

int* assign_pointer(int* prev)
{
    int j = 42;
    int* pi;

    if (prev == NULL)
      {
        pi = (int*)malloc(sizeof(int));
        if (pi == NULL) return NULL;
      }

    *pi = j;
    /* Defect: Writing to uninitialized pointer */

    return pi;
}
```

If `prev` is not `NULL`, the pointer `pi` is not assigned an address. However, `pi` is dereferenced on every execution paths, irrespective of whether `prev` is `NULL` or not.

#### Correction — Initialize Pointer on Every Execution Path

One possible correction is to assign an address to `pi` when `prev` is not `NULL`.

```
#include <stdlib.h>

int* assign_pointer(int* prev)
{
    int j = 42;
    int* pi;

    if (prev == NULL)
       {
        pi = (int*)malloc(sizeof(int));
        if (pi == NULL) return NULL;
       }
    /* Fix: Initialize pi in branches of if statement  */
    else
        pi = prev;

    *pi = j;

    return pi;
}
```

Expired Pointer Dereference

## Description

### Rule Description

*The program dereferences a pointer that contains a location for memory that was previously valid, but is no longer valid.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Accessing object with temporary lifetime**
- **Deallocation of previously deallocated pointer**
- **Environment pointer invalidated by previous operation**
- **Pointer or reference to stack variable leaving scope**
- **Use of automatic variable as putenv-family function argument**
- **Use of previously freed pointer**

## Examples

### Accessing object with temporary lifetime

#### Issue

This issue occurs when you attempt to read from or write to an object with temporary lifetime that is returned by a function call. In a structure or union returned by a function, and containing an array, the array members are temporary objects. The lifetime of temporary objects ends:

- When the full expression or full declarator containing the call ends, as defined in the C11 Standard.
- After the next sequence point, as defined in the C90 and C99 Standards. A sequence point is a point in the execution of a program where all previous evaluations are complete and no subsequent evaluation has started yet.

For C++ code, **Accessing object with temporary lifetime** raises a defect only when you write to an object with a temporary lifetime.

If the temporary lifetime object is returned by address, no defect is raised.

#### Risk

Modifying objects with temporary lifetime is undefined behavior and can cause abnormal program termination and portability issues.

#### Fix

Assign the object returned from the function call to a local variable. The content of the temporary lifetime object is copied to the variable. You can now modify it safely.

### Example — Modifying Temporary Lifetime Object Returned by Function Call

```
#include <stdio.h>
#include <assert.h>
#include <stdlib.h>
#include <string.h>

#define SIZE6 6

struct S_Array
{
    int t;
    int a[SIZE6];
};

struct S_Array func_temp(void);

/* func_temp() returns a struct value containing
* an array with a temporary lifetime.
*/
int func(void) {

/*Writing to temporary lifetime object is
 undefined behavior
 */
    return ++(func_temp().a[0]);
}

void main(void) {
    (void)func();
}
```

In this example, `func_temp()` returns by value a structure with an array member `a`. This member has temporary lifetime. Incrementing it is undefined behavior.

### Correction — Assign Returned Value to Local Variable Before Writing

One possible correction is to assign the return of the call to `func_temp()` to a local variable. The content of the temporary object `a` is copied to the variable, which you can safely increment.

```
 #include <stdio.h>
#include <assert.h>
#include <stdlib.h>
#include <string.h>

#define SIZE6 6

struct S_Array
{
    int t;
    int a[SIZE6];
};

struct S_Array func_temp(void);

int func(void) {

/* Assign object returned by function call to
```

```
 *local variable
 */
    struct S_Array s = func_temp();

/* Local variable can safely be
 *incremented
 */
    ++(s.a[0]);
    return s.a[0];
}

void main(void) {
    (void)func();
}
```

### Deallocation of previously deallocated pointer

**Issue**

This issue occurs when a block of memory is freed more than once using the `free` function without an intermediate allocation.

**Risk**

When a pointer is allocated dynamic memory with `malloc`, `calloc` or `realloc`, it points to a memory location on the heap. When you use the `free` function on this pointer, the associated block of memory is freed for reallocation. Trying to free this block of memory can result in a segmentation fault.

**Fix**

The fix depends on the root cause of the defect. See if you intended to allocate a memory block to the pointer between the first deallocation and the second. Otherwise, remove the second `free` statement.

As a good practice, after you free a memory block, assign the corresponding pointer to NULL. Before freeing pointers, check them for NULL values and handle the error. In this way, you are protected against freeing an already freed block.

**Example — Deallocation of Previously Deallocated Pointer Error**

```
#include <stdlib.h>

void allocate_and_free(void)
{

    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return;

    *pi = 2;
    free(pi);
    free (pi);
    /* Defect: pi has already been freed */
}
```

The first `free` statement releases the block of memory that `pi` refers to. The second `free` statement on `pi` releases a block of memory that has been freed already.

#### Correction — Remove Duplicate Deallocation

One possible correction is to remove the second `free` statement.

```
#include <stdlib.h>

void allocate_and_free(void)
{

    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return;

    *pi = 2;
    free(pi);
    /* Fix: remove second deallocation */
 }
```

#### Example — Freeing Pointer Previously Reallocated With Possibly Zero Size

```
#include <stdlib.h>

void reshape(char *buf, size_t size) {
  char *reshaped_buf = (char *)realloc(buf, size);
  if (reshaped_buf == NULL) {
    free(buf);
  }
}
```

In this example, the argument `size` of the `reshape()` function can be zero and result in a zero-size reallocation with `realloc()`. In some implementations such as the GNU library, zero-size reallocations free the memory leading to a double free defect.

#### Correction – Guard Against Zero-Size Reallocations

One possible correction is to check size argument of `realloc()` for zero values before use. If the size argument is zero, you can simply free the memory instead of reallocating it.

```
#include <stdlib.h>

void reshape(char *buf, size_t size) {
  if (size != 0) {
    char *reshaped_buf = (char *)realloc(buf, size);
    if (reshaped_buf == NULL) {
      free(buf);
    }
  }
  else {
    free(buf);
  }

}
```

### Environment pointer invalidated by previous operation

#### Issue

This issue occurs when you use the third argument of *main()* in a hosted environment to access the environment after an operation modifies the environment. In a hosted environment, many C implementations support the nonstandard syntax:

```
main (int argc, char *argv[], char *envp[])
```

A call to a `setenv` or `putenv` family function modifies the environment pointed to by `*envp`.

**Risk**

When you modify the environment through a call to a `setenv` or `putenv` family function, the environment memory can potentially be reallocated. The hosted environment pointer is not updated and might point to an incorrect location. A call to this pointer can return unexpected results or cause an abnormal program termination.

**Fix**

Do not use the hosted environment pointer. Instead, use global external variable `environ` in Linux, `_environ` or `_wenviron` in Windows, or their equivalent. When you modify the environment, these variables are updated.

**Example — Access Environment Through Pointer envp**

```
#include <stdio.h>
#include <stdlib.h>

extern int check_arguments(int argc, char **argv, char **envp);
extern void use_envp(char **envp);

/* envp is from main function */
int func(char **envp)
{
    /* Call to setenv may cause environment
     *memory to be reallocated
     */
    if (setenv(("MY_NEW_VAR"),("new_value"),1) != 0)
    {
        /* Handle error */
        return -1;
    }
    /* envp not updated after call to setenv, and may
     *point to incorrect location.
     **/
    if (envp != ((void *)0)) {
        use_envp(envp);
/* No defect on second access to
*envp because defect already raised */
    }
    return 0;
}

void  main(int argc, char **argv, char **envp)
{
    if (check_arguments(argc, argv, envp))
    {
        (void)func(envp);
    }
}
```

In this example, `envp` is accessed inside `func()` after a call to `setenv` that can reallocate the environment memory. `envp` can point to an incorrect location because it is not updated after `setenv` modifies the environment. No defect is raised when `use_envp()` is called because the defect is already raised on the previous line of code.

#### Correction — Use Global External Variable `environ`

One possible correction is to access the environment by using a variable that is always updated after a call to `setenv`. For instance, in the following code, the pointer `envp` is still available from `main()`, but the environment is accessed in `func()` through the global external variable `environ`.

```
#include <stdio.h>
#include <stdlib.h>
extern char **environ;

extern int check_arguments(int argc, char **argv, char **envp);
extern void use_envp(char **envp);

int func(void)
{
    if (setenv(("MY_NEW_VAR"), ("new_value"),1) != 0) {
        /* Handle error */
        return -1;
    }
  /* Use global external variable environ
   *which is always updated after a call to setenv */

    if (environ != NULL) {
        use_envp(environ);
    }
    return 0;
}

void  main(int argc, char **argv, char **envp)
{
    if (check_arguments(argc, argv, envp))
    {
        (void)func();
    }
}
```

### Pointer or reference to stack variable leaving scope

#### Issue

This issue occurs when a pointer or reference to a local variable leaves the scope of the variable. For instance:

- A function returns a pointer to a local variable.
- A function performs the assignment `globPtr = &locVar`. `globPtr` is a global pointer variable and `locVar` is a local variable.
- A function performs the assignment `*paramPtr = &locVar`. `paramPtr` is a function parameter that is, for instance, an `int**` pointer and `locVar` is a local `int` variable.
- A C++ method performs the assignment `memPtr = &locVar`. `memPtr` is a pointer data member of the class the method belongs to. `locVar` is a variable local to the method.
- (C++11 and later) A function returns a lambda expression object that captures local variables of the function by reference.

The defect also applies to memory allocated using the `alloca` function. The defect does not apply to static, local variables. Polyspace assumes that the local objects within a function definition are in the same scope.

**Risk**

Local variables are allocated an address on the stack. Once the scope of a local variable ends, this address is available for reuse. Using this address to access the local variable value outside the variable scope can cause unexpected behavior.

If a pointer to a local variable leaves the scope of the variable, Polyspace Bug Finder highlights the defect. The defect appears even if you do not use the address stored in the pointer. For maintainable code, it is a good practice to not allow the pointer to leave the variable scope. Even if you do not use the address in the pointer now, someone else using your function can use the address, causing undefined behavior.

**Fix**

Do not allow a pointer or reference to a local variable to leave the variable scope.

**Example — Pointer to Local Variable Returned from Function**

```
void func2(int *ptr) {
    *ptr = 0;
}

int* func1(void) {
    int ret = 0;
    return &ret ;
}
void main(void) {
    int* ptr = func1() ;
    func2(ptr) ;
}
```

In this example, `func1` returns a pointer to local variable `ret`.

In `main`, `ptr` points to the address of the local variable. When `ptr` is accessed in `func2`, the access is illegal because the scope of `ret` is limited to `func1`,

**Example — Pointer to Local Variable Escapes Through Lambda Expression**

```
auto createAdder(int amountToAdd) {
  int addThis = amountToAdd;
  auto adder = [&] (int initialAmount) {
      return (initialAmount + addThis);
  };
  return adder;
}

void func() {
  auto AddByTwo = createAdder(2);
  int res = AddByTwo(10);
}
```

In this example, the `createAdder` function defines a lambda expression `adder` that captures the local variable `addThis` by reference. The scope of `addThis` is limited to the `createAdder` function. When the object returned by `createAdder` is called, a reference to the variable `addThis` is accessed outside its scope. When accessed in this way, the value of `addThis` is undefined.

#### Correction – Capture Local Variables by Copy in Lambda Expression Instead of Reference

If a function returns a lambda expression object, avoid capturing local variables by reference in the lambda object. Capture the variables by copy instead.

Variables captured by copy have the same lifetime as the lambda object, but variables captured by reference often have a smaller lifetime than the lambda object itself. When the lambda object is used, these variables accessed outside scope have undefined values.

```
auto createAdder(int amountToAdd) {
  int addThis = amountToAdd;
  auto adder = [=] (int initialAmount) {
      return (initialAmount + addThis);
  };
  return adder;
}

void func() {
  auto AddByTwo = createAdder(2);
  int res = AddByTwo(10);
}
```

### Use of automatic variable as putenv-family function argument

#### Issue

This issue occurs when the argument of a `putenv`-family function is a local variable with automatic duration.

#### Risk

The function `putenv(char *string)` inserts a pointer to its supplied argument into the environment array, instead of making a copy of the argument. If the argument is an automatic variable, its memory can be overwritten after the function containing the `putenv()` call returns. A subsequent call to `getenv()` from another function returns the address of an out-of-scope variable that cannot be dereferenced legally. This out-of-scope variable can cause environment variables to take on unexpected values, cause the program to stop responding, or allow arbitrary code execution vulnerabilities.

#### Fix

Use `setenv()`/`unsetenv()` to set and unset environment variables. Alternatively, use `putenv`-family function arguments with dynamically allocated memory, or, if your application has no reentrancy requirements, arguments with static duration. For example, a single thread execution with no recursion or interrupts does not require reentrancy. It cannot be called (reentered) during its execution.

#### Example — Automatic Variable as Argument of putenv()

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define SIZE1024 1024

void func(int var)
{
    char env[SIZE1024];
    int retval = sprintf(env, "TEST=%s", var ? "1" : "0");
    if (retval <= 0) {
        /* Handle error */
    }
    /* Environment variable TEST is set using putenv().
    The argument passed to putenv is an automatic variable. */
    retval = putenv(env);
    if (retval != 0) {
        /* Handle error */
    }
}
```

In this example, `sprintf()` stores the character string `TEST=var` in `env`. The value of the environment variable `TEST` is then set to `var` by using `putenv()`. Because `env` is an automatic variable, the value of `TEST` can change once `func()` returns.

**Correction — Use `static` Variable for Argument of `putenv()`**

Declare `env` as a static-duration variable. The memory location of `env` is not overwritten for the duration of the program, even after `func()` returns.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define SIZE1024 1024
void func(int var)
{
    /* static duration variable */
    static char env[SIZE1024];
    int retval = sprintf(env,"TEST=%s", var ? "1" : "0");
    if (retval <= 0) {
        /* Handle error */
    }

    /* Environment variable TEST is set using putenv() */
    retval=putenv(env);
    if (retval != 0) {
        /* Handle error */
    }
}
```

**Correction — Use `setenv()` to Set Environment Variable Value**

To set the value of `TEST` to `var`, use `setenv()`.

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define SIZE1024 1024

void func(int var)
{
    /* Environment variable TEST is set using setenv() */
    int retval = setenv("TEST", var ? "1" : "0", 1);
    if (retval != 0) {
        /* Handle error */
    }
}
```

### Use of previously freed pointer

#### Issue

This issue occurs when you access a block of memory after freeing the block using the `free` function.

#### Risk

When a pointer is allocated dynamic memory with `malloc`, `calloc` or `realloc`, it points to a memory location on the heap. When you use the `free` function on this pointer, the associated block of memory is freed for reallocation. Trying to access this block of memory can result in unpredictable behavior or even a segmentation fault.

#### Fix

The fix depends on the root cause of the defect. See if you intended to free the memory later or allocate another memory block to the pointer before access.

As a good practice, after you free a memory block, assign the corresponding pointer to NULL. Before dereferencing pointers, check them for NULL values and handle the error. In this way, you are protected against accessing a freed block.

#### Example — Use of Previously Freed Pointer Error

```
#include <stdlib.h>
#include <stdio.h>
 int increment_content_of_address(int base_val, int shift)
   { 
    int j;
    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return 0;

    *pi = base_val;
    free(pi);

    j = *pi + shift;
    /* Defect: Reading a freed pointer */
 
    return j;
   }
```

The `free` statement releases the block of memory that `pi` refers to. Therefore, dereferencing`pi` after the `free` statement is not valid.

#### Correction — Free Pointer After Use

One possible correction is to free the pointer `pi` only after the last instance where it is accessed.

```
#include <stdlib.h>

int increment_content_of_address(int base_val, int shift)
{
    int j;
    int* pi = (int*)malloc(sizeof(int));
    if (pi == NULL) return 0;

    *pi = base_val;

    j = *pi + shift;
    *pi = 0;

    /* Fix: The pointer is freed after its last use */
    free(pi);
    return j;
}
```

CWE-825

# CWE Rule 839

Numeric Range Comparison Without Minimum Check

## Description

### Rule Description

*The program checks a value to ensure that it is less than or equal to a maximum, but it does not also verify that the value is greater than or equal to the minimum.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Pointer dereference with tainted offset**
- **Tainted sign change conversion**

## Examples

### Pointer dereference with tainted offset

#### Issue

This issue occurs when a pointer dereference uses an offset variable from an unknown or unsecure source.

This check focuses on dynamically allocated buffers. For static buffer offsets, see `Array access with tainted index`.

#### Risk

The index might be outside the valid array range. If the tainted index is outside the array range, it can cause:

- Buffer underflow/underwrite, or writing to memory before the beginning of the buffer.
- Buffer overflow, or writing to memory after the end of a buffer.
- Over reading a buffer, or accessing memory after the end of the targeted buffer.
- Under-reading a buffer, or accessing memory before the beginning of the targeted buffer.

An attacker can use an invalid read or write to compromise your program.

#### Fix

Validate the index before you use the variable to access the pointer. Check to make sure that the variable is inside the valid range and does not overflow.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

**Example — Dereference Pointer Array**

```
#include <stdio.h>
#include <stdlib.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if(pint) {
        /* Filling array */
        read_pint(pint);
        c = pint[offset];//Noncompliant
        free(pint);
    }
    return c;
}
```

In this example, the function initializes an integer pointer `pint`. The pointer is dereferenced using the input index `offset`. The value of `offset` could be outside the pointer range, causing an out-of-range error.

**Correction — Check Index Before Dereference**

One possible correction is to validate the value of `offset`. Continue with the pointer dereferencing only if `offset` is inside the valid range.

```
#include <stdlib.h>
#include <stdio.h>
enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};
extern void read_pint(int*);

int taintedptroffset(void) {
    int offset;
    scanf("%d",&offset);
    int* pint = (int*)calloc(SIZE10, sizeof(int));
    int c = 0;
    if (pint) {
        /* Filling array */
        read_pint(pint);
        if (offset>0 && offset<SIZE10) {
            c = pint[offset];
        }
        free(pint);
    }
    return c;
}
```

### Tainted sign change conversion

#### Issue

This issue occurs when values from unsecure sources are converted, implicitly or explicitly, from signed to unsigned values.

For example, functions that use `size_t` as arguments implicitly convert the argument to an unsigned integer. Some functions that implicitly convert `size_t` are:

```
bcmp
memcpy
memmove
strncmp
strncpy
calloc
malloc
memalign
```

#### Risk

If you convert a small negative number to unsigned, the result is a large positive number. The large positive number can create security vulnerabilities. For example, if you use the unsigned value in:

- Memory size routines — causes allocating memory issues.
- String manipulation routines — causes buffer overflow.
- Loop boundaries — causes infinite loops.

#### Fix

To avoid converting unsigned negative values, check that the value being converted is within an acceptable range. For example, if the value represents a size, validate that the value is not negative and less than the maximum value size.

#### Extend Checker

By default, Polyspace assumes that data from external sources are tainted. See “Sources of Tainting in a Polyspace Analysis”. To consider any data that does not originate in the current scope of Polyspace analysis as tainted, use the command line option `-consider-analysis-perimeter-as-trust-boundary`.

#### Example — Set Memory Value with Size Argument

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void bug_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size<SIZE128) {
        memset(str, 'c', size); //Noncompliant
    }
}
```

In this example, a `char` buffer is created and filled using `memset`. The size argument to `memset` is an input argument to the function.

The call to `memset` implicitly converts `size` to unsigned integer. If `size` is a large negative number, the absolute value could be too large to represent as an integer, causing a buffer overflow.

#### Correction — Check Value of `size`

One possible correction is to check if `size` is inside the valid range. This correction checks if `size` is greater than zero and less than the buffer size before calling `memset`.

```
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

enum {
    SIZE10  =  10,
    SIZE100 = 100,
    SIZE128 = 128
};

void corrected_taintedsignchange(void) {
    int size;
    scanf("%d",&size);
    char str[SIZE128] = "";
    if (size>0 && size<SIZE128) {
        memset(str, 'c', size);
    }
}
```

Access of Resource Using Incompatible Type ('Type Confusion')

## Description

### Rule Description

*The program allocates or initializes a resource such as a pointer, object, or variable using one type, but it later accesses that resource using a type that is incompatible with the original type.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Cast to pointer pointing to object of different type**
- **Reading memory reallocated from object of another type without reinitializing first**

## Examples

### Cast to pointer pointing to object of different type

#### Issue

The issue occurs when you perform a cast between a pointer to an object type and a pointer to a different object type.

#### Risk

If a pointer to an object is cast into a pointer to a different object, the resulting pointer can be incorrectly aligned. The incorrect alignment causes undefined behavior.

Even if the conversion produces a pointer that is correctly aligned, the behavior can be undefined if the pointer is used to access an object.

Exception: You can convert a pointer to object type into a pointer to one of these types:

- `char`
- `signed char`
- `unsigned char`

#### Example - Cast to Pointer Pointing to Object of Wider Type

```
signed   char *p1;
unsigned int *p2;

void foo(void){
  p2 = ( unsigned int * ) p1;     /* Non-compliant */
}
```

In this example, `p1` can point to a `signed char` object. However, `p1` is cast to a pointer that points to an object of wider type, `unsigned int`.

#### Example - Cast to Pointer Pointing to Object of Narrower Type

```
extern unsigned int read_value ( void );
extern void display ( unsigned int n );

void foo ( void ){
  unsigned int u = read_value ( );
  unsigned short *hi_p = ( unsigned short * ) &u;    /* Non-compliant  */
  *hi_p = 0;
  display ( u );
}
```

In this example, u is an `unsigned int` variable. &u is cast to a pointer that points to an object of narrower type, `unsigned short`.

On a big-endian machine, the statement `*hi_p = 0` attempts to clear the high bits of the memory location that &u points to. But, from the result of `display(u)`, you might find that the high bits have not been cleared.

#### Example - Cast Adding a Type Qualifier

```
const short *p;
const volatile short *q;
void foo (void){
  q = ( const volatile short * ) p;  /* Compliant */
}
```

In this example, both p and q can point to `short` objects. The cast between them adds a `volatile` qualifier only and is therefore compliant.

### Reading memory reallocated from object of another type without reinitializing first

#### Issue

This issue occurs when you do the following in sequence:

1. Reallocate memory to an object with a type that is different from the original allocation.

   For instance, in this code snippet, a memory originally allocated to a pointer with type `struct A*` is reallocated to a pointer with type `struct B*`:

   ```
   struct A;
   struct B;

   struct A *Aptr = (struct A*) malloc(sizeof(struct A));
   struct B *Bptr = (struct B*) realloc(Aptr, sizeof(struct B));
   ```
2. Read from this reallocated memory without reinitializing the memory first.

   Read accesses on the pointer to the reallocated memory can happen through pointer dereference or array indexing. Passing the pointer to a function that takes a pointer to a `const`-qualified object as the corresponding parameter also counts as a read access.

#### Risk

Reading from reallocated memory that has not been reinitialized leads to undefined behavior.

#### Fix

Reinitialize memory after reallocation and before the first read access.

The checker considers any write access on the pointer to the reallocated memory as satisfying the reinitialization requirement (even if the object might only be partially reinitialized). Write accesses on the pointer to the reallocated memory can happen through pointer dereference or array indexing. Passing the pointer to a function that takes a pointer to a non-`const`-qualified object as the corresponding parameter also counts as a write access.

**Example – Noncompliant: Reading from Reallocated Memory Without Reinitializing First**

```
#include<stdlib.h>

struct group {
    char *groupFirst;
    int groupSize;
};

struct groupWithID {
    int groupID;
    char *groupFirst;
    int groupSize;
};

char* readName();
int readSize();

void createGroup(int nextAvailableID) {
    struct group *aGroup;
    struct groupWithID *aGroupWithID;

    aGroup = (struct group*) malloc(sizeof(struct group));

    if(!aGroup) {
        /*Handle error*/
    }

    aGroup->groupFirst = readName();
    aGroup->groupSize  = readSize();

    /* Reassign to group with ID */
    aGroupWithID = (struct groupWithID*) realloc(aGroup, sizeof(struct groupWithID));
    if(!aGroupWithID) {
        free(aGroup);
        /*Handle error*/
    }

    if(aGroupWithID -> groupSize > 0) { /* Noncompliant */
        /* ... */
    }

    /* ...*/
    free(aGroupWithID);
}
```

In this example, the memory allocated to a `group*` pointer using the `malloc` function is reallocated to a `groupWithID*` pointer using the `realloc` function. There is a read access on the reallocated memory before the memory is reinitialized.

#### Correction – Reinitialize Memory After Reallocation and Before First Read

Reinitialize the memory assigned to the `groupWithID*` pointer before the first read access. All bits of the memory can be reinitialized using the `memset` function.

