Prandtl number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Prandtl number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Prandtl numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Prandtl number vector must be  $n$  elements long.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu (Re,Pr)** — Nusselt number at each breakpoint in lookup table over Reynolds and Prandtl numbers  
unitless numerical array

Nusselt number at each breakpoint in its lookup table over the Reynolds and Prandtl numbers. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any pair of Reynolds

and Prandtl numbers. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`. By determining the Nusselt number, the table feeds the calculation from which the heat transfer coefficient between fluid and wall derives.

The Nusselt numbers must be greater than zero. They must align from top to bottom in order of increasing Reynolds number and from left to right in order of increasing Prandtl numbers. The number of rows must equal the size of the **Reynolds number vector for Nusselt number** parameter, and the number of columns must equal the size of the **Prandtl number vector for Nusselt number** parameter.

### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of `Tabulated data - Nusselt number vs. Reynolds number & Prandtl number`.

**Fouling factor** — Measure of thermal resistance due to fouling deposits  
1.6e-4 K/W (default) | scalar with units of temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient  
100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

### Effects and Initial Conditions

**Gas initial temperature** — Temperature in the gas 1 or gas 2 channel at the start of simulation  
293.15 K (default) | scalar with units of temperature

Temperature in the gas 1 or gas 2 channel at the start of simulation.

**Gas 1|2 initial pressure** — Pressure in the gas 1 or gas 2 channel at the start of simulation  
0.101325 MPa (default) | scalar with units of pressure

Pressure in the gas 1 or gas 2 channel at the start of simulation.

## Version History

## Heat Exchanger (G-TL)

Heat exchanger for systems with gas and thermal liquid flows

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

### Description

The Heat Exchanger (G-TL) block models the complementary cooling and heating of fluids held briefly in thermal contact across a thin conductive wall. The wall can store heat in its bounds, adding to the heat transfer a slight transient delay that scales in proportion to its thermal mass. The fluids are single phase—pure gas on one side, pure liquid on the other. Neither fluid can switch phase and so, as latent heat is never released, the exchange is strictly one of sensible heat.

Sensible heat exchangers abound in machinery. The fuel heaters that in some jets keep ice from precipitating in fuel lines and from choking fuel strainers work by blasting bleed air still hot from the compressor over the fuel lines. The oil coolers that in some motorcycles keep lubricating oil from overheating work likewise by rushing ram air at ambient temperature over the oil lines. The bleed and ram air are gas flows and the fuel and oil are thermal liquid flows.

### Block Variants

The heat transfer model depends on the choice of block variant. The block has two variants: E-NTU Model and Simple Model. Use the **Modeling option** parameter to change the variant.

#### E-NTU Model

The default variant. Its heat transfer model derives from the Effectiveness-NTU method. Heat transfer in the steady state then proceeds at a fraction of the ideal rate which the flows, if kept each at its inlet temperature, and if cleared of every thermal resistance in between, could in theory support:

$$Q_{\text{Act}} = \epsilon Q_{\text{Max}}$$

where  $Q_{\text{Act}}$  the actual heat transfer rate,  $Q_{\text{Max}}$  is the ideal heat transfer rate, and  $\varepsilon$  is the fraction of the ideal rate actually observed in a real heat exchanger encumbered with losses. The fraction is the heat exchanger effectiveness, and it is a function of the number of transfer units, or NTU, a measure of the ease with which heat moves between flows, relative to the ease with which the flows absorb that heat:

$$NTU = \frac{1}{RC_{\text{Min}}},$$

where the fraction is the overall thermal conductance between the flows and  $C_{\text{Min}}$  is the smallest of the heat capacity rates from among the flows—that belonging to the flow least capable of absorbing heat. The heat capacity rate of a flow depends on the specific heat of the fluid ( $c_p$ ) and on its mass flow rate through the exchanger ( $\dot{m}$ ):

$$C = c_p \dot{m}.$$

The effectiveness depends also on the relative disposition of the flows, the number of passes between them, and the mixing condition for each. This dependence reflects in the effectiveness expression used, with different flow arrangements corresponding to different expressions. For a list of the effectiveness expressions, see the E-NTU Heat Transfer block.

### Flow Arrangement

Use the **Flow arrangement** block parameter to set how the flows meet in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those same tubes. The figure shows an example. The tube flow can make one pass through the shell flow (shown right) or, for greater exchanger effectiveness, multiple passes (left).

Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger, are assumed to manifest in the tabulated data.

### Mixing Condition

Use the **Cross flow arrangement** parameter to mix each of the flows, one of the flows, or none of the flows. Mixing in this context is the lateral movement of fluid in channels that have no internal barriers, normally guides, baffles, fins, or walls. Such movement serves to even out temperature variations in the transverse plane. Mixed flows have variable temperature in the longitudinal plane alone. Unmixed flows have variable temperature in both the transverse and longitudinal planes. The figure shows a mixed flow (**i**) and an unmixed flow (**ii**).

The distinction between mixed and unmixed flows is considered only in cross flow arrangements. There, longitudinal temperature variation in one fluid produces transverse temperature variation in the second fluid that mixing can even out. In counter and parallel flow arrangements, longitudinal temperature variation in one fluid produces longitudinal temperature variation in the second fluid and mixing, as it is of little effect here, is ignored.

#### **Effectiveness Curves**

Shell-and-tube exchangers with multiple passes (**iv.b-e** in the figure for 2, 3, and 4 passes) are most effective. Of exchangers with a single pass, those with counter flows (**ii**) are most effective and those with parallel flows (**i**) are least.

Cross-flow exchangers are intermediate in effectiveness, with mixing condition playing a factor. They are most effective when both flows are unmixed (**iii.a**) and least effective when both flows are mixed (**iii.b**). Mixing just the flow with the smallest heat capacity rate (**iii.c**) lowers the effectiveness more than mixing just the flow with the largest heat capacity rate (**iii.d**).

### Thermal Resistance

The overall thermal resistance,  $R$ , is the sum of the local resistances lining the heat transfer path. The local resistances arise from convection at the surfaces of the wall, conduction through the wall, and, if the wall sides are fouled, conduction through the layers of fouling. Expressed in order from gas side to thermal liquid side:

$$R = \frac{1}{U_G A_{Th,G}} + \frac{F_G}{A_{Th,G}} + R_W + \frac{F_{TL}}{A_{Th,TL}} + \frac{1}{U_{TL} A_{Th,TL}}$$

where  $U$  is the convective heat transfer coefficient,  $F$  is the fouling factor, and  $A_{Th}$  is the heat transfer surface area, each for the flow indicated in the subscript.  $R_W$  is the thermal resistance of the wall.

The wall thermal resistance and fouling factors are simple constants obtained from block parameters. The heat transfer coefficients are elaborate functions of fluid properties, flow geometry, and wall friction, and derive from standard empirical correlations between Reynolds, Nusselt, and Prandtl

numbers. The correlations depend on flow arrangement and mixing condition, and are detailed for each in the E-NTU Heat Transfer block on which the E-NTU Model variant is based.

### Thermal Mass

The wall is more than a thermal resistance for heat to pass through. It is also a thermal mass and, like the flows it divides, it can store heat in its bounds. The storage slows the transition between steady states so that a thermal perturbation on one side does not promptly manifest on the side across. The lag persists for the short time that it takes the heat flow rates from the two sides to balance each other. That time interval scales with the thermal mass of the wall:

$$C_{Q,W} = c_{p,W}M_W,$$

where  $c_{p,W}$  is the specific heat capacity and  $M_W$  the inertial mass of the wall. Their product gives the energy required to raise wall temperature by one degree. Use the **Wall thermal mass** block parameter to specify that product. The parameter is active when the **Wall thermal dynamics** setting is **On**.

Thermal mass is often negligible in low-pressure systems. Low pressure affords a thin wall with a transient response so fast that, on the time scale of the heat transfer, it is virtually instantaneous. The same is not true of high-pressure systems, common in the production of ammonia by the Haber process, where pressure can break 200 atmospheres. To withstand the high pressure, the wall is often thicker, and, as its thermal mass is heftier, so its transient response is slower.

Set the **Wall thermal dynamics** parameter to **Off** to ignore the transient lag, cut the differential variables that produce it, and, in reducing calculations, speed up the rate of simulation. Leave it **On** to capture the transient lag where it has a measurable effect. Experiment with the setting if necessary to determine whether to account for thermal mass. If simulation results differ to a considerable degree, and if simulation speed is not a factor, keep the setting **On**.

The wall, if modeled with thermal mass, is considered in halves. One half sits on the gas side and the other half sits on the thermal liquid side. The gas side is denoted side 1 and the thermal liquid side is denoted side 2. This notation is used in the calculations for heat transfer. The thermal mass divides evenly between the pair:

$$C_{Q,1} = C_{Q,2} = \frac{C_{Q,W}}{2}.$$

Energy is conserved in the wall. In the simple case of a wall half at steady state, heat gained from the fluid equals heat lost to the second half. The heat flows at the rate predicted by the E-NTU method for a wall without thermal mass. The rate is positive for heat flows directed from side 1 of the heat exchanger to side 2:

$$Q_1 = -Q_2 = \epsilon Q_{\text{Max}}.$$

In the transient state, the wall is in the course of storing or losing heat, and heat gained by one half no longer equals that lost to the second half. The difference in the heat flow rates varies over time in proportion to the rate at which the wall stores or loses heat. For side 1 of the heat exchanger:

$$Q_1 = \epsilon Q_{\text{Max}} + C_{Q,1}\dot{T}_{W,1},$$

where  $\dot{T}_{W,1}$  is the rate of change in temperature in the wall half. Its product with the thermal mass of the wall half gives the rate at which heat accumulates there. That rate is positive when temperature

rises and negative when it drops. The closer the rate is to zero the closer the wall is to steady state. For side 2 of the heat exchanger:  $Q_2 = -\epsilon Q_{\text{Max}} + C_{Q,2} \dot{T}_{W,2}$ ,

### Composite Structure

The E-NTU Model variant is a composite component built from simpler blocks. A Heat Exchanger Interface (G) block models the gas flow, a Heat Exchanger Interface (TL) block models the thermal liquid flow, and an E-NTU Heat Transfer block models the heat exchanged across the wall between the flows. The figure shows the block connections for the E-NTU Model block variant.

### Simple Model

The alternative variant. Its heat transfer model depends on the concept of *specific dissipation*, a measure of the heat transfer rate observed when gas and thermal liquid inlet temperatures differ by one degree. Its product with the inlet temperature difference gives the expected heat transfer rate:

$$Q = \xi(T_{\text{In,G}} - T_{\text{In,TL}}),$$

where  $\xi$  is specific dissipation and  $T_{\text{In}}$  is inlet temperature for gas (subscript G) or thermal liquid (subscript TL). The specific dissipation is a tabulated function of the mass flow rates into the exchanger through the gas and thermal liquid inlets:

$$\xi = f(\dot{m}_{\text{In,G}}, \dot{m}_{\text{In,TL}}),$$

To accommodate reverse flows, the tabulated data can extend over positive and negative flow rates, in which case the inlets can also be thought of as outlets. The data normally derives from measurement of heat transfer rate against temperature in a real prototype:

$$\xi = \frac{Q}{T_{\text{In,G}} - T_{\text{In,TL}}}.$$

The heat transfer model, as it relies almost entirely on tabulated data, and as that data normally derives from experiment, requires little detail about the exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger modeled, are assumed to manifest entirely in the tabulated data.

See the Specific Dissipation Heat Transfer block for more detail on the heat transfer calculations.

### Composite Structure

The Simple Model variant is a composite component. A Simple Heat Exchanger Interface (G) block models the gas flow and a Simple Heat Exchanger Interface (TL) block models the thermal liquid flow. Mass, momentum, and energy conservation in the flow channels derive from the corresponding

interface blocks. A Specific Dissipation Heat Transfer block captures the heat exchanged across the wall between the flows.

## Ports

### Conserving

**A1** — Gas port  
gas

Opening for gas to enter and exit its side of the heat exchanger.

**B1** — Gas port  
gas

Opening for gas to enter and exit its side of the heat exchanger.

**A2** — Thermal liquid port  
thermal liquid

Opening for thermal liquid to enter and exit its side of the heat exchanger.

**B2** — Thermal liquid port  
thermal liquid

Opening for thermal liquid to enter and exit its side of the heat exchanger.

## Parameters

**Modeling option** — Heat transfer model  
E-NTU Model | Simple model

Set the heat transfer model for the block.

### Block Variant: Simple Model

#### Heat Transfer

**Gas 1 mass flow rate vector, mdot1** — Mass flow rate of gas at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of gas at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of rows in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $m$  elements long.

**Thermal Liquid 2 mass flow rate vector, `mdot2`** — Mass flow rate of thermal liquid at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of thermal liquid at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Specific heat dissipation table, `SD(mdot1, mdot2)`** — Specific heat dissipation at each breakpoint in lookup table over mass flow rates of gas and thermal liquid  
numerical array with units of power over temperature

Specific heat dissipation at each breakpoint in its lookup table over the mass flow rates of gas and thermal liquid. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of gas and thermal liquid mass flow rates. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The specific heat dissipation values must be not be negative. They must align from top to bottom in order of increasing mass flow rate in the gas channel, and from left to right in order of increasing mass flow rate in the thermal liquid channel. The number of rows must equal the size of the **Gas 1 mass flow rate vector** parameter, and the number of columns must equal the size of the **Thermal liquid 2 mass flow rate vector** parameter.

**Check if violating maximum specific dissipation** — Warning condition for specific heat dissipation in excess of minimum heat capacity rate  
Warning (default) | None

Warning condition for specific heat dissipation in excess of minimum heat capacity rate. Heat capacity rate is the product of mass flow rate and specific heat, and its minimum value is the lowest between the flows. This minimum gives the specific dissipation for a heat exchanger with maximum effectiveness and cannot be exceeded. See the Specific Dissipation Heat Transfer block for more detail.

### Gas 1

**Mass flow rate vector** — Mass flow rate at each breakpoint in lookup table for pressure drop  
numerical array with units of mass per unit time

Mass flow rate at each breakpoint in the lookup table for the pressure drop. The block uses linear interpolation and nearest extrapolation to obtain the pressure drop at any mass flow rate.

The mass flow rates can be positive, zero, or negative and they can span across laminar, transient, and turbulent zones. The vector must have the same number of elements as the **Pressure drop vector** parameter and these elements must increase monotonically from left to right.

**Pressure drop vector** — Pressure drop at each breakpoint in lookup table over mass flow rate  
numerical array with units of pressure

Pressure drop at each breakpoint in its lookup table over the mass flow rate. The block uses linear interpolation and nearest extrapolation to obtain the pressure drop at any mass flow rate.

The pressure drops can be positive, zero, or negative, and they can span across laminar, transient, and turbulent zones. The vector must have the same number of elements as the **Mass flow rate vector** parameter and these elements must increase monotonically from left to right.

**Reference inflow temperature** — Absolute inlet temperature assumed in tabulated data  
293.15 K (default) | scalar with units of temperature

Absolute temperature established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Reference inflow pressure** — Absolute inlet pressure assumed in tabulated data  
0.101325 MPa (default) | scalar with units of pressure

Absolute pressure established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Mass flow rate threshold for flow reversal** — Upper bound of numerically smooth region for mass flow rate  
1e-3 kg/s (default) | scalar with units of mass/time

Mass flow rate below which its value is numerically smoothed to avoid discontinuities. See the Simple Heat Exchanger Interface block (on which the Simple Model variant is based) for detail on the calculations.

**Gas 1 volume** — Volume of fluid in the gas flow channel  
0.01 m<sup>3</sup> (default) | scalar with units of length cubed

Volume of fluid in the gas flow channel.

**Cross-sectional area at ports A1 and B1** — Flow area at the inlet and outlet of the flow channel  
0.01 m<sup>2</sup> (default) | scalar with units of length squared

Flow area at the inlet and outlet of the gas flow channel. Ports in the same flow channel are of the same size.

### Thermal Liquid 2

**Mass flow rate vector** — Mass flow rate at each breakpoint in lookup table for pressure drop  
numerical array with units of mass per unit time

Mass flow rate at each breakpoint in the lookup table for the pressure drop. The block uses linear interpolation and nearest extrapolation to obtain the pressure drop at any mass flow rate.

The mass flow rates can be positive, zero, or negative and they can span across laminar, transient, and turbulent zones. The vector must have the same number of elements as the **Pressure drop vector** parameter and these elements must increase monotonically from left to right.

**Pressure drop vector** — Pressure drop at each breakpoint in lookup table over mass flow rate  
numerical array with units of pressure

Pressure drop at each breakpoint in its lookup table over the mass flow rate. The block uses linear interpolation and nearest extrapolation to obtain the pressure drop at any mass flow rate.

The pressure drops can be positive, zero, or negative, and they can span across laminar, transient, and turbulent zones. The vector must have the same number of elements as the **Mass flow rate vector** parameter and these elements must increase monotonically from left to right.

**Reference inflow temperature** — Absolute inlet temperature assumed in tabulated data  
293.15 K (default) | scalar with units of temperature

Absolute temperature established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Reference inflow pressure** — Absolute inlet pressure assumed in tabulated data  
0.101325 MPa (default) | scalar with units of pressure

Absolute pressure established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Threshold mass flow rate for flow reversal** — Upper bound of numerically smooth region for mass flow rate  
1e-3 kg/s (default) | scalar with units of mass/time

Mass flow rate below which its value is numerically smoothed to avoid discontinuities. See the Simple Heat Exchanger Interface block (on which the Simple Model variant is based) for detail on the calculations.

**Fluid volume** — Volume of fluid in the thermal liquid flow channel  
0.01 m<sup>3</sup> (default) | scalar with units of length cubed

Volume of fluid in the thermal liquid flow channel.

**Cross-sectional area at ports A2 and B2** — Flow area at the inlet and outlet of the flow channel  
0.01 m<sup>2</sup> (default) | scalar with units of length squared

Flow area at the inlet and outlet of the thermal liquid flow channel. Ports in the same flow channel are of the same size.

### Block Variant: E-NTU Model

#### Common Tab

**Flow arrangement** — Manner in which the flows align in the heat exchanger  
Parallel or counter flow (default) | Shell and tube | Cross flow | Generic - effectiveness table

Manner in which the flows align in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those tubes. Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger.

**Number of shell passes** — Number of times the flow traverses the shell before exiting  
1 (default) | unitless scalar

Number of times the flow traverses the shell before exiting.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Cross flow type** — Mixing condition in each of the flow channels  
Both fluids mixed (default) | Both fluids unmixed | Thermal Liquid 1 mixed & Thermal Liquid 2 unmixed | Thermal Liquid 1 unmixed & Thermal Liquid 2 mixed

Mixing condition in each of the flow channels. Mixing in this context is the lateral movement of fluid as it proceeds along its flow channel toward the outlet. The flows remain separate from each other. Unmixed flows are common in channels with plates, baffles, or fins. This setting reflects in the effectiveness of the heat exchanger, with unmixed flows being most effective and mixed flows being least.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Number of heat transfer units vector, NTU** — Number of transfer units at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Number of transfer units at each breakpoint in the lookup table for the heat exchanger effectiveness number. The table is two-way, with both the number of transfer units and the thermal capacity ratio serving as independent coordinates. The block uses linear interpolation and nearest extrapolation to obtain the effectiveness at any number of transfer units.

The numbers specified must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of rows in the **Effectiveness table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the number of transfer units must be  $m$  elements long.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Generic - effectiveness table.

**Thermal capacity ratio vector, CR** — Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness. The table is two-way, with both the number of transfer units and the heat capacity rate ratio serving as independent coordinates. The block uses linear interpolation and nearest extrapolation to obtain the effectiveness at any thermal capacity ratio.

The thermal capacity ratios must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the thermal capacity ratio must be  $n$  elements long. The thermal capacity ratio is the fraction of minimum over maximum heat capacity rates.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of Generic - effectiveness table.

**Effectiveness table, E(NTU,CR)** — Heat exchanger effectiveness at each breakpoint in lookup table over the number of transfer units and thermal capacity ratio  
unitless numerical array

Heat exchanger effectiveness at each breakpoint in its lookup table over the number of transfer units and thermal capacity ratio. The block uses linear interpolation and nearest extrapolation to obtain the effectiveness at any pair of number of transfer units and thermal capacity ratio.

The effectiveness values must be not be negative. They must align from top to bottom in order of increasing number of transfer units and from left to right in order of increasing thermal capacity ratio. The number of rows must equal the size of the **Number of heat transfer units vector** parameter, and the number of columns must equal the size of the **Thermal capacity ratio vector** parameter.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of Generic - effectiveness table.

**Wall thermal dynamics** — Modeling assumption for transient response of wall to thermal changes  
Off (default) | On

Modeling assumption for the transient response of the wall to thermal changes. Set to On to impart a thermal mass to the wall and to capture the delay in its transient response to changes in temperature or heat flux. Such delays are relevant in thick walls, such as those required to sustain high pressures. The default setting assumes a wall thin enough for its transient response to be virtually instantaneous on the time scale of the heat transfer.

**Wall thermal mass** — Heat required to raise wall temperature by one degree  
447 J/K (default) | scalar with units of energy over temperature

Heat required to raise wall temperature by one degree. Thermal mass is the product of mass with specific heat and a measure of the ability to absorb heat. A wall with thermal mass has a transient response to sudden changes in surface temperature or heat flux. The larger the thermal mass, the slower that response, and the longer the time to steady state. The default value corresponds to a wall of stainless steel with a mass of approximately 1 kg.

#### Dependencies

This parameter applies solely to the **Wall thermal dynamics** setting of On.

**Wall thermal resistance** — Resistance of the wall to heat flow by thermal conduction  
1.6e-4 K/W (default) | scalar with units of temperature over power

Resistance of the wall to heat flow by thermal conduction. Wall resistance adds to convective and fouling resistances to determine the overall heat transfer coefficient between the flows.

**Gas 1**

**Minimum free-flow area** — Cross-sectional area of the flow channel at its narrowest point  
0.01 m<sup>2</sup> (default) | scalar with units of length squared

Total area of the flow cross section measured where the channel is its narrowest and the flow its fastest. If the channel is a collection of ducts, tubes, slots, or grooves, the area is the sum over the collection (minus any occlusion due to walls, ridges, plates, and other barriers).

**Hydraulic diameter for pressure loss** — Effective diameter of the flow channel at its narrowest point  
0.1 m (default) | scalar with units of length

Effective inner diameter of the flow at its narrowest point. For channels not circular in cross section, that diameter is of an imaginary circle equal in area to the flow cross section. Its value is the ratio of the minimum free-flow area to a fourth of its gross perimeter.

If the channel is a collection of ducts, tubes, slots, or grooves, the gross perimeter is the sum of the perimeters in the collection. If the channel is a single pipe or tube and it is circular in cross section, the hydraulic diameter is the same as the true diameter.

**Gas volume** — Total volume of fluid contained in the flow channel  
0.01 m<sup>3</sup> (default) | scalar with units of length squared

Total volume of fluid contained in the gas flow channel.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent zones  
2000 (default) | unitless scalar

Start of transition between laminar and turbulent zones. Above this number, inertial forces take hold and the flow grows progressively turbulent. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent zones  
4000 (default) | unitless scalar

End of transition between laminar and turbulent zones. Below this number, viscous forces take hold and the flow grows progressively laminar. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Pressure loss parameterization** — Mathematical model for pressure loss by viscous friction  
constant loss coefficient (default) | correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss by viscous friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (G) and Heat Exchanger Interface (TL) blocks for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
0.1 (default) | unitless scalar

Aggregate loss coefficient for all flow resistances in the flow channel—including the wall friction responsible for major loss and the local resistances, due to bends, elbows, and other geometry changes, responsible for minor loss.

The loss coefficient is an empirical dimensionless number commonly used to express the pressure loss due to viscous friction. It can be calculated from experimental data or, in some cases, obtained from product data sheets.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port

1 m (default) | unitless scalar with units of length

Total distance the flow must travel to reach across the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels in which the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to viscous friction at the wall.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes and Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed as a length

0.1 m (default) | scalar with units of length

Aggregate minor pressure loss expressed as a length. This length is that which all local resistances, such as elbows, tees, and unions, would add to the flow path if in their place was a simple wall extension. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Internal surface absolute roughness** — Mean height of surface protrusions behind wall friction

15e-6 m (default) | scalar with units of length

Mean height of the surface protrusions from which wall friction arises. Higher protrusions mean a rougher wall for more friction and so a steeper pressure loss. Surface roughness features in the Haaland correlation from which the Darcy friction factor derives and on which the pressure loss calculation depends.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions

64 (default) | unitless scalar

Pressure loss correction for flow cross section in laminar flow conditions. This parameter is commonly referred to as the shape factor. Its ratio to the Reynolds number gives the Darcy friction factor for the pressure loss calculation in the laminar zone. The default value belongs to cylindrical pipes and tubes.

The shape factor derives for certain shapes from the solution of the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96, as does a slender conduit between parallel plates.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in lookup table for Darcy friction factor

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Darcy friction factor. The block uses linear interpolation and nearest extrapolation to obtain the Darcy friction factor at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Darcy friction factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Tabulated data - Darcy friction factor vs. Reynolds number**.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in lookup table over Reynolds number

unitless numerical array

Darcy friction factor at each breakpoint in its lookup table over the Reynolds number. The block uses linear interpolation and nearest extrapolation to obtain the Darcy friction factor at any Reynolds number.

The Darcy friction factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Darcy friction factor** parameter, with which they are to combine to complete the tabulated breakpoints.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Tabulated data - Darcy friction factor vs. Reynolds number**.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in lookup table for Euler number

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Euler number. The block uses linear interpolation and nearest extrapolation to obtain the Euler number at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Euler number vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Euler number vector** — Euler number at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Euler number at each breakpoint in its lookup table over the Reynolds number. The block uses linear interpolation and nearest extrapolation to obtain the Euler number at any Reynolds number.

The Euler numbers must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Euler number** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Mathematical model for heat transfer between fluid and wall. The choice of model determines which expressions to apply and which parameters to specify for heat transfer calculation. See the E-NTU Heat Transfer block for the calculations by parameterization.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall  
0.4 m<sup>2</sup> (default) | scalar with units of length squared

Effective surface area used in heat transfer between fluid and wall. The effective surface area is the sum of primary and secondary surface areas, or those of the wall, where it is exposed to fluid, and of the fins, if any are used. Fin surface area is normally scaled by a fin efficiency factor.

**Fluid-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall  
0.4 m<sup>2</sup> (default) | unitless scalar

Heat transfer coefficient for convection between fluid and wall. Resistance due to fouling is captured separately in the **Fouling factor** parameter.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Constant heat transfer coefficient.

**Length of flow path for heat transfer** — Characteristic length traversed in heat transfer between fluid and wall  
1 m (default) | scalar with units of length

Characteristic length traversed in heat transfer between fluid and wall. This length factors in the calculation of the hydraulic diameter from which the heat transfer coefficient and the Reynolds number, as defined in the tabulated heat transfer parameterizations, derives.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow

3.66 (default) | positive unitless scalar

Constant assumed for Nusselt number in laminar flow. The Nusselt number factors in the calculation of the heat transfer coefficient between fluid and wall, on which the heat transfer rate depends. The default value belongs to cylindrical pipes and tubes.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Correlations for tubes.

**Reynolds number vector for Colburn factor** — Values of the Reynolds number at which to specify the Colburn factor data

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Colburn factor. The block uses linear interpolation and nearest extrapolation to obtain the Colburn factor at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Colburn factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in lookup table over Reynolds number

unitless numerical array

Colburn factor at each breakpoint in its lookup table over the Reynolds number. The block uses linear interpolation and nearest extrapolation to obtain the Euler number at any Reynolds number.

The Colburn factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Colburn factor** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block uses linear interpolation and nearest extrapolation to obtain the Nusselt number at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of rows in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Reynolds number vector must be  $m$  elements long.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Prandtl number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block uses linear interpolation and nearest extrapolation to obtain the Nusselt number at any Prandtl number.

The Prandtl numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Prandtl number vector must be  $n$  elements long.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu (Re,Pr)** — Nusselt number at each breakpoint in lookup table over Reynolds and Prandtl numbers  
unitless numerical array

Nusselt number at each breakpoint in its lookup table over the Reynolds and Prandtl numbers. The block uses linear interpolation and nearest extrapolation to obtain the Nusselt number at any pair of Reynolds and Prandtl numbers. By determining the Nusselt number, the table feeds the calculation from which the heat transfer coefficient between fluid and wall derives.

The Nusselt numbers must be greater than zero. They must align from top to bottom in order of increasing Reynolds number and from left to right in order of increasing Prandtl numbers. The number of rows must equal the size of the **Reynolds number vector for Nusselt number** parameter, and the number of columns must equal the size of the **Prandtl number vector for Nusselt number** parameter.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Fouling factor** — Measure of thermal resistance due to fouling deposits

1.6e-4 K/W (default) | scalar with units of temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient

100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

### **Thermal Liquid 2**

**Minimum free-flow area** — Cross-sectional area of the flow channel at its narrowest point

0.01 m<sup>2</sup> (default) | scalar with units of length squared

Total area of the flow cross section measured where the channel is its narrowest and the flow its fastest. If the channel is a collection of ducts, tubes, slots, or grooves, the area is the sum over the collection (minus any occlusion due to walls, ridges, plates, and other barriers).

**Hydraulic diameter for pressure loss** — Effective diameter of the flow channel at its narrowest point

0.1 m (default) | scalar with units of length

Effective inner diameter of the flow at its narrowest point. For channels not circular in cross section, that diameter is of an imaginary circle equal in area to the flow cross section. Its value is the ratio of the minimum free-flow area to a fourth of its gross perimeter.

If the channel is a collection of ducts, tubes, slots, or grooves, the gross perimeter is the sum of the perimeters in the collection. If the channel is a single pipe or tube and it is circular in cross section, the hydraulic diameter is the same as the true diameter.

**Liquid volume** — Total volume of fluid contained in the flow channel

0.01 m<sup>3</sup> (default) | scalar with units of length squared

Total volume of fluid contained in the thermal liquid flow channel.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent zones

2000 (default) | unitless scalar

Start of transition between laminar and turbulent zones. Above this number, inertial forces take hold and the flow grows progressively turbulent. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent zones

4000 (default) | unitless scalar

End of transition between laminar and turbulent zones. Below this number, viscous forces take hold and the flow grows progressively laminar. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Pressure loss parameterization** — Mathematical model for pressure loss by viscous friction  
 constant loss coefficient (default) | correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss by viscous friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (G) and Heat Exchanger Interface (TL) blocks for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
 0.1 (default) | unitless scalar

Aggregate loss coefficient for all flow resistances in the flow channel—including the wall friction responsible for major loss and the local resistances, due to bends, elbows, and other geometry changes, responsible for minor loss.

The loss coefficient is an empirical dimensionless number commonly used to express the pressure loss due to viscous friction. It can be calculated from experimental data or, in some cases, obtained from product data sheets.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port  
 1 m (default) | unitless scalar with units of length

Total distance the flow must travel to reach across the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels in which the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to viscous friction at the wall.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes and Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed as a length  
 0.1 m (default) | scalar with units of length

Aggregate minor pressure loss expressed as a length. This length is that which all local resistances, such as elbows, tees, and unions, would add to the flow path if in their place was a simple wall extension. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Internal surface absolute roughness** — Mean height of surface protrusions behind wall friction  
15e-6 m (default) | scalar with units of length

Mean height of the surface protrusions from which wall friction arises. Higher protrusions mean a rougher wall for more friction and so a steeper pressure loss. Surface roughness features in the Haaland correlation from which the Darcy friction factor derives and on which the pressure loss calculation depends.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions  
64 (default) | unitless scalar

Pressure loss correction for flow cross section in laminar flow conditions. This parameter is commonly referred to as the shape factor. Its ratio to the Reynolds number gives the Darcy friction factor for the pressure loss calculation in the laminar zone. The default value belongs to cylindrical pipes and tubes.

The shape factor derives for certain shapes from the solution of the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96, as does a slender conduit between parallel plates.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in lookup table for Darcy friction factor  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Darcy friction factor. The block uses linear interpolation and nearest extrapolation to obtain the Darcy friction factor at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Darcy friction factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Tabulated data - Darcy friction factor vs. Reynolds number**.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Darcy friction factor at each breakpoint in its lookup table over the Reynolds number. The block uses linear interpolation and nearest extrapolation to obtain the Darcy friction factor at any Reynolds number.

The Darcy friction factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Darcy friction factor** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Darcy friction factor vs. Reynolds number.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in lookup table for Euler number

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Euler number. The block uses linear interpolation and nearest extrapolation to obtain the Euler number at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Euler number vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Euler number vector** — Euler number at each breakpoint in lookup table over Reynolds number

unitless numerical array

Euler number at each breakpoint in its lookup table over the Reynolds number. The block uses linear interpolation and nearest extrapolation to obtain the Euler number at any Reynolds number.

The Euler numbers must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Euler number** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Mathematical model for heat transfer between fluid and wall. The choice of model determines which expressions to apply and which parameters to specify for heat transfer calculation. See the E-NTU Heat Transfer block for the calculations by parameterization.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall

0.4 m<sup>2</sup> (default) | scalar with units of length squared

Effective surface area used in heat transfer between fluid and wall. The effective surface area is the sum of primary and secondary surface areas, or those of the wall, where it is exposed to fluid, and of the fins, if any are used. Fin surface area is normally scaled by a fin efficiency factor.

**Fluid-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall

0.4 m<sup>2</sup> (default) | unitless scalar

Heat transfer coefficient for convection between fluid and wall. Resistance due to fouling is captured separately in the **Fouling factor** parameter.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Constant heat transfer coefficient.

**Length of flow path for heat transfer** — Characteristic length traversed in heat transfer between fluid and wall

1 m (default) | scalar with units of length

Characteristic length traversed in heat transfer between fluid and wall. This length factors in the calculation of the hydraulic diameter from which the heat transfer coefficient and the Reynolds number, as defined in the tabulated heat transfer parameterizations, derives.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow

3.66 (default) | positive unitless scalar

Constant assumed for Nusselt number in laminar flow. The Nusselt number factors in the calculation of the heat transfer coefficient between fluid and wall, on which the heat transfer rate depends. The default value belongs to cylindrical pipes and tubes.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Correlations for tubes.

**Reynolds number vector for Colburn factor** — Values of the Reynolds number at which to specify the Colburn factor data

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Colburn factor. The block uses linear interpolation and nearest extrapolation to obtain the Colburn factor at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Colburn factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Colburn factor at each breakpoint in its lookup table over the Reynolds number. The block uses linear interpolation and nearest extrapolation to obtain the Euler number at any Reynolds number.

The Colburn factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Colburn factor** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block uses linear interpolation and nearest extrapolation to obtain the Nusselt number at any Reynolds number.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of rows in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Reynolds number vector must be  $m$  elements long.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Prandtl number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block uses linear interpolation and nearest extrapolation to obtain the Nusselt number at any Prandtl number.

The Prandtl numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Prandtl number vector must be  $n$  elements long.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu (Re,Pr)** — Nusselt number at each breakpoint in lookup table over Reynolds and Prandtl numbers  
unitless numerical array

Nusselt number at each breakpoint in its lookup table over the Reynolds and Prandtl numbers. The block uses linear interpolation and nearest extrapolation to obtain the Nusselt number at any pair of Reynolds and Prandtl numbers. By determining the Nusselt number, the table feeds the calculation from which the heat transfer coefficient between fluid and wall derives.

The Nusselt numbers must be greater than zero. They must align from top to bottom in order of increasing Reynolds number and from left to right in order of increasing Prandtl numbers. The number of rows must equal the size of the **Reynolds number vector for Nusselt number** parameter, and the number of columns must equal the size of the **Prandtl number vector for Nusselt number** parameter.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Fouling factor** — Measure of thermal resistance due to fouling deposits  
1.6e-4 K/W (default) | scalar with units of temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient  
100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

#### Effects and Initial Conditions

**Gas 1 initial temperature** — Temperature in the gas channel at the start of simulation  
293.15 K (default) | scalar with units of temperature

Temperature in the gas channel at the start of simulation

**Gas 1 initial pressure** — Pressure in the gas channel at the start of simulation  
0.101325 MPa (default) | scalar with units of pressure

Pressure in the gas channel at the start of simulation.

**Thermal Liquid 2 dynamic compressibility** — Option to model pressure dynamics in the thermal liquid channel  
On (default) | Off

Option to model the pressure dynamics in the thermal liquid channel. Setting this parameter to Off removes the pressure derivative terms from the component energy and mass conservation equations. The pressure inside the heat exchanger is then reduced to the weighted average of the two port pressures.

**Thermal Liquid 2 initial temperature** — Temperature in the thermal liquid channel at the start of simulation

293.15 K (default) | scalar with units of temperature

Temperature in the thermal liquid channel at the start of simulation

**Thermal Liquid 2 initial pressure** — Pressure in the thermal liquid channel at the start of simulation

0.101325 MPa (default) | scalar with units of pressure

Pressure in the thermal liquid channel at the start of simulation.

## Heat Exchanger Interface (G)

Gas side of heat exchanger

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers / Fundamental Components

### Description

The Heat Exchanger Interface (G) block models thermal transfer by a gaseous flow within a heat exchanger. Use a second heat exchanger block to model the fluid pair. The interfaces can be in different fluid domains, such as one in liquid and one in gas. Use an E-NTU Heat Transfer block to couple the interfaces and capture the heat exchange between the fluids.

### Mass Balance

The fixed-volume construction of the block allows you to capture variations in fluid mass flow rates due to compressibility. The overall mass accumulation rate is equal to the sum of the mass flow rates through the ports:

$$\dot{M} = \dot{m}_A + \dot{m}_B,$$

where  $\dot{M}$  is the mass accumulation rate and  $\dot{m}$  is the mass flow rate. The subscripts denote ports **A** and **B**. The mass flow rate is positive when it is directed into the gas channel. Variations in density are reflected in the mass accumulation rate:

$$\dot{M} = \left[ \left( \frac{\partial \rho}{\partial p} \right)_u \frac{dp}{dt} + \left( \frac{\partial \rho}{\partial u} \right)_p \frac{du}{dt} \right] V,$$

where:

- $\rho$  is density.
- $p$  is pressure.
- $u$  is specific internal energy.
- $V$  is volume.

### Momentum Balance

Balancing momentum between the inlet and outlet ports of the heat exchanger dictates the flow direction and speed within the exchanger. Changes in momentum are due primarily due to friction losses from pipe turns, which translate to changes in pressure. Local resistances, such as bends, elbows, and tees can result in flow separation that leads to minor additional pressure losses. For steady flows, the mass flow rate remains constant.

A momentum balance is applied to each segment of the gas (pipe) volume. This figure shows a tube bank divided into two volumes and three nodes. The nodes correspond to ports **A**, **B**, and the fluid

volume, I. Fluid states, such as pressure and temperature, and fluid properties, such as density and viscosity, are defined at these nodes.

Note that flow inertia is negligible and the flow is considered to be quasi-steady state. The translation of transients to mass flow rates can be offset: due to coupling between density, pressure, and temperature, propagation of changes throughout the system is not instantaneous. Other sources and sinks of momentum, such as differences in head between ports or radial deformations of the channel wall, are not considered. The momentum balance for the half volume at port **A** is:

$$p_A - p_I = \Delta p_{f,A}$$

where  $p$  is the pressure at the node indicated in the subscript.  $\Delta p_{f,A}$  is the total pressure loss between the port node and the internal node due to friction. The total pressure loss includes both major and minor losses. For the half volume at port **B**, the momentum balance is:

$$p_B - p_I = \Delta p_{f,B}$$

### Friction

Pressure changes due to friction vary with the square of the mass flow rate for turbulent flows and with the magnitude of the mass flow rate for laminar flows. This pressure change is characterized by three dimensionless parameters: the Darcy friction factor, the pressure loss coefficient, and the Euler number. These numbers are calculated from empirical correlations or are estimated from lookup tables, depending on the **Pressure loss parameterization** parameter.

Classification of "laminar" or "turbulent" flow is based on the Reynolds number. When the Reynolds number is above the **Turbulent flow lower Reynolds number limit** parameter, the flow is fully turbulent. Below the **Laminar flow upper Reynolds number limit** parameter, the flow is fully laminar. Reynolds numbers in between these values indicate transitional flow. Transitional flows show characteristics of both laminar and turbulent flows. In the Simscape Fluids language, numerical blending is applied between these bounding values.

### Correlations for tubes

For tubes, the Darcy friction factor,  $f_D$ , is used. In the half volume at port **A**, the momentum balance is:

$$p_A - p_I = \frac{f_{D,A} \dot{m}_A |\dot{m}_A|}{2\rho_A D_H A_{\text{Min}}^2} \left( \frac{L + L_{\text{Add}}}{2} \right)$$

where  $L$  is the tube length and  $L_{\text{Add}}$  is the added tube length that would reproduce the minor viscous losses if used in place of elbows, tees, unions, or other local resistances.  $A$  is the tube cross-sectional area; in the event of a non-uniform cross-sectional area,  $A_{\text{min}}$  should be used.  $D_H$  is the tube hydraulic diameter, or the diameter of a circle equal in area to the tube cross section:

$$D_H = \sqrt{\frac{4A_{\text{Min}}}{\pi}}.$$

If the tube has a circular cross section, the hydraulic diameter and the tube diameter are the same.

For the half volume at port **B**, the momentum balance is:

$$p_B - p_I = \frac{f_{D,B} \dot{m}_B |\dot{m}_B| (L + L_{\text{Add}})}{2\rho_B D_H^2 A_{\text{Min}}^2}.$$

For turbulent flows, the Darcy friction factor is calculated with the Haaland correlation. The Reynolds number is established at the bounding port:

$$f_D = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2},$$

where  $\epsilon_R$  is wall roughness, taken as a characteristic height. This parameter is specified in the **Internal surface absolute roughness** parameter.

For laminar flows, the friction factor depends on the tube shape and is calculated with the tube shape factor:

$$f_D = \frac{\lambda}{\text{Re}},$$

where  $\lambda$  is the shape factor. The Reynolds number is calculated at the bounding port as:

$$\text{Re} = \frac{D_H \dot{m}}{\mu A_{\text{Min}}}.$$

Substituting  $\text{Re}$  into the pressure loss equation at port **A**, the momentum balance is reformulated as:

$$p_A - p_I = \frac{\lambda_A \mu_A \dot{m}_A}{2\rho_A D_H^2 A_{\text{Min}}^2} \left( \frac{L + L_{\text{Add}}}{2} \right),$$

Likewise, for the half volume at port **B**, the momentum balance is:

$$p_B - p_I = \frac{\lambda_B \mu_B \dot{m}_B}{2\rho_B D_H^2 A_{\text{Min}}^2} \left( \frac{L + L_{\text{Add}}}{2} \right).$$

### Using the constant loss coefficient

For channels other than tubes, use the pressure loss coefficient,  $\zeta$ . For turbulent flows in the half volume at port **A**, the momentum balance is:

$$p_A - p_I = \frac{1}{2} \zeta \frac{\dot{m}_A |\dot{m}_A|}{2\rho_A A_{\text{Min}}^2},$$

For turbulent flows in the half volume at port **B**, the momentum balance is:

$$p_B - p_I = \frac{1}{2} \xi \frac{\dot{m}_B |\dot{m}_B|}{2\rho_B A_{\text{Min}}^2},$$

For laminar flows in the half volume at port **A**, the momentum balance is:

$$p_A - p_I = \frac{1}{2} \xi \text{Re}_L \frac{\dot{m}_A \mu_A}{2D_H \rho_A A_{\text{Min}}},$$

where  $\text{Re}_L$  is the **Laminar flow upper Reynolds number limit** block parameter. For laminar flows in the half volume at port **B**, the momentum balance is:

$$p_B - p_I = \frac{1}{2} \xi \text{Re}_L \frac{\dot{m}_B \mu_B}{2D_H \rho_B A_{\text{Min}}}$$

#### Using Tabulated data - Darcy friction factor vs. Reynolds number

You can use tabulated data to determine the Darcy friction factor based on the Reynolds number for tube flows. For the half volume at port **A**, the momentum balance is:

$$p_A - p_I = \frac{f_{D,A} \dot{m}_A |\dot{m}_A|}{2\rho_A D_H A_{\text{Min}}^2} \left( \frac{L + L_{\text{Add}}}{2} \right).$$

For the half volume at port **B**, the momentum balance is:

$$p_B - p_I = \frac{f_{D,B} \dot{m}_B |\dot{m}_B|}{2\rho_B D_H A_{\text{Min}}^2} \left( \frac{L + L_{\text{Add}}}{2} \right).$$

For the turbulent regime, the friction factor is determined from a tabulated function of the Reynolds number:

$$f_D = f_D(\text{Re}).$$

The breakpoints of the tabulated function derive from the vector block parameters. The **Reynolds number vector for Darcy friction factor** parameter specifies the independent variable and the **Darcy friction factor vector** parameter specifies the dependent variable. Linear interpolation is applied between breakpoints. Outside of the tabulated data range, the nearest breakpoint determines the friction factor.

In the laminar regime, the friction factor is calculated from the shape factor,  $\lambda$ :

$$f_D = \frac{\lambda}{\text{Re}}.$$

#### Using Tabulated data - Euler number vs. Reynolds number

You can use tabulated data to determine the Euler number based on the Reynolds number. This calculation is dependent on flow regime, and the Euler number is formulated as a tabulated function of the Reynolds number:

$$\text{Eu} = \text{Eu}(\text{Re}).$$

The breakpoints in Tabulated data - Euler number vs. Reynolds number are specified by Reynolds number and Euler number vectors. The **Reynolds number vector for Euler number**

parameter specifies the independent variables, the Reynolds numbers, and the **Euler number vector** parameter specifies the dependent variable, the Euler number, at each Reynolds number. Linear interpolation is used to determine values between breakpoints. Outside of the tabulated data range, the value at the nearest breakpoint is used.

For turbulent flows, the momentum balance for the half volume at port **A** is:

$$p_A - p_I = \text{Eu}_A \frac{\dot{m}_A |\dot{m}_A|}{\rho_A A_{\text{Min}}^2},$$

where  $\text{Eu}$  is the Euler number at port **A**. For turbulent flows, the momentum balance for the half volume at port **B** is:

$$p_B - p_I = \text{Eu}_B \frac{\dot{m}_B |\dot{m}_B|}{\rho_B A_{\text{Min}}^2}.$$

For laminar flow in the half volume at port **A**, the momentum balance is:

$$p_A - p_I = \text{Eu}_L \text{Re}_L \frac{\dot{m}_A \mu_A}{4D_H \rho_A A_{\text{Min}}},$$

where  $\text{Re}_L$  is the **Laminar flow upper Reynolds number limit** parameter and  $\text{Eu}_L$  is the Euler number evaluated from tabulated data at that Reynolds number. For laminar flow in the half volume at port **B**, the momentum balance is:

$$p_B - p_I = \text{Eu}_L \text{Re}_L \frac{\dot{m}_B \mu_B}{4D_H \rho_B A_{\text{Min}}},$$

### Energy Balance

The energy balance within the gas volume is the sum of its flow rates across channel boundaries and the associated heat transfer. Energy can be transferred by advection at the ports and by convection at the wall. While conduction contributes to the energy balance at the ports, it is often negligible in comparison to advection. However, conduction is non-negligible in near-stationary fluids, such as when fluids are stagnant or changing direction. The energy balance equation is:

$$\dot{E}_{2P} = \phi_A + \phi_B + Q,$$

where:

- $\frac{\partial U}{\partial p}$  is the partial derivative of the internal energy of the gas volume with respect to pressure at constant temperature and volume.
- $p_I$  is the pressure of the gas volume.
- $\frac{\partial U}{\partial T}$  is the partial derivative of the internal energy of the gas volume with respect to temperature at constant pressure and volume.
- $T_I$  is the temperature of the gas volume.
- $\Phi_A$  and  $\Phi_B$  are energy flow rates at ports **A** and **B**, respectively.
- $Q$  is the heat transfer rate.

Advection and conduction are accounted for in  $\Phi$ , and convection is accounted for in  $Q$ . The heat transfer rate is positive when directed into the gas volume.

### Heat Transfer Rate

Heat transfer between the two heat exchanger fluids occurs in multiple ways: through convection at the fluid interfaces, conduction through layers of built-up fouling, and conduction through the thickness of the wall.

Heat transfer extends beyond the gas channel and therefore requires other blocks to model the entire heat exchanger system. A second heat exchanger interface block models the second flow channel while an E-NTU Heat Transfer block models the heat flow across the wall. Heat transfer parameters that are specific to the gas channel, but required by the E-NTU Heat Transfer block, are available through the physical signal ports:

- Port **C** outputs the heat capacity rate, which is a measure of the gas' ability to absorb heat and is required for calculating the number of heat transfer units (NTU). The heat capacity rate is calculated as:

$$C_R = c_p \dot{m},$$

where  $C_R$  is the heat capacity rate and  $c_p$  is the specific heat.

- Port **HC** outputs the heat transfer coefficient,  $U$ .

If the heat transfer coefficient is treated as a constant, its value is uniform across the flow channel. If the heat transfer coefficient is variable, it is calculated at each port from the expression:

$$U = \frac{Nu k}{D_{H,Q}},$$

where  $Nu$  is Nusselt number,  $k$  is thermal conductivity, and  $D_{H,Q}$  is a hydraulic diameter for heat transfer. The hydraulic diameter  $D_{H,Q}$  is calculated as:

$$D_{H,Q} = \frac{4A_{Min}L_Q}{S_Q},$$

where  $S_Q$  is the **Heat transfer surface area** parameter and  $L_Q$  is the **Length of flow path for heat transfer** parameter.

The lower bound of the mean heat transfer coefficient is the **Minimum gas-wall heat transfer coefficient** parameter.

### Nusselt Number

The Nusselt number is derived from empirical correlations with the Reynolds and Prandtl numbers. Use the **Heat transfer parametrization** parameter to select the most appropriate formulation for your simulation.

The simplest parameterization, **Constant heat transfer coefficient**, obtains the heat transfer coefficient directly from the value of the **Gas-wall heat transfer coefficient** parameter. **Correlations for tubes** uses analytical expressions with constant or calculated parameters to capture Nusselt number dependence on the flow regime for tube flows.

The remaining parameterizations are tabulated functions of the Reynolds number. These are useful for varying Nusselt numbers, or heat transfer coefficients, across flow regimes. The functions are generated from experimental data relating the Reynolds number to the Colburn factor or the Reynolds and Prandtl numbers to the Nusselt number.

### Constant heat transfer coefficient

Using **Constant heat transfer coefficient**, specified in the **Gas-wall heat transfer coefficient** parameter, sets the heat transfer coefficient as a constant, and does not use the Nusselt number in calculations. Use this parameterization as a simple approximation for gas flows confined to the laminar regime.

### Correlation for tubes

The Nusselt number depends on flow regime when using **Correlation for tubes**. For turbulent flows, its value changes in proportion to the Reynolds number and is calculated from the Gnielinski correlation:

$$\text{Nu} = \frac{\frac{f}{8}(\text{Re} - 1000)\text{Pr}}{1 + 12.7\sqrt{\frac{f}{8}(\text{Pr}^{2/3} - 1)}}$$

where Re is the Reynolds number, Nu is the Nusselt number, and Pr is the Prandtl number. The friction factor,  $f$ , is the same as the factor used in tube pressure loss calculations. For laminar flows, the Nusselt number is a constant. Its value is obtained from the **Nusselt number for laminar flow heat transfer** parameter,  $\text{Nu}_L$ :

$$\text{Nu} = \text{Nu}_L.$$

### Using Tabulated data - Colburn factor vs. Reynolds number

You can use tabulated data to determine the Colburn factor based on the Reynolds number. The Colburn equation is used to determine the Nusselt number, which varies in proportion to the Reynolds number. The Colburn  $j$ -factor is a measure of proportionality between the Reynolds, Prandtl, and Nusselt numbers:

$$\text{Nu} = j(\text{Re}_Q)\text{Re}_Q\text{Pr}^{1/3}.$$

$\text{Re}_Q$  is the Reynolds number based on the hydraulic diameter for heat transfer,  $D_{H,Q}$ , and from the minimum free-flow area of the channel,  $A_{\text{Min}}$ :

$$\text{Re}_Q = \frac{\dot{m}D_{H,Q}}{A_{\text{Min}}\mu}$$

### Using Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

You can use a tabulated function to determine the Nusselt number from the Prandtl and Reynolds numbers. Linear interpolation is used to determine values between breakpoints. The Nusselt number is a function of both Re and Pr, and therefore the **Reynolds number vector for Nusselt number**, **Prandtl number vector for Nusselt number**, and **Nusselt number table**,  $\text{Nu}(\text{Re}, \text{Pr})$  parameters define the table breakpoints:

$$\text{Nu} = \text{Nu}(\text{Re}_Q, \text{Pr}).$$

The tabulated Reynolds number must be calculated using the hydraulic diameter for heat transfer,  $D_{H,Q}$ .

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables” and “Initial Conditions for Blocks with Finite Gas Volume”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Gas port  
gas

Entry or exit point on the gas side of the heat exchanger.

**B** — Gas port  
gas

Entry or exit point on the gas side of the heat exchanger.

**H** — Thermal boundary  
thermal

Thermal boundary between the modeled fluid and the heat exchanger interface.

### Input

**C** — Heat capacity rate  
physical signal

Instantaneous value of the heat capacity rate for the gas flow, specified as a physical signal.

**HC** — Heat transfer coefficient  
physical signal

Instantaneous value of the heat transfer coefficient between gas flow and the wall, specified as a physical signal.

## Parameters

**Minimum free-flow area** — Cross-sectional area of flow channel at its narrowest point  
0.01 m<sup>2</sup> (default) | scalar with units of length squared

Cross-sectional area of the flow channel at its narrowest point. If the channel is a collection of ducts, tubes, slots, or grooves, this area is the sum of the areas in the collection, minus the blockage due to walls, ridges, plates, or other barriers.

**Hydraulic diameter** — Diameter or equivalent diameter of a circular channel  
0.1 m (default) | scalar with units of length

Effective inner diameter of the flow. If the diameter of the cross-section varies, the value of this parameter is the diameter at its narrowest point. For non-circular channels, the hydraulic diameter is the equivalent diameter of a circle with the same area of the existing channel.

If the channel is a collection of ducts, tubes, slots, or grooves, the gross perimeter is the sum of the perimeters in the collection. If the channel is a single pipe or tube that has a circular cross section, the hydraulic diameter is equal to the true diameter.

**Gas volume** — Total volume of fluid contained in flow channel  
0.01 m<sup>3</sup> (default) | scalar with units of length squared

Total volume of the fluid contained in the gas or thermal liquid flow channel.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent regimes  
2000 (default) | scalar

Start of the transition from the laminar regime to the turbulent regime. Above this number, inertial forces become increasingly dominant. The default value is given for circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent regimes  
4000 (default) | scalar

End of the transition from the laminar regime to the turbulent regime. Below this number, viscous forces become increasingly dominant. The default value is for circular pipes and tubes with smooth surfaces.

**Pressure loss parameterization** — Mathematical model for pressure loss due to friction  
constant loss coefficient (default) | correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss due to friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (TL) blocks for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
0.1 (default) | scalar

Aggregate loss coefficient for all flow resistances in the flow channel, including wall friction (major losses) and local resistances due to bends, elbows, and other geometry changes (minor losses).

The loss coefficient is an empirical, dimensionless number used to express the pressure losses due to friction. It can be calculated from experimental data or obtained from product data sheets.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port  
1 m (default) | scalar with units of length

Total distance the flow must travel between the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels

where the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to friction at the wall.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes or Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed in length

0.1 m (default) | scalar with units of length

Aggregate minor pressure loss, expressed as a length. The length of a straight channel results in equivalent losses to the sum of existing local resistances from elbows, tees, and unions. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes.

**Internal surface absolute roughness** — Mean height of wall surface variations that contribute to frictional losses

15e-6 m (default) | scalar with units of length

Mean height of the wall surface variations that contribute to frictional losses. The greater the mean height, the rougher the wall and the larger the pressure loss due to friction. Surface roughness is required to derive the Darcy friction factor from the Haaland correlation.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions

64 (default) | scalar

Pressure loss correction for laminar flow. This parameter is referred to as the shape factor, and can be used to derive the Darcy friction factor for pressure loss calculations in the laminar regime. The default value is for cylindrical pipes and tubes.

Some additional shape factors for non-circular cross-sections can be determined from analytical solutions to the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with an aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96. A slender conduit between parallel plates also has a shape factor of 96.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in Darcy friction factor lookup table

numerical array

Reynolds number at each breakpoint in the lookup table for the Darcy friction factor. The block interpolates between and extrapolates from the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is handled by the MATLAB® `linear` estimator and extrapolation is handled by the `nearest` function.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent regimes. The number of values in this vector must be equal to the size of the **Darcy friction factor vector** parameter to calculate tabulated breakpoints.

**Dependencies**

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in Reynolds number lookup table

numerical array

Darcy friction factor at each breakpoint in the lookup table of Reynolds numbers. The block interpolates between and extrapolates from the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is handled by the MATLAB `linear` estimator and extrapolation is handled by the nearest function.

The Darcy friction factor must not be negative and must align from left to right in order of increasing Reynolds number. The number of values in this vector must be equal to the size of the **Reynolds number vector for Darcy friction factor** parameter to calculate tabulated breakpoints.

**Dependencies**

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in the Euler number lookup table

numerical array

Reynolds number at each breakpoint in the Euler number lookup table. The block interpolates between and extrapolates from the breakpoints to obtain the Reynolds number at any Euler number. Interpolation is handled by the MATLAB `linear` estimator and extrapolation is handled by the nearest function.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent regimes. The number of values in this vector must be equal to the size of the **Euler number vector** parameter to calculate tabulated breakpoints.

**Dependencies**

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Euler number vs. Reynolds number.

**Euler number vector** — Euler number at each breakpoint in the Reynolds number lookup table

numerical array

Euler number at each breakpoint in the Reynolds number lookup table. The block interpolates between and extrapolates from the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is handled by the MATLAB `linear` estimator and extrapolation is handled by the nearest function.

The Euler number must not be negative and must align from left to right in order of increasing Reynolds number. The number of values in this vector must be equal to the size of the **Reynolds number vector for Euler number** parameter to calculate tabulated breakpoints.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Euler number vs. Reynolds number.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Mathematical model for heat transfer between the fluid and the wall. The choice of model determines which expressions to apply and which parameters to specify for heat transfer calculations. See the E-NTU Heat Transfer block for the calculations by parameterization.

**Gas-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall  
100 W/(m<sup>2</sup> \* K) (default) | scalar

Heat transfer coefficient for convection between the fluid and the wall.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Constant heat transfer coefficient.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall  
0.4 m<sup>2</sup> (default) | scalar with units of length squared

Effective surface area used in heat transfer between the fluid and the wall. The effective surface area is the sum of primary and secondary surface areas, the area where the wall is exposed to fluid and the fins, if any are used. Fin surface area is normally scaled by a fin efficiency factor.

**Length of flow path for heat transfer** — Characteristic length traversed in heat transfer between fluid and wall

1 m (default) | scalar with units of length

Characteristic length for heat transfer between fluid and wall. This length is used to determine the channel hydraulic diameter.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow

3.66 (default) | positive scalar

Constant value of the Nusselt number for laminar flows. The Nusselt number is required to calculate the heat transfer coefficient between the fluid and the wall. The default value is for cylindrical pipes and tubes.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Correlations for tubes.

**Reynolds number vector for Colburn factor** — Reynolds number at each breakpoint in Colburn factor lookup table

numerical array

Reynolds number at each breakpoint in the Colburn factor lookup table. The block interpolates between and extrapolates from the breakpoints to obtain the Colburn factor at any Reynolds number. Interpolation is handled by the MATLAB `linear` estimator and extrapolation is handled by the `nearest` function.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent regimes. The number of values in this vector must be equal to the size of the **Colburn factor vector** parameter to calculate tabulated breakpoints.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in Reynolds number lookup table

numerical array

The Colburn factor at each breakpoint in the Reynolds number lookup table. The block interpolates between and extrapolates from the breakpoints to obtain the Colburn factor at any Reynolds number. Interpolation is handled by the MATLAB `linear` estimator and extrapolation is handled by the `nearest` function.

The Colburn factor must be zero or positive and align from left to right in order of increasing Reynolds number. The number of values in this vector must be equal to the size of the **Reynolds number vector for Colburn factor** parameter to calculate tabulated breakpoints.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in Nusselt number lookup table

numerical array

The Reynolds number at each breakpoint in the Nusselt number lookup table. Either the Reynolds number or the Prandtl number can serve as an independent variable. The block interpolates between and extrapolates from the breakpoints to obtain the Nusselt number at any Reynolds number. Interpolation is handled by the MATLAB `linear` estimator and extrapolation is handled by the `nearest` function.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent regimes. The size of the vector must equal the number of rows in the **Nusselt number table, Nu(Re,Pr)** parameter. If the table has  $m$  rows and  $n$  columns, the Reynolds number vector must be  $m$  elements long.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in the Nusselt number lookup table  
numerical array

Prandtl number at each breakpoint in the Nusselt number lookup table. Either the Prandtl number or the Reynolds number can serve as an independent variable. The block interpolates between and extrapolates from the breakpoints to obtain the Nusselt number at any Prandtl number. Interpolation is handled by the MATLAB `linear` estimator and extrapolation is handled by the `nearest` function.

The Prandtl number must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent regimes. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Prandtl number vector must be  $n$  elements long.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu(Re,Pr)** — Nusselt number at each breakpoint in Reynolds-Prandtl number lookup table  
numerical array

The Nusselt number at each breakpoint in the Reynolds-Prandtl number lookup table. The block interpolates between and extrapolates from the breakpoints to obtain the Nusselt number at any pair of Reynolds and Prandtl numbers. The Nusselt number is required to calculate the heat transfer coefficient.

The Nusselt number must be greater than zero. Each value must align from top to bottom in order of increasing Reynolds number and from left to right in order of increasing Prandtl number. The number of rows must equal the size of the **Reynolds number vector for Nusselt number** parameter, and the number of columns must equal the size of the **Prandtl number vector for Nusselt number** parameter.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Threshold mass flow rate for flow reversal** — Upper bound of numerically smooth region for mass flow rate  
 $1e-4$  kg/s (default) | scalar with units of mass per unit time

The mass flow rate below which numerical smoothing is applied. This is employed to avoid discontinuity during flow stagnation. See the Simple Heat Exchanger Interface (G) block for more information about these calculations.

E-NTU Heat Transfer | Heat Exchanger Interface (TL)

# Heat Exchanger (TL)

Heat exchanger for systems with thermal liquid and controlled flows

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

## Description

The Heat Exchanger (TL) block models the cooling and heating of fluids through conduction over a thin wall. The properties of a single-phase thermal liquid are defined on the **Thermal Liquid** tab. The second fluid is a controlled fluid, which is specified only by the user-defined parameters on the **Controlled Fluid** tab. It does not receive any properties from the domain fluid network. The heat exchange between the fluids is based on the thermal liquid sensible heat.

## Block Variants

Two heat transfer models are available:

- The E-NTU Model
- The Simple Model

To set one of these models, use the **Modeling option** parameter.

### The E-NTU Model Variant

The E-NTU model, based on the Effectiveness-NTU method, is the block default variant. Steady-state heat transfer is determined based on a coefficient relating ideal to real losses in the system:

$$Q_{\text{Act}} = \epsilon Q_{\text{Max}}$$

where

- $Q_{\text{Act}}$  the actual heat transfer rate.

- $Q_{\text{Max}}$  is the ideal heat transfer rate.
- $\varepsilon$  is the heat exchanger effectiveness, which is based on the ratio of heat capacity rates,  $\frac{C_{\text{Min}}}{C_{\text{Max}}}$ , and the exchanger Number of Transfer Units:

$$NTU = \frac{1}{RC_{\text{Min}}},$$

where  $R$  is the overall thermal resistance, which is discussed in “Thermal Resistance” on page 1-1074 below.  $C_{\text{Min}}$  is the lesser heat capacity rate of the two fluids and  $C_{\text{Max}}$  is the greater heat capacity rate of the two fluids. The heat capacity rate is calculated as  $C = c_p \dot{m}$ .

Additionally, the exchanger effectiveness depends on the number of passes between the fluids and the fluid mixing conditions. For different parameterizations of  $\varepsilon$ , see E-NTU Heat Transfer. Connect an E-NTU Heat Transfer block to a Heat Exchanger (TL) block to specify the heat transfer properties in with the E-NTU method.

### Flow Arrangement

Use the **Flow arrangement** parameter to define the flow configuration in terms of pipe orientation or effectiveness tables. When using the shell-and-tube configuration, you can select the number of passes in the exchanger. A multi-pass exchanger resembles the image below.

A single-pass exchanger resembles the image below.

Other flow arrangements are possible through a generic parameterization by tabulated effectiveness data. This table does not require specific heat exchanger configuration details, such as flow arrangement, mixing, and passes, for modeling the heat transfer between the fluids.

### Mixing Condition

Use the **Cross flow type** parameter to model flows that are not restricted by baffles or walls, which homogenizes fluid temperature along the direction of flow of the second fluid and varies perpendicular to the second fluid flow. Unmixed flows vary in temperature both along and perpendicular to the flow direction of the second fluid. An example of a heat exchanger with one mixed and one unmixed fluid resembles the configuration below.

A heat exchanger with two unmixed fluids resembles the configuration below.

In counter and parallel flow arrangements, longitudinal temperature variation in one fluid results in a longitudinal change in temperature variation in the second fluid and mixing is not taken into account.

### Effectiveness Curves

Shell-and-tube exchangers with multiple passes (**iv.b-e** in the figure for 2, 3, and 4 passes) are the most effective type of heat exchanger. For single-pass heat exchangers, the counter-flow configuration (**ii**) is the most effective, and parallel flow (**i**) is the least.

Cross-flow exchangers are intermediate in effectiveness, with mixing condition playing a factor. They are most effective when both flows are unmixed (**iii.a**) and least effective when both flows are mixed (**iii.b**). Mixing just the flow with the smallest heat capacity rate (**iii.c**) lowers the effectiveness more than mixing just the flow with the largest heat capacity rate (**iii.d**).

### Thermal Resistance

The overall thermal resistance,  $R$ , is the sum of the local resistances to heat transfer due to convection, conduction, and fouling along the heat exchanger walls:

$$R = \frac{1}{U_{Th}A_{Th}} + \frac{F_{Th}}{A_{Th}} + R_W + \frac{F_C}{A_C} + \frac{1}{U_C A_C},$$

where:

- $U_{Th}$  is the heat transfer coefficient between the thermal liquid and the wall.
- $U_C$  is the heat transfer coefficient between the controlled fluid and the wall, which is received as a physical signal at port **HC2**.
- $F_{Th}$  is the thermal liquid **Fouling factor**.
- $F_C$  is the controlled fluid **Fouling factor**.
- $A_{Th}$  is the thermal liquid **Heat transfer surface area**.
- $A_C$  is the controlled fluid **Heat transfer surface area**.
- $R_W$  is the **Wall thermal resistance**.

The heat transfer coefficients depend on the heat exchanger configuration and fluid properties. See the E-NTU Heat Transfer reference page for more information.

### Composite Structure

When the Heat Exchanger (TL) block employs the E-NTU Model variant, it is a composite of the Heat Exchanger Interface (TL) and E-NTU Heat Transfer blocks:

### The Simple Model Variant

Heat transfer by the simple model is based on specific dissipation:

$$Q = \xi(T_{In,Th} - T_{In,C}),$$

where:

- $\xi$  is specific dissipation, which is a function of the mass flow rates of the thermal and controlled liquids.
- $T_{In,Th}$  is the thermal liquid inlet temperature.
- $T_{In,C}$  is the controlled liquid inlet temperature.

The simple model is based on linear interpolation of user-provided tabulated data and does not capture individual features of the heat exchanger.

### Composite Structure

When the Heat Exchanger (TL) block employs the Simple Model variant, it is a composite of the Simple Heat Exchanger Interface (TL) and Specific Dissipation Heat Transfer blocks:

## Ports

### Conserving

**A1** — Thermal liquid port  
thermal liquid

Opening for thermal liquid to enter and exit its side of the heat exchanger.

**B1** — Thermal liquid port  
thermal liquid

Opening for thermal liquid to enter and exit its side of the heat exchanger.

### Input

**C** — Heat capacity rate  
physical signal

Instantaneous value of the heat capacity rate for the controlled flow.

### Dependencies

This port is active only for the block variant of E-NTU Model.

**HC** — Heat transfer coefficient  
physical signal

Instantaneous value of the heat transfer coefficient between the controlled flow and the wall.

### Dependencies

This port is active only for the block variant of E-NTU Model.

**CP2** — Isobaric specific heat of controlled fluid  
physical signal

Instantaneous value of the isobaric specific heat for the controlled fluid.

### Dependencies

This port is active only for the block variant of Simple Model.

**M2** — Mass flow rate of controlled fluid  
physical signal

Instantaneous value of the mass flow rate of the controlled fluid.

### Dependencies

This port is active only for the block variant of `Simple Model`.

## Parameters

**Modeling option** — Heat transfer model

`E-NTU Model` | `Simple model`

Set the heat transfer model for the block.