```
#include<stdlib.h>
#include<string.h>

struct group {
    char *groupFirst;
    int groupSize;
};

struct groupWithID {
    int groupID;
    char *groupFirst;
    int groupSize;
};

char* readName();
int readSize();

void createGroup(int nextAvailableID) {
    struct group *aGroup;
    struct groupWithID *aGroupWithID;

    aGroup = (struct group*) malloc(sizeof(struct group));

    if(!aGroup) {
        /*Handle error*/
    }

    aGroup->groupFirst = readName();
    aGroup->groupSize  = readSize();

    /* Reassign to group with ID */
    aGroupWithID = (struct groupWithID*) realloc(aGroup, sizeof(struct groupWithID));
    if(!aGroupWithID) {
        free(aGroup);
        /*Handle error*/
    }

    memset(aGroupWithID, 0 , sizeof(struct groupWithID));
    /* Reinitialize group */
    if(aGroupWithID -> groupSize > 0) {
        /* ... */
    }

    /* ...*/
    free(aGroupWithID);
}
```

CWE-843

# CWE Rule 910

Use of Expired File Descriptor

## Description

### Rule Description

*The software uses or accesses a file descriptor after it has been closed.*

### Polyspace Implementation

The rule checker checks for **Use of previously closed resource**.

## Examples

### Use of previously closed resource

#### Issue

This issue occurs when a function operates on a stream that you closed earlier in your code.

#### Risk

The standard states that the value of a `FILE*` pointer is indeterminate after you close the stream associated with it. Operations using the `FILE*` pointer can produce unintended results.

#### Fix

One possible fix is to close the stream only at the end of operations. Another fix is to reopen the stream before using it again.

#### Example — Use of FILE* Pointer After Closing Stream

```
#include <stdio.h>

void func(void) {
    FILE *fp;
    void *ptr;

    fp = fopen("tmp","w");
    if(fp != NULL) {
        fclose(fp);
        fprintf(fp,"text");
    }
}
```

In this example, `fclose` closes the stream associated with `fp`. When you use `fprintf` on `fp` after `fclose`, the **Use of previously closed resource** defect appears.

#### Correction — Close Stream After All Operations

One possible correction is to reverse the order of the `fprintf` and `fclose` operations.

```
#include <stdio.h>
```

```
void func(void) {
    FILE *fp;
    void *ptr;

    fp = fopen("tmp","w");
    if(fp != NULL) {
        fprintf(fp,"text");
        fclose(fp);
    }
}
```

CWE-910

# CWE Rule 922

Insecure Storage of Sensitive Information

## Description

### Rule Description

*The software stores sensitive information without properly limiting read or write access by unauthorized actors.*

### Polyspace Implementation

The rule checker checks for these issues:

- **File manipulation after chroot() without chdir("/")**
- **Umask used with chmod-style arguments**
- **Use of non-secure temporary file**
- **Vulnerable permission assignments**

## Examples

### File manipulation after chroot() without chdir("/")

#### Issue

This issue occurs when you have access to a file system outside of the jail created by `chroot`. By calling `chroot`, you create a file system jail that confines access to a specific file subsystem. However, this jail is ineffective if you do not call `chdir("/")`.

#### Risk

If you do not call `chdir("/")` after creating a `chroot` jail, file manipulation functions that takes a path as an argument can access files outside of the jail. An attacker can still manipulate files outside the subsystem that you specified, making the chroot jail ineffective.

#### Fix

After calling `chroot`, call `chdir("/")` to make your `chroot` jail more secure.

#### Example — Open File in chroot-jail

```
#include <unistd.h>
#include <stdio.h>

const char root_path[] = "/var/ftproot";
const char log_path[] = "file.log";
FILE* chrootmisuse() {
    FILE* res;
    chroot(root_path);
    chdir("base");
    res = fopen(log_path, "r");
    return res;
}
```

This example uses `chroot` to create a chroot-jail. However, to use the `chroot` jail securely, you must call `chdir("\")` afterward. This example calls `chdir("base")`, which is not equivalent. Bug Finder also flags `fopen` because `fopen` opens a file in the vulnerable `chroot`-jail.

**Correction — Call `chdir("/")`**

Before opening files, call `chdir("/")`.

```
#include <unistd.h>
#include <stdio.h>

const char root_path[] = "/var/ftproot";
const char log_path[] = "file.log";
FILE* chrootmisuse() {
    FILE* res;
    chroot(root_path);
    chdir("/");
    res = fopen(log_path, "r");
    return res;
}
```

### Umask used with chmod-style arguments

**Issue**

This issue occurs when `umask` commands have arguments specified in the style of arguments to `chmod` and provide possibly unintended permissions. For instance:

- The `umask` command provides more permissions to the group than the current user.
- The `umask` command provides more permissions to other users than the group.

For new files, the `umask` argument or the mask value specifies which permissions *not* to set, in other words, which permissions to remove. The mask is bitwise-negated and then applied to new file permissions. In contrast, `chmod` sets the permissions as you specify them.

**Risk**

If you use `chmod`-style arguments, you specify opposite permissions of what you want. This mistake can give external users unintended read/write access to new files and folders.

**Fix**

To fix this defect, perform both of these tasks:

- Enable read permission for the user.
- Set the mask value so that the user (`u`) has equal or fewer permissions turned off than the group (`g`) and the group has equal or fewer permissions turned off than other users (`o`), or `u <= g <= o`.

You can see the umask value by calling,

```
umask
```

or the symbolic value by calling,

```
umask -S
```

**Example — Setting the Default Mask**

```
#include <stdio.h>
#include <assert.h>
#include <sys/types.h>
#include <sys/stat.h>

typedef mode_t (*umask_func)(mode_t);

const mode_t default_mode = (
    S_IRUSR    /* 00400 */
    | S_IWUSR  /* 00200 */
    | S_IRGRP  /* 00040 */
    | S_IWGRP  /* 00020 */
    | S_IROTH  /* 00004 */
    | S_IWOTH  /* 00002 */
    );         /* 00666 (i.e. -rw-rw-rw-) */

static void my_umask(mode_t mode)
{
    umask(mode);
}

int umask_use(mode_t m)
{
    my_umask(default_mode);
    return 0;
}
```

This example uses a function called `my_umask` to set the default mask mode. However, the `default_mode` variable gives the permissions 666 or `-rw-rw-rw`. `umask` negates this value. However, this negation means the default mask mode turns off read/write permissions for the user, group users, and other outside users.

**Correction — Negate Preferred Permissions**

One possible correction is to negate the `default_mode` argument to `my_umask`. This correction nullifies the negation `umask` for new files.

```
#include <stdio.h>
#include <assert.h>
#include <sys/types.h>
#include <sys/stat.h>

typedef mode_t (*umask_func)(mode_t);

const mode_t default_mode = (
    S_IRUSR    /* 00400 */
    | S_IWUSR  /* 00200 */
    | S_IRGRP  /* 00040 */
    | S_IWGRP  /* 00020 */
    | S_IROTH  /* 00004 */
    | S_IWOTH  /* 00002 */
    );         /* 00666 (i.e. -rw-rw-rw-) */

static void my_umask(mode_t mode)
{
    umask(mode);
}

int umask_use(mode_t m)
{
    my_umask(~default_mode);
    return 0;
}
```

### Use of non-secure temporary file

#### Issue

This issue occurs when you use temporary file routines that are not secure.

#### Risk

If an attacker guesses the file name generated by a standard temporary file routine, the attacker can:

- Cause a race condition when you generate the file name.
- Precreate a file of the same name, filled with malicious content. If your program reads the file, the attacker's file can inject the malicious code.
- Create a symbolic link to a file storing sensitive data. When your program writes to the temporary file, the sensitive data is deleted.

#### Fix

To create temporary files, use a more secure standard temporary file routine, such as `mkstemp` from POSIX.1-2001.

Also, when creating temporary files with routines that allow flags, such as `mkostemp`, use the exclusion flag `O_EXCL` to avoid race conditions.

#### Example — Temp File Created With tempnam

```
#define _BSD_SOURCE
#define _XOPEN_SOURCE
#define _GNU_SOURCE

#include <stdio.h>
#include <stdlib.h>
#include <sys/types.h>
#include <sys/stat.h>
#include <fcntl.h>
#include <unistd.h>

int test_temp()
{
    char tpl[] = "abcXXXXXX";
    char suff_tpl[] = "abcXXXXXXsuff";
    char *filename = NULL;
    int fd;

    filename = tempnam("/var/tmp", "foo_");

    if (filename != NULL)
    {
        printf("generated tmp name (%s) in (%s:%s:%s)\n",
               filename, getenv("TMPDIR") ? getenv("TMPDIR") : "$TMPDIR",
                 "/var/tmp", P_tmpdir);

        fd = open(filename, O_CREAT, S_IRWXU|S_IRUSR);
        if (fd != -1)
        {
            close(fd);
            unlink(filename);
            return 1;
        }
    }
    return 0;
}
```

In this example, Bug Finder flags `open` because it tries to use an unsecure temporary file. The file is opened without exclusive privileges. An attacker can access the file causing various risks on page 13-84.

#### Correction — Add O_EXCL Flag

One possible correction is to add the `O_EXCL` flag when you open the temporary file.

```
#define _BSD_SOURCE
#define _XOPEN_SOURCE
#define _GNU_SOURCE

#include <stdio.h>
#include <stdlib.h>
#include <sys/types.h>
#include <sys/stat.h>
#include <fcntl.h>
#include <unistd.h>

int test_temp()
{
    char tpl[] = "abcXXXXXX";
    char suff_tpl[] = "abcXXXXXXsuff";
    char *filename = NULL;
    int fd;

    filename = tempnam("/var/tmp", "foo_");

    if (filename != NULL)
    {
        printf("generated tmp name (%s) in (%s:%s:%s)\n",
                 filename, getenv("TMPDIR") ? getenv("TMPDIR") : "$TMPDIR",
                 "/var/tmp", P_tmpdir);

        fd = open(filename, O_CREAT|O_EXCL, S_IRWXU|S_IRUSR);
        if (fd != -1)
        {
            close(fd);
            unlink(filename);
            return 1;
        }
    }
    return 0;
}
```

### Vulnerable permission assignments

**Issue**

This issue occurs when functions that can change resource permissions, such as `chmod`, `umask`, `creat`, or `open`, specify permissions that allow unintended actors to modify or read the resource.

**Risk**

If you give outside users or outside groups a wider range or permissions than required, you potentially expose your sensitive information and your modifications. This defect is especially dangerous for permissions related to:

- Program configurations
- Program executions
- Sensitive user data

**Fix**

Set your permissions so that the user (`u`) has more permissions than the group (`g`), and so the group has more permissions than other users (`o`), or `u >= g >= o`.

**Example — Create File with Other Permissions**

```
#include <unistd.h>
#include <sys/types.h>
#include <sys/stat.h>
#include <fcntl.h>

void bug_dangerouspermissions(const char * log_path) {
    mode_t mode = S_IROTH | S_IXOTH | S_IWOTH;
    int fd = creat(log_path, mode);

    if (fd) {
        write(fd, "Hello\n", 6);
    }
    close(fd);
    unlink(log_path);
}
```

In this example, the `log_path` file is created with more rights for the other outside users, than the current user. The permissions are `---------rwx`.

**Correction — Modify User Permissions**

One possible correction is to modify the user permissions for the file. In this correction, the user has read/write/execute permissions, but other users do not.

```
#include <unistd.h>
#include <sys/types.h>
#include <sys/stat.h>
#include <fcntl.h>

void corrected_dangerouspermissions(const char * log_path) {
    mode_t mode = S_IRUSR | S_IXUSR | S_IWUSR;
    int fd = creat(log_path, mode);

    if (fd) {
        write(fd, "Hello\n", 6);
    }
    close(fd);
    unlink(log_path);
}
```

# CWE Rule 1071

Empty code block

## Description

### Rule Definition

*The source code contains a block that does not contain any code, i.e., the block is empty.*

### Polyspace Implementation

This rule checker checks for the issue **Empty Code Block**.

## Examples

### Empty Code Block

#### Issue

**Empty Code Block** occurs when a code block does not contain code.

#### Risk

Unintentional empty code block can occur if you do not complete implementation or if you accidentally delete code. Unintentional missing code can cause errors or unexpected results.

#### Fix

Remove the empty code block if possible. Fill in the missing or deleted code if the code block is unintentionally empty due to accidental code deletion or incomplete implementation. If you can't remove or implement missing code, an empty code block can be replaced by an empty instruction. For example:

```
while (true)
;
```

#### Example — Empty Code Block

In this example, the `for` loop code block is empty.

```
#include <iostream>
#include <vector>

int main()
{
    std::vector<int> a = { 0, 1, 2, 4, 8 };

    for (auto x : a)                //Noncompliant
    {

    }

    return 0;
}
```

#### Correction — Add Missing Code

By adding code to the `for` loop code block, the example becomes compliant. Alternatively, if you do not need the `for` loop, remove it from the code.

```
#include <iostream>
#include <vector>

int main()
{
    std::vector<int> a = { 0, 1, 2, 4, 8 };

    for (auto x : a)                            //Compliant
    {
        std::cout << x << std::endl;
    }

    return 0;
}
```

# CWE Rule 1335

Incorrect Bitwise Shift of Integer

## Description

### Rule Description

*An integer value is specified to be shifted by a negative amount or an amount greater than or equal to the number of bits contained in the value causing an unexpected or indeterminate result.*

### Polyspace Implementation

The rule checker checks for these issues:

- **Right operand of shift operation outside allowed bounds**
- **Shift of a negative value**

## Examples

### Right operand of shift operation outside allowed bounds

#### Issue

This issue occurs when a shift operation can result in values that cannot be represented by the result data type. The data type of a variable determines the number of bytes allocated for the variable storage and constrains the range of allowed values.

The exact storage allocation for different data types depends on your processor. See `Target processor type (-target)`.

#### Risk

Shift operation overflows can result in undefined behavior.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also “Interpret Bug Finder Results in Polyspace Desktop User Interface” or “Interpret Bug Finder Results in Polyspace Access Web Interface”.

You can fix the defect by:

- Using a bigger data type for the result of the shift operation so that all values can be accommodated.
- Checking for values that lead to the overflow and performing appropriate error handling.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Left Shift of Integer

```
int left_shift(void) {

    int foo = 33;
    return 1 << foo;
}
```

In the return statement of this function, bit-wise shift operation is performed shifting 1 `foo` bits to the left. However, an `int` has only 32 bits, so the range of the shift must be between 0 and 31. Therefore, this shift operation causes an overflow.

#### Correction — Different storage type

One possible correction is to store the shift operation result in a larger data type. In this example, by returning a `long long` instead of an `int`, the overflow defect is fixed.

```
long long left_shift(void) {

    int foo = 33;
    return 1LL << foo;
}
```

### Shift of a negative value

#### Issue

This issue occurs when a bit-wise shift is used on a variable that can have negative values.

#### Risk

Shifts on negative values overwrite the sign bit that identifies a number as negative. The shift operation can result in unexpected values.

#### Fix

The fix depends on the root cause of the defect. Often the result details (or source code tooltips in Polyspace as You Code) show a sequence of events that led to the defect. You can implement the fix on any event in the sequence. If the result details do not show this event history, you can search for previous references of variables relevant to the defect using right-click options in the source code and find related events. See also "Interpret Bug Finder Results in Polyspace Desktop User Interface" or "Interpret Bug Finder Results in Polyspace Access Web Interface".

To fix the defect, check for negative values before the bit-wise shift operation and perform appropriate error handling.

See examples of fixes below.

If you do not want to fix the issue, add comments to your result or code to avoid another review. See:

- "Address Results in Polyspace User Interface Through Bug Fixes or Justifications" if you review results in the Polyspace user interface.
- "Address Results in Polyspace Access Through Bug Fixes or Justifications" if you review results in a web browser.
- "Annotate Code and Hide Known or Acceptable Results" if you review results in an IDE.

#### Extend Checker

A default Bug Finder analysis might not raise this defect when the input values are unknown and only a subset of inputs cause an issue. To check for defects caused by specific system input values, run a stricter Bug Finder analysis. See "Extend Bug Finder Checkers to Find Defects from Specific System Input Values".

#### Example — Shifting a negative variable

```
int shifting(int val)
{
    int res = -1;
    return res << val;
}
```

In the return statement, the variable `res` is shifted a certain number of bits to the left. However, because `res` is negative, the shift might overwrite the sign bit.

#### Correction — Change the Data Type

One possible correction is to change the data type of the shifted variable to unsigned. This correction eliminates the sign bit, so left shifting does not change the sign of the variable.

```
int shifting(int val)
{
    unsigned int res = -1;
    return res << val;
}
```

Multiple Releases of Same Resource or Handle

## Description

### Rule Description

*The product attempts to close or release a resource or handle more than once, without any successful open between the close operations.*

### Polyspace Implementation

The rule checker checks for **Closing previously closed resource**.

## Examples

### Closing previously closed resource

#### Issue

This issue occurs when a function attempts to close a stream that was closed earlier in your code and not reopened later.

#### Risk

The standard states that the value of a `FILE*` pointer is indeterminate after you close the stream associated with it. Performing the close operation on the `FILE*` pointer again can cause unwanted behavior.

#### Fix

Remove the redundant close operation.

#### Example — Closing Previously Closed Resource

```
#include <stdio.h>

void func(char* data) {
    FILE* fp = fopen("file.txt", "w");
    if(fp!=NULL) {
        if(data)
            fputc(*data,fp);
        else
            fclose(fp);
    }
    fclose(fp);
}
```

In this example, if `fp` is not `NULL` and `data` is `NULL`, the `fclose` operation occurs on `fp` twice in succession.

**Correction — Remove Close Operation**

One possible correction is to remove the last `fclose` operation. To avoid a resource leak, you must also place an `fclose` operation in the `if(data)` block.

```
#include <stdio.h>

void func(char* data) {
    FILE* fp = fopen("file.txt", "w");
    if(fp!=NULL) {
        if(data) {
            fputc(*data,fp);
            fclose(fp);
        }
        else
            fclose(fp);
    }
}
```

# Guidelines

## Software Complexity

# Number of calling functions exceeds threshold

The number of distinct callers of a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of distinct callers of the function is greater than the defined checker threshold. For details about how Polyspace calculates the number of calling functions, see `Number of Calling Functions`.

Polyspace uses the default threshold 5 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Calling Functions` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- Issues arising in the flagged function might propagate to have unexpected impact in many places.
- The data flow in the file is convoluted and finding the root cause of an issue might be difficult.
- The flagged function might be performing multiple tasks.

These factors make the module difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the functions in your code so that:

- Each function performs one specific task.
- The functions have minimal side effects on other functions.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That are Called by Many Different Functions

```
void utilityFunc(){//Noncompliant
    //...
}

void task1(){
    utilityFunc();
    //...
}
void task2(){
    utilityFunc();
    //...
}
void task3(){
    utilityFunc();
    //...
}
void task4(){
    utilityFunc();
    //...
}
void task5(){
    utilityFunc();
    //...
}
void task6(){
    utilityFunc();
    //...
}
void task7(){
    utilityFunc();
    //...
}
```

In this example, the function `utilityFunc` is called by seven different functions. It might indicate that `utilityFunc` performs multiple tasks. An issue arising in `utilityFunc` might have unexpected impact in any of the seven function that calls `utilityFunc`. Such interdependency make the code difficult to maintain and debug. Polyspace flags the function `utilityFunc` as noncompliant.

#### Correction — Refactor the Function

One possible correction is to refactor the function. For instance, delegate the different tasks required by different tasks into two utility functions instead of one.

```
void utilityFuncA(){//Compliant
    //...
}
void utilityFuncB(){//Compliant
    //...
}

void task1(){
    utilityFuncA();
    //...
}
void task2(){
    utilityFuncA();
    //...
}
void task3(){
    utilityFuncA();
    //...
}
void task4(){
    utilityFuncB();
    //...
}
void task5(){
    utilityFuncB();
    //...
}
void task6(){
    utilityFuncB();
    //...
}
void task7(){
    utilityFuncB();
    //...
}
```

# Number of called functions exceeds threshold

The number of distinct function calls within the body of a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of calls to distinct functions within its body is greater than the defined checker threshold. For details about how Polyspace calculates the number of called functions, see `Number of Called Functions`.

Polyspace uses the default threshold 7 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see "Reduce Software Complexity by Using Polyspace Checkers".

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Called Functions` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The function depends on many functions and changes to any one of these functions might result in an unexpected behavior.
- The function performs too many tasks.
- The module might contain unexpected or unplanned development.

These factors make the module difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the functions in your code so that:

- Each function performs one specific task.
- The functions have minimal side effects on other functions.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That Call Too Many Functions

```
class A{
    //..
};
class B{
    //...
};
void transform1(A &a, B &b){
    //...
}
void transform2(A &a, B &b){
    //...
}
void transform3(A &a, B &b){
    //...
}
void transform4(A &a, B &b){
    //...
}
void transform5(A &a, B &b){
    //...
}
void transform6(A &a, B &b){
    //...
}
void transform7(A &a, B &b){
    //...
}
void transform8(A &a, B &b){
    //...
}
void main(){//Noncompliant
    A a;
    B b;
    transform1(a,b);
    transform2(a,b);
    transform3(a,b);
    transform4(a,b);
    transform5(a,b);
    transform6(a,b);
    transform7(a,b);
    transform8(a,b);
}
```

In this example, the function `main()` calls eight different functions which is greater than the defined threshold of function calls. Debugging `main()` is difficult because the issue might be caused by any of these eight functions. Polyspace flags the function `main()`.

#### Correction — Design Functions to Perform Specific Tasks

One possible correction is design functions that perform specific tasks. In this case, the individual tasks are already delegated to different functions, but `main()` performs too may of these tasks. Dividing the task load of main between multiple functions might make the functions easier to debug, maintain, and test.

```
class A{
    //..
};
class B{
    //...
};
void transform1(A &a, B &b){
    //...
}
void transform2(A &a, B &b){
    //...
}
void transform3(A &a, B &b){
    //...
}
void transform4(A &a, B &b){
    //...
}
void transform5(A &a, B &b){
    //...
}
void transform6(A &a, B &b){
    //...
}
void transform7(A &a, B &b){
    //...
}
void transform8(A &a, B &b){
    //...
}
void FirstStep(A &a, B &b){
    transform1(a,b);
    transform2(a,b);
    transform3(a,b);
}
void SecondStep(A &a, B &b){
    transform4(a,b);
    transform5(a,b);
    transform6(a,b);
}
void ThirdStep(A &a, B &b){
    transform7(a,b);
    transform8(a,b);
}
void main(){//Compliant
    A a;
    B b;
    FirstStep(a,b);
    SecondStep(a,b);
    ThirdStep(a,b);
}
```

# Comment density falls below threshold

The comment density of the module falls below the specified threshold

## Description

Polyspace calculates the comment density percentage of a file by taking the ratio of comments to number of executable lines in the file and then multiplying the ratio by 100. For instance, a comment density `20` indicates that the file contains 20% comments and 80% code statements. This defect is raised when the comment density falls below the specified threshold. For details about how Polyspace calculates comment density, see `Comment Density`

Polyspace uses the default threshold 80 unless you specify a threshold. Use `Set checkers by file (-checkers-selection-file)` to specify a selection file where you can set the threshold. See “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Comment Density` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The module is not properly documented.
- The module is overly long and dense.
- The module might contain unexpected or unplanned development.

These factors make the module difficult to maintain and debug.

### Fix

To fix this defect:

- Put more comments between your statements that conveys the developer intent.
- Alternatively, reduce the number of statements in the module. If the module contains multiple functions, consider splitting the module and documenting them separately.

To fix this check, either refactor your code or change the checker threshold. A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Poorly Documented Code

```
//File1.cpp        //Noncompliant
 long long power(double x, int n){
     long long BN = 1;
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }

 double AppxIndex(double m, double f){
     double U = (power(m,2) - 1)/(power(m,2)+2);
     double V = (power(m,4) + 27*power(m,2)+38)/(2*power(m,2)+3);
     return (1+2*f*power(U,2)*(1+power(m,2)*U*V +
                power(m,3)/power(m,3)*(U-V)))/( (1-2*f*power(U,2)
              *(1+power(m,2)*U*V + power(m,3)/power(m,3)*(U-V))));
 }
```

In this example, the code in `File1.cpp` does not contain sufficient comments to document the developer intent. lack of sufficient documentation makes the code difficult to understand. Subsequent debugging and maintenance of the code might be difficult. Polyspace flags the file as noncompliant to this rule.

#### Correction — Document the Developer intent with Comments

One possible correction is to document the developer intent by putting sufficient comments. This code contains comment that clearly document developers intent and conveys information that eases understanding, debugging, and maintaining the code.