### Block Variant: `Simple Model`

#### Heat Transfer Tab

**Thermal liquid mass flow rate vector** — Mass flow rate of thermal liquid at each breakpoint in lookup table for specific heat dissipation table

numerical array with units of mass over time

Mass flow rate of thermal liquid at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Controlled fluid mass flow rate vector** — Mass flow rate of controlled fluid at each breakpoint in lookup table for specific heat dissipation table

numerical array with units of mass over time

Mass flow rate of controlled fluid at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Specific heat dissipation table** — Specific heat dissipation at each breakpoint in lookup table over mass flow rates of thermal liquid and controlled fluid

numerical array with units of power over temperature

Specific heat dissipation at each breakpoint in its lookup table over the mass flow rates of thermal liquid and controlled fluid. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of thermal liquid and controlled fluid mass flow rates. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The specific heat dissipation values must not be negative. They must align from top to bottom in order of increasing mass flow rate in the thermal liquid channel, and from left to right in order of increasing mass flow rate in the controlled fluid channel. The number of rows must equal the size of

the **Thermal liquid mass flow rate vector** parameter, and the number of columns must equal the size of the **Controlled fluid mass flow rate vector** parameter.

**Check if violating maximum specific dissipation** — Warning condition for specific heat dissipation in excess of minimum heat capacity rate

Warning (default) | None

Warning condition for specific heat dissipation in excess of minimum heat capacity rate. Heat capacity rate is the product of mass flow rate and specific heat, and its minimum value is the lowest between the flows. This minimum gives the specific dissipation for a heat exchanger with maximum effectiveness and cannot be exceeded. See the Specific Dissipation Heat Transfer block for more detail.

#### **Pressure Loss Tab**

**Mass flow rate vector** — Mass flow rate at each breakpoint in lookup table for pressure drop  
numerical array with units of mass per unit time

Mass flow rate at each breakpoint in the lookup table for the pressure drop. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Pressure drop vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Pressure drop vector** — Pressure drop at each breakpoint in lookup table over mass flow rate  
numerical array with units of pressure

Pressure drop at each breakpoint in its lookup table over the mass flow rate. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The pressure drops can be positive, zero, or negative, and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Mass flow rate vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Reference inflow temperature** — Absolute inlet temperature assumed in tabulated data  
293.15 K (default) | scalar with units of temperature

Absolute temperature established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Reference inflow pressure** — Absolute inlet pressure assumed in tabulated data  
0.101325 MPa (default) | scalar with units of pressure

Absolute pressure established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Mass flow rate threshold for flow reversal** — Upper bound of numerically smooth region for mass flow rate

1e-3 kg/s (default) | scalar with units of mass/time

Mass flow rate below which its value is numerically smoothed to avoid discontinuities known to produce simulation errors at zero flow. See the Simple Heat Exchanger Interface (TL) block (on which the Simple Model variant is based) for detail on the calculations for the thermal liquid side of the exchanger.

**Thermal liquid volume** — Volume of fluid in the thermal liquid flow channel

0.01 m<sup>3</sup> (default) | scalar with units of length cubed

Volume of fluid in the thermal liquid flow channel.

**Cross-sectional area at ports A1 and B1** — Flow area at the inlet and outlet of the flow channel

0.01 m<sup>2</sup> (default) | scalar with units of length squared

Flow area at the inlet and outlet of the thermal liquid flow channel. The ports are of the same size.

### Block Variant: E-NTU Model

#### Common Tab

**Flow arrangement** — Manner in which the flows align in the heat exchanger

Parallel or counter flow (default) | Shell and tube | Cross flow | Generic - effectiveness table

Manner in which the flows align in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those tubes. Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger.

**Number of shell passes** — Number of times the flow traverses the shell before exiting

1 (default) | unitless scalar

Number of times the flow traverses the shell before exiting.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Cross flow type** — Mixing condition in each of the flow channels

Both fluids mixed (default) | Both fluids unmixed | Thermal liquid mixed & Controlled Fluid unmixed | Thermal liquid unmixed & Controlled Fluid mixed

Mixing condition in each of the flow channels. Mixing in this context is the lateral movement of fluid as it proceeds along its flow channel toward the outlet. The flows remain separate from each other. Unmixed flows are common in channels with plates, baffles, or fins. This setting reflects in the effectiveness of the heat exchanger, with unmixed flows being most effective and mixed flows being least.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Number of heat transfer units vector, NTU** — Number of transfer units at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Number of transfer units at each breakpoint in the lookup table for the heat exchanger effectiveness number. The table is two-way, with both the number of transfer units and the thermal capacity ratio serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any number of transfer units. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The numbers specified must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of rows in the **Effectiveness table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the number of transfer units must be  $m$  elements long.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Thermal capacity ratio vector, CR** — Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness. The table is two-way, with both the number of transfer units and the heat capacity rate ratio serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The thermal capacity ratios must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the thermal capacity ratio must be  $n$  elements long. The thermal capacity ratio is the fraction of minimum over maximum heat capacity rates.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Effectiveness table, E(NTU,CR)** — Heat exchanger effectiveness at each breakpoint in lookup table over the number of transfer units and thermal capacity ratio  
unitless numerical array

Heat exchanger effectiveness at each breakpoint in its lookup table over the number of transfer units and thermal capacity ratio. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of number of transfer units and thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The effectiveness values must be not be negative. They must align from top to bottom in order of increasing number of transfer units and from left to right in order of increasing thermal capacity ratio. The number of rows must equal the size of the **Number of heat transfer units vector** parameter, and the number of columns must equal the size of the **Thermal capacity ratio vector** parameter.

## Dependencies

This parameter applies solely to the **Flow arrangement** setting of Generic - effectiveness table.

**Wall thermal resistance** — Resistance of the wall to heat flow by thermal conduction

1.6e-4 K/W (default) | scalar with units of temperature over power

Resistance of the wall to heat flow by thermal conduction, and the inverse of thermal conductance, or the product of thermal conductivity with the ratio of surface area to length. Wall resistance adds to convective and fouling resistances to determine the overall heat transfer coefficient between the flows.

## Thermal liquid Tab

**Minimum free-flow area** — Cross-sectional area of the flow channel at its narrowest point

0.01 m<sup>2</sup> (default) | scalar with units of length squared

Cross-sectional area of the flow channel at its narrowest point. If the channel is a collection of ducts, tubes, slots, or grooves, the area is the sum of the areas in the collection—minus the occlusion due to walls, ridges, plates, or other barriers.

**Thermal liquid volume** — Total volume of fluid in the thermal liquid flow channel

0.01 m<sup>3</sup> (default) | scalar with units of length squared

Total volume of fluid contained in the thermal liquid flow channel.

**Hydraulic diameter for pressure loss** — Effective diameter of the flow channel at its narrowest point

0.1 m (default) | scalar with units of length

Effective inner diameter of the flow at its narrowest point. For channels not circular in cross section, that diameter is of an imaginary circle equal in area to the flow cross section. Its value is the ratio of the minimum free-flow area to a fourth of its gross perimeter.

If the channel is a collection of ducts, tubes, slots, or grooves, the gross perimeter is the sum of the perimeters in the collection. If the channel is a single pipe or tube and it is circular in cross section, the hydraulic diameter is the same as the true diameter.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent zones

2000 (default) | unitless scalar

Start of transition between laminar and turbulent zones. Above this number, inertial forces take hold and the flow grows progressively turbulent. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent zones

4000 (default) | unitless scalar

End of transition between laminar and turbulent zones. Below this number, viscous forces take hold and the flow grows progressively laminar. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Pressure loss parameterization** — Mathematical model for pressure loss by viscous friction  
constant loss coefficient (default) | correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss by viscous friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (TL) block for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
0.1 (default) | unitless scalar

Aggregate loss coefficient for all flow resistances in the flow channel—including the wall friction responsible for major loss and the local resistances, due to bends, elbows, and other geometry changes, responsible for minor loss.

The loss coefficient is an empirical dimensionless number commonly used to express the pressure loss due to viscous friction. It can be calculated from experimental data or, in some cases, obtained from product data sheets.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port  
1 m (default) | unitless scalar with units of length

Total distance the flow must travel to reach across the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels in which the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to viscous friction at the wall.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes and Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed as a length  
0.1 m (default) | scalar with units of length

Aggregate minor pressure loss expressed as a length. This length is that which all local resistances, such as elbows, tees, and unions, would add to the flow path if in their place was a simple wall extension. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Internal surface absolute roughness** — Mean height of surface protrusions behind wall friction  
15e-6 m (default) | scalar with units of length

Mean height of the surface protrusions from which wall friction arises. Higher protrusions mean a rougher wall for more friction and so a steeper pressure loss. Surface roughness features in the

Haaland correlation from which the Darcy friction factor derives and on which the pressure loss calculation depends.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions

64 (default) | unitless scalar

Pressure loss correction for flow cross section in laminar flow conditions. This parameter is commonly referred to as the shape factor. Its ratio to the Reynolds number gives the Darcy friction factor for the pressure loss calculation in the laminar zone. The default value belongs to cylindrical pipes and tubes.

The shape factor derives for certain shapes from the solution of the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96, as does a slender conduit between parallel plates.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in lookup table for Darcy friction factor

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Darcy friction factor. The block interpolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Darcy friction factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of **Tabulated data - Darcy friction factor vs. Reynolds number**.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in lookup table over Reynolds number

unitless numerical array

Darcy friction factor at each breakpoint in its lookup table over the Reynolds number. The block interpolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Darcy friction factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Darcy friction factor** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Darcy friction factor vs. Reynolds number.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in lookup table for Euler number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Euler number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Euler number vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Euler number vector** — Euler number at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Euler number at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Euler numbers must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Euler number** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Mathematical model for heat transfer between fluid and wall. The choice of model determines which expressions to apply and which parameters to specify for heat transfer calculation. See the E-NTU Heat Transfer block for the calculations by parameterization.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall  
0.4 m<sup>2</sup> (default) | scalar with units of length squared

Effective surface area used in heat transfer between fluid and wall. The effective surface area is the sum of primary and secondary surface areas, or those of the wall, where it is exposed to fluid, and of the fins, if any are used. Fin surface area is normally scaled by a fin efficiency factor.

**Thermal liquid-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall

0.4 m<sup>2</sup> (default) | unitless scalar

Heat transfer coefficient for convection between fluid and wall. Resistance due to fouling is captured separately in the **Fouling factor** parameter.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Constant heat transfer coefficient.

**Length of flow path for heat transfer** — Characteristic length traversed in heat transfer between fluid and wall

1 m (default) | scalar with units of length

Characteristic length traversed in heat transfer between fluid and wall. This length factors in the calculation of the hydraulic diameter from which the heat transfer coefficient and the Reynolds number, as defined in the tabulated heat transfer parameterizations, derives.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow

3.66 (default) | positive unitless scalar

Constant assumed for Nusselt number in laminar flow. The Nusselt number factors in the calculation of the heat transfer coefficient between fluid and wall, on which the heat transfer rate depends. The default value belongs to cylindrical pipes and tubes.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Correlations for tubes.

**Reynolds number vector for Colburn factor** — Values of the Reynolds number at which to specify the Colburn factor data

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Colburn factor. The block inter- and extrapolates the breakpoints to obtain the Colburn factor at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Colburn factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Colburn factor at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Colburn factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Colburn factor** parameter, with which they are to combine to complete the tabulated breakpoints.

#### **Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of rows in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Reynolds number vector must be  $m$  elements long.

#### **Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Prandtl number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Prandtl number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Prandtl numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Prandtl number vector must be  $n$  elements long.

#### **Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu (Re,Pr)** — Nusselt number at each breakpoint in lookup table over Reynolds and Prandtl numbers  
unitless numerical array

Nusselt number at each breakpoint in its lookup table over the Reynolds and Prandtl numbers. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any pair of Reynolds and Prandtl numbers. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`. By determining the Nusselt number, the table feeds the calculation from which the heat transfer coefficient between fluid and wall derives.

The Nusselt numbers must be greater than zero. They must align from top to bottom in order of increasing Reynolds number and from left to right in order of increasing Prandtl numbers. The number of rows must equal the size of the **Reynolds number vector for Nusselt number** parameter, and the number of columns must equal the size of the **Prandtl number vector for Nusselt number** parameter.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of `Tabulated data - Nusselt number vs. Reynolds number & Prandtl number`.

**Fouling factor** — Measure of thermal resistance due to fouling deposits  
1.6e-4 K/W (default) | scalar with units of temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient  
100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

#### Controlled Fluid Tab

**Heat transfer surface area** — Aggregate heat transfer surface area on the controlled fluid side  
0.4 m<sup>2</sup> (default) | scalar with units of length squared

Aggregate heat transfer surface area on the controlled fluid side

**Fouling factor** — Measure of thermal resistance due to fouling deposits  
1e-4 K/W (default) | scalar with units of length squared times temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the controlled fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient  
100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between the controlled fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

### **Effects and Initial Conditions**

**Thermal liquid initial temperature** — Temperature in the thermal liquid channel at the start of simulation

293.15 K (default) | scalar with units of temperature

Temperature in the thermal liquid channel at the start of simulation.

**Thermal liquid initial pressure** — Pressure in the thermal liquid channel at the start of simulation

0.101325 MPa (default) | scalar with units of pressure

Pressure in the thermal liquid channel at the start of simulation.

# Heat Exchanger (TL-TL)

Heat exchanger for systems with two thermal liquid flows

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

## Description

The Heat Exchanger (TL-TL) block models the complementary cooling and heating of fluids held briefly in thermal contact across a thin conductive wall. The wall can store heat in its bounds, adding to the heat transfer a slight transient delay that scales in proportion to its thermal mass. The fluids are single phase—each a thermal liquid. Neither fluid can switch phase and so, as latent heat is never released, the exchange is strictly one of sensible heat.

## Block Variants

The heat transfer model depends on the choice of block variant. The block has two variants: E-NTU Model and Simple Model. Use the **Modeling option** parameter to change the variant.

### E-NTU Model

The default variant. Its heat transfer model derives from the Effectiveness-NTU method. Heat transfer in the steady state then proceeds at a fraction of the ideal rate which the flows, if kept each at its inlet temperature, and if cleared of every thermal resistance in between, could in theory support:

$$Q_{\text{Act}} = \epsilon Q_{\text{Max}}$$

where  $Q_{\text{Act}}$  the actual heat transfer rate,  $Q_{\text{Max}}$  is the ideal heat transfer rate, and  $\epsilon$  is the fraction of the ideal rate actually observed in a real heat exchanger encumbered with losses. The fraction is the heat exchanger effectiveness, and it is a function of the number of transfer units, or NTU, a measure of the ease with which heat moves between flows, relative to the ease with which the flows absorb that heat:

$$NTU = \frac{1}{RC_{\text{Min}}},$$

where the fraction is the overall thermal conductance between the flows and  $C_{\text{Min}}$  is the smallest of the heat capacity rates from among the flows—that belonging to the flow least capable of absorbing heat. The heat capacity rate of a flow depends on the specific heat of the fluid ( $c_p$ ) and on its mass flow rate through the exchanger ( $\dot{m}$ ):

$$C = c_p \dot{m}.$$

The effectiveness depends also on the relative disposition of the flows, the number of passes between them, and the mixing condition for each. This dependence reflects in the effectiveness expression used, with different flow arrangements corresponding to different expressions. For a list of the effectiveness expressions, see the E-NTU Heat Transfer block.

### Flow Arrangement

Use the **Flow arrangement** parameter to set how the flows meet in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those same tubes. The figure shows an example. The tube flow can make one pass through the shell flow (shown right) or, for greater exchanger effectiveness, multiple passes (left).

Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger, are assumed to manifest in the tabulated data.

### Mixing Condition

Use the **Cross flow type** parameter to mix each of the flows, one of the flows, or none of the flows. Mixing in this context is the lateral movement of fluid in channels that have no internal barriers, normally guides, baffles, fins, or walls. Such movement serves to even out temperature variations in the transverse plane. Mixed flows have variable temperature in the longitudinal plane alone. Unmixed flows have variable temperature in both the transverse and longitudinal planes. The figure shows a mixed flow (**i**) and an unmixed flow (**ii**).

The distinction between mixed and unmixed flows is considered only in cross flow arrangements. There, longitudinal temperature variation in one fluid produces transverse temperature variation in the second fluid that mixing can even out. In counter and parallel flow arrangements, longitudinal temperature variation in one fluid produces longitudinal temperature variation in the second fluid and mixing, as it is of little effect here, is ignored.

#### Effectiveness Curves

Shell-and-tube exchangers with multiple passes (**iv.b-e** in the figure for 2, 3, and 4 passes) are most effective. Of exchangers with a single pass, those with counter flows (**ii**) are most effective and those with parallel flows (**i**) are least.

Cross-flow exchangers are intermediate in effectiveness, with mixing condition playing a factor. They are most effective when both flows are unmixed (**iii.a**) and least effective when both flows are mixed (**iii.b**). Mixing just the flow with the smallest heat capacity rate (**iii.c**) lowers the effectiveness more than mixing just the flow with the largest heat capacity rate (**iii.d**).

**Thermal Resistance**

The overall thermal resistance,  $R$ , is the sum of the local resistances lining the heat transfer path. The local resistances arise from convection at the surfaces of the wall, conduction through the wall, and, if the wall sides are fouled, conduction through the layers of fouling. Expressed in order from thermal liquid side 1 to thermal liquid side 2:

$$R = \frac{1}{U_1 A_{Th,1}} + \frac{F_1}{A_{Th,1}} + R_{W} + \frac{F_2}{A_{Th,2}} + \frac{1}{U_2 A_{Th,2}}$$

where  $U$  is the convective heat transfer coefficient,  $F$  is the fouling factor, and  $A_{Th}$  is the heat transfer surface area, each for the flow indicated in the subscript.  $R_W$  is the thermal resistance of the wall.

The wall thermal resistance and fouling factors are simple constants obtained from block parameters. The heat transfer coefficients are elaborate functions of fluid properties, flow geometry, and wall friction, and derive from standard empirical correlations between Reynolds, Nusselt, and Prandtl

numbers. The correlations depend on flow arrangement and mixing condition, and are detailed for each in the E-NTU Heat Transfer block on which the E-NTU Model variant is based.

### Thermal Mass

The wall is more than a thermal resistance for heat to pass through. It is also a thermal mass and, like the flows it divides, it can store heat in its bounds. The storage slows the transition between steady states so that a thermal perturbation on one side does not promptly manifest on the side across. The lag persists for the short time that it takes the heat flow rates from the two sides to balance each other. That time interval scales with the thermal mass of the wall:

$$C_{Q,W} = c_{p,W}M_W,$$

where  $c_{p,W}$  is the specific heat capacity and  $M_W$  the inertial mass of the wall. Their product gives the energy required to raise wall temperature by one degree. Use the **Wall thermal mass** parameter to specify that product. The parameter is active when the **Wall thermal dynamics** setting is **On**.

Thermal mass is often negligible in low-pressure systems. Low pressure affords a thin wall with a transient response so fast that, on the time scale of the heat transfer, it is virtually instantaneous. The same is not true of high-pressure systems, common in the production of ammonia by the Haber process, where pressure can break 200 atmospheres. To withstand the high pressure, the wall is often thicker, and, as its thermal mass is heftier, so its transient response is slower.

Set the **Wall thermal dynamics** parameter to **Off** to ignore the transient lag, cut the differential variables that produce it, and, in reducing calculations, speed up the rate of simulation. Leave it **On** to capture the transient lag where it has a measurable effect. Experiment with the setting if necessary to determine whether to account for thermal mass. If simulation results differ to a considerable degree, and if simulation speed is not a factor, keep the setting **On**.

The wall, if modeled with thermal mass, is considered in halves. One half sits on thermal liquid side 1 and the other half sits on thermal liquid side 2. The thermal mass divides evenly between the pair:

$$C_{Q,1} = C_{Q,2} = \frac{C_{Q,W}}{2}.$$

Energy is conserved in the wall. In the simple case of a wall half at steady state, heat gained from the fluid equals heat lost to the second half. The heat flows at the rate predicted by the E-NTU method for a wall without thermal mass. The rate is positive for heat flows directed from side 1 of the heat exchanger to side 2:

$$Q_1 = -Q_2 = \epsilon Q_{\text{Max}}.$$

In the transient state, the wall is in the course of storing or losing heat, and heat gained by one half no longer equals that lost to the second half. The difference in the heat flow rates varies over time in proportion to the rate at which the wall stores or loses heat. For side 1 of the heat exchanger:

$$Q_1 = \epsilon Q_{\text{Max}} + C_{Q,1} \dot{T}_{W,1},$$

where  $\dot{T}_{W,1}$  is the rate of change in temperature in the wall half. Its product with the thermal mass of the wall half gives the rate at which heat accumulates there. That rate is positive when temperature rises and negative when it drops. The closer the rate is to zero the closer the wall is to steady state.

For side 2 of the heat exchanger:  $Q_2 = -\epsilon Q_{\text{Max}} + C_{Q,2} \dot{T}_{W,2}$ ,

### Composite Structure

The E-NTU Model variant is a composite component built from simpler blocks. A Heat Exchanger Interface (TL) block models the thermal liquid flow on side 1 of the heat exchanger. Another models the thermal liquid flow on side 2. An E-NTU Heat Transfer block models the heat exchanged across the wall between the flows. The figure shows the block connections for the E-NTU Model block variant.

### Simple Model

The alternative variant. Its heat transfer model depends on the concept of *specific dissipation*, a measure of the heat transfer rate observed when thermal liquid 1 and thermal liquid 2 inlet temperatures differ by one degree. Its product with the inlet temperature difference gives the expected heat transfer rate:

$$Q = \xi(T_{In,1} - T_{In,2}),$$

where  $\xi$  is specific dissipation and  $T_{in}$  is inlet temperature for thermal liquid 1 (subscript 1) or thermal liquid 2 (subscript 2). The specific dissipation is a tabulated function of the mass flow rates into the exchanger through the thermal liquid 1 and thermal liquid 2 inlets:

$$\xi = f(\dot{m}_1, \dot{m}_2)$$

To accommodate reverse flows, the tabulated data can extend over positive and negative flow rates, in which case the inlets can also be thought of as outlets. The data normally derives from measurement of heat transfer rate against temperature in a real prototype:

$$\xi = \frac{Q}{T_{In,1} - T_{In,2}}$$

The heat transfer model, as it relies almost entirely on tabulated data, and as that data normally derives from experiment, requires little detail about the exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger modeled, are assumed to manifest entirely in the tabulated data.

See the Specific Dissipation Heat Transfer block for more detail on the heat transfer calculations.

### Composite Structure

The Simple Model variant is a composite component. A Simple Heat Exchanger Interface (TL) block models the thermal liquid flow on side 1 of the heat exchanger. Another models the thermal liquid flow on side 2. A Specific Dissipation Heat Transfer block captures the heat exchanged across the wall between the flows.

## Ports

### Conserving

**A1** — Thermal liquid 1 port  
thermal liquid

Opening for thermal liquid 1 to enter and exit its side of the heat exchanger.

**B1** — Thermal liquid 1 port  
thermal liquid

Opening for thermal liquid 1 to enter and exit its side of the heat exchanger.

**A2** — Thermal liquid 2 port  
thermal liquid

Opening for thermal liquid 2 to enter and exit its side of the heat exchanger.

**B2** — Thermal liquid 2 port  
thermal liquid

Opening for thermal liquid 2 to enter and exit its side of the heat exchanger.

## Parameters

**Modeling option** — Heat transfer model  
E-NTU Model | Simple model

Set the heat transfer model for the block.

### Block Variant: Simple Model

#### Heat Transfer Tab

**Thermal Liquid 1 mass flow rate vector** — Mass flow rate of thermal liquid 1 at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of thermal liquid 1 at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB linear type and extrapolation is nearest.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Thermal Liquid 2 mass flow rate vector** — Mass flow rate of thermal liquid 2 at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of thermal liquid 2 at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Specific heat dissipation table** — Specific heat dissipation at each breakpoint in lookup table over mass flow rates of thermal liquid 1 and thermal liquid 2  
numerical array with units of power over temperature

Specific heat dissipation at each breakpoint in its lookup table over the mass flow rates of thermal liquid 1 and thermal liquid 2. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of thermal liquid 1 and thermal liquid 2 mass flow rates. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The specific heat dissipation values must not be negative. They must align from top to bottom in order of increasing mass flow rate in the thermal liquid 1 channel, and from left to right in order of increasing mass flow rate in the thermal liquid 2 channel. The number of rows must equal the size of the **Thermal liquid 1 mass flow rate vector** parameter, and the number of columns must equal the size of the **Thermal liquid 2 mass flow rate vector** parameter.

**Check if violating maximum specific dissipation** — Warning condition for specific heat dissipation in excess of minimum heat capacity rate  
Warning (default) | None

Warning condition for specific heat dissipation in excess of minimum heat capacity rate. Heat capacity rate is the product of mass flow rate and specific heat, and its minimum value is the lowest between the flows. This minimum gives the specific dissipation for a heat exchanger with maximum effectiveness and cannot be exceeded. See the Specific Dissipation Heat Transfer block for more detail.

### Thermal Liquid 1|2 Tab

**Mass flow rate vector** — Mass flow rate at each breakpoint in lookup table for pressure drop  
numerical array with units of mass per unit time

Mass flow rate at each breakpoint in the lookup table for the pressure drop. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Pressure drop vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Pressure drop vector** — Pressure drop at each breakpoint in lookup table over mass flow rate  
numerical array with units of pressure

Pressure drop at each breakpoint in its lookup table over the mass flow rate. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The pressure drops can be positive, zero, or negative, and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Mass flow rate vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Reference inflow temperature** — Absolute inlet temperature assumed in tabulated data  
293.15 K (default) | scalar with units of temperature

Absolute temperature established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Reference inflow pressure** — Absolute inlet pressure assumed in tabulated data  
0.101325 MPa (default) | scalar with units of pressure

Absolute pressure established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Threshold mass flow rate for flow reversal** — Upper bound of numerically smooth region for mass flow rate  
1e-3 kg/s (default) | scalar with units of mass/time

Mass flow rate below which its value is numerically smoothed to avoid discontinuities known to produce simulation errors at zero flow. See the Simple Heat Exchanger Interface (TL) block (on which the Simple Model variant is based) for detail on the calculations.

**Fluid volume** — Volume of fluid in the thermal liquid 1 or thermal liquid 2 flow channel  
0.01 m<sup>3</sup> (default) | scalar with units of length cubed

Volume of fluid in the thermal liquid 1 or thermal liquid 2 flow channel.

**Cross-sectional area at ports A and B** — Flow area at the inlet and outlet of the flow channel  
0.01 m<sup>2</sup> (default) | scalar with units of length squared

Flow area at the inlet and outlet of the thermal liquid 1 or thermal liquid 2 flow channel. Ports in the same flow channel are of the same size.

### Block Variant: E-NTU Model

#### Common Tab

**Flow arrangement** — Manner in which the flows align in the heat exchanger  
Parallel or counter flow (default) | Shell and tube | Cross flow | Generic - effectiveness table

Manner in which the flows align in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those tubes. Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger.

**Number of shell passes** — Number of times the flow traverses the shell before exiting  
1 (default) | unitless scalar

Number of times the flow traverses the shell before exiting.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Cross flow type** — Mixing condition in each of the flow channels  
Both fluids mixed (default) | Both fluids unmixed | Thermal Liquid 1 mixed & Thermal Liquid 2 unmixed | Thermal Liquid 1 unmixed & Thermal Liquid 2 mixed

Mixing condition in each of the flow channels. Mixing in this context is the lateral movement of fluid as it proceeds along its flow channel toward the outlet. The flows remain separate from each other. Unmixed flows are common in channels with plates, baffles, or fins. This setting reflects in the effectiveness of the heat exchanger, with unmixed flows being most effective and mixed flows being least.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Number of heat transfer units vector, NTU** — Number of transfer units at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Number of transfer units at each breakpoint in the lookup table for the heat exchanger effectiveness number. The table is two-way, with both the number of transfer units and the thermal capacity ratio serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any number of transfer units. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The numbers specified must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of rows in the **Effectiveness table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the number of transfer units must be  $m$  elements long.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Generic - effectiveness table.

**Thermal capacity ratio vector, CR** — Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness. The table is two-way, with both the number of transfer units and the heat capacity rate ratio serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the

effectiveness at any thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The thermal capacity ratios must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the thermal capacity ratio must be  $n$  elements long. The thermal capacity ratio is the fraction of minimum over maximum heat capacity rates.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Effectiveness table, E(NTU,CR)** — Heat exchanger effectiveness at each breakpoint in lookup table over the number of transfer units and thermal capacity ratio  
unitless numerical array

Heat exchanger effectiveness at each breakpoint in its lookup table over the number of transfer units and thermal capacity ratio. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of number of transfer units and thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The effectiveness values must be not be negative. They must align from top to bottom in order of increasing number of transfer units and from left to right in order of increasing thermal capacity ratio. The number of rows must equal the size of the **Number of heat transfer units vector** parameter, and the number of columns must equal the size of the **Thermal capacity ratio vector** parameter.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Wall thermal dynamics** — Modeling assumption for transient response of wall to thermal changes  
`Off` (default) | `On`

Modeling assumption for the transient response of the wall to thermal changes. Set to `On` to impart a thermal mass to the wall and to capture the delay in its transient response to changes in temperature or heat flux. Such delays are relevant in thick walls, such as those required to sustain high pressures. The default setting assumes a wall thin enough for its transient response to be virtually instantaneous on the time scale of the heat transfer.

**Wall thermal mass** — Heat required to raise wall temperature by one degree  
`447 J/K` (default) | scalar with units of energy over temperature

Heat required to raise wall temperature by one degree. Thermal mass is the product of mass with specific heat and a measure of the ability to absorb heat. A wall with thermal mass has a transient response to sudden changes in surface temperature or heat flux. The larger the thermal mass, the slower that response, and the longer the time to steady state. The default value corresponds to a wall of stainless steel with a mass of approximately 1 kg.

#### Dependencies

This parameter applies solely to the **Wall thermal dynamics** setting of `On`.

**Wall thermal resistance** — Resistance of the wall to heat flow by thermal conduction

1.6e-4 K/W (default) | scalar with units of temperature over power

Resistance of the wall to heat flow by thermal conduction, and the inverse of thermal conductance, or the product of thermal conductivity with the ratio of surface area to length. Wall resistance adds to convective and fouling resistances to determine the overall heat transfer coefficient between the flows.

#### **Thermal Liquid 1|2 Tab**

**Minimum free-flow area** — Cross-sectional area of the flow channel at its narrowest point

0.01 m<sup>2</sup> (default) | scalar with units of length squared

Cross-sectional area of the flow channel at its narrowest point. If the channel is a collection of ducts, tubes, slots, or grooves, the area is the sum of the areas in the collection—minus the occlusion due to walls, ridges, plates, or other barriers.

**Fluid volume** — Total volume of fluid in the thermal liquid 1 or thermal liquid 2 flow channel

0.01 m<sup>3</sup> (default) | scalar with units of length squared

Total volume of fluid contained in the thermal liquid 1 or thermal liquid 2 flow channel.

**Hydraulic diameter for pressure loss** — Effective diameter of the flow channel at its narrowest point

0.1 m (default) | scalar with units of length

Effective inner diameter of the flow at its narrowest point. For channels not circular in cross section, that diameter is of an imaginary circle equal in area to the flow cross section. Its value is the ratio of the minimum free-flow area to a fourth of its gross perimeter.

If the channel is a collection of ducts, tubes, slots, or grooves, the gross perimeter is the sum of the perimeters in the collection. If the channel is a single pipe or tube and it is circular in cross section, the hydraulic diameter is the same as the true diameter.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent zones

2000 (default) | unitless scalar

Start of transition between laminar and turbulent zones. Above this number, inertial forces take hold and the flow grows progressively turbulent. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent zones

4000 (default) | unitless scalar

End of transition between laminar and turbulent zones. Below this number, viscous forces take hold and the flow grows progressively laminar. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Pressure loss parameterization** — Mathematical model for pressure loss by viscous friction

constant loss coefficient (default) | correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss by viscous friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (TL) block for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
0.1 (default) | unitless scalar

Aggregate loss coefficient for all flow resistances in the flow channel—including the wall friction responsible for major loss and the local resistances, due to bends, elbows, and other geometry changes, responsible for minor loss.

The loss coefficient is an empirical dimensionless number commonly used to express the pressure loss due to viscous friction. It can be calculated from experimental data or, in some cases, obtained from product data sheets.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port  
1 m (default) | unitless scalar with units of length

Total distance the flow must travel to reach across the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels in which the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to viscous friction at the wall.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes and Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed as a length  
0.1 m (default) | scalar with units of length

Aggregate minor pressure loss expressed as a length. This length is that which all local resistances, such as elbows, tees, and unions, would add to the flow path if in their place was a simple wall extension. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Internal surface absolute roughness** — Mean height of surface protrusions behind wall friction  
15e-6 m (default) | scalar with units of length

Mean height of the surface protrusions from which wall friction arises. Higher protrusions mean a rougher wall for more friction and so a steeper pressure loss. Surface roughness features in the Haaland correlation from which the Darcy friction factor derives and on which the pressure loss calculation depends.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions  
64 (default) | unitless scalar

Pressure loss correction for flow cross section in laminar flow conditions. This parameter is commonly referred to as the shape factor. Its ratio to the Reynolds number gives the Darcy friction factor for the pressure loss calculation in the laminar zone. The default value belongs to cylindrical pipes and tubes.

The shape factor derives for certain shapes from the solution of the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96, as does a slender conduit between parallel plates.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in lookup table for Darcy friction factor  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Darcy friction factor. The block interpolates and extrapolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Darcy friction factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Tabulated data - Darcy friction factor vs. Reynolds number**.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Darcy friction factor at each breakpoint in its lookup table over the Reynolds number. The block interpolates and extrapolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Darcy friction factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Darcy friction factor** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Darcy friction factor vs. Reynolds number.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in lookup table for Euler number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Euler number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Euler number vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Euler number vector** — Euler number at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Euler number at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Euler numbers must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Euler number** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Mathematical model for heat transfer between fluid and wall. The choice of model determines which expressions to apply and which parameters to specify for heat transfer calculation. See the E-NTU Heat Transfer block for the calculations by parameterization.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall  
0.4 m<sup>2</sup> (default) | scalar with units of length squared

Effective surface area used in heat transfer between fluid and wall. The effective surface area is the sum of primary and secondary surface areas, or those of the wall, where it is exposed to fluid, and of the fins, if any are used. Fin surface area is normally scaled by a fin efficiency factor.

**Liquid-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall

0.4 m<sup>2</sup> (default) | unitless scalar

Heat transfer coefficient for convection between fluid and wall. Resistance due to fouling is captured separately in the **Fouling factor** parameter.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Constant heat transfer coefficient.

**Length of flow path for heat transfer** — Characteristic length traversed in heat transfer between fluid and wall

1 m (default) | scalar with units of length

Characteristic length traversed in heat transfer between fluid and wall. This length factors in the calculation of the hydraulic diameter from which the heat transfer coefficient and the Reynolds number, as defined in the tabulated heat transfer parameterizations, derives.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow

3.66 (default) | positive unitless scalar

Constant assumed for Nusselt number in laminar flow. The Nusselt number factors in the calculation of the heat transfer coefficient between fluid and wall, on which the heat transfer rate depends. The default value belongs to cylindrical pipes and tubes.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Correlations for tubes.

**Reynolds number vector for Colburn factor** — Values of the Reynolds number at which to specify the Colburn factor data

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Colburn factor. The block inter- and extrapolates the breakpoints to obtain the Colburn factor at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Colburn factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Colburn factor at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Colburn factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Colburn factor** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of rows in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Reynolds number vector must be  $m$  elements long.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Prandtl number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Prandtl number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Prandtl numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Prandtl number vector must be  $n$  elements long.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu (Re,Pr)** — Nusselt number at each breakpoint in lookup table over Reynolds and Prandtl numbers  
unitless numerical array

Nusselt number at each breakpoint in its lookup table over the Reynolds and Prandtl numbers. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any pair of Reynolds and Prandtl numbers. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`. By determining the Nusselt number, the table feeds the calculation from which the heat transfer coefficient between fluid and wall derives.

The Nusselt numbers must be greater than zero. They must align from top to bottom in order of increasing Reynolds number and from left to right in order of increasing Prandtl numbers. The number of rows must equal the size of the **Reynolds number vector for Nusselt number** parameter, and the number of columns must equal the size of the **Prandtl number vector for Nusselt number** parameter.

### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of `Tabulated data - Nusselt number vs. Reynolds number & Prandtl number`.

**Fouling factor** — Measure of thermal resistance due to fouling deposits  
1.6e-4 K/W (default) | scalar with units of temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient  
100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

### Effects and Initial Conditions

**Thermal liquid dynamic compressibility** — Option to model pressure dynamics in the thermal liquid channel  
On (default) | Off

Option to model the pressure dynamics in the thermal liquid 1 or thermal liquid 2 channel. Setting this parameter to `Off` removes the pressure derivative terms from the component energy and mass conservation equations. The pressure inside the heat exchanger is then reduced to the weighted average of the two port pressures.

**Thermal Liquid initial temperature** — Temperature in the thermal liquid 1 or thermal liquid 2 channel at the start of simulation  
293.15 K (default) | scalar with units of temperature

Temperature in the thermal liquid 1 or thermal liquid 2 channel at the start of simulation.

**Thermal Liquid 1|2 initial pressure** — Pressure in the thermal liquid 1 or thermal liquid 2 channel at the start of simulation

0.101325 MPa (default) | scalar with units of pressure

Pressure in the thermal liquid 1 or thermal liquid 2 channel at the start of simulation.

## Heat Exchanger Interface (TL)

Thermal interface between a thermal liquid and its surroundings

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers / Fundamental Components

### Description

The Heat Exchanger Interface (TL) block represents a liquid interface in a thermal liquid network for heat transfer with other fluids. The block models the pressure drop and temperature change between the thermal liquid inlet and outlet of a thermal interface and when combined with the E-NTU Heat Transfer block models the heat transfer rate across the interface between two fluids.

### Mass Balance

The form of the mass balance equation depends on the dynamic compressibility setting. If the **Fluid dynamic compressibility** parameter is set to *Off*, the mass balance equation is

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  and  $\dot{m}_B$  are the mass flow rates into the interface through ports **A** and **B**.

If the **Fluid dynamic compressibility** parameter is set to *On*, the mass balance equation is

$$\dot{m}_A + \dot{m}_B = \left( \frac{dp}{dt} \frac{1}{\beta} - \frac{dT}{dt} \alpha \right) \rho V,$$

where:

- $p$  is the pressure of the thermal liquid volume.
- $T$  is the temperature of the thermal liquid volume.
- $\alpha$  is the isobaric thermal expansion coefficient of the thermal liquid volume.
- $\beta$  is the isothermal bulk modulus of the thermal liquid volume.
- $\rho$  is the mass density of the thermal liquid volume.
- $V$  is the volume of thermal liquid in the heat exchanger interface.

### Momentum Balance

The momentum balance in the heat exchanger interface depends on the fluid dynamic compressibility setting. If the **Fluid dynamic compressibility** parameter is set to *On*, the momentum balance factors in the internal pressure of the heat exchanger interface explicitly. The momentum balance in the half volume between port **A** and the internal interface node is

$$p_A - p = \Delta p_{Loss,A},$$

while in the half volume between port **B** and the internal interface node it is

$$p_B - p = \Delta p_{Loss,B},$$

where:

- $p_A$  and  $p_B$  are the pressures at ports **A** and **B**.
- $p$  is the pressure in the internal node of the interface volume.
- $\Delta p_{Loss,A}$  and  $\Delta p_{Loss,B}$  are the pressure losses between port **A** and the internal interface node and between port **B** and the internal interface node.

If the **Fluid dynamic compressibility** parameter is set to **Off**, the momentum balance in the interface volume is computed directly between ports **A** and **B** as

$$p_A - p_B = \Delta p_{Loss,A} - \Delta p_{Loss,B}.$$

### Pressure Loss Calculations

The exact form of the pressure loss terms depends on the **Pressure loss parameterization** setting in the block dialog box. If the pressure loss parameterization is set to **Constant loss coefficient**, the pressure loss in the half volume adjacent to port **A** is

$$\Delta p_{Loss,A} = \begin{cases} \dot{m}_A \mu_A (CP)_{Loss} Re_L \frac{1}{4D_{h,p} \rho_A S_{Min}}, & Re_A \leq Re_L \\ (CP)_{Loss} \frac{\dot{m}_A |\dot{m}_A|}{4\rho_A S_{Min}^2}, & Re_A \geq Re_T \end{cases},$$

while in the half volume adjacent to port **B** it is

$$\Delta p_{Loss,B} = \begin{cases} \dot{m}_B \mu_B (CP)_{Loss} Re_L \frac{1}{4D_{h,p} \rho_B S_{Min}}, & Re_B \leq Re_L \\ (CP)_{Loss} \frac{\dot{m}_B |\dot{m}_B|}{4\rho_B S_{Min}^2}, & Re_B \geq Re_T \end{cases},$$

where:

- $\mu_A$  and  $\mu_B$  are the fluid dynamic viscosities at ports **A** and **B**.
- $CP_{Loss}$  is the **Pressure loss coefficient** parameter specified in the block dialog box.
- $Re_L$  is the Reynolds number upper bound for the laminar flow regime.
- $Re_T$  is the Reynolds number lower bound for the turbulent flow regime.
- $D_{h,p}$  is the hydraulic diameter for pressure loss calculations.
- $\rho_A$  and  $\rho_B$  are the fluid mass densities at ports **A** and **B**.
- $S_{Min}$  is the total minimum free-flow area.

If the pressure loss parameterization is set to **Correlations for tubes**, the pressure loss in the half volume adjacent to port **A** is

$$\Delta p_{Loss, A} = \begin{cases} \dot{m}_A \mu_A \lambda \frac{(L_{press} + L_{add})}{4D_{h,p} \rho_A S_{Min}}, & Re_A \leq Re_L \\ f_{T,A} \frac{(L_{press} + L_{add})}{4D_{h,p}} \frac{\dot{m}_A |\dot{m}_A|}{\rho_A S_{Min}^2}, & Re_A \geq Re_T \end{cases},$$

while in the half volume adjacent to port **B** it is

$$\Delta p_{Loss, B} = \begin{cases} \dot{m}_B \mu_B \lambda \frac{(L_{press} + L_{add})}{4D_{h,p} \rho_B S_{Min}}, & Re_B \leq Re_L \\ f_{T,B} \frac{(L_{press} + L_{add})}{4D_{h,p}} \frac{\dot{m}_B |\dot{m}_B|}{\rho_B S_{Min}^2}, & Re_B \geq Re_T \end{cases},$$

where:

- $L_{press}$  is the flow path length from inlet to outlet.
- $L_{add}$  is the aggregate equivalent length of local resistances.
- $f_{T,A}$  and  $f_{T,B}$  are the turbulent-regime Darcy friction factors at ports **A** and **B**.

The Darcy friction factor in the half volume adjacent to port **A** is

$$f_{T,A} = \frac{1}{\left[ -1.8 \log_{10} \left( \frac{6.9}{Re_A} + \frac{r}{3.7D_{h,p}} \right)^{1.11} \right]^2},$$

while in the half volume adjacent to port **B** it is

$$f_{T,B} = \frac{1}{\left[ -1.8 \log_{10} \left( \frac{6.9}{Re_B} + \frac{r}{3.7D_{h,p}} \right)^{1.11} \right]^2},$$

where  $r$  is the internal surface absolute roughness.

If the pressure loss parameterization is set to Tabulated data – Darcy friction factor vs. Reynolds number, the pressure loss in the half volume adjacent to port **A** is

$$\Delta p_{Loss, A} = \begin{cases} \dot{m}_A \mu_A \lambda \frac{L_{press}}{4D_{h,p}^2 \rho_A S_{Min}}, & Re_A \leq Re_L \\ f(Re_A) \frac{L_{press}}{4D_{h,p}} \frac{\dot{m}_A |\dot{m}_A|}{\rho_A S_{Min}^2}, & Re_A \geq Re_T \end{cases},$$

while in the half volume adjacent to port **B** it is

$$\Delta p_{Loss, B} = \begin{cases} \dot{m}_B \mu_B \lambda \frac{L_{press}}{4D_{h,p}^2 \rho_B S_{Min}}, & Re_B \leq Re_L \\ f(Re_B) \frac{L_{press}}{4D_{h,p}} \frac{\dot{m}_B |\dot{m}_B|}{\rho_B S_{Min}^2}, & Re_B \geq Re_T \end{cases},$$

where:

- $\lambda$  is the shape factor for laminar flow viscous friction.
- $f(Re_A)$  and  $f(Re_B)$  are the Darcy friction factors at ports **A** and **B**. The block obtains the friction factors from tabulated data specified relative to the Reynolds number.

If the pressure loss parameterization is set to **Tabulated data – Euler number vs. Reynolds number**, the pressure loss in the half volume adjacent to port **A** is

$$\Delta p_{Loss, A} = \begin{cases} \dot{m}_A \mu_A Eu(Re_L) Re_L \frac{1}{4D_{h,p} \rho_A S_{Min}}, & Re_A \leq Re_L \\ Eu(Re_A) \frac{\dot{m}_A |\dot{m}_A|}{4\rho_A S_{Min}^2}, & Re_A \geq Re_T \end{cases},$$

while in the half volume adjacent to port **B** it is

$$\Delta p_{Loss, B} = \begin{cases} \dot{m}_B \mu_B Eu(Re_L) Re_L \frac{1}{4D_{h,p} \rho_B S_{Min}}, & Re_B \leq Re_L \\ Eu(Re_B) \frac{\dot{m}_B |\dot{m}_B|}{4\rho_B S_{Min}^2}, & Re_B \geq Re_T \end{cases},$$

where:

- $Eu(Re_L)$  is the Euler number at the Reynolds number upper bound for laminar flows.
- $Eu(Re_A)$  and  $Eu(Re_B)$  are the Euler numbers at ports **A** and **B**. The block obtains the Euler numbers from tabulated data specified relative to the Reynolds number.

### Energy Balance

The energy balance in the heat exchanger interface depends on the fluid dynamic compressibility setting. If the **Fluid dynamic compressibility** parameter is set to **On**, the energy balance is

$$\frac{dp}{dt} \frac{dU}{dp} + \frac{dT}{dt} \frac{dU}{dT} = \phi_A + \phi_B + Q_H,$$

where:

- $U$  is the internal energy contained in the volume of the heat exchanger interface.
- $\Phi_A$  and  $\Phi_B$  are the energy flow rates through ports **A** and **B** into the volume of the heat exchanger interface.
- $Q_H$  is the heat flow rate through port **H**, representing the interface wall, into the volume of the heat exchange interface.

The internal energy derivatives are defined as

$$\frac{dU}{dp} = \left[ \frac{1}{\beta} (\rho u + p) - T\alpha \right] V$$

and

$$\frac{dU}{dT} = \left[ c_p - \alpha \left( u + \frac{p}{\rho} \right) \right] \rho V,$$

where  $u$  is the specific internal energy of the thermal liquid, or the internal energy contained in a unit mass of the same.

If the **Fluid dynamic compressibility** parameter is set to **Off**, the thermal liquid density is treated as a constant. The bulk modulus is then effectively infinite and the thermal expansion coefficient zero. The pressure and temperature derivatives of the compressible case vanish and the energy balance is restated as

$$\frac{dE}{dt} = \phi_A + \phi_B + Q_H,$$

where  $E$  is the total internal energy of the incompressible thermal liquid, or

$$E = \rho uV.$$

### Heat Transfer Correlations

The block calculates and outputs the liquid-wall heat transfer coefficient value. The calculation depends on the **Heat transfer coefficient specification** setting in the block dialog box. If the heat transfer coefficient specification is **Constant heat transfer coefficient**, the heat transfer coefficient is simply the constant value specified in the block dialog box,

$$h_{L-W} = h_{Const},$$

where:

- $h_{L-W}$  is the liquid-wall heat transfer coefficient.
- $h_{Const}$  is the **Liquid-wall heat transfer coefficient value** specified in the block dialog box.

For all other heat transfer coefficient parameterizations, the heat transfer coefficient is defined as the arithmetic average of the port heat transfer coefficients:

$$h_{L-W} = \frac{h_A + h_B}{2},$$

where:

- $h_A$  and  $h_B$  are the liquid-wall heat transfer coefficients at ports **A** and **B**.

The heat transfer coefficient at port **A** is

$$h_A = \frac{Nu_A k_A}{D_{h,heat}},$$

while at port **B** it is

$$h_B = \frac{Nu_B k_B}{D_{h,heat}},$$

where:

- $Nu_A$  and  $Nu_B$  are the Nusselt numbers at ports **A** and **B**.
- $k_A$  and  $k_B$  are the thermal conductivities at ports **A** and **B**.
- $D_{h,heat}$  is the hydraulic diameter for heat transfer calculations.

The hydraulic diameter used in heat transfer calculations is defined as

$$D_{h,heat} = \frac{4S_{Min}L_{heat}}{S_{heat}},$$

where:

- $L_{\text{heat}}$  is the flow path length used in heat transfer calculations.
- $S_{\text{heat}}$  is the total heat transfer surface area.

### Nusselt Number Calculations

The Nusselt number calculation depends on the **Heat transfer coefficient specification** setting in the block dialog box. If the heat transfer specification is set to Correlations for tubes, the Nusselt number at port **A** is

$$Nu_A = \begin{cases} Nu_L, & Re_A \leq Re_L \\ \frac{(f_{T,A/\delta})(Re_A - 1000)Pr_A}{1 + 12.7(f_{T,A/\delta})^{1/2}(Pr_B^{2/3} - 1)}, & Re_A \geq Re_T' \end{cases}$$

while at port **B** it is

$$Nu_B = \begin{cases} Nu_L, & Re_B \leq Re_L \\ \frac{(f_{T,B/\delta})(Re_B - 1000)Pr_B}{1 + 12.7(f_{T,B/\delta})^{1/2}(Pr_B^{2/3} - 1)}, & Re_B \geq Re_T' \end{cases}$$

where:

- $Nu_L$  is the **Nusselt number for laminar flow heat transfer** value specified in the block dialog box.
- $Pr_A$  and  $Pr_B$  are the Prandtl numbers at ports **A** and **B**.

If the heat transfer specification is set to Tabulated data – Colburn data vs. Reynolds number, the Nusselt number at port **A** is

$$Nu_A = j(Re_{A,heat})Re_{A,heat}Pr_A^{1/3},$$

while at port **B** it is

$$Nu_B = j(Re_{B,heat})Re_{B,heat}Pr_B^{1/3},$$

where:

- $j(Re_{A,heat})$  and  $j(Re_{B,heat})$  are the Colburn numbers at ports **A** and **B**. The block obtains the Colburn numbers from tabulated data provided as a function of the Reynolds number.
- $Re_{A,heat}$  and  $Re_{B,heat}$  are the Reynolds numbers based on the hydraulic diameters for heat transfer calculations at ports **A** and **B**. This parameter is defined at port **A** as

$$Re_{A,heat} = \frac{\dot{m}_A D_{h,heat}}{S_{Min} \mu_A},$$

and at port **B** as

$$Re_B = \frac{\dot{m}_B D_{h,heat}}{S_{Min} \mu_B}.$$

If the heat transfer specification is set to Tabulated data – Nusselt number vs. Reynolds number & Prandtl number, the Nusselt number at port **A** is

$$Nu_A = Nu(Re_{A,heat}, Pr_A),$$

while at port **B** it is

$$Nu_B = Nu(Re_{B,heat}, Pr_B).$$

### Hydraulic Diameter Calculations

The hydraulic diameter used in heat transfer calculations can differ from the hydraulic diameter employed in pressure loss calculations, and are different if the heated and friction perimeters are not the same. For a concentric pipe heat exchanger with an annular cross-section, the hydraulic diameter for heat transfer calculations is

$$D_{h,heat} = \frac{4(\pi/4)(D_o^2 - D_i^2)}{\pi D_i} = \frac{D_o^2 - D_i^2}{D_i},$$

while the hydraulic diameter for pressure calculations is

$$D_{h,p} = \frac{4(\pi/4)(D_o^2 - D_i^2)}{\pi(D_i + D_o)} = D_o - D_i,$$

where:

- $D_o$  is the outer annulus diameter.
- $D_i$  is the inner annulus diameter.

### Annulus Schematic

The difference between the outer diameter and the inner diameter depicted in orange represents the thermal liquid. The blue region within the inner diameter is the fluid that exchanges heat with the thermal liquid.

## Ports

### Output

**C** – Heat capacity rate  
physical signal

Physical signal output port for the thermal capacity rate of the thermal liquid.

**HC** — Heat transfer coefficient  
physical signal

Physical signal output port for the heat transfer coefficient between the thermal liquid and the interface wall.

### Conserving

**A** — Thermal liquid port  
thermal liquid

Thermal liquid conserving port representing the thermal liquid inlet.

**B** — Thermal liquid port  
thermal liquid

Thermal liquid conserving port representing the thermal liquid outlet.

**H** — Thermal inlet temperature  
thermal

Thermal conserving port associated with the thermal liquid inlet temperature.

### Parameters

**Minimum free-flow area** — Cross-sectional area of flow channel at its narrowest point  
 $0.01 \text{ m}^2$  (default) | scalar

Aggregate flow area free of obstacles based on the smallest tube spacing or corrugation pitch.

**Hydraulic diameter for pressure loss** — Diameter or equivalent diameter of channel  
 $0.1 \text{ m}$  (default) | scalar

Hydraulic diameter of the tubes or channels comprising the heat exchange interface. The hydraulic diameter is the ratio of the flow cross-sectional area to the channel perimeter.

**Thermal liquid volume** — Total volume of fluid contained in flow channel  
 $0.01 \text{ m}^3$  (default) | scalar with units of length squared

Total volume of the fluid contained in the thermal liquid flow channel.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent regimes  
2000 (default) | scalar

Start of the transition from the laminar regime to the turbulent regime. Above this number, inertial forces become increasingly dominant. The default value is given for circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent regimes  
4000 (default) | scalar

End of the transition from the laminar regime to the turbulent regime. Below this number, viscous forces become increasingly dominant.

**Pressure loss parameterization** — Mathematical model for pressure loss due to friction  
Constant loss coefficient (default) | Correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss due to friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (TL) blocks for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
0.1 (default) | scalar

Aggregate loss coefficient for all flow resistances in the flow channel, including wall friction (major losses) and local resistances due to bends, elbows, and other geometry changes (minor losses).

The loss coefficient is an empirical, dimensionless number used to express the pressure losses due to friction. It can be calculated from experimental data or obtained from product data sheets.

#### **Dependencies**

To enable this parameter, set **Pressure loss parameterization** to Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port  
1 m (default) | scalar with units of length

Total distance the flow must travel between the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels where the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to friction at the wall.

#### **Dependencies**

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes or Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed in length  
0.1 m (default) | scalar

Aggregate minor pressure loss, expressed as a length. The length of a straight channel results in equivalent losses to the sum of existing local resistances from elbows, tees, and unions. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### **Dependencies**

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes.

**Internal surface absolute roughness** — Mean height of wall surface variations that contribute to frictional losses  
15e-6 m (default) | scalar with units of length

Average height of all surface defects on the internal surface of the pipe. The surface roughness enables the calculation of the friction factor in the turbulent flow regime.

#### **Dependencies**

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions

64 (default) | scalar

Pressure loss correction for laminar flow. This parameter is referred to as the shape factor, and can be used to derive the Darcy friction factor for pressure loss calculations in the laminar regime. The default value is for cylindrical pipes and tubes.

Some additional shape factors for non-circular cross-sections can be determined from analytical solutions to the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with an aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96. A slender conduit between parallel plates also has a shape factor of 96.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Correlations for tubes.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in Darcy friction factor lookup table

[400, 1000, 1500, 3000, 4000, 6000, 10000, 20000, 40000, 60000, 100000, 100000000] (default) | array

Vector of Reynolds numbers at which to specify the Darcy friction factor. The block uses this vector to create a lookup table for the Darcy friction factor.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in Reynolds number lookup table

[.264, .112, .071, .0417, .0387, .0268, .025, .0232, .0226, .022, .0214, .0214] (default) | array

Vector of Darcy friction factors corresponding to the values specified in the **Reynolds number vector for Darcy friction factor** parameter. The block uses this vector to create a lookup table for the Darcy friction factor.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in the Euler number lookup table

[50, 500, 1000, 2000] (default) | array

Vector of Reynolds numbers at which to specify the Euler number. The block uses this vector to create a lookup table for the Euler number.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Euler number vs. Reynolds number.

**Euler number vector** — Euler number at each breakpoint in the Reynolds number lookup table  
[4.4505, .6864, .4791, .3755] (default) | array

Vector of Euler numbers corresponding to the values specified in the **Reynolds number vector for Euler number** parameter. The block uses this vector to create a lookup table for the Euler number.

#### Dependencies

To enable this parameter, set **Pressure loss parameterization** to Tabulated data - Euler number vs. Reynolds number.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Parameterization used to compute the heat transfer rate between the heat exchanger fluids. You can assume a constant loss coefficient, use empirical correlations for tubes, or specify tabulated data for the Colburn or Nusselt number.

**Liquid-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall

100 W/(m<sup>2</sup> \* K) (default) | scalar

Heat transfer coefficient between the thermal liquid and the heat-transfer surface.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Constant heat transfer coefficient.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall  
0.4 m<sup>2</sup> (default) | scalar with units of length squared

Aggregate surface area available for heat transfer between the heat exchanger fluids.

**Length of flow path for heat transfer** — Characteristic length traversed in heat transfer between fluid and wall

1 m (default) | scalar with units of length

Distance traversed by the fluid along which heat exchange takes place.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow

3.66 (default) | positive scalar

Proportionality constant between convective and conductive heat transfer in the laminar regime. This parameter enables the calculation of convective heat transfer rates in laminar flows. The appropriate value to use depends on component geometry.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Correlations for tubes.

**Reynolds number vector for Colburn factor** — Reynolds number at each breakpoint in Colburn factor lookup table

[100, 150, 1000] (default) | array

Vector of Reynolds numbers at which to specify the Colburn factor. The block uses this vector to create a lookup table for the Colburn number. The number of values in this vector must be equal to the size of the **Colburn factor vector** parameter to calculate tabulated breakpoints.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in Reynolds number lookup table

[.019, .013, .002] (default) | array

Vector of Colburn factors corresponding to the values specified in the **Reynolds number vector for Colburn number** parameter. The block uses this vector to create a lookup table for the Colburn factor.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in Nusselt number lookup table

[100, 150, 1000] (default) | array

Vector of Reynolds numbers at which to specify the Nusselt number. The block uses this vector to create a lookup table for the Nusselt number.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in the Nusselt number lookup table

[1, 10] (default) | array

Vector of Prandtl numbers at which to specify the Nusselt number. The block uses this vector to create a lookup table for the Nusselt number.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu(Re,Pr)** — Nusselt number at each breakpoint in Reynolds-Prandtl number lookup table

[3.72, 4.21; 3.75, 4.44; 4.21, 7.15] (default) | array

Matrix of Nusselt numbers corresponding to the values specified in the **Reynolds number vector for Nusselt number** and **Prandtl number vector for Nusselt number** parameters. The block uses this vector to create a lookup table for the Nusselt factor.

### Dependencies

To enable this parameter, set **Heat transfer parameterization** to `Tabulated data - Nusselt number vs. Reynolds number & Prandtl number`.

**Fouling factor** — Increased resistance due to fouling  
`1e-4 m2*K/W` (default) | scalar

Empirical parameter used to quantify the increased thermal resistance due to dirt deposits on the heat transfer surface.

### Effects and Initial Conditions

**Thermal Liquid dynamic compressibility** — Setting for liquid compressibility in heat exchanger  
`On` (default) | `Off` | scalar

Option to model the pressure dynamics inside the heat exchanger. Setting this parameter to `Off` removes the pressure derivative terms from the component energy and mass conservation equations. The pressure inside the heat exchanger is then reduced to the weighted average of the two port pressures.

**Thermal Liquid initial temperature** — Initial temperature of thermal liquid  
`293.15 K` (default) | scalar

Temperature of the internal volume of thermal liquid at the start of simulation.

**Thermal Liquid initial pressure** — Initial pressure of thermal liquid  
`0.101325 MPa` (default) | scalar

Pressure of the internal volume of thermal liquid at the start of simulation.

## Version History

# Heat Exchanger (TL-MA)

Models heat exchange between a moist air network and a thermal liquid network

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

## Description

The Heat Exchanger (TL-MA) block models a heat exchanger with one moist air network, which flows between ports **A2** and **B2**, and one thermal liquid network, which flows between ports **A1** and **B1**. The fluid streams can be aligned in parallel, counter, or cross-flow configurations.

A thermal liquid-moist air heat exchanger is not appropriate for refrigeration cooling systems. See Condenser Evaporator (2P-MA) or Condenser Evaporator (TL-2P) for heat exchangers that can be employed in refrigeration applications.

You can model the moist air side as flow within tubes, flow around thermal liquid tubing, or by an empirical, generic parameterization. The moist air side comprises air, trace gas, and water vapor that may condense throughout the heat exchange cycle. The block model accounts for the latent heat that is released when water condenses on the heat transfer surface. This liquid layer does not collect on the surface and is assumed to be completely removed from the downstream moist air flow. The moisture condensation rate is returned as a physical signal at port **W**.

The block uses the Effectiveness-NTU (E-NTU) method to model heat transfer through the shared wall. Fouling on the exchanger walls, which increases thermal resistance and reduces the heat exchange between the two fluids, is also modeled. You can also optionally model fins on both the moist air and thermal liquid sides. Pressure loss due to viscous friction on both sides of the exchanger can be modeled analytically or by generic parameterization, which you can use to tune to your own data.

You can model the thermal liquid side as flow within tubes, flow around moist air tubing, or by an empirical, generic parameterization.

## Heat Exchanger Configuration

The heat exchanger effectiveness is based on the selected heat exchanger configuration, the fluid properties, the tube geometry and flow configuration on each side of the exchanger, and the usage and size of fins.

## Flow Arrangement

The **Flow arrangement** parameter assigns the relative flow paths between the two sides:

- **Parallel flow** indicates the fluids are moving in the same direction.
- **Counter flow** indicates the fluids are moving in parallel, but opposite directions.

- Cross flow indicates the fluids are moving perpendicular to each other.

**Thermal Mixing**

When **Flow arrangement** is set to Cross flow, use the **Cross flow arrangement** parameter to indicate whether the thermal liquid or moist air flows are separated into multiple paths by baffles or walls. Without these separations, the flow can mix freely and is considered *mixed*. Both fluids, one fluid, or neither fluid can be mixed in the cross-flow arrangement. Mixing homogenizes the fluid temperature along the direction of flow of the second fluid, and varies perpendicular to the second fluid flow.

Unmixed flows vary in temperature both along and perpendicular to the flow path of the second fluid.

### Sample Cross-Flow Configurations

Note that the flow direction during simulation does not impact the selected flow arrangement setting. The ports on the block do not reflect the physical positions of the ports in the physical heat exchange system.

All flow arrangements are single-pass, which means that the fluids do not make multiple turns in the exchanger for additional points of heat transfer. To model a multi-pass heat exchanger, you can arrange multiple Heat Exchanger (TL-MA) blocks in series or in parallel.

For example, to achieve a two-pass configuration on the moist air side and a single-pass configuration on the thermal liquid side, you can connect the moist air sides in series and the thermal liquid sides to the same input in parallel (such as two Mass Flow Rate Source blocks with half of the total mass flow rate), as shown below.

### Flow Geometry

The **Flow geometry** parameter sets the flow arrangement of the fluid of the respective dialog tab as either inside a tube or set of tubes, or perpendicular to a tube bank. You can also specify an empirical, generic configuration.

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, use the **Tube bank grid arrangement** parameter to define the tube bank alignment of the other fluid as either Inline or Staggered. The red, downward-pointing arrow in the figure below indicates the direction of the fluid flowing external to the tube bank. The Inline figure also shows the **Number of tube rows along flow direction** and the **Number of tube segments in each tube row** parameters. Here, *flow direction* refers to the fluid of the respective dialog tab, and *tube* refers to the tubing of the other fluid. The **Length of each tube segment in a tube row** parameter is indicated in the Staggered figure.

Number of tube segments  
in each tube row

### Inline

### Staggered

Length of each tube  
segment in a tube row

Only one fluid can have **Flow geometry** set to Flow perpendicular to bank of circular tubes at a time. The other fluid must be configured to either Flow inside one or more tubes or Generic. If **Flow geometry** for both fluids is set to Flow perpendicular to bank of circular tubes, you will receive an error.

### Fins

The heat exchanger configuration is without fins when the **Total fin surface area** parameter is set to 0 m<sup>2</sup>. Fins introduce additional surface area for additional heat transfer. Each fluid side has a separate fin area.

### Effectiveness-NTU Heat Transfer

The heat transfer rate is calculated over the averaged properties of both fluids.

The heat transfer is calculated as:

$$Q = \epsilon C_{\text{Min}}(T_{\text{In,TL}} - T_{\text{In,MA}}),$$

where:

- $C_{\text{Min}}$  is the lesser of the heat capacity rates of the two fluids. The heat capacity rate is the product of the fluid specific heat,  $c_p$ , and the fluid mass flow rate.  $C_{\text{Min}}$  is always positive.
- $T_{\text{In,TL}}$  is the inlet temperature of the thermal liquid.
- $T_{\text{In,MA}}$  is the inlet temperature of the moist air.
- $\epsilon$  is the heat exchanger effectiveness.

Effectiveness is a function of the heat capacity rate and the number of transfer units,  $NTU$ , and also varies based on the heat exchanger flow arrangement, which is discussed in more detail in “Effectiveness by Flow Arrangement” on page 1-1128. The  $NTU$  is calculated as:

$$NTU = \frac{1}{C_{\text{Min}}R},$$

where  $R$  is the total thermal resistance between the two flows, due to convection, conduction, and any fouling on the tube walls:

$$R = \frac{1}{U_{\text{TL}}A_{\text{Th,TL}}} + \frac{F_{\text{TL}}}{A_{\text{Th,TL}}} + R_{\text{W}} + \frac{F_{\text{MA}}}{A_{\text{Th,MA}}} + \frac{1}{U_{\text{MA}}A_{\text{Th,MA}}},$$

and where:

- $U$  is the convective heat transfer coefficient of the respective fluid. This coefficient is discussed in more detail in “Heat Transfer Coefficients” on page 1-1129.
- $F$  is the **Fouling factor** on the thermal liquid or moist air side, respectively.
- $R_{\text{W}}$  is the **Thermal resistance through heat transfer surface**.
- $A_{\text{Th}}$  is the heat transfer surface area of the respective side of the exchanger.  $A_{\text{Th}}$  is the sum of the wall surface area,  $A_{\text{W}}$ , and the **Total fin surface area**,  $A_{\text{F}}$ :

$$A_{\text{Th}} = A_{\text{W}} + \eta_{\text{F}}A_{\text{F}},$$

where  $\eta_{\text{F}}$  is the **Fin efficiency**.

### Effectiveness by Flow Arrangement

The heat exchanger effectiveness varies according to its flow configuration and the mixing in each fluid.

- When **Flow arrangement** is set to Parallel flow:

$$\epsilon = \frac{1 - \exp[-NTU(1 + C_R)]}{1 + C_R}$$

- When **Flow arrangement** is set to Counter flow:

$$\epsilon = \frac{1 - \exp[-NTU(1 - C_R)]}{1 - C_R \exp[-NTU(1 - C_R)]}$$

- When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to Both fluids unmixed:

$$\epsilon = 1 - \exp\left\{\frac{NTU^{0.22}}{C_R} [\exp(-C_R NTU^{0.78}) - 1]\right\}$$

- When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to Both fluids mixed:

$$\epsilon = \left[ \frac{1}{1 - \exp(-NTU)} + \frac{C_R}{1 - \exp(-C_R NTU)} - \frac{1}{NTU} \right]^{-1}$$

When one fluid is mixed and the other unmixed, the equation for effectiveness depends on the relative heat capacity rates of the fluids. When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to either Thermal Liquid 1 mixed & Moist Air 2 unmixed or Thermal Liquid 1 unmixed & Moist Air 2 mixed:

- When the fluid with  $C_{\max}$  is mixed and the fluid with  $C_{\min}$  is unmixed:

$$\epsilon = \frac{1}{C_R} (1 - \exp\{-C_R [1 - \exp(-NTU)]\})$$

- When the fluid with  $C_{\min}$  is mixed and the fluid with  $C_{\max}$  is unmixed:

$$\epsilon = 1 - \exp\left\{-\frac{1}{C_R} [1 - \exp(-C_R NTU)]\right\}$$

$C_R$  denotes the ratio between the heat capacity rates of the two fluids:

$$C_R = \frac{C_{\min}}{C_{\max}}$$

### Condensation

On the moist air side, a layer of condensation may form on the heat transfer surface. This liquid layer can influence the amount of heat transferred between the moist air and thermal liquid. The equations for E-NTU heat transfer above are given for *dry* heat transfer. To correct for the influence of condensation, the E-NTU equations are additionally calculated with the wet parameters listed below. Whichever of the two calculated heat flow rates results in a larger amount of moist air side cooling is used in heat calculations for each zone [1]. To use this method, the Lewis number is assumed to be close to 1 [1], which is true for moist air.

**E-NTU Quantities Used for Heat Transfer Rate Calculations**

	Dry calculation	Wet calculation
Moist air zone inlet temperature	$T_{in,MA}$	$T_{in,wb,MA}$
Heat capacity rate	$\bar{m}_{MA}\bar{c}_{p,MA}$	$\bar{m}_{MA}\bar{c}_{eq,MA}$
Heat transfer coefficient	$U_{MA}$	$U_{MA}\frac{\bar{c}_{eq,MA}}{\bar{c}_{p,MA}}$

where:

- $T_{in,MA}$  is the moist air inlet temperature.
- $T_{in,wb,MA}$  is the moist air wet-bulb temperature associated with  $T_{in,MA}$ .
- $\bar{m}_{MA}$  is the dry air mass flow rate.
- $\bar{c}_{p,MA}$  is the moist air heat capacity per unit mass of dry air.
- $\bar{c}_{eq,MA}$  is the equivalent heat capacity. The *equivalent heat capacity* is the change in the moist air specific enthalpy (per unit of dry air),  $\bar{h}_{MA}$ , with respect to temperature at saturated moist air conditions:

$$\bar{c}_{eq,MA} = \left( \frac{\partial \bar{h}_{MA}}{\partial T_{MA}} \right)_s.$$

The mass flow rate of the condensed water vapor leaving the moist air mass flow depends on the relative humidity between the moist air inlet and the channel wall and the heat exchanger NTUs:

$$\dot{m}_{cond} = -\bar{m}_{MA}(W_{wall,MA} - W_{in,MA})(1 - e^{-NTU_{MA}}),$$

where:

- $W_{wall,MA}$  is the humidity ratio at the heat transfer surface.
- $W_{in,MA}$  is the humidity ratio at the moist air flow inlet.
- $NTU_{MA}$  is the number of transfer units on the moist air side, calculated as:

$$NTU_{MA} = \frac{U_{MA}\frac{\bar{c}_{eq,MA}}{\bar{c}_{p,MA}}A_{Th,MA}}{\bar{m}_{MA}\bar{c}_{eq,MA}}.$$

The energy flow associated with water vapor condensation is based on the difference between the vapor specific enthalpy,  $h_{water,wall}$ , and the specific enthalpy of vaporization,  $h_{fg}$ , for water:

$$\phi_{Cond} = \dot{m}_{cond}(h_{water,wall} - h_{fg}).$$

The condensate is assumed to not accumulate on the heat transfer surface, and does not influence geometric parameters such as tube diameter.

**Heat Transfer Coefficients**

The equations below apply to both the thermal liquid and moist air sides and use the respective fluid properties.

### Flow Inside Tubes

The convective heat transfer coefficient varies according to the fluid Nusselt number:

$$U = \frac{Nu k}{D_H},$$

where:

- $Nu$  is the mean Nusselt number, which depends on the flow regime.
- $k$  is the fluid thermal conductivity.
- $D_H$  is tube hydraulic diameter.

For turbulent flows, the Nusselt number is calculated with the Gnielinski correlation:

$$Nu = \frac{\frac{fD}{8}(Re - 1000)Pr}{1 + 12.7\sqrt{\frac{f}{8}}(Pr^{2/3} - 1)},$$

where:

- $Re$  is the fluid Reynolds number.
- $Pr$  is the fluid Prandtl number.

For laminar flows, the Nusselt number is set by the **Laminar flow Nusselt number** parameter.

For transitional flows, the Nusselt number is a blend between the laminar and turbulent Nusselt numbers.

### Flow Across a Tube Bank

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the Nusselt number is calculated based on the Hagen number,  $Hg$ , and depends on the **Tube bank grid arrangement** setting:

$$Nu = \begin{cases} 0.404Lq^{1/3} \left( \frac{Re+1}{Re+1000} \right)^{0.1}, & \text{Inline} \\ 0.404Lq^{1/3}, & \text{Staggered} \end{cases}$$

where:

$$Lq = \begin{cases} 1.18Pr \left( \frac{4l_T/\pi - D}{l_L} \right) Hg(Re), & \text{Inline} \\ 0.92Pr \left( \frac{4l_T/\pi - D}{l_D} \right) Hg(Re), & \text{Staggered with } l_L \geq D \\ 0.92Pr \left( \frac{4l_T l_L/\pi - D^2}{l_L l_D} \right) Hg(Re), & \text{Staggered with } l_L < D \end{cases}$$

- $D$  is the **Tube outer diameter**.
- $l_L$  is the **Longitudinal tube pitch (along flow direction)**, the distance between the tube centers along the flow direction. *Flow direction* is the direction of flow of the external fluid.

- $l_T$  is the **Transverse tube pitch (perpendicular to flow direction)**, the distance between the centers of the tubing in one row of the other fluid.
- $l_D$  is the diagonal tube spacing, calculated as  $l_D = \sqrt{\left(\frac{l_T}{2}\right)^2 + l_L^2}$ .

For more information on calculating the Hagen number, see [6].

The measurements  $l_L$  and  $l_T$  are shown in the tube bank cross-section below. These distances are the same for both grid bank arrangement types.

### Cross-section of Tubing with Pitch Measurements

#### Empirical Nusselt Number Formulation

When the **Heat transfer coefficient model** parameter is set to Colburn equation or when **Flow geometry** is set to Generic, the Nusselt number is calculated by the empirical the Colburn equation:

$$\text{Nu} = a\text{Re}^b\text{Pr}^c,$$

where  $a$ ,  $b$ , and  $c$  are defined in the **Coefficients [a, b, c] for  $a\cdot\text{Re}^b\cdot\text{Pr}^c$**  parameter.

#### Pressure Loss

The equations below apply to both the thermal liquid and moist air sides and use the respective fluid properties.

#### Flows Inside Tubes

The pressure loss due to viscous friction varies depending on flow regime and configuration.

For turbulent flows, when the Reynolds number is above the **Turbulent flow lower Reynolds number limit** parameter, and when **Pressure loss model** is set to Correlations for flow inside tubes, the pressure loss due to friction is calculated in terms of the Darcy friction factor.

For the thermal liquid side, the pressure differential between a port **A1** and the internal node I1 is:

$$p_{A1} - p_{I1} = \frac{f_{D,A} \dot{m}_{A1} |\dot{m}_{A1}| \left( \frac{L + L_{Add}}{2} \right)}{2\rho D_H A_{CS}^2}$$

where:

- $\dot{m}_{A1}$  is the total flow rate through port **A1**.
- $f_{D,A}$  is the Darcy friction factor, according to the Haaland correlation. When the **Local resistance specification** parameter is `Aggregate equivalent length`,

$$f_{D,A1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{Re_{A1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2},$$

where  $\epsilon_R$  is the thermal liquid pipe **Internal surface absolute roughness**. The friction factor is dependent on the Reynolds number, and the block calculates this value at both ports for each liquid.

- $L$  is the **Total length of each tube** on the thermal liquid side.
- $L_{Add}$  is the thermal liquid side **Aggregate equivalent length of local resistances**, which is the equivalent length of a tube that introduces the same amount of loss as the sum of the losses due to other local resistances in the tube.
- $A_{CS}$  is the total tube cross-sectional area.

The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{f_{D,B} \dot{m}_{B1} |\dot{m}_{B1}| \left( \frac{L + L_{Add}}{2} \right)}{2\rho D_H A_{CS}^2}$$

where  $\dot{m}_{B1}$  is the total flow rate through port **B1**.

When the **Local resistance specification** parameter is `Aggregate equivalent length`, the Darcy friction factor at port **B1** is:

$$f_{D,B1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{Re_{B1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2}.$$

When the **Local resistance specification** parameter is `Local loss coefficient`, the Darcy friction factors at ports **A1** and **B1** are

$$f_{D,A1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{Re_{A1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2} + C_{localloss} \left( \frac{D_H}{L} \right)$$

$$f_{D,B1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{Re_{B1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2} + C_{localloss} \left( \frac{D_H}{L} \right)$$

where  $C_{localloss}$  is the value of the **Total local loss coefficient** parameter.

For laminar flows, when the Reynolds number is below the **Laminar flow upper Reynolds number limit** parameter, and when **Pressure loss model** is set to `Correlations for flow inside tubes`, the block calculates the pressure loss due to friction in terms of the **Laminar friction**

**constant for Darcy friction factor** parameter,  $\lambda$ .  $\lambda$  is a user-defined parameter when **Tube cross-section** is **Generic**. Otherwise, the block calculates the value internally.

The pressure differential between port **A1** and internal node I1 is:

$$p_{A1} - p_{I1} = \frac{\lambda \mu \dot{m}_{A1}}{2 \rho D_H^2 A_{CS}} \left( \frac{L + L_{Add}}{2} \right),$$

where  $\mu$  is the fluid dynamic viscosity. The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{\lambda \mu \dot{m}_{B1}}{2 \rho D_H^2 A_{CS}} \left( \frac{L + L_{Add}}{2} \right).$$

For transitional flows, when **Pressure loss model** is set to **Correlations for flow inside tubes**, the pressure differential due to viscous friction is a smoothed blend between the values for laminar and turbulent pressure losses.

#### Empirical Formulation for Flows Inside Tubes

When **Pressure loss model** is set to **Pressure loss coefficient** or when **Flow geometry** is set to **Generic**, the pressure losses due to viscous friction are calculated with an empirical pressure loss coefficient,  $\xi$ . The same equations apply to both the moist air and thermal liquid sides and use the respective fluid properties.

For the thermal liquid side, the pressure differential between port **A1** and internal node I1 is:

$$p_{A1} - p_{I1} = \frac{1}{2} \xi \frac{\dot{m}_{A1} |\dot{m}_{A1}|}{2 \rho A_{CS}^2}.$$

The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{1}{2} \xi \frac{\dot{m}_{B1} |\dot{m}_{B1}|}{2 \rho A_{CS}^2}.$$

#### Pressure Loss for Flow Across Tube Banks

When **Flow geometry** is set to **Flow perpendicular to bank of circular tubes**, the Hagen number is used to calculate the pressure loss due to viscous friction. The same equations apply to both the moist air and thermal liquid sides and use the respective fluid properties.

For the moist air side, the pressure differential between port **A2** and internal node I2 is:

$$p_{A2} - p_{I2} = \frac{1}{2} \frac{\mu^2 N_R}{\rho D^2} \text{Hg}(\text{Re}),$$

where:

- $\mu$  is the moist air fluid dynamic viscosity.
- $N_R$  is the **Number of tube rows along flow direction**. When moist air is flowing external to a tube bank, this is the number of thermal liquid tube rows along the direction of the moist air flow.

The pressure differential between port **B2** and internal node I2 is:

$$p_{B2} - p_{I2} = \frac{1}{2} \frac{\mu^2 N_R}{\rho D^2} \text{Hg}(\text{Re}).$$

### Empirical Formulation for Flows Across Tubes

When the **Pressure loss model** is set to Euler number per tube row or when **Flow geometry** is set to **Generic**, the pressure loss due to viscous friction is calculated with a pressure loss coefficient, in terms of the Euler number,  $Eu$ :

$$Eu = \frac{\xi}{N_R},$$

where  $\xi$  is the empirical pressure loss coefficient.

The pressure differential between port **A2** and internal node I2 is:

$$p_{A2} - p_{I2} = \frac{1}{2} N_R Eu \frac{\dot{m}_{A2} |\dot{m}_{A2}|}{2 \rho A_{CS}^2}.$$

The pressure differential between port **B2** and internal node I2 is:

$$p_{B2} - p_{I2} = \frac{1}{2} N_R Eu \frac{\dot{m}_{B2} |\dot{m}_{B2}|}{2 \rho A_{CS}^2}.$$

### Conservation Equations

#### Thermal Liquid

The total mass accumulation rate in the thermal liquid is defined as:

$$\frac{dM_{TL}}{dt} = \dot{m}_{A1} + \dot{m}_{B1},$$

where:

- $M_{TL}$  is the total mass of the thermal liquid.
- $\dot{m}_{A1}$  is the mass flow rate of the fluid at port **A1**.
- $\dot{m}_{B1}$  is the mass flow rate of the fluid at port **B1**.

The flow is positive when flowing into the block through the port.

The energy conservation equation relates the change in specific internal energy to the heat transfer by the fluid:

$$M_{TL} \frac{du_{TL}}{dt} + u_{TL}(\dot{m}_{A1} + \dot{m}_{B1}) = \phi_{A1} + \phi_{B1} - Q,$$

where:

- $u_{TL}$  is the thermal liquid specific internal energy.
- $\phi_{A1}$  is the energy flow rate at port **A1**.
- $\phi_{B1}$  is the energy flow rate at port **B1**.
- $Q$  is heat transfer rate, which is positive when leaving the thermal liquid volume.

**Moist Air**

There are three equations for mass conservation on the moist air side: one for the moist air mixture, one for condensed water vapor, and one for the trace gas.

---

**Note** If **Trace gas model** is set to **None** in the Moist Air Properties (MA) block, the trace gas is not modeled in blocks in the moist air network. In the Heat Exchanger (TL-MA) block, this means that the conservation equation for trace gas is set to 0.

---

The moist air mixture mass accumulation rate accounts for the changes of the entire moist air mass flow through the exchanger ports and the condensation mass flow rate:

$$\frac{dM_{MA}}{dt} = \dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}$$

The mass conservation equation for water vapor accounts for the water vapor transit through the moist air side and condensation formation:

$$\frac{dx_w}{dt} M_{MA} + x_w(\dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}) = \dot{m}_{w,A2} + \dot{m}_{w,B2} - \dot{m}_{Cond}$$

where:

- $x_w$  is the mass fraction of the vapor.  $\frac{dx_w}{dt}$  is the rate of change of this fraction.
- $\dot{m}_{w,A2}$  is the water vapor mass flow rate at port **A2**.
- $\dot{m}_{w,B2}$  is the water vapor mass flow rate at port **B2**.
- $\dot{m}_{Cond}$  is the rate of condensation.

The trace gas mass balance is:

$$\frac{dx_g}{dt} M_{MA} + x_g(\dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}) = \dot{m}_{g,A2} + \dot{m}_{g,B2}$$

where:

- $x_g$  is the mass fraction of the trace gas.  $\frac{dx_g}{dt}$  is the rate of change of this fraction.
- $\dot{m}_{g,A2}$  is the trace gas mass flow rate at port **A2**.
- $\dot{m}_{g,B2}$  is the trace gas mass flow rate at port **B2**.

Energy conservation on the moist air side accounts for the change in specific internal energy due to heat transfer and water vapor condensing out of the moist air mass:

$$M_{MA} \frac{du_{MA}}{dt} + u_{MA}(\dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}) = \phi_{A2} + \phi_{B2} + Q - \phi_{Cond}$$

where:

- $\phi_{A2}$  is the energy flow rate at port **A2**.

- $\phi_{B2}$  is the energy flow rate at port **B2**.
- $\phi_{\text{Cond}}$  is the energy flow rate due to condensation.

The heat transferred to or from the moist air,  $Q$ , is equal to the heat transferred from or to the thermal liquid.

## Ports

### Conserving

**A1** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

**B1** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

**A2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

**B2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

### Output

**W** — Moist air condensation rate  
physical signal

Water condensation rate in the moist air flow. The condensate does not accumulate on the heat transfer surface.

## Parameters

### Configuration

**Flow arrangement** — Flow path alignment  
Cross flow (default) | Parallel flow | Counter flow

Flow path alignment between heat exchanger sides. The available flow arrangements are:

- Parallel flow. The flows run in the same direction.
- Counter flow. The flows run parallel to each other, in the opposite directions.
- Cross flow. The flows run perpendicular to each other.

**Cross flow arrangement** — Thermal mixing condition in each of the flow channels  
Thermal Liquid 1 unmixed & Moist Air 2 mixed (default) | Both fluids unmixed |  
Thermal Liquid 1 mixed & Moist Air 2 unmixed | Both fluids mixed

Select whether each of the fluids can mix in its channel. Mixed flow means that the fluid is free to move in the transverse direction as it travels along the flow path. Unmixed flow means that the fluid is restricted to travel only along the flow path. For example, a side with fins is considered an unmixed flow.

### Dependencies

To enable this parameter, set **Flow arrangement** to Cross flow.

### Thermal resistance through heat transfer surface — Wall thermal resistance

0 K/kW (default) | positive scalar

Thermal resistance of the wall separating the two sides of the heat exchanger. The wall thermal resistance, wall fouling, and the fluid convective heat transfer coefficient influence the amount of heat transferred between the flows.

### Cross-sectional area at port A1 — Flow area at port A1

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **A1**.

### Cross-sectional area at port B1 — Flow area at port B1

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **B1**.

### Cross-sectional area at port A2 — Flow area at port A2

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air port **A2**.

### Cross-sectional area at port B2 — Area normal to flow at port B2

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air port **B2**.

## Thermal Liquid 1

### Flow geometry — Thermal liquid flow configuration

Flow inside one or more tubes (default) | Flow perpendicular to bank of circular tubes | Generic

Thermal liquid flow path. The flow can run externally over a set of tubes or internal to a tube or set of tubes. You can also specify a generic parameterization based on empirical values.

### Number of tubes — Number of thermal liquid tubes

25 (default) | positive scalar

Number of thermal liquid tubes. More tubes result in higher pressure losses due to viscous friction, but a larger amount of surface area for heat transfer.

### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

### Total length of each tube — Total length of each thermal liquid tube

1 m (default) | positive scalar

Total length of each thermal liquid tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Tube cross section** — Cross-sectional shape of a tube  
Circular (default) | Rectangular | Annular | Generic

Cross-sectional shape of one tube. Set to Generic to specify an arbitrary cross-sectional geometry.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Tube inner diameter** — Internal diameter of a single tube  
0.05 m (default) | positive scalar

Internal diameter of the cross-section of one tube. The cross-section and diameter are uniform along the tube. The size of the diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Circular.

**Tube width** — Internal width of a single tube  
0.05 m (default) | positive scalar

Internal width of the cross-section of one tube. The cross-section and width are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Tube height** — Internal height of a single tube  
0.05 m (default) | positive scalar

Internal height of one tube cross-section. The cross-section and height are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Annulus inner diameter (heat transfer surface)** — Smaller diameter of annular cross-section  
0.05 m (default) | positive scalar

Smaller diameter of the annular cross-section of one tube. The cross-section and inner diameter are uniform along the tube. The inner diameter influences the pressure loss and heat transfer calculations. Heat transfer occurs through the inner surface of the annulus.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Annular.

**Annulus outer diameter** — Larger diameter of annular cross-section

0.1 m (default) | positive scalar

Larger diameter of the annular cross-section of one tube. The cross-section and outer diameter are uniform along the tube. The outer diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Annular.

**Cross-sectional area per tube** — Internal flow area in each tube

0.002 m<sup>2</sup> (default) | positive scalar

Internal flow area of each tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Wetted perimeter of tube cross-section for pressure loss** — Perimeter of tube cross-section that fluid touches

0.15 m (default) | positive scalar

Perimeter of the tube cross-section that the fluid touches. The cross-section and perimeter are uniform along the tube. This value is applied in pressure loss calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Perimeter of tube cross-section for heat transfer** — Perimeter of a single tube for heat transfer calculations

0.15 m (default) | positive scalar

Tube perimeter for heat transfer calculations. This is often the same as the tube perimeter, but in cases such as the annular cross-section, this may be only the inner or outer diameter, depending on the heat-transferring surface. The cross-section and tube perimeter are uniform along the tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Pressure loss model** — Method of pressure loss calculation due to viscous friction

Correlation for flow inside tubes (default) | Euler number per tube row | Pressure loss coefficient | Correlation for flow over tube bank

Method of pressure loss calculation due to viscous friction. Different models are available for different flow configurations. The settings are:

- **Correlation for flow inside tubes.** Use this setting to calculate the pressure loss with the Haaland correlation.
- **Pressure loss coefficient.** Use this setting to calculate the pressure loss based on an empirical loss coefficient.
- **Euler number per tube row.** Use this setting to calculate the pressure loss based on an empirical Euler number.
- **Correlation for flow over tube bank.** Use this setting to calculate the pressure loss based on the Hagen number.

The pressure loss models available depend on the **Flow geometry** setting.

#### Dependencies

When **Flow geometry** is set to Flow inside one or more tubes, **Pressure loss model** can be set to either:

- Pressure loss coefficient.
- Correlation for flow inside tubes.

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, **Pressure loss model** can be set to either:

- Correlation for flow over tube bank.
- Euler number per tube row.

When **Flow geometry** is set to Generic, the **Pressure loss model** parameter is disabled. Pressure loss is calculated empirically with the **Pressure loss coefficient,  $\Delta p / (0.5 \cdot \rho \cdot v^2)$**  parameter.

**Pressure loss coefficient,  $\Delta p / (0.5 \cdot \rho \cdot v^2)$**  — Empirical loss coefficient for all pressure losses in the channel

10 (default) | positive scalar

Empirical loss coefficient for all pressure losses in the channel. This value accounts for wall friction and minor losses due to bends, elbows, and other geometry changes in the channel.

The loss coefficient can be calculated from a nominal operating condition or be tuned to fit experimental data. It is defined as:

$$\xi = \frac{\Delta p}{\frac{1}{2} \rho v^2},$$

where  $\Delta p$  is the pressure drop,  $\rho$  is the thermal liquid density, and  $v$  is the flow velocity.

#### Dependencies

To enable this parameter, set either:

- **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Pressure loss coefficient.
- **Flow geometry** to Generic.

**Local resistance specification** — Method for quantifying pressure losses  
Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses in the Haaland correlation.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Aggregate equivalent length of local resistances** — Combined length of all local resistances per tube

0.1 m (default) | positive scalar

Combined length of all local resistances per tube. This value is the length of tubing that results in the same pressure losses as the sum of all minor losses in the tube due to resistances such as bends, tees, or unions. A longer combined length results in larger pressure losses. The block adds the value of this parameter to the **Total length of each tube** parameter in the calculations of pressure loss due to friction.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlations for flow inside tubes, and **Local resistance specification** to Aggregate equivalent length.

**Total local loss coefficient** — Pressure loss coefficient

0.1 (default) | positive scalar

Local pressure loss coefficient over the system. You can use this parameter to calibrate your system to match experimental results.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlation for flow inside tubes, and **Local resistance specification** to Local loss coefficient.

**Internal surface absolute roughness** — Mean surface roughness height

15e-6 m (default) | positive scalar

Mean height of tube surface defects. A rougher wall results in larger pressure losses in the turbulent regime for pressure loss calculated with the Haaland correlation.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and either:

- **Pressure loss model**
- **Heat transfer coefficient model**

to Correlation for flow inside tubes.

**Laminar flow upper Reynolds number limit** — Largest Reynolds number that indicates laminar flow

2000 (default) | positive scalar

Largest Reynolds number that indicates laminar flow. Between this value and the **Turbulent flow lower Reynolds number limit**, the flow regime is transitional.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and either:

- **Pressure loss model**
- **Heat transfer model**

to Correlation for flow inside tubes.

**Turbulent flow lower Reynolds number limit** — Smallest Reynolds number that indicates turbulent flow

4000 (default) | positive scalar

Smallest Reynolds number that indicates turbulent flow. Between this value and the **Laminar flow upper Reynolds number limit**, the flow regime is transitional between the laminar and turbulent regimes.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Laminar friction constant for Darcy friction factor** — Coefficient of pressure loss due to viscous friction in laminar flows

64 (default) | positive scalar

Coefficient in pressure loss equations for viscous friction in laminar flows. This parameter is also known as the *shape factor*. The default value corresponds to a circular tube cross-section.

**Dependencies**

To enable this parameter, set **Flow geometry** to Correlation for flow inside tubes, **Tube cross section** to Generic, and **Pressure loss model** to Correlation for flow inside tubes.

**Heat transfer coefficient model** — Method of calculating heat transfer coefficient between fluid and wall

Correlation for flow over tube bank (default) | Colburn equation | Correlation for flow inside tubes

Method of calculating the heat transfer coefficient between the fluid and the wall. The available settings are:

- **Colburn equation**. Use this setting to calculate the heat transfer coefficient with user-defined variables *a*, *b*, and *c* of the Colburn equation.
- **Correlation for flow over tube bank**. Use this setting to calculate the heat transfer coefficient based on the tube bank correlation using the Hagen number.
- **Correlation for flow inside tubes**. Use this setting to calculate the heat transfer coefficient for pipe flows with the Gnielinski correlation.

**Dependencies**

To enable this parameter, set **Flow geometry** to either:

- Flow perpendicular to bank of circular tubes.
- Flow inside one or more tubes.

**Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$**  — Colburn equation coefficients  
[0.023, 0.8, 0.33] (default) | three-element vector

Three-element vector containing the empirical coefficients of the Colburn equation. The Colburn equation is a formulation for calculating the Nusselt Number. The general form of the Colburn equation is:

$$Nu = aRe^bPr^c.$$

When the **Heat transfer coefficient model** is set to **Colburn equation** and **Flow geometry** is set to Flow inside one or more tubes, or **Flow geometry** is set to Generic, the default Colburn equation is:

$$Nu = 0.023Re^{0.8}Pr^{1/3}.$$

When the **Heat transfer coefficient model** is set to **Colburn equation** and **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the default Colburn equation is:

$$Nu = 0.27Re^{0.63}Pr^{0.36}.$$

#### Dependencies

To enable this parameter, set:

##### 1 Flow geometry to either:

- Flow inside one or more tubes
- Flow perpendicular to bank of circular tubes

and **Heat transfer coefficient model** to Colburn equation.

##### 2 Flow geometry to Generic.

**Laminar flow Nusselt number** — Ratio of convective to conductive heat transfer in the laminar flow regime

3.66 (default) | positive scalar

Ratio of convective to conductive heat transfer in the laminar flow regime. The fluid Nusselt number influences the heat transfer rate and depends on the tube cross-section.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Tube cross-section** to Generic, and **Heat transfer parameterization** to Correlation for flow inside tubes.

**Tube bank grid arrangement** — Geometrical placement of tube rows in the bank

InLine (default) | Staggered

Alignment of tubes in a tube bank. Rows are either in line with their neighbors, or staggered.

- InLine: All tube rows are located directly behind each other.

- **Staggered:** Tubes of the one tube row are located at the gap between tubes of the previous tube row.

Tube alignment influences the Nusselt number and the heat transfer rate.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube rows along flow direction** — Number of moist air tube rows in the tube bank  
5 (default) | positive scalar

Number of moist air tube rows in a tube bank. The rows are aligned with the direction of thermal liquid flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube segments in each tube row** — Number of moist air tubes in each row of the tube bank  
5 (default) | positive scalar

Number of moist air tubes in each row of a tube bank. This measurement is perpendicular to the thermal liquid flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Length of each tube segment in a tube row** — Length of each moist air tube  
1 m (default) | positive scalar

Length of each moist air tube that spans a tube row. All tubes in a tube bank are the same length.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Tube outer diameter** — Outer diameter of a moist air tube  
0.05 m (default) | positive scalar

Outer diameter of a moist air tube. The cross-section is uniform along a tube and so the diameter is constant throughout. This value influences the losses in the flow across a tube bank due to viscous friction.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Longitudinal tube pitch (along flow direction)** — Center-to-center distance between moist air tube rows  
0.15 m (default) | positive scalar

Distance between tube centers of the moist air tube bank aligned with the direction of flow of the thermal liquid.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Transverse tube pitch (perpendicular to flow direction)** — Center-to-center distance between moist air fluid tubes in a row

0.15 (default) | positive scalar

Distance between the tube centers in a row of moist air tubes. This measurement is perpendicular to the thermal liquid flow direction. See “Heat Transfer Coefficients” on page 1-1129 for more information.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Euler number per tube row,  $\Delta p / (N \cdot 0.5 \cdot \rho \cdot v^2)$**  — Euler number for each row of the tube bank

10 (default) | positive scalar

Empirical coefficient for pressure drop across one tube row. The Euler number is the ratio between pressure drop and fluid momentum:

$$Eu = \frac{\Delta p}{N \frac{1}{2} \rho v^2},$$

where  $N$  is the **Number of tube rows along flow direction**,  $\Delta p$  is the pressure drop,  $\rho$  is the thermal liquid density, and  $v$  is the flow velocity.

Each tube row is located in a plane perpendicular to the thermal liquid flow.

#### Dependencies

To enable this parameter, set either:

- **Flow geometry** to Flow perpendicular to bank of circular tubes and **Pressure loss model** to Euler number per tube row.
- **Flow geometry** to Generic.

**Minimum free-flow area** — Smallest total flow area between inlet and outlet

0.01 m<sup>2</sup> (default) | positive scalar

Smallest total flow area between inlet and outlet. If the channel is a collection of ducts, tubes, slots, or grooves, the minimum free-flow area is the sum of the smallest areas.

#### Dependencies

To enable this parameter, set **Flow geometry** to Generic.

**Heat transfer surface area without fins** — Total area of the heat transfer surface excluding fins

2 m<sup>2</sup> (default) | positive scalar

Total area of the heat transfer surface, excluding fins.

**Dependencies**

To enable this parameter, set **Flow geometry** to `Generic`.

**Thermal liquid volume inside heat exchanger** — Total volume of thermal liquid in the heat exchanger

0.05 m<sup>3</sup> (default) | positive scalar

Total volume of thermal liquid in the heat exchanger.

**Dependencies**

To enable this parameter, set **Flow geometry** to `Generic`.

**Fouling factor** — Additional thermal resistance due to fouling deposits

0.1 m<sup>2</sup>\*K/kW (default) | positive scalar

Additional thermal resistance due to fouling layers on the surfaces of the wall. In real systems, fouling deposits grow over time. However, the growth is slow enough to be assumed constant during the simulation.

**Total fin surface area** — Total heat transfer surface area of all fins

0 m<sup>2</sup> (default) | positive scalar

Total heat transfer surface area of both sides of all fins. For example, if the fin is rectangular, the surface area is double the area of the rectangle.

The total heat transfer surface area is the sum of the channel surface area and the effective fin surface area, which is the product of the **Fin efficiency** and the **Total fin surface area**.

**Fin efficiency** — Ratio of actual-to-ideal transfer rates for fin

0.5 (default) | positive scalar in the range [0,1]

Ratio of actual heat transfer to ideal heat transfer through the fins if the entire fin is at the primary heat transfer surface temperature.

**Initial thermal liquid pressure** — Moist air pressure at the start of simulation

0.101325 MPa (default) | positive scalar

Thermal liquid pressure at the start of the simulation.

**Initial thermal liquid temperature** — Temperature at the start of simulation

293.15 K (default) | positive scalar | two-element vector

Temperature in the thermal liquid channel at the start of the simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial temperature in the channel. A vector value represents the initial temperature at the inlet and outlet in the form `[inlet, outlet]`. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Moist Air 2**

**Flow geometry** — Moist air flow configuration

Flow perpendicular to bank of circular tubes (default) | Flow inside one or more tubes | `Generic`

Moist air flow path. The flow can run externally over a set of tubes or internal to a tube or set of tubes. You can also specify a generic parameterization based on empirical values.

**Number of tubes** — Number of moist air tubes

25 (default) | positive scalar

Number of moist air tubes. More tubes result in higher pressure losses due to viscous friction, but a larger amount of surface area for heat transfer.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Total length of each tube** — Total length of each moist air tube

1 m (default) | positive scalar

Total length of each moist air tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Tube cross section** — Cross-sectional shape of a tube

Circular (default) | Rectangular | Annular | Generic

Cross-sectional shape of one tube. Set to Generic to specify an arbitrary cross-sectional geometry.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Tube inner diameter** — Internal diameter of a single tube

0.05 m (default) | positive scalar

Internal diameter of the cross-section of one tube. The cross-section and diameter are uniform along the tube. The size of the diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Circular.

**Tube width** — Internal width of a single tube

0.05 m (default) | positive scalar

Internal width of the cross-section of one tube. The cross-section and width are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Tube height** — Internal height of a single tube

0.05 m (default) | positive scalar

Internal height of one tube cross-section. The cross-section and height are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Annulus inner diameter (heat transfer surface)** — Smaller diameter of annular cross-section  
0.05 m (default) | positive scalar

Smaller diameter of the annular cross-section of one tube. The cross-section and inner diameter are uniform along the tube. The inner diameter influences the pressure loss and heat transfer calculations. Heat transfer occurs through the inner surface of the annulus.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Annular.

**Annulus outer diameter** — Larger diameter of annular cross-section  
0.1 m (default) | positive scalar

Larger diameter of the annular cross-section of one tube. The cross-section and outer diameter are uniform along the tube. The outer diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Annular.

**Cross-sectional area per tube** — Internal flow area in each tube  
0.002 m<sup>2</sup> (default) | positive scalar

Internal flow area of each tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Wetted perimeter of tube cross-section for pressure loss** — Perimeter of tube cross-section that fluid touches  
0.15 m (default) | positive scalar

Perimeter of the tube cross-section that the fluid touches. The cross-section and perimeter are uniform along the tube. This value is applied in pressure loss calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Perimeter of tube cross-section for heat transfer** — Perimeter of a single tube for heat transfer calculations  
0.15 m (default) | positive scalar

Tube perimeter for heat transfer calculations. This is often the same as the tube perimeter, but in cases such as the annular cross-section, this may be only the inner or outer diameter, depending on the heat-transferring surface. The cross-section and tube perimeter are uniform along the tube.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Pressure loss model** — Method of pressure loss calculation due to viscous friction

Correlation for flow inside tubes (default) | Euler number per tube row | Pressure loss coefficient | Correlation for flow over tube bank

Method of pressure loss calculation due to viscous friction. Different models are available for different flow configurations. The settings are:

- Correlation for flow inside tubes. Use this setting to calculate the pressure loss with the Haaland correlation.
- Pressure loss coefficient. Use this setting to calculate the pressure loss based on an empirical loss coefficient.
- Euler number per tube row. Use this setting to calculate the pressure loss based on an empirical Euler number.
- Correlation for flow over tube bank. Use this setting to calculate the pressure loss based on the Hagen number.

The pressure loss models available depend on the **Flow geometry** setting.

#### Dependencies

When **Flow geometry** is set to Flow inside one or more tubes, **Pressure loss model** can be set to either:

- Pressure loss coefficient.
- Correlation for flow inside tubes.

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, **Pressure loss model** can be set to either:

- Correlation for flow over tube bank.
- Euler number per tube row.

When **Flow geometry** is set to Generic, the **Pressure loss model** parameter is disabled. Pressure loss is calculated empirically with the **Pressure loss coefficient,  $\Delta p / (0.5 \cdot \rho \cdot v^2)$**  parameter.

**Pressure loss coefficient,  $\Delta p / (0.5 \cdot \rho \cdot v^2)$**  — Empirical loss coefficient for all pressure losses in the channel

10 (default) | positive scalar

Empirical loss coefficient for all pressure losses in the channel. This value accounts for wall friction and minor losses due to bends, elbows, and other geometry changes in the channel.

The loss coefficient can be calculated from a nominal operating condition or be tuned to fit experimental data. The coefficient is defined as:

$$\xi = \frac{\Delta p}{\frac{1}{2}\rho v^2},$$

where  $\Delta p$  is the pressure drop,  $\rho$  is the moist air density, and  $v$  is the flow velocity.

#### Dependencies

To enable this parameter, set either:

- **Flow geometry** to Generic.
- **Pressure loss model** to Pressure loss coefficient.

**Local resistance specification** — Method for quantifying pressure losses  
Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses in the Haaland correlation.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Aggregate equivalent length of local resistances** — Combined length of all local resistances per tube

0.1 m (default) | positive scalar

Combined length of all local resistances per tube. This value is the length of tubing that results in the same pressure losses as the sum of all minor losses in the tube due to resistances such as bends, tees, or unions. A longer combined length results in larger pressure losses. The block adds the value of this parameter to the **Total length of each tube** parameter in the calculations of pressure loss due to friction.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlations for flow inside tubes, and **Local resistance specification** to Aggregate equivalent length.

**Total local loss coefficient** — Pressure loss coefficient

0.1 (default) | positive scalar

Local pressure loss coefficient over the system. You can use this parameter to calibrate your system to match experimental results.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlation for flow inside tubes, and **Local resistance specification** to Local loss coefficient.

**Internal surface absolute roughness** — Mean surface roughness height

15e-6 m (default) | positive scalar

Mean height of tube surface defects. A rougher wall results in larger pressure losses in the turbulent regime for pressure loss calculated with the Haaland correlation.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and either:

- **Pressure loss model**
- **Heat transfer coefficient model**

to Correlation for flow inside tubes.

**Laminar flow upper Reynolds number limit** — Largest Reynolds number that indicates laminar flow

2000 (default) | positive scalar

Largest Reynolds number that indicates laminar flow. Between this value and the **Turbulent flow lower Reynolds number limit**, the flow regime is transitional.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Turbulent flow lower Reynolds number limit** — Smallest Reynolds number that indicates turbulent flow

4000 (default) | positive scalar

Smallest Reynolds number that indicates turbulent flow. Between this value and the **Laminar flow upper Reynolds number limit**, the flow regime is transitional between the laminar and turbulent regimes.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Laminar friction constant for Darcy friction factor** — Coefficient of pressure loss due to viscous friction in laminar flows

64 (default) | positive scalar

Coefficient in pressure loss equations for viscous friction in laminar flows. This parameter is also known as the *shape factor*. The default value corresponds to a circular tube cross-section.

**Dependencies**

To enable this parameter, set **Flow geometry** to Correlation for flow inside tubes, **Tube cross section** to Generic, and **Pressure loss model** to Correlation for flow inside tubes.

**Heat transfer coefficient model** — Method of calculating heat transfer coefficient between fluid and wall

Correlation for flow over tube bank (default) | Colburn equation | Correlation for flow inside tubes

Method of calculating the heat transfer coefficient between the fluid and the wall. The available settings are:

- Colburn equation. Use this setting to calculate the heat transfer coefficient with user-defined variables  $a$ ,  $b$ , and  $c$  of the Colburn equation.

- Correlation for flow over tube bank. Use this setting to calculate the heat transfer coefficient based on the tube bank correlation using the Hagen number.
- Correlation for flow inside tubes. Use this setting to calculate the heat transfer coefficient for pipe flows with the Gnielinski correlation.

### Dependencies

To enable this parameter, set **Flow geometry** to either:

- Flow perpendicular to bank of circular tubes .
- Flow inside one or more tubes.

**Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$**  — Colburn equation coefficients  
[0.023, 0.8, 0.33] (default) | three-element vector

Three-element vector containing the empirical coefficients of the Colburn equation. The Colburn equation is a formulation for calculating the Nusselt Number. The general form of the Colburn equation is:

$$Nu = aRe^bPr^c.$$

When the **Heat transfer coefficient model** is set to Colburn equation and **Flow geometry** is set to Flow inside one or more tubes, or **Flow geometry** is set to Generic, the default Colburn equation is:

$$Nu = 0.023Re^{0.8}Pr^{1/3}.$$

When the **Heat transfer coefficient model** is set to Colburn equation and **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the default Colburn equation is:

$$Nu = 0.27Re^{0.63}Pr^{0.36}.$$

### Dependencies

To enable this parameter, set:

**1 Flow geometry** to either:

- Flow inside one or more tubes
- Flow perpendicular to bank of circular tubes

and **Heat transfer coefficient model** to Colburn equation.

**2 Flow geometry** to Generic.

**Laminar flow Nusselt number** — Ratio of convective to conductive heat transfer in the laminar flow regime

3.66 (default) | positive scalar

Ratio of convective to conductive heat transfer in the laminar flow regime. The fluid Nusselt number influences the heat transfer rate and depends on the tube cross-section.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Tube cross-section** to Generic, and **Heat transfer parameterization** to Correlation for flow inside tubes.

**Tube bank grid arrangement** — Geometrical placement of thermal liquid rows in the bank  
 Inline (default) | Staggered

Alignment of tubes in a tube bank. Rows are either in line with their neighbors, or staggered.

- **Inline:** All tube rows are located directly behind each other.
- **Staggered:** Tubes of the one tube row are located at the gap between tubes of the previous tube row.

Tube alignment influences the Nusselt number and the heat transfer rate.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube rows along flow direction** — Number of thermal liquid tube rows in the tube bank  
 5 (default) | positive scalar

Number of thermal liquid fluid tube rows in a tube bank. The rows are aligned with the direction of moist air flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube segments in each tube row** — Number of thermal liquid tubes in each row of the tube bank  
 5 (default) | positive scalar

Number of thermal liquid tubes in each row of a tube bank. This measurement is perpendicular to the moist air flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Length of each tube segment in a tube row** — Length of each thermal liquid tube  
 1 m (default) | positive scalar

Length of each thermal liquid tube that spans a tube row. All tubes in a tube bank are the same length.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Tube outer diameter** — Outer diameter of a single thermal liquid tube

0.05 m (default) | positive scalar

Outer diameter of a thermal liquid tube. The cross-section is uniform along a tube and so the diameter is constant throughout. This value influences the losses in the flow across a tube bank due to viscous friction.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Longitudinal tube pitch (along flow direction)** — Center-to-center distance between thermal liquid tube rows

0.15 m (default) | positive scalar

Distance between tube centers of the thermal liquid tube bank, aligned with the direction of flow of the moist air.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Transverse tube pitch (perpendicular to flow direction)** — Center-to-center distance between thermal liquid tubes in a row

0.15 m (default) | positive scalar

Distance between the tube centers in a row of thermal liquid tubes. This measurement is perpendicular to the moist air flow direction. See “Heat Transfer Coefficients” on page 1-1129 for more information.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Euler number per tube row,  $\Delta p / (N \cdot 0.5 \cdot \rho \cdot v^2)$**  — Euler number for each row of the tube bank

10 (default) | positive scalar

Empirical coefficient for pressure drop across one tube row. The Euler number is the ratio between pressure drop and fluid momentum:

$$Eu = \frac{\Delta p}{N \frac{1}{2} \rho v^2},$$

where  $N$  is the **Number of tube rows along flow direction**,  $\Delta p$  is the pressure drop,  $\rho$  is the moist air mixture density, and  $v$  is the flow velocity.

Each tube row is located in a plane perpendicular to the moist air flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes and **Pressure loss model** to Euler number per tube row.

**Minimum free-flow area** — Smallest total flow area between inlet and outlet

0.01 m<sup>2</sup> (default) | positive scalar

Smallest total flow area between inlet and outlet. If the channel is a collection of ducts, tubes, slots, or grooves, the minimum free-flow area is the sum of the smallest areas.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Heat transfer surface area without fins** — Total area of the heat transfer surface excluding fins

2 m<sup>2</sup> (default) | positive scalar

Total area of the heat transfer surface, excluding fins.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Moist air volume inside heat exchanger** — Total volume of moist air in the heat exchanger

0.05 m<sup>3</sup> (default) | positive scalar

Total volume of moist air in the heat exchanger.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Fouling factor** — Additional thermal resistance due to fouling deposits

0.1 m<sup>2</sup>\*K/kW (default) | positive scalar

Additional thermal resistance due to fouling layers on the surfaces of the wall. In real systems, fouling deposits grow over time. However, the growth is slow enough to be assumed constant during the simulation.

**Total fin surface area** — Total heat transfer surface area of all fins

0 m<sup>2</sup> (default) | positive scalar

Total heat transfer surface area of both sides of all fins. For example, if the fin is rectangular, the surface area is double the area of the rectangle.

The total heat transfer surface area is the sum of the channel surface area and the effective fin surface area, which is the product of the **Fin efficiency** and the **Total fin surface area**.

**Fin efficiency** — Ratio of actual-to-ideal transfer rates for fin

0.5 (default) | positive scalar in the range [0,1]

Ratio of actual heat transfer to ideal heat transfer through the fins if the entire fin is at the primary heat transfer surface temperature.

**Initial moist air pressure** — Moist air pressure at the start of simulation

0.101325 MPa (default) | positive scalar

Moist air pressure at the start of the simulation.

**Initial moist air temperature** — Temperature at the start of simulation

293.15 K (default) | positive scalar | two-element vector

Temperature in the moist air fluid channel at the start of the simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial temperature in the channel. A vector value represents the initial temperature at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Initial moisture specification** — Moisture specification

Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Moisture specification, which can be set as relative humidity, specific humidity, water vapor mole fraction, or humidity ratio.

**Initial moist air relative humidity** — Relative humidity at the start of simulation

0.5 (default) | positive scalar in the range of [0,1] | two-element vector

Relative humidity in the moist air channel at the start of the simulation. The relative humidity is the ratio of the water vapor partial pressure to the water vapor saturation pressure, or the ratio of the water vapor mole fraction to the water vapor mole fraction at saturation.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial relative humidity in the channel. A vector value represents the initial relative humidity at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to Relative humidity.

**Initial moist air specific humidity** — Specific humidity at the start of simulation

0.01 (default) | positive scalar in the range of [0,1] | two-element vector

Specific humidity in the moist air channel at the start of simulation. The specific humidity is the mass fraction of water vapor to the combined total mass of water vapor, trace gas, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial specific humidity in the channel. A vector value represents the initial specific humidity at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to Specific humidity.

**Initial moist air water vapor mole fraction** — Mole fraction of water vapor at the start of simulation

0.01 (default) | positive scalar in the range [0,1] | two-element vector

Mole fraction of the water vapor in the moist air channel at the start of simulation. The water vapor mole fraction is relative to the combined molar quantity of water vapor, trace species, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial vapor mole fraction in the channel. A vector value represents the initial vapor mole fraction at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to `Mole fraction`.

**Initial moist air humidity ratio** — Humidity ratio at the start of simulation

0.01 (default) | positive scalar in the range [0,1] | two-element vector

Humidity ratio in the moist air channel at the start of the simulation. The humidity ratio is the ratio of the mass of water vapor to the mass of dry air and trace gas.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial humidity ratio in the channel. A vector value represents the initial humidity ratio at the inlet and outlet in the form `[inlet, outlet]`. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to `Humidity ratio`.

**Initial trace gas specification** — Measurement type of trace gas

`Mass fraction` (default) | `Mole fraction`

Measurement type of trace gas.

**Initial moist air trace gas mass fraction** — Amount of trace gas in the moist air channel

0.001 (default) | positive scalar in the range of [0,1] | two-element vector

Amount of trace gas in the moist air channel by mass fraction at the start of the simulation. The mass fraction is relative to the combined total mass of water vapor, trace gas, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean trace gas mass fraction in the channel. A vector value represents the initial trace gas mass fraction at the inlet and outlet in the form `[inlet, outlet]`. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

**Dependencies**

To enable this parameter, set **Initial trace gas specification** to `Mass fraction`.

**Initial moist air trace gas mole fraction** — Mole fraction of trace gas at the start of simulation

0.001 (default) | positive scalar in the range of [0,1] | two-element vector

Amount of trace gas in the moist air channel by mole fraction at the start of the simulation. The mole fraction is relative to the combined molar total of water vapor, trace gas, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean trace gas mole fraction in the channel. A vector value represents the initial trace gas mole fraction at the inlet and outlet in the form `[inlet, outlet]`. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

## Dependencies

To enable this parameter, set **Initial trace gas specification** to Mole fraction.

**Relative humidity at saturation** — Relative humidity point of condensation  
1 (default) | positive scalar in the range of [0,1]

Relative humidity point of condensation. Condensation occurs above this value. A value greater than 1 indicates a supersaturated vapor.

## Version History

### Introduced in R2020b

### R2023a: Model additional pressure losses by using a local loss coefficient

Set the **Local resistance specification** parameter to Local loss coefficient to specify the new method for quantifying pressure loss. This option allows you to model additional friction losses beyond the loss due the length of the pipes.

# Isothermal Liquid Predefined Properties (IL)

Set working fluid properties for an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Utilities

## Description

The Isothermal Liquid Predefined Properties (IL) block sets the working fluid liquid properties of your isothermal liquid network. The available predefined fluids are:

- “Water” on page 1-1159
- “Seawater” on page 1-1160
- “Ethylene-, Propylene-, and Glycerol-Water Mixtures” on page 1-1159
- “Aviation Fuel Jet-A” on page 1-1160
- “Diesel Fuel” on page 1-1160
- “SAE 5W-30” on page 1-1160

You can also model dissolved air in the system as a function of pressure. If you would like to specify your own working fluid properties, use the Foundation Library Isothermal Liquid Properties (IL) block. If you do not specify a fluid, the system defaults will apply. See “Specify Fluid Properties” for more details.

## Fluid Properties Range

### Water

Water properties are provided between the triple point, when the fluid temperature and pressure reach 273.160 K and 611.657 Pa, and the critical point, when the fluid temperature reaches 647.096 K.  $P_{\min}$  is set by the triple point or the saturation pressure, whichever is greater.

### Ethylene-, Propylene-, and Glycerol-Water Mixtures

The properties for ethylene-glycol, propylene-glycol, and glycerol are provided for temperatures above the solution freezing point. Note that the displayed minimum temperature when visualizing properties may be lower than the fluid freezing point; displayed temperatures are not updated for different mixture concentrations.

When specifying the mixture, you can define the concentration of ethylene glycol, propylene glycol, or glycerol to water by mass fraction or volume fraction in the **Concentration type** parameter.

Properties are available for concentration by mass between 0 and 0.6 and by volume between 0 and 1 for ethylene glycol; for concentration by mass between 0 and 0.6 and by volume between 0.1 and 0.6 for propylene glycol; and for concentration by mass between 0 and 0.6 for glycerol. Glycerol concentration by volume is not available.

The properties are stored as a function of temperature and concentration. All properties, except for density and the thermal expansion coefficient  $\alpha$  are maintained as constants for a range of pressures.

### **Seawater**

Seawater properties are provided for temperatures between 273.15 K and 393.15 K and for pressures above the system saturation pressure. The salinity concentration can range from 0 to 0.12 by mass.

The properties are stored as tabulated data with respect to pressure and temperature. The data is derived from MIT's Seawater software. For more information, see: <https://web.mit.edu/seawater/>

### **Aviation Fuel Jet-A**

The properties provided are for a general, representative fuel mixture based on Jet-A-4658 and Jet-A-3638 surrogates. The properties are provided at temperatures between 222.22 K and 645.61 K and pressures above the saturation point.

The properties are stored as tabulated data with respect to pressure and temperature.

### **Diesel Fuel**

Diesel properties are provided for temperatures between 238.20 K and 690.97 K and for pressures above the saturation point.

### **SAE 5W-30**

SAE 5W-30 properties are provided for temperatures between 235.15 K and 473.15 K and for pressures above 0.01 MPa. The properties at the system temperature and atmospheric pressure are based on measurements for temperatures between 29.85 °C and 74.85 °C (303 K to 348 K) and pressures between 7 MPa and 87 MPa. The block uses curve fits to define properties in extrapolated regions.

### **Dissolved Air**

You can optionally model air dissolved into the liquid system. Setting **Air dissolution model** to On models dissolution between **Atmospheric pressure** and the **Pressure at which all entrained air is dissolved** by Henry's law. For more information, see "Fluid Models with Entrained Air".

### **Visualizing Fluid Properties**

To visualize the fluid density and bulk modulus in your network, right-click on the Isothermal Liquid Predefined Properties (IL) block and select **Fluids > Plot Fluid Properties**:

Use the **Reload Data** button to regenerate the plot whenever the fluid selection or fluid parameters change.

## Ports

### Conserving

**A** — Connection port  
isothermal liquid

Isothermal liquid conserving port that connects the block to the network. This port connects to any point on an isothermal liquid connection line within a block diagram. When you connect the Isothermal Liquid Predefined Properties (IL) block to a network line, the liquid properties are propagated to all blocks in the circuit.

## Parameters

### Liquid

**Isothermal liquid** — Fluid choice

Water (default) | Seawater (MIT model) | Ethylene glycol and water mixture | Propylene glycol and water mixture | Glycerol and water mixture | Aviation fuel Jet-A | Diesel fuel | SAE 5W-30

Choice of working fluid in the system.

**Dissolved salt mass fraction (salinity)** — Salt concentration

3.5e-3 (default) | positive scalar between (0, 0.12]

Concentration of salt in water by mass.

#### Dependencies

To enable this parameter, set **Isothermal liquid** to Seawater (MIT).

**Concentration type** — Concentration by mass or volume

Volume fraction (default) | Mass fraction

Whether the solute is measured in water by mass or volume.

#### Dependencies

To enable this parameter, set **Isothermal liquid** to:

- Ethylene glycol and water mixture.
- Propylene glycol and water mixture.

**Ethylene glycol volume fraction** — Ethylene glycol concentration by volume

0.1 (default) | positive scalar between (0, 1.0]

Fraction of ethylene glycol in water, by volume.

#### Dependencies

To enable this parameter, set **Isothermal liquid** to Ethylene glycol and water mixture and **Concentration type** to Volume fraction.

**Ethylene glycol mass fraction** — Ethylene glycol concentration by mass

0.1 (default) | positive scalar between (0, 0.6]

Fraction of ethylene glycol in water, by mass.

#### Dependencies

To enable this parameter, set **Isothermal liquid** to Ethylene glycol and water mixture and **Concentration type** to Mass fraction.

**Isothermal bulk modulus at atmospheric pressure (no entrained air)** — Bulk modulus

2.1791 GPa (default) | positive scalar

Solution bulk modulus at atmospheric pressure.

**Dependencies**

To enable this parameter, set **Isothermal liquid** to:

- Ethylene glycol and water mixture.
- Propylene glycol and water mixture.
- Glycerol and water mixture.

**Minimum valid pressure** — Lower pressure limit  
0.01 (default) | positive scalar

Lower pressure limit during simulations. The **Atmospheric pressure** must greater than or equal to the **Minimum valid pressure**.

**Dependencies**

To enable this parameter, set **Isothermal liquid** to:

- Ethylene glycol and water mixture.
- Propylene glycol and water mixture.
- Glycerol and water mixture.

**Propylene glycol volume fraction** — Propylene glycol concentration by volume  
0.1 (default) | positive scalar between [0.1, 0.6]

Fraction of propylene glycol in water, by volume.

**Dependencies**

To enable this parameter, set **Isothermal liquid** to Propylene glycol and water mixture and **Concentration type** to Volume fraction.

**Propylene glycol mass fraction** — Propylene glycol concentration by mass  
0.1 (default) | positive scalar between (0, 0.6]

Fraction of propylene glycol in water, by mass.

**Dependencies**

To enable this parameter, set **Isothermal liquid** to Propylene glycol and water mixture and **Concentration type** to Mass fraction.

**Glycerol mass fraction** — Glycerol concentration by mass  
0.1 (default) | positive scalar between (0, 0.6]

Fraction of glycerol in water, by mass.

**Dependencies**

To enable this parameter, set **Isothermal liquid** to Glycerol and water mixture.

**System temperature** — Network temperature  
300 K (default) | positive scalar

Isothermal liquid network temperature.

**Viscosity derating factor** — Viscosity correction factor

1 (default) | positive scalar

Correction factor for fluids diverging from the clean fluid standard viscosity.

**Atmospheric pressure** — User-defined environmental pressure

0.101325 MPa (default) | positive scalar

Environmental pressure of the system.

**Pressure outside valid range** — Whether to notify when pressure is outside valid range

Error (default) | Warning | None

Select what happens if the fluid pressure goes beyond the valid range during simulation:

- **None** — The block does not return an error if the properties go out of range.
- **Warning** — The block issues a warning, but continues the simulation.
- **Error** — The block returns an error and stops the simulation.

**Entrained Air****Volumetric fraction of air that is entrained at atmospheric pressure** — System air entrainment at atmospheric pressure

0.005 (default) | positive scalar

Air entrainment in fluid network at atmospheric pressure.

**Air polytropic index** — Polytropic process exponent

1.0 (default) | positive scalar between [0, 1]

Exponent of the equation that governs the polytropic process relating fluid pressure and volume.

**Air density at atmospheric condition** — Air density1.225 kg/m<sup>3</sup> (default) | positive scalar

Air density at the pressure defined in the **Atmospheric pressure** parameter.

**Air dissolution model** — Air entrainment model

On (default) | Off

Whether to account for of air dissolution into the fluid network. Air dissolution into the liquid is modeled between the **Atmospheric pressure** and the **Pressure at which all entrained air is dissolved** by Henry's Law.

**Pressure at which all entrained air is dissolved** — Upper pressure limit for air entrainment

3 MPa (default) | positive scalar

Upper pressure limit for air entrainment into the fluid.

**Dependencies**

To enable this parameter, set **Air dissolution model** to On.

## Version History

Introduced in R2020a

### R2023a: Numerical adjustments for SAE 5W-30

When the **Isothermal liquid** parameter is SAE 5W-30, the block includes numerical adjustments to the density, bulk modulus, thermal expansion coefficient, and specific internal energy to make the data more closely match experimental data.

### R2023a: Control block behavior when fluid properties go out of range during simulation

Previously, if fluid properties went beyond the valid range during simulation, the block would return an error. You can now use the new **Pressure outside valid range** parameter to control the block behavior if fluid properties go out of range during simulation

### Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Hydraulic Utilities

## Description

The Hydraulic Fluid block lets you specify the type of hydraulic fluid used in a loop of hydraulic blocks. It provides the hydraulic fluid properties, such as kinematic viscosity, density, and bulk modulus, for all the hydraulic blocks in the loop. These fluid properties are assumed to be constant during simulation time. The density is determined by the type of fluid, while kinematic viscosity additionally requires that the temperature is specified.

The bulk modulus value shown in the block dialog box is the bulk modulus of pure liquid, and is determined by the type of fluid and by the temperature. When the fluid properties are used in hydraulic blocks, such as Constant Volume Hydraulic Chamber or Variable Hydraulic Chamber, the fluid is represented as a mixture of liquid and a small amount of entrained, nondissolved gas, which is specified in the Hydraulic Fluid block as **Relative amount of trapped air**. The mixture bulk modulus in these blocks is determined as:

$$E = E_l \frac{1 + \alpha \left( \frac{p_a}{p_a + p} \right)^{1/n}}{1 + \alpha \frac{p_a^{1/n}}{n \cdot (p_a + p)} \frac{n+1}{n} E_l}$$

where

$E_l$	Pure liquid bulk modulus
$p_a$	Atmospheric pressure
$\alpha$	Relative gas content at atmospheric pressure, $\alpha = V_G/V_L$
$V_G$	Gas volume at atmospheric pressure
$V_L$	Volume of liquid
$n$	Gas-specific heat ratio

The main objective of representing fluid as a mixture of liquid and gas is to introduce an approximate model of cavitation, which takes place in a chamber if pressure drops below fluid vapor saturation

level. As it is seen in the graph below, the bulk modulus of a mixture decreases at  $p \rightarrow p_a$ , thus considerably slowing down further pressure change. At high pressure,  $p \gg p_a$ , a small amount of nondissolved gas has practically no effect on the system behavior.

Cavitation is an inherently thermodynamic process, requiring consideration of multiple-phase fluids, heat transfers, and so on, and as such cannot be accurately simulated with Simscape Fluids software. But the simplified version implemented in the block is good enough to signal if pressure falls below dangerous level, and to prevent computation failure that normally occurs at negative pressures.

The Hydraulic Fluid block offers a selection of predefined fluids. See “Fluid Properties” on page 1-1167 for how you can get information on the fluid properties used in the block. Once you select a fluid name, you can also specify the temperature of the fluid and the relative amount of entrained, nondissolved gas.

Each topologically distinct hydraulic loop in a diagram requires the properties of its working fluid to be specified. You can specify these properties either by selecting a predefined fluid using a Hydraulic Fluid block, or by specifying parameters of a custom fluid using a Custom Hydraulic Fluid block, which is available in the Simscape Foundation library. If no Hydraulic Fluid block or Custom Hydraulic Fluid block is attached to a loop, the hydraulic blocks in this loop use the default fluid, which is equivalent to fluid defined by a Custom Hydraulic Fluid block with the default parameter values.

### Fluid Properties

When you select a fluid type, the **Fluid Properties** section in the block dialog box displays these fluid property values:

- Density \*kg/m<sup>3</sup>)

- Viscosity (cSt)
- Bulk modulus (Pa)

You can also get information on the fluids and their properties through the MATLAB command line. In the following example, the first command brings you the list of available fluids, and the second command plots the properties of a selected fluid from the list, in this case, Skydrol LD-4.

- 1** In the MATLAB Command Window, type:

```
props = sh_stockfluidproperties
```

The system responds with a list of available fluids:

```
props =  
  
    skydrol_ld_4: [1x1 struct]  
    skydrol_500_4: [1x1 struct]  
    skydrol_5: [1x1 struct]  
    hy_jet: [1x1 struct]  
    f_83282: [1x1 struct]  
    f_5606: [1x1 struct]

props.skydrol_ld_4.plot()
```

The plot window opens:

Fluid properties for the Skydrol family of hydraulic fluids were obtained from literature provided by the manufacturer, Solutia, Inc. More information is available on their website at: <http://www.skydrol.com>.

## Ports

### Conserving

**G** — Connection port  
hydraulic

Hydraulic conserving port that connects the block to the network. You can connect it to any point on a hydraulic connection line in a block diagram. When you connect the Hydraulic Fluid block to a connection line, the software automatically identifies the hydraulic blocks connected to the particular circuit and propagates the fluid properties to all the blocks in the circuit.

## Parameters

### Hydraulic fluid index — Hydraulic fluid type

Skydrol LD-4 (default) | Skydrol 500B-4 | Skydrol 5 | HyJet-4A | Fluid MIL-F-83282 | Fluid MIL-F-5606 | Fluid MIL-F-87257 | Oil-10W | Oil-30W | Oil-50W | Oil SAE-30 | Oil SAE-50 | Transmission fluid ATF (Dexron III) | ISO VG 22 (ESSO UNIVIS N 22) | ISO VG 32 (ESSO UNIVIS N 32) | ISO VG 46 (ESSO UNIVIS N 46) | Brake fluid DOT3 | Brake fluid DOT4 | Brake fluid DOT5 | Gasoline | Diesel fuel | Jet fuel | Water-Glycol 60/40 | Water

Hydraulic fluid type. Select one of the predefined fluids:

- Skydrol LD-4
- Skydrol 500B-4
- Skydrol 5
- HyJet-4A
- Fluid MIL-F-83282
- Fluid MIL-F-5606
- Fluid MIL-F-87257
- Oil-10W
- Oil-30W
- Oil-50W
- Oil SAE-30
- Oil SAE-50
- Transmission fluid ATF (Dexron III)
- ISO VG 22 (ESSO UNIVIS N 22)
- ISO VG 32 (ESSO UNIVIS N 32)
- ISO VG 46 (ESSO UNIVIS N 46)
- Brake fluid DOT3
- Brake fluid DOT4
- Brake fluid DOT5
- Gasoline
- Diesel fuel
- Jet fuel
- Water-Glycol 60/40
- Water

**System temperature (degC)** — Fluid temperature, in degrees C  
60 (default) | positive scalar

Fluid temperature, in degrees C.

**Relative amount of trapped air** — Amount of entrained, nondissolved gas in the fluid  
0.005 (default) | scalar in the range of [0,1)

Amount of entrained, nondissolved gas in the fluid. The amount is specified as the ratio of gas volume at normal conditions to the fluid volume in the chamber. Therefore, the parameter value must be less than 1. In practice, the relative amount of trapped air is always greater than 0. If set to 0, ideal fluid is assumed.

**Viscosity derating factor** — Proportionality coefficient for fluid viscosity  
1 (default) | scalar in the range of [0.5,1.5]

Proportionality coefficient that you can use to adjust fluid viscosity, if needed. Specify a value between 0.5 and 1.5.

**Pressure below absolute zero** — Determines how the block handles the out-of-range assertion during simulation

Error (default) | Warning

Determines how the block handles the out-of-range assertion during simulation:

- **Error** — If the pressure falls below absolute zero, the simulation stops and you get an error message.
- **Warning** — If the pressure falls below absolute zero, you get a warning but the simulation continues. Use this option when modeling systems where cavitation can occur in extreme cases.

## Version History

**Introduced in R2006a**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Extended Capabilities

**C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

## Fan (MA)

Fan in moist air network

### Libraries:

Simscape / Fluids / Moist Air / Turbomachinery

## Description

The Fan (MA) block represents a fan in a moist air network. You can model the torque and pressure gain over the fan as a function of static pressure and flow rate or by using 1D or 2D tabulated reference pressure, shaft speed, and flow rate data.

By default, flow and pressure gain are from port **A** to port **B**. Port **C** represents the fan casing, and port **R** represents the fan shaft. You can specify the normal operating shaft direction in the **Mechanical orientation** parameter. If the shaft begins to spin in the opposite direction, the pressure difference across the fan drops to zero.

### Parameterization by Nominal Pressure, Flow Rate, and Shaft Speed

When you set the **Fan parameterization** parameter to **Static pressure and flow rate at reference shaft speed**, the block uses the analytical fan affinity laws and reference pressure differential to calculate the pressure gain from port **A** to port **B**:

$$p_B - p_A = \Delta p_{ref} \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2,$$

where:

- $\Delta p_{ref}$  is the reference pressure differential. The block uses a quadratic fit of the fan pressure differential values at the **Maximum static pressure gain at zero flow**, **Nominal static pressure gain**, and **Maximum volumetric flow rate at zero pressure** parameters.
- $\omega$  is the shaft angular velocity,  $\omega_R - \omega_C$ .
- $\omega_{ref}$  is the **Reference shaft speed** parameter.
- $\frac{D}{D_{ref}}$  is the **Fan diameter scale factor** parameter.

The block calculates the shaft torque from the reference mechanical power and the fan affinity laws:

$$\tau = \Phi_{ref} \frac{\omega^2}{\omega_{ref}^3} \left( \frac{D}{D_{ref}} \right)^5.$$

Where  $\Phi_{ref}$  is the proportion of the pressure gain to the fan efficiency:

$$\Phi_{ref} = \frac{q_{ref} \Delta p_{ref}}{\eta_{ref}}.$$

When you set the **Shaft power specification** parameter to **Fan efficiency**, the block uses a quadratic fit of efficiency between the fan peak performance,  $\eta_{nom}$ , and 0.  $\eta_{nom}$  is equivalent to the

**Nominal efficiency** parameter, which the block interprets as the peak efficiency. If you set the **Shaft power specification** parameter to Brake power, the block derives the nominal fan efficiency from the nominal brake power,  $\Phi_{nom}$ , at peak or nominal conditions:

$$\eta_{nom} = \frac{q_{nom} \Delta p_{nom}}{\Phi_{nom}}.$$

The block assumes the efficiency is zero when there is no flow or when the flow reaches the maximum volumetric flow rate at zero pressure. The block uses the current flow  $q$  to compute the reference flow rate as:

$$q_{ref} = q \frac{\omega_{ref}}{\omega} \left( \frac{D_{ref}}{D} \right)^3.$$

### 1-D Tabulated Data Parameterization: Pressure as a Function of Flow Rate at Reference Shaft Speed

When you set the **Fan parameterization** parameter to 1D tabulated data - static pressure vs. flow rate at reference shaft speed, you can model fan performance as a function of volumetric flow rate. The block interpolates the pressure gain from port **A** to port **B** from the 1-D **Static pressure gain vector** parameter,  $\Delta p_{ref}(q_{ref})$ :

$$p_B - p_A = \Delta p_{ref}(q_{ref}) \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2.$$

Here,  $\rho$  is the moist air density, and  $\rho_{ref}$  is the reference density, which is equivalent to the **Reference density** parameter. The block calculates the shaft torque from the reference mechanical power and the fan affinity laws:

$$\tau = \Phi_{ref}(q_{ref}) \frac{\omega^2}{\omega_{ref}^3} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5,$$

where  $\rho_{ref}$  is the **Reference density**.

The block uses the current flow  $q$  to compute the reference flow rate:

$$q_{ref} = q \frac{\omega_{ref}}{\omega} \left( \frac{D_{ref}}{D} \right)^3.$$

When the simulation is outside the range of the provided tables, the block extrapolates pressure based on the average slope of the fan curves and the reference torque to the nearest point.

### 2-D Tabulated Data Parameterization: Pressure as a Function of Shaft Speed and Flow Rate

When you set the **Fan parameterization** parameter to 2D tabulated data - static pressure vs. shaft speed and flow rate, you can model fan performance as a 2-D function of volumetric flow rate and angular velocity. The block interpolates the pressure gain from port **A** to port **B** from the 2-D **Static pressure gain table**,  $\mathbf{dp}(\mathbf{w}, \mathbf{q})$  parameter. The block defines the reference pressure gain,  $\Delta p_{ref}(q_{ref}, \omega)$ , as

$$p_B - p_A = \Delta p_{ref}(q_{ref}, \omega) \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^2.$$

The block calculates shaft torque from the reference mechanical power and the fan affinity laws:

$$\tau = \frac{\Phi_{ref}(q_{ref}, \omega)}{\omega} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5,$$

where the reference mechanical power is a function of the reference flow rate and the current shaft speed.

The block uses the current flow  $q$  to compute the reference flow rate:

$$q_{ref} = q \left( \frac{D_{ref}}{D} \right)^3.$$

When the simulation is outside the range of the provided tables, the block extrapolates pressure based on the average slope of the fan curves and the reference torque to the nearest point.