```
//File1.c        //Compliant
// r = power(x,n) returns the nth power of x into y
// r is long long
// x is double
// n must be integer
 long long power(double x, int n){
     long long BN = 1;
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }
 // n = AppxIndex(m,f) calculates the approximate
//  effective index of a material
// n is a double, represent the effective index of a mixture
// m is a double, represents the relative index of the
//                  inclusion compared to the background material
// f is a double, represents the filling factor of the inclusion
// The function implements the formula in the doi 10.XXYY
 double AppxIndex(double m, double f){
     // This function implements the formula for approximate index
     // The first term is U:
     double U = (power(m,2) - 1)/(power(m,2)+2);
     //The second term is V:
     double V = (power(m,4) + 27*power(m,2)+38)/(2*power(m,2)+3);
     // Calculate the denominator
     double den = ( (1-2*f*power(U,2)*
              (1+power(m,2)*U*V + power(m,3)/power(m,3)*(U-V))));
     // Calculate the numerator
     double num = (1+2*f*power(U,2)
              *(1+power(m,2)*U*V + power(m,3)/power(m,3)*(U-V)));
     // Calculate the aproximate index
     // Return by value
```

```
    return num/den;
}
```

# Call tree complexity exceeds threshold

The call tree complexity of a file is greater than the defined threshold

## Description

The call tree complexity of a file represents the complexity between different levels of its function call tree. Polyspace calculates the call tree complexity of a file as:

$$\textit{Call tree Complexity} = \textit{number of call occurrences} - \textit{number of function definitions} + 1 \qquad (28\text{-}1)$$

This defect is raised when the calculated call tree complexity of a file exceeds the defined call tree complexity threshold of the file. For details about how Polyspace calculates call tree complexity, see `Estimated Function Coupling`

Polyspace uses the default threshold 20 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Estimated Function Coupling` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The interdependency of the functions in the file is unacceptably high.
- Changes in one function in the file might introduce bugs or unexpected behavior in other functions in the file.
- Reusing a single function of the file might be difficult because of interdependencies with other functions.

These factors make the file difficult to maintain, test, and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the functions in your code so that:

- Each function performs one specific task.
- The functions have minimal side effects on other functions.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Overly Complex Function Call Tree

```
//Noncompliant
 long long power(double x, int n){
     long long BN = 1;
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }

 double AppxIndex(double m, double f){
     double U = (power(m,2) - 1)/(power(m,2)+2);
     double V = (power(m,4) + 27*power(m,2)+38)/(2*power(m,2)+3);
     return (1+2*f*power(U,2)*(1+power(m,2)*U*V + power(m,3)/
         power(m,3)*(U-V)))/( (1-2*f*power(U,2)*(1+power(m,2)*U*V
        + power(m,3)/power(m,3)*(U-V))));
 }
```

In this example, the function `power` is called many times in the function `AppIndex`. The high interdependency between these two functions results in a call tree complexity of 12, which is greater than the threshold 10. This high value implies that changes in `power` might require rewriting or revising `AppIndex`. Polyspace flags the file as noncompliant.

#### Correction — Design Functions to Perform One Specific Task

One possible correction is to refactor the code so that a function performs one specific task. In this code, the functions have a lower interdependency. For instance, `CalculateU` and `CalculateV` are completely independent of each other. By designing the functions to perform one specific task, isolating any unexpected behavior is easier. This code is easier to debug, test, and maintain.

```
//Compliant
 long long power(double x, int n){
     long long BN = 1;
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }
 double CalculateU(double m){
     return (power(m,2) - 1)/(power(m,2)+2);
 }
 double CalculateV(double m){//Compliant
     return (power(m,4) + 27*power(m,2)+38)/(2*power(m,2)+3);
 }
 double CalculateMid(double m, double f){//Compliant
     double U = CalculateU(m);
     double V = CalculateU(m);
     return 2*f*power(U,2)*(1+power(m,2)*U*V
              + power(m,3)/power(m,3)*(U-V));
 }
 double AppxIndex(double m, double f){//Compliant
     return (1+CalculateMid(m,f))/( (1-CalculateMid(m,f)));
 }
```

# Number of lines in function body exceeds threshold

The number of lines in the body of a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of lines within the body of the function is greater than the defined checker threshold. For details about how Polyspace calculates the number of lines in the body of a function, see `Number of Lines Within Body`

Polyspace uses the default threshold 1200 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Lines Within Body` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that the function is too long. Lengthy function are difficult to read and understand. Maintaining, testing and debugging lengthy functions might be costly in terms of resource and time.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, make the functions modular. That is, design your code so that each function performs one specific task with as little side effect as possible. Modular design of function make them easy to test, debug, and maintain. Modular functions also enables efficient code reuse and might reduce code duplication.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Lengthy Functions

```
#include <cmath>
#include <math.h>
#include <stddef.h>
#include <stdlib.h>
#define CREAL_T
typedef float real32_T;
typedef double real64_T;
typedef struct {
  real32_T re;
  real32_T im;
} creal32_T;

typedef struct {
  real64_T re;
  real64_T im;
} creal_T;
// Function Declarations
static double rt_powd_snf(double u0, double u1);

void CalculateAppxIndex(double r, double epsilon_s, double epsilon_h, double//Noncompliant
  lambda, double f, creal_T *eps_eff, creal_T *mu_eff)
{
  double n_h;
  double m;
  double a;
  double alpha_e_re;
  double alpha_e_im;
  double alpha_m_re;
  double alpha_m_im;
  int l;
  double br;

  //  sphere radius is 1 micron;
  //  the refractive index of inclusion
  n_h = std::sqrt(epsilon_h);

  //  the refractive index of host
  m = std::sqrt(epsilon_s) / n_h;
  n_h = 6.2831853071795862 * n_h * r / lambda;

  //  size parameter;
  a = (n_h + m) + 2.0;
  m = n_h - m;

  //  polarizability
  n_h = 6.2831853071795862 * rt_powd_snf(r, 3.0) / rt_powd_snf(n_h, 3.0);
  alpha_e_re = 0.0;
  alpha_e_im = 0.0;
  alpha_m_re = 0.0;
  alpha_m_im = 0.0;
  for (l = 0; l < 5; l++) {
    alpha_e_re += 0.0 * ((2.0 * (1.0 + (double)l) + 1.0) * a);
    alpha_e_im += (2.0 * (1.0 + (double)l) + 1.0) * a;
    alpha_m_re += 0.0 * ((2.0 * (1.0 + (double)l) + 1.0) * (m + 2.0));
    alpha_m_im += (2.0 * (1.0 + (double)l) + 1.0) * (m + 2.0);

    //  alpha = alpha + 1i* [(2*l+1)*(an(l) + bn(l))];
  }

  alpha_m_re *= n_h;
  alpha_m_im *= n_h;

  // alpha = aa*alpha;
  n_h = f / (4.1887902047863905 * rt_powd_snf(r, 3.0));
```

```
alpha_e_re *= n_h;
alpha_e_im *= n_h;
alpha_m_re *= n_h;
alpha_m_im *= n_h;
if (alpha_e_im == 0.0) {
  m = alpha_e_re / 3.0;
  n_h = 0.0;
} else if (alpha_e_re == 0.0) {
  m = 0.0;
  n_h = alpha_e_im / 3.0;
} else {
  m = alpha_e_re / 3.0;
  n_h = alpha_e_im / 3.0;
}

br = 1.0 - m;
m = 0.0 - n_h;
if (m == 0.0) {
  if (alpha_e_im == 0.0) {
    m = alpha_e_re / br;
    alpha_e_im = 0.0;
  } else if (alpha_e_re == 0.0) {
    m = 0.0;
    alpha_e_im /= br;
  } else {
    m = alpha_e_re / br;
    alpha_e_im /= br;
  }
} else {
  n_h = std::abs(m);
  if (br > n_h) {
    a = m / br;
    n_h = br + a * m;
    m = (alpha_e_re + a * alpha_e_im) / n_h;
    alpha_e_im = (alpha_e_im - a * alpha_e_re) / n_h;
  } else if (n_h == br) {
    if (br > 0.0) {
      a = 0.5;
    } else {
      a = -0.5;
    }

    if (m > 0.0) {
      n_h = 0.5;
    } else {
      n_h = -0.5;
    }

    m = alpha_e_re * a + alpha_e_im * n_h;
    alpha_e_im = alpha_e_im * a - alpha_e_re * n_h;
  } else {
    a = br / m;
    n_h = m + a * br;
    m = (a * alpha_e_re + alpha_e_im) / n_h;
    alpha_e_im = (a * alpha_e_im - alpha_e_re) / n_h;
  }
}
```

```
eps_eff->re = epsilon_h * (1.0 + m);
eps_eff->im = epsilon_h * alpha_e_im;
if (alpha_m_im == 0.0) {
  m = alpha_m_re / 3.0;
  n_h = 0.0;
} else if (alpha_m_re == 0.0) {
  m = 0.0;
  n_h = alpha_m_im / 3.0;
} else {
  m = alpha_m_re / 3.0;
  n_h = alpha_m_im / 3.0;
}

br = 1.0 - m;
m = 0.0 - n_h;
if (m == 0.0) {
  if (alpha_m_im == 0.0) {
    m = alpha_m_re / br;
    alpha_m_im = 0.0;
  } else if (alpha_m_re == 0.0) {
    m = 0.0;
    alpha_m_im /= br;
  } else {
    m = alpha_m_re / br;
    alpha_m_im /= br;
  }
} else {
  n_h = std::abs(m);
  if (br > n_h) {
    a = m / br;
    n_h = br + a * m;
    m = (alpha_m_re + a * alpha_m_im) / n_h;
    alpha_m_im = (alpha_m_im - a * alpha_m_re) / n_h;
  } else if (n_h == br) {
    if (br > 0.0) {
      a = 0.5;
    } else {
      a = -0.5;
    }

    if (m > 0.0) {
      n_h = 0.5;
    } else {
      n_h = -0.5;
    }

    m = alpha_m_re * a + alpha_m_im * n_h;
    alpha_m_im = alpha_m_im * a - alpha_m_re * n_h;
  } else {
    a = br / m;
    n_h = m + a * br;
    m = (a * alpha_m_re + alpha_m_im) / n_h;
    alpha_m_im = (a * alpha_m_im - alpha_m_re) / n_h;
  }
}

mu_eff->re = 1.0 + m;
mu_eff->im = alpha_m_im;
```

```
}
```

In this example, the length of the function `CalculateAppxIndex` exceeds the defined threshold of 100.

**Correction — Refactor the Code**

One possible correction is to refactor the code so that a function perform one specific task. In this case, different tasks in the `CalculateAppxIndex` are delegated to other functions modular functions so that each functions performs one specific tasks.

```
#include <cmath>
#include <math.h>
#include <stddef.h>
#include <stdlib.h>
#define CREAL_T
typedef float real32_T;
typedef double real64_T;
typedef struct {
  real32_T re;
  real32_T im;
} creal32_T;

typedef struct {
  real64_T re;
  real64_T im;
} creal_T;
// Function Declarations
static double rt_powd_snf(double u0, double u1);
void PolarizabilityE(double&, double&, double&,double& );
void PolarizabilityM(double&, double&, double&,double& );
void Eps_eff(double&,double&,creal_T*);
void Mu_eff(double&,double&,creal_T*);
void CalculateAppxIndex(double r, double epsilon_s, double epsilon_h, double //Compliant
  lambda, double f, creal_T *eps_eff, creal_T *mu_eff)
{
  double n_h;
  double m;
  double a;
  double alpha_e_re;
  double alpha_e_im;
  double alpha_m_re;
  double alpha_m_im;
  int l;
  double br;

  //  sphere radius is 1 micron;
  //  the refractive index of inclusion
  n_h = std::sqrt(epsilon_h);

  //  the refractive index of host
  m = std::sqrt(epsilon_s) / n_h;
  n_h = 6.2831853071795862 * n_h * r / lambda;

  //  size parameter;
  a = (n_h + m) + 2.0;
  m = n_h - m;

 PolarizabilityE(a,m,alpha_e_re,alpha_e_im);
 PolarizabilityM(a,m,alpha_e_re,alpha_e_im);
 Eps_eff(alpha_e_re,alpha_e_im, eps_eff);
 Mu_eff(alpha_e_re,alpha_e_im, mu_eff);
}
```

# Number of executable lines in function body exceeds threshold

The number of executable lines in the body of a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of executable lines within the body of the function is greater than the defined checker threshold. For details about how Polyspace calculates the number of executable lines in a function, see `Number of Executable Lines`

Polyspace uses the default threshold 1000 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see "Reduce Software Complexity by Using Polyspace Checkers".

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Executable Lines` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The function is overly long and performs multiple tasks.
- The function is likely to develop unexpected issues. The chance of an unexpected error increases with more lines of executable code.
- The function might contain unexpected or unplanned development.

These factors make the function difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the functions in your code so that:

- Each function is reasonably concise.
- Each function performs one specific task.
- The functions have minimal side effects on other functions.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Overly Long Functions

This example shows how Polyspace flags functions that have more executable lines that the defines threshold of executable lines. For this example, the threshold is defined at 50. The function

CalculateAppxIndex has 116 executable line. The large number of executable lines indicate that the function is overly long. While length of a function is not a big problem by itself, overly long functions might be poorly designed, with complex data flow, many local variables, and performing many tasks. Polyspace flags the function.

```
#include <cmath>
#include <math.h>
#include <stddef.h>
#include <stdlib.h>
#define CREAL_T
typedef float real32_T;
typedef double real64_T;
typedef struct {
  real32_T re;
  real32_T im;
} creal32_T;

typedef struct {
  real64_T re;
  real64_T im;
} creal_T;
// Function Declarations
static double rt_powd_snf(double u0, double u1);

void CalculateAppxIndex(double r, double epsilon_s, double epsilon_h, double//Noncompliant
  lambda, double f, creal_T *eps_eff, creal_T *mu_eff)
{
  double n_h;
  double m;
  double a;
  double alpha_e_re;
  double alpha_e_im;
  double alpha_m_re;
  double alpha_m_im;
  int l;
  double br;

  //  sphere radius is 1 micron;
  //  the refractive index of inclusion
  n_h = std::sqrt(epsilon_h);

  //  the refractive index of host
  m = std::sqrt(epsilon_s) / n_h;
  n_h = 6.2831853071795862 * n_h * r / lambda;

  //  size parameter;
  a = (n_h + m) + 2.0;
  m = n_h - m;

  //  polarizability
  n_h = 6.2831853071795862 * rt_powd_snf(r, 3.0) / rt_powd_snf(n_h, 3.0);
  alpha_e_re = 0.0;
  alpha_e_im = 0.0;
  alpha_m_re = 0.0;
  alpha_m_im = 0.0;
  for (l = 0; l < 5; l++) {
```

```
  alpha_e_re += 0.0 * ((2.0 * (1.0 + (double)l) + 1.0) * a);

      n_h = m + a * br;
      m = (a * alpha_m_re + alpha_m_im) / n_h;
      alpha_m_im = (a * alpha_m_im - alpha_m_re) / n_h;
    }
  }

  mu_eff->re = 1.0 + m;
  mu_eff->im = alpha_m_im;
}
```

#### Correction — Refactor Functions

One possible correction is to refactor the function so that separate tasks are delegated to separate functions.

# Number of goto statements exceeds threshold

The number of goto statements in a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of goto statements in the function is greater than the define threshold. For details about how Polyspace calculates the number of goto statements, see Number of Goto Statements

Polyspace uses the default threshold zero unless you specify a threshold. To specify a selection file where you can set the threshold, use Set checkers by file (-checkers-selection-file). Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using polyspace-comments-import, Polyspace copies any review information on the code metric Number of Goto Statements in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The module has an overly complicated flow of execution.
- The module might contain unexpected or unplanned development.

With multiple goto statements, it is difficult to determine the exact order of code execution in the module. This confusion might lead to bugs or an incorrect result. The complex data flow of such code makes the module difficult to maintain and debug.

### Fix

To fix this check, either change the checker threshold or refactor your code. You can replace most uses of the goto statement by more straightforward control structures. In instances where a goto statement is necessary, document it and justify the checker by using an annotation in the code. You might want to change the threshold to avoid triggering this check when checking legacy codebases.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Using goto Statements

```
#include<stdbool.h>
bool* getCondition();
void foo(){//Noncompliant
    bool* cond;
    cond = getCondition();
    while(*(cond+0)){
        //...
        while(*(cond+1)){
            //...
            while(*(cond+2)){
                //...
                if(*(cond+3)){
                goto HARDBREAK;
                }
            }
        }
    }
HARDBREAK:
        ;
        //....
        return;
}
```

In this example, a `goto` statement is used for conditionally breaking the flow of execution out of a deeply nested control structure. Polyspace flags the function because the number of `goto` statements in the function greater than the defined threshold, which is zero by default.

#### Correction — Refactor the Code or Change the Threshold

One possible correction is to refactor the code so that there are no `goto` statements in the code. For instance, you might want to use a `return` statement to get out of a deeply nested structure.

```
#include<stdbool.h>
bool* getCondition();
void foo(){//Compliant
    bool* cond;
    cond = getCondition();
    while(*(cond+0)){
        //...
        while(*(cond+1)){
            //...
            while(*(cond+2)){
                //...
                if(*(cond+3)){
                return;
                }
            }
        }
    }

}
```

Alternatively, you might consider this instance of `goto` as acceptable. In that case, change the threshold by modifying the checkers selection XML file to resolve the check.

## Check Information

# Depth of call nesting exceeds threshold

The nesting depth of control structures in a function is greater than the defined nesting depth threshold of a function

## Description

This defect is raised when the nesting depth of control structures in a function, such as `for`, `if-else`, `switch`, or `while`, exceeds the defined nesting depth threshold. For details about how Polyspace calculates the nesting depth, see `Number of Call Levels`.

Polyspace uses the default threshold 4 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Call Levels` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The function is difficult to read and understand.
- The function performs too many tasks at once.
- The function contains unexpected or unplanned development.

These factors make the module difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring your code:

- Design the function to perform a single task.
- Delegate unrelated tasks to other functions.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That Have Excessive Call Nesting

```
int foo(int i, int j, int k) //Noncompliant
{
    int m=0;
    for (i=0; i<10; i++)
    {
        for (j=0; j<10; j++)
        {
            for (k=0; k<10; k++)
            {
                if (i < 2 && j>5 && k<7 )
                m += 1;
                else
                {
                    if (i > 5 && j<8 && k >8){
                        m +=-1 ;
                    }

                    else{
                        m += 2;
                    }
                }
            }
        }
    }
    return m;
}
```

In this example, the depth of call nesting is 5, which is above the default threshold of 4. The function iterates over three integers and modifies the integer `m` conditionally. The high depth of nesting makes reading and understanding the function difficult.

**Correction — Refactor the Function**

One possible correction is to delegate different tasks to different functions. For instance, delegate the conditional actions in `foo` to another function `bar`.

```
int bar(int i, int j, int k){//Compliant
int m = 0;
    if (i < 2 && j>5 && k<7 ){
        m = 1;
    }
    else
    {
        if (i > 5 && j<8 && k >8){
            m =-1 ;
        }

        else{
            m = 2;
        }
    }
return m;
}

int foo(int i, int j, int k) //Compliant
{
    int m=0;
    for (i=0; i<10; i++)
    {
        for (j=0; j<10; j++)
        {
            for (k=0; k<10; k++)
            {
                m += bar(i,j,k);
            }
        }
    }
    return m;
}
```

# Number of local static variables exceeds threshold

The number of local static variables in a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of local static variables in the function is greater than the defined checker threshold. For details about how Polyspace calculates the number of local static variables in a function, see `Number of Local Static Variables`.

Polyspace uses the default threshold 20 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see "Reduce Software Complexity by Using Polyspace Checkers".

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Local Static Variables` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

The content of a static variable might be influenced by many different ways. When your function has too many static variables, it indicates that the data in your code is not properly encapsulated and your functions might have unexpected interdependencies. These factor make your code difficult to test and maintain, and might introduce bugs that are difficult to diagnose.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring your code:

- Encapsulate and modularize independent data or code.
- Communicate between functions by using local variables instead of global or static variables.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That Have Too Many Static Variables

```
void foo(void){//Noncompliant

    static int a;
    static int b;
    static int c;
    static int d;
    static int e;
    static int f;
    static int g;
    //...
}
```

In this example, the function `foo` has seven local static variables, which is more than the specified threshold of five. Polyspace flags the function.

#### Correction — Encapsulate Related Data

One possible correction is to encapsulate related data in structures or classes. In this code, the related integer variables are encapsulated into a structure. The function `foo` now contains only one static copy of the structure..

```
typedef struct {
    int a;
    int b;
    int c;
    int d;
    int e;
    int f;
    int g;
} data_vars;
void foo(void){//Compliant

    static data_vars A;
    //...
}
```

# Number of local non-static variables exceeds threshold

The number of local nonstatic variables in a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of local nonstatic variables in the function is greater than the defined checker threshold. For details about how Polyspace calculates the number of local nonstatic variables in a function, see `Number of Local Non-Static Variables`.

Polyspace uses the default threshold 20 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see "Reduce Software Complexity by Using Polyspace Checkers".

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Local Non-Static Variables` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The function is overly long.
- The function performs many tasks rather than one specific task.

These factors make the module difficult to maintain and debug.

### Fix

To fix this check, either refactor your code, or change the checker threshold. When refactoring your code:

- Consider splitting a function into smaller modules that performs a specific task.
- Consider bundling variables that have a similar role into containers such as classes, structures, vectors, or maps.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions with Excessive Number of Local Nonstatic variables

```
#include <string>
void foo(void){//Noncompliant

    int Value1,Value2,Value3,Value4,Value5,Value6,Value7,Value8,Value9,Value10,Value11;
    std::string Name1,Name2,Name3,Name4,Name5,Name6,Name7,Name8,Name9,Name10,Name11;
    //....

}
```

In this example, The names and associated value of eleven separate entities are declared as separate variables. it is difficult to keep track of such a high number of variables. If you need to include more entities in the code, you need to declare more variables. This kind of code is difficult to test, maintain, and debug. Polyspace flags the function.

#### Correction — Bundle Related Data into Containers

One possible correction is to bundle the related data into containers. For instance, in this code the data is bundled into a `std::map` container, which is then wrapped in a class. Then in the code, you need to declare only one local variable and use the variable to store, manage, and access the data. This code is easier to maintain, test, and debug.

```
#include <string>
#include <map>
class Instance{
    public:
    Instance();
    Instance(int, std::string);
    protected:
    addData(int,std::string);
    getValue(std::string);
    //...
    private:
    std::map<std::string, int> DataMap;

};
void foo(void){//Compliant

    Instance A;
    //....
    A.addData(5,"Name");

}
```

### Topics

“Reduce Software Complexity by Using Polyspace Checkers”
“Modify Default Behavior of Bug Finder Checkers”

# Number of function calls exceeds threshold

The number of function calls in a function is greater than the defined call occurrence threshold of a function

## Description

This defect is raised when the body of a function contains more calls to functions than the specified call occurrence threshold of a function. For details about how Polyspace calculates the number of function call occurrences, see `Number of Call Occurrences`

Polyspace uses the default threshold 50 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Call Occurrences` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The function performs too many tasks.
- The function might have high interdependency with multiple other functions.
- Changes in some other function might have unexpected impact on the flagged function.

These factors make the function difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the functions in your code so that:

- Each function performs one specific task.
- The functions have minimal side effects on other functions.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That Have Too Many Function Calls

```
long long power(double x, int n){
    long long BN = 1;
    for(int i = 0; i<n;++i){
        BN*=x;
```

```
     }
     return BN;
 }
long long factorial(int n){
     long long BN = 1;
     for(int i = 1; i<=n;++i){
         BN*=i;
     }
     return BN;
 }

 double AppxIndex(double m, double f){//Noncompliant
     double U = (power(m,2) - 1)/(power(m,2)*factorial(2));
     double V = (power(m,4) + 27*power(m,2)+38)/factorial(3)*(2*power(m,2)+3);
     return (1+2*f*power(U,2)*(1+power(m,2)*factorial(static_cast<int>(U/V))
       + power(m,3)/power(m,3)*(U-V)))/( (1-2*f*power(U,2)*(1+power(m,2)*
        factorial(static_cast<int>(U/V)) + power(m,3)/power(m,3)*(U-V)))); }
```

The function AppxIndex contains 17 different function calls, which is greater than the specified call occurrence threshold of 10. Such high call occurrence indicate that this function is doing too many tasks. It also indicates that the function has high interdependencies with other functions. These factor make AppIndex difficult to maintain, test, or debug.

**Correction — Refactor Code**

One possible correction is to refactor the function. Here, the function is split into smaller functions that performs specific tasks.

```
  long long power(double x, int n){//Compliant
    long long BN = 1;
    for(int i = 0; i<n;++i){
        BN*=x;
    }
    return BN;
}
long long factorial(int n){//Compliant
    long long BN = 1;
    for(int i = 1; i<=n;++i){
        BN*=i;
    }
    return BN;
}

double CalculateU(double m){//Compliant
    return (power(m,2) - 1)/(power(m,2)*factorial(2));
}

double CalculateV(double m){//Compliant
    return (power(m,4) + 27*power(m,2)+38)/factorial(3)*(2*power(m,2)+3);
}

double CalculateMid(double m, double f){//Compliant
    double U = CalculateU(m);
    double V = CalculateU(m);
    return (2*f*power(U,2)*(1+power(m,2)*factorial(static_cast<int>(U/V))
             + power(m,3)/power(m,3)*(U-V)));
}
```

```
double AppxIndex(double m, double f){//Compliant

    return (1+CalculateMid(m,f))/( (1-CalculateMid(m,f)));
}
```

# Number of function parameters exceeds threshold

The number of arguments of a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of its arguments is greater than the defined checker threshold. For details about how Polyspace calculates the number of parameters, see `Number of Function Parameters`

Polyspace uses the default threshold 5 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see "Reduce Software Complexity by Using Polyspace Checkers".

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Function Parameters` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker indicates that:

- The function might have unacceptably high degree of dependence on other functions.
- The function might be performing more than one specific task. A best practice is to delegate one specific task to one function.
- The function might contain unexpected or unplanned development.
- The function might hinder performance because registers cannot hold all parameters.

These factors make the function difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the threshold in the checker selection XML. You might want to split the function into smaller chunks that performs a specific task and does not take more than the number of parameters specified as threshold. If the parameters of a functions are related, you might consider bundling them into structures.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions With Excessive Numbers of Parameters

```
#include<vector>
#include<complex>
#define PI 3.1416
std::vector<std::complex<double> >CalculateCoefficient(double, double, int);
```

```
double CalculateMfactor(double, double);
std::complex<double> CalculateEffectiveIndex(//Noncompliant
                    double Radius, double Index1, double Index2,
                     double Wavelength, double FillFactor,
                     int Cutoff){
    double RelativeIndex = Index1/Index2;
    double SizeParameter = 2*PI*Radius*Index1/Wavelength;
    std::complex<double> Polarization = 0;
    std::vector<std::complex<double>> Coefficient=
          CalculateCoefficient(RelativeIndex,SizeParameter,Cutoff);
        //...
     for (const auto& z : Coefficient){
         Polarization += z;
     }
     double Multiplier = CalculateMfactor(FillFactor,Radius);
     std::complex<double> Neff = (1.0 + Multiplier*Polarization)/
                (1.0 - Multiplier*Polarization);
     return Neff;
}
```

In this example, the function `CalculateEffectiveIndex` takes six parameters, which is greater than the defined threshold five. The high number of parameter indicate that the function might be performing more than one specific task, and it might have high degree of dependencies with other functions. Polyspace flags the function as noncompliant.

#### Correction — Refactor The Code so that Functions Perform One Specific Task

One possible correction is to refactor the function so that it performs one specific task. In this code, the function `CalculateEffectiveIndex` is refactored into two smaller functions, each of which performs one specific task. The functions are easier to debug and maintain because they take less parameters than the defined threshold. Polyspace does not flag these functions.