### Missing Data

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table, dp(w,q)**, **Efficiency table, eta(w,q)**, and **Mechanical power table, W(w,q)** parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### 2-D Tabulated Data Parameterization: Flow Rate as a Function of Shaft Speed and Pressure

When you set the **Fan parameterization** parameter to 2D tabulated data - flow rate vs. shaft speed and static pressure, you can model the flow rate through the fan as a 2-D function of pressure and angular velocity. The volumetric flow rate is interpolated from the 2-D **Volumetric flow rate table, q(w,dp)** parameter,  $q_{ref}$ . The reference flow rate is a function of the reference pressure gain,  $\Delta p_{ref}$ , and the current shaft speed,  $\omega$ :

$$q = q_{ref}(\Delta p_{ref}, \omega) \left( \frac{D}{D_{ref}} \right)^3,$$

where the reference pressure gain derives from the pressure differential over the fan:

$$\Delta p_{ref} = (p_B - p_A) \left( \frac{\rho_{ref}}{\rho} \right) \left( \frac{D_{ref}}{D} \right)^2.$$

The shaft torque derives from the reference mechanical power and the fan affinity laws:

$$\tau = \frac{\Phi_{ref}(\Delta p_{ref}, \omega)}{\omega} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5,$$

where the reference mechanical power is a function of the reference flow rate and the current shaft speed.

When the simulation is outside the range of the provided tables, the block extrapolates pressure based on the average slope of the fan curves and the reference torque to the nearest point.

### Missing Data

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$ , Efficiency table,  $\eta(w,dp)$ , and Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Power and Efficiency

You can specify shaft power as either fan efficiency or brake power.

The block calculates efficiency as

$$\eta = \frac{\Phi_{fluid}}{\Phi_{brake}},$$

where the *brake power*, or mechanical power measured at the shaft, is

$$\Phi_{brake} = \tau\omega.$$

The block calculates fluid power as

$$\Phi_{fluid} = q(p_B - p_A).$$

The block calculates torque as

$$\tau = \frac{\Phi_{brake}}{\omega}.$$

### Visualizing the Fan Curve

You can check the parameterized fan performance by plotting the pressure, power, efficiency, and torque as a function of the flow. To generate a plot of the current fan settings, right-click on the block and select **Fluids > Plot Fan Characteristics**. If you change settings or data, click **Apply** on the block parameters and click **Reload Data** on the fan curve figure.

The default block parameterization results in these plots:

### Assumptions and Limitations

- If the shaft rotates opposite to the specified mechanical orientation, pressure difference across the block drops to zero and the results may not be accurate.
- The block assumes that the fan is quasi-steady.
- The block simulates fan performance in terms of static pressure rise, and not total fan pressure.

### Ports

#### Conserving

**A** — Fluid entry  
moist air

Moist air conserving port associated with the fluid.

**B** — Fluid exit  
moist air

Moist air conserving port associated with the fluid.

**R** — Shaft  
mechanical rotational

Mechanical rotational conserving port associated with the shaft.

### **C** — Casing

mechanical rotational

Mechanical rotational conserving port associated with the casing.

## Parameters

### **Fan parameterization** — Fan performance model

Static pressure and flow rate at reference shaft speed (default) | 1D tabulated data - static pressure vs. flow rate at reference shaft speed | 2D tabulated data - static pressure vs. shaft speed and flow rate | 2D tabulated data - flow rate vs. shaft speed and static pressure

Fan performance model, specified as:

- **Static pressure and flow rate at reference shaft speed:** Specify fan performance based on typical, nominal, or rated pressure gain and volumetric flow rate.
- **1D tabulated data – static pressure vs flow rate at reference shaft speed:** Specify fan performance based on interpolation of pressure gain data as a function of volumetric flow rate.
- **2D tabulated data – static pressure vs shaft speed and flow rate:** Specify fan performance based on the interpolation of pressure gain data as a function of shaft speed and volumetric flow rate.
- **2D tabulated data – flow rate vs shaft speed and static pressure:** Specify fan performance based on the interpolation of volumetric flow rate data as a function of shaft speed and pressure gain.

### **Shaft power specification** — Power definition

Fan efficiency (default) | Brake power

Fan power specification, specified as:

- **Fan efficiency:** Derive the mechanical power from the fan efficiency.
- **Mechanical power:** Specify the mechanical power directly.

### **Nominal volumetric flow rate** — Flow rate at reference shaft speed

$0.12 \text{ m}^3/\text{s}$  (default) | positive scalar

Volumetric flow rate through the fan at the reference shaft speed under nominal, typical, or rated operating conditions.

### **Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

### **Nominal static pressure gain** — Pressure gain at reference shaft speed

5400 Pa (default) | positive scalar

Pressure increase from port **A** to port **B** at the reference shaft speed under nominal, typical, or rated operating conditions.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

**Nominal efficiency** — Efficiency at reference shaft speed

0.40 (default) | positive scalar

Efficiency of converting the shaft power to fluid power at the reference shaft speed under nominal, typical, or rated operating conditions.

**Dependencies**

To enable this parameter, set:

- **Fan parameterization** to Static pressure and flow rate at reference shaft speed.
- **Shaft power specification** to Fan efficiency.

**Nominal mechanical power** — Power at nominal efficiency

1620 W (default) | positive scalar

Mechanical power driving moist air flow at the reference shaft speed under nominal, typical, or rated operating conditions.

**Dependencies**

To enable this parameter, set:

- **Fan parameterization** to Static pressure and flow rate at reference shaft speed.
- **Shaft power specification** to Brake power.

**Maximum static pressure gain at zero flow** — Maximum pressure at reference shaft speed

6400 Pa (default) | positive scalar

Pressure increase from port **A** to port **B** at the reference shaft speed when there is no flow through the fan.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

**Maximum volumetric flow rate at zero pressure** — Maximum flow rate at reference shaft speed

0.24 m<sup>3</sup>/s (default) | positive scalar

Free-delivery volumetric flow rate at the reference shaft speed and constant pressure.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

**Reference shaft speed** — Fan curve reference speed

3000 rpm (default) | positive scalar

Reference shaft angular velocity corresponding to the fan characteristic curve data.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed or 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Minimum shaft speed threshold as fraction of reference** — Threshold for minimum shaft speed  
1e-2 (default) | positive scalar

Threshold for the minimum shaft speed as a fraction of the reference shaft speed. The block uses this value to prevent the shaft speed from becoming zero and causing a division by zero error in the expression for  $q_{ref}$ .

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed or 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Volumetric flow rate vector** — Fan curve flow rate vector  
[.0278, .0556, .0833, .111, .139, .167] m<sup>3</sup>/s (default) | vector

Vector of volumetric flow rate grid points for the 1-D interpolation of the fan characteristic curve. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

**Dependencies**

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Static pressure gain vector** — Pressure gain for given volumetric flow rate  
[6410, 6375, 6018, 5366, 4501, 3609] Pa (default) | vector

Vector of pressure gain data points. Each element in the vector corresponds to an element in the **Volumetric flow rate vector** parameter. The pressure gain is the increase in pressure from port **A** to port **B** at the reference shaft speed. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

**Dependencies**

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Efficiency vector** — Efficiency for given volumetric flow rate  
[.257, .394, .453, .47, .459, .415] (default) | vector

Vector of fan efficiency data points. Each element in the vector corresponds to an element in the **Volumetric flow rate vector** parameter. The efficiency is the ratio of fluid power to shaft mechanical power at the reference shaft speed.

**Dependencies**

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed and **Shaft power specification** to Fan efficiency.

**Mechanical power vector** — Power for parameterization of torque  
[693, 900, 1107, 1267, 1363, 1452] W (default) | 1-by- $n$  vector

Vector of shaft mechanical power data points. Each element in the vector corresponds to an element in the **Volumetric flow rate vector** parameter. The mechanical power is the power that drives the fan at the reference shaft speed. These values can be negative if the fan data extends beyond the normal operating region.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed and **Shaft power specification** to Brake power.

**Reference density** — Density associated with fan curve data  
1.2 kg/m<sup>3</sup> (default) | positive scalar

Moist air density for a given characteristic fan curve.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed, 2D tabulated data - static pressure vs. shaft speed and flow rate or 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Shaft speed vector,  $w$**  — Shaft angular velocity for given  
[2400; 3000; 3600] rpm (default) | vector

Vector of shaft angular velocity grid points for the 2-D interpolation of the fan characteristic curves.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate or 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Volumetric flow rate vector,  $q$**  — Flow rate for parameterization of pressure gain  
[.0278, .0556, .0833, .111, .139, .167] m<sup>3</sup>/s (default) | 1-by- $n$  vector

Vector of volumetric flow rate grid points for the 2-D interpolation of the fan characteristic curves. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate.

**Static pressure gain table,  $dp(w,q)$**  — Pressure for parameterization of pressure  
[4111, 4010, 3551, 2881, 2167, 1453; 6410, 6375, 6018, 5366, 4501, 3609; 9217, 9285, 9022, 8428, 7552, 6482] Pa (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of pressure gain data points for the 2-D interpolation of the pressure gain. The pressure gain is the increase in pressure from port **A** to port **B**. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- $N$  is the number of elements in the **Volumetric flow rate vector,  $q$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table,  $dp(w,q)$** , **Efficiency table,  $\eta(w,q)$** , and **Mechanical power table,  $W(w,q)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate.

**Efficiency table,  $\eta(w,q)$**  — Efficiency for parameterization of torque

[.3, .434, .468, .459, .4, .3; .257, .394, .453, .47, .459, .415; .225, .359, .434, .461, .47, .459] 1 (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of efficiency data points for the 2-D interpolation of torque. The efficiency is the ratio of fluid power to shaft mechanical power.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter.
- $N$  is the number of elements in the **Volumetric flow rate vector,  $q$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table,  $dp(w,q)$** , **Efficiency table,  $\eta(w,q)$** , and **Mechanical power table,  $W(w,q)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate and **Shaft power specification** to Fan efficiency.

**Mechanical power table,  $W(w,q)$**  — Mechanical power for parameterization of torque

[381, 514, 632, 697, 753, 809; 693, 900, 1107, 1267, 1363, 1452; 1139, 1438, 1732, 2029, 2233, 2358] W (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  table of mechanical power data points for the 2-D interpolation of torque. These values can be negative if the fan data extends beyond the normal operating region. The mechanical power is the power that drives the fan.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- $N$  is the number of elements in the **Volumetric flow rate vector,  $q$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table,  $dp(w,q)$** , **Efficiency table,  $\eta(w,q)$** , and **Mechanical power table,  $W(w,q)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate and **Shaft power specification** to Brake power.

**Static pressure gain vector,  $dp$**  — Pressure for parameterization of flow rate  
[31, 62, 93, 124] Pa (default) | 1-by- $N$  vector

Vector of pressure gain grid points for the 2-D interpolation of the fan characteristic curves. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Volumetric flow rate table,  $q(w,dp)$**  — Flow rate for parameterization of flow rate  
[.802, .759, .703, .611; .936, .902, .862, .81; 1.056, 1.027, .994, .956]  
 $m^3/s$  (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rate data points for the 2-D interpolation of volumetric flow rate. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- $N$  is the number of elements in the **Static pressure gain vector,  $Dp$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$** , **Efficiency table,  $\eta(w,dp)$** , and **Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Efficiency table,  $\eta(w,dp)$**  — Efficiency for parameterization of torque  
 [.088, .162, .22, .261; .068, .128, .18, .222; .055, .105, .148, .188] (default)  
 | *M*-by-*N* matrix

*M*-by-*N* matrix of efficiency data points for the 2-D interpolation of torque. The efficiency is the ratio of fluid power to shaft mechanical power. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **Shaft speed vector,  $w$**  parameter.
- *N* is the number of elements in the **Static pressure gain vector,  $Dp$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$** , **Efficiency table,  $\eta(w,dp)$** , and **Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure and **Shaft power specification** to Fan efficiency.

**Mechanical power table,  $W(w,dp)$**  — Mechanical power for parameterization of torque  
 [283, 290, 297, 290; 427, 437, 445, 452; 595, 606, 625, 631] W (default) | *M*-by-*N*  
 matrix

*M*-by-*N* matrix of mechanical power data points for the 2-D interpolation of torque. These values can be negative if the fan data extends beyond the normal operating region. The mechanical power is the power that drives the fan. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- *N* is the number of elements in the **Static pressure gain vector,  $Dp$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$ , Efficiency table,  $\eta(w,dp)$ , and Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure and **Shaft power specification** to Brake power.

**Fan diameter scale factor** — Model-to-reference scale factor

1 (default) | positive scalar

Geometric scale factor to increase or decrease the size of the simulated fan from the given fan parameterization. The scaling may not be accurate for scale factors much larger or much smaller than 1.

**Mechanical orientation** — Rotational orientation

Positive angular velocity of port R relative to port C corresponds to normal fan operation (default) | Negative angular velocity of port R relative to port C corresponds to normal fan operation

Normal operating shaft direction. By default, flow and pressure gain are from port **A** to port **B**.

**Inlet flow area (port A)** — Port A area

$0.01 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the moist air flow at the fan inlet.

**Outlet flow area (port B)** — Port B area

$0.01 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the moist air flow at the fan outlet.

## Version History

**Introduced in R2021b**

### **R2023a: Expose threshold for low shaft speed**

Use the **Minimum shaft speed threshold as fraction of reference** parameter to control the minimum shaft speed threshold as a fraction of the reference shaft speed. The **Minimum shaft speed threshold as fraction of reference** parameter is available in the block when the **Fan parameterization** parameter is Static pressure and flow rate at reference shaft speed or 1D tabulated data – static pressure vs flow rate at reference shaft speed.

### **R2022b: Extend performance beyond normal operating conditions**

Both the 1-D and 2-D parameterizations now allow negative values. When simulation is outside the range of the provided table, block extrapolates the pressure based on the average slope of the fan curves.

You can now use NaN elements where data is unavailable. These 2-D tabulated fan parameters support contiguous NaN elements in the upper-right portion of the table:

- **Static pressure gain table,  $dp(w,q)$**
- **Efficiency table,  $\eta(w,q)$**
- **Mechanical power table,  $W(w,q)$**
- **Volumetric flow rate table,  $q(w,dp)$**
- **Efficiency table,  $\eta(w,dp)$**
- **Mechanical power table,  $W(w,dp)$**

For each block, if the shaft rotates opposite to the specified mechanical orientation, the pressure difference across the block drops to zero and the results may not be accurate.

---

## Library

Pipelines

## Description

The Hydraulic Pipeline block models hydraulic pipelines with circular and noncircular cross sections. The block accounts for friction loss along the pipe length and for fluid compressibility. The block does not account for fluid inertia and cannot be used for predicting effects like water hammer or changes in pressure caused by fluid acceleration.

The model is built of Simscape Foundation library building blocks and its schematic diagram is shown below.

The Hydraulic Resistive Tube blocks account for friction losses, while the Constant Volume Hydraulic Chamber block accounts for fluid compressibility. By using the block parameters, you can set the model to simulate pipeline with rigid or flexible walls, including simulation of hydraulic hoses with elastic and viscoelastic properties.

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure loss is determined as  $p = p_A - p_B$ .

## Basic Assumptions and Limitations

- Flow is assumed to be fully developed along the pipe length.
- Fluid inertia is not taken into account.

## Parameters

### Pipe cross section type

The type of pipe cross section: **Circular** or **Noncircular**. For a circular pipe, you specify its internal diameter. For a noncircular pipe, you specify its hydraulic diameter and pipe cross-sectional area. The default value of the parameter is **Circular**.

### Pipe internal diameter

Pipe internal diameter. The parameter is used if **Pipe cross section type** is set to **Circular**. The default value is 0.01 m.

### Noncircular pipe cross-sectional area

Pipe cross-sectional area. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is  $1e-4 \text{ m}^2$ .

### Noncircular pipe hydraulic diameter

Hydraulic diameter of the pipe cross section. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is 0.0112 m.

### Geometrical shape factor

Used for computing friction factor at laminar flow. The shape of the pipe cross section determines the value. For a pipe with a noncircular cross section, set the factor to an appropriate value, for example, 56 for a square, 96 for concentric annulus, 62 for rectangle (2:1), and so on. The default value is 64, which corresponds to a pipe with a circular cross section.

### Pipe length

Pipe geometrical length. The default value is 5 m.

### Aggregate equivalent length of local resistances

This parameter represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. This length is added to the geometrical pipe length only for hydraulic resistance computation. The fluid volume depends on pipe geometrical length only. The default value is 1 m.

### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer's catalogs. The default value is  $15e-6 \text{ m}$ , which corresponds to drawn tubing.

### Laminar flow upper margin

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

### Turbulent flow lower margin

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

**Pipe wall type**

The parameter is available only for circular pipes and can have one of two values: **Rigid Wall** or **Flexible Wall**. If the parameter is set to **Rigid Wall**, wall compliance is not taken into account, which can improve computational efficiency. The value **Flexible Wall** is recommended for hoses and metal pipes where wall compliance can affect the system behavior. The default value is **Rigid Wall**.

**Static pressure-diameter coefficient**

Coefficient that establishes relationship between the pressure and the internal diameter at steady-state conditions. This coefficient can be determined analytically for cylindrical metal pipes or experimentally for hoses. The parameter is used if the **Pipe wall type** parameter is set to **Flexible Wall**. The default value is  $2e-12$  m/Pa.

**Viscoelastic process time constant**

Time constant in the transfer function that relates pipe internal diameter to pressure variations. By using this parameter, the simulated elastic or viscoelastic process is approximated with the first-order lag. The value is determined experimentally or provided by the manufacturer. The parameter is used if the **Pipe wall type** parameter is set to **Flexible Wall**. The default value is 0.01 s.

**Specific heat ratio**

Gas-specific heat ratio for the Constant Volume Hydraulic Chamber block. The default value is 1.4.

**Initial pressure**

Initial pressure in the pipe. This parameter specifies the initial condition for use in computing the block's initial state at the beginning of a simulation run. For more information, see "Initial Conditions Computation". The default value is 0.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Pipe cross section type**
- **Pipe wall type**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the values of the **Pipe cross section type** and **Pipe wall type** parameters at the time the model entered Restricted mode.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

Low-Pressure Blocks

## Description

The Hydraulic Pipe LP block models hydraulic pipelines with circular and noncircular cross sections. The block accounts for friction loss along the pipe length and for fluid compressibility. The block does not account for fluid inertia and cannot be used for predicting effects like water hammer or changes in pressure caused by fluid acceleration.

The model is a structural model and its schematic diagram is shown below.

The Resistive Pipe LP blocks account for friction losses, while the Constant Volume Hydraulic Chamber block accounts for fluid compressibility. To reduce model complexity, you can use this block to simulate not only a pipe itself, but also a combination of pipes and local resistances such as bends, fittings, inlet and outlet losses, associated with the pipe. You must convert the resistances into their equivalent lengths, and then sum up all the resistances to obtain their aggregate length. Then add this length to the pipe geometrical length. By using the block parameters, you can set the model to simulate pipeline with rigid or flexible walls, including simulation of hydraulic hoses with elastic and viscoelastic properties.

The difference in elevation between ports A and B is distributed evenly between pipe segments.

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure loss is determined as  $p = p_A - p_B$ .

## Basic Assumptions and Limitations

- Flow is assumed to be fully developed along the pipe length.
- Fluid inertia is not taken into account.

### Basic Parameters Tab

#### Pipe cross section type

The type of pipe cross section: **Circular** or **Noncircular**. For a circular pipe, you specify its internal diameter. For a noncircular pipe, you specify its hydraulic diameter and pipe cross-sectional area. The default value of the parameter is **Circular**.

#### Pipe internal diameter

Pipe internal diameter. The parameter is used if **Pipe cross section type** is set to **Circular**. The default value is 0.01 m.

#### Noncircular pipe cross-sectional area

Pipe cross-sectional area. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is  $1e-4 \text{ m}^2$ .

#### Noncircular pipe hydraulic diameter

Hydraulic diameter of the pipe cross section. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is 0.0112 m.

#### Geometrical shape factor

Used for computing friction factor at laminar flow. The shape of the pipe cross section determines the value. For a pipe with a noncircular cross section, set the factor to an appropriate value, for example, 56 for a square, 96 for concentric annulus, 62 for rectangle (2:1), and so on. The default value is 64, which corresponds to a pipe with a circular cross section.

#### Pipe length

Pipe geometrical length. The default value is 5 m.

#### Aggregate equivalent length of local resistances

This parameter represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. This length is added to the geometrical pipe length only for hydraulic resistance computation. The fluid volume depends on pipe geometrical length only. The default value is 1 m.

#### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer’s catalogs. The default value is  $15e-6 \text{ m}$ , which corresponds to drawn tubing.

**Laminar flow upper Reynolds number**

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

**Turbulent flow lower Reynolds number**

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

**Initial pressure**

Gauge pressure in the pipe at time zero. The default value is 0 Pa.

**Wall Compliance Tab****Pipe wall type**

The parameter is available only for circular pipes and can have one of two values: **Rigid** or **Flexible**. If the parameter is set to **Rigid**, wall compliance is not taken into account, which can improve computational efficiency. The value **Flexible** is recommended for hoses and metal pipes where wall compliance can affect the system behavior. The default value is **Rigid**.

**Static pressure-diameter coefficient**

Coefficient that establishes relationship between the pressure and the internal diameter at steady-state conditions. This coefficient can be determined analytically for cylindrical metal pipes or experimentally for hoses. The parameter is used if the **Pipe wall type** parameter is set to **Flexible**. The default value is  $2e-12$  m/Pa.

**Viscoelastic process time constant**

Time constant in the transfer function that relates pipe internal diameter to pressure variations. By using this parameter, the simulated elastic or viscoelastic process is approximated with the first-order lag. The value is determined experimentally or provided by the manufacturer. The parameter is used if the **Pipe wall type** parameter is set to **Flexible**. The default value is 0.01 s.

**Specific heat ratio**

Gas-specific heat ratio for the Constant Volume Hydraulic Chamber block. The default value is 1.4. If **Pipe cross section type** is set to **Noncircular**, then this is the only parameter on the Wall Compliance tab.

**Vertical Position Tab****Port A elevation from reference plane**

Vertical position of port **A** with respect to a reference plane. The reference plane is assumed to be the same as that used in the **Port B elevation from reference plane** parameter. The default value is 0m.

**Port B elevation from reference plane**

Vertical position of port **B** with respect to a reference plane. The reference plane is assumed to be the same as that used in the **Port A elevation from reference plane** parameter. The default value is 0m.

**Gravitational acceleration**

Value of the gravitational acceleration constant ( $g$ ). The block uses this value to compute the pressure differential between the ports due to a change in elevation. The default value is  $9.80665$  m/s<sup>2</sup>.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Pipe cross section type**
- **Pipe wall type**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the values of the **Pipe cross section type** and **Pipe wall type** parameters at the time the model entered Restricted mode.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

## Library

Low-Pressure Blocks

## Description

The Hydraulic Pipe LP with Variable Elevation block models hydraulic pipelines with circular and noncircular cross sections. The block accounts for friction loss along the pipe length and for fluid compressibility. The block does not account for fluid inertia and cannot be used for predicting effects like water hammer or changes in pressure caused by fluid acceleration. Use this block for low-pressure system simulation in which the pipe ends change their positions with respect to the reference plane. The elevations are provided through respective physical signal inputs.

The model is a structural model and its schematic diagram is shown below.

The Resistive Pipe LP with Variable Elevation blocks account for friction losses, while the Constant Volume Hydraulic Chamber block accounts for fluid compressibility. To reduce model complexity, you can use this block to simulate not only a pipe itself, but also a combination of pipes and local resistances such as bends, fittings, inlet and outlet losses, associated with the pipe. You must convert the resistances into their equivalent lengths, and then sum up all the resistances to obtain their aggregate length. Then add this length to the pipe geometrical length. By using the block parameters, you can set the model to simulate pipeline with rigid or flexible walls, including simulation of hydraulic hoses with elastic and viscoelastic properties.

The difference in elevation between ports A and B is assumed to be distributed evenly between pipe segments. Thus, the elevation of the pipe middle point is computed as

$$el\_M = \frac{el\_A + el\_B}{2}$$

where

$el\_M$	Elevation of the pipe middle point
$el\_A, el\_B$	Elevations of the pipe ends A and B, respectively

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure loss is determined as  $p = p_A - p_B$ .

## Basic Assumptions and Limitations

- Flow is assumed to be fully developed along the pipe length.
- Fluid inertia is not taken into account.
- The pipe elevation is distributed evenly along the pipe length.

## Parameters

- “Basic Parameters Tab” on page 1-1197

- “Wall Compliance Tab” on page 1-1198

## Basic Parameters Tab

### Pipe cross section type

The type of pipe cross section: **Circular** or **Noncircular**. For a circular pipe, you specify its internal diameter. For a noncircular pipe, you specify its hydraulic diameter and pipe cross-sectional area. The default value of the parameter is **Circular**.

### Pipe internal diameter

Pipe internal diameter. The parameter is used if **Pipe cross section type** is set to **Circular**. The default value is 0.01 m.

### Noncircular pipe cross-sectional area

Pipe cross-sectional area. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is  $1e-4 \text{ m}^2$ .

### Noncircular pipe hydraulic diameter

Hydraulic diameter of the pipe cross section. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is 0.0112 m.

### Geometrical shape factor

Used for computing friction factor at laminar flow. The shape of the pipe cross section determines the value. For a pipe with a noncircular cross section, set the factor to an appropriate value, for example, 56 for a square, 96 for concentric annulus, 62 for rectangle (2:1), and so on. The default value is 64, which corresponds to a pipe with a circular cross section.

### Pipe length

Pipe geometrical length. The default value is 5 m.

### Aggregate equivalent length of local resistances

This parameter represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. This length is added to the geometrical pipe length only for hydraulic resistance computation. The fluid volume depends on pipe geometrical length only. The default value is 1 m.

### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer’s catalogs. The default value is  $1.5e-5 \text{ m}$ , which corresponds to drawn tubing.

### Laminar flow upper Reynolds number limit

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

### Turbulent flow lower Reynolds number limit

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

### Gravitational acceleration

Value of the gravitational acceleration constant ( $g$ ). The block uses this parameter to calculate time changes in pressure due to time changes in elevation. The default value is  $9.80655 \text{ m/s}^2$ .

**Initial pressure**

Gauge pressure in the pipe at time zero. The default value is 0 Pa.

**Wall Compliance Tab****Pipe wall type**

The parameter is available only for circular pipes and can have one of two values: **Rigid** or **Flexible**. If the parameter is set to **Rigid**, wall compliance is not taken into account, which can improve computational efficiency. The value **Flexible** is recommended for hoses and metal pipes where wall compliance can affect the system behavior. The default value is **Rigid**.

**Static pressure-diameter coefficient**

Coefficient that establishes relationship between the pressure and the internal diameter at steady-state conditions. This coefficient can be determined analytically for cylindrical metal pipes or experimentally for hoses. The parameter is used if the **Pipe wall type** parameter is set to **Flexible**. The default value is  $2e-12$  m/Pa.

**Viscoelastic process time constant**

Time constant in the transfer function that relates pipe internal diameter to pressure variations. By using this parameter, the simulated elastic or viscoelastic process is approximated with the first-order lag. The value is determined experimentally or provided by the manufacturer. The parameter is used if the **Pipe wall type** parameter is set to **Flexible**. The default value is 0.01 s.

**Specific heat ratio**

Gas-specific heat ratio for the Constant Volume Hydraulic Chamber block. The default value is 1.4. If **Pipe cross section type** is set to **Noncircular**, then this is the only parameter on the Wall Compliance tab.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

e1\_A

Physical signal input port that controls pipe elevation at port A.

e1\_B

Physical signal input port that controls pipe elevation at port B.

## Examples

For an example of using this block, see the “Aircraft Fuel Supply System with Three Tanks” example.

## Library

Valve Actuators

## Description

Use the Hydraulic Single-Acting Valve Actuator block as a pilot actuator for directional, pressure, or flow control valves in applications where all the forces, except spring force, and flow consumption can be neglected.

The actuator consists of a piston and a spring. The spring, which can be preloaded, tends to keep the piston at the initial position. As pressure applied to the piston develops enough force to overcome the spring preload, the piston moves to the opposite position until it reaches its maximum stroke.

The actuator is simulated according to the following equations:

$$F = p \cdot A$$

$$L = \frac{\text{stroke}}{F_{\max} - F_{pr}}$$

$$s = \begin{cases} 0 & \text{for } F < = F_{pr} \\ L \cdot (F - F_{pr}) \cdot or & \text{for } F_{pr} < F < F_{max} \\ stroke \cdot or & \text{for } F > = F_{max} \end{cases}$$

where

$p$	Pressure applied to the piston
$s$	Piston displacement
$A$	Piston area
$F$	Instantaneous spring force
$F_{pr}$	Spring preload force
$F_{max}$	Spring force at maximum piston displacement
$stroke$	Piston stroke
$or$	Actuator orientation with respect to the globally assigned positive direction. If pressure applied at port X moves the piston in positive direction, $or$ equals 1. If pressure applied at port X moves the piston in negative direction, $or$ equals -1.

Connection X is a hydraulic conserving port associated with the valve chamber. Connection P is a physical signal port whose output corresponds to piston displacement. Pressure applied at port X moves the piston in the positive or negative direction, depending on the value of the **Actuator orientation** parameter.

## Basic Assumptions and Limitations

- No loading, such as inertia, friction, hydraulic force, and so on, is taken into account. The only force considered is a spring force.
- No flow consumption associated with the piston motion, leakage, or fluid compressibility is taken into account.

## Parameters

### Piston area

Effective piston area. The default value is  $2e-4 \text{ m}^2$ .

### Preload force

Spring preload force. The default value is 20 N.

### Full stroke force

Force necessary to move the piston to maximum stroke. The default value is 70 N.

### Piston stroke

Piston stroke. The default value is  $5e-3 \text{ m}$ .

### Actuator orientation

Specifies actuator orientation with respect to the globally assigned positive direction. The actuator can be installed in two different ways, depending upon whether it moves the piston in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port X moves the piston in the negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Actuator orientation**

All other block parameters are available for modification.

## Ports

The block has the following ports:

X

Hydraulic conserving port associated with the valve chamber.

P

Physical signal port that outputs piston displacement.

## Examples

The following example shows a model of a pressure-relief valve built using the Hydraulic Single-Acting Valve Actuator and Orifice with Variable Area Round Holes blocks.

## Hydraulically Operated Remote Control Valve

(To be removed) Normally closed or normally open hydraulically operated remote control valve

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

### Library

Directional Valves

### Description

The Hydraulically Operated Remote Control Valve block represents a hydraulically operated remote control valve as a data-sheet-based model, meaning that most of the model parameters are generally available in catalogs or manufacturer data sheets. Hydraulically operated remote control valves are widely used in hydraulic systems as hydraulic switches, unloading and sequencing valves. You can also use them as pressure-relief and pressure-reducing valves. The block covers both the normally closed and normally open configurations, shown in the following figure.

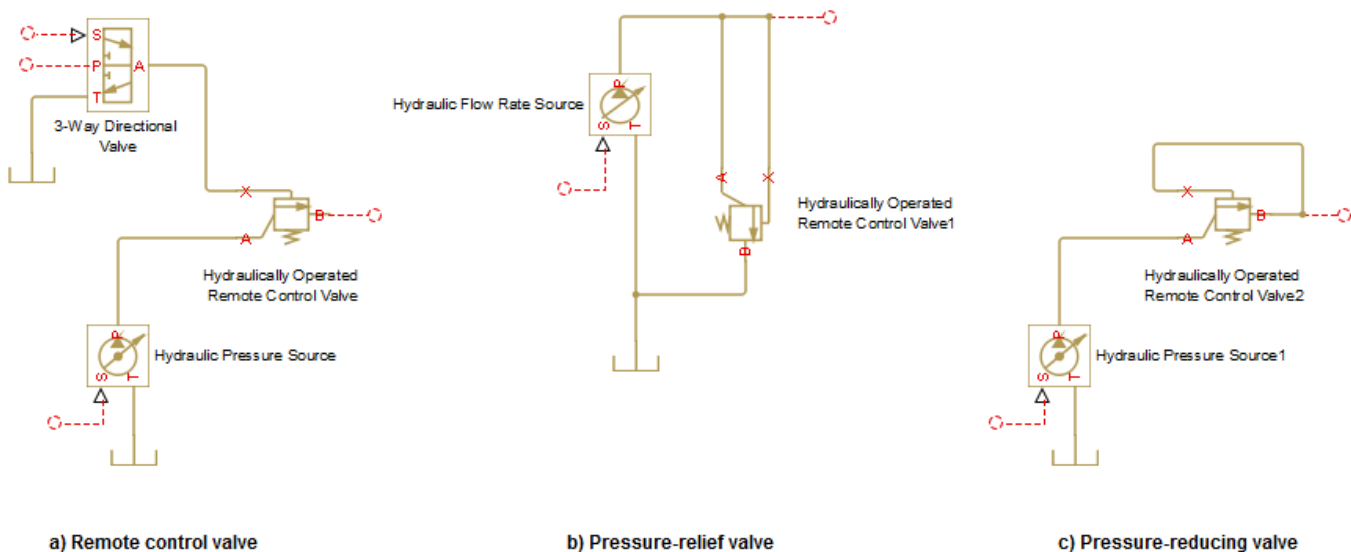

The valve opens (closes) by the pilot pressure. The valve control member remains in its initial position as long as the pilot pressure is lower than the cracking pressure. When cracking pressure is reached, the valve control member (spool, ball, poppet, and so on) is forced off its seat and starts opening the

normally closed valve, or closing the normally open valve. The control member displacement is directly proportional to pilot pressure. The member reaches its maximum displacement after the pilot pressure becomes equal or greater than the preset maximum value. The valve maximum area, cracking pressure, and maximum pressure are the key parameters of the block. These three parameters are usually provided in catalogs or data sheets.

In addition to the maximum area, the leakage area is also required to characterize the valve. The main purpose of the parameter is not to account for possible leakage, even though this is also important, but to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. An isolated or “hanging” part of the system could affect computational efficiency and even cause failure of computation. Therefore, the parameter value must be greater than zero.

Schematic fragments in the next illustration show some typical valve applications: remote control valve (a), pressure-relief valve (b), and pressure-reducing valve (c).

The flow rate through the orifice is proportional to the orifice opening and the pressure differential across the orifice.

By default, the block does not include valve opening dynamics, and the valve sets its opening area directly as a function of pressure:

$$A = A(p)$$

Adding valve opening dynamics provides continuous behavior that is more physically realistic, and is particularly helpful in situations with rapid valve opening and closing. The pressure-dependent orifice passage area  $A(p)$  in the block equations then becomes the steady-state area, and the instantaneous orifice passage area in the flow equation is determined as follows:

$$A(t = 0) = A_{init}$$

$$\frac{dA}{dt} = \frac{A(p) - A}{\tau}$$

In either case, the flow rate through the valve is determined according to the following equations:

$$q = C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

For the normally closed valve, the instantaneous orifice passage area  $A(p)$  is computed with the equations:

$$A(p) = \begin{cases} A_{leak} & \text{for } p_p \leq p_{crack} \\ A_{leak} + gain \cdot (p_p - p_{crack}) & \text{for } p_{crack} < p_p < p_{max} \\ A_{max} & \text{for } p_p \geq p_{max} \end{cases}$$

For the normally open valve, the equations are similar:

$$A(p) = \begin{cases} A_{max} & \text{for } p_p \leq p_{crack} \\ A_{max} - gain \cdot (p_p - p_{crack}) & \text{for } p_{crack} < p_p < p_{max} \\ A_{leak} & \text{for } p_p \geq p_{max} \end{cases}$$

The rest of the equations apply to both valve configurations:

$$gain = \frac{A_{max} - A_{leak}}{p_{max} - p_{crack}}$$

$$\Delta p = p_A - p_B,$$

where

$q$	Flow rate through the valve
$p$	Pressure differential across the valve
$p_A, p_B$	Gauge pressures at the block terminals
$p_p$	Gage pressure at the pilot terminal
$C_D$	Flow discharge coefficient
$\rho$	Fluid density
$\tau$	Time constant for the first order response of the valve opening
$t$	Time
$A$	Instantaneous orifice passage area
$A(p)$	Pressure-dependent orifice passage area
$A_{init}$	Initial open area of the valve
$A_{max}$	Fully open valve passage area
$A_{leak}$	Closed valve leakage area
$p_{crack}$	Valve cracking pressure
$p_{max}$	Pilot pressure to shift the control member to its maximum
$p_{cr}$	Minimum pressure for turbulent flow, when the block transitions from laminar to turbulent regime

The minimum pressure for turbulent flow,  $p_{cr}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = (p_{avg} + p_{atm})(1 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{avg}$	Average pressure between the block terminals
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$D_H$	Orifice hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

Connections A and B are hydraulic conserving ports associated with the inlet and the outlet of the valve. Connection X is the pilot port, which is a hydraulic conserving port that provides the pilot pressure. The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure differential is determined as  $\Delta p = p_A - p_B$ .

## Basic Assumptions and Limitations

- Control member displacement is linearly proportional to pilot pressure.
- No flow consumption is associated with the pilot chamber.
- No loading on the valve, such as inertia, friction, spring, and so on, is considered.

## Parameters

### Valve type

Select the valve configuration: Normally closed valve or Normally open valve. The default is Normally closed valve.

### Maximum passage area

Valve passage maximum cross-sectional area. The default value is  $1e-4 \text{ m}^2$ .

**Cracking pressure**

Pressure level at which the valve control member is forced off its seat and starts to either open or close the valve, depending on the valve type. The default value is  $3e4$  Pa.

**Maximum control member displacement pressure**

Pilot pressure at which the valve control member shifts to its maximum displacement and remains there until the pressure falls below this level. Its value must be higher than the cracking pressure. The default value is  $1.2e5$  Pa.

**Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.7$ .

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is  $0.999$ . This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is  $12$ , which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than  $0$ . The default value is  $1e-12$  m<sup>2</sup>.

**Opening dynamics**

Select one of the following options:

- **Do not include valve opening dynamics** — The valve sets its orifice passage area directly as a function of pressure. If the area changes instantaneously, so does the flow equation. This is the default.
- **Include valve opening dynamics** — Provide continuous behavior that is more physically realistic, by adding a first-order lag during valve opening and closing. Use this option in hydraulic simulations with the local solver for real-time simulation. This option is also helpful if you are interested in valve opening dynamics in variable step simulations.

### Opening time constant

The time constant for the first order response of the valve opening. This parameter is available only if **Opening dynamics** is set to Include valve opening dynamics. The default value is 0.1 s.

### Initial area

The initial opening area of the valve. This parameter is available only if **Opening dynamics** is set to Include valve opening dynamics. The default value is  $1e-12 \text{ m}^2$ .

### Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Valve type**
- **Opening dynamics**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Opening dynamics** parameter at the time the model entered Restricted mode.

### Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

### Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

X

Hydraulic conserving port that acts as the control port and provides the pilot pressure.

## Version History

### Introduced in R2012b

#### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

## Interface (2P-G)

Two-phase fluid and gas network interface

### Libraries:

Simscape / Fluids / Fluid Network Interfaces

### Description

The Interface (2P-G) block represents a flow connection between a two-phase fluid network and a gas network. Pressure, temperature, and mass flow rate are equal at the interface. The block does not transfer the fluid properties of each fluid network across the interface. To conserve fluid properties, ensure that the Gas Properties (G) block and the Two-Phase Fluid Properties (2P) block have corresponding settings.

The fluid at the **2P** port must remain superheated. You can use the **Two-phase fluid superheated vapor check** parameter to choose what action the block performs if the fluid does not meet this condition.

### Mass and Momentum Balance

The block conserves mass such that

$$\dot{m}_{2P} + \dot{m}_G = 0,$$

where:

- $\dot{m}_G$  is the mass flow rate into port **G**.
- $\dot{m}_{2P}$  is the mass flow rate into port **2P**.

The port pressures are equal:

$$P_G = P_{2P}.$$

### Energy Balance

The temperature is constant between the two fluid ports. The block calculates the energy balance over the interface as

$$\Phi_G + \Phi_{2P} = \dot{m}_G \left( h_G + \frac{w_G^2}{2} \right) + \dot{m}_{2P} \left( h_{2P} + \frac{w_{2P}^2}{2} \right),$$

where:

- $\Phi_G$  is the energy flow rate into port **G**.
- $\Phi_{2P}$  is the energy flow rate into port **2P**.
- $h_G$  is the specific enthalpy at port **G**.
- $h_{2P}$  is the specific enthalpy at port **2P**.

- $v_G$  is the specific volume at port **G**.
- $v_{2P}$  is the specific volume at port **2P**.
- $w_G$  is the flow velocity at port **G** such that

$$w_G = \frac{\dot{m}_G v_G}{S},$$

where  $S$  is the value of the **Cross-sectional area at ports 2P and G** parameter.

- $w_{2P}$  is the flow velocity at port **2P** such that

$$w_{2P} = \frac{\dot{m}_{2P} v_{2P}}{S}.$$

## Ports

### Conserving

**2P** — Two-phase port  
two-phase fluid

Two-phase fluid conserving port associated with the two-phase fluid at the interface.

**G** — Fluid port  
gas

Gas conserving port associated with the gas at the interface.

## Parameters

**Cross-sectional area at ports 2P and G** — Port area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the two-phase fluid and gas ports.

**Two-phase fluid superheated vapor check** — Two-phase fluid superheated conditions check  
None (default) | Warning | Error

Action to perform when the fluid at port **2P** does not meet superheated conditions.

Interface (2P-TL) | Interface (2P-MA) | Interface (G-MA)

## Interface (2P-MA)

Two-phase fluid and moist air network interface

### Libraries:

Simscape / Fluids / Fluid Network Interfaces

### Description

The Interface (2P-MA) block represents a flow connection between a two-phase fluid network and moist air network. Pressure, temperature, and mass flow rate are equal at the interface. The block does not transfer the fluid properties of each fluid network across the interface. When moist air leaves port **MA**, the block assigns the values of the **Interface relative humidity** and **Interface trace gas mass fraction** parameters to the signal. However, when moist air enters port **MA**, the block retains the upstream values.

You can choose whether to maintain constant moisture and trace gas amounts at the interface or to specify them using the **W** or **Tw** and **TG** ports respectively. The fluid at the **2P** port must remain superheated. You can use the **Two-phase fluid superheated vapor check** parameter to choose what action the block performs if the fluid does not meet this condition.

### Equations

The block conserves mass such that

$$\dot{m}_{2P} + \dot{m}_{MA} = 0,$$

where:

- $\dot{m}_{2P}$  is the mass flow rate into port **2P**.
- $\dot{m}_{MA}$  is the mass flow rate into port **MA**.

The block maintains equal port pressures and temperatures such that

$$p_{2P} = p_{MA}$$

$$T_{2P} = T_{MA}$$

The block calculates the energy balance over the interface as

$$\Phi_{2P} + \Phi_{MA} = \dot{m}_{2P} \left( h_{2P} + \frac{w_{2P}^2}{2} \right) + \dot{m}_{MA} \left( h_{MA} + \frac{w_{MA}^2}{2} \right),$$

where:

- $\Phi_{2P}$  is the energy flow rate into port **2P**.
- $\Phi_{MA}$  is the energy flow rate into port **MA**.
- $h_{2P}$  is the specific enthalpy at port **2P**.
- $h_{MA}$  is the specific enthalpy at port **MA**.

- $v_{2P}$  is the specific volume at port **2P**.
- $v_{MA}$  is the specific volume at port **MA**.
- $w_{2P}$  is the flow velocity at port **2P**.
- $w_{MA}$  is the flow velocity at port **MA**.

For a given cross-sectional area,  $S$ , the block defines  $w_{2P}$  as

$$w_{2P} = \frac{\dot{m}_{2P} v_{2P}}{S},$$

and  $w_{MA}$  as

$$w_{MA} = \frac{\dot{m}_{MA} v_{MA}}{S},$$

where

$$v_{MA} = \frac{R_I T_{MA}}{p_{MA}}.$$

You specify  $S$  using the **Cross-sectional area at ports 2P and MA** parameter. The block computes the specific gas constant of the interface mixture,  $R_I$ , as a function of the fluid on either side such that

$$R_I = f(R_A, R_W, R_G, x_{WI}, x_{GI}),$$

where:

- $R_A$  is the dry air specific gas constant.
- $R_W$  is the water vapor specific gas constant.
- $R_G$  is the trace gas specific gas constant.
- $x_{WI}$  is the interface specific humidity. The block determines this value when the flow exits port **MA**, based on your parameter settings:
  - When **Moisture and trace gas specification** is Constant, the block calculates  $x_{WI}$  based on the method specified with the **Interface moisture specification** parameter.
  - When **Moisture and trace gas specification** is Controlled, the block bases  $x_{WI}$  on the input that you supply at port **W** or port **Tw**.
- $x_{GI}$  is the interface trace gas mass fraction. The block determines this value when the flow exits port **MA**, based on your parameter settings:
  - When **Moisture and trace gas specification** is Constant, the block calculates  $x_{GI}$  based on the value of the **Interface trace gas mass fraction** or **Interface trace gas mole fraction** parameter.
  - When **Moisture and trace gas specification** is Controlled, the block bases  $x_{GI}$  on the input that you supply at port **TG**.

## Ports

### Input

**W** — Moisture, unitless  
physical signal

Physical signal port associated with the moisture content at the interface.

#### Dependencies

To enable this port, set **Moisture and trace gas specification** to Controlled and **Interface moisture specification** to Relative humidity, Specific humidity, Mole fraction, or Humidity ratio.

**Tw** — Temperature, K  
physical signal

Physical signal port associated with the wet-bulb temperature at the interface, in K.

#### Dependencies

To enable this port, set **Moisture and trace gas specification** to Controlled and **Interface moisture specification** to Wet-bulb temperature.

**TG** — Trace gas, unitless  
physical signal

Physical signal port associated with the trace gas at the interface.

#### Dependencies

To enable this port, set **Moisture and trace gas specification** to Controlled.

#### Conserving

**2P** — Two-phase port  
two-phase fluid

Two-phase fluid conserving port associated with the two-phase fluid at the interface.

**MA** — Moist air port  
moist air

Moist air conserving port associated with the moist air at the interface.

## Parameters

**Moisture and trace gas specification** — Interface moisture and trace gas control option  
Constant (default) | Controlled

Option to maintain a constant interface or to specify the moisture and trace gas amounts via physical signal ports. When you select Controlled, the block exposes the **W** and **TG** ports.

**Interface moisture specification** — Moisture parameterization option  
Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio |  
Wet-bulb temperature

Whether to calculate moisture using relative humidity, specific humidity, mole fraction, humidity ratio, or wet-bulb temperature.

**Interface relative humidity** — Relative humidity at interface  
0.5 (default) | positive scalar

Relative humidity at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Relative humidity.

**Interface specific humidity** — Specific humidity at interface

0.01 (default) | positive scalar

Specific humidity at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Specific humidity.

**Interface water vapor mole fraction** — Water vapor mole fraction at interface

0.01 (default) | positive scalar

Water vapor mole fraction at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Mole fraction.

**Interface humidity ratio** — Humidity ratio at interface

0.01 (default) | positive scalar

Humidity ratio at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Humidity ratio.

**Interface wet-bulb temperature** — Wet-bulb temperature at interface

287 K (default) | positive scalar

Wet bulb temperature at the interface. The block uses this value to calculate moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Wet-bulb temperature.

**Interface trace gas specification** — Trace gas parameterization

Mass fraction (default) | Mole fraction

Whether to parameterize the trace gas at the interface using mass fraction or mole fraction.

**Interface trace gas mass fraction** — Trace gas mass fraction at interface

0.001 (default) | positive scalar

Mass fraction of trace gas at the interface.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface trace gas specification** to Mass fraction.

**Interface trace gas mole fraction** — Trace gas mole fraction at interface  
0.001 (default) | positive scalar

Mole fraction of trace gas at the interface.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface trace gas specification** to Mole fraction.

**Relative humidity at saturation** — Saturation point relative humidity  
1 (default) | positive scalar

Relative humidity at the point of saturation.

**Cross-sectional area at ports 2P and MA** — Port area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the two-phase fluid and moist air ports.

**Two-phase fluid superheated vapor check** — Two-phase fluid superheated conditions check  
None (default) | Warning | Error

Action to perform when the fluid at the interface does not meet superheated conditions.

**Inputs outside valid range** — Option to monitor or control invalid inputs  
Limit to valid values (default) | Warn and limit to valid values | Error

Monitor or control invalid inputs. When you select `Limit to valid values`, the block saturates the inputs within the bounds. You can choose to have the block issue a warning when it limits the inputs by selecting `Warn and limit to valid values`, or you can stop the simulation when the block receives invalid inputs by selecting `Error`.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Controlled.

## Version History

### Introduced in R2022a

#### R2023a: New moisture specification option

The block has a new option for the **Interface moisture specification** parameter. This option, called `Wet-bulb temperature`, allows you to input data in the form of a wet-bulb temperature.

Interface (2P-G) | Interface (2P-TL) | Interface (G-MA)

## Interface (2P-TL)

Two-phase fluid and thermal liquid network interface

### Libraries:

Simscape / Fluids / Fluid Network Interfaces

### Description

The Interface (2P-TL) block represents a flow connection between a two-phase fluid network and a thermal liquid network. Pressure, temperature, and mass flow rate are equal at the interface. The block does not transfer the fluid properties of each fluid network across the interface. To conserve fluid properties, ensure that the Thermal Liquid Properties (TL) block and the Two-Phase Fluid Properties (2P) block have the same settings.

The fluid at the **2P** port must remain subcooled. You can use the **Two-phase fluid subcooled liquid check** parameter to choose what action the block performs if the fluid does not meet this condition.

### Mass and Momentum Balance

The block conserves mass such that

$$\dot{m}_{TL} + \dot{m}_{2P} = 0,$$

where:

- $\dot{m}_{TL}$  is the mass flow rate into port **TL**.
- $\dot{m}_{2P}$  is the mass flow rate into port **2P**.

The port pressures are equal:

$$P_{TL} = P_{2P}.$$

### Energy Balance

The temperature is constant between the two fluid ports. The block calculates the energy balance over the interface as

$$\Phi_{TL} + \Phi_{2P} = \dot{m}_{TL} \left( u_{TL} + p_{TL} v_{TL} + \frac{w_{TL}^2}{2} \right) + \dot{m}_{2P} \left( u_{2P} + p_{2P} v_{2P} + \frac{w_{2P}^2}{2} \right),$$

where:

- $\Phi_{TL}$  is the energy flow rate into port **TL**.
- $\Phi_{2P}$  is the energy flow rate into port **2P**.
- $h_{TL}$  is the specific internal energy at port **TL**.
- $h_{2P}$  is the specific internal energy at port **2P**.
- $v_{TL}$  is the specific volume at port **TL**.

- $v_{2P}$  is the specific volume at port **2P**.
- $w_{TL}$  is the flow velocity at port **TL**

$$w_{TL} = \frac{\dot{m}_{TL} v_{TL}}{S},$$

- $w_{2P}$  is the flow velocity at port **2P**

$$w_{2P} = \frac{\dot{m}_{2P} v_{2P}}{S}.$$

- $S$  is the value of the **Cross-sectional area at ports 2P and TL** parameter.

## Ports

### Conserving

**2P** — Two-phase port  
two-phase fluid

Two-phase fluid conserving port associated with the two-phase fluid at the interface.

**TL** — Fluid port  
thermal liquid

Thermal liquid conserving port associated with the thermal liquid at the interface.

## Parameters

**Cross-sectional area at ports 2P and TL** — Port area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the thermal liquid and two-phase fluid ports.

**Two-phase fluid subcooled liquid check** — Two-phase fluid subcooled conditions check  
None (default) | Warning | Error

Action to perform when the fluid at port **2P** does not meet subcooled conditions.

Interface (2P-G) | Interface (TL-IL) | Interface (2P-MA)

## Interface (G-MA)

Gas and moist air network interface

### Libraries:

Simscape / Fluids / Fluid Network Interfaces

### Description

The Interface (G-MA) block represents a flow connection between a gas network and moist air network. Pressure, temperature, and mass flow rate are equal at the interface. The block does not transfer the fluid properties of each fluid network across the interface. To conserve fluid properties, ensure that the Gas Properties (G) block and the Moist Air Properties (MA) block have the same settings. When moist air leaves port **MA**, the block assigns the values of the **Interface specific humidity** and **Interface trace gas mass fraction** parameters to the signal. However, when moist air enters port **MA**, the block retains the upstream values.

You can choose whether to maintain constant moisture and trace gas amounts at the interface or to specify them using the **W** or **Tw** and **TG** ports, respectively.

### Mass and Momentum Balance

The block conserves mass such that

$$\dot{m}_G + \dot{m}_{MA} = 0,$$

where:

- $\dot{m}_G$  is the mass flow rate into port **G**.
- $\dot{m}_{MA}$  is the mass flow rate into port **MA**.

The block maintains equal port pressures and temperatures such that

$$p_G = p_{MA}$$

$$T_G = T_{MA}$$

### Energy Balance

The block calculates the energy balance over the interface as

$$\Phi_G + \Phi_{MA} = \dot{m}_G \left( h_G + \frac{w_G^2}{2} \right) + \dot{m}_{MA} \left( h_{MA} + \frac{w_{MA}^2}{2} \right),$$

where:

- $\Phi_G$  is the energy flow rate into port **G**.
- $\Phi_{MA}$  is the energy flow rate into port **MA**.
- $h_G$  is the specific enthalpy at port **G**.
- $h_{MA}$  is the specific enthalpy at port **MA**.

- $v_G$  is the specific volume at port **G**.
- $v_{MA}$  is the specific volume at port **MA**.
- $w_G$  is the flow velocity at port **G**.
- $w_{MA}$  is the flow velocity at port **MA**.

For a given cross-sectional area,  $S$ , the block defines  $w_G$  as

$$w_G = \frac{\dot{m}_G v_G}{S},$$

and  $w_{MA}$  as

$$w_{MA} = \frac{\dot{m}_{MA} v_{MA}}{S},$$

where:

$$v_{MA} = \frac{R_I T_{MA}}{p_{MA}}.$$

The specific gas constant of the mixture at the interface is a function of the fluid on either side such that

$$R_I = f(R_A, R_W R_G, x_{WI}, x_{GI}),$$

where:

- $R_A$  is the dry air specific gas constant.
- $R_W$  is the water vapor specific gas constant.
- $R_G$  is the trace gas specific gas constant.
- $x_{WI}$  is the interface specific humidity. The block determines this value when the flow exits port **MA**, based on your parameter settings:
  - When **Moisture and trace gas specification** is Constant, the block calculates  $x_{WI}$  based on the method specified with the **Interface moisture specification** parameter.
  - When **Moisture and trace gas specification** is Controlled, the block bases  $x_{WI}$  on the input that you supply at port **W** or port **Tw**.
- $x_{GI}$  is the interface trace gas mass fraction. The block determines this value when the flow exits port **MA**, based on your parameter settings:
  - When **Moisture and trace gas specification** is Constant, the block calculates  $x_{GI}$  based on the value of the **Interface trace gas mass fraction** or **Interface trace gas mole fraction** parameter.
  - When **Moisture and trace gas specification** is Controlled, the block bases  $x_{GI}$  on the input that you supply at port **TG**.

## Ports

### Input

**W** — Moisture, unitless  
physical signal

Physical signal port associated with the moisture content at the interface.

#### Dependencies

To enable this port, set **Moisture and trace gas specification** to Controlled and **Interface moisture specification** to Relative humidity, Specific humidity, Mole fraction, or Humidity ratio.

**Tw** — Temperature, K  
physical signal

Physical signal port associated with the wet-bulb temperature at the interface, in K.

#### Dependencies

To enable this port, set **Moisture and trace gas specification** to Controlled and **Interface moisture specification** to Wet-bulb temperature.

**TG** — Trace gas, unitless  
physical signal

Physical signal port associated with the trace gasses at the interface.

#### Dependencies

To enable this port, set **Moisture and trace gas specification** to Controlled.

#### Conserving

**G** — Fluid port  
gas

Gas conserving port associated with the gas at the interface.

**MA** — Moist air port  
moist air

Moist air conserving port associated with the moist air at the interface.

## Parameters

**Moisture and trace gas specification** — Interface moisture control option  
Constant (default) | Controlled

Option to maintain a constant interface or to specify the moisture and trace gas amounts via physical signal ports. When you select Controlled, the block exposes the **W** and **TG** ports.

**Interface moisture specification** — Moisture parameterization option  
Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio |  
Wet-bulb temperature

Whether to calculate moisture using relative humidity, specific humidity, mole fraction, humidity ratio, or wet-bulb temperature.

**Interface relative humidity** — Relative humidity at interface  
0.5 (default) | positive scalar

Relative humidity at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Relative humidity.

**Interface specific humidity** — Specific humidity at interface

0.01 (default) | positive scalar

Specific humidity at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Specific humidity.

**Interface water vapor mole fraction** — Water vapor mole fraction at interface

0.01 (default) | positive scalar

Water vapor mole fraction at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Mole fraction.

**Interface humidity ratio** — Humidity ratio at interface

0.01 (default) | positive scalar

Humidity ratio at the interface. The block uses this value to calculate the moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Humidity ratio.

**Interface wet-bulb temperature** — Wet-bulb temperature at interface

287 K (default) | positive scalar

Wet bulb temperature at the interface. The block uses this value to calculate moisture.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface moisture specification** to Wet-bulb temperature.

**Interface trace gas specification** — Trace gas parameterization

Mass fraction (default) | Mole fraction

Whether to parameterize the trace gas at the interface using mass fraction or mole fraction.

**Interface trace gas mass fraction** — Trace gas mass fraction at the interface

0.001 (default) | positive scalar

Mass fraction of trace gas at the interface.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface trace gas specification** to Mass fraction.

**Interface trace gas mole fraction** — Trace gas mole fraction at the interface  
0.001 (default) | positive scalar

Mole fraction of trace gas at the interface.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Constant and **Interface trace gas specification** to Mole fraction.

**Relative humidity at saturation** — Saturation point relative humidity  
1 (default) | positive scalar

Relative humidity at the point of saturation.

**Cross-sectional area at ports G and MA** — Port area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the gas and moist air ports.

**Inputs outside valid range** — Option to monitor or control invalid inputs  
Limit to valid values (default) | Warn and limit to valid values | Error

Monitor or control invalid inputs. When you select **Limit to valid values**, the block saturates the inputs within the bounds. You can choose to have the block issue a warning when it limits the inputs by selecting **Warn and limit to valid values**, or you can stop the simulation when the block receives invalid inputs by selecting **Error**.

**Dependencies**

To enable this parameter, set **Moisture and trace gas specification** to Controlled.

## Version History

Introduced in R2022a

**R2023a: New moisture specification option**

The block has a new option for the **Interface moisture specification** parameter. This option, called **Wet-bulb temperature**, allows you to input data in the form of a wet-bulb temperature.

Interface (2P-G) | Interface (2P-MA)

# Interface (TL-IL)

Connection between thermal and isothermal networks

**Libraries:**  
Simscape / Fluids / Fluid Network Interfaces

## Description

The Interface block is a connector between thermal and isothermal fluid networks. The fluid mass flow rate and pressure are matched between the networks, but fluid properties are not passed between the two networks. To maintain fluid properties between the thermal and isothermal components of your model, connect an Isothermal Liquid Predefined Properties (IL) block with the desired properties to the isothermal network side.

You can connect Thermal Liquid library blocks with Isothermal Liquid library or Hydraulics (Isothermal) library blocks. The temperature set in the isothermal system can either be **Constant** or **Controlled**. In the case of a **Controlled** temperature system, the isothermal network temperature is set by the thermal liquid temperature. In the **Constant** temperature setting, you specify the isothermal network temperature directly.

### Thermal Liquid - Isothermal Liquid

When **Fluids domain interface** is set to Thermal Liquid (TL) - Isothermal Liquid (IL), the mass flow rate is conserved over the two mass-flow-rate-based networks:

$$\dot{m}_{TL} + \dot{m}_{IL} = 0,$$

where:

- $\dot{m}_{TL}$  is the mass flow rate at the thermal liquid interface.
- $\dot{m}_{IL}$  is the mass flow rate at the isothermal liquid interface.

The fluid absolute pressure is maintained between the thermal, internal, and isothermal sections of the Interface block:

$$p_{TL} = p_{IL}.$$

## Thermal Liquid - Hydraulics (Isothermal)

The Hydraulics (Isothermal) Liquid library is based on volumetric flow rate. To maintain flow continuity between both sides of the interface, the volumetric flow rate is multiplied by the fluid density:

$$\dot{m}_{TL} + q_H \rho_H = 0,$$

where:

- $q_H$  is the Hydraulics (Isothermal) volumetric flow rate.
- $\rho_H$  is the local Hydraulics (Isothermal) fluid density.

The Hydraulics (Isothermal) Liquid library blocks are constructed in terms of gauge pressures. Pressure is converted to absolute pressure internally to match the thermal network pressure:

$$p_H + p_{atm} = p_{TL}.$$

## Ports

### Conserving

**TL** — Liquid port  
thermal liquid

Entry or exit port to the thermal liquid network.

**IL** — Liquid port  
isothermal liquid

Entry or exit port to the isothermal liquid network.

### Dependencies

To enable this port, set **Fluids domain interface** to Thermal Liquid (TL) - Isothermal Liquid (IL).

**H** — Liquid port  
isothermal liquid

Entry or exit port to the hydraulics (isothermal) liquid network.

### Dependencies

To enable this port, set **Fluids domain interface** to Thermal Liquid (TL) - Hydraulic (H).

## Parameters

**Fluids domain interface** — Connecting library types  
Thermal Liquid (TL) - Isothermal Liquid (IL) (default) | Thermal Liquid (TL) - Hydraulic (H)

Specifies the connecting library types.

**Temperature specification** — Isothermal network temperature  
Constant (default) | Controlled

Sets the isothermal network temperature. In the Constant setting, you can specify the isothermal network temperature in the **Hydraulic temperature** parameter. In the Controlled setting, the temperature in the isothermal network is set by the thermal network.

**Interface temperature** — Isothermal network temperature  
293.15 K (default) | positive scalar

Specifies the fluid temperature transmitted from the thermal liquid network to the hydraulic or isothermal liquid network.

#### Dependencies

To enable this parameter, set **Temperature specification** to Constant.

**Cross-sectional area at port TL** — Thermal liquid port area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the thermal liquid port.

# Jet Pump

(To be removed) Jet liquid-liquid pump

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Pumps and Motors

## Description

The Jet Pump block represents a jet liquid-liquid pump consisting of a nozzle, throat, and diffuser, as shown in this illustration.

The model is based on these equations, described in [1]:

$$q_1 = \frac{A_n}{\sqrt{1 + K_n}} \sqrt{\frac{2}{\rho} (p_1 - p_0)} \quad (1-8)$$

$$q_2 = \frac{A_n \cdot c}{\sqrt{1 + K_{en}}} \sqrt{\frac{2}{\rho} (p_2 - p_0)} \quad (1-9)$$

$$p_d - p_0 = Zb^2 \left( \frac{2}{b} + \frac{2}{1-b} M^2 - (1 + M)^2 \cdot (1 + K_{th} + K_{di} + a^2) \right) \quad (1-10)$$

$$b = \frac{A_n}{A_{th}}$$

$$c = \frac{1 - b}{b}$$

$$Z = \rho \frac{V_n^2}{2} = \rho \frac{q_1^2}{2A_n^2}$$

$$M = \frac{q_2}{q_1}$$

where:

$q_1$	Primary flow rate pumped through the nozzle
$q_2$	Secondary flow rate
$q_d$	Output flow rate
$p_1$	Pressure at the nozzle inlet
$p_2$	Pressure at the secondary flow rate inlet
$p_0$	Pressure at the throat inlet
$p_d$	Pressure at the pump outlet
$A_n$	Nozzle area
$A_{th}$	Throat area
$a$	Diffuser area ratio, $A_{th} / A_d$
$A_d$	Diffuser outlet area
$K_n$	Nozzle hydraulic loss coefficient
$K_{en}$	Throat entry hydraulic loss coefficient
$K_{th}$	Throat hydraulic loss coefficient
$K_{di}$	Diffuser hydraulic loss coefficient
$\rho$	Fluid density

Equation 1 on page 1-1230 describes the nozzle, Equation 2 on page 1-1230 describes the throat entry, and Equation 3 on page 1-1230 describes the combination of the throat and the diffuser. The equations correspond to a standard configuration of the pump, where all the longitudinal dimensions conform to established, empirically determined values. For more details, see [1].

The pump parameters are closely related to each other, and the methodology described in [1] is recommended to determine their initial values.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can

come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Assumptions and Limitations

- The model is based on the one-dimensional theory.
- The primary and secondary flows enter the mixing throat with uniform velocity distribution, and the mixed flow leaves the diffuser with uniform velocity distribution.
- The fluid in the primary and secondary flows is the same.
- The fluid is assumed to be incompressible and containing no gas.

## Ports

### Conserving

**A** — Nozzle entry  
hydraulic

Hydraulic conserving port associated with the nozzle entry. The nozzle is the primary flow entry.

**S** — Pump suction  
hydraulic

Hydraulic conserving port associated with the pump suction. The pump suction is the secondary flow entry.

**P** — Pump outlet  
hydraulic

Hydraulic conserving port associated with the pump outlet.

**N** — Internal nonvisible port associated with throat entry section of pump  
hydraulic

Internal hydraulic conserving port associated with the throat entry section of the pump. This port is not visible on the block icon. You can view the variables associated with the port by logging the simulation data. For more information, see “Data Logging”.

## Parameters

**Nozzle area** — Cross-sectional area of nozzle  
1 cm<sup>2</sup> (default) | positive scalar

Cross-sectional area of the nozzle.

**Throat area** — Cross-sectional area of throat  
4 cm<sup>2</sup> (default) | positive scalar

Cross-sectional area of the throat. The throat area is usually two to four times larger than the nozzle area.

**Diffuser inlet/outlet area ratio** — Ratio between inlet and outlet diffuser areas

0.224 (default) | positive scalar

Ratio between the inlet and outlet diffuser areas. For a standard pump with a 5°-7° included-angle diffuser, the ratio is close to 0.2.

**Nozzle loss coefficient** — Hydraulic friction loss coefficient in nozzle

0.05 (default) | positive scalar

Hydraulic friction loss coefficient in the nozzle.

**Throat entry loss coefficient** — Hydraulic friction loss coefficient in throat entry

0.005 (default) | positive scalar

Hydraulic friction loss coefficient in the throat entry.

**Throat loss coefficient** — Hydraulic friction loss coefficient in throat

0.1 (default) | positive scalar

Hydraulic friction loss coefficient in the throat.

**Diffuser loss coefficient** — Hydraulic friction loss coefficient in diffuser

0.1 (default) | positive scalar

Hydraulic friction loss coefficient in the diffuser.

## Version History

## Jet Pump (IL)

Liquid-liquid jet pump in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors

### Description

The Jet Pump (IL) block models a liquid-liquid jet pump in an isothermal liquid network with the same motive and suction fluids. The motive enters the primary nozzle at port **A**, which draws in the suction fluid through input port **S**. After mixing in the throat, the combined flow expands through the diffuser and is discharged at port **B**. The total pressure change over the pump is the sum of the individual contributions of friction and area change in each section of the pump and momentum changes in the throat. The sign convention for the equations below correspond to positive flow into the throat.

### Jet Pump Schematic

#### Changes in Pressure Due to Area Changes

The mass flow rate is conserved in the pump:

$$\dot{m}_A + \dot{m}_S + \dot{m}_B = 0,$$

where  $\dot{m}_A$  is the mass flow rate through port **A**,  $\dot{m}_S$  is the mass flow rate through port **S**, and  $\dot{m}_B$  is the mass flow rate through port **B**.

Using mass conservation and the Bernoulli Principle, the area changes over the pump segments can be expressed in terms of pressure change. The pressure change associated with the nozzle is:

$$\Delta p_{a, \text{Nozzle}} = \frac{\dot{m}_A^2}{4\rho A_N^2},$$

or 0, whichever is greater. The formulation depends on:

- $A_N$ , the **Nozzle area**, taken at its widest section.
- $\rho$ , the fluid density.

It is assumed that the nozzle inlet is much larger than the nozzle outlet.

Although the geometry of a typical suction inlet is not shaped like a nozzle, it effectively experiences the same type of area reduction as it enters the throat around the nozzle outlet. This annulus is assumed to be much smaller than the suction inlet. The pressure change due to this area reduction is:

$$\Delta p_{a, Annulus} = \frac{\dot{m}_S}{4\rho(A_T - A_N)^2},$$

or 0, whichever is greater.  $A_T$  is the cross-sectional area of the throat. The pressure change over the diffuser expansion is:

$$\Delta p_{a, Diffuser} = -\frac{\dot{m}_B^2}{2\rho A_T^2}(1 - a^2),$$

where  $a$  is the **Diffuser inlet to outlet area ratio**.

---

**Reversed Flows** In the case of reversed flow, the effect of the nozzle area on pressure change is not modeled, and therefore flow traveling from the throat through the nozzle will not undergo any pressure gain. This ensures the numerical stability of the block during simulation of reversed flows.

---

### Changes in Pressure Due to Mixing

Mixing between the motive and suction flows occurs in the throat. This change in momentum is associated with a change in pressure:

$$\Delta p_{mixing} = \frac{\frac{\dot{m}_A^2}{b} + \frac{\dot{m}_S^2}{1-b} - \dot{m}_B^2}{\rho A_T},$$

where  $b$  is the **Nozzle to throat area ratio**, which is defined between the largest and smallest cross-sectional areas of the nozzle.

### Pressure Losses Due to Friction

The flow experiences losses due to friction in the nozzle, secondary suction inlet, throat, and diffuser. These losses are calculated based on a coefficient defined for each section and the area, or area ratio, between different sections of the pump. Note that friction incurs pressure losses, irrespective of flow direction. The pressure loss in the nozzle due to friction is:

$$\Delta p_{f, Nozzle} = K_N \frac{\dot{m}_A |\dot{m}_A|}{2\rho A_N^2},$$

where  $K_N$  is the **Primary flow nozzle loss coefficient**. The pressure loss due to friction in the suction flow through the annulus is:

$$\Delta p_{f, Annulus} = K_S \frac{\dot{m}_S |\dot{m}_S|}{2\rho(A_T - A_N)^2},$$

where  $K_S$  is the **Secondary flow entry loss coefficient**. The pressure loss in the throat due to friction is:

$$\Delta p_{f, Throat} = K_T \frac{\dot{m}_B |\dot{m}_B|}{2\rho A_T^2},$$

where  $K_T$  is the **Throat loss coefficient**. The pressure loss in the diffuser due to friction is:

$$\Delta p_{f, Diffuser} = K_D \frac{\dot{m}_B |\dot{m}_B|}{2\rho A_T^2},$$

where  $K_D$  is the **Diffuser loss coefficient**. Note that the sign corresponds to negative flow from the throat toward port **B**. Losses are defined for the regions of highest velocity in the flow. For this reason, the throat area, which is equal to the diffuser inlet area, is used in the diffuser loss equation.

### Saturation Pressure in the Nozzle

Cavitation occurs when a region of low pressure in the flow falls below the vapor saturation pressure. This creates pockets of vapor in the liquid and impedes any further increase in flow through the pump. You can model this flow rate limit by specifying a **Minimum nozzle pressure**, beyond which the fluid velocity will remain constant. The total pressure change over the pump depends on this pressure threshold at the nozzle outlet. Between the nozzle and the diffuser, the pressure change is either

$$p_B - p_N = \Delta p_{mixing} + \Delta p_{f, Throat} + \Delta p_{f, Diffuser} - \Delta p_{a, Diffuser}$$

or  $p_B - p_{N, \min}$ , whichever is smaller.

The total pressure change in the nozzle is:

$$p_A - p_N = \Delta p_{a, Nozzle} + \Delta p_{f, Nozzle}.$$

The total pressure change in the annulus is:

$$p_S - p_N = \Delta p_{a, Annulus} + \Delta p_{f, Annulus}.$$

### Assumptions and Limitations

- The motive and suction liquids are the same.
- Mixing in the throat is assumed to be uniform and complete.
- The nozzle inlet is much larger than the nozzle outlet, and the suction jet annulus is much smaller than the suction inlet.
- The change in pressure due to the nozzle is not modeled for reversed flows.
- Any effect of cavitation is modeled as a maximum limit on the flow rate in the throat.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Motive liquid inlet port.

**S** — Liquid port  
isothermal liquid

Suction liquid inlet port.

**B** — Liquid port  
isothermal liquid

Mixed fluid outlet port.

## Parameters

**Nozzle area** — Nozzle inlet area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the inlet nozzle at its widest section. The motive liquid enters the jet pump through the nozzle.

**Nozzle to throat area ratio** — Nozzle outlet to throat area  
0.25 (default) | positive scalar

Characteristic ratio of the nozzle outlet and throat cross-sectional areas.

**Diffuser inlet to outlet area ratio** — Diffuser geometry ratio  
0.25 (default) | positive scalar

Characteristic ratio of the diffuser inlet and outlet cross-sectional areas.

**Primary flow nozzle loss coefficient** — Friction loss coefficient  
0.05 (default) | positive scalar

Characterizes the losses in pressure due to nozzle friction in the motive flow.

**Secondary flow entry loss coefficient** — Friction loss coefficient  
0.005 (default) | positive scalar

Characterizes the losses in pressure in the suction flow due to the suction inlet friction.

**Throat loss coefficient** — Friction loss coefficient  
0.1 (default) | positive scalar

Characterizes the losses in pressure in the mixture due to throat friction.

**Diffuser loss coefficient** — Friction loss coefficient  
0.1 (default) | positive scalar

Characterizes the losses in pressure due in the mixed flow due to friction in the diffuser.

**Minimum nozzle pressure** — Minimum pressure at the nozzle outlet

0.1 Pa (default) | positive scalar

Sets the maximum allowed pressure change in the jet pump. If pressures at the nozzle exit fall below this value, the block simulates the effect of cavitation by restricting the fluid velocity to the velocity at the minimum nozzle pressure.

# Journal Bearing Pressure-Fed

(To be removed) Hydraulic portion of pressure-fed journal bearing

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Library

Orifices

## Description

The Journal Bearing Pressure-Fed block simulates the hydraulic portion of a pressure-fed journal bearing, shown in the following illustration.

The lubricant under pressure  $p$  is pumped into the circumferential groove at the center of the bearing. The groove divides the bearing into two half-bearings. The lubricant exits through the end grooves located at a distance  $l$  from the central groove. The model is intended to be used in lubrication system simulation to assess the flow consumption through the pressure-fed journal

bearing. The flow regime is assumed to be laminar due to very small clearances between the journal and the bushing.

The flow rate is computed using the Hagen-Poiseuille equation (see [1] on page 1-1241):

$$q = \frac{\pi p r c^3}{3 \mu l} (1 + 1.5 \varepsilon^2)$$

where

$q$	Volumetric flow rate
$p$	Pressure differential across the bearing
$r$	Journal radius
$c$	Radial clearance at neutral position
$\mu$	Dynamic viscosity
$l$	Length of the half-bearing
$\varepsilon$	Relative eccentricity, $\varepsilon = e / r$
$e$	Eccentricity or journal deflection from the central position

The journal radial displacement, which controls the bearing eccentricity, is imported through the physical signal port J. Connections A and B are hydraulic conserving ports associated with the bearing inlet and outlet, respectively. The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B and the pressure differential is determined as  $\Delta p = p_A - p_B$ . Positive signal at the physical signal port J increases the eccentricity and is limited to the radial clearance of the bearing.

## Basic Assumptions and Limitations

The flow regime is assumed to be laminar due to small clearances.

## Parameters

### Journal radius

The radius of the journal. The parameter must be positive. The default value is 0.05 m.

### Radial clearance

The radial clearance between the journal and the bushing at neutral position. The parameter must be positive. The default value is 2e-4 m.

### Bearing half-length

The length of the half-bearing, that is, the distance between each of the end grooves and the central groove. The parameter must be positive. The default value is 0.025 m.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**

- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the bearing inlet.

B

Hydraulic conserving port associated with the bearing outlet.

J

Physical signal port that controls the journal deflection.

Local Hydraulic Resistances

### Description

The Local Resistance block represents a generic local hydraulic resistance, such as a bend, elbow, fitting, filter, local change in the flow cross section, and so on. The pressure loss caused by resistance is computed based on the pressure loss coefficient, which is usually provided in catalogs, data sheets, or hydraulic textbooks. The pressure loss coefficient can be specified either as a constant, or by a table, in which it is tabulated versus Reynolds number.

The pressure drop between port **A** and port **B** is:

$$\Delta p = p_A - p_B,$$

where:

- $p$  is the pressure drop.
- $p_A$  is the gauge pressure at port **A**.
- $p_B$  is the gauge pressure at port **B**.

If the **Model parameterization** parameter is set to `By semi-empirical formulas`, the pressure drop is related to the volumetric flow rate by the expression:

$$q = A \sqrt{\frac{2}{K \cdot \rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

where:

- $q$  is the volumetric flow rate.
- $A$  is the flow area.

- $K$  is the pressure loss coefficient of the flow resistance.
- $\rho$  is the fluid density.
- $p_{Cr}$  is the minimum pressure for turbulent flow.

If the **Model parameterization** parameter is set to **By loss coefficient vs. Re table**, the pressure drop is related to the volumetric flow rate by the expression:

$$p = K(\text{Re})\rho \frac{q|q|}{2A^2}$$

where  $K$  is now a function of the Reynolds number (Re). Its value is specified in the block dialog box in tabulated form against the Reynolds number:

$$\text{Re} = \frac{q \cdot D_H}{A \cdot \nu}$$

where:

- $D_H$  is the hydraulic diameter of the flow resistance:

$$D_H = \sqrt{\frac{4A}{\pi}}$$

- $\nu$  is the kinematic viscosity.

For a constant pressure loss coefficient, the minimum pressure for turbulent flow,  $p_{Cr}$ , is calculated according to the laminar transition specification method:

- **By pressure ratio** — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{Cr} = (p_{\text{avg}} + p_{\text{atm}})(1 - B_{\text{lam}})$$

$$p_{\text{avg}} = (p_A + p_B)/2$$

where

$p_{\text{avg}}$	Average pressure between the block terminals
$p_{\text{atm}}$	Atmospheric pressure, 101325 Pa
$B_{\text{lam}}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- **By Reynolds number** — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{Cr} = K \frac{\rho}{2} \left( \frac{\text{Re}_{Cr} \cdot \nu}{D_H} \right)^2$$

where

$\text{Re}_{Cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)
------------------	---

The block provides two parameterizations:

- **By semi-empirical formulas** — The pressure loss coefficient is assumed to be constant for a specific flow direction. The flow regime can be either laminar or turbulent, depending on the Reynolds number.
- **By loss coefficient vs. Re table** — The pressure loss coefficient is specified as a function of the Reynolds number. The flow regime is assumed to be turbulent at all times. You must ensure that the loss coefficient data corresponds to this flow regime.

The resistance can be symmetrical or asymmetrical. In symmetrical resistances, the pressure loss practically does not depend on flow direction and one value of the coefficient is used for both the direct and reverse flow. For asymmetrical resistances, the separate coefficients are provided for each flow direction. If the loss coefficient is specified by a table, the table must cover both the positive and the negative flow regions.

Connections A and B are conserving hydraulic ports associated with the block inlet and outlet, respectively.

The block positive direction is from port A to port B. This means that the flow rate is positive if fluid flows from A to B, and the pressure loss is determined as  $\Delta p = p_A - p_B$ .

### **Variables**

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## **Basic Assumptions and Limitations**

- Fluid inertia is not taken into account.
- If you select parameterization by the table-specified relationship  $K=f(Re)$ , the flow is assumed to be completely turbulent.

## **Parameters**

### **Parameters Tab**

#### **Resistance area**

The smallest passage area. The default value is  $1e-4 \text{ m}^2$ .

#### **Model parameterization**

Select one of the following methods for specifying the pressure loss coefficient:

- **By semi-empirical formulas** — Provide a scalar value for the pressure loss coefficient. For asymmetrical resistances, you have to provide separate coefficients for direct and reverse flow. This is the default method.
- **By loss coefficient vs. Re table** — Provide tabulated data of loss coefficients and corresponding Reynolds numbers. The loss coefficient is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods. For

asymmetrical resistances, the table must cover both the positive and the negative flow regions.

### **Pressure loss coefficient for direct flow**

Loss coefficient for the direct flow (flowing from A to B). For simple ideal configurations, the value of the coefficient can be determined analytically, but in most cases its value is determined empirically and provided in textbooks and data sheets (for example, see [1] on page 1-1247). The default value is 2. This parameter is used if **Model parameterization** is set to *By semi-empirical formulas*.

### **Pressure loss coefficient for reverse flow**

Loss coefficient for the reverse flow (flowing from B to A). The parameter is similar to the loss coefficient for the direct flow and must be set to the same value if the resistance is symmetrical. The default value is 2. This parameter is used if **Model parameterization** is set to *By semi-empirical formulas*.

### **Laminar transition specification**

If **Model parameterization** is set to *By semi-empirical formulas*, select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to *Pressure ratio*.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 150. This parameter is visible only if the **Laminar transition specification** parameter is set to *Reynolds number*.

### **Reynolds number vector**

Specify the vector of input values for Reynolds numbers as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values are [-4000, -3000, -2000, -1000, -500, -200, -100, -50, -40, -30, -20, -15, -10, 10, 20, 30, 40, 50, 100, 200, 500, 1000, 2000, 4000, 5000, 10000]. This parameter is used if **Model parameterization** is set to *By loss coefficient vs. Re table*.

### **Loss coefficient vector**

Specify the vector of the loss coefficient values as a one-dimensional array. The loss coefficient vector must be of the same size as the Reynolds numbers vector. The default values are [0.25, 0.3, 0.65, 0.9, 0.65, 0.75, 0.90, 1.15, 1.35, 1.65, 2.3, 2.8, 3.10, 5, 2.7, 1.8, 1.46, 1.3, 0.9, 0.65, 0.42, 0.3, 0.20, 0.40, 0.42, 0.25]. This

parameter is used if **Model parameterization** is set to `By loss coefficient vs. Re table`.

### **Interpolation method**

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) block reference page. This parameter is used if **Model parameterization** is set to `By loss coefficient vs. Re table`.

### **Extrapolation method**

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) block reference page. This parameter is used if **Model parameterization** is set to `By loss coefficient vs. Re table`.

## **Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Model parameterization**
- **Interpolation method**
- **Extrapolation method**
- **Laminar transition specification**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Model parameterization** parameter at the time the model entered Restricted mode.

## **Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the resistance inlet.

B

Hydraulic conserving port associated with the resistance outlet.

## Local Resistance (IL)

Pipe resistances in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

### Description

The Local Resistance (IL) block models pressure loss due to user-defined pipe resistances in an isothermal liquid system. You can specify different loss coefficients for forward and reversed flows through the pipe segment. For pipe bends, you can also choose to use the Isothermal Liquid library blocks Pipe Bend (IL) and Elbow (IL) or, for area changes, the Area Change (IL) block.

The loss factor is parameterized by either a constant relationship based on the pipe pressure or by user-supplied tabular data for loss coefficients based on the Reynolds number.

### Constant Loss Factor

Segments with loss factors that remain constant over a range of flow velocities are calculated as:

$$k_{loss} = k_{loss,BA} + \frac{(k_{loss,AB} - k_{loss,BA})}{2} \left[ \tanh\left(\frac{3\Delta p}{\Delta p_{crit}}\right) + 1 \right],$$

where:

- $k_{loss,AB}$  and  $k_{loss,BA}$  are the **Forward flow loss coefficient (from A to B)** and **Reverse flow loss coefficient (from B to A)** parameters, respectively.
- $\Delta p$  is the pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$  is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , which is the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\bar{\rho}}{2} k_{loss,crit} \left( \frac{\nu Re_{crit}}{D_h} \right)^2,$$

where:

- $k_{loss,crit}$  is the loss factor associated with the critical pressure, and is based on an average of the forward and reverse loss coefficients.
- $\nu$  is the fluid kinematic viscosity.
- $\bar{\rho}$  is the average fluid density.
- $D_h$  is the segment hydraulic diameter, which is the equivalent diameter of a pipe with a non-circular cross-section:  $D_h = \sqrt{\frac{4}{\pi A_{flow}}}$ ., where  $A_{flow}$  is the **Flow area**.

### Tabulated Loss Coefficient

The loss coefficient can alternatively be interpolated from user-provided Reynolds number and loss coefficient data. The vector of Reynolds numbers can have both positive and negative values, indicating forward and reverse flow, respectively:  $k_{loss} = TLU(Re)$ .

### Mass Flow Rate

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the valve is calculated as:

$$\dot{m} = A_{flow} \frac{\sqrt{2\bar{\rho}}}{\sqrt{k_{loss}}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where  $k_{loss}$  is the flow loss coefficient, which is selected between the **Forward flow loss coefficient (from A to B)** and **Reverse flow loss coefficient (from B to A)** based on the block flow direction.

### Energy Balance

The block balances energy such that

$$\Phi_A + \Phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pipe segment. Flow is positive from port **A** to port **B**.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pipe segment. Flow is positive from port **A** to port **B**.

## Parameters

**Local loss parametrization** — Loss factor calculation method

Constant (default) | Tabulated data - loss coefficient vs. Reynolds number

Method of calculating the pipe segment loss factor. The loss factor is parameterized by either a linear relationship between the segment pressure drop and constant loss factor or by interpolation of user-provided loss factor and Reynolds number data.

**Forward flow loss coefficient (from A to B)** — Loss coefficient for flow from A to B  
1 (default) | positive scalar

Loss coefficient associated with pressure loss for flows from port **A** to port **B**.

**Reverse flow loss coefficient (from B to A)** — Loss coefficient for flow from B to A  
1 (default) | positive scalar

Loss coefficient associated with pressure loss for flows from port **B** to port **A**.

**Reynolds number vector** — Vector of Reynolds numbers for tabular parameterization  
[-500, -200, -100, -50, -40, -30, -20, -10, 10, 20, 30, 40, 50, 100, 200, 500, 1000, 2000] (default) | 1-by-*n* vector

Vector of Reynolds numbers for the tabular parameterization of the loss coefficient. The vector elements must correspond one-to-one with the elements in the **Loss coefficient vector** parameter. The elements are listed in ascending order.

#### **Dependencies**

To enable this parameter, set **Local loss parameterization** to Tabulated data - loss coefficient vs. Reynolds number.

**Loss coefficient vector** — Vector of loss coefficients for tabular parameterization  
[.65, .75, .9, 1.15, 1.35, 1.65, 2.3, 3.1, 4, 2.7, 1.8, 1.46, 1.3, .9, .65, .42, .3, .2] (default) | 1-by-*n* vector

Vector of loss coefficients for the tabular parameterization of the loss coefficient. The vector elements must correspond one-to-one with the elements in the **Reynolds number vector** parameter. The elements must be greater than 0.

#### **Dependencies**

To enable this parameter, set **Local loss parameterization** to Tabulated data - loss coefficient vs. Reynolds number.

**Flow area** — Segment cross-sectional area  
1e-3 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the pipe segment.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

## Local Resistance (TL)

Pipe resistance in a thermal liquid network

### Libraries:

Simscape / Fluids / Thermal Liquid / Pipes & Fittings

### Description

The Local Resistance (TL) block represents pressure loss due to user-defined pipe resistance in a thermal liquid network. You can specify different loss coefficients for forward and reversed flows through the pipe segment. For pipe bends, you can also choose to use the Thermal Liquid library blocks Pipe Bend (TL) and Elbow (TL) or, for area changes, the Sudden Area Change (TL) block.

The loss factor is parameterized by either a constant relationship based on the pipe pressure or by user-supplied tabular data for loss coefficients based on the Reynolds number.

### Constant Loss Factor

Segments with loss factors that remain constant over a range of flow velocities are calculated as:

$$k_{loss} = k_{loss,BA} + \frac{(k_{loss,AB} - k_{loss,BA})}{2} \left[ \tanh\left(\frac{3\Delta p}{\Delta p_{crit}}\right) + 1 \right],$$

where:

- $k_{loss,AB}$  and  $k_{loss,BA}$  are the **Forward flow loss coefficient (from A to B)** and **Reverse flow loss coefficient (from B to A)** parameters, respectively.
- $\Delta p$  is the pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , which is the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\bar{\rho}}{2} k_{loss,crit} \left( \frac{\nu Re_{crit}}{D_h} \right)^2,$$

where:

- $k_{loss,crit}$  is the loss factor associated with the critical pressure, and is based on an average of the forward and reverse loss coefficients.
- $\nu$  is the fluid kinematic viscosity.
- $\bar{\rho}$  is the average fluid density.
- $D_h$  is the segment hydraulic diameter, which is the equivalent diameter of a pipe with a non-circular cross-section:  $D_h = \sqrt{\frac{4}{\pi A_{flow}}}$ , where  $A_{flow}$  is the **Flow area**.

## Tabulated Loss Coefficient

The loss coefficient can alternatively be interpolated from user-provided Reynolds number and loss coefficient data. The vector of Reynolds numbers can have both positive and negative values, indicating forward and reverse flow, respectively:  $k_{loss} = TLU(Re)$ .

## Mass Flow Rate

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the valve is calculated as:

$$\dot{m} = A_{flow} \frac{\sqrt{2\bar{\rho}}}{\sqrt{k_{loss}}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where  $k_{loss}$  is the flow loss coefficient, which is selected between the **Forward flow loss coefficient (from A to B)** and **Reverse flow loss coefficient (from B to A)** based on the block flow direction.

## Energy Balance

The block balances energy such that

$$\Phi_A + \Phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the entry or exit port to the pipe segment. Flow is positive from port **A** to port **B**.

**B** — Liquid port  
isothermal liquid

Thermal liquid conserving port associated with the entry or exit port to the pipe segment. Flow is positive from port **A** to port **B**.

## Parameters

**Local loss parametrization** — Loss factor calculation method

Constant (default) | Tabulated data - loss coefficient vs. Reynolds number

Method of calculating the pipe segment loss factor. The loss factor is parameterized by either a linear relationship between the segment pressure drop and constant loss factor or by interpolation of user-provided loss factor and Reynolds number data.

**Forward flow loss coefficient (from A to B)** — Loss coefficient for flow from A to B  
1 (default) | positive scalar

Loss coefficient associated with pressure loss for flows from port **A** to port **B**.

**Reverse flow loss coefficient (from B to A)** — Loss coefficient for flow from B to A  
1 (default) | positive scalar

Loss coefficient associated with pressure loss for flows from port **B** to port **A**.

**Reynolds number vector** — Vector of Reynolds numbers for tabular parameterization  
[-500, -200, -100, -50, -40, -30, -20, -10, 10, 20, 30, 40, 50, 100, 200, 500, 1000, 2000] (default) | 1-by-*n* vector

Vector of Reynolds numbers for the tabular parameterization of the loss coefficient. The vector elements must correspond one-to-one with the elements in the **Loss coefficient vector** parameter. The elements are listed in ascending order.

#### **Dependencies**

To enable this parameter, set **Local loss parameterization** to Tabulated data - loss coefficient vs. Reynolds number.

**Loss coefficient vector** — Vector of loss coefficients for tabular parameterization  
[.65, .75, .9, 1.15, 1.35, 1.65, 2.3, 3.1, 4, 2.7, 1.8, 1.46, 1.3, .9, .65, .42, .3, .2] (default) | 1-by-*n* vector

Vector of loss coefficients for the tabular parameterization of the loss coefficient. The vector elements must correspond one-to-one with the elements in the **Reynolds number vector** parameter. The elements must be greater than 0.

#### **Dependencies**

To enable this parameter, set **Local loss parameterization** to Tabulated data - loss coefficient vs. Reynolds number.

**Flow area** — Segment cross-sectional area  
 $1e-3 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the pipe segment.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

# Multiposition Valve Actuator

Multiposition actuator in any fluid domain

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Actuators

## Description

The Multiposition Valve Actuator block models a multiposition actuator in any fluid domain. You can use it in combination with any valve block that takes a physical signal as input. The actuator position is influenced by the input signal and switching time, and not by loading.

### Two-Position Actuator Movement

Actuation begins when the signal at port **A** exceeds 50% of the **Nominal signal value**. After the time period set by the **Switching-on time** parameter, the actuator begins to move toward the **Push-pin stroke limit**. When the input signal at port **A** falls below 50% of the **Nominal signal value**, the actuator reverses its direction after the time period set by the **Switching-off time** parameter. The motion can be interrupted mid-stroke.

### Actuator position

In the image above,  $t_{de}$  is the **Switching-on time**, which is equal to the time periods  $t_{ae}$  and  $t_{ve}$ . In region  $t_{ae}$ , the actuator moves at constant acceleration with parabolic displacement. In region  $t_{ve}$ , the actuator moves linearly, with constant velocity, toward full push-pin extension. The actuator switches direction when the control signal is off:

- $t_{dr}$  is a transitional no-displacement time period set by the **Switching-off time**.

- 2  $t_{ar}$  is a period of acceleration with parabolic displacement.
- 3  $t_{vr}$  is period of linear displacement toward the actuator **Initial position**.

When **Actuator positions** is set to 2, the **Actuator travel direction** parameter sets the direction of the push-pin motion.

The actuator motion can be interrupted at any time. If the push-pin motion is disrupted mid-stroke, the switch-on and switch-off times are adjusted proportionally to the push-pin position, relative to the push-pin stroke.

### Three-Position Actuator Movement

When **Actuator positions** is set to 3, the signal at port **A** moves the actuator in a positive direction and the signal received at port **B** moves the actuator in a negative direction. Only one signal, from one port, is processed at a time. To switch control between ports **A** and **B**, or between positive and negative displacement control, the actuator must first move to a neutral position. If the push-pin motion is disrupted mid-stroke, the switch-on and switch-off times are adjusted proportionally to the push-pin position, relative to the push-pin stroke. The actuator motion can be interrupted at any time.

When controlled by the signal at port **A**, the three-position actuator has the same displacement profile as the two-position actuator when **Actuator travel direction** is set to **Positive**. When controlled by the signal at port **B**, it has the same profile as the two-position actuator when **Actuator travel direction** is set to **Negative**.

## Ports

### Input

**A** — Input signal  
physical signal

Input port, specified as a physical signal.

When **Actuator positions** is set to 2, this port can either control negative or positive actuator movement, according to the **Actuator orientation** setting.

When **Actuator positions** is set to 3, this port receives a physical signal that corresponds to a positive actuator displacement direction.

**B** — Input signal  
physical signal

Input port for negative actuator displacement, received as a physical signal.

### Dependencies

To enable this port, set **Actuator positions** to 3.

### Output

**S** — Actuator position, m  
physical signal

Actuator position, in m, specified as a physical signal.

If you use the Multiposition Valve Actuator block with a valve from the Gas Library, the gas block converts the actuator signal units of m to units of 1.

## Parameters

**Actuator positions** — Number of valve position signals  
2 (default) | 3

Number of valve position signals. When set to 2, the actuator receives one signal and sets one position signal. When set to 3, the actuator receives a positive and a negative signal and sets one position signal.

**Push-pin stroke** — Maximum push-pin extension  
0.01 m (default) | positive scalar

Maximum push-pin extension.

**Switching-on time** — Signal transition time period  
0.1 s (default) | positive scalar

Transitional time period before the actuator begins to move. The period begins after the input signal rises above 50% of the **Nominal signal value**.

**Switching-off time** — Signal transition time period  
0.1 s (default) | positive scalar

Transitional time period before the actuator reverses motion. The period begins after the input signal falls below 50% of the **Nominal signal value**.

**Nominal signal value** — Nominal signal for fully extended actuator  
24 (default) | positive scalar

Nominal signal for fully extended actuator. The actuator motion is triggered when the input signal reaches 50% of the **Nominal signal value**.

**Initial position** — Actuator starting position  
Retracted (default) | Extended | Neutral

Starting position of the actuator. Retracted and Extended correspond to the actuator push-pin stroke limits.

When **Actuator positions** is set to 2, the **Initial position** default is Retracted. When **Actuator positions** is set to 3, the **Initial position** default is Neutral. Neutral corresponds to the middle of the **Push-pin stroke**.

**Actuator orientation** — Direction of actuator motion  
Positive (default) | Negative

Direction of the actuator motion in response to the physical signal input. The Positive setting corresponds to push-pin extension.

### Dependencies

To enable this parameter, set **Actuator positions** to 2.

## M-Way N-Position Directional Valve (IL)

M-way, N-position valve in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The M-Way N-Position Directional Valve (IL) block represents a spool-operated directional valve with an arbitrary configuration of ports, spool positions, and orifices. The block accepts up to ten ports, ten spool positions, and 20 orifices. Valves with many configurations are most common in construction, agriculture, and some vehicle applications. This block simplifies complex parameterizations by allowing you to apply the same area characteristics to all flow paths. You can also individually specify the area characteristics for each flow path. You can parameterize the valve by specifying the opening area or by using tabulated data that represents volumetric flow rate for a fully open orifice at varied pressure drops. The block uses a variable orifice to control the flow between a given pair of connected ports. The physical signal at port **S** triggers the spool motion to open or shut the valve. For more details about how the block calculates flow rate through a variable orifice, see Orifice (IL).

You can generate a characteristic plot of the valve by right-clicking the block and selecting **Fluids > Plot Valve Characteristics**. To update the plot after changing the block parameters, click the **Reload Data** button. You can control the shape of the characteristic plot. To select which lines are visible, click the appropriate orifice on the legend.

The default valve characteristic plot is:

The figure indicates locations A1, A2, B1, and B2.

Position 1 is at spool travel of -1 mm. Position 2 is at spool travel of 0 mm, and Position 3 is at spool travel of 1 mm. Locations A1 and A2 represent the left- and right-side transition regions of the orifice opening area, respectively. Locations B1 and B2 represent the left- and right-side fully open regions of the orifice opening area, respectively. The current spool position is the separation between B1 and B2. When you set **Area characteristics** to Identical for all flow paths.

- $A1 = (\text{distance between spool positions 1 and 2}) * (\text{value of the } \mathbf{Inter\text{-}position\ spool\ travel\ fraction\ for\ which\ orifices\ transition\ between\ open\text{-}closed}$  parameter)
- $A2 = (\text{distance between spool positions 2 and 3}) * (\text{value of the } \mathbf{Inter\text{-}position\ spool\ travel\ fraction\ for\ which\ orifices\ transition\ between\ open\text{-}closed}$  parameter)
- $B1 = (\text{distance between spool positions 1 and 2}) * (\text{value of the } \mathbf{Inter\text{-}position\ spool\ travel\ fraction\ for\ which\ orifices\ remain\ fully\ open}$  parameter)
- $B2 = (\text{distance between spool positions 2 and 3}) * (\text{value of the } \mathbf{Inter\text{-}position\ spool\ travel\ fraction\ for\ which\ orifices\ remain\ fully\ open}$  parameter)

When you set **Area characteristics** to Different for each flow path:

- $A1 = A2 = \text{value of the } \mathbf{Spool\ travel\ for\ which\ orifice\ 2\ transitions\ between\ open\text{-}closed}$  parameter.
- $B1 = B2 = \text{value of the } \mathbf{Spool\ travel\ for\ which\ orifice\ 2\ remains\ fully\ open}$  parameter.

### Orifice Parameterization

When you set **Area parameterization** to Different for each flow path, you can parameterize each orifice by using the parameters in the **Orifice 1,...,20** sections. For example, if you set **Number of orifices** to 3, the block includes sections for **Orifice 1**, **Orifice 2**, and **Orifice 3**. Each section has the same parameter names followed by the number for that section.

The block icon updates automatically to indicate the orifice configuration, which you control with the appropriate **Ports connected by orifice...** parameter. If you connect one odd-numbered port to one even-numbered port, the block icon shows an arrow that points to the second listed port. The block icon indicates when a parameterization is invalid.

### Assumptions and Limitations

- The block supports only linearly varying opening areas.
- The block assumes that each orifice has a symmetric opening and closing about the spool position when you set **Area characteristics** to **Different** for each flow path.
- The block assumes that each orifice has a symmetric opening and closing scaled with the spacing of the **Spool travel at each spool position index** parameter when you set **Area characteristics** to **Identical** for each flow path.

## Ports

### Input

**S** — Spool displacement, m  
physical signal

Physical signal input port associated with the spool displacement, in m.

### Conserving

**1** — Port 1  
isothermal liquid

Isothermal liquid conserving port associated with port 1.

**2,...,10** — Ports with parameter dependencies  
isothermal liquid

Isothermal liquid conserving ports associated with port 2 through 10, where the number of ports is equal to the **Number of ports** parameter.

### Dependencies

To enable ports 2 through 10, set **Number of ports** to the number of ports you want.

## Parameters

### Valve Configuration

**Number of ports** — Number of valve ports  
2 (default) | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10

Number of ports associated with the valve, *M*. You can select up to ten.

**Number of spool positions** — Number of spool positions  
2 (default) | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10

Number of spool positions, *N*. You can select up to ten.

**Number of orifices** — Number of orifices

1 (default) | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18 | 19 | 20

Number of orifices. You can select up to 20.

**Spool travel at each spool position index** — Spool travel[-2, 0, 2, 4] mm (default) | vector of length  $N$ 

Spool travel values. Each element corresponds to a different spool position index. The length of this vector must be equal to length of the **Number of spool positions** parameter,  $N$ . A value of 0 represents a neutral spool position.

**Area characteristics** — Area characteristic parameterization option

Identical for all flow paths (default) | Different for each flow path

Whether to apply identical or different parameterizations for each orifice.

**Inter-position spool travel fraction for which orifices remain fully open** — Fully open flow between spool positions

0.5 (default) | scalar in the range [0,1)

Fractional distance between adjacent spool positions for which each orifice remains at the maximum opening area.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for each flow path.

**Inter-position spool travel fraction for which orifices transition between open-closed** —

Spool travel from open to closed

0.1 (default) | nonnegative scalar

Fractional distance between adjacent spool positions over which the orifice area transitions between maximum area and leakage area.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for each flow path.

**Orifice parameterization** — Orifice parameterization

Orifice area (default) | Tabulated data - Volumetric flow rate vs. pressure drop

Whether to parameterize each orifice by area or by using tabulated volumetric flow rate data according to pressure drop.

**Maximum orifice area** — Maximum orifice area1e-4 m<sup>2</sup> (default) | positive scalar

Maximum opening area for all orifices.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for each flow path and **Orifice parameterization** to `Orifice area`.

**Leakage area fraction** — Leakage area fraction

0.01 (default) | positive scalar

Leakage area as a fraction of the value of the **Maximum orifice area** parameter.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to `Orifice area`.

**Cross-sectional area at ports** — Cross-sectional area for all ports  
`inf m^2 (default) | positive scalar`

Cross-sectional area for all ports.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to `Orifice area`.

**Discharge coefficient** — Discharge coefficient  
`0.64 (default) | positive scalar`

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to `Orifice area`.

**Critical Reynolds number** — Critical Reynolds number  
`150 (default) | positive scalar`

Upper Reynolds number limit for laminar flow through the orifice.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to `Orifice area`.

**Smoothing factor** — Numerical smoothing factor  
`0.01 (default) | positive scalar`

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to improve the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to `Orifice area`.

**Pressure recovery** — Option to account for pressure increases in area expansions  
`Off (default) | On`

Whether to account for pressure increase when fluid flows from a region of smaller restriction area to a region of larger cross-sectional area.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to `Orifice area`.

**Pressure drop vector** — Tabulated pressure drop  
`[-.1, .3, .5, .7] MPa (default) | vector of length X`

Tabulated pressure drop values for all orifices. The elements of this vector correspond one-to-one with the **Fully open volumetric flow rate vector** parameter.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for each flow path and **Orifice parameterization** to `Tabulated data - Volumetric flow rate vs. pressure drop`.

**Fully open volumetric flow rate vector** — Tabulated volumetric flow rate  
`[-.0009, .0016, .002, .0024] m^3/s (default) | vector of length X`

Volumetric flow rate for a fully open orifice at a given pressure drop. The elements of this vector correspond one-to-one with the **Pressure drop vector** parameter.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for each flow path and **Orifice parameterization** to `Tabulated data - Volumetric flow rate vs. pressure drop`.

**Leakage flow rate fraction** — Leakage flow rate fraction  
`0.01 (default) | positive scalar`

Leakage as a fraction of the **Fully open volumetric flow rate vector** parameter.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to `Tabulated data - Volumetric flow rate vs. pressure drop`.

**Orifice 1**

This section includes only the parameters for orifice 1. The remaining orifice parameters are identical to orifice 1 except for their number and the cases mentioned in the parameter descriptions for orifice 1. To learn more, see “Orifice Parameterization” on page 1-1262.

**Ports connected by orifice 1** — Ports connected by orifice 1  
`[3, 2] (default) | vector of length 2`

The two fluid ports connected by orifice 1. The first element is the valve port connected to the orifice A port. The second element is the valve port connected to the orifice B port. In the **Simscape Results Explorer** app, the variables `mdot_A` and `mdot_B` are mass flow rates into the Orifice (IL) block A and B ports, respectively. `p_diff` is the pressure drop from port A to port B of the orifice. In the block icon, for ports connected to a single orifice, the arrow points to the port represented by the second element of this parameter. The default values for the other orifices are:

- Orifice 2: [4, 5]
- Orifice 3: [2, 1]
- Orifice 4: [3, 4]
- Orifice 5-Orifice 20: [1, 2]

**Spool position indices where orifice 1 is open** — Orifice 1 open positions  
`[1, 4] (default) | vector of length 1 to N`

Spool positions for which orifice 1 is open. The vector must be strictly monotonically increasing with values between 1 and the value of the **Number of spool positions** parameter. The default values for the other orifices are:

- Orifice 2: [1, 4]
- Orifice 3: [3, 4]
- Orifice 4: [3, 4]
- Orifice 5-Orifice 20: 1

**Spool travel for which orifice 1 remains fully open** — Fully open spool travel

1 mm (default) | nonnegative scalar

Spool travel across which the orifice maintains the maximum opening area. The center of this spool travel distance is at the value of the **Spool position with open orifice 1** parameter.

**Dependencies**

To enable this parameter, set **Area characteristics** to Different for each flow path.

**Spool travel for which orifice 1 transitions between open-closed** — Threshold spool travel

0.2 mm (default) | positive scalar

Spool travel across which the orifice transitions from fully open to fully closed.

**Dependencies**

To enable this parameter, set **Area characteristics** to Different for each flow path.

**Maximum area of orifice 1** — Orifice area when fully open

$1e-4 \text{ m}^2$  (default) | positive scalar

Opening area of orifice 1.

**Dependencies**

To enable this parameter, set **Area characteristics** to Different for each flow path.

**Pressure drop vector of orifice 1** — Orifice 1 pressure drop

[-.1, .3, .5, .7] MPa (default) | vector of length X

Vector of pressure drop values for orifice 1. These values correspond one-to-one with the **Fully open volumetric flow rate vector of orifice 1** parameter.

**Dependencies**

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. pressure drop.

**Fully open volumetric flow rate vector of orifice 1** — Orifice 1 fully open volumetric flow rate

[-.0009, .0016, .002, .0024]  $\text{m}^3/\text{s}$  (default) | vector of length X

Volumetric flow rate when orifice 1 is fully open for a given pressure drop. These values correspond one-to-one with the **Pressure drop vector of orifice 1** parameter.

**Dependencies**

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. pressure drop.

## Library

Flow Control Valves

## Description

The Needle Valve block models a variable orifice created by a conical needle and a round sharp-edged orifice in thin material.

The flow rate through the valve is proportional to the valve opening and to the pressure differential across the valve. The flow rate is determined according to the following equations:

$$q = C_D \cdot A(h) \sqrt{\frac{2}{\rho} \frac{\Delta p}{(\Delta p^2 + p_{Cr}^2)^{1/4}}}$$

$$\Delta p = p_A - p_B,$$

$$h = x_0 + x$$

$$h_{\max} = d_s \frac{1 - \sqrt{1 - \cos \frac{\alpha}{2}}}{\sin \alpha}$$

$$A(h) = \begin{cases} A_{leak} & \text{for } h \leq 0 \\ \pi \cdot \left( d_s - h \cdot \sin \frac{\alpha}{2} \cdot \cos \frac{\alpha}{2} \right) \cdot h \cdot \sin \frac{\alpha}{2} + A_{leak} & \text{for } 0 < h < h_{\max} \\ A_{\max} + A_{leak} & \text{for } h \geq h_{\max} \end{cases}$$

$$A_{\max} = \frac{\pi d_s^2}{4}$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A(h)$	Instantaneous orifice passage area
$x_0$	Initial opening
$x$	Needle displacement from initial position
$h$	Valve opening
$h_{\max}$	Maximum needle stroke
$d_s$	Orifice diameter
$\alpha$	Needle angle
$\rho$	Fluid density
$A_{leak}$	Closed valve leakage area
$A_{\max}$	Maximum valve open area
$p_{cr}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{cr}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = (p_{avg} + p_{atm})(1 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{avg}$	Average pressure between the block terminals
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$D_H$	Valve instantaneous hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B and the pressure differential is determined as  $\Delta p = p_A - p_B$ . Positive signal at the physical signal port S opens the valve.

## Basic Assumptions and Limitations

- Fluid inertia is not taken into account.
- The flow passage area is assumed to be equal to the frustum side surface area.

## Parameters

### Valve orifice diameter

The diameter of the orifice of the valve. The default value is 0.005 m.

### Needle cone angle

The angle of the valve conical needle. The parameter value must be in the range between 0 and 180 degrees. The default value is 90 degrees.

### Initial opening

The initial opening of the valve. You can specify both positive and negative values. The default value is 0.

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.65.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 10. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## **Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## **Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

S

Physical signal port to control spool displacement.

## **Version History**

**Introduced in R2006a**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## **Extended Capabilities**

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

### **See Also**

Ball Valve | Gate Valve | Poppet Valve | Pressure-Compensated Flow Control Valve

## Needle Valve (IL)

Needle valve in an isothermal liquid system

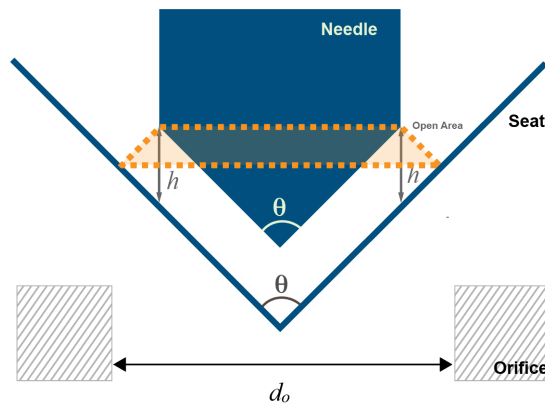

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Flow Control Valves

### Description

The Needle Valve (IL) block models flow reductions by a needle valve. The valve comprises a conical needle and a round, sharp-edged seat. The needle opens or closes according to the displacement signal at port **S**. A positive signal retracts the needle and opens the valve.

### Opening Area

### Needle Valve Schematic

### Needle Valve Top View

The opening area of the valve is calculated as:

$$A_{open} = \pi h \sin\left(\frac{\theta}{2}\right) \left[ d_o - \frac{h}{2} \sin(\theta) \right] + A_{leak}$$

where:

- $h$  is the vertical distance between the outer edge of the needle and the seat, as indicated in the schematic above.
- $\theta$  is the seat cone angle, which always matches the **Needle cone angle**.
- $d_0$  is the **Seat orifice diameter**.
- $A_{leak}$  is the **Leakage area**.

The opening area is bounded by the maximum displacement  $h_{max}$ :

$$h_{max} = \frac{d_0 \left[ 1 - \sqrt{1 - \cos\left(\frac{\theta}{2}\right)} \right]}{\sin(\theta)}.$$

For any needle displacement larger than  $h_{max}$ ,  $A_{open}$  is the sum of the maximum orifice area and the **Leakage area**:

$$A_{open} = \frac{\pi}{4} d_0^2 + A_{leak}.$$

For any combination of the signal at port **S** and the needle offset that is less than 0, the minimum valve area is the **Leakage area**.

If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the displacement between  $\theta$  and  $h_{max}$ . For more information, see “Numerical Smoothing”.

### Mass Flow Rate Equation

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the valve is calculated as:

$$\dot{m} = \frac{C_d A_{valve} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 \right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{valve}$  is the instantaneous valve open area.
- $A_{port}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{valve}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area.  $PR_{loss}$  is calculated as:

$$PR_{loss} = \frac{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{valve}}{A_{port}}}{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{valve}}{A_{port}}}$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{loss}$  is 1.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

### Input

**S** — Needle displacement, m  
physical signal

Control member displacement in m, specified as a physical signal. A positive signal retracts the needle and opens the valve.

## Parameters

**Seat orifice diameter** — Diameter of seat  
5e-3 m (default) | positive scalar

Diameter of the seat orifice.

**Needle cone angle** — Control member geometry angle  
90 deg (default) | positive scalar

Control member geometry angle. Refer to the “Needle Valve Schematic” on page 1-1274 in the valve description.

**Needle position when in the seat** — Needle offset  
0 m (default) | scalar

Needle offset when the valve is closed. A positive, nonzero value indicates a partially open valve. A negative, nonzero value indicates an overlapped valve that remains closed for an initial displacement set by the physical signal at port **S**.

**Leakage area** — Gap area when in fully closed position

$1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Cross-sectional area at ports A and B** — Area at conserving ports

$\text{inf m}^2$  (default) | positive scalar

Areas at the entry and exit ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor accounting for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Pressure recovery** — Whether to account for pressure increase in area expansions

off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

## Version History

Poppet Valve (IL) | Gate Valve (IL) | Shuttle Valve (IL)

## Orifice (IL)

Constant-area or variable-area orifice in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Orifices

### Description

The Orifice (IL) block models the flow through a local restriction with a constant or variable opening area. For variable orifices, a control member connected to port **S** sets the opening position. The opening area is parametrized either linearly or by lookup table.

For orifices that open and close based on the displacement of a central spool, see Spool Orifice (IL).

You can enable fault modeling behavior by setting **Enable faults** to On.

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = \rho v_A A_A + \rho v_B A_B = 0.$$

This mass balance implies that there is an increase in velocity when there is a decrease in area, and a reduction in velocity when the flow discharges into a larger area. In accordance with the Bernoulli principle, this change in velocity results in a region of lower pressure in the orifice and a higher pressure in the expansion zone. The resulting increase in pressure, which is called *pressure recovery*, depends on the discharge coefficient of the orifice and the ratio of the orifice and port areas.

### Constant Orifices

For constant orifices, the orifice area,  $A_{\text{orifice}}$ , does not change over the course of the simulation.

### Using the Constant Area Parameterization

The block calculates the mass flow rate as

$$\dot{m} = \frac{C_d A_{\text{orifice}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{orifice}}}{A_{\text{port}}}\right)^2\right)}} \sqrt{p_A - p_B} \approx \frac{C_d A_{\text{orifice}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{orifice}}}{A_{\text{port}}}\right)^2\right)}} \frac{p_A - p_B}{\left[(p_A - p_B)^2 + \Delta p_{\text{crit}}\right]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{\text{orifice}}$  is the instantaneous orifice open area.
- $A_{\text{port}}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.

$PR_{\text{loss}}$  and  $\Delta p_{\text{crit}}$  are calculated in the same manner for constant and variable orifices and are defined in the “Pressure Loss” on page 1-1280 and “Critical Pressure” on page 1-1281 sections below.

This approximation for  $\dot{m}$  and the Local Restriction (IL) block are the same.

#### Using the Tabulated data - Volumetric flow rate vs. pressure drop Parameterization

The volumetric flow rate is determined from the tabulated values of the pressure differential,  $\Delta p$ , which you can provide. If you provide only non-negative values for both the volumetric flow rate and pressure drop vectors, the block extrapolates the table to contain negative values. The volumetric flow rate is interpolated from this extended table.

If the **Volumetric flow rate vector** and **Pressure drop vector** parameters contain both negative and positive values but no 0, the block inserts an origin into the vectors to ensure the valve does not have nonzero flow rate when the pressure drop is 0, which is non-physical.

#### Variable Orifices

For variable orifices, setting **Opening orientation** to **Positive control member displacement opens orifice** opens the orifice when the signal at **S** is positive, while a **Negative control member displacement opens orifice** orientation opens the orifice when the signal at **S** is negative. In both cases, the signal is positive and the orifice opening is set by the magnitude of the signal.

#### Using the Linear - Area vs. control member position Parameterization

The orifice area  $A_{\text{orifice}}$  is based on the control member position and the ratio of orifice area and maximum control member position:

$$A_{\text{orifice}} = \frac{(A_{\text{max}} - A_{\text{leak}})}{\Delta S}(S - S_{\text{min}})\varepsilon + A_{\text{leak}}$$

where:

- $S_{\text{min}}$  is the control member position when the orifice is fully closed.
- $\Delta S$  is the **Control member travel between closed and open orifice**.
- $A_{\text{max}}$  is the **Maximum orifice area**.
- $A_{\text{leak}}$  is the **Leakage area**.
- $\varepsilon$  is the **Opening orientation**.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the orifice area between  $A_{\text{leak}}$  and  $A_{\text{max}}$ . For more information, see “Numerical Smoothing”.

The volumetric flow rate is determined by the pressure-flow rate equation:

$$\dot{m} = \frac{C_d A_{orifice} \sqrt{2\rho}}{\sqrt{PR_{loss} \left(1 - \left(\frac{A_{orifice}}{A}\right)^2\right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where  $A$  is the **Cross-sectional area at ports A and B**.

#### Using the Tabulated data - Area vs. control member position Parameterization

When you use the Tabulated data - Area vs. control member position parameterization, the orifice area  $A_{orifice}$  is interpolated from the tabulated values of opening area and the control member position,  $\Delta S$ , which you can provide. As with the Linear - Area vs. control member position parameterization, the volumetric flow rate is determined by the pressure-flow rate equation:

$$\dot{m} = \frac{C_d A_{orifice} \sqrt{2\rho}}{\sqrt{PR_{loss} \left(1 - \left(\frac{A_{orifice}}{A}\right)^2\right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where  $A_{orifice}$  is:

- $A_{max}$ , the last element of the **Orifice area vector**, if the opening is larger than the maximum specified opening.
- $A_{leak}$ , the first element of the **Orifice area vector**, if the orifice opening is less than the minimum opening.
- $A_{orifice}$  if the calculated area is between the limits of the **Orifice area vector**.

$A_{open}$  is a function of the control member position received at port **S**. The block queries between data points with linear interpolation and uses nearest extrapolation for points beyond the table boundaries.

#### Using the Tabulated data - Volumetric flow rate vs. control member position and pressure drop Parameterization

The Tabulated data - Volumetric flow rate vs. control member position and pressure drop parameterization interpolates the volumetric flow rate directly from a user-provided volumetric flow rate table, which is based on the control member position and pressure drop over the orifice. The block queries between data points with linear interpolation and uses linear extrapolation for points beyond the table boundaries.

This data can include negative pressure drops and negative opening values. If a negative pressure drop is included in the dataset, the volumetric flow rate will change direction. However, the flow rate will remain unchanged for negative opening values.

If the **Pressure drop vector, dp** parameter does not contain a 0 and the **Volumetric flow rate table, q(s,dp)** parameter does not contain a corresponding column of 0's, the block inserts them to ensure the valve does not have nonzero flow rate when the pressure drop is 0, which is non-physical.

#### Pressure Loss

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area. The pressure loss term,  $PR_{loss}$  is calculated as:

$$PR_{\text{loss}} = \frac{\sqrt{1 - \left(\frac{A_{\text{orifice}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{\text{orifice}}}{A_{\text{port}}}}{\sqrt{1 - \left(\frac{A_{\text{orifice}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{\text{orifice}}}{A_{\text{port}}}}$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{\text{loss}}$  is 1.

### Critical Pressure

The critical pressure difference,  $\Delta p_{\text{crit}}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{\text{crit}}$ , which is the point of transition between laminar and turbulent flow in the fluid:

$$\Delta p_{\text{crit}} = \frac{\pi \bar{\rho}}{8 A_{\text{orifice}}} \left( \frac{\nu Re_{\text{crit}}}{C_d} \right)^2.$$

### Faults

When **Orifice type** is set to **Variable** and faults are enabled, the orifice open area becomes stuck at a specified value in response to one or both of these triggers:

- Simulation time — Faulting occurs at a specified time.
- Simulation behavior — Faulting occurs in response to an external trigger. This exposes port **T**.

Three fault options are available in the **Opening area when faulted** parameter:

- Closed — The orifice freezes at its smallest value, depending on the **Orifice parameterization**:
  - When **Orifice parameterization** is set to **Linear - Area vs. control member position**, the orifice freezes at the **Leakage area**.
  - When **Orifice parameterization** is set to **Tabulated data - Area vs. control member position**, the orifice freezes at the first element of the **Orifice area vector**.
  - When **Orifice parameterization** is set to **Tabulated data - Volumetric flow rate vs. control member position and pressure drop**, the orifice freezes at the first row of the **Volumetric flow rate table, q(s,dp)**.
- Open — The orifice freezes at its largest value, depending on the **Orifice parameterization**:
  - When **Orifice parameterization** is set to **Linear - Area vs. control member position**, the orifice freezes at the **Maximum orifice area**.
  - When **Orifice parameterization** is set to **Tabulated data - Area vs. control member position**, the orifice freezes at the last element of the **Orifice area vector**.
  - When **Orifice parameterization** is set to **Tabulated data - Volumetric flow rate vs. control member position and pressure drop**, the orifice freezes at the last row of the **Volumetric flow rate table, q(s,dp)**.
- Maintain at last value — The orifice seizes at the open area or volumetric flow rate when the trigger occurs.

Due to numerical smoothing at the extremes of the orifice area, the minimum area applied is larger than the parameter value, and the maximum is smaller than the parameter value, in proportion to the **Smoothing factor** value.

Once triggered, the orifice remains at the faulted area for the rest of the simulation.

You can set the block to issue a fault report as a warning or error message in the Simulink Diagnostic Viewer with the **Reporting when fault occurs** parameter.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit point to the orifice.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit point to the orifice.

### Input

**S** — Control member displacement  
physical signal

Control member displacement that sets orifice opening.

**T** — External fault trigger  
physical signal

Physical signal port for an external fault trigger. Triggering occurs when the value is greater than 0.5. There is no unit associated with the trigger value.

### Dependencies

This port is visible when **Enable faults** is set to On and **Enable external fault trigger** is set to On.

## Parameters

### Parameters

**Orifice type** — Type of orifice  
Variable (default) | Constant

Type of orifice, defined by the orifice area. When set to **Variable**, the orifice area varies according to the input signal received at port **S**.

**Orifice parameterization** — Method of calculating orifice area  
Orifice Area (default) | Tabulated data - volumetric flow rate vs. pressure drop |  
Linear - area vs. control member position | Tabulated data - Area vs. control  
member position | Tabulated data - Volumetric flow rate vs. control member  
position and pressure drop

Method of calculating orifice area over simulation. When **Orifice type** is set to **Constant**, there are two parameterization options.

- **Orifice area** (default). The assigned area does not change over the simulation.
- **Tabulated data - Volumetric flow rate vs. pressure drop**. The area remains constant, but the volumetric flow rate through the orifice can vary. This value is interpolated directly from the **Volumetric flow rate vector** and the **Pressure drop vector** dataset.

When the **Orifice type** is set to **Variable**, there are three parameterization options.

- **Linear - Area vs. control member position**. Area is determined by a linear relationship to the control member position with respect to a fully open or fully closed orifice. The position is set by a varying physical signal at port **S**.
- **Tabulated data - Area vs. control member position**. The opening area is interpolated from the **Control member position vector** and the **Orifice area vector** based on the control member position received at port **S**.
- **Tabulated data - Volumetric flow rate vs. control member position and pressure drop**. The volumetric flow rate is directly interpolated from the user- provided **Control member position vector, s, Pressure drop vector, dp, and Volumetric flow rate table, q(s,dp)** parameters based on the control member position received at port **S** and the pressure drop across ports **A** and **B**.

**Orifice area** — Area of orifice opening  
 $1e-3 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the orifice opening.

#### Dependencies

To enable this parameter, set **Orifice type** to **Constant** and **Orifice parameterization** to **Orifice area**.

**Pressure drop vector** — Vector of differential pressure values for tabulated parameterization  
 $[-4, -3, -2, -1, -.5, 0, .5, 1, 2, 3, 4]$  MPa (default) | 1-by- $n$  vector

Vector of pressure differential values for the tabulated parameterization of volumetric flow rate. The values in this vector correspond one-to-one to values in the **Volumetric flow rate vector** parameter. The pressure drop vector values are listed in ascending order. The volumetric flow rate is interpolated directly from the **Volumetric flow rate vector**, which depends on the **Pressure drop vector** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to **Constant** and **Orifice parameterization** to **Tabulated data - Volumetric flow rate vs. pressure drop**.

**Volumetric flow rate vector** — Vector of volumetric flow rate values  
 $[-2.44, -2.12, -1.68, -1.22, -.84, 0, .85, 1.21, 1.7, 2.09, 2.41]$   $\cdot 1e-3$   
 $\text{m}^3/\text{s}$  (default) | 1-by- $n$  vector

Vector of volumetric flow rate values for the tabulated parameterization of volumetric flow rate. The values in this vector correspond one-to-one to values in the **Pressure drop vector**. The volumetric flow rate is interpolated directly from the provided **Volumetric flow rate vector**, which depends on the **Pressure drop vector** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. pressure drop.

**Control member position at closed orifice** — Control member offset  
0 m (default) | scalar

Initial control member offset when the variable orifice is fully closed.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable.

**Control member travel between closed and open orifice** — Control member maximum stroke  
5e-3 m (default) | positive scalar

Maximum distance the control member travels between closed and open orifice. The orifice is fully open at the sum of the **Control member position at closed orifice** and **Control member travel between closed and open orifice**,

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

**Maximum orifice area** — Maximum orifice opening area  
1e-4 m<sup>2</sup> (default) | positive scalar

Maximum orifice area experienced during simulation. When using Tabulated data - Area vs. control member position, the maximum orifice area is the last element of the **Orifice area vector**.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

**Leakage area** — Orifice gap area when in fully closed position  
1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in fully closed position. Any area smaller than this value is maintained at the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

.

**Control member position vector** — Vector of control member positions  
[0, .002, .004, .007, .017] m (default) | 1-by-*n* vector

Vector of control member positions for the tabulated parameterization of orifice area. The vector elements correspond one-to-one to the values in the **Orifice area vector**. The vector elements must

be either strictly monotonically increasing or decreasing. The orifice opening area is interpolated from the **Orifice area vector**, which depends on the **Control member position vector** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Orifice area vector** — Vector of orifice opening area values

[1e-09, 2.0352e-07, 4.0736e-05, .00011438, .00034356] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of orifice area values for the tabulated parameterization of orifice area. The values in this vector correspond one-to-one with the elements in the **Control member position vector**. If the vector is increasing, the first element of this vector is the orifice leakage area and the last element is the maximum orifice area. If the vector is decreasing, the first element of this vector is the orifice maximum orifice area and the last element is the leakage area. The orifice opening area is interpolated from the **Orifice area vector**, which depends on the **Control member position vector**.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Cross-sectional area at ports A and B** — Area at orifice entry or exit

inf m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. This area is used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

#### Dependencies

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.
- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Opening orientation** — Direction of member movement that opens the orifice

Positive control member displacement opens orifice (default) | Negative control member displacement opens orifice

Direction of member displacement that opens a variable orifice. A positive orientation means that a positive signal at **S** opens the orifice. A negative orientation means that a negative signal at **S** opens the orifice.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

#### Dependencies

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.
- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

#### Dependencies

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.
- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
on (default) | off

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area. This increase in pressure is not captured when you clear the **Pressure recovery** check box.

#### Dependencies

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.
- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Control member position vector, s** — Vector of opening values  
[0, .002, .004, .007, .017] m (default) | 1-by-*n* vector

Vector of control member positions for tabulated parametrization of volumetric flow rate. The control member position vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 2-D dependent **Volumetric flow rate table, q(s,dp)** parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop.

**Pressure drop vector, dp** — Vector of pressure drop values  
[.3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for tabulated parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Control member position vector, *s*** parameter for the 2-D dependent **Volumetric flow rate table, *q(s,dp)*** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop.

**Volumetric flow rate table, *q(s,dp)*** — Array of volumetric flow rate values

[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13] .\* 1e-3 m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and control member position. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **Pressure drop vector, *dp*** parameter.
- *N* is the number of elements in the **Control member position vector, *s*** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop.

#### Faults

**Enable faults** — Fault option

Off (default) | On

Enable externally or temporally triggered faults. When faulting occurs, the valve area normally set by the opening parameterization will be set to the value specified in the **Opening area when faulted** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable.

**Opening area when faulted** — Set faulted area

Closed (default) | Open | Maintain at last value

Sets the faulted orifice area. You can choose for the orifice to seize at the fully closed or fully open position, or at the valve area when faulting is triggered.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable **Enable faults** to On.

**Enable external fault trigger** — External trigger option

Off (default) | On

Enables port **T**. A physical signal at port **T** that is greater than 0.5 triggers faulting.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable**Enable faults** to On.

**Enable temporal fault trigger** — Temporal trigger option

Off (default) | On

Enables fault triggering at a specified time. When the **Simulation time for fault event** is reached, the orifice area will be set to the value specified in the **Opening area when faulted** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable**Enable faults** to On.

**Simulation time for fault event** — Time at which faulting is triggered

5 s (default) | positive scalar

When the **Simulation time for fault event** is reached, the orifice area is set to the value specified in the **Opening area when faulted** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable, **Enable faults** to On, and **Enable temporal fault trigger** to On.

**Reporting when fault occurs** — Fault condition report

None (default) | Warning | Error

Reporting preference for the fault condition. When reporting is set to **Warning** or **Error**, a message is displayed in the Simulink Diagnostic Viewer. When **Error** is selected, the simulation will stop if faulting occurs.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable**Enable faults** to On.

## Version History

Introduced in R2020a

## Orifice (G)

Flow restriction in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices

## Description

The Orifice (G) block represents the pressure loss incurred in a gas network due to a purely resistive element of fixed or variable size, such as a flow restriction, orifice, or valve. You can use orifices to measure and report gas flow characteristics.

### Orifice Parameterizations

The block behavior depends on the **Orifice parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area** — The size of the flow restriction determines the block parametrization.

### Opening Characteristics

When you set **Orifice type** to **Variable**, the block uses the input at port **L** to control certain parameters. This input is the control signal and it is associated with stroke or lift percent. The control signal ranges in value from 0 to 1. If you specify a lesser or greater value, the block saturates the value to the nearest of the two limits.

The conversion from a control signal to the chosen measure of flow capacity depends on the **Opening characteristic** parameterization. Flow is maximally restricted when the control signal is 0 and minimally restricted when the control signal is 1. In between these values, the flow rate achieved within the resistive element depends on whether the opening parameterization is linear or based on tabulated data:

- **Linear** — The measure of flow capacity is proportional to the control signal at port **L**. The two values vary in tandem until the control signal either drops below 0 or rises above 1. As the control signal rises from 0 to 1, the measure of flow capacity scales from the specified minimum to the specified maximum.

When you set **Orifice parameterization** to **Sonic conductance**, the block treats the critical pressure ratio and subsonic index as constants that are independent of control signal. When you set **Orifice parameterization** to **Cv flow coefficient** or **Kv flow coefficient**, the block treats the parameter **xT pressure differential ratio factor at choked flow** as a constant independent of the control signal.

- **Tabulated** — The block calculates the measure of flow capacity as a function of the control signal at port **L**. This function is based on a one-way lookup table. The tabulated data must be specified so the measure of flow capacity increases monotonically with the control signal.

When you set **Orifice parameterization** to **Sonic conductance**, the block treats the critical pressure ratio as a function of the control signal and treats the subsonic index as a constant. When you set **Orifice parameterization** to **Cv flow coefficient** or **Kv flow coefficient**, the block treats the parameter **xT pressure differential ratio factor at choked flow** as a function of the control signal.

### Numerical Smoothing

When the **Orifice type** parameter is **Variable**, the **Opening characteristic** parameter is **Linear**, and the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the control signal from port **L**. Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Momentum Balance

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to **Cv flow coefficient parameterization**, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}}$$

where:

- $C_v$  is the flow coefficient.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.
- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3 p_{in} F_\gamma x_T}$$

where:

- $F_\gamma$  is the ratio of the isentropic exponent to 1.4.
- $x_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ .

$$\dot{m} = C_v N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{\rho_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3F_\gamma x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_\gamma x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3} C_v N_6 \sqrt{F_\gamma x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, see [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}} \left[ 1 - \left( \frac{\frac{p_{out}}{p_{in}} - B_{crit}}{1 - B_{crit}} \right)^{2m} \right],$$

where:

- $C$  is the sonic conductance.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.
- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ ,

$$\dot{m} = C \rho_{ref} \sqrt{\frac{T_{ref}}{T_{avg}}} \left[ 1 - \left( \frac{B_{lam} - B_{crit}}{1 - B_{crit}} \right)^{2m} \right] \left( \frac{p_{in} - p_{out}}{1 - B_{lam}} \right).$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{in} \rho_{in} \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}} \left[ \frac{1 - \left(\frac{p_{out}}{p_{in}}\right)^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}}}\right]}$$

where:

- $S_r$  is the orifice or valve area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \left[ \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 B_{lam}^{\frac{2}{\gamma}}}\right] \left( \frac{p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}}}{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}\right)}$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left(\frac{\gamma+1}{2}\right)^{\frac{2}{\gamma-1}} - \left(\frac{S_R}{S}\right)^2}}$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area parameterization, see [4].

### Mass Balance

The block assumes the volume and mass of fluid inside the resistive element is very small and ignores these values. As a result, no amount of fluid can accumulate in the resistive element. By the principle of conservation of mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to

outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

### Assumptions and Limitations

- The **Sonic** conductance setting of the **Orifice parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the **Orifice area** parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Input

**L** — Orifice opening, unitless  
physical signal

Control signal that specifies the opening of the orifice. In some valves, this represents the stroke or lift percent. The orifice is fully closed at a value of 0 and fully open at a value of 1.

### Dependencies

To enable this parameter, set **Orifice type** to **Variable**.

### Conserving

**A** — Flow passage  
gas

Gas conserving port associated with the opening through which the flow enters or exits the flow resistance. The block has no intrinsic directionality. The port can serve as the inlet or outlet, depending on the direction of the flow.

**B** — Flow passage  
gas

Gas conserving port associated with the opening through which the flow enters or exits the flow resistance. The block has no intrinsic directionality. The port can serve as the inlet or outlet, depending on the direction of the flow.

## Parameters

**Orifice type** — Type of orifice  
Variable (default) | Constant

Type of orifice defined by the orifice area. When you set this parameter to **Variable**, the orifice area varies according to the input signal received at port **L**.

**Orifice parameterization** — Parameterization used to specify flow characteristics of orifice  
Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- Cv flow coefficient — The flow coefficient  $C_v$  determines the block parameterization.
- Kv flow coefficient — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- Sonic conductance — The sonic conductance of the resistive element at steady state determines the block parameterization.
- Orifice area — The size of the flow restriction determines the block parameterization.

**Opening characteristic** — Method to convert from control signal to measure of flow capacity  
Linear (default) | Tabulated

Method by which to convert the control signal specified at port **L** to the chosen measure of flow capacity.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable.

**Opening fraction vector** — Control signal values at which to specify tabulated parameter data  
 $\theta$  : 0.2 : 1 (default) | vector of positive numbers

Vector of control signal values at which to specify the chosen measure of flow capacity: **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector**. The control signal is between  $\theta$  and 1, with each value corresponding to an opening fraction of the resistive element. The greater the value, the greater the opening and easier the flow.

The opening fractions must increase monotonically across the vector from left to right. The size of this vector must be the same as the **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable, and **Opening characteristic** to Tabulated.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the control signal specified at port **L** is 1 and restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to Cv flow coefficient, and **Opening characteristic** to Linear.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Cv flow coefficient or Kv flow coefficient.

**Leakage flow fraction** — Ratio of flow rates  
1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable, and **Opening characteristic** to Linear.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable, and **Opening characteristic** to Linear.

**Cv flow coefficient vector** — Cv coefficients corresponding to values in opening fraction vector  
[1e-06, .8, 1.6, 2.4, 3.2, 4] (default) | vector of positive numbers

Vector of  $C_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector**.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to Cv flow coefficient, and **Opening characteristic** to Tabulated.

**Cv flow coefficient** — Flow coefficient  
4 (default) | positive scalar

Value of the constant  $C_v$  flow coefficient. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Cv flow coefficient.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component  
3.6 (default) | positive scalar

Value of the  $K_v$  flow coefficient when the control signal specified at port **L** is 1 and the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to  $K_v$  flow coefficient, and **Opening characteristic** to Linear.

**$K_v$  flow coefficient vector** —  $K_v$  coefficients corresponding to values in opening fraction vector [1e-06, .72, 1.44, 2.16, 2.88, 3.6] (default) | vector of positive numbers

Vector of  $K_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to  $K_v$  flow coefficient, and **Opening characteristic** to Tabulated.

**$K_v$  flow coefficient** — Flow coefficient  
3.6 (default) | positive scalar

Value of the constant  $K_v$  flow coefficient. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to  $K_v$  flow coefficient.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12 l/(bar\*s) (default) | positive scalar

Value of the sonic conductance when the control signal specified at port **L** is 1 and cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

**Dependencies**

To enable this parameter, set either:

- **Orifice type** to Constant and **Orifice parameterization** to Sonic conductance.

- **Orifice type** to Variable, **Orifice parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Sonic conductance.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Sonic conductance.

**Sonic conductance vector** — Sonic conductances corresponding to values in opening fraction vector  
[1e-05, 2.4, 4.8, 7.2, 9.6, 12] l/(bar\*s) (default) | vector of positive values

Vector of sonic conductances inside the resistive element. Each conductance corresponds to a value in the **Opening fraction vector** parameter. The sonic conductances must increase monotonically from left to right, with greater opening fractions representing greater sonic conductances. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to Sonic conductance, and **Opening characteristic** to Tabulated.

**Critical pressure ratio vector** — Critical pressure ratios corresponding to values in opening fraction vector  
0.3 \* ones(1,6) (default) | vector of positive numbers

Vector of critical pressure ratios at which the flow first chokes, with each critical pressure ratio corresponding to a value in the **Opening fraction vector** parameter. The critical pressure ratio is the fraction of downstream-to-upstream pressures at which the flow velocity reaches the local speed of sound. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to Sonic conductance, and **Opening characteristic** to Tabulated.