```
#include<vector>
#include<complex>
#define PI 3.1416
std::vector<std::complex<double>>CalculateCoefficient(double, double, int);
double CalculateMfactor(double, double);

std::complex<double> CalculatePolarization(//Compliant
        double Radius, double Index1, double Index2,
        double Wavelength, int Cutoff){
    double RelativeIndex = Index1/Index2;
    double SizeParameter = 2*PI*Radius*Index1/Wavelength;
    std::complex<double> Polarization = 0;
    std::vector<std::complex<double> > Coefficient=
              CalculateCoefficient(RelativeIndex,SizeParameter,Cutoff);
        //...
     for (const auto& z : Coefficient){
         Polarization += z;
     }

     return Polarization;
}

std::complex<double> CalculateEffectiveIndex
      (std::complex<double> Polarization, double Multiplier){//Compliant
     std::complex<double> Neff = (1.0 + Multiplier*Polarization)/
              (1.0 - Multiplier*Polarization);
     return Neff;
}
```

# Number of static paths exceeds threshold

The number of static paths in a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of static paths in the function is greater than the defined checker threshold. For details about how Polyspace calculates the number of static paths in a function, see `Number of Paths`

Polyspace uses the default threshold 80 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Paths` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that the function has too many possible execution paths. When there are too many execution paths, it might be difficult to test all paths exhaustively. Such functions are difficult to debug, test and maintain.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring your code:

- Avoid putting control structures in long sequences.
- Split a complex function into multiple functions that are simpler and easy to test.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That Have High Number of Paths

```
int afunc (int x);
int foo(int x,int y) //Noncompliant
{
    int flag;
    if (x <= 0){
        if (x > 10 ) { return 0; }
    }
    if (x<-240) {
        if (x < -2565) {
            return (x < -253 ? 0: afunc (x <22566 ? 1: afunc(x < -25103 ? 0: 6)));
        }
    }
    for (int i = 0; i< 10; i++)
    {
        while (x < y ) flag = 1;
        do {++x;} while (i<7);
        flag = 0;
    }
    return flag;
}
```

In this example, the function `foo` has many branching statements points, resulting in a path number of 45, which is greater than the specified threshold of 40. Because the function has many execution paths, testing the function is difficult and testing might fail to cover all execution paths. Polyspace flags the function as noncompliant.

#### Correction — Refactor Your Code

One possible correction is to split the function into two functions.

```
int afunc (int x);
int foo2(int x,int y)//Compliant
{

    if (x <= 0){
        if (x > 10 ) { return 0; }
    }
    if (x<-240) {
        if (x < -2565) {
            return (x < -253 ? 0: afunc (x <22566 ? 1: afunc(x < -25103 ? 0: 6)));
        }
    }
}

int bar(int x,int y){//Complaint
    int flag;
    for (int i = 0; i< 10; i++)
    {
        while (x < y ) flag = 1;
        do {++x;} while (i<7);
        flag = 0;
    }
    return flag;
}
```

The functions `foo2` and `bar` have acceptable number of paths and are easier to test compared to `foo`.

# Number of return statements exceeds threshold

The number of `return` statements in a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of `return` statement in the function is greater than the defined checker threshold. For details about how Polyspace calculates the number of return statements in a function, see `Number of Return Statements`

Polyspace uses the default threshold 1 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see "Reduce Software Complexity by Using Polyspace Checkers".

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Return Statements` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Having multiple return statements makes it difficult to determine what object a function might return. Such confusion might lead to bugs and maintenance issues that are difficult to debug.

### Fix

To fix this check, use a single return statement. For instance, store the return value in an object and define it conditionally instead of returning different objects in different conditionalized return statement.

## Examples

### Avoid Multiple `return` Statements

```
int afunc (int x);
int foo2(int x,int y)//Noncompliant
{

    if (x <= 0){
        if (x > 10 ) { return 0; }
    }
    if (x<-240) {
        if (x < -2565) {
            return (x < -253 ? 0: afunc (x <22566 ? 1: afunc(x < -25103 ? 0: 6)));
        }
    }
}
```

In this example, the `return` statement of `foo` is conditionalized, leading to two `return` statements, which exceeds the default return statement threshold of one. Polyspace flags the function `foo` as noncompliant.

#### Correction — Declare Object to Store Return value

One possible correction is to declare an object which is then conditionally defined to have the appropriate return value. This object is then returned by the function by using a single return statement.

```
int afunc (int x);
int foo2(int x,int y)//Compliant
{
    int returnData;
    if (x <= 0){
        if (x > 10 ) { returnData =  0; }
    }
    if (x<-240) {
        if (x < -2565) {
            returnData =  (x < -253 ? 0: afunc (x <22566 ? 1: afunc(x < -25103 ? 0: 6)));
        }
    }
    return returnData;
}
```

# Number of statements exceeds threshold

The number of statements in a function is greater than the defined threshold

## Description

This defect is raised on a function when the number of statements in the function is greater than the defined threshold of the checker. For details about how Polyspace calculates the number of statements in a function, see `Number of Instructions`.

Polyspace uses the default threshold 50 unless you specify a threshold for the checker. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Instructions` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The purpose of the function is unclear.
- The function performs multiple tasks.
- The function has high interdependency with other modules.
- The function contains unexpected or unplanned development.

These factors make the module difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the functions in your code so that:

- Each function performs one specific task.
- The functions have minimal side effects on other functions.
- Independent data and code are properly isolated and encapsulated.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Overly Long Functions

```
#include <cmath>
#include <math.h>
#include <stddef.h>
```

```
#include <stdlib.h>
#define CREAL_T
typedef float real32_T;
typedef double real64_T;
typedef struct {
  real32_T re;
  real32_T im;
} creal32_T;

typedef struct {
  real64_T re;
  real64_T im;
} creal_T;
// Function Declarations
static double rt_powd_snf(double u0, double u1);

void CalculateAppxIndex(double r, double epsilon_s, double epsilon_h, double //Noncompliant
  lambda, double f, creal_T *eps_eff, creal_T *mu_eff)
{
  double n_h;
  double m;
  double a;
  double alpha_e_re;
  double alpha_e_im;
  double alpha_m_re;
  double alpha_m_im;
  int l;
  double br;

  //  sphere radius is 1 micron;
  //  the refractive index of inclusion
  n_h = std::sqrt(epsilon_h);

  //  the refractive index of host
  m = std::sqrt(epsilon_s) / n_h;
  n_h = 6.2831853071795862 * n_h * r / lambda;

  //  size parameter;
  a = (n_h + m) + 2.0;
  m = n_h - m;

  //  polarizability
  n_h = 6.2831853071795862 * rt_powd_snf(r, 3.0) / rt_powd_snf(n_h, 3.0);
  alpha_e_re = 0.0;
  alpha_e_im = 0.0;
  alpha_m_re = 0.0;
  alpha_m_im = 0.0;
  for (l = 0; l < 5; l++) {
    alpha_e_re += 0.0 * ((2.0 * (1.0 + (double)l) + 1.0) * a);
    alpha_e_im += (2.0 * (1.0 + (double)l) + 1.0) * a;
    alpha_m_re += 0.0 * ((2.0 * (1.0 + (double)l) + 1.0) * (m + 2.0));
    alpha_m_im += (2.0 * (1.0 + (double)l) + 1.0) * (m + 2.0);

    //  alpha = alpha + 1i* [(2*l+1)*(an(l) + bn(l))];
  }

  alpha_e_re *= n_h;
  alpha_e_im *= n_h;
```

```
alpha_m_re *= n_h;
alpha_m_im *= n_h;

// alpha = aa*alpha;
n_h = f / (4.1887902047863905 * rt_powd_snf(r, 3.0));
alpha_e_re *= n_h;
alpha_e_im *= n_h;
alpha_m_re *= n_h;
alpha_m_im *= n_h;
if (alpha_e_im == 0.0) {
  m = alpha_e_re / 3.0;
  n_h = 0.0;
} else if (alpha_e_re == 0.0) {
  m = 0.0;
  n_h = alpha_e_im / 3.0;
} else {
  m = alpha_e_re / 3.0;
  n_h = alpha_e_im / 3.0;
}

br = 1.0 - m;
m = 0.0 - n_h;
if (m == 0.0) {
  if (alpha_e_im == 0.0) {
    m = alpha_e_re / br;
    alpha_e_im = 0.0;
  } else if (alpha_e_re == 0.0) {
    m = 0.0;
    alpha_e_im /= br;
  } else {
    m = alpha_e_re / br;
    alpha_e_im /= br;
  }
} else {
  n_h = std::abs(m);
  if (br > n_h) {
    a = m / br;
    n_h = br + a * m;
    m = (alpha_e_re + a * alpha_e_im) / n_h;
    alpha_e_im = (alpha_e_im - a * alpha_e_re) / n_h;
  } else if (n_h == br) {
    if (br > 0.0) {
      a = 0.5;
    } else {
      a = -0.5;
    }

    if (m > 0.0) {
      n_h = 0.5;
    } else {
      n_h = -0.5;
    }

    m = alpha_e_re * a + alpha_e_im * n_h;
    alpha_e_im = alpha_e_im * a - alpha_e_re * n_h;
  } else {
    a = br / m;
    n_h = m + a * br;
```

```
      m = (a * alpha_e_re + alpha_e_im) / n_h;
      alpha_e_im = (a * alpha_e_im - alpha_e_re) / n_h;
    }
  }

  eps_eff->re = epsilon_h * (1.0 + m);
  eps_eff->im = epsilon_h * alpha_e_im;
  if (alpha_m_im == 0.0) {
    m = alpha_m_re / 3.0;
    n_h = 0.0;
  } else if (alpha_m_re == 0.0) {
    m = 0.0;
    n_h = alpha_m_im / 3.0;
  } else {
    m = alpha_m_re / 3.0;
    n_h = alpha_m_im / 3.0;
  }

  br = 1.0 - m;
  m = 0.0 - n_h;
  if (m == 0.0) {
    if (alpha_m_im == 0.0) {
      m = alpha_m_re / br;
      alpha_m_im = 0.0;
    } else if (alpha_m_re == 0.0) {
      m = 0.0;
      alpha_m_im /= br;
    } else {
      m = alpha_m_re / br;
      alpha_m_im /= br;
    }
  } else {
    n_h = std::abs(m);
    if (br > n_h) {
      a = m / br;
      n_h = br + a * m;
      m = (alpha_m_re + a * alpha_m_im) / n_h;
      alpha_m_im = (alpha_m_im - a * alpha_m_re) / n_h;
    } else if (n_h == br) {
      if (br > 0.0) {
        a = 0.5;
      } else {
        a = -0.5;
      }

      if (m > 0.0) {
        n_h = 0.5;
      } else {
        n_h = -0.5;
      }

      m = alpha_m_re * a + alpha_m_im * n_h;
      alpha_m_im = alpha_m_im * a - alpha_m_re * n_h;
    } else {
      a = br / m;
      n_h = m + a * br;
      m = (a * alpha_m_re + alpha_m_im) / n_h;
      alpha_m_im = (a * alpha_m_im - alpha_m_re) / n_h;
    }
  }

  mu_eff->re = 1.0 + m;
  mu_eff->im = alpha_m_im;
}
```

In this example, the function `CalculateAppxIndex` has more instructions than the default threshold of 50. Such high number of instructions indicate that the function has an ill-defined purpose and performs many tasks at once. The function is difficult to debug. Polyspace flags the function.

#### Correction — Delegate Independent Tasks to Functions

One possible correction is to refactor the function by delegating individual functions to smaller functions. Such modular design enables easier debugging and efficient code reuse.

```
#include <cmath>
#include <math.h>
#include <stddef.h>
#include <stdlib.h>
#define CREAL_T
typedef float real32_T;
typedef double real64_T;
typedef struct {
  real32_T re;
  real32_T im;
} creal32_T;

typedef struct {
  real64_T re;
  real64_T im;
} creal_T;
// Function Declarations
static double rt_powd_snf(double u0, double u1);
void PolarizabilityE(double&, double&, double&,double& );
void PolarizabilityM(double&, double&, double&,double& );
void Eps_eff(double&,double&,creal_T*);
void Mu_eff(double&,double&,creal_T*);
void CalculateAppxIndex(double r, double epsilon_s, double epsilon_h, double
  lambda, double f, creal_T *eps_eff, creal_T *mu_eff)//Compliant
{
  double n_h;
  double m;
  double a;
  double alpha_e_re;
  double alpha_e_im;
  double alpha_m_re;
  double alpha_m_im;
  int l;
  double br;

  //  sphere radius is 1 micron;
  //  the refractive index of inclusion
  n_h = std::sqrt(epsilon_h);

  //  the refractive index of host
  m = std::sqrt(epsilon_s) / n_h;
  n_h = 6.2831853071795862 * n_h * r / lambda;

  //  size parameter;
  a = (n_h + m) + 2.0;
  m = n_h - m;

 PolarizabilityE(a,m,alpha_e_re,alpha_e_im);
 PolarizabilityM(a,m,alpha_e_re,alpha_e_im);
 Eps_eff(alpha_e_re,alpha_e_im, eps_eff);
 Mu_eff(alpha_e_re,alpha_e_im, mu_eff);
}
```

# Number of lines exceeds threshold

The number of total lines in a file is greater than the defined threshold

## Description

This defect is raised on a file when the number of total lines in the file is greater than the defined threshold of the checker. For details about how Polyspace calculates the total number of lines in a file, see `Number of Lines`.

Polyspace uses the default threshold 10,000 unless you specify a threshold for the checker. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Number of Lines` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- The file is too long.
- The file contains too many different functions.
- The file contains too many verbose comments.

These factors make the file difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the modules of your project so that:

- Related and independent code is encapsulated and separated.
- The modules are separated based on tasks of appropriate scope.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Overdeveloped Files

```
//file1.cpp
#include <cmath>//Noncompliant
#include <math.h>
#include <stddef.h>
#include <stdlib.h>
#define CREAL_T
```

```
typedef float real32_T;
typedef double real64_T;
typedef struct {
  real32_T re;
  real32_T im;
} creal32_T;

typedef struct {
  real64_T re;
  real64_T im;
} creal_T;
// Function Declarations
static double rt_powd_snf(double u0, double u1);

void CalculateAppxIndex(double r, double epsilon_s, double epsilon_h, double
  lambda, double f, creal_T *eps_eff, creal_T *mu_eff)
{
  double n_h;
  double m;
  double a;
  double alpha_e_re;
  double alpha_e_im;
  double alpha_m_re;
  double alpha_m_im;
  int l;
  double br;

  //  sphere radius is 1 micron;
  //  the refractive index of inclusion
  n_h = std::sqrt(epsilon_h);

  //  the refractive index of host

    alpha_m_im = (a * alpha_m_im - alpha_m_re) / n_h;
  }
}
```

```
  mu_eff->re = 1.0 + m;
  mu_eff->im = alpha_m_im;
}
```

In this example, the file `file1.cpp` has 184 lines, which is more than the specified checker threshold of 100. This file might be overdeveloped. Polyspace raises the defect.

**Correction — Refactor Your Code**

One possible correction is to distribute the different modules of the code into different files. For instance, the different tasks in `CalculateAppxIndex` are delegated to other functions and their implementations are moved to `file2.cpp`. The type definitions and header file inclusions are moved to another header file. The file `file1.cpp` now has 40 lines, which is below the threshold.

```
//file2.cpp//Compliant
//Implementations of these functions:
void PolarizabilityE(double&, double&, double&,double& ){
//...
}
void PolarizabilityM(double&, double&, double&,double& ){
//...
}
void Eps_eff(double&,double&,creal_T*){
//...}

void Mu_eff(double&,double&,creal_T*){
//...
}

//header.h//Compliant
#include <cmath>
#include <math.h>
#include <stddef.h>
#include <stdlib.h>
#define CREAL_T
typedef float real32_T;
typedef double real64_T;
typedef struct {
  real32_T re;
  real32_T im;
} creal32_T;

typedef struct {
  real64_T re;
  real64_T im;
} creal_T;

//file1.cpp//Compliant
#include"header.h"
#include"file2.cpp"
// Function Declarations
static double rt_powd_snf(double u0, double u1);
void PolarizabilityE(double&, double&, double&,double& );
void PolarizabilityM(double&, double&, double&,double& );
void Eps_eff(double&,double&,creal_T*);
void Mu_eff(double&,double&,creal_T*);
void CalculateAppxIndex(double r, double epsilon_s,
  double epsilon_h, double
  lambda, double f, creal_T *eps_eff, creal_T *mu_eff)
{
  double n_h;
  double m;
  double a;
  double alpha_e_re;
  double alpha_e_im;
  double alpha_m_re;
  double alpha_m_im;
  int l;
  double br;

  //  sphere radius is 1 micron;
  //  the refractive index of inclusion
  n_h = std::sqrt(epsilon_h);

  //  the refractive index of host
  m = std::sqrt(epsilon_s) / n_h;
  n_h = 6.2831853071795862 * n_h * r / lambda;

  //  size parameter;
  a = (n_h + m) + 2.0;
  m = n_h - m;

# Cyclomatic complexity exceeds threshold

The cyclomatic complexity of a function is greater than the defined cyclomatic complexity threshold of a function

## Description

Polyspace calculates the cyclomatic complexity of a function by adding one to the number of decision points. A decision point is a statement that causes your program to branch into two paths. This defect is raised when the cyclomatic complexity of a function is greater than the defined cyclomatic complexity threshold. For details about how Polyspace calculates cyclomatic complexity, see `Cyclomatic Complexity`.

Polyspace uses the default threshold 10 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Cyclomatic Complexity` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that the function contains too many branches. Such functions are difficult to test and might contain unknown defects or bugs that are difficult to debug.

### Fix

To fix this check:

- Refactor your code to avoid nested control structures.
- Refactor your code to split a complex function into multiple functions that are simpler and easy to test.
- Modify the checker selection XML file to raise the cyclomatic complexity threshold.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That Have High Cyclomatic Complexity

```
int afunc (int x);
int foo(int x,int y) //Noncompliant
{
    int flag;
    if (x <= 0){
        if (x > 10 ) { return 0; }
    }
    if (x<-240) {
        if (x < -2565) {
            return (x < -253 ? 0: afunc (x <22566 ? 1: afunc(x < -25103 ? 0: 6)));
        }
    }
    for (int i = 0; i< 10; i++)
    {
        while (x < y ) flag = 1;
        do {++x;} while (i<7);
        flag = 0;
    }
    return flag;
}
```

In this example, the function `foo` has too many decision points, resulting in a cyclomatic complexity of 11, which is greater than the default threshold of 10. Because the function has many decision points, testing the function is difficult and testing might fail to cover all execution paths. Polyspace flags the function as noncompliant.

#### Correction — Refactor the Function

One possible correction is to split the function into two functions.

```
int afunc (int x);
int foo2(int x,int y)//Compliant
{

    if (x <= 0){
        if (x > 10 ) { return 0; }
    }
    if (x<-240) {
        if (x < -2565) {
            return (x < -253 ? 0: afunc (x <22566 ? 1: afunc(x < -25103 ? 0: 6)));
        }
    }
}

int bar(int x,int y){//Complaint
    int flag;
    for (int i = 0; i< 10; i++)
    {
        while (x < y ) flag = 1;
        do {++x;} while (i<7);
        flag = 0;
    }
    return flag;
}
```

The functions `foo2` and `bar` have acceptable cyclomatic complexity and are easier to test compared to `foo`.

"Modify Default Behavior of Bug Finder Checkers"

# Language scope exceeds threshold

The language scope of a function is greater than the defined threshold

## Description

Language scope represents the cost of maintaining or updating a function. For instance, if an operand occurs many times in a function, then changing the operand name is costly. The language scope of such a function would be high. This defect is raised when the language scope of a function exceeds the defined threshold. For details about how Polyspace calculates language scope, see `Language Scope`.

**Note** The language scope calculated by Polyspace is a floating point number. In this checker, the floating point language scope is converted to an integer by rounding it to the second decimal place and then multiplying it by 100.

Polyspace uses the default threshold 400 unless you specify a threshold. To specify a selection file where you can set the threshold, use `Set checkers by file (-checkers-selection-file)`. Also see “Reduce Software Complexity by Using Polyspace Checkers”.

When you import comments from previous analyses by using `polyspace-comments-import`, Polyspace copies any review information on the code metric `Language Scope` in the previous result to this checker in the current result. If the current result contains the same code metric, the review information is copied to the code metric as well.

### Risk

Violation of this checker might indicate that:

- Change to an operand might require many change in the function.
- The function might be performing multiple tasks at once.
- The function might have high degree of interdependency with other functions.

These factors make the module difficult to maintain and debug.

### Fix

To fix this check, either refactor your code or change the checker threshold. When refactoring the code, design the functions in your code so that:

- Each function performs one specific task.
- The functions have minimal side effects on other functions.

A best practice is to check the complexity of a module early in development to avoid costly post-development refactoring.

## Examples

### Avoid Functions That Have Many Recurrence of Operands

```
 long long power(double x, int n){
     long long BN = 1;
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }

 double AppxIndex(double m, double f){//Noncompliant
     double U = (power(m,2) - 1)/(power(m,2)+2);
     double V = (power(m,4) + 27*power(m,2)+38)/(2*power(m,2)+3);
     return (1+2*f*power(U,2)*(1+power(m,2)*U*V + power(m,3)/
                power(m,3)*(U-V)))/( (1-2*f*power(U,2)*(1+power(m,2)*U*V +
                power(m,3)/power(m,3)*(U-V))));
 }
```

In this example, In this function, the operand `power` is repeated many times. Any change to `power` requires careful examination of the function to make sure unexpected behaviors are not introduced. The language scope of the function `AppxIndex` is700, which is above the default language scope of 400. Polyspace flags the function as noncompliant

#### Correction — Refactor the Code

One possible correction is to refactor the code so that operands are not repeated many times. In this example, the function `AppxIndex` is refactored so that unrelated tasks are performed by independent functions. These functions are compliant.

```
// This code calculates effective index of materials  as decribed in
// the formula in 10.1364...
// power(x,n) returns the nth power of x (x^n)
// n is an integer
// x is a double
// return type is long long
long long power(double x, int n){//Compliant
    long long BN = 1;
    for(int i = 0; i<n;++i){
        BN*=x;
    }
    return BN;
}
// CalculateU(m) calculates the first intermediate variable
// required to calculate  polarization
// m is the relative refractive index
// return type is double;
double CalculateU(double m){//Compliant
    return (power(m,2) - 1)/(power(m,2)+2);
}
// CalculateV(m) calculates the second intermediate variable
// required to calculate  polarization
// m is the relative refractive index
// return type is double;
double CalculateV(double m){//Compliant
    return (power(m,4) + 27*power(m,2)+38)/(2*power(m,2)+3);
}
```

```
// CalculateMid(m,f) calculates the large term present in both numerator and denominator
// of the effective index calculation
// m is the relative refractive index
// f is the fillfactor
// return type is double;
double CalculateMid(double m, double f){//Compliant
    double U = CalculateU(m);
    double V = CalculateU(m);
    return 2*f*power(U,2)*(1+power(m,2)*U*V + power(m,3)/power(m,3)*(U-V));
}
//AppxIndex(m,f) calculates the approximate effective index
// m is the relative refractive index
// f is the fillfactor
//return type is double
double AppxIndex(double m, double f){//Compliant
    return (1+CalculateMid(m,f))/( (1-CalculateMid(m,f)));
}
```

# Custom Coding Rules

# Group 1: Files

The custom rules 1.*x* in Polyspace enforce naming conventions for files and folders. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 1.1 | All source file names must follow the specified pattern. | Only the base name is checked. A source file is a file that is not included. |
| 1.2 | All source folder names must follow the specified pattern. | Only the folder name is checked. A source file is a file that is not included. |
| 1.3 | All include file names must follow the specified pattern. | Only the base name is checked. An include file is a file that is included. |
| 1.4 | All include folder names must follow the specified pattern. | Only the folder name is checked. An include file is a file that is included. |

# Group 2: Preprocessing

The custom rules 2.*x* in Polyspace enforce naming conventions for macros. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 2.1 | All macros must follow the specified pattern. | Macro names are checked before preprocessing. |
| 2.2 | All macro parameters must follow the specified pattern. | Macro parameters are checked before preprocessing. |

# Group 3: Type definitions

The custom rules 3.*x* in Polyspace enforce naming conventions for `typedef` aliases.