**Sonic conductance** — Measure of flow rate capacity in choked flow regime

12 1/(bar\*s) (default) | positive scalar

Ratio, measured at the onset of choking, of the mass flow rate through the resistive element to the product of the upstream pressure and mass density at standard conditions as defined in ISO 8778. This parameter determines the maximum flow rate allowed at a given upstream pressure.

**Dependencies**

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Sonic conductance.

**Maximum orifice area** — Flow area corresponding to maximally open component

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice opening when the control signal specified at port **L** is 1 and the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to Orifice area, and **Opening characteristic** to Linear.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Orifice area.

**Orifice area vector** — Vector of orifice opening area values

[1e-10, 2e-05, 4e-05, 6e-05, 8e-05, .0001] m<sup>2</sup> (default) | vector

Vector of cross-sectional areas of the orifice opening. The values in this vector correspond one-to-one with the elements in the **Opening fraction vector** parameter. The first element of this vector is the orifice leakage area and the last element is the maximum orifice area.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable, **Orifice parameterization** to Orifice area, and **Opening characteristic** to Tabulated.

**Orifice area** — Area of orifice opening

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice opening.

**Dependencies**

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes

0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports

0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

Introduced in R2018a

### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Orifice parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.

### R2022b: Separate orifice blocks combined into one

The Orifice (G) block replaces the Orifice ISO 6358 (G) and Variable Orifice ISO 6358 (G). Use the new **Orifice Type** parameter to choose between Constant and Variable.

### Library

Orifices

### Description

The block models a variable orifice created by a cylindrical spool and a set of round holes drilled in the sleeve. All the holes are of the same diameter, evenly spread along the sleeve perimeter, and their center lines are located in the same plane. The flow rate through the orifice is proportional to the orifice opening and to the pressure differential across the orifice. The following schematic shows the cross section of an orifice with variable round holes, where

$q$	Flow rate
$h$	Orifice opening
$x$	Spool displacement from initial position
$d_0$	Orifice hole diameter

### Orifice Opening Area

The aggregate opening area provided by the round holes is computed during simulation from the *orifice opening*, a measure of the instantaneous spool position:

$$h = \begin{cases} h_{\text{Min}}, & \text{if } (x_0 + \delta x) \leq h_{\text{Min}} \\ x_0 + \delta x, & \text{else} \end{cases}$$

where:

- $h$  is the orifice opening. The subscript **Min** refers to the minimum value corresponding to a fully closed orifice. This value is calculated during simulation from block parameters.
- $x$  is the spool displacement specified through physical signal port **S**. The subscript  $\theta$  denotes the opening offset specified in the **Initial opening** block parameter.
- $\delta$  is the orifice opening orientation: +1 if positive, -1 if negative. This value is specified in the **Orifice orientation** block parameter.

The minimum orifice opening  $h_{\text{Min}}$  is calculated approximately using the expression:

$$h_{\text{Min}} \approx \frac{d_o}{2} \left[ 1 - \cos\left(\frac{\pi D_{h,\text{Min}}}{2n_o d_o}\right) \right]$$

where:

- $d_o$  is the diameter of an individual hole. This value is obtained from the **Diameter of round holes** block parameter. The holes are assumed to be identical in size.
- $n_o$  is the number of round holes comprising the orifice. This value is obtained from the **Number of round holes** block parameter.
- $D_{h,\text{Min}}$  is the minimum value of the hydraulic diameter of the orifice as a whole. This value is calculated from the minimum opening area specified in the **Leakage area** block parameter:

$$D_{h,\text{Min}} = \frac{\pi d_o^2}{4}$$

The opening area of the orifice (the sum over the various round holes) is calculated from the conditional expression:

$$A(h) = \begin{cases} A_{\text{Leak}} & \text{for } h \leq 0 \\ \left[ \frac{1}{8} n_o \cdot d_o^2 \left[ 2 \arccos \left( 1 - \frac{2h}{d_o} \right) - \sin \left( 2 \arccos \left( 1 - \frac{2h}{d_o} \right) \right) \right] \right] + A_{\text{Leak}} & \text{for } 0 < h < d_o, \\ A_{\text{Max}} + A_{\text{Leak}} & \text{for } h \geq d_o \end{cases}$$

where:

- $A_{\text{Leak}}$  is the opening area in the fully closed position, when only leakage remains. This value is obtained from the **Leakage area** block parameter.
- $A_{\text{Max}}$  is the opening area in the fully open position, when the holes are open to full capacity. This value is calculated from the number and diameter of the holes:

$$A_{\text{Max}} = n_o \pi \frac{d_o^2}{4}$$

### Orifice Flow Rate

The net flow rate through the orifice is calculated as:

$$q = C_D \cdot A(h) \sqrt{\frac{2}{\rho} \frac{\Delta p}{(\Delta p^2 + p_{\text{Cr}}^2)^{1/4}}}$$

where:

- $q$  is the volumetric flow rate through the orifice (the sum of the flow rates through the various holes).
- $C_D$  is the discharge coefficient of the orifice. This value is obtained from the **Flow discharge coefficient** block parameter.
- $A$  is the aggregate opening area of the orifice (calculated as a function of the orifice opening  $h$ ).
- $\Delta p$  is the pressure differential from port **A** to port **B**:

$$\Delta p = p_A - p_B,$$

where  $p$  is the gauge pressure through the port indicated in the subscript.

- $p_{\text{Cr}}$  is the calculated value of the critical pressure (from port **A** to port **B**) at which the flow is considered to shift between laminar and turbulent regimes.

### Critical Pressure Differential

The calculation of the critical pressure differential varies with the setting of the **Laminar transition specification** block parameter:

- By **pressure ratio** — Obtain the critical pressure differential from the critical pressure ratio:

$$p_{\text{Cr}} = (p_{\text{Avg}} + p_{\text{Atm}})(1 - \beta),$$

where  $\beta$  is the critical pressure ratio, obtained from the **Laminar flow pressure ratio** block parameter, defined as the ratio of the outlet pressure to the inlet pressure at the transition point between laminar and turbulent regimes. The subscript **Atm** denotes the atmospheric value

(0.101325 MPa at standard reference conditions) and the subscript Avg the average of the gauge pressures at the ports:

$$p_{\text{Avg}} = \frac{p_A + p_B}{2},$$

- By Reynolds number — Obtain the critical pressure differential from the critical Reynolds number:

$$p_{\text{Cr}} = \frac{\rho}{2} \left( \frac{\text{Re}_{\text{Cr}} \cdot \nu}{C_D \cdot D_H} \right)^2,$$

where  $\text{Re}_{\text{Cr}}$  is the critical Reynolds number, at which the flow can be said to transition between laminar and turbulent regimes,  $\nu$  is the average of the kinematic viscosities at the ports, and  $D_h$  is the hydraulic diameter of the orifice:

$$D_h = \begin{cases} D_{h,\text{Min}}, & \text{if } h \leq h_{\text{Min}} \\ d_o + D_{h,\text{Min}}, & \text{if } h > d_o \\ \frac{4A}{P}, & \text{else} \end{cases},$$

with  $P$  as the sum of the perimeters of the holes:

$$P = n_o d_o \left[ 2 \arccos \left( 1 - \frac{2h}{d_o} \right) + 2 \arcsin \left( \arccos \left[ 1 - \frac{2h}{d_o} \right] \right) \right]$$

## Basic Assumptions and Limitations

- Fluid inertia is ignored.

## Parameters

### Diameter of round holes

Diameter of the orifice holes. The default value is 5e-3 m.

### Number of round holes

Number of holes. The default value is 6.

### Flow discharge coefficient

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.6.

### Initial opening

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The value of initial opening does not depend on the orifice orientation. The default value is 0.

### Orifice orientation

The parameter is introduced to specify the effect of the orifice control member motion on the valve opening. The parameter can be set to one of two options: `Opens in positive direction` or `Opens in negative direction`. The value `Opens in positive direction` specifies an orifice whose control member opens the valve when it is shifted in the globally

assigned positive direction. The parameter is extremely useful for building a multi-orifice valve with all the orifices being controlled by the same spool. The default value is `Opens in positive direction`.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is `0.999`. This parameter is visible only if the **Laminar transition specification** parameter is set to `Pressure ratio`.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is `10`. This parameter is visible only if the **Laminar transition specification** parameter is set to `Reynolds number`.

### Leakage area

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is `1e-15 m2`.

### Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Orifice orientation**

All other block parameters are available for modification.

### Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

### Ports

The block has the following ports:

**A**

Hydraulic conserving port associated with the orifice inlet.

**B**

Hydraulic conserving port associated with the orifice outlet.

**S**

Physical signal port to control spool displacement.

The flow rate is positive if fluid flows from port A to port B. Positive signal at the physical signal port S opens or closes the orifice depending on the value of the parameter **Orifice orientation**.

## Library

Orifices

## Description

The block models a variable orifice created by a cylindrical sharp-edged spool and a rectangular slot in a sleeve. The flow rate through the orifice is proportional to the orifice opening and to the pressure differential across the orifice. The flow rate is determined according to the following equations:

$$q = C_D \cdot A(h) \sqrt{\frac{2}{\rho} \frac{\Delta p}{(\Delta p^2 + p_{Cr}^2)^{1/4}}}$$

$$\Delta p = p_A - p_B,$$

$$h = x_0 + x \cdot or$$

$$A(h) = \begin{cases} A_{leak} & \text{if } b \cdot h < A_{leak} \\ b \cdot h & \text{otherwise} \end{cases}$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A(h)$	Instantaneous orifice passage area
$b$	Width of the orifice slot
$x_0$	Initial opening

$x$	Spool displacement from initial position
$h$	Orifice opening
$or$	Orifice orientation indicator. The variable assumes +1 value if a spool displacement in the globally assigned positive direction opens the orifice, and -1 if positive motion decreases the opening.
$\rho$	Fluid density
$A_{leak}$	Closed orifice leakage area
$p_{cr}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{cr}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = (p_{avg} + p_{atm})(1 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{avg}$	Average pressure between the block terminals
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$D_H$	Instantaneous orifice hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B and the pressure differential is determined as  $\Delta p = p_A - p_B$ . Positive signal at the physical signal port S opens or closes the orifice depending on the value of the parameter **Orifice orientation**.

### Basic Assumptions and Limitations

- Fluid inertia is not taken into account.

## Parameters

### Orifice width

The width of the rectangular slot. The default value is  $1e-2$  m.

### Flow discharge coefficient

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.7$ .

### Initial opening

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The value of initial opening does not depend on the orifice orientation. The default value is  $0$ .

### Orifice orientation

The parameter is introduced to specify the effect of the orifice control member motion on the valve opening. The parameter can be set to one of two options: `Opens in positive direction` or `Opens in negative direction`. The value `Opens in positive direction` specifies an orifice whose control member opens the valve when it is shifted in the globally assigned positive direction. The parameter is extremely useful for building a multi-orifice valve with all the orifices being controlled by the same spool. The default value is `Opens in positive direction`.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- `Pressure ratio` — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- `Reynolds number` — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is  $0.999$ . This parameter is visible only if the **Laminar transition specification** parameter is set to `Pressure ratio`.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is  $12$ . This parameter is visible only if the **Laminar transition specification** parameter is set to `Reynolds number`.

### Leakage area

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than  $0$ . The default value is  $1e-12$  m<sup>2</sup>.

### Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Orifice orientation**

All other block parameters are available for modification.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the orifice inlet.

B

Hydraulic conserving port associated with the orifice outlet.

S

Physical signal port to control spool displacement.

The flow rate is positive if fluid flows from port A to port B. Positive signal at the physical signal port S opens or closes the orifice depending on the value of the parameter **Orifice orientation**.

## Version History

## Orifice (2P)

Constant- or variable-area orifice in a two-phase fluid network

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Valves & Orifices

## Description

The Orifice (2P) block models pressure loss due to a constant or variable area orifice in a two-phase fluid network. The orifice can be constant or variable. When **Orifice type** is set to **Variable**, the physical signal at port **S** sets the position of the control member, which opens and closes the orifice.

Fluid properties inside the valve are calculated from inlet conditions. There is no heat exchange between the fluid and the environment, and therefore phase change inside the orifice only occurs due to a pressure drop or a propagated phase change from another part of the model.

A number of block parameters are based on nominal operating conditions, which correspond to the orifice rated performance, such as a specification on a manufacturer datasheet.

### Constant Area

When you set **Orifice type** to **Constant**, the orifice has a constant area. The mass flow rate through the orifice is:

$$\dot{m}_A = \dot{m}_{nom} \left[ \sqrt{\frac{v_{nom}}{2\Delta p_{nom}}} \right] \sqrt{\frac{2}{v_{in}} \frac{\Delta p}{(\Delta p^2 + \Delta p_{lam}^2)^{0.25}}},$$

where:

- $\Delta p$  is the pressure drop over the orifice,  $p_A - p_B$ .
- $\Delta p_{lam}$  is the pressure transition threshold between laminar and turbulent flow, which is calculated from the **Laminar flow pressure ratio**,  $B_{lam}$ :

$$\Delta p_{lam} = \frac{(p_A + p_B)}{2} (1 - B_{lam}).$$

- $\dot{m}_{nom}$  is the **Nominal mass flow rate**.
- $\Delta p_{nom}$  is the **Nominal pressure drop rate**.
- $v_{nom}$  is the nominal inlet specific volume. This value is determined from the fluid properties tabulated data based on the **Nominal inlet condition specification** parameter.
- $v_{in}$  is the inlet specific volume.

### Variable Area

When you set **Orifice type** to **Variable**, the block is configured for a variable opening, which is set by the control member position at **S**. The block calculates the mass flow rate through the variable-area orifice as:

$$\dot{m}_A = \lambda \dot{m}_{nom} \left[ \sqrt{\frac{v_{nom}}{2\Delta p_{nom}}} \right] \sqrt{\frac{2}{v_{in} (\Delta p^2 + \Delta p_{lam}^2)^{0.25}}},$$

where  $\lambda$  is the orifice opening fraction.

### Control Member Displacement

The orifice opening, which is expressed as a fraction of the total orifice open area, is determined by the input signal at **S**, the **Control member travel between closed and open orifice** parameter,  $\Delta S$ , and a leakage value that improves numerical stability when the orifice is closed:

$$\lambda = \varepsilon(1 - f_{leak}) \frac{(S - S_{min})}{\Delta S} + f_{leak},$$

where:

- $\varepsilon$  is the **Opening orientation**. This value is +1 when the setting is Positive control member displacement opens orifice and -1 when the setting is Negative control member displacement opens orifice.
- $f_{leak}$  is the **Closed orifice leakage as a fraction of nominal flow**.
- $S_{min}$  is the **Control member position at closed orifice**.

### Fluid Specific Volume Dynamics

When the fluid at the orifice inlet is a liquid-vapor mixture, the block calculates the specific volume as:

$$v_{in} = (1 - x_{dyn})v_{liq} + x_{dyn}v_{vap},$$

where:

- $x_{dyn}$  is the inlet vapor quality. The block applies a first-order lag to the inlet vapor quality of the mixture.
- $v_{liq}$  is the liquid specific volume of the fluid.
- $v_{vap}$  is the vapor specific volume of the fluid.

If the inlet fluid is liquid or vapor,  $v_{in}$  is the respective liquid or vapor specific volume.

### Vapor Quality Lag

If the inlet vapor quality is a liquid-vapor mixture, the block applies a first-order time lag:

$$\frac{dx_{dyn}}{dt} = \frac{x_{in} - x_{dyn}}{\tau},$$

where:

- $x_{dyn}$  is the dynamic vapor quality.
- $x_{in}$  is the current inlet vapor quality.
- $\tau$  is the **Inlet phase change time constant**.

If the inlet fluid is a subcooled liquid or superheated vapor,  $x_{dyn}$  is equal to  $x_{in}$ .

### Mass Balance

Mass is conserved in the orifice:

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

### Energy Balance

Energy is conserved in the orifice:

$$\Phi_A + \Phi_B = 0,$$

where:

- $\Phi_A$  is the energy flow at port **A**.
- $\Phi_B$  is the energy flow at port **B**.

### Assumptions and Limitations

- The block does not model pressure recovery downstream of the valve.
- There is no heat exchange between the valve and the environment.
- The block does not model choked flow.

## Ports

### Conserving

**A** — Fluid port  
two-phase fluid

Fluid entry or exit port.

**B** — Fluid port  
two-phase fluid

Fluid entry or exit port.

### Input

**S** — Control member position  
physical signal

Control member position that sets the orifice opening.

### Dependencies

To enable this port, set **Orifice type** to Variable.

## Parameters

**Orifice type** — Constant or variable orifice

Variable (default) | Constant

Type of orifice. When set to **Variable**, the orifice area varies according to the input signal received at port **S**.

**Nominal mass flow rate** — Rated mass flow rate

0.1 kg/s (default) | positive scalar

Typical, rated, or design mass flow rate through a constant orifice.

### Dependencies

To enable this parameter, set **Orifice type** to **Constant**.

**Nominal pressure drop** — Rated pressure drop

0.001 MPa (default) | positive scalar

Typical, rated, or design pressure drop through a constant orifice.

### Dependencies

To enable this parameter, set **Orifice type** to **Constant**.

**Control member position at closed orifice** — Control member offset

0 m (default) | positive scalar

Control member offset, or the value at **S** when the orifice is fully closed.

### Dependencies

To enable this parameter, set **Orifice type** to **Variable**.

**Control member travel between closed and open orifice** — Control member stroke

5e-3 m (default) | positive scalar

Distance the control member travels between a closed and open orifice. When you set **Opening orientation** to **Positive control member displacement opens orifice**, the orifice is fully open at the sum of the **Control member position at closed orifice** and **Control member travel between closed and open orifice** parameters. When you set **Opening orientation** to **Negative control member displacement opens orifice**, the orifice is fully open at the difference between the **Control member position at closed orifice** and **Control member travel between closed and open orifice** parameters.

### Dependencies

To enable this parameter, set **Orifice type** to **Variable**.

**Opening orientation** — Direction of displacement that opens the orifice

Positive control member displacement opens orifice (default) | Negative control member displacement opens orifice

Direction of member displacement that opens a variable orifice. A positive orientation means that an increase in the signal at **S** opens the orifice. A negative orientation means that a decrease in the signal at **S** opens the orifice.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable.

**Nominal mass flow rate at maximum opening** — Rated mass flow rate

0.1 kg/s (default) | positive scalar

Mass flow rate through a fully open orifice under typical, design, or rated conditions.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable.

**Nominal pressure drop at maximum opening** — Rated pressure drop

0.001 MPa (default) | positive scalar

Pressure drop over a fully open orifice under typical, design, or rated conditions.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable.

**Nominal inlet condition specification** — Method of determining inlet fluid state

Temperature (default) | Vapor quality | Vapor void fraction | Specific enthalpy | Specific internal energy

Method of determining inlet fluid state. The orifice nominal inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet pressure** — Inlet fluid pressure

0.101325 MPa (default) | positive scalar

Inlet pressure in nominal conditions. The inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet temperature** — Fluid temperature

293.15 K (default) | positive scalar

Inlet fluid temperature in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Inlet vapor quality mass fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet mixture vapor quality by mass fraction in nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor quality.

**Nominal inlet vapor void fraction** — Inlet volume fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet mixture volume fraction in nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor void fraction.

**Nominal inlet specific enthalpy** — Inlet fluid specific enthalpy

1500 kJ/kg (default) | positive scalar

Inlet specific enthalpy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific enthalpy.

**Nominal inlet specific internal energy** — Inlet specific internal energy

1500 kJ/kg (default) | positive scalar

Inlet specific internal energy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific internal energy.

**Cross-sectional area at ports A and B** — Valve port areas

0.01 m<sup>2</sup> (default) | positive scalar

Area of the orifice ports **A** and **B**.

**Closed orifice leakage as a fraction of nominal flow** — Fractional flow when orifice is closed

1e-6 (default) | positive scalar

Fractional flow rate through the orifice when it is fully closed. This parameter contributes to numerical stability by maintaining continuity in the fluid network.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regions.

**Laminar flow pressure ratio** — Laminar-turbulent transition pressure ratio

0.999 (default) | positive scalar

Ratio of the orifice outlet pressure to orifice inlet pressure at which the fluid transitions between the laminar and turbulent regimes. The pressure loss corresponds to the mass flow rate linearly in laminar flows and quadratically in turbulent flows.

**Inlet phase change time constant** — Lag for mixture specific volume

0.1 s (default) | positive scalar

Time lag for liquid-vapor mixtures in computing the fluid specific volume. This parameter does not influence the specific volume when the inlet fluid is a fully supercooled liquid or fully superheated vapor.

Check Valve (2P) | Pressure-Reducing Valve (2P) | Pressure Relief Valve (2P) | Thermostatic Expansion Valve (2P)

## P-H Diagram (2P)

Thermodynamic scope for two-phase fluid networks

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Utilities

## Description

The P-H Diagram (2P) block plots a p-h diagram of the pressure with respect to the specific enthalpy of a thermodynamic, two-phase fluid. A p-h diagram indicates the fluid state at key points during a thermodynamic cycle.

The plot units are MPa for pressure, kJ/kg for specific enthalpy, and K for the temperature contours.

Each numbered point on the diagram indicates the fluid state after a dynamic process in the refrigeration cycle:

- 1 Cool vapor at low pressure
- 2 Hot vapor at high pressure
- 3 Hot liquid at high pressure
- 4 Mixed vapor and liquid at low pressure

To use the P-H Diagram (2P) block:

- 1 Place a Thermodynamic Properties Sensor (2P) and a Pressure, Temperature & Internal Energy Sensor (2P) block at each location you want to monitor.

---

**Note** The Pressure & Internal Energy Sensor (2P) block measures a differential pressure. Connect port **A** to the monitor point and port **B** to an Absolute Reference (2P) block.

---

- 2 Convert the Simscape physical signals to Simulink signals with a PS-Simulink Converter block.
- 3 Use a Mux block to combine the pressure signals. Connect the output signal to the P-H Diagram (2P) **p** port.
- 4 Use a Mux block to combine the converted specific enthalpy signals and connect the output signal to the **h** port.
- 5 Before running the simulation, double-click the P-H Diagram (2P) block, then click the Select

fluid properties button  to set the network fluid properties.

If you do not select the fluid properties, the block uses the default two-phase network fluid, which is water.

### P-H Diagram Playback

You can also replay the animation from the most recent simulation. After running the model, double-click the block and use the buttons at the top of the window to control the animation. Use the drop-down menu to the right of the **Time** field to control the rate of the playback. The replay controls are disabled before you run a simulation, when the model is loaded, and when the simulation is running.

Use the playback slider or **Time** field to control the simulation cycle. If you enter a time that is not a model time step, the block displays the next closest time step.

To save the current iteration of the plot, point to the plot area. From the icons in the top-right corner of the plot, click the Export icon  and select the Save As button  to save the plot.

## Ports

### Input

**p** — Pressure, MPa  
vector

Vector of pressures. The vector must have same number of elements as the enthalpy signal at port **h**

**h** — Specific enthalpy, kJ/kg  
vector

Vector of specific enthalpies. The vector must have same number of elements as the pressure signal at port **p**.

Thermostatic Expansion Valve (2P)

## Partially Filled Pipe (IL)

Pipe with variable liquid volume in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

### Description

The Partially Filled Pipe (IL) block models a pipe with the capacity for varying internal liquid levels. The pipe may also become completely dry during simulation.

In addition to liquid connections at ports **A** and **B**, port **AL** receives the inlet liquid level from connected blocks as a physical signal. If the value at **AL** is greater than zero, **A** is submerged. If the value at **AL** is less than or equal to zero, the port is exposed. The pipe liquid level is transmitted as a physical signal to connecting blocks at port **L**.

Port **A** is always higher than port **B**. If port **A** becomes exposed, the pipe can be filled through port **B**. When fluid enters the pipe through port **B**, the mass flow rate through port **A** is 0 until the pipe is fully filled, at which point  $\dot{m}_A = -\dot{m}_B$ .

### When to Use the Partially Filled Pipe (IL) Block

This block can be used in conjunction with the Tank (IL) block when fluid levels are expected to fall below the tank inlet. Multiple Partially Filled Pipe (IL) blocks can also be connected in series or parallel. However, because a partially filled pipe can only be filled at port **B**, if port **A** of one block in a parallel configuration becomes exposed, it may not be possible to refill this pipe if its connection at port **B** cannot refill the pipe.

### Pressure Loss Over the Pipe

The pressure differential over the pipe,  $p_A - p_B$ , comprises losses due to wall friction and hydrostatic pressure differences between the liquid surface height and the liquid height at port **A**:

$$p_A - p_B = \Delta p_{loss} + \Delta p_{elev}.$$

Friction losses depend on the fluid regime in the pipe. If the flow is laminar, the friction losses are:

$$\Delta p_{loss} = \frac{-\dot{m}_B \nu f_s \hat{L}}{2D_h^2 A^2},$$

where:

- $\nu$  is the fluid kinematic viscosity.
- $f_s$  is the **Laminar friction constant for Darcy friction factor**.

- $\widehat{L}$  is the sum of the pipe length and its **Aggregate equivalent length of local resistances**, in proportion to the pipe fill level:  $\widehat{L} = (L + L_{add})\frac{l}{l_{\max}}$ .
- $l, l_{\max}$  are the liquid level and the **Elevation drop from port A to port B**, respectively.
- $D_h$  is the pipe hydraulic diameter. If the pipe cross-section is not circular, the hydraulic diameter is the equivalent circular diameter.

If the flow is turbulent, the friction losses are:

$$\Delta p_{\text{loss}} = \frac{-\dot{m}_B |\dot{m}_B| f \widehat{L}}{2\rho D_h^2 A^2}.$$

$f$  is the Darcy friction factor for turbulent flows, which is determined by the empirical Haaland correlation:

$$f = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}} + \left( \frac{\varepsilon}{3.7 D_h} \right)^{1.11} \right] \right\}^{-2},$$

where  $\varepsilon$  is the **Internal surface absolute roughness**. The Reynolds number is based on the mass flow rate at port **B** and the pipe hydraulic diameter.

The hydrostatic pressure difference is  $\Delta p_{\text{elev}} = \rho g l$ .

### Mass Flow Rate

The flow in the pipe is dictated by the internal fluid level and the conditions at port **B**. The pipe can be filled or drained at **B** if the pipe is partially empty. If the pipe is fully filled,  $\dot{m}_A = \dot{m}_B$ , and mass is conserved:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass of fluid in the pipe is determined by the relative fill level of the pipe:

$$M = \rho A L \frac{l}{l_{\max}}.$$

### Assumptions and Limitations

This block does not account for dynamic compressibility or fluid inertia, and does not model the dynamics of air (or second liquid) in the pipe.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Fluid entry or exit to the pipe. Port **A** is always higher than port **B**. When port **A** is submerged,  $\dot{m}_A = \dot{m}_B$ . When port **A** is exposed,  $\dot{m}_A = 0$ .

**B** — Liquid port  
isothermal liquid

Fluid entry or exit to the pipe. Port **A** is always higher than port **B**. When port **A** is submerged,  $\dot{m}_A = \dot{m}_B$ . When port **A** is exposed, any flow into or out of port **B** changes the liquid level in the pipe. A dry or partially dry pipe can only be filled through port **B**.

### Input

**AL** — Relative liquid level of connected block, m  
physical signal

Relative liquid level of the connected block in m, specified as a physical signal. If the signal at **AL** is positive, the pipe end is submerged. Otherwise the port is exposed.

### Output

**L** — Pipe liquid level, m  
physical signal

Liquid level in the pipe in m, returned as a physical signal..

## Parameters

### Geometry

**Pipe length** — Pipe length  
5 m (default) | positive scalar

Pipe length.

**Cross-sectional area** — Pipe cross-sectional area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the pipe.

**Hydraulic diameter** — Hydraulic diameter  
0.1128 m (default) | positive scalar

Hydraulic diameter used in calculations of the pipe Reynolds number. For non-circular pipes, the hydraulic diameter is the effective diameter of the fluid in the pipe. For circular pipes, the hydraulic diameter and pipe diameter are the same.

**Elevation drop from port A to port B** — Vertical distance between A and B  
5 m (default) | positive scalar

Vertical change in elevation of the pipe. Port **A** is always higher than port **B**.

**Initial liquid level** — Starting liquid level  
5 m (default) | positive scalar

Liquid level in the pipe at the beginning of the simulation.

**Liquid level below zero** — Whether to notify if no liquid is in pipe  
Error (default) | None | Warning

Whether to notify if no liquid is in the pipe. Set this parameter to **Warning** if you would like to receive a warning when this occurs during simulation. Set the parameter to **Error** if you would like the simulation to stop when this occurs.

**Gravitational acceleration** — Acceleration of gravity

9.81 m/s<sup>2</sup> (default) | positive scalar

Acceleration of gravity constant.

### Friction

**Aggregate equivalent length of local resistances** — Contribution of pipe geometry to hydraulic losses

1 m (default) | positive scalar

Length of pipe that would produce the equivalent hydraulic losses as would a pipe with bends, area changes, or other non-uniform attributes.

**Internal surface absolute roughness** — Pipe wall roughness

15e-6 m (default) | positive scalar

Pipe wall absolute roughness. This parameter is used to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

**Laminar flow upper Reynolds number limit** — Laminar flow upper threshold

2000 (default) | positive scalar

Upper Reynolds number limit to laminar flow. Beyond this number, the fluid regime is transitional and approaches the turbulent regime and becomes fully turbulent at the **Turbulent flow lower Reynolds number limit**.

**Turbulent flow lower Reynolds number limit** — Turbulent flow lower threshold

4000 (default) | positive scalar

Lower Reynolds number limit for turbulent flow. Below this number, the flow regime is transitional and approaches laminar flow and becomes fully laminar at the **Laminar flow upper Reynolds number limit**.

**Laminar friction constant for Darcy friction factor** — Pipe friction constant for laminar flows

64 (default) | positive scalar

Pipe friction constant for laminar flows. The laminar Darcy friction factor captures the contribution of wall friction in pressure loss calculations.

Pipe (IL) | Tank (IL)

## Partially Filled Pipe (TL)

Pipe with variable liquid volume in an thermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

### Description

The Partially Filled Pipe (TL) block represents a pipe with the capacity for varying internal liquid levels. The pipe may also become completely dry during simulation.

In addition to liquid connections at ports **A** and **B**, port **AL** receives the inlet liquid level from connected blocks as a physical signal. If the value at **AL** is greater than zero, **A** is submerged. If the value at **AL** is less than or equal to zero, the port is exposed. The pipe liquid level is transmitted as a physical signal to connecting blocks at port **L**.

Port **A** is always higher than port **B**. If port **A** becomes exposed, the pipe can be filled through port **B**. When fluid enters the pipe through port **B**, the mass flow rate through port **A** is 0 until the pipe is fully filled, at which point  $\dot{m}_A = -\dot{m}_B$ .

### When to Use the Partially Filled Pipe (TL) Block

This block can be used in conjunction with the Tank (TL) block when fluid levels are expected to fall below the tank inlet. Multiple Partially Filled Pipe (TL) blocks can also be connected in series or parallel. However, because the block can only be filled at port **B**, if port **A** of one block in a parallel configuration becomes exposed, it may not be possible to refill this pipe if its connection at port **B** cannot refill the pipe.

### Pressure Loss Over the Pipe

The pressure differential over the pipe,  $p_A - p_B$ , comprises losses due to wall friction and hydrostatic pressure differences between the liquid surface height and the liquid height at port **A**:

$$p_A - p_B = \Delta p_{loss} + \Delta p_{elev}.$$

Friction losses depend on the fluid regime in the pipe. If the flow is laminar, the friction losses are:

$$\Delta p_{loss} = \frac{-\dot{m}_B \nu f_s \hat{L}}{2D_h^2 A^2},$$

where:

- $\nu$  is the fluid kinematic viscosity.
- $f_s$  is the **Laminar friction constant for Darcy friction factor**.

- $\widehat{L}$  is the sum of the pipe length and its **Aggregate equivalent length of local resistances**, in proportion to the pipe fill level:  $\widehat{L} = (L + L_{add})\frac{l}{l_{\max}}$ .
- $l, l_{\max}$  are the liquid level and the **Elevation drop from port A to port B**, respectively.
- $D_h$  is the pipe hydraulic diameter. If the pipe cross-section is not circular, the hydraulic diameter is the equivalent circular diameter.

If the flow is turbulent, the friction losses are:

$$\Delta p_{\text{loss}} = \frac{-\dot{m}_B |\dot{m}_B| f \widehat{L}}{2\rho D_h^2 A^2}.$$

$f$  is the Darcy friction factor for turbulent flows, which is determined by the empirical Haaland correlation:

$$f = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}} + \left( \frac{\varepsilon}{3.7 D_h} \right)^{1.11} \right] \right\}^{-2},$$

where  $\varepsilon$  is the **Internal surface absolute roughness** parameter. The Reynolds number is based on the mass flow rate at port **B** and the pipe hydraulic diameter.

The hydrostatic pressure difference is  $\Delta p_{\text{elev}} = \rho g l$ .

### Mass Flow Rate

The flow in the pipe is dictated by the internal fluid level and the conditions at port **B**. The pipe can be filled or drained at **B** if the pipe is partially empty. If the pipe is fully filled,  $\dot{m}_A = \dot{m}_B$ , and mass is conserved:

$$\dot{m}_A + \dot{m}_B = 0.$$

The block determines the mass of fluid in the pipe by the relative fill level of the pipe:

$$M = \rho A L \frac{l}{l_{\max}}.$$

### Energy Balance

The block balances energy flow such that when port **A** is submerged,

$$M c_v \frac{dT}{dt} = \phi_A + \phi_B - \dot{m}_B g l.$$

When port **A** is exposed,

$$M c_v \frac{dT}{dt} = \phi_A + \phi_B - \dot{m}_B h - \dot{m}_B g l,$$

where  $c_v$  is the specific heat at constant volume,  $T$  is the fluid temperature, and  $h$  is the specific enthalpy.

## Assumptions and Limitations

This block does not account for dynamic compressibility or fluid inertia, and does not model the dynamics of air (or second liquid) in the pipe.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port. Port **A** is always higher than port **B**. When port **A** is submerged,  $\dot{m}_A = \dot{m}_B$ . When port **A** is exposed,  $\dot{m}_A = 0$ .

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port. Port **A** is always higher than port **B**. When port **A** is submerged,  $\dot{m}_A = \dot{m}_B$ . When port **A** is exposed, any flow into or out of port **B** changes the liquid level in the pipe. A dry or partially dry pipe can only be filled through port **B**.

### Input

**AL** — Relative liquid level of connected block, m  
physical signal

Relative liquid level of the connected block in m, specified as a physical signal. If the signal at **AL** is positive, the pipe end is submerged. Otherwise the port is exposed.

### Output

**L** — Pipe liquid level, m  
physical signal

Liquid level in the pipe in m, returned as a physical signal..

## Parameters

### Geometry

**Pipe length** — Pipe length  
5 m (default) | positive scalar

Pipe length.

**Cross-sectional area** — Pipe cross-sectional area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the pipe.

**Hydraulic diameter** — Hydraulic diameter  
0.1128 m (default) | positive scalar

Hydraulic diameter used in calculations of the pipe Reynolds number. For non-circular pipes, the hydraulic diameter is the effective diameter of the fluid in the pipe. For circular pipes, the hydraulic diameter and pipe diameter are the same.

**Elevation drop from port A to port B** — Vertical distance between A and B  
5 m (default) | positive scalar

Vertical change in elevation of the pipe. Port **A** is always higher than port **B**.

**Initial liquid level** — Starting liquid level  
5 m (default) | positive scalar

Liquid level in the pipe at the beginning of the simulation.

**Liquid level below zero** — Whether to notify if no liquid is in pipe  
Error (default) | None | Warning

Whether to notify if no liquid is in the pipe. Set this parameter to **Warning** if you would like to receive a warning when this occurs during simulation. Set the parameter to **Error** if you would like the simulation to stop when this occurs.

**Gravitational acceleration** — Acceleration of gravity  
9.81 m/s<sup>2</sup> (default) | positive scalar

Acceleration of gravity constant.

## Friction

**Aggregate equivalent length of local resistances** — Contribution of pipe geometry to hydraulic losses

1 m (default) | positive scalar

Length of pipe that would produce the equivalent hydraulic losses as would a pipe with bends, area changes, or other non-uniform attributes.

**Internal surface absolute roughness** — Pipe wall roughness  
15e-6 m (default) | positive scalar

Pipe wall absolute roughness. This parameter is used to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

**Laminar flow upper Reynolds number limit** — Laminar flow upper threshold  
2000 (default) | positive scalar

Upper Reynolds number limit to laminar flow. Beyond this number, the fluid regime is transitional and approaches the turbulent regime and becomes fully turbulent at the **Turbulent flow lower Reynolds number limit**.

**Turbulent flow lower Reynolds number limit** — Turbulent flow lower threshold  
4000 (default) | positive scalar

Lower Reynolds number limit for turbulent flow. Below this number, the flow regime is transitional and approaches laminar flow and becomes fully laminar at the **Laminar flow upper Reynolds number limit**.

**Laminar friction constant for Darcy friction factor** — Pipe friction constant for laminar flows  
64 (default) | positive scalar

Pipe friction constant for laminar flows. The laminar Darcy friction factor captures the contribution of wall friction in pressure loss calculations.

### **Initial Conditions**

**Initial liquid temperature** — Liquid temperature at start of simulation  
293.15 K (default)

Liquid temperature at the beginning of the simulation.

# Partially Filled Vertical Pipe LP

(To be removed) Partially filled vertical pipe connecting two tanks

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Library

Low-Pressure Blocks

## Description

The Partially Filled Vertical Pipe LP block models a vertical pipe connecting two tanks. The block takes into account the possibility that the top tank gets emptied, and therefore the top part of the pipe can be exposed. The fluid level in the pipe then settles at some intermediate position, depending on pressures at both ports.

The following schematic diagram shows two tanks connected by a partially filled vertical pipe, where:

- $h_A$  and  $h_B$  are the elevations of ports A and B, respectively
- $h_p$  is the fluid level in the pipe
- $L$  is the length of the pipe

The tank is assumed to be empty when fluid volume becomes less than a specified value. If the upstream tank is emptied, the flow rate through port A is assumed to be 0, and the tank pressurization pressure propagates through port A to the pipe. When pressure increases at the bottom port B, the fluid flows upstream. After the pipe is completely filled, the fluid can start filling the top tank.

You must connect port A to a component that provides data on fluid volume (such as the Reservoir block or any of the tank blocks). Port A elevation must be greater than port B elevation.

You can connect port B to any hydraulic component, with one restriction: the component must keep the port submerged at all times.

The pipe hydraulic resistance is proportional to the length of fluid in the pipe (wet length). The shorter the wet length, the lower the resistance. To avoid zero resistance as wet length approaches 0, the volume of fluid in the pipe is limited to the same minimum value as the tank. After the minimum volume is reached, the flow rate through port B is assumed to be 0.

It is a good practice to connect port B either to another tank or to a pressure source. When you connect it to a pressure source, it is good practice to insert some hydraulic resistance (fixed orifice, valve, and so on) between the pipe and the source, to avoid zero resistance.

The block models pipes with circular and noncircular cross sections. The block accounts for friction losses, variable fluid level in the pipe, and resulting variable heads at the ports. The block is based on the assumption of steady-state fluid momentum conditions. For additional information, see “Basic Assumptions and Limitations” on page 1-1334. To account for local resistances (such as bends, fittings, inlet and outlet losses, and so on), convert the resistances into their equivalent lengths, sum up all the resistances to obtain their aggregate length, and then add this length to the pipe geometrical length. The ratio between the added and the current wet length of the pipe is maintained constant as the pipe is emptied or filled with fluid.

Flow rates through the pipe ports are computed individually because they are different when the top port is exposed. The flow rates are proportional to the flow-regime-dependent friction factor and the pressure differential. The friction factor in turbulent regime is determined with the Haaland approximation [1 on page 1-1337]:

$$f = \frac{1}{\left(-1.8 \log_{10} \left( \frac{6.9}{Re} + \left( \frac{k/D_H}{3.7} \right)^{1.11} \right)\right)^2}$$

$$Re = \frac{q \cdot D_H}{A \cdot \nu}$$

where

$f$	Friction factor
$k$	Height of the roughness on the pipe internal surface
$Re$	Reynolds number
$q$	Flow rate
$D_H$	Pipe hydraulic diameter
$A$	Pipe cross-sectional area
$\nu$	Fluid kinematic viscosity

At laminar regime, the friction factor is determined as

$$f = \frac{s}{Re}$$

where  $s$  is the geometrical shape factor, or Poiseuille number [1 on page 1-1337], defined as a function of the Fanning factor for various noncircular shapes: rectangle, concentric annulus, ellipse, and circular sector.

The friction factor during the transition from laminar to turbulent regimes is determined with the linear interpolation between extreme points of the regimes. As a result of these assumptions, the pipe is simulated according to the following equations:

$$q_A = \begin{cases} 0 & \text{for } p > = 0, V < V_{\min} \\ A \sqrt{\frac{1}{f} \frac{D_H}{L_{ef}}} \sqrt{\frac{2}{\rho} \cdot p} & \text{for } p > = 0, V > = V_{\min}, Re > = Re_{cr} \\ 2 \cdot A \cdot \frac{D_H^2}{s \cdot \nu \cdot \rho \cdot L_{ef}} \cdot p & \text{for } p > = 0, V > = V_{\min}, Re < Re_{cr} \\ 0 & \text{for } p < 0, L_F < = L \\ 2 \cdot A \cdot \frac{D_H^2}{s \cdot \nu \cdot \rho \cdot L_{ef}} \cdot p & \text{for } p < 0, L_F > L, Re < Re_{cr} \\ A \sqrt{\frac{1}{f} \frac{D_H}{L_{ef}}} \sqrt{\frac{2}{\rho} \cdot |p|} & \text{for } p < 0, L_F > L, Re > = Re_{cr} \end{cases}$$

$$q_B = \begin{cases} 0 & \text{for } p > = 0, V_F < V_{\min} \\ A \sqrt{\frac{1}{f} \frac{D_H}{L_{ef}}} \sqrt{\frac{2}{\rho} \cdot |p|} \cdot \text{sign}(p) & \text{for } p > = 0, V_F > = V_{\min}, Re > = Re_{cr} \\ 2 \cdot A \cdot \frac{D_H^2}{s \cdot \nu \cdot \rho \cdot L_{ef}} \cdot p & \text{for } p > = 0, V_F > = V_{\min}, Re < Re_{cr} \end{cases}$$

$$q_A - q_B = \frac{dV_p}{dt}$$

$$L_F = \frac{V_p}{A}$$

$$L_{ef} = L_F \left( 1 + \frac{L_{ad}}{L} \right)$$

$$h_p = L_F \frac{h_A - h_B}{L}$$

$$p = p_A - p_B + \rho \cdot g \cdot h_p$$

where

$q_A, q_B$	Flow rates through port A and B, respectively
$p_A, p_B$	Pressures at port A and B, respectively
$h_A, h_B$	Port A and port B elevations, respectively
$L$	Geometrical pipe length
$L_{ad}$	Aggregate equivalent length of local resistances
$L_F$	Pipe wet length
$L_{ef}$	Effective pipe length
$\rho$	Fluid density
$p$	Pressure differential across the pipe
$V$	Fluid volume in the upstream tank
$V_p$	Volume of fluid in the pipe
$V_{min}$	Minimum volume of fluid in the tank, or in the pipe. If $V$ becomes less than $V_{min}$ , then the upstream tank is considered empty, the flow rate through port A is assumed to be 0, and the tank pressurization pressure propagates through port A to the pipe. If $V_p$ becomes less than $V_{min}$ , then the pipe is considered empty and the flow rate through port B is assumed to be 0.
$h_p$	Fluid elevation in the pipe
$Re_{cr}$	Critical Reynolds number
$g$	Gravity acceleration

Flow rate A is considered positive when fluid flows into the pipe. Flow rate B is considered positive when fluid flows out of the pipe.

## Basic Assumptions and Limitations

- The block is based on the assumption of steady-state fluid momentum conditions.
- Fluid inertia and fluid compressibility are not taken into account.
- Flow is assumed to be fully developed along the pipe length, therefore the end effects are not considered.

- To account for local resistances in the pipe, you must convert the resistances into their equivalent lengths, sum them up to obtain their aggregate length, and then add this aggregate length to the pipe geometrical length.
- The elevation of port A must be greater than that of port B.
- Port A must be connected to the hydraulic port of the top tank. The fluid volume in the top tank must be input into the Partially Filled Vertical Pipe LP block through the physical signal port V. If you use one of the standard Simscape Fluids reservoir or tank blocks, connect its physical output port directly to the input port V. If you use a custom tank block, it must have a port that exports fluid volume in the tank as a physical signal, and you must connect this output port to the input port V.
- Port B must not be exposed.
- The friction factor at turbulent regime is computed with the Haaland approximation.
- The friction factor at laminar regime is determined as the Poiseuille number divided by the Reynolds number.
- The friction factor during transition from laminar to turbulent regime is computed with the linear interpolation.

## Parameters

- “Basic Parameters Tab” on page 1-1335
- “Vertical Position Tab” on page 1-1336

### Basic Parameters Tab

#### Pipe type

The type of pipe cross section: **Circular** or **Noncircular**. For a circular pipe, you specify its internal diameter. For a noncircular pipe, you specify its hydraulic diameter and pipe cross-sectional area. The default value of the parameter is **Circular**.

#### Pipe internal diameter

Pipe internal diameter. The parameter is available if **Pipe type** is set to **Circular**. The default value is 0.01 m.

#### Noncircular pipe cross-sectional area

Pipe cross-sectional area. The parameter is available if **Pipe type** is set to **Noncircular**. The default value is 0.08 m<sup>2</sup>.

#### Noncircular pipe hydraulic diameter

Hydraulic diameter of the pipe cross section. The parameter is available if **Pipe type** is set to **Noncircular**. The default value is 0.1 m.

#### Geometrical shape factor

Used for computing friction factor at laminar flow. The shape of the pipe cross section determines the value. For a pipe with a noncircular cross section, set the factor to an appropriate value, for example, 56 for a square, 96 for concentric annulus, 62 for rectangle (2:1), and so on [1 on page 1-1337]. The default value is 64, which corresponds to a pipe with a circular cross section.

#### Pipe length

Pipe geometrical length. The default value is 100 m.

#### Aggregate equivalent length of local resistances

Represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/

outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. The default value is 50 m.

**Tank minimum volume**

Minimum volume of fluid in the upstream tank, or in the pipe, corresponding to  $V_{\min}$  in the block equations. The tank or pipe is considered empty if its fluid volume becomes less than  $V_{\min}$ . The default value is  $1e-4 \text{ m}^3$ .

**Laminar flow upper margin**

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

**Turbulent flow lower margin**

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

**Internal surface roughness height**

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer catalogs. The default value is  $5e-5 \text{ m}$ .

**Vertical Position Tab****Port A elevation wrt reference plane**

The vertical position of the pipe port A with respect to the reference plane. The default value is 50 m.

**Port B elevation wrt reference plane**

The vertical position of the pipe port B with respect to the reference plane. The default value is 0.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Pipe type**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Pipe type** parameter at the time the model entered Restricted mode.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

- A Hydraulic conserving port associated with the pipe inlet.
- B Hydraulic conserving port associated with the pipe outlet.
- V Physical signal input port that provides data on fluid volume in the upstream tank.
- L Physical signal output port that exports the pipe fluid level.

### Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Directional Valves

### Description

The Pilot-Operated Check Valve block represents a hydraulic pilot-operated check valve as a data-sheet-based model. The purpose of the check valve is to permit flow in one direction and block it in the opposite direction, as shown in the following figure.

Unlike a conventional check valve, the pilot-operated check valve can be opened by inlet pressure  $p_A$ , pilot pressure  $p_X$ , or both. The force acting on the poppet is based on the expression

$$F = p_A \cdot A_A + p_X \cdot A_X - p_B \cdot A_B$$

where

$p_A, p_B$	Gauge pressures at the valve terminals
$p_X$	Pressure—gauge or differential—at the pilot terminal
$A_A$	Area of the spool in the A chamber
$A_B$	Area of the spool in the B chamber
$A_X$	Area of the pilot chamber

The force equation is commonly expressed in the slightly modified form

$$p_e = p_A + p_X \cdot k_p - p_B$$

where  $k_p = A_X / A_A$  is usually referred to as pilot ratio and  $p_e$  is the effective pressure differential across the control member. The valve remains closed while this pressure differential across the valve is lower than the valve cracking pressure. When cracking pressure is reached, the valve control member is forced off its seat, thus creating a passage between the inlet and outlet. If the flow rate is high enough and pressure continues to rise, the area is further increased until the control member reaches its maximum. At this moment, the valve passage area is at its maximum. The valve maximum area and the cracking and maximum pressures are generally provided in the catalogs and are the three key parameters of the block.

The pilot pressure can be a differential value relative to the inlet (port **A**) or a gauge value (relative to the environment). You can select an appropriate setting—**Pressure differential (pX - pA)** or **Pressure at port X**—using the **Pressure control specification** dropdown list. If **Pressure at port X** is selected:

$$p_X = p_{X,Abs} - p_{Atm}$$

where the subscript **Atm** denotes atmospheric pressure. The subscript **X, Abs** denotes the absolute value at the pilot port. If **Pressure differential (pX - pA)** is selected:

$$p_X = p_{X,Abs} - p_{A,Abs}$$

where the subscript **A, Abs** similarly denotes the absolute value at the inlet of the valve (port **A**). The pilot pressure differential is constrained to be greater than or equal to zero—if its calculated value should be negative, zero is assumed in the control pressure calculation.

In addition to the maximum area, the leakage area is also required to characterize the valve. The main purpose of the parameter is not to account for possible leakage, even though this is also important, but to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. An isolated or “hanging” part of the system could affect computational efficiency and even cause failure of computation. Therefore, the parameter value must be greater than zero.

By default, the block does not include valve opening dynamics, and the valve sets its opening area directly as a function of pressure:

$$A = A(p)$$

Adding valve opening dynamics provides continuous behavior that is more physically realistic, and is particularly helpful in situations with rapid valve opening and closing. The pressure-dependent orifice passage area  $A(p)$  in the block equations then becomes the steady-state area, and the instantaneous orifice passage area in the flow equation is determined as follows:

$$A(t = 0) = A_{init}$$

$$\frac{dA}{dt} = \frac{A(p) - A}{\tau}$$

In either case, the flow rate through the valve is determined according to the following equations:

$$q = C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

$$p_e = p_A + p_X \cdot k_p - p_B$$

$$A(p) = \begin{cases} A_{leak} & \text{for } p_e \leq p_{crack} \\ A_{leak} + k \cdot (p_e - p_{crack}) & \text{for } p_{crack} < p_e < p_{max} \\ A_{max} & \text{for } p_e \geq p_{max} \end{cases}$$

$$k = \frac{A_{max} - A_{leak}}{p_{max} - p_{crack}}$$

$$\Delta p = p_A - p_B,$$

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$q$	Flow rate through the valve
$p$	Pressure differential across the valve
$p_e$	Equivalent pressure differential across the control member
$p_A, p_B$	Gauge pressures at the valve terminals
$p_X$	Gauge pressure at the pilot terminal
$k_p$	Pilot ratio, $k_p = A_X / A_A$
$k$	Valve gain coefficient
$C_D$	Flow discharge coefficient
$A$	Instantaneous orifice passage area
$A(p)$	Pressure-dependent orifice passage area
$A_{init}$	Initial open area of the valve
$A_{max}$	Fully open valve passage area
$A_{leak}$	Closed valve leakage area
$p_{crack}$	Valve cracking pressure
$p_{max}$	Pressure needed to fully open the valve
$p_{cr}$	Minimum pressure for turbulent flow
$Re_{cr}$	Critical Reynolds number
$D_H$	Instantaneous orifice hydraulic diameter

$\rho$	Fluid density
$\nu$	Fluid kinematic viscosity
$\tau$	Time constant for the first order response of the valve opening
$t$	Time

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure differential is determined as  $\Delta p = p_A - p_B$ .

## Assumptions and Limitations

- Valve opening is linearly proportional to the effective pressure differential.
- No loading on the valve, such as inertia, friction, spring, and so on, is considered.
- No flow consumption is associated with the pilot chamber.

## Ports

### Conserving

**A** — Valve inlet  
hydraulic

Hydraulic conserving port associated with the valve inlet.

**B** — Valve outlet  
hydraulic

Hydraulic conserving port associated with the valve outlet.

**X** — Valve pilot terminal  
hydraulic

Hydraulic conserving port associated with the valve pilot terminal.

## Parameters

**Pressure control specification** — Choice of pressure measurement to use as pilot control signal  
Pressure differential ( $p_X - p_A$ ) (default) | Pressure at port X

Choice of pressure measurement to use as pilot control signal:

- Pressure differential ( $p_X - p_A$ ) — The effective pressure differential is a function of the pressure drop from the pilot port (**X**) to the inlet (**A**).
- Pressure at port X — The effective pressure differential is a function of the gauge pressure at the inlet.

The block uses the chosen measurement to calculate the effective pressure differential across the valve. See the block description for the calculations.

**Cracking pressure** — Pressure level at which the orifice of the valve starts to open  
3e4 Pa (default) | positive scalar

Pressure level at which the orifice of the valve starts to open.

**Maximum opening pressure** — Pressure differential across the valve needed to fully open the valve  
1.2e5 Pa (default) | positive scalar

Pressure differential across the valve needed to fully open the valve. Its value must be higher than the cracking pressure.

**Pilot ratio** — Ratio between effective area in the pilot chamber to the effective area in the inlet chamber  
5 (default) | positive scalar

Ratio between effective area in the pilot chamber to the effective area in the inlet chamber.

**Maximum passage area** — Valve passage maximum cross-sectional area  
1e-4 m<sup>2</sup> (default) | positive scalar

Valve passage maximum cross-sectional area.

**Leakage area** — Helps maintain numerical integrity of the circuit  
1e-12 m<sup>2</sup> (default) | positive scalar

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0.

**Laminar transition specification** — Select how block transitions between the laminar and turbulent regimes  
Pressure ratio (default) | Reynolds number

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio** — Pressure ratio at which the flow transitions between laminar and turbulent regimes  
0.999 (default) | positive scalar in the range of [0,1]

Pressure ratio at which the flow transitions between laminar and turbulent regimes.

#### **Dependencies**

This parameter is visible only if the **Laminar transition specification** parameter is set to Pressure ratio.

**Critical Reynolds number** — Maximum Reynolds number for laminar flow  
12 (default) | positive scalar

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges.

**Dependencies**

This parameter is visible only if the **Laminar transition specification** parameter is set to Reynolds number.

**Flow discharge coefficient** — Semi-empirical parameter for valve capacity characterization  
0.7 (default) | positive scalar

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets.

**Opening dynamics** — Specify whether to include valve opening dynamics in simulation  
Do not include valve opening dynamics (default) | Include valve opening dynamics

Select one of the following options:

- **Do not include valve opening dynamics** — The valve sets its orifice passage area directly as a function of pressure. If the area changes instantaneously, so does the flow equation.
- **Include valve opening dynamics** — Provide continuous behavior that is more physically realistic, by adding a first-order lag during valve opening and closing. Use this option in hydraulic simulations with the local solver for real-time simulation. This option is also helpful if you are interested in valve opening dynamics in variable step simulations.

**Opening time constant** — Time constant for the first order response of the valve opening  
0.1 s (default) | positive scalar

The time constant for the first order response of the valve opening.

**Dependencies**

To enable this parameter, set **Opening dynamics** to Include valve opening dynamics.

**Initial area** — Initial opening area of the valve  
1e-12 m<sup>2</sup> (default) | positive scalar

The initial opening area of the valve.

**Dependencies**

To enable this parameter, set **Opening dynamics** to Include valve opening dynamics.

## Version History

**Introduced in R2006a****R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

Check Valve

## Pilot-Operated Check Valve (IL)

Check valve with pilot pressure control in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The Pilot-Operated Check Valve (IL) block models a flow-control valve with variable flow directionality based on the pilot-line pressure. Flow is normally restricted to travel from port **A** to port **B** in either a connected or disconnected spool-poppet configuration, according to the **Pilot configuration** parameter.

### Pilot-Operated Check Valve Schematic

The control pressure,  $p_{\text{control}}$  is:

$$p_{\text{control}} = p_{\text{pilot}}k_p + (p_A - p_B),$$

where:

- $p_{\text{pilot}}$  is the control pilot pressure differential.
- $k_p$  is the **Pilot ratio**, the ratio of the area at port **X** to the area at port **A**:  $k_p = \frac{A_X}{A_A}$ .
- $p_A - p_B$  is the pressure differential over the valve.

When the control pressure exceeds the **Cracking pressure differential**, the poppet moves to allow flow from port **B** to port **A**.

There is no mass flow between port **X** and ports **A** and **B**.

### Valve Pressure Control with a Pilot Port

The pilot pressure differential for valve control can be configured in two ways:

- When the **Opening pilot pressure specification** parameter is set to Pressure at port X relative to port A, the pilot pressure is the pressure differential between port X and port A.
- When **Opening pilot pressure specification** is set to Pressure at port X relative to atmospheric pressure, the pilot pressure is the pressure difference between port X and atmospheric pressure.

When **Pilot configuration** is set to Disconnected pilot spool and poppet, the relative pressure at port X must be positive. If the measured pilot pressure is negative, the control pressure is only based on the pressure differential between ports A and B. In the Rigidly connected pilot spool and poppet setting, the pilot pressure is the measured pressure differential according to the opening specification.

### Mass Flow Rate Equation

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the valve is calculated as:

$$\dot{m} = \frac{C_d A_{\text{valve}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2\right) [\Delta p^2 + \Delta p_{\text{crit}}^2]^{1/4}}} \Delta p$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{\text{valve}}$  is the instantaneous valve open area.
- $A_{\text{port}}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference,  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{\text{crit}}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{\text{crit}}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{\text{crit}} = \frac{\pi \bar{\rho}}{8 A_{\text{valve}}} \left( \frac{\nu Re_{\text{crit}}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area.  $PR_{\text{loss}}$  is calculated as:

$$PR_{\text{loss}} = \frac{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{loss}$  is 1.

The opening area,  $A_{valve}$ , is also impacted by the valve opening dynamics.

### Opening Parameterization

The linear parameterization of the valve area is

$$A_{valve} = \hat{p}(A_{max} - A_{leak}) + A_{leak},$$

where the normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{cracking}}{p_{max} - p_{cracking}}.$$

When the valve is in a near-open or near-closed position, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{max}$  and  $p_{cracking}$ . For more information, see “Numerical Smoothing”.

### Opening Dynamics

If opening dynamics are modeled, a lag is introduced to the flow response to the modeled control pressure.  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ ; otherwise,  $p_{control}$  is the steady-state pressure. The instantaneous change in dynamic control pressure is calculated based on the **Opening time constant**,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, the **Opening dynamics** check box is cleared.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry point to the valve. When the control pressure exceeds the cracking pressure, liquid is able to exit from this port.

**B** — Liquid port  
isothermal liquid

Liquid exit point from the valve. When the control pressure exceeds the cracking pressure, liquid is able to enter the valve from this port.

**X** — Pressure port  
isothermal liquid

Pressure port that contributes to the flow control through the valve.

## Parameters

### **Pilot configuration** — Valve geometry

Rigidly connected pilot spool and poppet (default) | Disconnected pilot spool and poppet

Valve geometry. The valve can either have an opening mechanism that is connected to the valve poppet, in the case of the Rigidly connected pilot spool and poppet setting, or an opening mechanism that is aligned with, but moves freely away from, the valve poppet, in the case of the Disconnected pilot spool and poppet setting. The configuration choice determines the pilot pressure calculation.

### **Opening pilot pressure specification** — Reference pressure differential for valve control

Pressure at port X relative to port A (default) | Pressure at port X relative to atmospheric pressure

Reference pressure differential used for valve control. This differential defines the pilot pressure differential, which is added to the pressure differential between ports **A** and **B** and compared against the valve threshold **Cracking pressure differential**.

### **Cracking pressure differential** — Pressure threshold

0.01 MPa (default) | positive scalar

Set pressure for the valve operation.

### **Maximum opening pressure differential** — Maximum pressure differential in opened valve

0.02 MPa (default) | positive scalar

Maximum pressure differential in an opened valve. This value provides an upper limit to simulation pressures so that results remain physical.

### **Pilot ratio** — Pilot port area ratio

1 (default) | positive scalar in the range of (0,1]

Ratio of port area **X** to port area **A**.

### **Maximum opening area** — Maximum valve area

1e-4 m<sup>2</sup> (default) | positive scalar

Maximum valve area. This value is used to determine the normalized valve pressure and the valve opening area during operation.

### **Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

### **Cross-sectional area at ports A and B** — Area at conserving ports

inf m<sup>2</sup> (default) | positive scalar

Areas at the entry and exit ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor accounting for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

12 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Pressure recovery** — Whether to account for pressure increase in area expansions

off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Opening dynamics** — Whether to introduce flow lag due to valve opening

off (default) | on

Whether to account for transient effects to the fluid system due to opening the valve. Selecting **Opening dynamics** approximates the opening conditions by introducing a first-order lag in the pressure response. The **Opening time constant** also impacts the modeled opening dynamics.

**Opening time constant** — Valve opening time constant

0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state conditions when opening or closing the valve from one position to another. This parameter impacts the modeled opening dynamics.

### Dependencies

To enable this parameter, select **Opening dynamics**.

## Pilot-Operated Check Valve (TL)

Check valve with control port to enable flow in reverse direction

### Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The Pilot-Operated Check Valve (TL) block models a check valve with an override mechanism to allow for backflow when activated. (A check valve in turn is an orifice with a unidirectional opening mechanism installed to prevent just that backflow.)

The override mechanism adds a third port—the *pilot*—to the valve. During normal operation, the pilot port is inactive and the valve behaves as any other check valve. Its orifice is then open only when the pressure gradient across it drops from inlet to outlet. Backflow, which requires the reverse pressure gradient, cannot occur. This mode protects components upstream of the valve against pressure surges, temperature spikes, and (in real systems) chemical contamination arising from points downstream.

When backflow is desired, the pilot port is pressurized and the control element of the valve—often a ball or piston—is forced off its seat. The valve is then open to flow in both directions, with a reverse pressure drop (aimed from outlet to inlet) sufficing to drive the flow upstream. (The seat, which lies in the path of the flow, determines if the valve is open. When it is covered—by a ball, piston, or other control element—the flow is cut off and the valve is closed.)

The valve opens by degrees, beginning at its cracking pressure, and continuing to the end of its pressure regulation range. The cracking pressure gives the initial resistance, due to friction or spring forces, that the valve must overcome to open by a sliver (or to *crack* open). Below this threshold, the valve is closed and only leakage flow can pass. Past the end of the pressure regulation range, the valve is fully open and the flow at a maximum (determined by the instantaneous pressure conditions).

The cracking pressure assumes an important role in check valves installed upside down. There, the weight of the opening element—such as a ball or piston—and the elevation head of the fluid can act to open the valve. (The elevation head can arise in a model from a pipe upstream of the inlet when it is vertical or given a slant.) A sufficient cracking pressure keeps the valve from opening inadvertently even if placed at a disadvantageous angle.

### Control Pressure

The opening of the valve depends both on the pilot pressure and on the pressure drop from inlet to outlet:

$$p_{\text{ctl}} = k_X p_X + p_A - p_B,$$

where  $p$  is gauge pressure and  $k$  is the pilot ratio—the proportion of the pilot opening area ( $S_X$ ) to the valve opening area ( $S_R$ ). The subscript  $X$  denotes a pilot value and the subscripts  $A$  and  $B$  the inlet and outlet values, respectively. The port pressures are variables determined (against absolute zero) during simulation.

The pilot pressure can be a differential value relative to the inlet (port **A**) or a gauge value (relative to the environment). You can select an appropriate setting—**Pressure differential (pX - pA)** or **Pressure at port X**—using the **Pressure control specification** dropdown list. If **Pressure at port X** is selected:

$$p_X = p_{X,Abs} - p_{Atm},$$

where the subscript **Atm** denotes the atmospheric value (obtained from the Thermal Liquid Settings (TL) or Thermal Liquid Properties (TL) block of the model). The subscript **X, Abs** denotes the absolute value at the pilot port. If **Pressure differential (pX - pA)** is selected:

$$p_X = p_{X,Abs} - p_{A,Abs}$$

where the subscript **A, Abs** similarly denotes the absolute value at the inlet of the valve (port **A**). The pilot pressure differential is constrained to be greater than or equal to zero—if its calculated value should be negative, zero is assumed in the control pressure calculation.

### Control Pressure Overshoot

The degree to which the control pressure exceeds the cracking pressure determines how much the valve will open. The pressure overshoot is expressed here as a fraction of the (width of the) pressure regulation range:

$$\hat{p} = \frac{p_{Ctl} - p_{Crk}}{p_{Max} - p_{Crk}}.$$

The control pressure,  $p_{Ctl}$ , cracking pressure,  $p_{Crk}$ , and maximum opening pressure,  $p_{Max}$ , correspond to the control pressure specification chosen: **Pressure differential** or **Pressure at port A**.

The fraction—technically, the overshoot *normalized*—is valued at **0** in the fully closed valve and **1** in the fully open valve. If the calculation should return a value outside of these bounds, the nearest of the two is used instead. (In other words, the fraction *saturates* at **0** and **1**.)

### Opening Parameterization

The linear parameterization of the valve area is

$$A_{valve} = \hat{p}(A_{max} - A_{leak}) + A_{leak},$$

where the normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{cracking}}{p_{max} - p_{cracking}}.$$

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{cracking}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

### Opening Area

The valve area opens linearly with the smoothed control pressure,

$$S = (S_{Max} - S_{Min})\hat{p} + S_{Min},$$

where  $S_{Max}$  is the maximum valve area and  $S_{Min}$  is the value of the **Leakage area** parameter.

### Momentum Balance

The causes of those pressure losses incurred in the passages of the valve are ignored in the block. Whatever their natures—sudden area changes, flow passage contortions—only their cumulative effect is considered during simulation. This effect is captured in the block by the discharge coefficient, a measure of the mass flow rate through the valve relative to the theoretical value that it would have in an ideal valve. Expressing the momentum balance in the valve in terms of the pressure drop induced in the flow:

$$p_A - p_B = \frac{\dot{m}_{Avg} \sqrt{\dot{m}_{Avg}^2 + \dot{m}_{Crit}^2}}{2\rho_{Avg} C_D S^{*2}} \left[ 1 - \left( \frac{S^*}{S} \right)^2 \right] \xi_p,$$

where  $\rho$  is density,  $C_D$  is the discharge coefficient, and  $\xi_p$  is the pressure drop ratio—a measure of the extent to which the pressure recovery at the outlet contributes to the total pressure drop of the valve. The subscript Avg denotes an average of the values at the thermal liquid ports. The critical mass flow rate,  $\dot{m}_{Crit}$ , is calculated from the critical Reynolds number—that at which the flow in the valve is assumed to transition from laminar to turbulent:

$$\dot{m}_{Crit} = Re_{Crit} \mu_{Avg} \sqrt{\frac{\pi}{4}} S,$$

where  $\mu$  denotes dynamic viscosity. The pressure drop ratio is calculated as:

$$\xi_p = \frac{\sqrt{1 - \left( \frac{S^*}{S} \right)^2 (1 - C_D^2)} - C_D \frac{S^*}{S}}{\sqrt{1 - \left( \frac{S^*}{S} \right)^2 (1 - C_D^2)} + C_D \frac{S^*}{S}}.$$

### Mass Balance

The volume of fluid inside the valve, and therefore the mass of the same, is assumed to be very small and it is, for modeling purposes, ignored. As a result, no amount of fluid can accumulate there. By the principle of conservation of mass, the mass flow rate into the valve through one port must therefore equal that out of the valve through the other port:

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate *into* the valve through port **A** or **B**.

### Energy Balance

The valve is modeled as an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. With these assumptions, energy can flow by advection only, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows must then always equal zero:

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is defined as the energy flow rate *into* the valve through one of the ports (**A** or **B**).

## Ports

### Conserving

**A** — Valve entrance  
thermal liquid

Opening through which the working fluid must, during normal operation (when the pilot mechanism is disabled), enter the valve. This port can serve as an exit only when the pilot port is pressurized to a sufficient degree.

**B** — Valve entrance  
thermal liquid

Opening through which the working fluid must, during normal operation (when the pilot mechanism is disabled), exit the valve.

**X** — Pilot port  
thermal liquid

Opening by which to actuate (by the application of a sufficient pressure) the pilot mechanism that opens the valve for reverse flow.

## Parameters

**Pressure control specification** — Choice of pressure measurement to use as valve control signal  
Pressure differential (pX-pA) (default) | Pressure at port X

Choice of pressure measurement to use as pilot control signal. The block uses the chosen measurement to calculate the control pressure of the valve. (See the block description for the calculations.)

In the default setting (Pressure differential (pX - pA)), the control pressure is a function of the pressure drop from the pilot port (**X**) to the inlet (**A**). In the alternate setting (**Pressure at port X**), it is a function of the gauge pressure at the inlet.

**Cracking pressure differential** — Effective control pressure at which the valve first opens  
0.01 MPa (default) | positive scalar in units of pressure

Effective pressure differential at which the valve begins to open. This differential—the *control pressure* in the block description—is the sum of the pressure drop from inlet to outlet with the product of the pilot pressure and the pilot ratio. (The pilot pressure used depends on the setting of the **Pressure control specification** parameter.)

**Maximum opening pressure differential** — Effective control pressure at which the valve is fully open  
0.02 MPa (default) | positive scalar in units of pressure

Effective pressure differential at which the valve is fully open. This differential—the *control pressure* in the block description—is the sum of the pressure drop from inlet to outlet with the product of the pilot pressure and the pilot ratio. (The pilot pressure used depends on the setting of the **Pressure control specification** parameter.)

**Pilot ratio** — Ratio of pilot port area to inlet port area

1 (default) | positive unitless scalar

Ratio of the pilot port area to the inlet port area.

**Maximum opening area** — Opening area in the fully open position due to sealing imperfections

$1e-4 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of the valve in the fully open position, when the valve is at the upper limit of the pressure regulation range.

**Leakage area** — Opening area in the maximally closed position due to sealing imperfections

$1e-10 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of the valve in the maximally closed position, when only internal leakage between the ports remains. This parameter serves primarily to ensure that closure of the valve does not cause portions of the fluid network to become isolated (a condition known to cause problems in simulation). The exact value specified here is less important than its being a (very small) number greater than zero.

**Smoothing factor** — Amount of smoothing to apply to the valve opening area function

0 (default)

Amount of smoothing to apply to the opening area function of the valve. This parameter determines the widths of the regions to be smoothed—one located at the fully open position, the other at the fully closed position.

The smoothing superposes on each region of the opening area function a nonlinear segment (a third-order polynomial function, from which the smoothing arises). The greater the value specified here, the greater the smoothing is, and the broader the nonlinear segments become.

At the default value of 0, no smoothing is applied. The transitions to the maximally closed and fully open positions then introduce discontinuities (associated with zero-crossings), which tend to slow down the rate of simulation.

**Cross-sectional area at ports A and B** — Area normal to the flow path at the valve ports

$0.01 \text{ m}^2$  (default) | positive scalar in units of area

Area normal to the flow path at the valve ports. The ports are assumed to be the same in size. The flow area specified here should ideally match those of the inlets of adjoining components.

**Discharge coefficient** — Empirical factor defined as the ratio of actual to ideal mass flow rates

0.64 (default) | positive unitless scalar

Ratio of the actual flow rate through the valve to the theoretical value that it would have in an ideal valve. This semi-empirical parameter measures the flow allowed through the valve: the greater its value, the greater the flow rate. Refer to the valve data sheet, if available, for this parameter.

**Critical Reynolds number** — Reynolds number at the boundary between laminar and turbulent flow regimes

150 (default) | positive unitless scalar

Reynolds number at which the flow is assumed to transition between laminar and turbulent regimes.

## Pilot-Operated Check Valve (G)

Check valve with control port in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Directional Control Valves

### Description

The Pilot-Operated Check Valve (G) block represents a check valve with an override mechanism that allows backflow when activated. A check valve is an orifice with a unidirectional opening mechanism that prevents backflow.

The **X** port of the block represents a pilot port that serves as an override mechanism. During normal operation, the pilot port is inactive and the valve behaves as a check valve. In a check valve, the orifice only opens when the pressure gradient across the valve drops from inlet to outlet. The orifice opening prevents backflow, which requires the reverse pressure gradient, and protects the upstream components of the valve from downstream pressure surges, temperature spikes, and chemical contamination.

For sufficient values at port **X**, the block pressurizes the pilot port and forces the control element of the valve off its seat, permitting backflow. The valve is then open to flow in both directions, with a reverse pressure drop from outlet to inlet driving the flow upstream. The seat, which lies in the path of the flow, determines if the valve is open. When it is covered, the flow is cut off and the valve is closed.

The valve begins opening at the cracking pressure and continues opening until the end of the pressure regulation range. The cracking pressure is the initial resistance, due to friction or spring forces, that the valve must overcome to crack open. Below this threshold, the valve is closed and only leakage flow can pass. Past the end of the pressure regulation range, the valve is fully open and the flow at the maximum value is determined by the instantaneous pressure conditions.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

### Control and Other Pressures

The opening of the valve depends on the pilot pressure and the pressure drop from the inlet to the outlet. The pressure that opens the valve is

$$P_{Ctrl} = k_{pilot}P_{pilot} + P_A - P_B,$$

where:

- $P_{pilot}$  is the pilot pressure.

- $k_{pilot}$  is the pilot ratio.
- $P_A$  is the gauge pressure at port **A**.
- $P_B$  is the gauge pressure at port **B**.

The block determines the port pressures against absolute zero during simulation.

The pilot pressure can be relative to the inlet, port **A**, or relative to the environment. You can select the pilot pressure by setting the **Pilot pressure specification** parameter to Pressure difference of port X relative to port B or Gauge pressure at port X.

If you select Gauge pressure at port X, the pilot pressure is

$$P_{pilot} = P_X - P_{atm},$$

where  $P_{Atm}$  is the atmospheric pressure specified in the Gas Properties (G) block of the model and  $P_X$  is the absolute value of the pressure at the pilot port. If you select Pressure difference of port X relative to port A, the pilot pressure is

$$P_{pilot} = P_X - P_A,$$

where  $P_A$  is the absolute value of pressure at the inlet of the valve, port **A**.

When the **Pilot configuration** parameter is Rigidly connected pilot spool and poppet, the pilot spool transmits both positive and negative pilot forces and the block uses  $P_{pilot}$  as is in the equation for  $P_{Ctrl}$ . When the **Pilot configuration** parameter is Disconnected pilot spool and poppet, the pilot spool transmits only positive pilot pressure forces and  $P_{pilot}$  is limited to positive values. The block uses  $\max(P_{pilot}, 0)$  in the equation for  $P_{Ctrl}$ .

### Fraction of Valve Opening

The degree to which the control pressure exceeds the cracking pressure determines how much the valve opens. The fraction of valve opening is

$$\hat{p} = \frac{P_{Ctrl} - P_{Crk}}{P_{Max} - P_{Crk}},$$

where:

- $P_{Ctrl}$  is the control pressure.
- $P_{Crk}$  is the cracking pressure specified by the **Cracking pressure differential** parameter.
- $P_{Max}$  is the maximum opening pressure specified by the **Maximum opening pressure differential** parameter.

The fraction is normalized so that it is 0 in the fully closed valve and 1 in the fully open valve. If the calculation returns a value outside of these bounds, the block saturates the value to the nearest of the two limits.

### Numerical Smoothing

When the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the normalized control pressure,  $\hat{p}$ . Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

## Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area** — The size of the flow restriction determines the block parameterization.

The block scales the specified flow capacity by the fraction of valve opening. As the fraction of valve opening rises from 0 to 1, the measure of flow capacity scales from its specified minimum to its specified maximum.

## Momentum Balance

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to Cv flow coefficient parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}},$$

where:

- $C_v$  is the flow coefficient.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.
- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3 p_{in} F_y x_T},$$

where:

- $F_y$  is the ratio of the isentropic exponent to 1.4.
- $x_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_v N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{\rho_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3F_{\gamma}x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_{\gamma}x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3}C_v N_6 \sqrt{F_{\gamma}x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, see [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}} \left[ 1 - \left( \frac{\frac{p_{out}}{p_{in}} - B_{crit}}{1 - B_{crit}} \right)^2 \right]^m,$$

where:

- $C$  is the sonic conductance.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.
- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ ,

$$\dot{m} = C \rho_{ref} \sqrt{\frac{T_{ref}}{T_{avg}}} \left[ 1 - \left( \frac{B_{lam} - B_{crit}}{1 - B_{crit}} \right)^2 \right]^m \left( \frac{p_{in} - p_{out}}{1 - B_{lam}} \right).$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{in} \rho_{in} \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}} \left[ \frac{1 - \left(\frac{p_{out}}{p_{in}}\right)^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}}}\right]}$$

where:

- $S_r$  is the orifice or valve area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \left[ \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 B_{lam}^{\frac{2}{\gamma}}}\right] \left( p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}} \right)}$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_R \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left(\frac{\gamma+1}{2}\right)^{\frac{2}{\gamma-1}} - \left(\frac{S_R}{S}\right)^2}}$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area parameterization, see [4].

### Mass Balance

The block assumes the volume and mass of fluid inside the valve is very small and ignores these values. As a result, no amount of fluid can accumulate in the valve. By the principle of conservation of mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

### Assumptions and Limitations

- The **Sonic conductance** setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the **Orifice area** parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Conserving

**A** — Valve entrance

gas

Gas conserving port associated with the opening through which the flow must enter the valve during normal operation when the pilot mechanism is disabled. This port can serve as an exit only when the pilot port is pressurized to a sufficient degree.

**B** — Valve entrance

gas

Gas conserving port associated with the opening through which the flow must exit the valve during normal operation when the pilot mechanism is disabled.

**X** — Pilot port

gas

Gas conserving port associated with the opening by which to actuate, by the application of a sufficient pressure, the pilot mechanism that opens the valve for reverse flow.

## Parameters

**Pilot configuration** — Method for handling negative pilot pressure forces

Rigidly connected pilot spool and poppet (default) | Disconnected pilot spool and poppet

Method the block uses when the pilot pressure is negative:

- **Rigidly connected pilot spool and poppet** — The pilot spool transmits both positive and negative pilot pressure forces, so the block uses  $p_{pilot}$  as is.
- **Disconnected pilot spool and poppet** — The pilot spool only transmits positive pilot pressure forces, so the block limits  $p_{pilot}$  to positive values only. The block replaces negative values with zero.

**Pilot pressure specification** — Choice of pressure measurement to use as valve control signal

Pressure difference of port X relative to port A (default) | Gauge pressure at port X

Choice of pressure measurement to use as valve control signal. The block uses this setting to determine when the valve should begin to open. In the default setting, **Pressure difference of port X relative to port A**, the opening pressure of the valve is expressed as a pressure drop from the pilot port, **X**, to the inlet, **A**. In the alternative setting, **Gauge pressure at port X**, it is expressed as a gauge inlet pressure measured against the environment pressure.

**Cracking pressure differential** — Effective control pressure at which the valve first opens  
0.01 MPa (default) | positive scalar

Effective pressure differential at which the valve begins to open. This differential is the sum of the pressure drop from inlet to outlet with the product of the pilot pressure and the pilot ratio. The pilot pressure used depends on the setting of the **Pilot pressure specification** parameter.

**Maximum opening pressure differential** — Effective control pressure at which the valve is fully open  
0.02 MPa (default) | positive scalar

Effective pressure differential at which the valve is fully open. This differential is the sum of the pressure drop from inlet to outlet with the product of the pilot pressure and the pilot ratio. The pilot pressure used depends on the setting of the **Pilot pressure specification** parameter.

**Pilot ratio** — Ratio of pilot port area to inlet port area  
1 (default) | positive scalar

Ratio of the pilot port area to the inlet port area.

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice  
Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization.
- **Orifice area** — The size of the flow restriction determines the block parametrization.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component  
3.6 (default) | positive scalar

Maximum value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Kv flow coefficient.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12 l/(bar\*s) (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference density** — ISO 8778 reference density

1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`.

**Maximum orifice area** — Flow area corresponding to maximally open component

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Leakage flow fraction** — Ratio of flow rates

1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes

0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports

0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

**Introduced in R2018b**

## R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.
- **Pilot configuration**

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.
- The **Pressure control specification** parameter has been renamed to **Pilot pressure specification**. The options for this parameter have been renamed to **Pressure difference of port X relative to port A** and **Gauge pressure at port X**.

## Pilot Valve Actuator (IL)

Single-acting or double-acting actuator controlled by a pilot pressure in an isothermal liquid network

### Libraries:

Simscape / Fluids / Valve Actuators & Forces

### Description

The Pilot Valve Actuator (IL) block models a single-acting or double-acting actuator controlled by a pilot pressure for control of a connected valve or orifice in an isothermal liquid network.

For the single-acting actuator, when the control pressure,  $P_X - P_{atm}$ , exceeds the **Spring preload force at port X**, the piston begins to actuate in the direction assigned by the **Mechanical orientation** parameter.

For the double-acting actuator, the control pressure  $P_{control}$  is the difference between  $P_X - P_{atm}$  and  $P_Y - P_{atm}$ . The piston actuates in the direction of the larger applied pressure differential, opposing the spring force at the opposite port. When the piston motion reverses, this spring does not extend and does not exert a counterbalancing force on the piston position.

The pistons at port **X** and port **Y** are attached to a single spool. Both springs restore the spool to its neutral position when  $F_{spool}$  falls below the opposing spring preload force. For single-acting actuators, the neutral position is at port **X**. For double-acting actuators, the neutral position is at the center of the actuator.

### Single-Acting Actuator

The force on the piston is created by the pressure differential between port **X** and atmospheric pressure:

$$F_{spool} = (p_X - p_{atm})A_X,$$

where  $A_X$  is the **Piston area at port X**. When  $F_{spool}$  is greater than the **Spring preload force at port X**, the piston begins to move.

Schematic of a Single-Acting Actuator

### Piston Displacement

The instantaneous piston displacement is calculated as:

$$\dot{x}_{dyn} = \frac{x_{steady} - x_{dyn}}{\tau},$$

where the steady piston position,  $x_{steady}$ , is the piston position at the current pressure differential, proportional to the spring force at maximum piston stroke:

$$x_{steady} = F_{x_{stroke}}\varepsilon = \frac{F_{spool} - F_{pre}}{F_{max} - F_{pre}}x_{stroke}\varepsilon,$$

where:

- $F_{pre}$  is the **Spring preload force at port X**.
- $F_{max}$  is the maximum spring force acting against piston displacement,  $F_{max} = Kx_{stroke} + F_{pre}$ , and where  $K$  is the **Spring stiffness at port X**.
- $x_{stroke}$  is the **Piston stroke from port X**.
- $\varepsilon$  is the **Mechanical orientation**, which indicates piston movement in a positive direction (extension) or negative direction (retraction).

If the force on the piston is less than the **Spring preload force at X**, the piston remains at the neutral position or moves to the neutral position. If the force on the piston meets or exceeds the maximum spring force, the piston remains at the stroke until the applied pressure changes.

### Double-Acting Actuator

The difference between the forces at ports **X** and **Y** dictates the piston motion:

$$F_{spool} = (p_X - p_{atm})A_X - (p_Y - p_{atm})A_Y.$$

The pressure applied at port **X** shifts the spool away from the chamber at **X** and opposes the spring at port **Y**. Similarly, the pressure applied at port **Y** shifts the spool away from the chamber at **Y** and opposes the spring at port **X**. When the spool reverses direction, the formerly extended spring compresses, exerting a force on the spool. The formerly compressed spring, the spring at the port in the direction of motion, does not extend and does not influence the spool position.

## Schematic of a Double-Acting Actuator

### Piston Displacement

The piston displacement is calculated as:

$$\dot{x}_{dyn} = \frac{x_{steady} - x_{dyn}}{\tau},$$

where the steady piston position,  $x_{steady}$ , is the piston position at the current pressure differential, proportional to the spring force at maximum piston stroke:

$$x_{steady} = (F_Y x_{stroke, Y} - F_X x_{stroke, X}) \varepsilon = \left( \frac{F_{spool} - F_{pre, Y}}{F_{max, Y} - F_{pre, Y}} x_{stroke, Y} - \frac{(-F_{spool} - F_{pre, X})}{F_{max, X} - F_{pre, X}} x_{stroke, X} \right) \varepsilon,$$

where:

- $F_{pre, X}$  and  $F_{pre, Y}$  are the **Spring preload force at port X** and **Spring preload force at port Y**, respectively.
- $F_{max, X}$  and  $F_{max, Y}$  are the maximum spring forces acting against piston displacement at ports **X** and **Y**, respectively, where:

$$F_{max} = K x_{stroke} + F_{pre},$$

$K$  is the spring stiffness per port.

- $x_{stroke}$  is the piston stroke per port.
- $\varepsilon$  is the **Mechanical orientation**, which assigns the signal for piston movement as positive (extension) or negative (retraction).

If the force on the piston is less than the respective port spring preload force, the piston remains or returns to the neutral position. If the force on the piston meets or exceeds the maximum spring force for the respective port, the piston remains at the piston stroke until the applied pressure changes.

## Numerically-Smoothed Force

When the actuator is close to full extension or full retraction, you can maintain numerical robustness in your simulation by adjusting the block **Smoothing factor**. With a nonzero smoothing factor, a smoothing function is applied to all calculated forces, but primarily influences the simulation at the extremes of the piston motion.

When **Actuator configuration** is set to **Single-acting**, the normalized force on the piston is calculated as:

$$\widehat{F}_X = \frac{F_{spool} - F_{Pre}}{F_{max} - F_{Pre}}.$$

When **Actuator configuration** is set to **Double-acting**, the normalized force on the piston at **X** is calculated as:

$$\widehat{F}_X = \frac{-F_{spool} - F_{Pre,X}}{F_{max,X} - F_{Pre,X}}.$$

and the normalized force at **Y** is calculated as:

$$\widehat{F}_Y = \frac{F_{spool} - F_{Pre,Y}}{F_{max,Y} - F_{Pre,Y}}.$$

When the **Smoothing factor** is nonzero, the block smoothes each normalized force between 0 and 1.

For more information, see “Numerical Smoothing”.

## Ports

### Conserving

**X** — Pressure port  $P_X$   
isothermal liquid

Pressure at port **X**. There is no mass flow through the port.

**Y** — Pressure port  $P_Y$   
isothermal liquid

Pressure at port **Y**. There is no mass flow through the port.

### Dependencies

To enable this port, set **Actuator type** to **Double-acting**.

### Output

**S** — Piston displacement, m  
physical signal

Piston displacement, specified as a physical signal. The displacement sign corresponds to the direction specified in the **Mechanical orientation** parameter.

## Parameters

**Actuator configuration** — Type of actuator modeled  
Single-acting (default) | Double-acting

Type of actuator modeled.

**Piston area at port X** — Cross-sectional area of piston rod at port X  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the piston rod at port **X**.

**Piston area at port Y** — Cross-sectional area of piston rod at port Y  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the piston rod at port **Y**.

### Dependencies

To enable this parameter, set **Actuator type** to Double-acting.

**Spring preload force** — Force in the neutral position  
20 N (default) | scalar

Force acting against the piston in the neutral position.

### Dependencies

To enable this parameter, set **Actuator type** to Single-acting.

**Spring preload force at port X** — Force at port X in the neutral position  
20 N (default) | scalar

Force at port **X** in the neutral position.

### Dependencies

To enable this parameter, set **Actuator type** to Double-acting.

**Spring preload force at port Y** — Force at port Y in the neutral position  
20 N (default) | scalar

Force at port **Y** in the neutral position.

### Dependencies

To enable this parameter, set **Actuator type** to Double-acting.

**Spring stiffness** — Stiffness coefficient  
 $15e3 \text{ N/m}$  (default) | positive scalar

Spring stiffness factor. The maximum spring force is determined from the stiffness,  $K$ , and the **Spring preload force**:  $F_{\max} = Kx_{\text{stroke}} + F_{\text{pre}}$

### Dependencies

To enable this parameter, set **Actuator type** to Single-acting.

**Spring stiffness at port X** — Stiffness coefficient at port X  
15e3 N/m (default) | positive scalar

Port **X** spring stiffness. The maximum spring force is determined from the stiffness,  $K$ , and the **Spring preload force at port X**:  $F_{\max} = Kx_{\text{stroke}} + F_{\text{pre}}$

**Dependencies**

To enable this parameter, set **Actuator type** to Double-acting.

**Spring stiffness at port Y** — Stiffness coefficient at port Y  
15e3 N/m (default) | positive scalar

Port **Y** spring stiffness. The maximum spring force is determined from the stiffness,  $K$ , and the **Spring preload force at port Y**:  $F_{\max} = Kx_{\text{stroke}} + F_{\text{pre}}$

**Dependencies**

To enable this parameter, set **Actuator type** to Double-acting.

**Piston stroke** — Maximum piston travel distance  
5e-3 m (default) | positive scalar

Maximum piston travel distance.

**Dependencies**

To enable this parameter, set **Actuator type** to Single-acting.

**Piston stroke from port X** — Maximum piston travel distance at port X  
5e-3 m (default) | positive scalar

Maximum piston travel distance at port **X**.

**Dependencies**

To enable this parameter, set **Actuator type** to Double-acting.

**Piston stroke from port Y** — Maximum piston travel distance at port Y  
5e-3 m (default) | positive scalar

Maximum piston travel distance at port **Y**.

**Dependencies**

To enable this parameter, set **Actuator type** to Double-acting.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Actuator dynamics** — Whether to account for transients during actuation  
Off (default) | On

Whether to account for transient effects in the spool position due to actuation. Setting **Actuator dynamics** to On approximates actuator motion by introducing a first-order lag in the spool position. The **Actuator time constant** also impacts the modeled dynamics.

**Actuator time constant** — Piston displacement time constant

0.1 s (default) | positive scalar

Constant that captures the time required for the piston to reach steady-state when moving from one position to another. This parameter impacts the modeled actuator dynamics.

#### Dependencies

To enable this parameter, set **Actuator dynamics** to On.

**Mechanical orientation** — Piston displacement direction

Pilot pressure at port X causes positive piston displacement (default) | Pilot pressure at port X causes negative piston displacement

Sets the piston displacement direction based on the configuration at port **X**. If **Actuator configuration** is set to Double-acting, the displacement force at port **Y** acts in the opposite direction of the force at port **X**. Pilot pressure at port X causes positive piston displacement corresponds to positive displacement when the pressure at **X** pushes the piston towards port **Y**. Pilot pressure at port X causes negative piston displacement corresponds to negative displacement when the pressure at **X** pushes the piston towards port **Y**.

## Pipe Bend

(To be removed) Hydraulic resistance in pipe bend

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Library

Local Hydraulic Resistances

### Description

The Pipe Bend block represents a pipe bend as a local hydraulic resistance. The pressure loss in the bend is assumed to consist of

- Loss in the straight pipe
- Loss due to curvature

The loss in a straight pipe is simulated with the Hydraulic Resistive Tube block. The loss due to curvature is simulated with the Local Resistance block, and the pressure loss coefficient is determined in accordance with the Crane Co. recommendations (see [1] on page 1-1378, p. A-29). The flow regime is checked in the underlying Local Resistance block by comparing the Reynolds number to the specified critical Reynolds number value.

The pressure loss due to curvature for turbulent flow regime is determined according to the following formula:

$$p = K \frac{\rho}{2A^2} q |q|$$

where

$q$	Flow rate
$p$	Pressure loss
$K$	Pressure loss coefficient
$A$	Bend cross-sectional area
$\rho$	Fluid density

For laminar flow regime, the formula for pressure loss computation is modified, as described in the reference documentation for the Local Resistance block.

The pressure loss coefficient is determined according to recommendation provided in [1] on page 1-1378:

$$K = K_d \cdot K_r \cdot K_\alpha$$

where

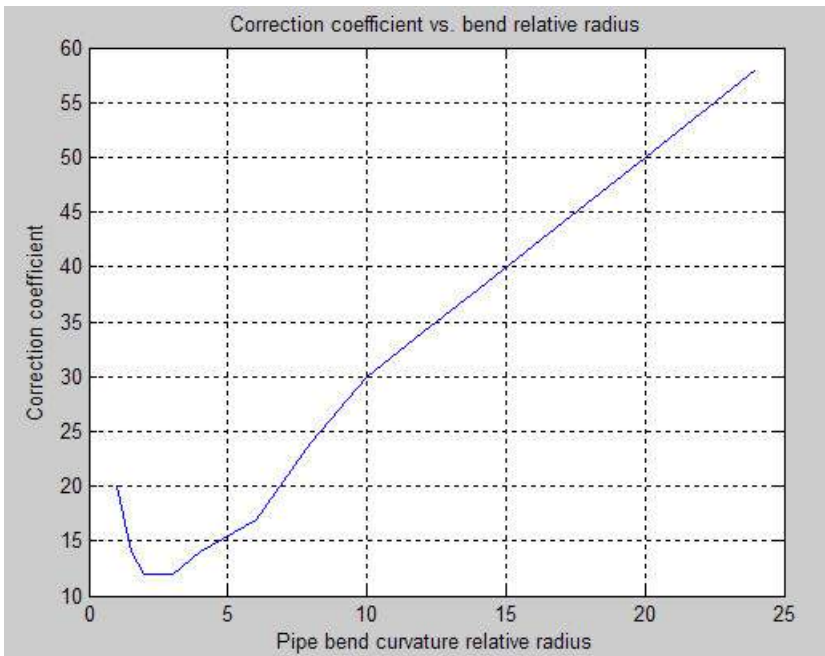

$K_d$	Base friction factor coefficient
$K_r$	Correction coefficient accounting for the bend curvature
$K_\alpha$	Correction coefficient accounting for the bend angle

The base friction factor coefficient is determined according to the following table.

**Note** Friction factors for pipes with diameters greater than 525 mm are determined by extrapolation.

The correction coefficient accounting for the bend curvature is determined according to the next table.

The bend curvature relative radius is calculated as

$$r = \text{bend radius} / \text{pipe diameter}$$

**Note** For pipes with the bend curvature relative radius value outside the range of  $1 > r > 24$ , correction coefficients are determined by extrapolation.

Correction for non-90° bends is performed with the empirical formula (see [2] on page 1-1378, Fig. 4.6):

$$K_{\alpha} = \alpha(0.0142 - 3.703 \cdot 10^{-5} \alpha)$$

where

$\alpha$	Bend angle in degrees ( $0 \leq \alpha \leq 180$ )
----------	--

Connections A and B are conserving hydraulic ports associated with the block inlet and outlet, respectively.

The block positive direction is from port A to port B. This means that the flow rate is positive if fluid flows from A to B, and the pressure differential is determined as  $p = p_A - p_B$ .

---

**Warning** The formulas used in the Pipe Bend block are very approximate, especially in the laminar and transient flow regions. For more accurate results, use a combination of the Local Resistance block with a table-specified  $K=f(Re)$  relationship and the Hydraulic Resistive Tube block.

---

## Basic Assumptions and Limitations

- Fluid inertia and wall compliance are not taken into account.
- The bend is assumed to be made of a clean commercial steel pipe.

## Parameters

### Pipe diameter

The internal diameter of the pipe. The default value is 0.01 m.

### Bend radius

The radius of the bend. The default value is 0.04 m.

### Bend angle

The angle of the bend. The value must be in the range between 0 and 180 degrees. The default value is 90 deg.

### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer's catalogs. The default value is 1.5e-5 m, which corresponds to drawn tubing.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 350.

### Fluid compressibility

Dynamic compressibility setting. Select **On** to make the fluid density dependent on pressure and temperature. Select **Off** to treat the fluid density as a constant. Dynamic compressibility impacts the transient response of the fluid at small time scales and can slow down simulation.

### Initial liquid pressure (gauge)

Gauge pressure in the pipe bend at time zero. The default value is 0 Pa.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the bend inlet.

B

Hydraulic conserving port associated with the bend outlet.

## Pipe Bend (G)

Pipe bend segment in a gas network

### Libraries:

Simscape / Fluids / Gas / Pipes & Fittings

## Description

The Pipe Bend (G) block represents a curved pipe in a gas network. You can define the pipe characteristics to calculate losses due to friction and pipe curvature and optionally model fluid compressibility.

### Pipe Curvature Loss Coefficient

The coefficient for pressure losses due to geometry changes comprises an angle correction factor,  $C_{angle}$ , and a bend coefficient,  $C_{bend}$ :

$$K_{loss} = C_{angle}C_{bend}.$$

The block calculates  $C_{angle}$  as:

$$C_{angle} = 0.0148\theta - 3.9716 \cdot 10^{-5}\theta^2,$$

where  $\theta$  is the value of the **Bend angle** parameter, in degrees.

The block calculates  $C_{bend}$  from the tabulated ratio of the bend radius,  $r$ , to the pipe diameter,  $d$ , for 90° bends from Crane [1]:

$r/d$	1	1.5	2	3	4	6	8	10	12	14	16	20
$K$	$20 f_T$	$14 f_T$	$12 f_T$	$12 f_T$	$14 f_T$	$17 f_T$	$24 f_T$	$30 f_T$	$34 f_T$	$38 f_T$	$42 f_T$	$50 f_T$

The block interpolates the friction factor,  $f_T$ , for clean commercial steel from tabular data based on the pipe diameter [1]. This table contains the pipe friction data for clean commercial steel pipe with flow in the zone of complete turbulence.

Nominal size	1/2"	3/4"	1"	1 1/4"	1 1/2"	2"	2 1/2, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction factor, $f_T$	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

The correction factor is valid for a ratio of bend radius to diameter between 1 and 24. Beyond this range, the block employs nearest-neighbor extrapolation.

### Losses Due to Friction in Laminar Flows

The pressure loss formulations are the same for the flow at ports **A** and **B**.

When the flow in the pipe is fully laminar, or below  $Re = 2000$ , the pressure loss over the bend is

$$\Delta p_{loss} = \frac{\mu \lambda}{2 \rho_I d^2 A} \frac{L}{2} \dot{m}_{port}$$

where:

- $\mu$  is the relative humidity.
- $\lambda$  is the Darcy friction factor constant, which is 64 for laminar flow.
- $\rho_I$  is the internal fluid density.
- $d$  is the pipe diameter.
- $L$  is the bend length segment, which is the product of the **Bend radius** and the **Bend angle** parameters:  $L_{bend} = r_{bend} \theta$ .
- $A$  is the pipe cross-sectional area,  $\frac{\pi}{4} d^2$ .
- $\dot{m}_{port}$  is the mass flow rate at the respective port.

### Losses due to Friction in Turbulent Flows

When the flow is fully turbulent, or greater than  $Re = 4000$ , the pressure loss in the pipe is:

$$\Delta p_{loss} = \left( \frac{f_D L}{2d} + \frac{K_{loss}}{2} \right) \frac{\dot{m}_{port} |\dot{m}_{port}|}{2 \rho_I A^2}$$

where  $f_D$  is the Darcy friction factor. The block approximates this value by using the empirical Haaland equation and the **Internal surface absolute roughness** parameter. The block takes the differential over each half of the pipe segment, between port **A** to an internal node, and between the internal node and port **B**.

### Pressure Differential

The block calculates the pressure loss over the bend based on the internal fluid volume pressure,  $p_I$ :

$$p_A - p_I = \Delta p_{loss, A}$$

$$p_B - p_I = \Delta p_{loss, B}$$

## Mass Balance

Mass conservation relates the mass flow rates to the dynamics of the pressure and temperature of the internal node representing the gas volume

$$\frac{\partial M}{\partial p} \frac{dp_I}{dt} + \frac{\partial M}{\partial T} \frac{dT_I}{dt} = \dot{m}_A + \dot{m}_B,$$

where:

- $\frac{\partial M}{\partial p}$  is the partial derivative of the mass of the gas volume with respect to pressure at constant temperature and volume.
- $\frac{\partial M}{\partial T}$  is the partial derivative of the mass of the gas volume with respect to temperature at constant pressure and volume.
- $p_I$  is the pressure of the gas volume.
- $T_I$  is the temperature of the gas volume.
- $t$  is time.
- $\dot{m}_A$  and  $\dot{m}_B$  are the mass flow rates at ports **A** and **B**, respectively. The flow rate at a port is positive when gas flows into the block through that port.

## Energy Balance

Energy conservation relates the energy and heat flow rates to the dynamics of the pressure and temperature of the internal node that represents the gas volume

$$\frac{\partial U}{\partial p} \frac{dp_I}{dt} + \frac{\partial U}{\partial T} \frac{dT_I}{dt} = \Phi_A + \Phi_B,$$

where:

- $\frac{\partial U}{\partial p}$  is the partial derivative of the internal energy of the gas volume with respect to pressure at constant temperature and volume.
- $\frac{\partial U}{\partial T}$  is the partial derivative of the internal energy of the gas volume with respect to temperature at constant pressure and volume.
- $\Phi_A$  and  $\Phi_B$  are the energy flow rates at ports **A** and **B**, respectively.

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
gas

Gas conserving port associated with the liquid entry or exit port

**B** — Liquid port  
gas

Gas conserving port associated with the liquid entry or exit port

## Parameters

**Pipe diameter** — Pipe diameter  
0.01 m (default) | positive scalar

Diameter of the pipe.

**Bend radius** — Bend circle radius  
0.04 m (default) | positive scalar

Radius of the circle formed by the pipe bend.

**Bend angle** — Bend angle  
90 deg (default) | positive scalar

Swept degree of the pipe bend.

**Internal surface absolute roughness** — Pipe wall roughness  
15e-6 m (default) | positive scalar

Pipe wall absolute roughness. The block uses this parameter to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

## Version History

## Pipe Bend (IL)

Pipe bend segment in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

## Description

The Pipe Bend (IL) block models a curved pipe in an isothermal liquid network. You can define the pipe characteristics to calculate losses due to friction and pipe curvature and optionally model fluid compressibility.

### Pipe Curvature Loss Coefficient

The coefficient for pressure losses due to geometry changes comprises an angle correction factor,  $C_{angle}$ , and a bend coefficient,  $C_{bend}$ :

$$K_{loss} = C_{angle} C_{bend}.$$

The block calculates  $C_{angle}$  as:

$$C_{angle} = 0.0148\theta - 3.9716 \cdot 10^{-5}\theta^2,$$

where  $\theta$  is the value of the **Bend angle** parameter, in degrees.

The block calculates  $C_{bend}$  from the tabulated ratio of the bend radius,  $r$ , to the pipe diameter,  $d$ , for 90° bends from Crane [1]:

$r/d$	1	1.5	2	3	4	6	8	10	12	14	16	20
$K$	$20 f_T$	$14 f_T$	$12 f_T$	$12 f_T$	$14 f_T$	$17 f_T$	$24 f_T$	$30 f_T$	$34 f_T$	$38 f_T$	$42 f_T$	$50 f_T$

The block interpolates the friction factor,  $f_T$ , for clean commercial steel from tabular data based on the pipe diameter [1]. This table contains the pipe friction data for clean commercial steel pipe with flow in the zone of complete turbulence.

Nominal size	1/2"	3/4"	1"	1 1/4"	1 1/2"	2"	2 1/2, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction factor, $f_T$	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

The correction factor is valid for a ratio of bend radius to diameter between 1 and 24. Beyond this range, the block employs nearest-neighbor extrapolation.

**Losses Due to Friction in Laminar Flows**

The pressure loss formulations are the same for the flow at ports **A** and **B**.

When the flow in the pipe is fully laminar, or below  $Re = 2000$ , the pressure loss over the bend is:

$$\Delta p_{loss} = \frac{\mu \lambda}{2 \rho_I d^2 A} \frac{L}{2} \dot{m}_{port}$$

where:

- $\mu$  is the fluid dynamic viscosity.
- $\lambda$  is the Darcy friction factor constant, which is 64 for laminar flow.
- $\rho_I$  is the internal fluid density.
- $d$  is the pipe diameter.
- $L$  is the bend length segment, the product of the **Bend radius** and the **Bend angle**:  
 $L_{bend} = r_{bend} \theta$ .
- $A$  is the pipe cross-sectional area,  $\frac{\pi}{4} d^2$ .
- $\dot{m}_{port}$  is the mass flow rate at the respective port.

**Losses due to Friction in Turbulent Flows**

When the flow is fully turbulent, or greater than  $Re = 4000$ , the pressure loss in the pipe is:

$$\Delta p_{loss} = \left( \frac{f_D L}{2d} + \frac{K_{loss}}{2} \right) \frac{\dot{m}_{port} |\dot{m}_{port}|}{2 \rho_I A^2}$$

where  $f_D$  is the Darcy friction factor. This is approximated by the empirical Haaland equation and is based on the **Internal surface absolute roughness**. The differential is taken over half of the pipe segment, between port **A** to an internal node, and between the internal node and port **B**.

**Pressure Differential for Incompressible Fluids**

When the flow is incompressible, the pressure loss over the bend is:

$$p_A - p_B = \Delta p_{loss, A} - \Delta p_{loss, B}$$

**Pressure Differential for Compressible Fluids**

When the flow is compressible, the pressure loss over the bend is calculated based on the internal fluid volume pressure,  $p_I$ :

$$p_A - p_I = \Delta p_{loss, A}$$

$$p_B - p_I = \Delta p_{loss, B}$$

### Mass Conservation

For an incompressible fluid, the mass flow into the pipe equals the mass flow out of the pipe:

$$\dot{m}_A + \dot{m}_B = 0.$$

When the fluid is compressible, the difference between the mass flow into and out of the pipe depends on the fluid density change due to compressibility:

$$\dot{m}_A + \dot{m}_B = \dot{p}_I \frac{d\rho_I}{dp_I} V,$$

where  $V$  is the product of the pipe cross-sectional area and bend length,  $AL$ .

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port.

## Parameters

**Pipe diameter** — Pipe diameter  
0.01 m (default) | positive scalar

Diameter of the pipe.

**Bend radius** — Bend circle radius  
0.04 m (default) | positive scalar

Radius of the circle formed by the pipe bend.

**Bend angle** — Bend angle  
90 deg (default) | positive scalar

Swept degree of the pipe bend.

**Internal surface absolute roughness** — Pipe wall roughness  
15e-6 m (default) | positive scalar

Pipe wall absolute roughness. This parameter is used to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

**Fluid dynamic compressibility** — Whether to model fluid compressibility  
off (default) | on

Whether to model any change in fluid mass due to fluid compressibility. When you select **Fluid compressibility**, mass changes due to varying fluid density in the segment are calculated. The fluid volume in the pipe remains constant. In the Isothermal Liquid library, all blocks calculate density as a function of pressure.

**Initial liquid pressure** — Pipe pressure at beginning of simulation  
0.101325 MPa (default) | positive scalar

Pipe pressure at the beginning of the simulation.

#### **Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

# Pipe Bend (MA)

Pipe bend segment in a moist air network

## Libraries:

Simscape / Fluids / Moist Air / Pipes & Fittings

## Description

The Pipe Bend (MA) block represents a curved pipe in a moist air network. You can define the pipe characteristics to calculate losses due to friction and pipe curvature and optionally model fluid compressibility.

### Pipe Curvature Loss Coefficient

The coefficient for pressure losses due to geometry changes comprises an angle correction factor,  $C_{angle}$ , and a bend coefficient,  $C_{bend}$ :

$$K_{loss} = C_{angle}C_{bend}.$$

The block calculates  $C_{angle}$  as:

$$C_{angle} = 0.0148\theta - 3.9716 \cdot 10^{-5}\theta^2,$$

where  $\theta$  is the value of the **Bend angle** parameter, in degrees.

The block calculates  $C_{bend}$  from the tabulated ratio of the bend radius,  $r$ , to the pipe diameter,  $d$ , for 90° bends from Crane [1]:

$r/d$	1	1.5	2	3	4	6	8	10	12	14	16	20
$K$	$20 f_T$	$14 f_T$	$12 f_T$	$12 f_T$	$14 f_T$	$17 f_T$	$24 f_T$	$30 f_T$	$34 f_T$	$38 f_T$	$42 f_T$	$50 f_T$

The block interpolates the friction factor,  $f_T$ , for clean commercial steel from tabular data based on the pipe diameter [1]. This table contains the pipe friction data for clean commercial steel pipe with flow in the zone of complete turbulence.

Nominal size	1/2"	3/4"	1"	1 1/4"	1 1/2"	2"	2 1/2, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction factor, $f_T$	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

The correction factor is valid for a ratio of bend radius to diameter between 1 and 24. Beyond this range, the block employs nearest-neighbor extrapolation.

### Losses Due to Friction in Laminar Flows

The pressure loss formulations are the same for the flow at ports **A** and **B**.

When the flow in the pipe is fully laminar, or below  $Re = 2000$ , the pressure loss over the bend is

$$\Delta p_{loss} = \frac{\mu \lambda}{2 \rho_I d^2 A} \frac{L}{2} \dot{m}_{port}$$

where:

- $\mu$  is the relative humidity.
- $\lambda$  is the Darcy friction factor constant, which is 64 for laminar flow.
- $\rho_I$  is the internal fluid density.
- $d$  is the pipe diameter.
- $L$  is the bend length segment, which is the product of the **Bend radius** and the **Bend angle** parameters:  $L_{bend} = r_{bend} \theta$ .
- $A$  is the pipe cross-sectional area,  $\frac{\pi}{4} d^2$ .
- $\dot{m}_{port}$  is the mass flow rate at the respective port.

### Losses due to Friction in Turbulent Flows

When the flow is fully turbulent, or greater than  $Re = 4000$ , the pressure loss in the pipe is:

$$\Delta p_{loss} = \left( \frac{f_D L}{2d} + \frac{K_{loss}}{2} \right) \frac{\dot{m}_{port} |\dot{m}_{port}|}{2 \rho_I A^2}$$

where  $f_D$  is the Darcy friction factor. The block approximates this value by using the empirical Haaland equation and the **Internal surface absolute roughness** parameter. The block takes the differential over each half of the pipe segment, between port **A** to an internal node, and between the internal node and port **B**.

### Pressure Differential

The block calculates the pressure loss over the bend based on the internal fluid volume pressure,  $p_I$  :

$$p_A - p_I = \Delta p_{loss, A}$$

$$p_B - p_I = \Delta p_{loss, B}$$

## Mass and Energy Balance

The net flow rates into the moist air volume inside the pipe bend are

$$\begin{aligned}\dot{m}_{total} &= \dot{m}_A + \dot{m}_B \\ \Phi_{total} &= \Phi_A + \Phi_B \\ \dot{m}_{w, total} &= \dot{m}_{wA} + \dot{m}_{wB} \\ \dot{m}_{g, total} &= \dot{m}_{gA} + \dot{m}_{gB}\end{aligned}$$

where:

- $\dot{m}$  is the mass flow rate. The subscript  $w$  denotes water vapor and the subscript  $g$  denotes trace gas.
- $\Phi$  is the energy flow rate.

Mixture mass conservation relates the mixture mass flow rate to the dynamics of the pressure, temperature, and mass fractions of the internal moist air volume

$$\left( \frac{1}{\rho_I} \frac{d\rho_I}{dt} - \frac{1}{T_I} \frac{dT_I}{dt} \right) \rho_I V + \frac{R_a - R_w}{R_I} (\dot{m}_{w, total} - x_w \dot{m}_{total}) + \frac{R_a - R_g}{R_I} (\dot{m}_{g, total} - x_g \dot{m}_{total}) = \dot{m}_{total},$$

where:

- $p_I$  is the pressure of the internal volume.
- $\rho_I$  is the density of the internal volume.
- $T_I$  is the temperature of the internal volume.
- $V$  is the volume.
- $R_a, R_g, R_w,$  and  $R_I$  are the specific gas constants of the air, gas, water vapor, and internal volume, respectively.
- $x_w$  is the specific humidity.
- $x_g$  is the trace gas mass fraction.

Energy conservation relates the energy flow rate to the dynamics of the pressure, temperature, and mass fractions of the internal moist air volume

$$\begin{aligned}\rho_I (c_{pI} - R_I) V \frac{dT_I}{dt} + (u_{wI} - u_{aI}) (\dot{m}_{w, total} - x_w \dot{m}_{total}) + (u_{gI} - u_{aI}) (\dot{m}_{g, total} - x_g \dot{m}_{total}) + u_I \dot{m}_{total} \\ = \Phi_{total},\end{aligned}$$

where:

- $u_I$  is the internal energy.
- $c_{pI}$  is the specific heat.

Water vapor mass conservation relates the water vapor mass flow rate to the dynamics of the moisture level in the internal moist air volume

$$\frac{dx_{wI}}{dt} \rho_I V + x_{wI} \dot{m}_{total} = \dot{m}_{w, total}.$$

Similarly, trace gas mass conservation relates the trace gas mass flow rate to the dynamics of the trace gas level in the internal moist air volume

$$\frac{dx_{gI}}{dt}\rho_I V + x_{gI}\dot{m}_{total} = \dot{m}_{g,total}$$

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
moist air

Moist air conserving port associated with the liquid entry or exit port.

**B** — Liquid port  
moist air

Moist air conserving port associated with the liquid entry or exit port.

## Parameters

**Pipe diameter** — Pipe diameter  
0.01 m (default) | positive scalar

Diameter of the pipe.

**Bend radius** — Bend circle radius  
0.04 m (default) | positive scalar

Radius of the circle formed by the pipe bend.

**Bend angle** — Bend angle  
90 deg (default) | positive scalar

Swept degree of the pipe bend.

**Internal surface absolute roughness** — Pipe wall roughness  
15e-6 m (default) | positive scalar

Pipe wall absolute roughness. The block uses this parameter to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

## Pipe Bend (TL)

Pipe bend segment in a thermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

## Description

The Pipe Bend (TL) block models a curved pipe in a thermal liquid network. You can define the pipe characteristics to calculate losses due to friction and pipe curvature and optionally model fluid compressibility.

### Pipe Curvature Loss Coefficient

The coefficient for pressure losses due to geometry changes comprises an angle correction factor,  $C_{angle}$ , and a bend coefficient,  $C_{bend}$ :

$$K_{loss} = C_{angle} C_{bend}.$$

The block calculates  $C_{angle}$  as:

$$C_{angle} = 0.0148\theta - 3.9716 \cdot 10^{-5}\theta^2,$$

where  $\theta$  is the value of the **Bend angle** parameter, in degrees.

The block calculates  $C_{bend}$  from the tabulated ratio of the bend radius,  $r$ , to the pipe diameter,  $d$ , for 90° bends from Crane [1]:

$r/d$	1	1.5	2	3	4	6	8	10	12	14	16	20
$K$	$20 f_T$	$14 f_T$	$12 f_T$	$12 f_T$	$14 f_T$	$17 f_T$	$24 f_T$	$30 f_T$	$34 f_T$	$38 f_T$	$42 f_T$	$50 f_T$

The block interpolates the friction factor,  $f_T$ , for clean commercial steel from tabular data based on the pipe diameter [1]. This table contains the pipe friction data for clean commercial steel pipe with flow in the zone of complete turbulence.

Nominal size	½"	¾"	1"	1 ¼"	1 ½"	2"	2 ½, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction factor, $f_T$	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

The correction factor is valid for a ratio of bend radius to diameter between 1 and 24. Beyond this range, the block employs nearest-neighbor extrapolation.

### Losses Due to Friction in Laminar Flows

The pressure loss formulations are the same for the flow at ports **A** and **B**.

When the flow in the pipe is fully laminar, or below  $Re = 2000$ , the pressure loss over the bend is:

$$\Delta p_{loss} = \frac{\mu \lambda}{2 \rho_I d^2 A} \frac{L}{2} \dot{m}_{port}$$

where:

- $\mu$  is the fluid dynamic viscosity.
- $\lambda$  is the Darcy friction factor constant, which is 64 for laminar flow.
- $\rho_I$  is the internal fluid density.
- $d$  is the pipe diameter.
- $L$  is the bend length segment, the product of the **Bend radius** and the **Bend angle**:  
 $L_{bend} = r_{bend} \theta$ .
- $A$  is the pipe cross-sectional area,  $\frac{\pi}{4} d^2$ .
- $\dot{m}_{port}$  is the mass flow rate at the respective port.

### Losses due to Friction in Turbulent Flows

When the flow is fully turbulent, or greater than  $Re = 4000$ , the pressure loss in the pipe is:

$$\Delta p_{loss} = \left( \frac{f_D L}{2d} + \frac{K_{loss}}{2} \right) \frac{\dot{m}_{port} |\dot{m}_{port}|}{2 \rho_I A^2}$$

where  $f_D$  is the Darcy friction factor. This is approximated by the empirical Haaland equation and is based on the **Internal surface absolute roughness**. The differential is taken over half of the pipe segment, between port **A** to an internal node, and between the internal node and port **B**.

### Pressure Differential for Incompressible Fluids

When the flow is incompressible, the pressure loss over the bend is:

$$p_A - p_B = \Delta p_{loss, A} - \Delta p_{loss, B}$$

### Pressure Differential for Compressible Fluids

When the flow is compressible, the pressure loss over the bend is calculated based on the internal fluid volume pressure,  $p_I$ :

$$p_A - p_I = \Delta p_{loss, A}$$

$$p_B - p_I = \Delta p_{loss, B}$$

### Mass Conservation

For an incompressible fluid, the mass flow into the pipe equals the mass flow out of the pipe:

$$\dot{m}_A + \dot{m}_B = 0.$$

For a flexible pipe with a compressible fluid, the pipe mass conservation equation is: This dependence is captured by the bulk modulus and thermal expansion coefficient of the thermal liquid:

$$\dot{m}_A + \dot{m}_B = \rho_I \dot{V} + \rho_I V \left( \frac{\dot{p}_I}{\beta_I} - \alpha_I \dot{T}_I \right),$$

where:

- $p_I$  is the thermal liquid pressure at the internal node I.
- $\dot{T}_I$  is the rate of change of the thermal liquid temperature at the internal node I.
- $\beta_I$  is the thermal liquid bulk modulus.
- $\alpha$  is the liquid thermal expansion coefficient.

### Energy Conservation

The energy conservation equation for the block is

$$V \frac{d(\rho u)}{dt} = \phi_A + \phi_B,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with one end of the pipe bend.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with one end of the pipe bend.

## Parameters

**Pipe diameter** — Pipe diameter  
0.01 m (default) | positive scalar

Diameter of the pipe.

**Bend radius** — Bend circle radius

0.04 m (default) | positive scalar

Radius of the circle formed by the pipe bend.

**Bend angle** — Bend angle

90 deg (default) | positive scalar

Swept degree of the pipe bend.

**Internal surface absolute roughness** — Pipe wall roughness

15e-6 m (default) | positive scalar

Pipe wall absolute roughness. This parameter is used to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

off (default) | on

Whether to model any change in fluid mass due to fluid compressibility. When you select **Fluid dynamic compressibility**, mass changes due to varying fluid density in the segment are calculated. The fluid volume in the pipe remains constant. In the Isothermal Liquid library, all blocks calculate density as a function of pressure.

**Initial liquid temperature** — Liquid temperature at start of simulation

293.15 K (default)

Liquid temperature at the beginning of the simulation.

**Initial liquid pressure** — Pipe pressure at beginning of simulation

0.101325 MPa (default) | positive scalar

Pipe pressure at the beginning of the simulation.

**Dependencies**

To enable this parameter, set select **Fluid dynamic compressibility**.

## Version History

Introduced in R2022a

## Extended Capabilities

**C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

## Pipe (TL)

Closed conduit that transports fluid between thermal liquid components

### Libraries:

Simscape / Fluids / Thermal Liquid / Pipes & Fittings

## Description

The Pipe (TL) block represents thermal liquid flow through a pipe. The block finds the temperature across the pipe from the differential between ports, pipe elevation, and any additional heat transfer at port **H**.

The pipe can have a constant or varying elevation between ports **A** and **B**. For a constant elevation differential, use the **Elevation gain from port A to port B** parameter. You can specify a variable elevation by setting **Elevation gain specification** to Variable. This exposes physical signal port **EL**.

You can optionally include the effects of fluid dynamic compressibility, inertia, and wall flexibility. When the block includes these phenomena, it calculates the flow properties for each number of pipe segments that you specify.

## Pipe Geometry

Use the **Cross-sectional geometry** parameter to specify the shape of the pipe.

### Circular

The nominal hydraulic diameter,  $D_N$ , and the pipe diameter,  $d_{circle}$ , are both equal to the **Pipe diameter** parameter. The pipe cross-sectional area is  $S_N = \frac{\pi}{4} d_{circle}^2$ .

### Annular

The nominal hydraulic diameter is the difference between the **Pipe outer diameter** and **Pipe inner diameter** parameters  $D_N = d_{outer} - d_{inner}$ . The pipe cross-sectional area is  $S_N = \frac{\pi}{4} (d_{outer}^2 - d_{inner}^2)$ .

### Rectangular

The nominal hydraulic diameter is

$$D_N = \frac{2hw}{h+w},$$

where:

- $h$  is the **Pipe height** parameter.
- $w$  is the **Pipe width** parameter.

The pipe cross-sectional area is  $S_N = wh$ .

### Elliptical

The nominal hydraulic diameter is

$$D_N = 2a_{maj}b_{min} \frac{\left(64 - 16\left(\frac{a_{maj} - b_{min}}{a_{maj} + b_{min}}\right)^2\right)}{(a_{maj} + b_{min})\left(64 - 3\left(\frac{a_{maj} - b_{min}}{a_{maj} + b_{min}}\right)^4\right)},$$

where:

- $a_{maj}$  is the **Pipe major axis** parameter.
- $b_{min}$  is the **Pipe minor axis** parameter.

The pipe cross-sectional area is  $S_N = \frac{\pi}{4}a_{maj}b_{min}$ .

### Isosceles Triangular

The nominal hydraulic diameter is

$$D_N = l_{side} \frac{\sin(\theta)}{1 + \sin\left(\frac{\theta}{2}\right)},$$

where:

- $l_{side}$  is the **Pipe side length** parameter.
- $\theta$  is the **Pipe vertex angle** parameter.

The pipe cross-sectional area is  $S_N = \frac{l_{side}^2}{2}\sin(\theta)$ .

### Custom

When the **Cross-sectional geometry** parameter is Custom, you can specify the pipe cross-sectional area with the **Cross-sectional area** parameter. The nominal hydraulic diameter is the value of the **Hydraulic diameter** parameter.

### Pipe Flexibility

You can model flexible walls for all cross-sectional geometries. When you set **Pipe wall specification** to Flexible, the block assumes uniform expansion along all directions and preserves the defined cross-sectional shape.

The deformation of the pipe diameter is calculated as:

$$\dot{D} = \frac{D_S - D}{\tau},$$

where:

- $D_S$  is the post-deformation, steady-state pipe diameter, and

$$D_S = D_N + K_c(p - p_{atm}),$$

where  $K_c$  is the **Static pressure-diameter compliance**,  $p$  is the tube pressure, and  $p_{atm}$  is the atmospheric pressure. Assuming elastic deformation of a thin-walled, open-ended pipe, you can calculate  $K_c$  as:

$$K_c = \frac{D^2}{2tE},$$

where  $t$  is the pipe wall thickness and  $E$  is Young's modulus.

- $D_N$  is the nominal pipe diameter, or the diameter previous to deformation

$$D_N = \sqrt{\frac{4S_N}{\pi}},$$

where  $S_N$  is the pipe cross-sectional area.

- $D$  is the nominal hydraulic diameter.
- $\tau$  is the **Viscoelastic pressure time constant** parameter.

### Heat Transfer at the Pipe Wall

You can include heat transfer to and from the pipe walls in multiple ways. There are two analytical models: the Gnielinski correlation, which models the Nusselt number as a function of the Reynolds and Prandtl numbers with predefined coefficients, and the Dittus-Boelter correlation -  $Nusselt = a \cdot Re^b \cdot Pr^c$ , which models the Nusselt number as a function of the Reynolds and Prandtl numbers with user-defined coefficients.

The Nominal temperature differential vs. nominal mass flow rate, Tabulated data - Colburn factor vs. Reynolds number, and Tabulated data - Nusselt number vs. Reynolds number & Prandtl number are lookup table parameterizations based on user-supplied data.

Heat transfer between the fluid and pipe wall occurs through convection,  $Q_{Conv}$  and conduction,  $Q_{Cond}$ , where the net heat flow rate,  $Q_H$  is  $Q_H = Q_{Conv} + Q_{Cond}$ .

Heat transfer due to conduction is:

$$Q_{Cond} = \frac{k_I S_H}{D} (T_H - T_I),$$

where:

- $D$  is the nominal hydraulic diameter,  $D_N$ , if the pipe walls are rigid, and is the pipe steady-state diameter,  $D_S$ , if the pipe walls are flexible.
- $k_I$  is the thermal conductivity of the thermal liquid, defined internally for each pipe segment.
- $S_H$  is the surface area of the pipe wall.

- $T_H$  is the pipe wall temperature.
- $T_I$  is the fluid temperature, taken at the pipe internal node.

Heat transfer due to convection is:

$$Q_{\text{Conv}} = c_{p,\text{Avg}} |\dot{m}_{\text{Avg}}| (T_H - T_{\text{In}}) \left[ 1 - \exp\left(-\frac{hS_H}{c_{p,\text{Avg}} |\dot{m}_{\text{Avg}}|}\right) \right],$$

where:

- $c_{p,\text{Avg}}$  is the average fluid specific heat which the block calculates using a lookup table.
- $\dot{m}_{\text{Avg}}$  is the average mass flow rate through the pipe.
- $T_{\text{In}}$  is the fluid inlet port temperature.
- $h$  is the pipe heat transfer coefficient.

The heat transfer coefficient  $h$  is:

$$h = \frac{\text{Nu} k_{\text{Avg}}}{D},$$

except when parameterizing by Nominal temperature differential vs. nominal mass flow rate, where  $k_{\text{Avg}}$  is the average thermal conductivity of the thermal liquid over the entire pipe and  $Nu$  is the average Nusselt number in the pipe.

### Analytical Parameterizations

When **Heat transfer parameterization** is set to Gnielinski correlation and the flow is turbulent, the average Nusselt number is calculated as:

$$\text{Nu} = \frac{f/8(\text{Re}-1000)\text{Pr}}{1 + 12.7(f/8)^{1/2}(\text{Pr}^{2/3} - 1)},$$

where:

- $f$  is the average Darcy friction factor, according to the Haaland correlation:

$$f = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}} + \left( \frac{\epsilon_R}{3.7D} \right)^{1.11} \right] \right\}^{-2},$$

where  $\epsilon_R$  is the pipe **Internal surface absolute roughness**.

- $Re$  is the Reynolds number.
- $Pr$  is the Prandtl number.

When the flow is laminar, the data from [1] determines how the Nusselt number depends on the **Cross-sectional geometry** parameter:

- When **Cross-sectional geometry** is Circular, the Nusselt number is 3.66.
- When **Cross-sectional geometry** is Annular, the block calculates the Nusselt number from tabulated data using a lookup table with linear interpolation and nearest extrapolation.

$\frac{D_{inner}}{D_{outer}}$	Nussult number
1/20	17.46
1/10	11.56
1/4	7.37
1/2	5.74
1	4.86

The block adjusts the calculated Nussult number with a correction factor  $F = 0.86 \left( \frac{D_{outer}}{D_{inner}} \right)^{0.16}$ .

- When **Cross-sectional geometry** is Rectangular, the block calculates the Nussult number from tabulated data using a lookup table with linear interpolation and nearest extrapolation.

$\frac{\min(h, w)}{\max(h, w)}$	Nussult number
0	7.54
1/8	5.60
1/6	5.14
1/4	4.44
1/3	3.96
1/2	3.39
1	2.98

- When **Cross-sectional geometry** is Elliptical, the block calculates the Nussult number from tabulated data using a lookup table with linear interpolation and nearest extrapolation.

$\frac{b_{min}}{a_{maj}}$	Nussult number
1/16	3.65
1/8	3.72
1/4	3.79
1/2	3.74
1	3.66

- When **Cross-sectional geometry** is Isosceles triangular, the block calculates the Nussult number from tabulated data using a lookup table with linear interpolation and nearest extrapolation.

$\theta$	Nussult number
$10\pi/180$	1.61
$30\pi/180$	2.26
$60\pi/180$	2.47
$90\pi/180$	2.34

$\theta$	Nusselt number
$120\pi/180$	2.00

- When **Cross-sectional geometry** is Custom, the Nusselt number is the value of the **Nusselt number for laminar flow heat transfer** parameter.

When **Heat transfer parameterization** is set to Dittus-Boelter correlation and the flow is turbulent, the average Nusselt number is calculated as:

$$\text{Nu} = a\text{Re}^b\text{Pr}^c,$$

where:

- $a$  is the value of the **Coefficient a** parameter.
- $b$  is the value of the **Exponent b** parameter.
- $c$  is the value of the **Exponent c** parameter.

The block default Dittus-Boelter correlation is:

$$\text{Nu} = 0.023\text{Re}^{0.8}\text{Pr}^{0.4}.$$

When the flow is laminar, the Nusselt number depends on the **Cross-sectional geometry** parameter.

#### Parameterization By Tabulated Data

When **Heat transfer parameterization** is set to Tabulated data - Colburn factor vs. Reynolds number, the average Nusselt number is calculated as:

$$\text{Nu} = J_M(\text{Re})\text{RePr}^{1/3}.$$

where  $J_M$  is the Colburn-Chilton factor.

When **Heat transfer parameterization** is set to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number, the Nusselt number is interpolated from the three-dimensional array of average Nusselt number as a function of both average Reynolds number and average Prandtl number:

$$\text{Nu} = \text{Nu}(\text{Re}, \text{Pr}).$$

When **Heat transfer parameterization** is set to Nominal temperature difference vs. nominal mass flow rate and the flow is turbulent, the heat transfer coefficient is calculated as:

$$h = \frac{h_N D_N^{1.8} \dot{m}_{\text{Avg}}^{0.8}}{\dot{m}_N^{0.8} D^{1.8}},$$

where:

- $\dot{m}_N$  is the **Nominal mass flow rate**.
- $\dot{m}_{\text{Avg}}$  is the average mass flow rate:

$$\dot{m}_{\text{Avg}} = \frac{\dot{m}_A + \dot{m}_B}{2}.$$

- $h_N$  is the nominal heat transfer coefficient, which is calculated as:

$$h_N = \frac{\dot{m}_N c_{p,N}}{S_{H,N}} \ln \left( \frac{T_{H,N} - T_{In,N}}{T_{H,N} - T_{Out,N}} \right),$$

where:

- $S_{H,N}$  is the nominal wall surface area.
- $T_{H,N}$  is the **Nominal wall temperature**.
- $T_{In,N}$  is the **Nominal inflow temperature**.
- $T_{Out,N}$  is the **Nominal outflow temperature**.

This relationship is based on the assumption that the Nusselt number is proportional to the Reynolds number:

$$\frac{hD}{k} \propto \left( \frac{\dot{m}D}{S\mu} \right)^{0.8}.$$

If the pipe walls are rigid, the expression for the heat transfer coefficient becomes:

$$h = \frac{h_N}{\dot{m}_N^{0.8}} \dot{m}_{Avg}^{0.8}.$$

## Pressure Loss Due to Friction

### Haaland Correlation

The analytical Haaland correlation models losses due to wall friction either by *aggregate equivalent length*, which accounts for resistances due to nonuniformities as an added straight-pipe length that results in equivalent losses, or by *local loss coefficient*, which directly applies a loss coefficient for pipe nonuniformities.

When the **Local resistances specification** parameter is set to **Aggregate equivalent length** and the flow in the pipe is lower than the **Laminar flow upper Reynolds number limit**, the pressure loss over all pipe segments is:

$$\Delta p_{f,A} = \frac{\nu \lambda}{2D^2 S} \frac{L + L_{add}}{2} \dot{m}_A,$$

$$\Delta p_{f,B} = \frac{\nu \lambda}{2D^2 S} \frac{L + L_{add}}{2} \dot{m}_B,$$

where:

- $\nu$  is the fluid kinematic viscosity.
- $\lambda$  is the **Laminar friction constant for Darcy friction factor**, which you can define when **Cross-sectional geometry** is set to Custom and is otherwise equal to 64.
- $D$  is the pipe hydraulic diameter.
- $L_{add}$  is the **Aggregate equivalent length of local resistances**.
- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

When the Reynolds number is greater than the **Turbulent flow lower Reynolds number limit**, the pressure loss in the pipe is:

$$\Delta p_{f,A} = \frac{f}{2\rho_f S^2} \frac{L + L_{add}}{2} \dot{m}_A |\dot{m}_A|,$$

$$\Delta p_{f,B} = \frac{f}{2\rho_f S^2} \frac{L + L_{add}}{2} \dot{m}_B |\dot{m}_B|,$$

where:

- $f$  is the Darcy friction factor. This is approximated by the empirical Haaland equation and is based on the **Surface roughness specification**,  $\varepsilon$ , and pipe hydraulic diameter:

$$f = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}} + \left( \frac{\varepsilon}{3.7 D_h} \right)^{1.11} \right] \right\}^{-2},$$

Pipe roughness for brass, lead, copper, plastic, steel, wrought iron, and galvanized steel or iron are provided as ASHRAE standard values. You can also supply your own **Internal surface absolute roughness** with the Custom setting.

- $\rho_f$  is the internal fluid density.

When the **Local resistances specification** parameter is set to Local loss coefficient and the flow in the pipe is lower than the **Laminar flow upper Reynolds number limit**, the pressure loss over all pipe segments is:

$$\Delta p_{f,A} = \frac{v\lambda}{2D^2 S} \frac{L}{2} \dot{m}_A.$$

$$\Delta p_{f,B} = \frac{v\lambda}{2D^2 S} \frac{L}{2} \dot{m}_B.$$

When the Reynolds number is greater than the **Turbulent flow lower Reynolds number limit**, the pressure loss in the pipe is:

$$\Delta p_{f,A} = \left( \frac{fL}{D} + C_{loss,total} \right) \frac{1}{2\rho_f S^2} \dot{m}_A |\dot{m}_A|,$$

$$\Delta p_{f,B} = \left( \frac{fL}{D} + C_{loss,total} \right) \frac{1}{2\rho_f S^2} \dot{m}_B |\dot{m}_B|,$$

where  $C_{loss,total}$  is the loss coefficient, which can be defined in the **Total local loss coefficient** parameter as either a single coefficient or the sum of all loss coefficients along the pipe.

#### Nominal Pressure Drop vs. Nominal Mass Flow Rate

The Nominal Pressure Drop vs. Nominal Mass Flow Rate parameterization characterizes losses with a loss coefficient for rigid or flexible walls. When the fluid is incompressible, the pressure loss over the entire pipe due to wall friction is:

$$\Delta p_{f,A} = K_p \dot{m}_A \sqrt{\dot{m}_A^2 + \dot{m}_{th}^2},$$

where  $K_p$  is:

$$K_p = \frac{\Delta p_N}{\dot{m}_N^2},$$

where:

- $\Delta p_N$  is the **Nominal pressure drop**, which can be defined either as a scalar or a vector.
- $\dot{m}_N$  is the **Nominal mass flow rate**, which can be defined either as a scalar or a vector.

When the **Nominal pressure drop** and **Nominal mass flow rate** parameters are supplied as vectors, the scalar value  $K_p$  is determined from a least-squares fit of the vector elements.

#### Tabulated Data - Darcy Friction Factor vs. Reynolds Number

Pressure losses due to viscous friction can also be determined from user-provided tabulated data of the **Darcy friction factor vector** and the **Reynolds number vector for turbulent Darcy friction factor** parameters. Linear interpolation is employed between data points.

#### Momentum Balance

The pressure differential over the pipe is due to the pressure at the pipe ports, friction at the pipe walls, and hydrostatic changes due to any change in elevation:

$$p_A - p_B = \Delta p_f + \rho_I g \Delta z,$$

where:

- $p_A$  is the pressure at a port **A**.
- $p_B$  is the pressure at a port **B**.
- $\Delta p_f$  is the pressure differential due to viscous friction,  $\Delta p_{f,A} + \Delta p_{f,B}$ .
- $g$  is **Gravitational acceleration**.
- $\Delta z$  the elevation differential between port **A** and port **B**, or  $z_A - z_B$ .
- $\rho_I$  is the internal fluid density, which is measured at each pipe segment. If fluid dynamic compressibility is not modeled, this is:

$$\rho_I = \frac{p_A + p_B}{2}.$$

When fluid inertia is not modeled, the momentum balance between port **A** and internal node I is:

$$p_A - p_I = \Delta p_{f,A} + \rho_I g \frac{\Delta z}{2}.$$

When fluid inertia is not modeled, the momentum balance between port **B** and internal node I is:

$$p_B - p_I = \Delta p_{f,B} - \rho_I g \frac{\Delta z}{2}.$$

When fluid inertia is modeled, the momentum balance between port **A** and internal node I is:

$$p_A - p_I = \Delta p_{f,A} + \rho_I g \frac{\Delta z}{2} + \frac{\dot{m}_A L}{S} \frac{1}{2},$$

where:

- $\ddot{m}_A$  is the fluid inertia at port **A**.
- $L$  is the **Pipe length**.
- $S$  is the **Nominal cross-sectional area**.

When fluid inertia is modeled, the momentum balance between port **B** and internal node I is:

$$p_B - p_I = \Delta p_{f,B} - \rho_l g \frac{\Delta z}{2} + \frac{\ddot{m}_B L}{S} \frac{1}{2},$$

where

$\ddot{m}_B$  is the fluid inertia at port **B**.

### Pipe Discretization

You can divide the pipe into multiple segments. If a pipe has more than one segment, the mass flow, energy flow, and momentum balance equations are calculated for each segment. Having multiple pipe segments can allow you to track changes to variables such as fluid density when fluid dynamic compressibility is modeled.

If you would like to capture specific phenomena in your application, such as water hammer, choose a number of segments that provides sufficient resolution of the transient. The following formula, from the Nyquist sampling theorem, provides a rule of thumb for pipe discretization into a minimum of  $N$  segments:

$$N = 2L \frac{f}{c},$$

where:

- $L$  is the **Pipe length**.
- $f$  is the transient frequency.
- $c$  is the speed of sound.

For some applications, you may need to connect Pipe (TL) blocks in series. For example, you may require multiple pipe segments to define a thermal boundary condition along the length of a pipe. In this case, model the pipe segments by using a Pipe (TL) block for each segment and use the thermal ports to set the thermal boundary condition.