For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 3.1 | All integer types must follow the specified pattern. | Applies to integer and Boolean types specified by `typedef` statements. For example:<br>- `typedef signed long int64_t;`<br>- `typedef int64_t sLong_t;`<br>Does not apply to enumeration types. |
| 3.2 | All float types must follow the specified pattern. | Applies to double and float types specified by `typedef` statements. For example:<br>- `typedef double float64_t;`<br>- `typedef float64_t Lfloat;` |
| 3.3 | All pointer types must follow the specified pattern. | Applies to pointer types specified by `typedef` statements. For example:<br>- `typedef int* p_int;`<br>- `typedef p_int int_;` |
| 3.4 | All array types must follow the specified pattern. | Applies to array types specified by `typedef` statements. For example:<br>- `typedef int a_int_3[3];`<br>- `typedef int3_arr in3af[3];` |
| 3.5 | All function pointer types must follow the specified pattern. | Applies to function pointer types specified by `typedef` statements. For example:<br>- `typedef void (*func_fp)(int);`<br>- `typedef func_fp funcc;` |

# Group 4: Structures

The custom rules 4.*x* in Polyspace enforce naming conventions for structured data types. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 4.1 | All `struct` tags must follow the specified pattern. | |
| 4.2 | All `struct` types must follow the specified pattern. | `struct` types are aliases for previously defined structures (defined with the `typedef` or `using` keyword). |
| 4.3 | All `struct` fields must follow the specified pattern. | |
| 4.4 | All `struct` bit fields must follow the specified pattern. | |

# Group 5: Classes (C++)

The custom rules 5.*x* in Polyspace enforce naming conventions for classes and class members. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 5.1 | All class names must follow the specified pattern. | |
| 5.2 | All class types must follow the specified pattern. | Class types are aliases for previously defined classes (defined with the `typedef` or `using` keyword). |
| 5.3 | All data members must follow the specified pattern. | |
| 5.4 | All function members must follow the specified pattern. | |
| 5.5 | All static data members must follow the specified pattern. | |
| 5.6 | All static function members must follow the specified pattern. | |
| 5.7 | All bitfield members must follow the specified pattern. | |

# Group 6: Enumerations

The custom rules 6.*x* in Polyspace enforce naming conventions for enumerations. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 6.1 | All enumeration tags must follow the specified pattern. | |
| 6.2 | All enumeration types must follow the specified pattern. | Enumeration types are aliases for previously defined enumerations (defined with the `typedef` or `using` keyword). |
| 6.3 | All enumeration constants must follow the specified pattern. | |

# Group 7: Functions

The custom rules 7.*x* in Polyspace enforce naming conventions for functions and function parameters. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 7.1 | All global functions must follow the specified pattern. | A global function is a function with external linkage. |
| 7.2 | All static functions must follow the specified pattern. | A static function is a function with internal linkage. This rule does not apply to class member functions. |
| 7.3 | All function parameters must follow the specified pattern. | In C++, applies to non-member functions. |

# Group 8: Constants

The custom rules 8.*x* in Polyspace enforce naming conventions for constants. For information on how to enable these rules, see `Check custom rules (-custom-rules)`. These rules do not apply to constants that are defined within a class or to constants that are function parameters.

| Number | Rule | Details |
|---|---|---|
| 8.1 | All global nonstatic constants must follow the specified pattern. | A global nonstatic constant is a constant with external linkage. |
| 8.2 | All global static constants must follow the specified pattern. | A global static constant is a constant with internal linkage. |
| 8.3 | All local nonstatic constants must follow the specified pattern. | A local nonstatic constant is a constant without linkage. |
| 8.4 | All local static constants must follow the specified pattern. | A local static constant is a constant declared static in a function. |
| 8.5 | All floating constants must follow the specified pattern. | |

# Group 9: Variables

The custom rules 9.*x* in Polyspace enforce naming conventions for variables. For information on how to enable these rules, see `Check custom rules (-custom-rules)`. These rules do not apply to variables that are defined within a class or to variables that are function parameters.

| Number | Rule | Details |
|---|---|---|
| 9.1 | All global nonstatic variables must follow the specified pattern. | A global nonstatic variable is a variable with external linkage. |
| 9.2 | All global static variables must follow the specified pattern. | A global static variable is a variable with internal linkage. |
| 9.3 | All local nonstatic variables must follow the specified pattern. | A local nonstatic variable is a variable without linkage. |
| 9.4 | All local static variables must follow the specified pattern. | A local static variable is a variable declared static in a function. |

# Group 10: Name spaces (C++)

The custom rules 10.*x* in Polyspace enforce naming conventions for namespaces. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule |
|---|---|
| 10.1 | All names spaces must follow the specified pattern. |

# Group 11: Class templates (C++)

The custom rules 11.*x* in Polyspace enforce naming conventions for class templates. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 11.1 | All class templates must follow the specified pattern. | |
| 11.2 | All class template parameters must follow the specified pattern. | |

# Group 12: Function templates (C++)

The custom rules 12.*x* in Polyspace enforce naming conventions for function templates. For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 12.1 | All function templates must follow the specified pattern. | Applies to nonmember function templates. |
| 12.2 | All function template parameters must follow the specified pattern. | Applies to member and nonmember function templates. |
| 12.3 | All function template members must follow the specified pattern. | |

# Group 20: Style

The custom rules 20.*x* in Polyspace enforce coding style conventions such as number of characters per line.

For information on how to enable these rules, see `Check custom rules (-custom-rules)`.

| Number | Rule | Details |
|---|---|---|
| 20.1 | Source line length must not exceed specified number of characters. | When configuring the checker, specify:<br>• A number for the character limit. Use the **Pattern** column on the configuration or the `pattern=` line in the custom rules text file. # Polyspace Results: Code Metrics

30

# Code Metrics

# Comment Density

Ratio of number of comments to number of statements

## Description

This metric specifies the ratio of comments to statements expressed as a percentage.

Based on Hersteller Initiative Software (HIS) code complexity standard:

- Polyspace ignores these comments:
  - Comments that are included before the first statement. For instance, in this code, the first comment is ignored:

    ```
    // This function implements a hashtble
    extern void hashdef();
    ```
  - Comments that start with the source code line. For instance, this comment does not count as a comment for the metric but counts as a statement instead:

    ```
     remove(i); // Remove employee record
    ```
  - Comments that appear after the first line of a multiline comment. That is, multiline comments count as one comment. For instance, this is considered a single comment:

    ```
    // This function implements
    // regular maintenance on an internal database
    ```
- Polyspace calculates this metric after preprocessing the code. If your code contains macros, they are expanded before calculating the comment density.
- Polyspace does not count these statements:
  - Structure field and class member declarations
  - Template declarations
  - Class member function definition within the class
- A statement typically ends with a semicolon, but with some exceptions. Exceptions include semicolons in `for` loops or structure field declarations. For instance, the initialization, condition, and increment within parentheses in a `for` loop is counted as one statement. This statement counts as a single statement:

  ```
  for(i=0; i <100; i++)
  ```

  If you also declare the loop counter at initialization, that statement counts as two statements.

Polyspace does not calculate this metric for the included header files.

The recommended lower limit for this metric is 20. For better readability of your code, place at least one comment for every five statements. The value of this metric is clamped to 100. Such a value indicates that your code might contain more comment than statements.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Comment Density Calculation

```
    struct record {
    char name[40];
    long double salary;
    int isEmployed;
};

struct record dataBase[100];

struct record fetch(void);
void remove(int);

void maintenanceRoutines() {
// This function implements
// regular maintenance on an internal database
    int i;
    struct record tempRecord;

    for(i=0; i <100; i++) {
        tempRecord = fetch(); // This function fetches a record
        // from the database
        if(tempRecord.isEmployed == 0)
            remove(i);         // Remove employee record
        //from the database
    }
}
```

In this example, the comment density is 38. The calculation is done as shown in the table:

| Code | Running Total of Comments | Running Total of Statements |
|---|---|---|
| `struct record {`<br>`    char name[40];`<br>`    long double salary;`<br>`    int isEmployed;`<br>`};` | 0 | 1 |
| `struct record dataBase[100];`<br>`struct record fetch(void);`<br>`void remove(int);` | 0 | 4 |
| `void maintenanceRoutines() {` | 0 | 4 |
| `// This function implements`<br>`// regular maintenance on an internal database` | 1 | 4 |
| `int i;`<br>`struct record tempRecord;` | 1 | 6 |
| `for(i=0; i <100; i++) {` | 1 | 6 |

| Code | Running Total of Comments | Running Total of Statements |
|---|---|---|
| `tempRecord = fetch(); // This`<br>`function fetches a record`<br>`// from the database` | 2 | 7 |
| `if(tempRecord.isEmployed == 0)`<br>`remove(i);`<br>`// Remove employee record`<br>`//from the database`<br>`}`<br>`}` | 3 | 8 |

There are three comments and eight statements. The comment density is 3/8*100 = 38.

# Cyclomatic Complexity

Number of linearly independent paths in function body

## Description

This metric calculates the number of decision points in a function and adds one to the total. A decision point is a statement that causes your program to branch into two paths.

The recommended upper limit for this metric is 10. If the cyclomatic complexity is high, the code is both difficult to read and can cause more orange checks. Therefore, try to limit the value of this metric.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

### Computation Details

The metric calculation uses the following rules to identify decision points:

- An `if` statement is one decision point.
- The statements `for` and `while` count as one decision point, even when no condition is evaluated, for example, in infinite loops.
- Boolean combinations `(&&, ||)` do not count as decision points.
- `case` statements do not count as decision points unless they are followed by a `break` statement. For instance, this code has a cyclomatic complexity of two:

  ```
  switch(num) {
          case 0:
          case 1:
          case 2:
              break;
          case 3:
          case 4:
      }
  ```

- The calculation is done after preprocessing:
  - Macros are expanded.
  - Conditional compilation is applied. The blocks hidden by preprocessing directives are ignored.

## Examples

### Function with Nested `if` Statements

```
int foo(int x,int y)
{
    int flag;
    if (x <= 0)
        /* Decision point 1*/
        flag = 1;
```

```
    else
    {
        if (x < y )
            /* Decision point 2*/
            flag = 1;
        else if (x==y)
            /* Decision point 3*/
            flag = 0;
        else
            flag = -1;
    }
    return flag;
}
```

In this example, the cyclomatic complexity of `foo` is 4.

#### Function with ? Operator

```
int foo (int x, int y) {
    if((x <0) ||(y < 0))
        /* Decision point 1*/
        return 0;
    else
        return (x > y ? x: y);
        /* Decision point 2*/
}
```

In this example, the cyclomatic complexity of `foo` is 3. The `?` operator is the second decision point.

#### Function with `switch` Statement

```
#include <stdio.h>

int foo(int x,int y, int ch)
{
    int val = 0;
    switch(ch) {
    case 1:
        /* Decision point 1*/
        val = x + y;
        break;
    case 2:
        /* Decision point 2*/
        val = x - y;
        break;
    default:
        printf("Invalid choice.");
    }
    return val;
}
```

In this example, the cyclomatic complexity of `foo` is 3.

#### Function with Nesting of Different Control-Flow Statements

```
int foo(int x,int y, int bound)
```

```
{
    int count = 0;
    if (x <= y)
        /* Decision point 1*/
        count = 1;
    else
        while(x>y) {
            /* Decision point 2*/
            x--;
            if(count< bound) {
                /* Decision point 3*/
                count++;
            }
        }
    return count;
}
```

In this example, the cyclomatic complexity of `foo` is 4.

# Estimated Function Coupling

Measure of complexity between levels of call tree

## Description

This metric provides an approximate measure of complexity between different levels of the call tree. The metric is defined as:

*number of call occurrences – number of function definitions + 1*

If there are more function definitions than function calls, the estimated function coupling result is negative.

This metric:

- Counts function calls and function definitions in the current file only.

  It does not count function definitions in a header file included in the current file.
- Treats `static` and `inline` functions like any other function.

## Examples

### Same Function Called Multiple Times

```
void checkBounds(int *);
int getUnboundedValue();

int getBoundedValue(void) {
    int num = getUnboundedValue();
    checkBounds(&num);
    return num;
}

void main() {
    int input1=getBoundedValue(), input2= getBoundedValue(), prod;
    prod = input1 * input2;
    checkBounds(&prod);
}
```

In this example, there are:

- 5 call occurrences. Both `getBoundedValue` and `checkBounds` are called twice and `getUnboundedValue` is called once.
- 2 function definitions. `main` and `getBoundedValue` are defined.

Therefore, the Estimated function coupling is `5 - 2 + 1 = 4`.

### Negative Estimated Function Coupling

```
int foobar(int a, int b){
    return a+b;
}

int bar(int b){
    return b+2;
}

int foo(int a){
    return a<<2;
}

int main(int x){
    foobar(x,x+2);
    return 0;
}
```

This example shows how you can get a negative estimated function coupling result. In this example, you see:

- `1` function call in `main`.
- `4` defined functions: `foobar`, `bar`, `foo`, and `main`.

Therefore, the estimated function coupling is `1 - 4 + 1 = -2`.

# Higher Estimate of Size of Local Variables

Total size of all local variables in function

## Description

**Note** Use Code Prover instead of Bug Finder for estimating the size of local variables. Support for estimating local variable size in Bug Finder will be removed in a future release. See “Version History” on page 30-13.

This metric provides a conservative estimate of the total size of local variables in a function. The metric is the sum of the following sizes in bytes:

- Size of function return value
- Sizes of function parameters
- Sizes of local variables
- Additional padding introduced for memory alignment

Your actual stack usage due to local variables can be different from the metric value.

- Some of the variables are stored in registers instead of on the stack.
- Your compiler performs variable liveness analysis to enable certain memory optimizations. For instance, compilers store the address to which the execution returns following the function call. When computing this metric, Polyspace does not consider these optimizations.
- Your compiler uses additional memory during a function call. When computing this metric, Polyspace does not consider this hidden memory usage.
- Compilers optimize temporary variables in different ways. This metric excludes temporary variables. Only the variables that are explicitly declared by the user are considered.

However, the metric provides a reasonable estimate of the stack usage due to local variables.

To determine the sizes of basic types, the software uses your specifications for `Target processor type (-target)`. The metric also takes into account `#pragma pack` directives in your code.

## Examples

### All Variables of Same Type

```
int flag();

int func(int param) {
  int var_1;
  int var_2;
  if (flag()) {
      int var_3;
      int var_4;
    } else {
      int var_5;
    }
}
```

In this example, assuming 4 bytes for `int`, the higher estimate of local variable size for `func`is 28. The breakup of the size is shown in this table.

| Variable | Size (in Bytes) | Running Total |
|---|---|---|
| Return value | 4 | 4 |
| Parameter `param` | 4 | 8 |
| Local variables `var_1` and `var_2` | `4+4=8` | 16 |
| Local variables defined in the `if` condition | `(4+4)+4=12`<br>The size of variables in the first branch is eight bytes. The size in the second branch is four bytes. The sum of the two branches is 12 bytes. | 28 |

No padding is introduced for memory alignment because all the variables involved have the same type.

### Variables of Different Types

```
char func(char param) {
  int var_1;
  char var_2;
  double var_3;
}
```

In this example, assuming one byte for `char`, four bytes for `int` and eight bytes for `double` and four bytes for alignment, the higher estimate of local variable size for `func` is 20. The alignment is usually the word size on your platform. In your Polyspace project, you specify the alignment through your target processor. For more information, see the Alignment column in `Target processor type (-target)`.

The breakup of the size is shown in this table.

| Variable | Size (in Bytes) | Running Total |
|---|---|---|
| Return value | 1 | 1 |
| Additional padding introduced before `param` is stored | 0<br>No memory alignment is required because the next variable `param` has the same size. | 1 |
| Parameter `param` | 1 | 2 |

| Variable | Size (in Bytes) | Running Total |
|---|---|---|
| Additional padding introduced before `var_1` is stored | 2<br>Memory must be aligned using padding because the next variable `var_1` requires four bytes. The storage must start from a memory address at a multiple of four. | 4 |
| `var_1` | 4 | 8 |
| Additional padding introduced before `var_2` is stored | 0<br>No memory alignment is required because the next variable `var_2` has smaller size. | 8 |
| `var_2` | 1 | 9 |
| Additional padding introduced before `var_3` is stored | 3<br>Memory must be aligned using padding because the next variable `var_3` has eight bytes. The storage must start from a memory address at a multiple of the alignment, four bytes. | 12 |
| `var_3` | 8 | 20 |

The rules for the amount of padding are:

- If the next variable stored has the same or smaller size, no padding is required.
- If the next variable has a greater size:
  - If the variable size is the same as or less than the alignment on the platform, the amount of padding must be sufficient so that the storage address is a multiple of its size.
  - If the variable size is greater than the alignment on the platform, the amount of padding must be sufficient so that the storage address is a multiple of the alignment.

### C++ Methods and Objects

```
class MySimpleClass {
  public:

    MySimpleClass() {};

    MySimpleClass(int) {};

    ~MySimpleClass() {};
};

int main() {
  MySimpleClass c;
  return 0;
}
```

In this example, the estimated local variable sizes are:

- Constructor `MySimpleClass::MySimpleClass()`: Four bytes.

  The size comes from the `this` pointer, which is an implicit argument to the constructor. You specify the pointer size using the option `Target processor type (-target)`.
- Constructor `MySimpleClass::MySimpleClass(int)`: Eight bytes.

  The size comes from the `this` pointer and the `int` argument.
- Destructor `MySimpleClass::~MySimpleClass()`: Four bytes.

  The size comes from the `this` pointer.
- `main()`: Five bytes.

  The size comes from the `int` return value and the size of object `c`. The minimum size of an object is the alignment that you specify using the option `Target processor type (-target)`.

### C++ Functions with Object Arguments

```
class MyClass {
  public:
    MyClass() {};
    MyClass(int) {};
    ~MyClass() {};
  private:
    int i[10];
};
void func1(const MyClass& c) {
}

void func2() {
  func1(4);
}
```

In this example, the estimated local variable size for `func2()` is 0. When `func2()` calls `func1()`, a temporary object of the class `MyClass` is created. The temporary variable is excluded from the calculation. Because there are no explicitly declared variables in the body of `func2`, the reported metric value is 0.

## Metric Information

**Group:** Function
**Acronym:** `LOCAL_VARS_MAX`
**HIS Metric**: No

# Version History

**Introduced in R2016b**

**R2022a: To be removed**
*Warns starting in R2022a*

Checking for local variable size estimates by using Bug Finder is not recommended. This workflow will be removed in a future release. To check for stack usage and local variable size estimates, use Code Prover. See `Calculate stack usage (-stack-usage)`. To see how Code Prover computes this code metric, see `Higher Estimate of Size of Local Variables`.

`Lower Estimate of Size of Local Variables` | `Calculate code metrics (-code-metrics)` | `Calculate stack usage (-stack-usage)`

# Language Scope

Language scope

## Description

This metric measures the cost of maintaining or changing a function. It is calculated as:

`(N1 + N2)/(n1 + n2)`

Where:

- `N1` is the number of occurrences of operators.

  Other than identifiers (variable or function names) and literal constants, everything else counts as operators.
- `N2` is the number of occurrences of operands.
- `n1` is the number of distinct operators.
- `n2` is the number of distinct operands.

  The metric considers a literal constant with a suffix as different from the constant without the suffix. For instance, 0 and `0U` are considered different.

When reporting this metric, Polyspace rounds the calculated language scope to the first decimal place. Because the intent of this metric is to indicate the maintainability of a function, language scope of functions defined within local classes are not computed.

**Tip** To find `N1 + N2`, count the total number of tokens. To find `n1 + n2`, count the number of unique tokens.

The recommended upper limit for this metric is 4. For lower maintenance cost for a function, try to enforce an upper limit on this metric. For instance, if the same operand occurs many times, to change the operand name, you have to make many substitutions.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Language Scope Calculation

```
int g(int);
int f(int i)
{
    if (i == 1)
        return i;
    else
        return i * g(i-1);
}
```

In this example:

- N1 = 19.
- N2 = 9.
- n1 = 12.

  The distinct operators are int, (, ), {, if, ==, return, else, *, -, ;, }.
- n2 = 4.

  The distinct operands are f, i, 1 and g.

The language scope of f is (19 + 9) / (12 + 4) = 1.8.

#### C++ Namespaces in Language Scope Calculation

```
namespace std {
  int func2() {
    return 123;
  }
};

namespace my_namespace {
  using namespace std;

  int func1(int a, int b) {
    return func2();
  }
};
```

In this example, the namespace std is implicitly associated with func2. The language scope computation treats func2() as std::func2(). Likewise, the computation treats func1() as my_namespace::func1().

For instance, the language scope value for func1 is 1.3. To break down this calculation:

- N1 + N2 = 20.
- n1 + n2 = 15.

  The distinct operators are int, ::, (, comma, ), {, return, ;, and }.

  The distinct operands are my_namespace, func1, a, b, std, and func2.

# Lower Estimate of Size of Local Variables

Total size of local variables in function taking nested scopes into account

## Description

**Note** Use Code Prover instead of Bug Finder for estimating the size of local variables. Support for estimating local variable size in Bug Finder will be removed in a future release. See "Version History" on page 30-22.

This metric provides an optimistic estimate of the total size of local variables in a function. The metric is the sum of the following sizes in bytes:

- Size of function return value
- Sizes of function parameters
- Sizes of local variables

  Suppose that the function has variable definitions in nested scopes as follows:

  ```
  type func (type param_1, ...) {

    {
      /* Scope 1 */
      type var_1, ...;
    }
    {
      /* Scope 2 */
      type var_2, ...;
    }
  }
  ```

  The software computes the total variable size in each scope and uses whichever total is greatest. For instance, if a conditional statement has variable definitions, the software computes the total variable size in each branch, and then uses whichever total is greatest. If a nested scope itself has further nested scopes, the same process is repeated for the inner scopes.

  A variable defined in a nested scope is not visible outside the scope. Therefore, some compilers reuse stack space for variables defined in separate scopes. This metric provides a more accurate estimate of stack usage for such compilers. Otherwise, use the metric `Higher Estimate of Size of Local Variables`. This metric adds the size of all local variables, whether or not they are defined in nested scopes.
- Additional padding introduced for memory alignment

Your actual stack usage due to local variables can be different from the metric value.

- Some of the variables are stored in registers instead of on the stack.
- Your compiler performs variable liveness analysis to enable certain memory optimizations. When computing this metric, Polyspace does not consider these optimizations.

- Your compiler uses additional memory during a function call. For instance, compilers store the address to which the execution returns following the function call. When computing this metric, Polyspace does not consider this hidden memory usage.
- Compilers optimize temporary variables in different ways. This metric excludes temporary variables. Only the variables that are explicitly declared by the user are considered.

However, the metric provides a reasonable estimate of the stack usage due to local variables.

When a function returns a `class`, `struct`, or `union` that has a copy constructor, the compiler might perform a return value optimization. Instead of returning a class object, the function might use a pointer to pass the value. This optimization might change the value of this metric.

To determine the sizes of basic types, the software uses your specifications for `Target processor type (-target)`. The metric also takes into account `#pragma pack` directives in your code.

## Examples

### All Variables of Same Type

```
int flag();

int func(int param) {
  int var_1;
  int var_2;
  if (flag()) {
      int var_3;
      int var_4;
    } else {
      int var_5;
    }
}
```

In this example, assuming four bytes for `int`, the lower estimate of local variable size is 24. The breakup of the metric is shown in this table.

| Variable | Size (in Bytes) | Running Total |
|---|---|---|
| Return value | 4 | 4 |
| Parameter `param` | 4 | 8 |
| Local variables `var_1` and `var_2` | `4+4=8` | 16 |
| Local variables defined in the `if` condition | `max(4+4,4)= 8`<br>The size of variables in the first branch is eight bytes. The size in the second branch is four bytes. The maximum of the two branches is eight bytes. | 24 |

No padding is introduced for memory alignment because all the variables involved have the same type.

### Variables of Different Types

```
char func(char param) {
  int var_1;
  char var_2;
  double var_3;
}
```

In this example, assuming one byte for `char`, four bytes for `int`, eight bytes for `double` and four bytes for alignment, the lower estimate of local variable size is 20. The alignment is usually the word size on your platform. In your Polyspace project, you specify the alignment through your target processor. For more information, see the Alignment column in `Target processor type (-target)`.

The breakup of the size is shown in this table.

| Variable | Size (in Bytes) | Running Total |
|---|---|---|
| Return value | 1 | 1 |
| Additional padding introduced before `param` is stored | 0<br>No memory alignment is required because the next variable `param` has the same size. | 1 |
| Parameter `param` | 1 | 2 |
| Additional padding introduced before `var_1` is stored | 2<br>Memory must be aligned using padding because the next variable `var_1` requires four bytes. The storage must start from a memory address at a multiple of four. | 4 |
| `var_1` | 4 | 8 |
| Additional padding introduced before `var_2` is stored | 0<br>No memory alignment is required because the next variable `var_2` has smaller size. | 8 |
| `var_2` | 1 | 9 |
| Additional padding introduced before `var_3` is stored | 3<br>Memory must be aligned using padding because the next variable `var_3` requires eight bytes. The storage must start from a memory address at a multiple of the alignment, four bytes. | 12 |

| Variable | Size (in Bytes) | Running Total |
|---|---|---|
| var_3 | 8 | 20 |

The rules for the amount of padding are:

- If the next variable stored has the same or smaller size, no padding is required.
- If the next variable has a greater size:
  - If the variable size is the same as or less than the alignment on the platform, the amount of padding must be sufficient so that the storage address is a multiple of its size.
  - If the variable size is greater than the alignment on the platform, the amount of padding must be sufficient so that the storage address is a multiple of the alignment.

### C++ Methods and Objects

```
class MySimpleClass {
  public:

    MySimpleClass() {};

    MySimpleClass(int) {};

    ~MySimpleClass() {};
};

int main() {
  MySimpleClass c;
  return 0;
}
```

In this example, the estimated local variable sizes are:

- Constructor `MySimpleClass::MySimpleClass()`: Four bytes.

  The size comes from the `this` pointer, which is an implicit argument to the constructor. You specify the pointer size using the option `Target processor type (-target)`.
- Constructor `MySimpleClass::MySimpleClass(int)`: Eight bytes.

  The size comes from the `this` pointer and the `int` argument.
- Destructor `MySimpleClass::~MySimpleClass()`: Four bytes.

  The size comes from the `this` pointer.
- `main()`: Five bytes.

  The size comes from the `int` return value and the size of object `c`. The minimum size of an object is the alignment that you specify using the option `Target processor type (-target)`.

### C++ Functions with Object Arguments

```
class MyClass {
  public:
    MyClass() {};
    MyClass(int) {};
    ~MyClass() {};
  private:
    int i[10];
};
void func1(const MyClass& c) {
}

void func2() {
  func1(4);
}
```

In this example, the estimated local variable size for `func2()` is 0. When `func2()` calls `func1()`, a temporary object of the class `MyClass` is created. The temporary variable is excluded from the calculation. Because there are no explicitly declared variables in the body of `func2`, the reported metric value is 0.

#### Functions that Return Classes

```
class WrapperA {
private:
    int       start;
    int       end;
public:

    virtual int get_start() {
        return start;
    }
};

WrapperA aG;

WrapperA get_WrapperA_1() {
    //...
    return aG;
}

WrapperA  get_WrapperA_2() {
    //...
    WrapperA bL;
    return bL;
}

int main(){
    return 1;
}
```

In this example, the functions `get_WrapperA_1` and `get_WrapperA_2` return objects of the class `WrapperA`. You might expect the estimate for `get_WrapperA_1` to be equal to the size of `aG`. After return type optimization, `get_wrapperA_1()` contains a `WrapperA*` type pointer which points to a copy of `aG`. The lower estimate of the local variable size for `get_wrapperA_1()` is four bytes.

Similarly, after the return type optimization, `get_WrapperA_2` contains a `WrapperA` object and a `WrapperA*` pointer. The lower estimate of the local variable size for `get_wrapperA_2()` is 16 bytes.

### Metric Information

**Group:** Function
**Acronym:** `LOCAL_VARS_MIN`
**HIS Metric**: No

## Version History

**Introduced in R2016b**

#### R2022a: To be removed

*Warns starting in R2022a*

Checking for local variable size estimates by using Bug Finder is not recommended. This workflow will be removed in a future release. To check for stack usage and local variable size estimates, use Code Prover. See `Calculate stack usage (-stack-usage)`. To see how Code Prover computes this code metric, see `Lower Estimate of Size of Local Variables`.

# Maximum Stack Usage

Total size of local variables in function plus maximum stack usage from callees

## Description

*This metric is reported in a Code Prover analysis only.*

This metric provides a conservative estimate of the stack usage by a function. The metric is the sum of these sizes in bytes:

- `Higher Estimate of Size of Local Variables` (Polyspace Code Prover)
- Maximum value from the stack usages of the function callees. The computation uses the maximum stack usage of each callee.

  For instance, in this example, the maximum stack usage of `func` is the same as the maximum stack usage of `func1` or `func2`, *whichever is greater*.

  ```
  void func(void) {
      func1();
      func2();
  }
  ```

  If the function calls are in different branches of a conditional statement, this metric considers the branch with the greatest stack usage.

  The analysis does the stack size estimation later on when it has resolved which function calls actually occur. For instance, if a function call occurs in unreachable code, the stack size does not take the call into account. The analysis can also take into account calls through function pointers.

Your actual stack usage can be different from the metric value.

- Some of the variables are stored in registers instead of on the stack.
- Your compiler performs variable liveness analysis to enable certain memory optimizations. When estimating this metric, Polyspace does not consider these optimizations.
- Your compiler uses additional memory during a function call. For instance, compilers store the address to which the execution returns following the function call. When estimating this metric, Polyspace does not consider this hidden memory usage.
- Compilers optimize temporary variables in different ways. This metric excludes temporary variables. Only the variables that are explicitly declared by the user are considered.

However, the metric provides a reasonable estimate of the stack usage.

To determine the sizes of basic types, the software uses your specifications for `Target processor type (-target)`. The metric takes into account `#pragma pack` directives in your code.

## Examples

### Function with One Callee

```
double func(int);
double func2(int);
```

```
double func(int status) {
    double res = func2(status);
    return res;
}

double func2(int status) {
    double res;
    if(status == 0) {
      int temp;
      res = 0.0;
    }
    else {
      double temp;
      res = 1.0;
    }
    return res;
}
```

In this example, assuming four bytes for `int` and eight bytes for `double`, the maximum stack usages are:

- `func2`: 32 bytes

  This value includes the sizes of its parameter (4 bytes), local variable `res` (8 bytes), local variable `temp` counted twice (4+8=12 bytes), and return value (8 bytes).

  The metric does not take into account that the first `temp` is no longer live when the second `temp` is defined.
- `func`: 52 bytes

  This value includes the sizes of its parameter, local variable `res`, and return value, a total of 20 bytes. This value includes the 32 bytes of maximum stack usage by its callee, `func2`.

#### Function with Multiple Callees

```
void func1(int);
void func2(void);

void func(int status) {
    func1(status);
    func2();
}

void func1(int status) {
    if(status == 0) {
      int val;
    }
    else {
      double val2;
    }
}
```

```
void func2(void) {
    double val;
}
```

In this example, assuming four bytes for `int` and eight bytes for `double`, the maximum stack usages are:

- `func1`: 16 bytes

  This value includes the sizes of its parameter (4 bytes) and local variables `val` and `val2` (4+8=12 bytes).
- `func2`: 8 bytes
- `func`: 20 bytes

  This value includes the sizes of its parameter (4 bytes) and the maximum of stack usages of `func1` and `func2` (16 bytes).

### Function with Multiple Callees in Different Branches

```
void func1(void);
void func2(void);

void func(int status) {
    if(status==0)
        func1();
    else
        func2();
}

void func1(void) {
    double val;
}

void func2(void) {
    int val;
}
```

In this example, assuming four bytes for `int` and eight bytes for `double`, the maximum stack usages are:

- `func1`: 8 bytes
- `func2`: 4 bytes
- `func`: 12 bytes

  This value includes the sizes of its parameter (4 bytes) and the maximum stack usage from the two branches (8 bytes).

### Functions with Variable Number of Parameters (Variadic Functions)

```
#include <stdarg.h>
```

```
void fun_vararg(int x, ...) {
  va_list ap;
  va_start(ap, x);
  int i;
  for (i=0; i<x; i++) {
    int j = va_arg(ap, int);
  }
  va_end(ap);
}

void call_fun_vararg1(void) {
  long long int l = 0;
  fun_vararg(3, 4, 5, 6, l);
}

void call_fun_vararg2(void) {
  fun_vararg(1,0);
}
```

In this function, `fun_vararg` is a function with variable number of parameters. The maximum stack usage of `fun_vararg` takes into account the call to `fun_vararg` with the maximum number of arguments. The call with the maximum number of arguments is the call in `call_fun_vararg1` with five arguments (one for the fixed parameter and four for the variable parameters). The maximum stack usages are:

- `fun_vararg`: 36 bytes.

  This value takes into account:

  - The size of the fixed parameter `x` (4 bytes).
  - The sizes of the variable parameters from the call with the maximum number of parameters. In that call, there are four variable arguments: three `int` and one `long long int` variable (3 times 4 + 1 times 8 = 20 bytes).
  - The sizes of the local variables `i`, `j` and `ap` (12 bytes). The size of the `va_list` variable uses the pointer size defined in the target (in this case, 4 bytes).
- `call_fun_vararg1`: 44 bytes.

  This value takes into account:

  - The stack size usage of `fun_vararg` with five arguments (36 bytes).
  - The size of local variable `l` (8 bytes).
- `call_fun_vararg2`: 20 bytes.

  Since `call_fun_vararg2` has no local variables, this value is the same as the stack size usage of `fun_vararg` with two arguments (20 bytes, of which 12 bytes are for the local variables and 8 bytes are for the two parameters of `fun_vararg`).

# Minimum Stack Usage

Total size of local variables in function taking nested scopes into account plus maximum stack usage from callees

## Description

*This metric is reported in a Code Prover analysis only.*

This metric provides an optimistic estimate of the stack usage by a function. Unlike the metric `Maximum Stack Usage` (Polyspace Code Prover), this metric takes nested scopes into account. For instance, if variables are defined in two mutually exclusive branches of a conditional statement, the metric considers that the stack space allocated to the variables in one branch can be reused in the other branch.

The metric is the sum of these sizes in bytes:

- `Lower Estimate of Size of Local Variables` (Polyspace Code Prover).
- Maximum value from the stack usages of the function callees. The computation uses the minimum stack usage of each callee.

  For instance, in this example, the minimum stack usage of `func` is the same as the minimum stack usage of `func1` or `func2`, *whichever is greater*.

  ```
  void func(void) {
      func1();
      func2();
  }
  ```

  If the function calls are in different branches of a conditional statement, this metric considers the branch with the least stack usage.

  The analysis does the stack size estimation later on when it has resolved which function calls actually occur. For instance, if a function call occurs in unreachable code, the stack size does not take the call into account. The analysis can also take into account calls through function pointers.

Your actual stack usage can be different from the metric value.

- Some of the variables are stored in registers instead of on the stack.
- Your compiler performs variable liveness analysis to enable certain memory optimizations. When estimating this metric, Polyspace does not consider these optimizations.
- Your compiler uses additional memory during a function call. For instance, compilers store the address to which the execution returns following the function call. When estimating this metric, Polyspace does not consider this hidden memory usage.
- Compilers optimize temporary variables in different ways. This metric excludes temporary variables. Only the variables that are explicitly declared by the user are considered.

However, the metric provides a reasonable estimate of the stack usage.

To determine the sizes of basic types, the software uses your specifications for `Target processor type (-target)`. The metric takes into account `#pragma pack` directives in your code.

## Examples

### Function with One Callee

```
double func2(int);

double func(int status) {
    double res = func2(status);
    return res;
}

double func2(int status) {
    double res;
    if(status == 0) {
      int temp;
      res = 0.0;
    }
   else {
      double temp;
      res = 1.0;
    }
   return res;
}
```

In this example, assuming four bytes for `int` and eight bytes for `double`, the minimum stack usages are:

- `func2`: 28 bytes

  This value includes the sizes of its parameter (4 bytes), local variable `res` (8 bytes), one of the two local variables `temp` (8 bytes), and return value (8 bytes).

  The metric takes into account that the first `temp` is no longer live when the second `temp` is defined. It uses the variable `temp` with data type `double` because its size is greater.
- `func`: 48 bytes

  This value includes the sizes of its parameter, local variable `res`, and return value, a total of 20 bytes. This value includes the 28 bytes of minimum stack usage by its callee, `func2`.

### Function with Multiple Callees

```
void func1(int);
void func2(void);

void func(int status) {
    func1(status);
    func2();
}

void func1(int status) {
    if(status == 0) {
      int val;
    }
    else {
      double val2;
    }
}

void func2(void) {
    double val;
}
```

In this example, assuming four bytes for `int` and eight bytes for `double`, the minimum stack usages are:

- `func1`: 12 bytes

  This value includes the sizes of its parameter (4 bytes) and the larger of the two local variables, in this case, `val2` (8 bytes).
- `func2`: 8 bytes
- `func`: 16 bytes

  This value includes the sizes of its parameter (4 bytes) and the maximum of stack usages of `func1` and `func2` (12 bytes).

### Function with Multiple Callees in Different Branches

```
void func1(void);
void func2(void);

void func(int status) {
    if(status==0)
        func1();
    else
        func2();
}

void func1(void) {
    double val;
}

void func2(void) {
    int val;
}
```

In this example, assuming four bytes for `int` and eight bytes for `double`, the minimum stack usages are:

- `func1`: 8 bytes
- `func2`: 4 bytes
- `func`: 8 bytes

This value includes the sizes of its parameter (4 bytes) and the minimum stack usage from the two branches (4 bytes).

### Functions with Variable Number of Parameters (Variadic Functions)

```
#include <stdarg.h>

void fun_vararg(int x, ...) {
  va_list ap;
  va_start(ap, x);
  int i;
  for (i=0; i<x; i++) {
    int j = va_arg(ap, int);
  }
  va_end(ap);
}

void call_fun_vararg1(void) {
  long long int l = 0;
  fun_vararg(3, 4, 5, 6, l);
}

void call_fun_vararg2(void) {
  fun_vararg(1,0);
}
```

In this function, `fun_vararg` is a function with variable number of parameters. The minimum stack usage of `fun_vararg` takes into account the call to `fun_vararg` with the minimum number of arguments. The call with the minimum number of arguments is the call in `call_fun_vararg2` with two arguments (one for the fixed parameter and one for the variable parameter). The minimum stack usages are:

- `fun_vararg`: 20 bytes.

  This value takes into account:

  - The size of the fixed parameter `x` (4 bytes).
  - The sizes of the variable parameters from the call with the minimum number of parameters. In that call, there is only one variable argument of type `int` (4 bytes).
  - The sizes of the local variables `i`, `j` and `ap` (12 bytes). The size of the `va_list` variable uses the pointer size defined in the target (in this case, 4 bytes).
- `call_fun_vararg1`: 44 bytes.

  This value takes into account:

  - The stack size usage of `fun_vararg` with five arguments (36 bytes, of which 12 bytes are for the local variable sizes and 20 bytes are for the fixed and variable parameters of `fun_vararg`).
  - The size of local variable `l` (8 bytes).
- `call_fun_vararg2`: 20 bytes.

Since `call_fun_vararg2` has no local variables, this value is the same as the stack size usage of `fun_vararg` with two arguments (20 bytes).

# Number of Call Levels

Maximum depth of nesting of control flow structures

## Description

This metric specifies the maximum nesting depth of control flow statements such as `if`, `switch`, `for`, or `while` in a function. A function without control-flow statements has a call level 1.

The recommended upper limit for this metric is 4. For better readability of your code, try to enforce an upper limit for this metric.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Function with Nested `if` Statements

```
int foo(int x,int y)
{
    int flag = 0;
    if (x <= 0)
        /* Call level 1*/
        flag = 1;
    else
    {
        if (x <= y )
            /* Call level 2*/
            flag = 1;
        else
            flag = -1;
    }
    return flag;
}
```

In this example, the number of call levels of `foo` is 2.

### Function with Nesting of Different Control-Flow Statements

```
int foo(int x,int y, int bound)
{
    int count = 0;
    if (x <= y)
        /* Call level 1*/
        count = 1;
    else
        while(x>y) {
            /* Call level 2*/
            x--;
            if(count< bound) {
                /* Call level 3*/
                count++;
            }
        }
    return count;
}
```

In this example, the number of call levels of `foo` is 3.

`Calculate code metrics (-code-metrics)`

### Topics

“Compute Code Complexity Metrics Using Polyspace”

# Number of Call Occurrences

Number of calls in function body

## Description

This metric specifies the number of function calls in the body of a function.

This metric includes:

- Calls in unreachable code.
- Calls to standard library functions.
- Calls to constructors and destructors.

The metric excludes:

- Calls through a function pointer.
- Calls to virtual functions.
- Calls to `assert`. Polyspace considers `assert` as a macro and not a function.
- Inlined functions. Compilers might inline certain function calls, such as the default constructors and destructors.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”. To enforce violation of code metrics limits as Bug Finder defects, use the Software Complexity checkers. See “Reduce Software Complexity by Using Polyspace Checkers”

## Examples

### Same Function Called Multiple Times

```
int func1(void);
int func2(void);

int foo() {
    return (func1() + func1()*func1() + 2*func2());
}
```

In this example, the number of call occurrences in `foo` is 4.

### Function Called in a Loop

```
#include<stdio.h>
int getVal(void);

void fillArraySize10(int *arr) {
    for(int i=0; i<10; i++)
        arr[i]=getVal();
}

int getVal(void) {
    int val;
    printf("Enter a value:");
    scanf("%d", &val);
    return val;
}
```

In this example, the number of call occurrences in `fillArraySize10` is 1.

#### Recursive Function

```
#include <stdio.h>
int fibonacci(int);

void main() {
 int count;
 printf("How many numbers ?");
 scanf("%d",&count);
 fibonacci(count);
}

int fibonacci(int num)
{
   if ( num == 0 )
      return 0;
   else if ( num == 1 )
      return 1;
   else
      return ( fibonacci(num-1) + fibonacci(num-2) );
}
```

In this example, the number of call occurrences in `fibonacci` is 2.

#### Constructor Function

```
#include<iostream>
class A{
    public:
    A(){
        std::cout<<"Create A\n";
    }
    ~A() = default;
    A(const A&)=default;
    A(A&&) = default;
    virtual void bar(){ std::cout<<"A";}
};
class B: public A{
    public:
    B() = default;
     void bar() override {std::cout<<"B";}
};

void func(A& a){
    a.bar();
}

int main(){
    A obj;
    A obj2 = obj;
    B objB;
    func(obj);
    return 0;
}
```

In this example, the number of call occurances in `main` is three:

1. The constructor of class `A` in `A obj;`. This user defined constructor counts as a function call.
2. The constructor of class `B` in `B objB;`. Because the constructor of the base class `A` is user-defined, the constructor of `B` counts as a function call even though `B::B()` is declared as `=default`.
3. The call to function `func`.

The class `A` uses the default or implicit copy constructor. The call to the copy constructor in `A obj2 = obj;` does not count as a function call.

## Metric Information

`Number of Called Functions` | `Calculate code metrics (-code-metrics)`

# Number of Called Functions

Number of distinct functions called within the body of a function

## Description

This metric specifies the number of distinct functions that are called by a function within its body.

This metric includes:

- Calls in unreachable code.
- Calls to standard library functions.
- Calls to user defined constructors and destructors.

The metric excludes:

- Calls through a function pointer.
- Calls to virtual functions.
- Calls to `assert`. Polyspace considers `assert` as a macro and not a function.
- Inlined functions. Compilers might inline certain function calls, such as the default or implicit constructors and destructors.

The recommended upper limit for this metric is 7. For more self-contained code, try to enforce an upper limit on this metric.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”. To enforce violation of code metrics limits as Bug Finder defects, use the Software Complexity checkers. See “Reduce Software Complexity by Using Polyspace Checkers”

## Examples

### Same Function Called Multiple Times

```
int func1(void);
int func2(void);

int foo() {
    return (func1() + func1()*func1() + 2*func2());
}
```

In this example, the number of called functions in `foo` is 2. The called functions are `func1` and `func2`.

### Recursive Function

```
#include <stdio.h>
int fibonacci(int);

void main() {
 int count;
 printf("How many numbers ?");
 scanf("%d",&count);
 fibonacci(count);
}

int fibonacci(int num)
{
   if ( num == 0 )
      return 0;
   else if ( num == 1 )
      return 1;
   else
      return ( fibonacci(num-1) + fibonacci(num-2) );
}
```

In this example, the number of called functions in `fibonacci` is 1. The called function is `fibonacci` itself.

### Constructor Function

```
            #include<iostream>
class A{
    public:
    A(){
        std::cout<<"Create A\n";
    }
    ~A() = default;
    A(const A&)=default;
    A(A&&) = default;
    virtual void bar(){ std::cout<<"A";}
};
class B: public A{
    public:
    B() = default;
     void bar() override {std::cout<<"B";}
};

void func(A& a){
    a.bar();
}

int main(){
    A obj;
    A obj2 = obj;
    B objB;
    func(obj);
    return 0;
}
```

In this example, the number of called function in `main` is three:

1. The constructor of class `A`. This user defined constructor counts as a function call.
2. The constructor of class `B`. Because the constructor of the base class `A` is user-defined, the constructor of `B` counts as a function call even though `B::B()` is declared as `=default`.
3. The function `func`.

The class `A` uses the default or implicit copy constructor. The call to the copy constructor in `A obj2 = obj;` does not count as a function call.

## Metric Information

**Group**: Function
**Acronym**: `CALLS`
**HIS Metric**: Yes

## See Also

`Number of Call Occurrences` | `Number of Calling Functions` | `Calculate code metrics (-code-metrics)`

### Topics

"Compute Code Complexity Metrics Using Polyspace"

# Number of Calling Functions

Number of distinct callers of a function

## Description

This metric measures the number of distinct callers of a function.

In C++ , Polyspace does not calculate this metric for virtual functions and compiler generated implicit functions, such as default constructors and destructors. The metric is calculated for user-defined constructors and destructors. In a class hierarchy, if a base class has user-defined constructors, Polyspace counts this metric for corresponding constructors of the derived classes.

The recommended upper limit for this metric is 5. For more self-contained code, try to enforce an upper limit on this metric.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

### Computation Details

Note that the metric:

- Takes into account direct callers only.
- Does not consider calls through a function pointer.
- Takes into account all function calls, including ones in unreachable code.

  However, if a caller calls a function more than once, the caller is counted only once when this metric is calculated.

## Examples

### Same Function Calling a Function Multiple Times

```
#include <stdio.h>

    int getVal() {
    int myVal;
    printf("Enter a value:");
    scanf("%d", &myVal);
    return myVal;
}

int func() {
    int val=getVal();
    if(val<0)
        return 0;
    else
        return val;
}

int func2() {
    int val=getVal();
    while(val<0)
        val=getVal();
    return val;
}
```

In this example, the number of calling functions for `getVal` is 2. The calling functions are `func` and `func2`.

#### Recursive Function

```
#include <stdio.h>

    int fibonacci(int num)
{
   if ( num == 0 )
      return 0;
   else if ( num == 1 )
      return 1;
   else
      return ( fibonacci(num-1) + fibonacci(num-2) );
}

void main() {
 int count;
 printf("How many numbers ?");
 scanf("%d",&count);
 fibonacci(count);
}
```

In this example, the number of calling functions for `fibonacci` is 2. The calling functions are `main` and `fibonacci` itself.

#### Constructor Function

```

                #include<iostream>
class A{
    public:

    A(){
        std::cout<<"Create A\n";
    }
    ~A() = default;
    A(const A&)=default;
    A(A&&) = default;
    virtual void bar(){ std::cout<<"A";}
};
class B: public A{
    public:
    B() = default;
     void bar() override {std::cout<<"B";}
};

void func(A& a){
    a.bar();
}
int main(){
    A obj;
    A obj2 = obj;
    B objB;
    func(obj);
    return 0;
}
```

In this example:

- The number of calling functions for `A::A` is two. `A::A` is called once to create `obj` and again to create `objB`. Similarly, the number of calling function for `B::` is one.
- Because both `A::bar` and `B::bar` are virtual functions, Polyspace does not calculate their number of calling functions.
- The number of calling function for `func` is one.

## Metric Information

# Number of Direct Recursions

Number of instances of a function calling itself directly

## Description

This metric specifies the number of direct recursions in your project.

A direct recursion is a recursion where a function calls itself in its own body. If indirect recursions do not occur, the number of direct recursions is equal to the number of recursive functions.

The recommended upper limit for this metric is 0. To avoid the possibility of exceeding available stack space, do not use recursions in your code. To detect use of recursions, check for violations of `MISRA C:2012 Rule 17.2`.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Direct Recursion

```
int getVal(void);
int sum(int val) {
    if(val<0)
        return 0;
    else
        return (val + sum(val-1));
}

void main() {
    int count = getVal(), total;
    assert(count > 0 && count <100);
    total = sum(count);
}
```

In this example, the number of direct recursions is 1.

## Metric Information

**Group**: Project
**Acronym**: `AP_CG_DIRECT_CYCLE`
**HIS Metric**: Yes

## See Also

`MISRA C:2012 Rule 17.2` | `Calculate code metrics (-code-metrics)`

“Compute Code Complexity Metrics Using Polyspace”

# Number of Executable Lines

Number of executable lines in function body

## Description

This metric measures the number of executable lines in a function body. When calculating the value of this metric, Polyspace excludes declarations, comments, blank lines, braces or preprocessing directives.

If the function body contains a `#include` directive, the included file source code is also calculated as part of this metric.

This metric is not calculated for C++ templates and its value is reported as `Not computed`.

## Examples

### Function with Declarations, Braces and Comments

```
void func(int, double);

    int getSign(int arg) {//Excluded
    int sign; //Excluded
    static int siNumber = 0; //Excluded
    double dNumber = 5;//Excluded
    if(arg<0) {
        sign=-1;
        func(-arg,dNumber);
        ++siNumber;
        /* func takes positive first argument */   //Excluded
    }//Excluded
    else if(arg==0)
    sign=0;
    else {
        sign=1;
        func(arg,dNumber);
        ++siNumber;
    }//Excluded
    return sign;
}//Excluded
```

In this example, the number of executable lines of `getSign` is 11. The calculation excludes:

- The definition of the function.
- The variable declarations.
- The comment `/* ... */`.
- The lines with braces only.

## Metric Information

**Group**: Function
**Acronym**: FXLN

**HIS Metric**: No

## See Also

Number of Lines Within Body | Number of Instructions | Calculate code metrics (-code-metrics)

# Number of Files

Number of source files

## Description

This metric calculates the number of source files in your project.

## Examples

### Source File Calling Function in Included File

```
#include<iostream>
#include"pow.cpp"

double power(double, double);
//Function to calculate approximate index
 double AppxIndex(double m, double f){
     double U = (power(m,2) - 1)/(power(m,2)+2); //First term
     double V = (power(m,4) + 27*power(m,2)+38)/
     (2*power(m,2)+3);// Second term
     return (1+2*f*power(U,2)*(1+power(m,2)*U*V +
      power(m,3)/power(m,3)*(U-V)))
     /( (1-2*f*power(U,2)*(1+power(m,2)*U*V
     + power(m,3)/power(m,3)*(U-V))));
 }

 int main(){
     return 0;
 }
```

In this example, the code calls the function `power`, which is defined in an included source file `pow.cpp`. When analysing the code, Polyspace does not consider the included source file. Because the included source file is not considered in the analysis, Polyspace evaluates the number of source file to be one.

## Metric Information

**Group**: Project
**Acronym**: `FILES`
**HIS Metric**: No

# Number of Function Parameters

Number of function arguments

## Description

This metric measures the number of function arguments.

If ellipsis is used to denote variable number of arguments, when calculating this metric, the ellipsis is not counted.

The recommended upper limit for this metric is 5. For less dependency between functions and fewer side effects, try to enforce an upper limit on this metric.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Function with Fixed Arguments

```
int initializeArray(int* arr, int size) {
}
```

In this example, `initializeArray` has two parameters.

### Function with Type Definition in Arguments

```
int getValueInLoc(struct {int* arr; int size;}myArray, int loc) {
}
```

In this example, `getValueInLoc` has two parameters.

### Function with Variable Arguments

```
double average ( int num, ... )
{
    va_list arg;
    double sum = 0;

    va_start ( arg, num );

    for ( int x = 0; x < num; x++ )
    {
        sum += va_arg ( arg, double );
    }
    va_end ( arg);

    return sum / num;
}
```

In this example, `average` has one parameter. The ellipsis denoting variable number of arguments is not counted.

# Number of Goto Statements

Number of `goto` statements

## Description

This metric measures the number of `goto` statements in a function.

`break` and `continue` statements are not counted.

The recommended upper limit on this metric is 0. For better readability of your code, avoid `goto` statements in your code. To detect use of `goto` statements, check for violations of `MISRA C:2012 Rule 15.1`.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Function with goto Statements

```
#define SIZE 10
int initialize(int **arr, int loc);
void printString(int *);
void printErrorMessage(void);
void printExecutionMessage(void);

int main()
{
    int *arrayOfStrings[SIZE],len[SIZE],i;
    for ( i = 0; i < SIZE; i++ )
    {
        len[i] = initialize(arrayOfStrings,i);
    }

    for ( i = 0; i < SIZE; i++ )
    {
        if(len[i] == 0)
            goto emptyString;
        else
            goto nonEmptyString;
        loop: printExecutionMessage();
    }

emptyString:
    printErrorMessage();
    goto loop;
nonEmptyString:
    printString(arrayOfStrings[i]);
    goto loop;
}
```

In this example, the function `main` has 4 `goto` statements.

# Number of Header Files

Number of included header files

## Description

This metric measures the number of header files in the project that is considered in an analysis. Both directly and indirectly included header files are counted.

The metric gives a slightly different number than the actual number of header files that you use because Polyspace® internal header files and header files included by those files are also counted. For the same reason, the metric can vary slightly even if you do not explicitly include new header files or remove inclusion of header files from your code. For instance, the number of Polyspace® internal header files can vary if you change your analysis options.

## Examples

### Header Files Not Considered in Analysis

```
#include<iostream>
#include<string>
// FUnction to calculate power
 long long power(double x, int n){
     long long BN = 1;// long long
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }
```

In this example, the code does not call any of the functions defined in the `iostream` and `string`. These headers are not considered in the analysis. Polyspace calculates this metric to be zero.

## Metric Information

**Group**: Project

# Number of Instructions

Number of instructions per function

## Description

This metric measures the number of instructions in a function body.

The recommended upper limit for this metric is 50. For more modular code, try to enforce an upper limit for this metric.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

### Computation Details

The metric is calculated using the following rules:

- A simple statement ending with a `;` is one instruction.

  If the statement is empty, it does not count as an instruction.
- A variable declaration counts as one instruction if either of these conditions are true:
  - The variable is nonstatic and it is initialized. For instance:

    ```
    int var = 0;// Single statement
    ```

    Declarations of static variables not counted as statements. These might be initialized in compile time in C++
  - The variable is initialized by a function call, such as a constructor. For instance:

    ```
    class A{
    public:
        A();
        A(int in){
            /*..*/
        }
    };
    //...
    A obj(5);//Calls A::A(int). This is considered a single statement.
    ```
- Control flow statements such as `if`, `for`, `break`, `goto`, `return`, `switch`, `while`, `do-while` count as one instruction.
- The following do not count as instructions by themselves:
  - Beginning of a block of code

    For instance, the following counts as one instruction:

    ```
    {
        int var = 1;
    }
    ```
  - Labels

For instance, the following counts as two instructions. The `case` labels do not count as instructions.

```
switch (1) {  // Instruction 1: switch
    case 0:
    case 1:
    case 2:
    default:
    break;    // Instruction 2: break
 }
```

## Examples

### Calculation of Number of Instructions

```
int func(int* arr, int size) {
    int i, countPos=0, countNeg=0, countZero = 0;
    for(i=0; i<size; i++) {
        if(arr[i] >0)
            countPos++;
        else if(arr[i] ==0)
            countZero++;
        else
            countNeg++;
    }
}
```

In this example, the number of instructions in `func` is 9. The instructions are:

1. `countPos=0`
2. `countNeg=0`
3. `countZero=0`
4. `for(i=0;i<size;i++) { ... }`
5. `if(arr[i] >=0)`
6. `countPos++`
7. `else if(arr[i]==0)`

   The ending `else` is counted as part of the `if-else` instruction.
8. `countZero++`
9. `countNeg++`

**Note** This metric is different from the number of executable lines. For instance:

- `for(i=0;i<size;i++)` has 1 instruction and 1 executable line.
- The following code has 1 instruction but 3 executable lines.

```
for(i=0;
    i<size;
    i++)
```

## Metric Information

**Group**: Function
**Acronym**: STMT
**HIS Metric**: Yes

# Number of Lines

Total number of lines in a file

## Description

This metric calculates the number of lines in a file. When calculating the value of this metric, Polyspace includes comments and blank lines.

This metric is calculated for source files and header files in the same folders as source files. If you want:

- The metric reported for other header files, change the default value of the option `Generate results for sources and (-generate-results-for)`.
- The metric not reported for header files at all, change the value of the option `Do not generate results for (-do-not-generate-results-for)` to `all-headers`.

## Examples

### Code Containing Comments and Blank Lines

```
// Function to calculate power
 long long power(double x, int n){
     long long BN = 1;// long long
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }
//Function to calculate approximate index
 double AppxIndex(double m, double f){
     double U = (power(m,2) - 1)/(power(m,2)+2); //First term
     double V = (power(m,4) + 27*power(m,2)+38)/
     (2*power(m,2)+3);// Second term
     return (1+2*f*power(U,2)*(1+power(m,2)*U*V +
      power(m,3)/power(m,3)*(U-V)))
     /( (1-2*f*power(U,2)*(1+power(m,2)*U*V
     + power(m,3)/power(m,3)*(U-V))));
 }
```

Because Polyspace includes comments and blank lines when calculating this metric, the total number of line in this file is 18.

## Metric Information

**Group**: File
**Acronym**: `TOTAL_LINES`
**HIS Metric**: No

## See Also

Number of Lines Without Comment | Calculate code metrics (-code-metrics)

# Number of Lines Within Body

Number of lines in function body

## Description

This metric calculates the number of lines in a function body. When calculating the value of this metric, Polyspace includes declarations, comments, blank lines, braces, and preprocessing directives. The initialization list of a member function is considered to be within the function body when calculating this metric.

If the function body contains a `#include` directive, the included file source code is also calculated as part of this metric.

This metric is not calculated for C++ templates and its value is reported as `Not computed`.

## Examples

### Function with Declarations, Braces, and Comments

```
void func(int);

int getSign(int arg) {
    int sign;
    if(arg<0) {
        sign=-1;
        func(-arg);
        /* func takes positive arguments */
    }
    else if(arg==0)
        sign=0;
    else {
        sign=1;
        func(arg);
    }
    return sign;
}
```

In this example, the number of executable lines of `getSign` is 13. The calculation includes:

- The declaration `int sign;`.
- The comment `/* ... */`.
- The two lines with braces only.

### Member Function with Initialization List

```
class A {
    bool val;
    char c;
    int i;
public:
    A();
    void foo();
};

void A::foo() {}

A::A(): val(false),
        c('A'),
        i(42)
{}
```

In this example, the function `A::foo()` has no executable lines. The value of the metric for this function is zero. The member function `A::A()` has three initializations in an initialization list. Polyspace considers these initializations to be within the function body. Because the function does not have an explicit return statement, the compiler generates an implicit return statement. Including the implicit return and the initializations, the value of this metric for `A::A()` is 4.

## Metric Information

**Group**: Function
**Acronym**: `FLIN`
**HIS Metric**: No

## See Also

`Number of Executable Lines` | `Calculate code metrics (-code-metrics)`

# Number of Lines Without Comment

Number of lines of code excluding lines that are comments or blank

## Description

This metric calculates the number of executable lines in a file. When calculating the value of this metric, Polyspace excludes lines that are comments or blank.

This metric is calculated for source files and header files in the same folders as source files. If you want:

- The metric reported for other header files, change the default value of the option `Generate results for sources and (-generate-results-for)`.
- The metric not reported for header files at all, change the value of the option `Do not generate results for (-do-not-generate-results-for)` to `all-headers`.

## Examples

### Inline Comments

```
// Function to calculate power
 long long power(double x, int n){
     long long BN = 1;// long long
     for(int i = 0; i<n;++i){
         BN*=x;
     }
     return BN;
 }
//Function to calculate approximate index
 double AppxIndex(double m, double f){
     double U = (power(m,2) - 1)/(power(m,2)+2); //First term
     double V = (power(m,4) + 27*power(m,2)+38)/
     (2*power(m,2)+3);// Second term
     return (1+2*f*power(U,2)*(1+power(m,2)*U*V +
      power(m,3)/power(m,3)*(U-V)))
     /( (1-2*f*power(U,2)*(1+power(m,2)*U*V
     + power(m,3)/power(m,3)*(U-V))));
 }
```

In this example, Polyspace calculates the number of lines in the file that are neither comment nor blank lines. Ignoring lines that are comments, such as the line `// FUnction to calculate power`, and blank lines, Polyspace evaluates the metric as `16`. When evaluating this metric, the lines of code that contain inline comments are counted as lines of code.

## Metric Information

`Number of Lines` | `Calculate code metrics (-code-metrics)`

# Number of Local Non-Static Variables

Total number of local variables in function

## Description

This metric provides the number of declared local variables in a function.

The metric excludes static variables and temporary variables. To find number of static variables, use the metric `Number of Local Static Variables`.

## Examples

### Non-Structured Variables

```
int flag();

int func(int param) {
  int var_1;
  int var_2;
  if (flag()) {
      int var_3;
      int var_4;
    } else {
      int var_5;
    }
}
```

In this example, the number of local non-static variables in `func` is 5. The number does not include the function arguments and return value.

### Arrays and Structured Variables

```
typedef struct myStruct{
   char  arr1[50];
   char  arr2[50];
   int   val;
} myStruct;

void func(void) {
  myStruct var;
  char localArr[50];
}
```

In this example, the number of local non-static variables in `func` is 2: the structured variable `var` and the array `localArr`.

### Variables in Class Methods

```
class Rectangle {
    int width, height;
```

```
  public:
    void set (int,int);
    int area (void);
} rect;

int Rectangle::area (void) {
    int temp;
    temp = width * height;
    return(temp);
}
```

In this example, the number of local non-static variables in `Rectangle::area` is 1: the variable `temp`.

# Version History

**Introduced in R2017a**

## See Also

`Higher Estimate of Size of Local Variables` | `Number of Local Non-Static Variables` | `Calculate code metrics (-code-metrics)`

# Number of Paths

Estimated static path count

## Description

This metric measures the number of static paths in a function.

The recommended upper limit for this metric is 80. If the number of paths is high, the code is difficult to read and can cause more orange checks. Try to limit the value of this metric.

To enforce limits on metrics, see "Compute Code Complexity Metrics Using Polyspace".

### Computation Details

The number of paths is calculated according to these rules:

- If the statements in a function do not break the control flow, the number of paths is one.

  Even an empty statement such as `;` or empty block such as `{}` counts as one path.
- A control flow statement introduces branches and adds to the original one path.

  - `if-else if-else`: Each `if` keyword introduces a new branch. The contribution from an `if-else if-else` block is the number of branches plus one (the original path). If a catch-all `else` is present, all paths go through the block; otherwise, one path bypasses the block.

    For instance, a function with an `if(..) {} else if(..) {} else {}` statement has three paths. A function with one `if() {}` only has two paths, one that goes through the `if` block and one that bypasses the block.
  - `switch-case`: Each `case` label introduces a new branch. The contribution from a `switch` block is the number of `case` labels plus one (the original path). If a catch-all `default` is present, all paths go through the block; otherwise, one path bypasses the block.

    For instance, a function with a statement `switch (var) { case 1: .. break; case 2: .. break; default: .. }` has three paths, all going through the `switch` block. If you omit the `default`, the function still has three paths, two going through the `switch` block and one bypassing the block.
  - `for` and `while`: Each loop statement introduces a new branch. The contribution from a loop is two - a path that goes through the loop and a path that bypasses the loop.
  - `do-while`: Each `do-while` statement introduces a new branch except when the condition of the `while` statement is explicitly false. Statements written as `do{/*..*/}while(0)` do not function as loops. Such statements are often used for enclosing multiple lines of macros within braces. For instance, this `do-while` statement serves to encapsulate the multiline macro rather than create a new path:

    ```
    #define myfunc(x) do{ ...\\
                          ...\\
                          ...}while(0);
    ```

    Polyspace considers such statements to be a single path.

  Note that a statement with a ternary operator such as

```
result = a > b ? a : b;
```

is not considered as a statement that breaks the control flow.

- If more than one control flow statement are present in a sequence without any nesting, the number of paths is the product of the contributions from each control flow statement.

  For instance, if a function has three `for` loops and two `if-else` blocks, one after another, the number of paths is 2 × 2 × 2 × 2 × 2 = 32.

  If many control flow statements are present in a function, the number of paths can be large. Nested control flow statements reduce the number of paths at the cost of increasing the depth of nesting. For an example, see “Function with Nested Control Flow Statements” on page 30-67.
- The software displays specific values in cases where the metric is not calculated:
  - If `goto` statements are present in the body of the function, Polyspace cannot calculate the number of paths and shows the number of paths as `Not Computed` instead.
  - If the number of paths reaches an upper limit of 1,000,000,000, Polyspace stops the calculation and displays just the upper limit. The actual value might be higher.
- The number of path is calculated statically. This statically calculated number represents the upper limit of the possible path in a function. Typically, the number of possible path during run time is lower than the number Polyspace reports.
- Polyspace ignores compiler generated conditional statements in C++ when calculating the number of paths. The compiler might generate implicit conditional statements in operations such as initializing static variables or calling virtual functions.

## Examples

### Function with One Path

```
int func(int ch) {
    return (ch * 2);
}
```

In this example, `func` has one path.

### Function with Control Flow Statement Causing Multiple Paths

```
void func(int ch) {
    switch (ch)
    {
    case 1:
        break;
    case 2:
        break;
    case 3:
        break;
    case 4:
        break;
    default:
    }
}
```

In this example, `func` has five paths. Apart from the path that goes through the `default`, each `case` label followed by a statement causes the creation of a new path.

### Function with Nested Control Flow Statements

```
void func()
{
    int i = 0, j = 0, k = 0;
    for (i=0; i<10; i++)
    {
        for (j=0; j<10; j++)
        {
            for (k=0; k<10; k++)
            {
                if (i < 2 )
                    ;
                else
                {
                    if (i > 5)
                        ;
                    else
                        ;
                }
            }
        }
    }
}
```

In this example, `func` has six paths: three from the `for` statements, two from the `if` statements plus the original path that bypasses all control flow statements.

### Function with Control Flow Statements in Sequence

```
int look_up(int a, int b){
    if(a==b){
        return 1;
    }
    if(a>b+2){
        return 2;
    }
    if((a+b) < 10){
        return 3;
    }
    if((a+b) > 11){
        return 4;
    }
    if((a+b) >20 && (b-a)!=0){
        return 3;
    }
}
```

In this example, there are five `if` statements in sequence. Each `if` statements introduces two possible execution path. The total number of path is `2 × 2 × 2 × 2 × 2 = 32`. Control statements in sequence increases the number of path quickly. If the number of path is higher than acceptable, consider refactoring your function.

# Number of Potentially Unprotected Shared Variables

Number of unprotected shared variables

## Description

This metric measures the number of variables with the following properties:

- The variable is used in more than one task.
- At least one operation on the variable is not protected from interruption by operations in other tasks.

## Examples

### Unprotected Shared Variables

```
#include <limits.h>
int shared_var;

void inc() {
    shared_var+=2;
}

void reset() {
    shared_var = 0;
}

void task() {
    volatile int randomValue = 0;
    while(randomValue) {
        reset();
        inc();
        inc();
    }
}

void interrupt() {
    shared_var = INT_MAX;
}

void interrupt_handler() {
    volatile int randomValue = 0;
    while(randomValue) {
        interrupt();
    }
}

void main() {
}
```

In this example, Polyspace calculates the number of potentially unprotected shared variable to be one. The shared variabel `shared_var` is unprotected if you specify `task` and `interrupt_handler` as entry points and do not specify protection mechanisms.

The operation `shared_var = INT_MAX` can interrupt the other operations on `shared_var` and cause unpredictable behavior.

### Metric Information

`Calculate code metrics (-code-metrics)`

# Number of Protected Shared Variables

Number of protected shared variables

## Description

This metric measures the number of variables with the following properties:

- The variable is used in more than one task.
- All operations on the variable are protected from interruption through critical sections or temporal exclusions.

## Examples

### Shared Variables Protected Through Temporal Exclusion

```
#include <limits.h>
int shared_var;

void inc() {
    shared_var+=2;
}

void reset() {
    shared_var = 0;
}

void task() {
    volatile int randomValue = 0;
    while(randomValue) {
        reset();
        inc();
        inc();
    }
}

void interrupt() {
    shared_var = INT_MAX;
}

void interrupt_handler() {
    volatile int randomValue = 0;
    while(randomValue) {
        interrupt();
    }
}

void main() {
}
```

In this example, `shared_var` is a protected shared variable if you specify the following options:

| Option | Value |
|---|---|
| Tasks (-entry-points) | task<br>interrupt_handler |
| Temporally exclusive tasks (-temporal-exclusions-file) | temporal_exclusion.txt |

In the command line, specify these options to run the example:

```
-entry-points task,interrupt_handler  -temporal-exclusions-file temporal_exclusion.txt
```

`temporal_exclusion.txt` is a text file containing the temporally exclusive tasks separated by a space in a single line:

```
task interrupt_handler
```

The variable is shared between `task` and `interrupt_handler`. However, because `task` and `interrupt_handler` are temporally exclusive, operations on the variable cannot interrupt each other.

#### Shared Variables Protected Through Critical Sections

```
#include <limits.h>
int shared_var;

void inc() {
    shared_var+=2;
}

void reset() {
    shared_var = 0;
}

void take_semaphore(void);
void give_semaphore(void);

void task() {
    volatile int randomValue = 0;
    while(randomValue) {
        take_semaphore();
        reset();
        inc();
        inc();
        give_semaphore();
    }
}

void interrupt() {
    shared_var = INT_MAX;
}

void interrupt_handler() {
    volatile int randomValue = 0;
    while(randomValue) {
        take_semaphore();
        interrupt();
        give_semaphore();
    }
}

void main() {
}
```

In this example, `shared_var` is a protected shared variable if you specify the following:

| Option | Value | |
|---|---|---|
| **Entry points** | `task`<br>`interrupt_handler` | |
| **Critical section details** | **Starting routine** | **Ending routine** |
| | `take_semaphore` | `give_semaphore` |

In the command line, specify these options to run the example:

```
-critical-section-begin  take_semaphore:cs1
-critical-section-end give_semaphore:cs1
-entry-points task,interrupt_handle
```

The variable is shared between `task` and `interrupt_handler`. However, because operations on the variable are between calls to the starting and ending procedure of the same critical section, they cannot interrupt each other.

# Number of Recursions

Number of call graph cycles over one or more functions

## Description

The metric provides a quantitative estimate of the number of recursion cycles in your project. The metric is the sum of:

- Number of direct recursions (self recursive functions or functions calling themselves).
- Number of strongly connected components formed by the indirect recursion cycles in your project. If you consider the recursion cycles as a directed graph, the graph is strongly connected if there is a path between all pairs of vertices.

  To compute the number of strongly connected components:

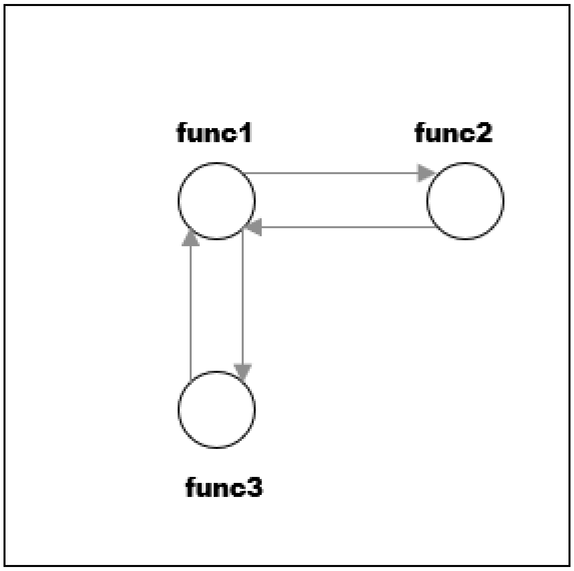
  1. Draw the recursion cycles in your code.

     For instance, the recursion cycles in this example are shown below.

     ```
     volatile int checkStatus;
     void func1() {
        if(checkStatus) {
             func2();
        }
        else {
             func3();
        }
     }

     func2() {
        func1();
     }

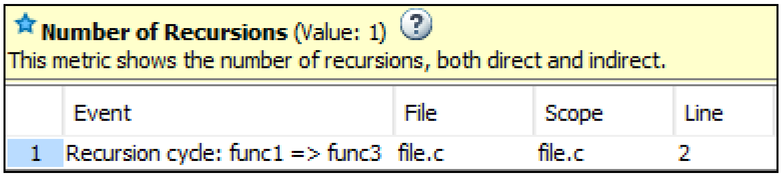
     func3() {
        func1();
     }
     ```



2 Identify the number of strongly connected components formed by the recursion cycles.

In the preceding example, there is one strongly connected component. You can move from any vertex to another vertex by following the paths in the graph.

The event list below the metric shows one of the recursion cycles in the strongly connected component.



**Number of Recursions** (Value: 1)
This metric shows the number of recursions, both direct and indirect.

| | Event | File | Scope | Line |
|---|---|---|---|---|
| 1 | Recursion cycle: func1 => func3 | file.c | file.c | 2 |

Calls through a function pointer are not considered.

The recommended upper limit for this metric is 0. To avoid the possibility of exceeding available stack space, do not use recursions in your code. Recursions can tend to exhaust stack space easily. See examples of stack size growth with recursions described for this CERT-C rule that forbids recursions.

To detect use of recursions, check for violations of one of `MISRA C:2012 Rule 17.2`,MISRA C: 2004 Rule 16.2, `MISRA C++:2008 Rule 7-5-4` or JSF Rule 119. Note that:

- The rule checkers report each function that calls itself, directly or indirectly. Even if several functions are involved in one recursion cycle, each function is individually reported.
- The rule checkers consider explicit function calls only. For instance, in C++ code, the rule checkers ignore implicit calls to constructors during object creation. However, the metrics computation considers both implicit and explicit calls.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Direct Recursion

```
int getVal(void);
int sum(int val) {
    if(val<0)
        return 0;
    else
        return (val + sum(val-1));
}

void main() {
    int count = getVal(), total;
    assert(count > 0 && count <100);
    total = sum(count);
}
```

In this example, the number of recursions is 1.

A direct recursion is a recursion where a function calls itself in its own body. For direct recursions, the number of recursions is equal to the number of recursive functions.

### Indirect Recursion with One Call Graph Cycle

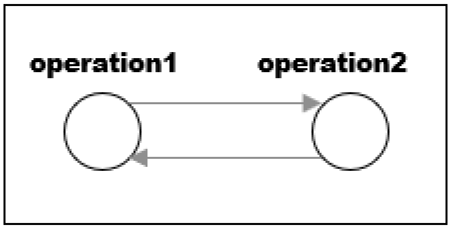
```
volatile int signal;
void operation2(void);

void operation1(void) {
    int stop = signal%2;
    if(!stop)
        operation2();
}

void operation2(void) {
    operation1();
}

void main() {
    operation1();
}
```

In this example, the number of recursions is one. The two functions `operation1` and `operation2` are involved in the call graph cycle `operation1` → `operation2` → `operation1`.



An indirect function is a recursion where a function calls itself through other functions. For indirect recursions, the number of recursions can be different from the number of recursive functions.

### Multiple Call Graph Cycles Forming One Strongly Connected Component

```
volatile int checkStatus;
void func1() {
   if(checkStatus) {
        func2();
   }
   else {
        func3();
   }
}

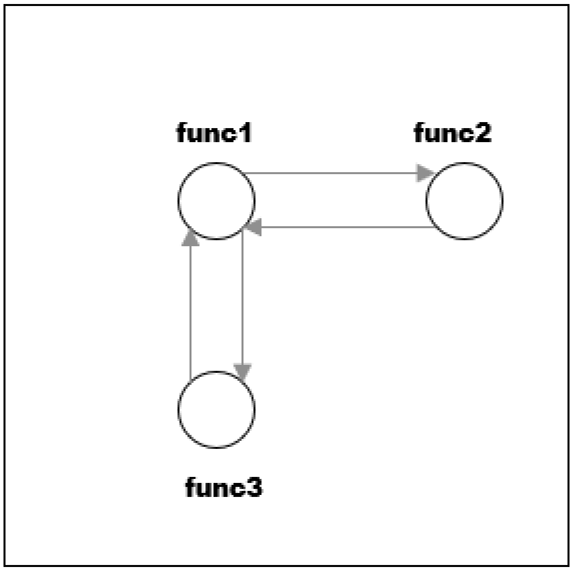
func2() {
   func1();
}

func3() {
   func1();
}
```

In this example, there are two call graph cycles:

- `func1` → `func2` → `func1`
- `func1` → `func3` → `func1`

However, the cycles form one strongly connected component. You can move from any vertex to another vertex by following the paths in the graph. Hence, the number of recursions is one.



### Indirect Recursion with Two Call Graph Cycles

```
volatile int signal;
void operation1_1();
void operation2_1();
void operation1() {
    int stop = signal%2;
    if(!stop)
        operation1_1();
}

void operation1_1() {
    operation1();
}

void operation2() {
    int stop = signal%2;
    if(!stop)
        operation2_1();
}

void operation2_1() {
    operation2();
}

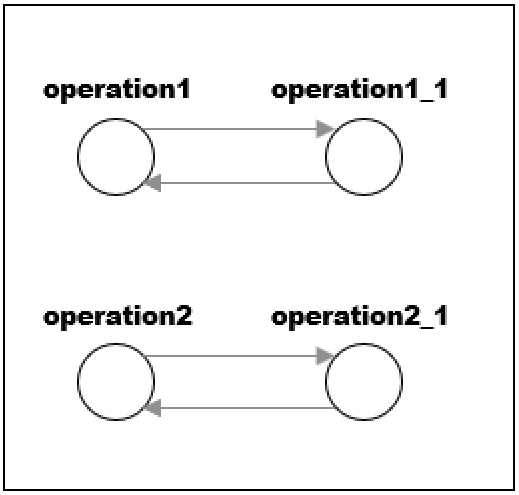
void main(){
    operation1();
    operation2();
}
```

In this example, the number of recursions is two.

There are two call graph cycles:

- `operation1` → `operation1_1` → `operation1`
- `operation2` → `operation2_1` → `operation2`

The call graph cycles form two strongly connected components.



**Same Function Called in Direct and Indirect Recursion**

```
volatile int signal;
void operation2();
void operation1() {
    int stop = signal%3;
    if(stop==1)
        operation1();
    else if(stop==2)
        operation2();
}

void operation2() {
    operation1();
}

void main() {
    operation1();
}
```

In this example, the number of recursions is two:

- The strongly connected component formed by the cycle `operation1` → `operation2` → `operation1`.
- The self-recursive function `operation1`.

# Number of Return Statements

Number of `return` statements in a function

## Description

This metric measures the number of `return` statements in a function.

The recommended upper limit for this metric is 1. If one return statement is present, when reading the code, you can easily identify what the function returns.

To enforce limits on metrics, see “Compute Code Complexity Metrics Using Polyspace”.

## Examples

### Function with Return Points

```
int getSign (int arg) {
    if(arg <0)
        return -1;
    else if(arg > 0)
        return 1;
    return 0;
}
```

In this example, `getSign` has 3 `return` statements.

# Program Maximum Stack Usage

Maximum stack usage in the analyzed program

## Description

*This metric is reported in a Code Prover analysis only.*

This metric shows the maximum stack usage from your program.

The metric shows the maximum stack usage for the function with the highest stack usage. If you provide a complete application, the function with the highest stack usage is typically the `main` function because the `main` function is at the top of the call hierarchy. In multitasking or multithreaded applications, the program maximum stack usage is the maximum stack usage of the task or thread with the highest stack usage. For a description of maximum stack usage for a function, see the metric `Maximum Stack Usage` (Polyspace Code Prover).

## Metric Information

### Topics

“Determination of Program Stack Usage” (Polyspace Code Prover)

# Program Minimum Stack Usage

Maximum stack usage in the analyzed program taking nested scopes into account

## Description

*This metric is reported in a Code Prover analysis only.*

This metric shows the maximum stack usage from your program, taking nested scopes into account. The metric provides a lower bound to the stack usage since unlike the `Program Maximum Stack Usage` (Polyspace Code Prover), the metric takes into account possible stack space reuse within a function and does not simply add the sizes of all local variables in a function.

The metric shows the minimum stack usage for the function with the highest stack usage. If you provide a complete application, the function with the highest stack usage is typically the `main` function because the `main` function is at the top of the call hierarchy. In multitasking or multithreaded applications, the program minimum stack usage is the minimum stack usage of the task or thread with the highest stack usage. For a description of minimum stack usage for a function, see the metric `Minimum Stack Usage` (Polyspace Code Prover).

Considering nested scopes is useful for compilers that reuse stack space for variables defined in nested scopes. For instance, in this code, the space for `var_1` is reused for `var_2`.

```
type func (type param_1, ...) {

  {
    /* Scope 1 */
    type var_1, ...;
  }
  {
    /* Scope 2 */
    type var_2, ...;
  }
}
```

# Call Hierarchy

Create table showing call graph in source code

## Description

This component creates a table showing the call hierarchy in your source code. For each function call in your source code, the table displays the following information:

- Level of call hierarchy, where the function is called.

  Each level is denoted by |. If a function call appears in the table as `|||-> `*`file_name.function_name`*, the function call occurs at the third level of the hierarchy. Beginning from `main` or an entry point, there are three function calls leading to the current call.
- File containing the function call.

  In Code Prover, the line and column is also displayed.
- File containing the function definition.

  In Code Prover, the line and column where the function definition begins is also displayed.

In addition, the table also displays uncalled functions.

This table captures the information available on the **Call Hierarchy** pane in the Polyspace user interface.

# Code and Verification Information

Create table of verification times and code characteristics

## Description

This component creates tables containing verification times and code characteristics such as number of lines.

## Properties

### Include Verification Time Information

If you select this option, the report contains verification times broken down by phase.

- For Polyspace Bug Finder, the phases are `compilation`, `pass0`, `pass1`, etc.
- For Polyspace Code Prover, the phases are `compilation`, `global`, `function`, etc.

### Include Code Details

If you select this option, the report contains the following code characteristics:

- Number of files
- Number of lines
- Number of lines without comment

# Code Verification Summary

Create table of Polyspace analysis results

## Description

This component creates tables containing the following results:

- Number of results
- Number of coding rule violations for each coding rule type such as MISRA C
- Number of defects, for Polyspace Bug Finder results
- Number of checks of each color, for Polyspace Code Prover results
- Whether the project passed or failed the software quality objective

## Properties

### Include Checks from Polyspace Standard Library Stub Functions

Unless you deselect this option, the tables contain Polyspace Code Prover checks that appear in Polyspace stubs for the standard library functions.

## See Also

# Coding Rules Details

Create table of coding rule violations broken down by file

## Description

This component creates tables containing coding rule violations broken down by each file in the Polyspace project. For each rule violation, the table contains the following information:

- Rule number
- Rule description
- Function containing the violation
- (Code Prover only) Line and column number
- Review information such as classification, status and comments

## Properties

### Select Coding Rules Type

Using this option, you can choose which coding rule violations to display. You can display violations for the following set of coding rules:

- MISRA C rules
- MISRA AC AGC rules
- MISRA C++ rules
- JSF C++ rules
- Custom coding rules

### Display by

Using this option, you can break down the display of coding rule violations by file.

# Coding Rules Summary

Create table with number of coding rule violations

## Description

This component creates a table containing the number of coding rule violations. You can choose whether to break this information down by rule number or file.

## Properties

### Select Coding Rules Type

Using this option, you can choose which coding rule violations to display. You can display violations for the following set of coding rules:

- MISRA C rules
- MISRA AC AGC rules
- MISRA C++ rules
- JSF C++ rules
- Custom coding rules

### Include Files/Rules with No Problems Detected

If you select this option, the table displays:

- Files that do not contain coding rule violations
- Rules that your code does not violate

### Display by

Using this option, you can break down the display of coding rule violations by:

- Rule number
- File

# Configuration Parameters

Create table of analysis options, assumptions and coding rules configuration

## Description

This component creates the following tables:

- *Polyspace settings*: The analysis options that you used to obtain your results. The table lists command-line version of the options along with their values.
- *Analysis assumptions*: The assumptions used to obtain your Code Prover results. The table lists only the modifiable assumptions. For assumptions that you cannot change, see the Polyspace documentation.
- *Coding rules configuration*: The coding rules whose violations you checked for. The table lists the rule number, rule description and other information about the rules.
- *Files with compilation errors*: If your project has source files with compilation errors, these files are listed.

# Recursive Functions

Create table of recursive functions

## Description

This component creates a table containing the recursive functions in your source code (along with the files containing the functions).

- For each direct recursion (function calling itself directly), the table lists the recursive function.
- For each indirect recursion cycle (function calling itself through other functions), the table lists one function in the cycle.

For instance, the following code contains two indirect recursion cycles.

```
volatile int signal;

void operation1() {
    int stop = signal%2;
    if(!stop)
        operation1_1();
}

void operation1_1() {
    operation1();
}

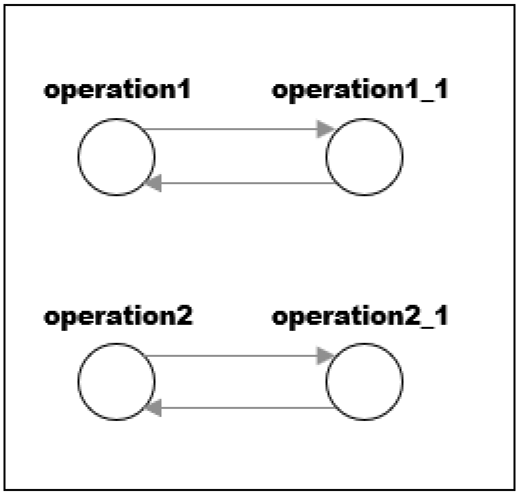
void operation2() {
    int stop = signal%2;
    if(!stop)
        operation2_1();
}

void operation2_1() {
    operation2();
}

void main(){
    operation1();
    operation2();
}
```

The two call graph cycles are:

- `operation1` → `operation1_1` → `operation1`
- `operation2` → `operation2_1` → `operation2`



This report component shows one function from each of the two cycles: `operation1` and `operation2`. To see the full cycle, open the results in the Polyspace user interface.

# Report Customization (Filtering)

Create filters that apply to your Polyspace reports

## Description

This component allows you to filter unwanted information from existing Polyspace report templates. To apply global filters, place this component immediately below the node representing the report name.

## Properties

### Code Metrics Filters

The properties in table below apply to the inclusion of code metrics in your report.

| Property | Purpose | User Action |
|---|---|---|
| **Include Project Metrics** | Choose whether to include metrics about your Polyspace project. | Select the check box to include project metrics. |
| **Project metrics to include** | Specify project metrics to include or exclude from report. | Enter a MATLAB regular expression. |
| **Include File Metrics** | Choose whether to include per file metrics in report. | Select the check box to include per file metrics. |
| **File Metrics > Files to include** | Specify files to include or exclude when reporting file metrics. | Enter a MATLAB regular expression. |
| **File metrics to include** | Specify file metrics to include or exclude from report. | Enter a MATLAB regular expression. |
| **Include Function Metrics** | Choose whether to include per function metrics in report. | Select the check box to include per function metrics. |
| **Function Metrics > Files to include** | Specify files to include or exclude when reporting function metrics. | Enter a MATLAB regular expression. |
| **Functions to include** | Specify functions to include or exclude when reporting function metrics. | Enter a MATLAB regular expression. |
| **Function metrics to include** | Specify function metrics to include or exclude from report. | Enter a MATLAB regular expression. |

### Coding Rules Filters

The properties in table below apply to the inclusion of coding rule violations in your report.

| Property | Purpose | User Action |
|---|---|---|
| **Files to include** | Specify files to include or exclude when reporting coding rule violations. | Enter a MATLAB regular expression. |
| **Coding rule numbers to include** | Specify coding rules to include or exclude when reporting coding rule violations. | Enter a MATLAB regular expression. |
| **Classifications to include** | Specify classifications to include or exclude when reporting coding rule violations. | Enter a MATLAB regular expression. |
| **Status types to include** | Specify statuses to include or exclude when reporting coding rule violations. | Enter a MATLAB regular expression. |

#### Run-time Check Filters

The properties in table below apply to the inclusion of Polyspace Code Prover checks in your report.

| Property | Purpose |
|---|---|
| **Red Checks** | Specify whether to include red checks in your report. Red checks indicate proven run-time errors. |
| **Gray Checks** | Specify whether to include gray checks in your report. Gray checks indicate unreachable code. |
| **Orange Checks** | Specify whether to include orange checks in your report. Orange checks indicate possible run-time errors. |
| **Green Checks** | Specify whether to include green checks in your report. Green checks indicate that an operation does not contain a specific run-time error. |
| **Inspection Point Checks** | Specify whether to include inspection point checks in your report. These checks allow an user to find the values that a variable can take at a certain point in the code. |
| **Unreachable Functions** | Specify whether to include unreachable functions in your report. |

#### Advanced Filters

The properties in table below apply to the inclusion of metrics, coding rule violations and Polyspace Code Prover checks in your report.

| Property | Purpose | User Action |
|---|---|---|
| **Justification status** | Choose whether to report only justified checks, only unjustified checks or all checks. | Choose an option from the dropdown list. |

| Property | Purpose | User Action |
|---|---|---|
| **Files to include** | Specify files to include or exclude from your report. | Enter a MATLAB regular expression. |
| **Check types to include** | Specify Polyspace Code Prover checks to include in your report. | Enter a MATLAB regular expression. |
| **Function names to include** | Specify functions to include or exclude from your report. | Enter a MATLAB regular expression. |
| **Classification types to include** | Specify classifications to include or exclude from your report. | Enter a MATLAB regular expression. |
| **Status types to include** | Specify statuses to include or exclude from your report. | Enter a MATLAB regular expression. |
| **Comments to include** | Specify comments to include or exclude from your report. | Enter a MATLAB regular expression. |

# Run-time Checks Details Ordered by Color/File

Create overrides for global filters in Polyspace reports (Code Prover only)

## Description

This component adds detailed information about the run-time checks to your report. This component can also be used to override global filters in specific chapters of your report. Use the following workflow when using filters in your report:

1. To create filters that apply to all chapters of your report, use the **Report Customization (Filtering)** component. For more information, see `Report Customization (Filtering)`.
2. To override some of the filters in individual chapters, use the **Run-time Checks Details Ordered by Color/File** component. Select the **Override Global Report filter** box.

## Properties

### Categories To Include

The properties in table below apply to the inclusion of Polyspace Code Prover checks in your report.

| Property | Purpose |
|---|---|
| **Red Checks** | Specify whether to include red checks in your report. Red checks indicate proven run-time errors. |
| **Gray Checks** | Specify whether to include gray checks in your report. Gray checks indicate unreachable code. |
| **Orange Checks** | Specify whether to include orange checks in your report. Orange checks indicate possible run-time errors. |
| **Green Checks** | Specify whether to include green checks in your report. Green checks indicate that an operation does not contain a specific run-time error. |
| **Inspection Point Checks** | Specify whether to include inspection point checks in your report. These checks allow an user to find the values that a variable can take at a certain point in the code. |
| **Unreachable Functions** | Specify whether to include unreachable functions in your report. |

### Advanced Filters

The properties in table below apply to the inclusion of metrics, coding rule violations and Polyspace Code Prover checks in your report.

| Property | Purpose | User Action |
|---|---|---|
| **Justification status** | Choose whether to report only justified checks, only unjustified checks or all checks. | Choose an option from the dropdown list. |
| **Files to include** | Specify files to include or exclude from your report. | Enter a regular MATLAB expression. |
| **Check types to include** | Specify Polyspace Code Prover checks to include in your report. | Enter a regular MATLAB expression. |
| **Function names to include** | Specify functions to include or exclude from your report. | Enter a regular MATLAB expression. |
| **Classification types to include** | Specify classifications to include or exclude from your report. | Enter a regular MATLAB expression. |
| **Status types to include** | Specify statuses to include or exclude from your report. | Enter a regular MATLAB expression. |
| **Comments to include** | Specify comments to include or exclude from your report. | Enter a regular MATLAB expression. |

# Run-time Checks Details Ordered by Review Information

Create table with run-time checks ordered by review information (Code Prover only)

## Description

This component creates tables displaying the Polyspace Code Prover checks in your code. All checks with same combination of **Severity** and **Status** appear in the same table.

## See Also

# Run-time Checks Summary Ordered by File

Create table with run-time checks ordered by file (Code Prover only)

## Description

This component creates a table displaying the number of Polyspace Code Prover checks per file in your code.

## Properties

### Sort the data

Use this option to sort the rows in the table alphabetically by filename or by percentage of unproven code.

### Display as

Use this option to display the number of checks in a table or in bar charts.

### Display ratio of checks in a file

Select this option to display the number of checks of a certain color as a ratio of total number of checks in the file.

### Include checks from Polyspace standard library stub functions

Select this option to include the checks from Polyspace standard library stub functions in your display.

# Software Quality Objectives - Run-time Checks Details

Create table of result details for results downloaded from Polyspace Metrics

## Description

This component creates tables showing results downloaded from Polyspace Metrics.

The component `Software Quality Objectives - Run-time Checks Summary` shows the distribution of results. This component shows individual instances of results. Each file has a dedicated table showing the findings in the file.

# Variable Access

Create table showing global variable access in source code (Code Prover only)

## Description

This component creates a table showing the global variable access in your source code. For each global variable, the table displays the following information:

- Variable name.

  The entry for each variable is denoted by |.
- Type of the variable.
- Number of read and write operations on the variable.
- Details of read and write operations. For each read or write operation, the table displays the following information:
  - File and function containing the operation in the form *`file_name.function_name`*.

    The entry for each read or write operation is denoted by `||`. Write operations are denoted by < and read operations by >.
  - Line and column number of the operation.

This table captures the information available on the **Variable Access** pane in the Polyspace user interface.

The table showing variable access contains only the names of files. Below this table, a second table shows the full paths to files (in two columns, **Filename** and **Full filename**). If a variable access occurs in a Standard library function, the two columns contain this information:

- **Filename**: `__polyspace__stdstubs.c` (the file containing Polyspace implementation of Standard Library functions)
- **Full filename**: `Std library`

# Polyspace Bug Finder Assumptions

# 32

# Approximations Used During Bug Finder Analysis

# Inputs in Polyspace Bug Finder

A Bug Finder analysis by default does not return a defect caused by a special value of an unknown input unless the input is subsequently bounded in the code. Polyspace makes no assumption about the value of unbounded inputs when your source code is incomplete. For example, in the following code Bug Finder detects a **division by zero** in `foo_1()`, but not in `foo_2()`:

```
int foo_1(int p)
{
  int x = 0;
  if ( p > -10 && p < 10 )  /* p is bounded by if statement */
      x = 100/p;    /* Division by zero detected */

  return x;
}

int foo_2(int p)    /* p is unbounded */
{
  int x = 0;
  x = 100/p;    /* Division by zero not detected */

  return x;
}
```

To set bounds on your input, add constraints in your code such as `assert` or `if`. At the cost of a possibly longer runtime, you can perform a more exhaustive analysis where all values of function inputs are considered when showing defects. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

# Global Variables in Polyspace Bug Finder

When you run a Bug Finder analysis, Polyspace makes certain assumptions about the initialization of global variables. These assumptions depend on how you declare and define global variables. For example, in this code

```
int foo(void) {
    return 1/gvar;
}
```

Bug Finder detects a **division by zero** defect with the variable `gvar` in these cases:

- You define `int gvar;` in the source code and provide a `main` function that calls `foo`. Bug Finder follows ANSI standards that state the variable is initialized to zero.
- You define `int gvar;` or declare `extern int gvar;` in the source code. Another function calls `foo` and sets `gvar=0`. Otherwise, when your source files are incomplete and do not contain a `main` function, Bug Finder makes no assumption about the initialization of `gvar`.
- You declare `const int gvar;`. Bug Finder assumes `gvar` is initialized to zero due to the `const` keyword.

At the cost of a possibly longer runtime, you can perform a more exhaustive analysis where all values are considered for each read of a global variable by `foo` or of its callees when showing defects. See “Extend Bug Finder Checkers to Find Defects from Specific System Input Values”.

# Volatile Variables in Polyspace Bug Finder

You use the `volatile` keyword to inform the compiler that the value of a variable might change at any time without an explicit write operation. When you run an analysis, Polyspace Bug Finder makes these assumptions about volatile variables:

- **Global volatile variables**

  - If you declare a global volatile variable as `const`, Polyspace uses the initialization value of the variable or the initialization range if you use the `PERMANENT` **Init Mode** to constrain the range of the variable externally. Polyspace uses the initialization value or range for every read of the variable. See “External Constraints for Polyspace Analysis”.

    For instance, in this code:

    ```
    const volatile volatile_var; // Global variable initialized to 0
    const volatile volatile_var_10=10;
    const volatile volatile_var_drs=3; // Variable constrained to range [-5 .. 5]

    int func(void){
        int i= 10 % volatile_var; // Defect
        int j= 10 % volatile_var_10; // No defect
        int k= 10 % volatile_var_drs; // Defect
        return i+j+k;
    }
    ```

    Polyspace detects an **Integer division by zero** defect for `volatile_var` since it is initialized to zero. Polyspace detects an **Integer division by zero** for `volatile_var_drs` because it is externally constrained to the range [-5 .. 5]. All reads of `volatile_var_10` cause no defect.

  - For non-`const` global volatile variables, Polyspace ignores the initialization value of the variable, and then considers the input unknown for each read of the variable. If you use the `PERMANENT` **Init Mode** to constrain the range of the variable externally, Polyspace uses this range for every read of the variable. See “External Constraints for Polyspace Analysis”.

    For instance, in this code:

    ```
    volatile volatile_var; // Global variable initialized to 0
    volatile volatile_var_drs=3; // Variable constrained to range [-5 .. 5]

    int func(void){
        int i= 10 % volatile_var; // No defect
        int j= 10 % volatile_var_drs; // Defect
        return i+j;
    }
    ```

  Polyspace detects an **Integer division by zero** defect for `volatile_var_drs` because it is externally constrained to the range [-5 .. 5]. All reads of `volatile_var` cause no defect.

- **Local volatile variables**

  Polyspace ignores the initialization value of local volatile variables, and then considers the input unknown for each read of the variable. For example, in this code:

  ```
  int foo(void){
      volatile var=0;
      return 1/var; // No defect
  }
  ```

  Polyspace detects no defect. You cannot use external constraints to constrain the range of local variables.

At the cost of a possibly longer runtime, you can perform a more exhaustive analysis where Polyspace considers all values for each read of a volatile variable. See `Run stricter checks considering` `all values of system inputs (-checks-using-system-input-values)`. When you use this option to analyze all the preceding code examples, Polyspace detects additional **Integer division by zero** defects on the lines labeled with comment `// No defect`, including for the local volatile variable example.

# Duplicate Code Detection in Polyspace Bug Finder

Sections of code that do the same operations require unnecessary additional maintenance. Duplicated code also increases the chances you will update the code in one place but forget to update the other. Using Polyspace Bug Finder, you can detect sections of code that are exact or partial duplicates of each other.

## Duplicate Code Checkers

Polyspace Bug Finder reports duplicate code using these checkers. Using these checkers, you can find opportunities for refactoring your code into more maintainable modules.

| Defect | Description | Defect Group |
|---|---|---|
| `Duplicated code` | A section of code is duplicated in other places. | Good Practice |
| `Partially duplicated code` | A section of code is duplicated in other places with very minor changes. | Good Practice |
| `Possible copy-paste error` | A section of code is duplicated in other places with exactly one minor change. | Programming |

## Limitations of Duplicate Code Detection

The defect checker does not flag certain blocks as duplicates. For instance:

- The blocks of code considered duplicates have to typically consist of more than six consecutive lines. This restriction is put in place to prevent excess false positives. For instance, if a single line or a couple of lines is repeated in multiple places, this repetition is not an issue.
- The checker does not detect duplicate code sections containing the following constructs:

  - Conditional statements – `if`, `switch`, and so on.
  - Loops – `for`, `while`, and so on.

  The checker detects only those duplicate code sections that do not involve branching.
- The checker resolves preprocessor directives such as `#ifdef`-s before analyzing the code for duplicate blocks. For instance, depending on whether the macro `PCDEBUG` is defined or not, the lines in the following `#ifdef` form part of the analysis or get removed from the analysis:

  ```
  #ifdef PCDEBUG
  //Block of code
  #endif
  ```