### Mass Balance

For a rigid pipe with an incompressible fluid, the pipe mass conservation equation is:

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

For a flexible pipe with an incompressible fluid, the pipe mass conservation equation is:

$$\dot{m}_A + \dot{m}_B = \rho_I \dot{V},$$

where:

- $\rho_I$  is the thermal liquid density at internal node I. Each pipe segment has an internal node.
- $\dot{V}$  is the rate of deformation of the pipe volume.

For a flexible pipe with a compressible fluid, the pipe mass conservation equation is: This dependence is captured by the bulk modulus and thermal expansion coefficient of the thermal liquid:

$$\dot{m}_A + \dot{m}_B = \rho_I \dot{V} + \rho_I V \left( \frac{\dot{p}_I}{\beta_I} + \alpha_I \dot{T}_I \right),$$

where:

- $p_I$  is the thermal liquid pressure at the internal node I.
- $\dot{T}_I$  is the rate of change of the thermal liquid temperature at the internal node I.
- $\beta_I$  is the thermal liquid bulk modulus.
- $\alpha$  is the liquid thermal expansion coefficient.

### Energy Balance

The energy accumulation rate in the pipe at internal node I is defined as:

$$\dot{E} = \phi_A + \phi_B + \phi_H - \dot{m}_{Avg} g \Delta z,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.
- $\phi_H$  is the energy flow rate at port **H**.

If the fluid is incompressible, the expression for energy accumulation rate is:

$$\dot{E} = \frac{d}{dt} \rho_I u_I V,$$

where:

- $u_I$  is the fluid specific internal energy at node I.
- $V$  is the pipe volume.

If the fluid is compressible, the expression for energy accumulation rate is:

$$\dot{E} = \rho_1 V \left( \frac{\partial u}{\partial p} \frac{dp}{dt} + \frac{\partial u}{\partial T} \frac{dT}{dt} \right)_1.$$

If the fluid is compressible and the pipe walls are flexible, the expression for energy accumulation rate is:

$$\dot{E} = \rho_1 V \left( \frac{\partial u}{\partial p} \frac{dp}{dt} + \frac{\partial u}{\partial T} \frac{dT}{dt} \right)_1 + (\rho_1 u_1 + p_1) \left( \frac{dV}{dt} \right)_1.$$

## Ports

### Input

**EL** — Port elevation difference  
physical signal

Variable elevation differential between port **A** and **B**, specified as a physical signal.

### Conserving

**A** — Pipe opening  
thermal liquid

Liquid entry or exit port to the pipe.

**B** — Pipe opening  
thermal liquid

Liquid entry or exit port to the pipe.

**H** — Pipe wall  
thermal

Pipe wall temperature.

## Parameters

### Configuration

**Fluid dynamic compressibility** — Whether to model fluid dynamic compressibility  
on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure.

**Fluid inertia** — Whether to model fluid acceleration  
off (default) | on

Whether to account for acceleration in the mass flow rate due to the mass of the fluid.

### Dependencies

To enable this parameter, select **Fluid dynamic compressibility**.

**Number of segments** — Pipe discretization

1 (default) | positive unitless scalar

Number of pipe divisions. Each division represents an individual segment over which pressure is calculated, depending on the pipe inlet pressure, fluid compressibility, and wall flexibility, if applicable. The fluid volume in each segment remains fixed.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

**Pipe total length** — Total pipe length

5 m (default) | positive scalar in units of length

Total pipe length across all pipe segments.

**Cross-sectional geometry** — Pipe geometry

Circular (default) | Annular | Rectangular | Elliptical | Isosceles triangular | Custom

Cross-sectional pipe geometry. A nominal hydraulic diameter and nominal cross-sectional area is calculated based on the cross-sectional geometry.

**Pipe diameter** — Pipe diameter

0.1 m (default) | positive scalar

Diameter for circular cross-sectional pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Circular.

**Pipe inner diameter** — Pipe inner diameter

0.05 m (default) | positive scalar

Inner diameter for annular pipe flow, or flow between two concentric pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Annular.

**Pipe outer diameter** — Pipe outer diameter

0.1 m (default) | positive scalar

Outer diameter for annular pipe flow, or flow between two concentric pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Annular.

**Pipe width** — Rectangular pipe width

0.1 m (default) | positive scalar

Width of rectangular pipe.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Rectangular.

**Pipe height** — Rectangular pipe height

0.1 m (default) | positive scalar

Height of rectangular pipe.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Rectangular.

**Pipe major axis** — Elliptical pipe major axis

0.1 m (default) | positive scalar

Major axis for elliptical pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Elliptical.

**Pipe minor axis** — Elliptical pipe minor axis

0.05 m (default) | positive scalar

Minor axis for elliptical pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Elliptical.

**Pipe side length** — Triangular pipe side length

0.1 m (default) | positive scalar

Length of the two equal sides of isosceles-triangular pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Isosceles triangular.

**Pipe vertex angle** — Triangular pipe vertex angle

30 deg (default) | positive scalar

Vertex angle for triangular pipes. The value must be less than 180 degrees.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Isosceles triangular.

**Cross-sectional area** — Cross-sectional pipe area without deformation

0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the pipe without deformations.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Custom.

**Pipe wall specification** — Specifies wall flexibility

Rigid (default) | Flexible

Specifies pipe walls as rigid or flexible. Flexible walls are modeled by a uniform radial expansion that maintains the original pipe cross-sectional shape.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

**Hydraulic diameter** — Effective diameter of noncircular pipes

0.1128 m (default) | positive scalar in units of length

Effective diameter used in heat transfer, momentum balance, and pipe flexibility equations. For noncircular pipes, the hydraulic diameter is the effective diameter of the fluid in the pipe. For circular pipes, the hydraulic diameter and pipe diameter are the same.

**Dependencies**

To enable this parameter, either:

- Clear the **Fluid dynamic compressibility** check box and set **Cross-sectional geometry** to Custom.
- Select **Fluid dynamic compressibility**, set the **Pipe wall specification** parameter to Rigid and set **Cross-sectional geometry** to Custom.

**Elevation gain specification** — Set pipe elevation property

Constant (default) | Variable

Set the pipe elevation as either Constant or Variable. Selecting Variable exposes the physical signal port **EL**.

**Elevation gain from port A to port B** — Change in elevation from port A to port B

0 m (default) | positive scalar in units of length

Elevation differential for constant-elevation pipes. The elevation gain must be less than or equal to the **Pipe total length**.

**Dependencies**

To enable this parameter, set **Elevation gain specification** to Constant.

**Gravitational acceleration** — Acceleration due to gravity at mean pipe elevation

9.81 m/s<sup>2</sup> (default) | positive scalar in units of length/time<sup>2</sup>

Constant of the gravitational acceleration ( $g$ ) at the mean elevation of the pipe.

**Static pressure-diameter compliance** — Measure of pipe deformation

1.2e-6 m/MPa (default) | positive scalar in units of length/pressure

Coefficient of pipe radial deformation due to changes in pressure. This is a material property of the pipe.

**Dependencies**

To enable this parameter, set **Pipe wall specification** to Flexible.

**Viscoelastic process time constant** — Pipe deformation time constant

0.01 s (default) | positive scalar in units of time

Time required for the wall to reach steady-state after pipe deformation. This parameter impacts the dynamic change in pipe volume.

**Dependencies**

To enable this parameter, set **Pipe wall specification** to Flexible.

**Viscous Friction****Viscous friction parameterization** — Friction model

Haaland correlation (default) | Nominal pressure drop vs. nominal mass flow rate |  
Tabulated data - Darcy friction factor vs. Reynolds number

Parameterization of pressure losses due to wall friction. Both analytical and tabular formulations are available.

**Local resistances specification** — Method for quantifying pressure losses in the Haaland correlation

Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses due to pipe nonuniformities.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation.

**Total local loss coefficient** — Defines loss coefficient over the pipe

0.1 (default) | positive scalar

Loss coefficient associated with each pipe nonuniformity. You can input a single loss coefficient or the sum of all loss coefficients along the pipe.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation and **Local resistance specifications** to Local loss coefficient.

**Aggregate equivalent length of local resistances** — Minor pressure loss in the pipe expressed as a length

1 m (default) | positive scalar

Length of pipe that would produce the equivalent hydraulic losses as would a pipe with bends, area changes, or other nonuniformities. The effective length of the pipe is the sum of the **Pipe length** and the **Aggregate equivalent length of local resistances**.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation and **Local resistances specification** to Aggregate equivalent length.

**Surface roughness specification** — Pipe material for roughness specification

Commercially smooth brass, lead, copper, or plastic pipe: 1.52 um (default) |  
Steel and wrought iron : 46 um | Galvanized iron or steel : 152 um | Cast iron :  
259 um | Custom

Absolute surface roughness based on pipe material. The provided values are ASHRAE standard roughness values. You can also input your own value by setting **Surface roughness specification** to Custom.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation.

**Internal surface absolute roughness** — Pipe wall absolute roughness

1.5e-5 m (default) | positive scalar in units of length

Pipe wall absolute roughness. This parameter is used to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation and **Surface roughness specification** Custom.

**Laminar friction constant for Darcy friction factor** — Friction constant for laminar flows

64 (default) | positive scalar

Friction constant for laminar flows. The Darcy friction factor captures the contribution of wall friction in pressure loss calculations. If **Cross-sectional geometry** is not set to Custom, this parameter is internally set to 64.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Custom.

**Laminar flow upper Reynolds number limit** — Reynolds number below which the flow is laminar

2e+3 (default) | positive scalar

Reynolds number below which the flow is laminar. Above this threshold, the flow transitions to turbulent, reaching the turbulent regime at the **Turbulent flow lower Reynolds number limit** setting.

**Turbulent flow lower Reynolds number limit** — Reynolds number above which the flow is turbulent

4e+3 (default) | positive scalar

Reynolds number above which the flow is turbulent. Below this threshold, the flow gradually transitions to laminar, reaching the laminar regime at the **Laminar flow upper Reynolds number limit** setting.

**Nominal mass flow rate** — Pipe mass flow rate

[0.1 1] kg/s (default) | scalar or vector of numbers in units of mass/time

Pipe nominal mass flow rate used to calculate the pressure loss coefficient, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal pressure drop** parameter. When this parameter is supplied as a vector, the scalar value  $K_p$  is determined as a least-squares fit of the vector elements.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Nominal pressure drop vs. nominal mass flow rate.

**Nominal pressure drop** — Pressure drop over the pipe

[0.001 0.01] MPa (default) | scalar or vector of numbers in units of pressure

Pipe nominal pressure drop used to calculate the pressure loss coefficient, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal mass flow rate** parameter. When this parameter is supplied as a vector, the scalar value  $K_p$  is determined as a least-squares fit of the vector elements.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Nominal pressure drop vs. nominal mass flow rate.

**Mass flow rate threshold for flow reversal** — Threshold below which numerical smoothing is applied

1e-6 kg/s (default) | positive scalar in units of mass/time

Mass flow rate threshold for reversed flow. A transition region is defined around 0 kg/s between the positive and negative values of the mass flow rate threshold. Within this transition region, numerical smoothing is applied to the flow response. The threshold value must be greater than 0.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Nominal pressure drop vs. nominal mass flow rate.

**Reynolds number vector for turbulent Darcy friction factor** — Reynolds numbers at which to tabulate the Darcy friction factor

[ 400 1000 1.5e+3 3e+3 4e+3 6e+3 1e+4 2e+4 4e+4 6e+4 1e+5 1e+8 ] (default) | vector of positive numbers

Vector of Reynolds numbers for the tabular parameterization of the Darcy friction factor. The vector elements form an independent axis with the **Darcy friction factor vector** parameter. The vector elements must be listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Darcy friction factor vector** — Darcy friction factors at the tabulated Reynolds numbers

[ 0.264 0.112 0.07099999999999999 0.0417 0.0387 0.0268 0.025 0.0232 0.0226 0.022 0.0214 0.0214 ] (default) | vector of positive numbers

Vector of Darcy friction factors for the tabular parameterization of the Darcy friction factor. The vector elements must correspond one-to-one with the elements in the **Reynolds number vector for turbulent Darcy friction factor** parameter, and must be unique and greater than or equal to 0.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Heat Transfer**

**Heat transfer parameterization** — Method by which to capture the convective heat transfer with the pipe wall

Gnielinski correlation | Nominal temperature differential vs. nominal mass flow rate (default) | Dittus-Boelter correlation | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Method of calculating the heat transfer coefficient between the fluid and the pipe wall. Analytical and tabulated data parameterizations are available.

**Nusselt number for laminar flow heat transfer** — Nusselt number to use in the heat transfer calculations for laminar flows

3.66 (default)

Ratio of convective to conductive heat transfer in the laminar flow regime. The fluid Nusselt number influences the heat transfer rate.

#### Dependencies

To enable this parameter, set **Cross-sectional geometry** to Custom and set **Heat transfer parameterization** to either:

- Gnielinski correlation.
- Nominal temperature differential vs. nominal mass flow rate.
- Dittus-Boelter correlation.

**Nominal mass flow rate** — Pipe mass flow rate

[0.1 1] kg/s (default) | scalar or vector of numbers in units of mass/time

Pipe nominal mass flow rate used to calculate the heat transfer coefficient, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal inflow temperature** parameter. When this parameter is supplied as a vector, the scalar value  $h_p$  is determined as a least-squares fit of the vector elements.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Nominal temperature differential vs. nominal mass flow rate.

**Nominal inflow temperature** — Pipe inlet temperature

[293.15 293.15] K (default) | scalar or vector of numbers in units of temperature

Nominal fluid inlet temperature used to calculate the heat transfer coefficient, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal mass flow rate** parameter. When this parameter is supplied as a vector, the scalar value  $h$  is determined as a least-squares fit of the vector elements.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Nominal temperature differential vs. nominal mass flow rate.

**Nominal outflow temperature** — Pipe outlet temperature

[300 300] K (default) | scalar or vector of numbers in units of temperature

Nominal fluid outlet temperature used to calculate the heat transfer coefficient, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal mass flow rate** parameter. When this parameter is supplied as a vector, the scalar value  $h$  is determined as a least-squares fit of the vector elements.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Nominal temperature differential vs. nominal mass flow rate.

**Nominal inflow pressure** — Pipe inlet pressure

[0.101325 0.101325] MPa (default) | scalar or vector of numbers in units of pressure

Nominal fluid inlet pressure used to calculate the heat transfer coefficient, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal mass flow rate** parameter. When this parameter is supplied as a vector, the scalar value  $h$  is determined as a least-squares fit of the vector elements.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Nominal temperature differential vs. nominal mass flow rate.

**Nominal wall temperature** — Pipe wall temperature

[303.15 303.15] K (default) | scalar or vector of numbers in units of temperature

Pipe wall temperature used to calculate the heat transfer coefficient, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal mass flow rate** parameter. When this parameter is supplied as a vector, the scalar value  $h$  is determined as a least-squares fit of the vector elements.

**Dependencies**

To enable this temperature, set **Heat transfer parameterization** to Nominal temperature differential vs. nominal mass flow rate.

**Coefficient a** — Empirical constant  $a$  of the Dittus-Boelter correlation

0.023 (default) | positive scalar

Empirical constant  $a$  to use in the Dittus-Boelter correlation. The correlation relates the Nusselt number in turbulent flows to the heat transfer coefficient.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Dittus-Boelter correlation.

**Exponent b** — Empirical constant  $b$  of the Dittus-Boelter correlation

0.8 (default) | positive scalar

Empirical constant  $b$  to use in the Dittus-Boelter correlation. The correlation relates the Nusselt number in turbulent flows to the heat transfer coefficient.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Dittus-Boelter correlation.

**Exponent c** — Empirical constant  $c$  of the Dittus-Boelter correlation

0.4 (default) | positive scalar

Empirical constant  $c$  to use in the Dittus-Boelter correlation. The correlation relates the Nusselt number in turbulent flows to the heat transfer coefficient. The default value reflects heat transfer to the fluid.

**Dependencies**

To enable this parameter, set **Heat transfer parameterization** to Dittus-Boelter correlation.

**Reynolds number vector for Colburn factor** — Reynolds numbers at which to tabulate the Colburn factor

[100 150 1000] (default) | vector of positive numbers

Vector of Reynolds numbers for the tabular parameterization of the Colburn factor. The vector elements form an independent axis with the **Colburn factor vector** parameter. The vector elements must be listed in ascending order and must be greater than 0. This parameter must have the same number of elements as the **Colburn factor vector**. For reversed flows, or flows from **B** to **A**, the same data is applied in the opposite direction.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factors at which the tabulated Reynolds numbers

[0.019 0.013 0.002] (default) | vector of positive numbers

Vector of Colburn factors for the tabular parameterization of the Colburn factor. The vector elements form an independent axis with the **Reynolds number vector for Colburn factor** parameter. This parameter must have the same number of elements as the **Reynolds number vector for Colburn factor**.

#### Dependencies

This parameter is active when the **Heat transfer parameterization** block parameter is set to Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at which to tabulate the Nusselt number

[100 150 100] (default) | vector of positive numbers

Vector of Reynolds numbers for the tabular parameterization of Nusselt number. This vector forms an independent axis with the **Prandtl number vector for Nusselt number** parameter for the 2-D dependent **Nusselt number table**. The vector elements must be listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl numbers at which to tabulate the Nusselt number

[1 10] (default) | vector of positive numbers

Vector of Prandtl numbers for the tabular parameterization of Nusselt number. This vector forms an independent axis with the **Reynolds number vector for Nusselt number** parameter for the 2-D dependent **Nusselt number table**. The vector elements must be listed in ascending order.

#### Dependencies

To enable this parameter, set **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table** — Nusselt numbers at the tabulated Reynolds and Prandtl numbers

[ 3.72 4.21; 3.75 4.44; 4.21 7.15 ] (default) | matrix of positive numbers

$M$ -by- $N$  matrix of Nusselt numbers at the specified Reynolds and Prandtl numbers. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Reynolds number vector for Nusselt number** parameter.
- $N$  is the number of vector elements in the **Prandtl number vector for Nusselt number** parameter.

### Dependencies

To enable this parameter, **Heat transfer parameterization** to Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

### Initial Conditions

**Initial liquid temperature** — Absolute temperature in the pipe at the start of simulation  
293.15 K (default) | positive scalar or vector in units of temperature

Liquid temperature at the start of the simulation, specified as a scalar or vector. A vector  $n$  elements long defines the liquid temperature for each of  $n$  pipe segments. If the vector is two elements long, the temperature along the pipe is linearly distributed between the two element values. If the vector is three or more elements long, the initial temperature in the  $n$ th segment is set by the  $n$ th element of the vector.

**Initial liquid pressure** — Absolute pressure in the pipe at the start of simulation  
0.101325 MPa (default) | positive scalar or vector in units of pressure

Absolute liquid pressure at the start of the simulation, specified as a scalar or vector. A vector  $n$  elements long defines the liquid pressure for each of  $n$  pipe segments. If the vector is two elements long, the pressure along the pipe is linearly distributed between the two element values. If the vector is three or more elements long, the initial pressure in the  $n$ th segment is set by the  $n$ th element of the vector.

## Version History

Introduced in R2016a

### R2023a: Model pipe characteristics

You can now use new parameters for the Pipe (TL) block to control pipe attributes. Use the **Cross-sectional geometry** parameter to specify the cross-sectional pipe shape. Use the **Surface roughness specification** parameter to use the pipe wall material to determine surface roughness.

# Pipe (IL)

Pipe segment in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

## Description

The Pipe (IL) block models flow in a rigid or flexible-walled pipe with losses due to wall friction. The effects of dynamic compressibility, fluid inertia, and pipe elevation can be optionally modeled. You can define multiple pipe segments and set the liquid pressure for each segment. By segmenting the pipe and selecting **Fluid inertia**, you can model events such as water hammer in your system.

## Pipe Characteristics

The pipe block can be divided into segments with the **Number of segments** parameter. When the pipe is composed of a number of segments, the pressure in each segment is calculated based on the inlet pressure and the effect on the segment mass flow rate of the fluid compressibility and wall flexibility, if applicable. The fluid volume in each segment remains fixed. For a two-segment pipe, the pressure evolves linearly with respect to the pressure defined at ports **A** and **B**. For a pipe with three or more segments, you can specify the fluid pressure in each segment in vector or scalar form in the **Initial liquid pressure** parameter. The scalar form will apply a constant value over all segments.

## Flexible Walls

You can model flexible walls for all cross-sectional geometries. When you set **Pipe wall specification** to **Flexible**, the block assumes uniform expansion along all directions and preserves the defined cross-sectional shape. This setting may not result in physical results for noncircular cross-sectional areas undergoing high pressure relative to atmospheric pressure. When you model flexible walls, you can use the **Volumetric expansion specification** parameter to control the method for specifying the volumetric expansion of the pipe cross-sectional area.

When the **Volumetric expansion specification** parameter is **Cross-sectional area vs. pressure**, the change in volume is modeled by

$$\dot{V} = L \left( \frac{\dot{A}}{\tau} \right),$$

where:

- $A = S_N + K_{ps}(p - p_{atm}) - S$ .
- $L$  is the **Pipe length** parameter.
- $S_N$  is the nominal pipe cross-sectional area defined for each shape.
- $S$  is the current pipe cross-sectional area.
- $p$  is the internal pipe pressure.

- $p_{atm}$  is the atmospheric pressure.
- $K_{ps}$  is the **Static gauge pressure to cross-sectional area gain** parameter.

To calculate  $K_{ps}$  assuming uniform elastic deformation of a thin-walled, open-ended cylindrical pipe, use:

$$K_{ps} = \frac{\Delta D}{\Delta p} = \frac{\pi D_N^3}{4tE},$$

where  $t$  is the pipe wall thickness and  $E$  is Young's modulus.

- $\tau$  is the **Volumetric expansion time constant**.

When the **Volumetric expansion specification** parameter is Cross-sectional area vs. pressure - Tabulated, the block uses the same equation for  $\dot{V}$  as the Cross-sectional area vs. pressure setting. The block calculates  $A$  with the table lookup function

$$A = S_N + \text{tablelookup}(p_{ps}, A_{ps}, (p - p_{atm}), \text{interpolation} = \text{linear}, \text{extrapolation} = \text{linear}),$$

where  $p_{ps}$  is the **Static gauge pressure vector** parameter and  $A_{ps}$  is the **Cross sectional area gain vector** parameter.

When the **Volumetric expansion specification** parameter is Hydraulic diameter vs. pressure, the change in volume is modeled by

$$\dot{V} = \frac{\pi}{2}DL \left( \frac{D_{static} - D}{\tau} \right),$$

where:

- $D_{static} = D_N + K_{pd}(p - p_{atm})$ .
- $D_N$  is the nominal hydraulic diameter defined for each shape.
- $D$  is the current pipe hydraulic diameter.
- $K_{pd}$  is the **Static gauge pressure to hydraulic diameter gain** parameter. To calculate  $K_{ps}$  assuming uniform elastic deformation of a thin-walled, open-ended cylindrical pipe, use:

$$K_{pd} = \frac{\Delta D}{\Delta p} = \frac{D_N^2}{2tE}.$$

When the **Volumetric expansion specification** parameter is Based on material properties, the block uses the same equation for  $\dot{V}$  as the Hydraulic diameter vs. pressure setting but calculates  $D_{static}$  depending on the value of the **Material behavior** parameter

$$D_{static} = D_N(1 + \epsilon_{hoop}).$$

This parameterization assumes a cylindrical thin-walled pressure vessel where  $\sigma_{radial} = 0$ .

When the **Material behavior** parameter is Linear elastic,

$$\epsilon_{hoop} = \frac{1}{E}[\sigma_{hoop} - \nu\sigma_{longitudinal}],$$

where:

- $E$  is the value of the **Young's modulus** parameter.
- $\nu$  is the value of the **Poisson's ratio** parameter.
- $\sigma_{hoop} = \frac{pD}{2t}$  where  $t$  is the value of the **Pipe wall thickness** parameter.
- $\sigma_{longitudinal} = \frac{pD}{4t}$ .

When the **Material behavior** parameter is Multilinear elastic, the block calculates the von Mises stress,  $\sigma_v$ , which simplifies to  $\sigma_v = \sqrt{\frac{3}{4} \frac{pD}{2t}}$ , to determine the equivalent strain. The hoop strain is

$$\epsilon_{hoop} = \epsilon_{hoop}^{elastic} + \epsilon_{hoop}^{plastic}$$

$$\epsilon_{hoop}^{elastic} = \frac{1}{E} [\sigma_{hoop} - \nu \sigma_{longitudinal}]$$

$$\epsilon_{hoop_{i,j}}^{plastic} = \frac{3}{2} \left( \frac{1}{E_S} - \frac{1}{E} \right) S_{i,j}$$

where:

- The block calculates the Young's Modulus,  $E$ , from the first elements of the **Stress vector** and **Strain vector** parameters.
- $E_S = \frac{\sigma_{total}}{\epsilon_{total}}$ , where  $\sigma_{total}$  and  $\epsilon_{total}$  are the equivalent total stress and the equivalent total strain, respectively. The block calculates the equivalent total strain from the von Mises stress and the stress-strain curve.
- $S_{i,j} = \sigma_{i,j} - \left[ \frac{\sigma_{hoop} + \sigma_{longitudinal} + \sigma_{radial}}{3} \right] \delta_{i,j}$ , where  $\sigma_{i,j}$  are the elements of the Cauchy stress tensor.

If you do not model flexible walls,  $S_N = S$  and  $D_N = D$ .

#### Circular

The nominal hydraulic diameter and the **Pipe diameter**,  $d_{circle}$ , are the same. The pipe cross sectional area is:  $S_N = \frac{\pi}{4} d_{circle}^2$ .

#### Annular

The nominal hydraulic diameter,  $D_{h,nom}$ , is the difference between the **Pipe outer diameter** and **Pipe inner diameter**,  $d_o - d_i$ . The pipe cross sectional area is  $S_N = \frac{\pi}{4} (d_o^2 - d_i^2)$ .

#### Rectangular

The nominal hydraulic diameter is:

$$D_N = \frac{2hw}{h+w},$$

where:

- $h$  is the **Pipe height**.
- $w$  is the **Pipe width**.

The pipe cross sectional area is  $S_N = wh$ .

### Elliptical

The nominal hydraulic diameter is:

$$D_N = 2a_{maj}b_{min} \frac{\left(64 - 16\left(\frac{a_{maj} - b_{min}}{a_{maj} + b_{min}}\right)^2\right)}{(a_{maj} + b_{min})\left(64 - 3\left(\frac{a_{maj} - b_{min}}{a_{maj} + b_{min}}\right)^4\right)},$$

where:

- $a_{maj}$  is the **Pipe major axis**.
- $b_{min}$  is the **Pipe minor axis**.

The pipe cross sectional area is  $S_N = \frac{\pi}{4}a_{maj}b_{min}$ .

### Isosceles Triangular

The nominal hydraulic diameter is:

$$D_N = l_{side} \frac{\sin(\theta)}{1 + \sin\left(\frac{\theta}{2}\right)}$$

where:

- $l_{side}$  is the **Pipe side length**.
- $\theta$  is the **Pipe vertex angle**.

The pipe cross sectional area is  $S_N = \frac{l_{side}^2}{2}\sin(\theta)$ .

## Pressure Loss Due to Friction

### Haaland Correlation

The analytical Haaland correlation models losses due to wall friction either by *aggregate equivalent length*, which accounts for resistances due to nonuniformities as an added straight-pipe length that results in equivalent losses, or by *local loss coefficient*, which directly applies a loss coefficient for pipe nonuniformities.

When the **Local resistances specification** parameter is set to **Aggregate equivalent length** and the flow in the pipe is lower than the **Laminar flow upper Reynolds number limit**, the pressure loss over all pipe segments is:

$$\Delta p_{f,A} = \frac{v\lambda}{2D^2S} \frac{L + L_{add}}{2} \dot{m}_A,$$

$$\Delta p_{f,B} = \frac{v\lambda}{2D^2S} \frac{L + L_{add}}{2} \dot{m}_B,$$

where:

- $\nu$  is the fluid kinematic viscosity.
- $\lambda$  is the **Laminar friction constant for Darcy friction factor**, which you can define when **Cross-sectional geometry** is set to Custom and is otherwise equal to 64.
- $D$  is the pipe hydraulic diameter.
- $L_{add}$  is the **Aggregate equivalent length of local resistances**.
- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

When the Reynolds number is greater than the **Turbulent flow lower Reynolds number limit**, the pressure loss in the pipe is:

$$\Delta p_{f,A} = \frac{f}{2\rho_I S^2} \frac{L + L_{add}}{2} \dot{m}_A |\dot{m}_A|,$$

$$\Delta p_{f,B} = \frac{f}{2\rho_I S^2} \frac{L + L_{add}}{2} \dot{m}_B |\dot{m}_B|,$$

where:

- $f$  is the Darcy friction factor. This is approximated by the empirical Haaland equation and is based on the **Surface roughness specification**,  $\varepsilon$ , and pipe hydraulic diameter:

$$f = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}} + \left( \frac{\varepsilon}{3.7 D_h} \right)^{1.11} \right] \right\}^{-2},$$

Pipe roughness for brass, lead, copper, plastic, steel, wrought iron, and galvanized steel or iron are provided as ASHRAE standard values. You can also supply your own **Internal surface absolute roughness** with the Custom setting.

- $\rho_I$  is the internal fluid density.

When the **Local resistances specification** parameter is set to Local loss coefficient and the flow in the pipe is lower than the **Laminar flow upper Reynolds number limit**, the pressure loss over all pipe segments is:

$$\Delta p_{f,A} = \frac{\nu \lambda}{2D^2 S} \frac{L}{2} \dot{m}_A.$$

$$\Delta p_{f,B} = \frac{\nu \lambda}{2D^2 S} \frac{L}{2} \dot{m}_B.$$

When the Reynolds number is greater than the **Turbulent flow lower Reynolds number limit**, the pressure loss in the pipe is:

$$\Delta p_{f,A} = \left( \frac{f \frac{L}{2}}{D} + C_{loss, total} \right) \frac{1}{2\rho_I S^2} \dot{m}_A |\dot{m}_A|,$$

$$\Delta p_{f,B} = \left( \frac{f \frac{L}{2}}{D} + C_{loss, total} \right) \frac{1}{2\rho_I S^2} \dot{m}_B |\dot{m}_B|,$$

where  $C_{\text{loss, total}}$  is the loss coefficient, which can be defined in the **Total local loss coefficient** parameter as either a single coefficient or the sum of all loss coefficients along the pipe.

### Nominal Pressure Drop vs. Nominal Mass Flow Rate

The Nominal Pressure Drop vs. Nominal Mass Flow Rate parameterization characterizes losses with a loss coefficient for rigid or flexible walls. When the fluid is incompressible, the pressure loss over the entire pipe due to wall friction is:

$$\Delta p_{f, A} = K_p \dot{m}_A \sqrt{\dot{m}_A^2 + \dot{m}_{th}^2},$$

where  $K_p$  is:

$$K_p = \frac{\Delta p_N}{\dot{m}_N^2},$$

where:

- $\Delta p_N$  is the **Nominal pressure drop**, which can be defined either as a scalar or a vector.
- $\dot{m}_N$  is the **Nominal mass flow rate**, which can be defined either as a scalar or a vector.

When the **Nominal pressure drop** and **Nominal mass flow rate** parameters are supplied as vectors, the scalar value  $K_p$  is determined from a least-squares fit of the vector elements.

### Tabulated Data - Darcy Friction Factor vs. Reynolds Number

Pressure losses due to viscous friction can also be determined from user-provided tabulated data of the **Darcy friction factor vector** and the **Reynolds number vector for turbulent Darcy friction factor** parameters. Linear interpolation is employed between data points.

### Pipe Discretization

You can divide the pipe into multiple segments. If a pipe has more than one segment, the mass flow and momentum balance equations are calculated for each segment.

If you would like to capture specific phenomena in your application, such as water hammer, choose a number of segments that provides sufficient resolution of the transient. The following formula, from the Nyquist sampling theorem, provides a rule of thumb for pipe discretization into a minimum of  $N$  segments:

$$N = 2L \frac{f}{c},$$

where:

- $L$  is the **Pipe length**.
- $f$  is the transient frequency.
- $c$  is the speed of sound.

### Momentum Balance

For an incompressible fluid, the mass flow into the pipe equals the mass flow out of the pipe:

$$\dot{m}_A + \dot{m}_B = 0.$$

When the fluid is compressible and pipe walls are rigid, the difference between the mass flow into and out of the pipe depends on the fluid density change due to compressibility:

$$\dot{m}_A + \dot{m}_B = \dot{\rho}_I \frac{d\rho_I}{d\rho_I} V,$$

When the fluid is compressible and the pipe walls are flexible, the difference between the mass flow into and out of the pipe is based on the change in fluid density due to compressibility, and the amount of fluid accumulated in the newly deformed regions of the pipe:

$$\dot{m}_A + \dot{m}_B = \dot{\rho}_I \frac{d\rho_I}{d\rho_I} V + \rho_I \dot{V}.$$

The changes in momentum between the pipe inlet and outlet comprises the changes in pressure due to pipe wall friction, which is modeled according to the **Viscous friction parameterization** and pipe elevation. For a pipe that does not model fluid inertia, the momentum balance is:

$$p_A - p_I = \Delta p_{f,A} + \rho_I \frac{\Delta z}{2} g,$$

$$p_B - p_I = \Delta p_{f,B} - \rho_I \frac{\Delta z}{2} g,$$

where:

- $p_A$  is the pressure at port **A**.
- $p_I$  is the fluid volume internal pressure.
- $p_B$  is the pressure at port **B**.
- $\Delta p_f$  is the pressure loss due to wall friction, parameterized by the **Viscous friction losses** specification according to the respective port.
- $\Delta z$  is the pipe elevation. In the case of constant-elevation pipes, this is the **Elevation gain from port A to port B** parameter; otherwise, it is received as a physical signal at port **EL**.
- $g$  is the gravitational acceleration. In the case of a fixed gravitational constant, this is the **Gravitational acceleration** parameter; otherwise, it is received as a physical signal at port **G**.

For a pipe with modeled fluid inertia, the momentum balance is:

$$p_A - p_I = \Delta p_{f,A} + \rho_I \frac{\Delta z}{2} g + \ddot{m}_A \frac{L}{2S},$$

$$p_B - p_I = \Delta p_{f,B} - \rho_I \frac{\Delta z}{2} g + \ddot{m}_B \frac{L}{2S},$$

where:

- $\ddot{m}$  is the fluid acceleration at its respective port.
- $S$  is the pipe cross-sectional area.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port.

### Inputs

**EL** — Elevation  
physical signal

Variable elevation from port **A** to port **B**, specified as a physical signal. The elevation magnitude must be less than or equal to the pipe length. If the signal falls below the value of **-Pipe length**, the value at **EL** is maintained at **-pipe length**. If the signal exceeds the value of **Pipe length**, the value at **EL** is maintained at **pipe length**.

### Dependencies

To enable this port, set **Elevation gain specification** to Variable.

**G** — Gravitational acceleration  
physical signal

Variable gravitational acceleration, specified as a physical signal.

### Dependencies

To enable this port, set **Gravitational acceleration specification** to Variable.

## Parameters

### Configuration

**Pipe length** — Pipe length  
5 m (default) | positive scalar

Total pipe length across all pipe segments.

**Number of segments** — Number of pipe divisions  
1 (default) | positive integer

Number of pipe divisions. Each division represents an individual segment for which pressure is calculated, depending on the pipe inlet pressure, fluid compressibility, and wall flexibility, if applicable. The fluid volume in each segment remains fixed.

**Cross-sectional geometry** — Pipe geometry

Circular (default) | Annular | Rectangular | Elliptical | Isosceles triangular | Custom

Cross-sectional pipe geometry. A nominal hydraulic diameter and nominal cross-sectional area is calculated based on the cross-sectional geometry.

**Pipe diameter** — Pipe diameter

0.1 m (default) | positive scalar

Diameter for circular cross-sectional pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Circular.

**Pipe inner diameter** — Pipe inner diameter

0.05 m (default) | positive scalar

Inner diameter for annular pipe flow, or flow between two concentric pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Annular.

**Pipe outer diameter** — Pipe outer diameter

0.1 m (default) | positive scalar

Outer diameter for annular pipe flow, or flow between two concentric pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Annular.

**Pipe width** — Rectangular pipe width

0.1 m (default) | positive scalar

Width of rectangular pipe.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Rectangular.

**Pipe height** — Rectangular pipe height

0.1 m (default) | positive scalar

Height of rectangular pipe.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Rectangular.

**Pipe major axis** — Ellipsoidal pipe major axis

0.1 m (default) | positive scalar

Major axis for ellipsoidal pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Elliptical.

**Pipe minor axis** — Ellipsoidal pipe minor axis

0.05 m (default) | positive scalar

Minor axis for ellipsoidal pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Elliptical.

**Pipe side length** — Triangular pipe side length

0.1 m (default) | positive scalar

Length of the two equal sides of isosceles-triangular pipes.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Isosceles triangular.

**Pipe vertex angle** — Triangular pipe vertex angle

30 deg (default) | positive scalar

Vertex angle for triangular pipes. The value must be less than 180 degrees.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Isosceles triangular.

**Hydraulic diameter** — Hydraulic diameter

0.1128 m (default) | positive scalar

Hydraulic diameter used in calculations of the pipe Reynolds number. For noncircular pipes, the hydraulic diameter is the effective diameter of the fluid in the pipe. For circular pipes, the hydraulic diameter and pipe diameter are the same.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Custom.

**Cross-sectional area** — Pipe cross-sectional area

0.01 m<sup>2</sup> (default) | positive scalar

Pipe cross-sectional area for a custom pipe geometry.

**Dependencies**

To enable this parameter, set **Cross-sectional geometry** to Custom.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid dynamic compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Fluid inertia** — Fluid acceleration

off (default) | on

Whether to account for resistance to changes in the flow rate due to the fluid mass.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility**.

**Elevation gain specification** — Pipe elevation specification  
Constant (default) | Variable

Whether the pipe elevation remains constant or variable from port **A** to **B**.

**Elevation gain from port A to port B** — Constant pipe elevation differential  
0 m (default) | scalar

Elevation differential for constant-elevation pipes. The elevation gain must be less than or equal to the **Pipe length**.

#### Dependencies

To enable this parameter, set **Elevation gain specification** to Constant.

**Gravitational acceleration specification** — Acceleration specification  
Constant (default) | Variable

Whether the gravitational constant is constant or variable.

**Gravitational acceleration** — Gravitational acceleration  
9.81 m/s<sup>2</sup> (default) | positive scalar

Gravitational acceleration for environments with constant gravitational acceleration.

#### Dependencies

To enable this parameter, set **Gravitational acceleration specification** to Constant.

### Viscous Friction

**Viscous friction parameterization** — Method of calculating pressure loss due to wall friction  
Haaland correlation (default) | Nominal pressure drop vs. nominal mass flow rate |  
Tabulated data - Darcy friction factor vs. Reynolds number

Parameterization of pressure losses due to wall friction. Both analytical and tabular formulations are available.

**Local resistances specification** — Method for quantifying pressure losses in the Haaland correlation  
Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses due to pipe nonuniformities.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation.

**Total local loss coefficient** — Defines loss coefficient over the pipe  
0.1 (default) | positive scalar

Loss coefficient associated with each pipe nonuniformity. You can input a single loss coefficient or the sum of all loss coefficients along the pipe.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation and **Local resistance specifications** to Local loss coefficient.

**Aggregate equivalent length of local resistances** — Contribution of pipe geometry to hydraulic losses

1 m (default) | positive scalar

Length of pipe that would produce the equivalent hydraulic losses as would a pipe with bends, area changes, or other nonuniform attributes. The effective length of the pipe is the sum of the **Pipe length** and the **Aggregate equivalent length of local resistances**.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation and **Local resistance specifications** to Aggregate equivalent length.

**Surface roughness specification** — Pipe material for roughness specification

Commercially smooth brass, lead, copper, or plastic pipe: 1.52  $\mu\text{m}$  (default) | Steel and wrought iron : 46  $\mu\text{m}$  | Galvanized iron or steel : 152  $\mu\text{m}$  | Cast iron : 259  $\mu\text{m}$  | Custom

Absolute surface roughness based on pipe material. The provided values are ASHRAE standard roughness values. You can also input your own value by setting **Surface roughness specification** to Custom.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation.

**Internal surface absolute roughness** — Pipe wall roughness

15e-6 m (default) | positive scalar

Pipe wall absolute roughness. This parameter is used to determine the Darcy friction factor, which contributes to pressure loss in the pipe.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to Haaland correlation and **Surface roughness specification** to Custom.

**Laminar flow upper Reynolds number limit** — Laminar flow upper threshold

2000 (default) | positive scalar

Upper Reynolds number limit to laminar flow. Beyond this number, the fluid regime is transitional, approaches the turbulent regime, and becomes fully turbulent at the **Turbulent flow lower Reynolds number limit**.

**Dependencies**

To enable this parameter, set **Viscous friction parameterization** to either:

- Haaland correlation
- Tabulated data - Darcy friction factor vs. Reynolds number

**Turbulent flow lower Reynolds number limit** — Turbulent flow lower threshold  
4000 (default) | positive scalar

Lower Reynolds number limit for turbulent flow. Below this number, the flow regime is transitional, approaches laminar flow, and becomes fully laminar at the **Laminar flow upper Reynolds number limit**.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to either:

- Haaland correlation
- Tabulated data - Darcy friction factor vs. Reynolds number

**Nominal mass flow rate** — Mass flow rate for calculating loss coefficient  
[ .1, 1] kg/s (default) | positive scalar | 1-by- $n$  vector

Nominal mass flow rate used for calculating the pressure loss coefficient for rigid and flexible pipes, specified as a scalar or a vector. All nominal values must be greater than 0 and have the same number of elements as the **Nominal pressure drop** parameter. When this parameter is supplied as a vector, the scalar value  $K_{loss}$  is determined as a least-squares fit of the vector elements.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to Nominal pressure drop vs. nominal mass flow rate.

**Nominal pressure drop** — Pressure drop for calculating loss coefficient  
[ .001, .01] MPa (default) | positive scalar | 1-by- $n$  vector

Nominal pressure drop used for calculating the pressure loss coefficient for rigid and flexible pipes, specified as a scalar or vector. All nominal values must be greater than 0 and must have the same number of elements as the **Nominal mass flow rate** parameter. When this parameter is supplied as a vector, the scalar value  $K_{loss}$  is determined as a least-squares fit of the vector elements.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to Nominal pressure drop vs. nominal mass flow rate.

**Mass flow rate threshold for flow reversal** — Mass flow rate threshold  
1e-6 kg/s (default) | positive scalar

Mass flow rate threshold for reversed flow. A transition region is defined around 0 kg/s between the positive and negative values of the mass flow rate threshold. Within this transition region, numerical smoothing is applied to the flow response. The threshold value must be greater than 0.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to Nominal pressure drop vs. nominal mass flow rate.

**Reynolds number vector for turbulent Darcy friction factor** — Vector of Reynolds numbers for tabular parameterization  
[400, 1000, 1500, 3000, 4000, 6000, 10000, 20000, 40000, 60000, 100000, 100000000] (default) | 1-by- $n$  vector

Vector of Reynolds numbers for the tabular parameterization of the Darcy friction factor. The vector elements form an independent axis with the **Darcy friction factor vector** parameter. The vector elements must be listed in ascending order. A positive Reynolds number corresponds to flow from port **A** to port **B**.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Darcy friction factor vector** — Vector of friction factors for tabular parameterization

[.264, .112, .071, .0417, .0387, .0268, .025, .0232, .0226, .022, .0214, .0214] (default) | 1-by-*n* vector

Vector of Darcy friction factors for the tabular parameterization of the Darcy friction factor. The vector elements must correspond one-to-one with the elements in the **Reynolds number vector for turbulent Darcy friction factor** parameter, and must be unique and greater than or equal to 0.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to Tabulated data - Darcy friction factor vs. Reynolds number.

**Laminar friction constant for Darcy friction factor** — Friction constant for laminar flows

64 (default) | positive scalar

Friction constant for laminar flows. The Darcy friction factor captures the contribution of wall friction in pressure loss calculations. If **Cross-sectional geometry** is not set to Custom, this parameter is internally set to 64.

#### Dependencies

To enable this parameter, set **Viscous friction parameterization** to either:

- Haaland correlation
- Tabulated data - Darcy friction factor vs. Reynolds number

and **Cross-sectional geometry** to Custom.

### Pipe Wall

**Pipe wall specification** — Specifies wall flexibility

Rigid (default) | Flexible

Specifies wall flexibility. This parameter is independent of pipe cross-sectional geometry. The Flexible setting preserves the initial pipe shape and applies equal expansion of the cross-sectional area. It may not be accurate for non-circular cross-sectional geometry under high deformation.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility**.

**Volumetric expansion specification** — Linear expansion correlation

Cross-sectional area vs. pressure (default) | Cross-sectional area vs. pressure - Tabulated | Hydraulic diameter vs. pressure | Based on material properties

Linear expansion correlation. The settings correlate the new cross-sectional area or hydraulic diameter to the pipe pressure.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible.

**Static gauge pressure to cross-sectional area gain** — Coefficient for area-dependent pipe deformation

$1e-6 \text{ m}^2/\text{MPa}$  (default) | positive scalar

Coefficient for calculating pipe deformation for the Cross-sectional area vs. pressure setting. The gain is multiplied by the pressure differential between the segment pressure and atmospheric pressure.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility**, and set **Pipe wall specification** to Flexible and **Volumetric expansion specification** to Cross-sectional area vs. pressure.

**Static gauge pressure vector** — Vector of gauge pressures

[.1, 1] MPa (default) | vector

Vector that contains the gauge pressures. The block uses this vector in a table lookup to calculate the pipe cross-sectional area. The vector entries must be strictly positive and monotonically increasing and the vector must be the same length as the **Cross sectional area gain vector** parameter.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible and **Volumetric expansion specification** to Cross-sectional area vs. pressure - Tabulated.

**Cross sectional area gain vector** — Vector of pipe cross-sectional areas

[ $1e-05$ ,  $1.1e-05$ ]  $\text{m}^2$  (default) | vector

Vector that contains the pipe cross-sectional areas. The block uses this vector in a table lookup to calculate the pipe cross sectional-area at other pressures. The vector entries must be strictly positive and monotonically increasing and the vector must be the same length as the **Static gauge pressure vector** parameter.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible and **Volumetric expansion specification** to Cross-sectional area vs. pressure - Tabulated.

**Static gauge pressure to hydraulic diameter gain** — Coefficient for diameter-dependent pipe deformation

$1e-6 \text{ m}/\text{MPa}$  (default) | positive scalar

Coefficient for calculating pipe deformation for the Hydraulic diameter vs. pressure setting. The gain is multiplied by the pressure differential between the segment pressure and atmospheric pressure.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible and **Volumetric expansion specification** to Hydraulic diameter vs. pressure.

**Material behavior** — Method used to specify material behavior

Linear Elastic (default) | Multilinear Elastic

Method the block uses to calculate the material behavior.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible and **Volumetric expansion specification** to Based on material properties.

**Pipe wall thickness** — Width of pipe wall

0.05 m (default) | positive scalar

Thickness of the pipe wall. The block uses this value to calculate stress.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible and **Volumetric expansion specification** to Based on material properties.

**Young's modulus** — Young's modulus of pipe wall material

69 GPa (default) | positive scalar

Young's modulus of the material that makes up the pipe wall.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible, **Volumetric expansion specification** to Based on material properties, and **Material behavior** to Linear Elastic.

**Poisson's ratio** — Poisson's ratio of pipe wall material

0.33 (default) | positive scalar

Poisson's ratio of the material that makes up the pipe wall.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible and **Volumetric expansion specification** to Based on material properties.

**Stress vector** — Stress vector of pipe wall material

[276, 310] MPa (default) | vector

Vector containing the stress values for the material that makes up the pipe wall.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible, **Volumetric expansion specification** to Based on material properties, and **Material behavior** to Multilinear Elastic.

**Strain vector** — Strain vector of pipe wall material  
[.004, .02] (default) | vector

Vector containing the strain values for the material that makes up the pipe wall.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible, **Volumetric expansion specification** to Based on material properties, and **Material behavior** to Multilinear Elastic.

**Check if stress exceeds specified allowable level** — Notification when stress is above specified max

None (default) | Warning | Error

Whether the block does nothing, generates a warning, or generates an error when the stress is above the maximum stress specified by the **Maximum allowable stress** parameter.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible, **Volumetric expansion specification** to Based on material properties, and **Material behavior** to Multilinear Elastic.

**Maximum allowable stress** — Maximum allowed stress on pipe wall

400 MPa (default) | positive scalar

Maximum stress the block allows on the pipe wall. Control what the block does if the stress exceeds this value with the **Check if stress exceeds specified allowable level** parameter.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible, **Volumetric expansion specification** to Based on material properties, **Material behavior** to Multilinear Elastic and **Check if stress exceeds specified allowable level** to Warning or Error.

**Volumetric expansion time constant** — Pipe deformation time constant

0.01 s (default) | positive scalar

Time required for the wall to reach steady-state after pipe deformation. This parameter impacts the dynamic change in pipe volume.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility** and set **Pipe wall specification** to Flexible.

#### Initial Conditions

**Initial liquid pressure** — Initial pressure in pipe or pipe segment

0.101325 MPa (default) | positive scalar | 1-by- $n$  vector

Initial liquid pressure, specified as a scalar or vector. A vector  $n$  elements long defines the liquid pressure for each of  $n$  pipe segments. If the vector is two elements long, the pressure along the pipe is linearly distributed between the two element values. If the vector is three or more elements long, the initial pressure in the  $n$ th segment is set by the  $n$ th element of the vector.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

**Initial mass flow rate from port A to port B** — Initial mass flow rate for inertia calculation  
0 kg/s (default) | scalar

Initial mass flow rate for pipes with simulated fluid inertia.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility** and **Fluid inertia**.

## Version History

**Introduced in R2020a**

### R2023a: Use Additional Flexible Pipe Parameterizations

You can now use new parameterization methods when the **Pipe wall specification** parameter is Flexible. To use the new parameterizations, set the **Volumetric expansion specification** parameter to Cross-sectional area vs. pressure - Tabulated or Based on material properties.

# Pneumo-Hydraulic Actuator

Double-acting cylinder operated by hydraulic and pneumatic power

## Library

Hydraulic Cylinders

## Description

The Pneumo-Hydraulic Actuator block simulates a pneumo-hydraulic actuator, implemented as a double-acting cylinder with one side connected to a hydraulic power supply and another side operated by pneumatic power. Such devices are widely used as pneumo-hydraulic pumps, intensifiers, and converters of various types. The following illustration shows a few examples of the pneumo-hydraulic actuator: a) with rigid separator; b) with flexible separator; c) pneumo-hydraulic intensifier.

The block provides two main modeling variants, accessible by right-clicking the block in your block diagram and then selecting the appropriate option from the context menu, under **Simscape > Block choices**:

- **One mechanical port** — Use this variant to model just the load on the piston. In this case, the cylinder is assumed to be grounded.
- **Two mechanical ports** — Use this variant to model the load on the actuator cylinder, as well as the piston. This variant also lets you include liquid compressibility on the hydraulic side of the actuator.

### Configuration with One Mechanical Port

Use this variant of the block when the load is applied only to the piston and the cylinder clamping structure is grounded. The hydraulic part of the model accounts only for fluid consumption associated with the piston velocity. The pneumatic part of the model is built with the ideal gas relationships. To

simulate the limit on the piston motion, the hard stop is included in the model. The piston effective area is assumed to be constant. As a result, the model is described with the following equations:

$$q_H = A_H \cdot v$$

$$F_H = A_H \cdot p$$

$$F_P = A_P \cdot p$$

$$F_{HS} = \begin{cases} K \cdot (x - stroke) + D \cdot v & \text{for } x > stroke \\ K \cdot x + D \cdot v & \text{for } x < 0 \\ 0 & \text{for } 0 \leq x \leq stroke \end{cases}$$

$$F_H = F_P + F_{HS} + F_L$$

$$v = \frac{dx}{dt}$$

$$V_P = V_0 + A_P \cdot (stroke - x)$$

$$G = \frac{V_P}{RT} \left( \frac{dp}{dt} - \frac{p}{T} \frac{dT}{dt} \right) - \frac{A_P}{RT} p \cdot v$$

$$Q_P = \frac{c_v \cdot V_P}{R} \frac{dp}{dt} - \frac{c_p \cdot A_P}{R} p \cdot v + Q_{HE}$$

where

$q_H$	Hydraulic volumetric flow rate
$p$	Pressure in the actuator chambers
$A_H$	Hydraulic side effective area
$A_P$	Pneumatic side effective area
$v$	Piston velocity
$F_H$	Force developed by piston on hydraulic side
$F_P$	Force developed by piston on pneumatic side
$F_{HS}$	Hard stop force
$F_L$	Force developed by external load connected to port L
$K$	Hard stop stiffness
$D$	Hard stop damping
$stroke$	Piston stroke
$x$	Piston displacement
$V_P$	Chamber volume on pneumatic side
$V_0$	Chamber dead volume on pneumatic side
$G$	Gas mass flow rate
$R$	Gas constant
$T$	Gas absolute temperature

$Q_P$	Heat flow through the pneumatic chamber
$c_v$	Gas specific heat at constant volume
$c_p$	Gas specific heat at constant pressure
$Q_{HE}$	Heat flow through the thermal port E

The model is suitable for building pneumo-hydraulic or hydro-pneumatic pumps, intensifiers, and similar devices. You can simulate piston loading (such as inertia, springs, friction) by modeling the load externally and connecting it to port L. Similarly, simulate the heat exchange with the environment through the external thermal port E, which corresponds to the gas in the chamber. Use blocks from the Simscape Foundation library, such as the Convective Heat Transfer, Conductive Heat Transfer, Thermal Mass, and so on, depending on the actual system configuration.

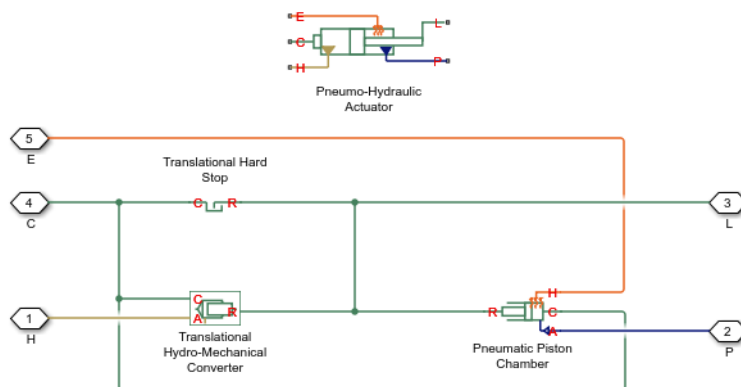

Port P is the pneumatic conserving port associated with the pneumatic side of the actuator. Port H is the hydraulic conserving port associated with the hydraulic inlet.

The block directionality assumes that pressure in the hydraulic chamber causes the piston to move in the positive direction, while pressure in the pneumatic chamber tends to move the piston in the negative direction. Flow rates are considered positive if they flow into the actuator.

### Configuration with Two Mechanical Ports

This variant of the block is suitable when the forces on both piston and cylinder are considered. This is a composite component and is built of the following blocks from the Simscape Foundation library:

- Translational Hydro-Mechanical Converter
- Pneumatic Piston Chamber
- Translational Hard Stop

Connections R and C are mechanical translational ports corresponding to the cylinder rod and cylinder clamping structure, respectively. Connection H is a hydraulic conserving port that is connected to the hydraulic Translational Hydro-Mechanical Converter. Connection P is a pneumatic conserving port that is connected to the pneumatic port of the Pneumatic Piston Chamber block. Connection E is a thermal conserving port associated with the gas in the pneumatic chamber. The fluid pressure, either on the hydraulic or pneumatic side, is transformed into mechanical energy through the converter. The piston (rod) motion is limited with the mechanical Translational Hard Stop block in such a way that the rod can travel only between cylinder caps. The fluid compressibility can also be taken into account on the hydraulic side.

You can control the block directionality using the **Converter orientation** parameter. If the **Converter orientation** is set to **Act in positive direction**, the pressure in the hydraulic chamber causes the piston to move in the positive direction, while the pressure in the pneumatic chamber tends to move the piston in the negative direction. Flow rates are considered positive if they flow into the actuator.

## Basic Assumptions and Limitations

- The effective piston area in each chamber is assumed to be constant.
- The leakage flow between chambers is assumed to be negligible because pressures in the chambers are equal.
- In **One mechanical port** configuration, on the hydraulic side, fluid compressibility is not taken into account. However, in **Two mechanical ports** configuration, you have an option to include fluid compressibility by setting the **Compressibility** parameter to **On**.
- On the pneumatic side, the mass flow rate and heat flow computations assume that the gas is ideal.
- In **One mechanical port** configuration, the cylinder is always assumed be grounded.
- In **Two mechanical ports** configuration, no loading on piston rod, such as inertia, friction, spring, and so on, is taken into account. If necessary, you can easily add them by connecting an appropriate building block to cylinder port R.

## Parameters

- “Hydraulic Side Tab” on page 1-1440
- “Pneumatic Side Tab” on page 1-1441
- “Hard Stop Tab” on page 1-1441

### Hydraulic Side Tab

#### Hydraulic side piston area

Effective piston area on the hydraulic side. The default value is  $2e-3 \text{ m}^2$ .

#### Stroke

Piston maximum travel between caps. The default value is  $0.2 \text{ m}$ .

#### Piston initial distance from hydraulic port H

The distance between the piston and the cap on the hydraulic side at the beginning of simulation. This value cannot exceed the piston stroke. The default value is  $0$ .

#### Compressibility

This parameter is visible only in the **Two mechanical ports** configuration. Specifies whether fluid density on the hydraulic side is taken as constant or varying with pressure. The default value is **Off**, in which case the block models an ideal transducer. If you select **On**, the block dialog box displays additional parameters that let you model dynamic variations of the liquid density without adding any extra blocks.

#### Hydraulic side dead volume

This parameter is visible only when the **Compressibility** parameter is set to **On**. Fluid volume in hydraulic chamber that remains in the chamber after the rod is fully retracted. The default value is  $1e-4 \text{ m}^3$ .

**Specific heat ratio**

This parameter is visible only when the **Compressibility** parameter is set to On. Gas-specific heat ratio. The default value is 1.4.

**Initial liquid pressure (relative)**

This parameter is visible only when the **Compressibility** parameter is set to On. The initial relative pressure of fluid in the hydraulic converter. This parameter specifies the initial condition for use in block's initial state at the beginning of a simulation run. The default value is 0.

**Converter orientation**

This parameter is visible only in the **Two mechanical ports** configuration. Specifies hydraulic cylinder orientation with respect to the globally assigned positive direction. The cylinder can be installed in two different ways, depending upon whether it exerts force in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port H exerts force in negative direction, set the parameter to **Acts in negative direction**. The default value is **Acts in positive direction**.

**Pneumatic Side Tab****Pneumatic side piston area**

Effective piston area on the pneumatic side. The default value is  $1e-3 \text{ m}^2$ .

**Pneumatic side dead volume**

Gas volume in pneumatic chamber that remains in the chamber after the rod is fully retracted. The default value is  $1e-4 \text{ m}^3$ .

**Initial gas pressure (absolute)**

The initial absolute gas pressure in the pneumatic chamber. The default value is 101325 Pa.

**Initial gas temperature**

The initial gas temperature in the pneumatic chamber. The default value is 293.15 K.

**Hard Stop Tab****Hard stop stiffness**

The hard stop model implemented in the block assumes that the stop resists penetration of the piston with force proportional to the penetration. This parameter sets the stiffness of the contact between the stop and the piston. The default value is  $1e6 \text{ N/m}$ .

**Hard stop damping**

The damping in the hard stop model accounts for dissipation in the piston-stop contact. The default value is  $150 \text{ N*s/m}$ .

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Compressibility**
- **Converter orientation**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the values of the **Compressibility** parameter at the time the model entered Restricted mode.

## Ports

The block has the following ports:

H

Hydraulic conserving port associated with the actuator hydraulic chamber.

P

Pneumatic conserving port associated with the actuator pneumatic chamber.

E

Thermal conserving port associated with the gas in the pneumatic chamber. You can simulate the heat exchange with the environment through this port.

L

Mechanical translational conserving port associated with the actuator piston. You can model the load on the piston, such as external force, inertia, friction, or spring, and connect it through this port.

R

Mechanical translational conserving port associated with the actuator clamping structure, which is exposed by selecting the **Two mechanical ports** variant. You can model the load on the actuator casing through this port.

# Poppet Valve

(To be removed) Hydraulic poppet valve

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Library

Flow Control Valves

## Description

The Poppet Valve block models a variable orifice created by a cylindrical sharp-edged stem and a conical seat.

The flow rate through the valve is proportional to the valve opening and to the pressure differential across the valve. The flow rate is determined according to the following equations:

$$q = C_D \cdot A(h) \sqrt{\frac{2}{\rho} \frac{\Delta p}{(\Delta p^2 + p_{Cr}^2)^{1/4}}}$$

$$\Delta p = p_A - p_B,$$

$$h = x_0 + x$$

$$h_{\max} = d_s \frac{\sqrt{1 + \cos \frac{\alpha}{2}} - 1}{\sin \alpha}$$

$$A(h) = \begin{cases} A_{leak} & \text{for } h < = 0 \\ \pi \cdot \left( d_s + h \cdot \sin \frac{\alpha}{2} \cdot \cos \frac{\alpha}{2} \right) \cdot h \cdot \sin \frac{\alpha}{2} + A_{leak} & \text{for } 0 < h < h_{\max} \\ A_{\max} + A_{leak} & \text{for } h > = h_{\max} \end{cases}$$

$$A_{\max} = \frac{\pi d_s^2}{4}$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A(h)$	Instantaneous orifice passage area
$x_0$	Initial opening
$x$	Stem displacement from initial position
$h$	Valve opening
$h_{\max}$	Maximum valve opening. The passage area remains constant and equal to $A_{\max}$ after this.
$d_s$	Stem diameter
$\alpha$	Cone angle
$\rho$	Fluid density
$A_{leak}$	Closed valve leakage area
$A_{\max}$	Maximum valve open area
$p_{cr}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{cr}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = (p_{avg} + p_{atm})(1 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{avg}$	Average pressure between the block terminals
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$D_H$	Valve instantaneous hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B and the pressure differential is determined as  $\Delta p = p_A - p_B$ . Positive signal at the physical signal port S opens the valve.

## Basic Assumptions and Limitations

- Fluid inertia is not taken into account.
- The flow passage area is assumed to be equal to the frustum side surface area.

## Parameters

### Valve stem diameter

The diameter of the valve stem. The default value is 0.01 m.

### Seat cone angle

The angle of the valve conical seat. The parameter value must be in the range between 0 and 180 degrees. The default value is 120 degrees.

### Initial opening

The initial opening of the valve. The parameter value must be nonnegative. The default value is 0.

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.65.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 10. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## **Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## **Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

S

Physical signal port to control spool displacement.

## **Version History**

**Introduced in R2006a**

**R2023a: To be removed**

# Poppet Valve (IL)

Poppet valve in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Flow Control Valves

## Description

The Poppet Valve (IL) block represents a flow-control valve in an isothermal liquid system. The poppet can either be a cylinder or a ball. You can choose between sharp-edged and conical seats. The poppet opens or closes according to the displacement signal at port **S**. A positive signal retracts the poppet and opens the valve.

## Poppet Valve Schematic

## Poppet Valve Top View

### Cylindrical Stem Poppet Opening Area

The opening area of the valve is calculated as:

$$A_{open} = \pi h \sin\left(\frac{\theta}{2}\right) \left[ d_s + \frac{h}{2} \sin(\theta) \right] + A_{leak},$$

where:

- $h$  is the vertical distance between the outer edge of the cylinder and the seat, indicated in the schematic above.
- $\theta$  is the **Seat cone angle**.
- $d_s$  is the **Stem diameter**.
- $A_{leak}$  is the **Leakage area**.

The opening area is bounded by the maximum displacement  $h_{max}$ :

$$h_{max} = \frac{d_s \left[ \sqrt{1 + \cos\left(\frac{\theta}{2}\right)} - 1 \right]}{\sin(\theta)}.$$

For any stem displacement larger than  $h_{max}$ ,  $A_{open}$  is the sum of the maximum orifice area and the **Leakage area**:

$$A_{open} = \frac{\pi}{4} d_s^2 + A_{leak}.$$

For any combination of the signal at port **S** and the cylinder offset less than 0, the minimum valve area is the **Leakage area**.

## Round Ball Poppet Opening Area

### Sharp-edged Seat Geometry

The opening area of the valve is calculated as:

$$A_{open, sharp - edged} = \pi r_O \sqrt{(G_{sharp} + h)^2 + r_O^2} \left[ 1 - \frac{r_B^2}{(G_{sharp} + h)^2 + r_O^2} \right] + A_{leak},$$

where:

- $h$  is the vertical distance between the outer edge of the cylinder and the seat, indicated in the schematic above.
- $r_O$  is the seat orifice radius, calculated from the **Seat orifice diameter**.
- $r_B$  is the radius of the ball, calculated from the **Ball diameter**.
- $G_{sharp}$  is the geometric parameter:  $G_{sharp} = \sqrt{r_B^2 - r_O^2}$ .
- $A_{leak}$  is the **Leakage area**.

The opening area is bounded by the maximum displacement  $h_{max}$ :

$$h_{max} = \sqrt{\frac{2r_B^2 - r_O^2 + r_O \sqrt{r_O^2 + 4r_B^2}}{2}} - G_{sharp}.$$

For any ball displacement larger than  $h_{max}$ ,  $A_{open}$  is the sum of the maximum orifice area and the **Leakage area**:

$$A_{open} = \frac{\pi}{4}d_O^2 + A_{leak}.$$

For any combination of the signal at port **S** and the ball offset that is less than 0, the minimum valve area is the **Leakage area**.

**Conical Seat Geometry**

The opening area of the valve is calculated as:

$$A_{open, conical} = G_{conical}h + \frac{\pi}{2}\sin(\theta)\sin\left(\frac{\theta}{2}\right)h^2 + A_{leak},$$

where:

- $h$  is the vertical distance between the outer edge of the cylinder and the seat, indicated in the schematic above.
- $\theta$  is the **Seat cone angle**.
- $G_{conical}$  is the geometric parameter:  $G_{conical} = \pi r_B \sin(\theta)$ , where  $r_B$  is the ball radius.
- $A_{leak}$  is the **Leakage area**.

The opening area is bounded by the maximum displacement  $h_{max}$ :

$$h_{max} = \frac{\sqrt{r_B^2 + \frac{r_O^2}{\cos\left(\frac{\theta}{2}\right)} - r_B}}{\sin\left(\frac{\theta}{2}\right)}.$$

For any ball displacement larger than  $h_{max}$ ,  $A_{open}$  is the sum of the maximum orifice area and the **Leakage area**:

$$A_{open} = \frac{\pi}{4}d_O^2 + A_{leak}.$$

For any combination of the signal at port **S** and the ball offset that is less than 0, the minimum valve area is the **Leakage area**.

**Numerically Smoothed Displacement**

The block calculates the poppet displacement,  $h$ , such that

$$h = \begin{cases} 0, & (S - S_{min}) \leq 0 \\ h_{Max}, & (S - S_{min}) \geq h_{Max} \\ (S - S_{min}), & \text{Else} \end{cases}$$

where:

- $S$  is the physical signal input.
- $S_{min}$  is the **Poppet position when in the seat** parameter.
- $h_{Max}$  is the maximum displacement.

If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the poppet displacement between 0 and  $h_{Max}$ .

For more information, see “Numerical Smoothing”.

### Mass Flow Rate Equation

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the valve is calculated as:

$$\dot{m} = \frac{C_d A_{\text{valve}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2\right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{\text{crit}}^2]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{\text{valve}}$  is the current valve open area.
- $A_{\text{port}}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{\text{crit}}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{\text{crit}}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{\text{crit}} = \frac{\pi \bar{\rho}}{8 A_{\text{valve}}} \left( \frac{\nu Re_{\text{crit}}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area.  $PR_{\text{loss}}$  is calculated as:

$$PR_{\text{loss}} = \frac{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2} (1 - C_d^2) - C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2} (1 - C_d^2) + C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{\text{loss}}$  is 1.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

### Input

**S** — Stem displacement, m  
physical signal

Displacement of the valve control member in m, specified as a physical signal..

### Parameters

**Poppet geometry** — Type of poppet  
Cylindrical stem (default) | Round ball

Type of poppet. You can choose either a cylindrical or ball-shaped control member.

**Valve seat specification** — Geometry of valve seat  
Sharp-edged (default) | Conical

Geometry of valve seat. The block uses this parameter to calculate the open area between the poppet and seat.

#### Dependencies

To enable this parameter, set **Poppet geometry** to Round ball.

**Ball diameter** — Diameter of ball control member  
0.01 m (default) | positive scalar

Diameter of the ball control member.

#### Dependencies

To enable this parameter, set **Poppet geometry** to Round ball.

**Seat orifice diameter** — Seat orifice diameter  
7e-3 m (default) | positive scalar

Seat orifice diameter.

#### Dependencies

To enable this parameter, set **Poppet geometry** to Round ball.

**Stem diameter** — Diameter of cylindrical stem  
0.01 m (default) | positive scalar

Diameter of the cylindrical stem.

#### Dependencies

To enable this parameter, set **Poppet geometry** to Cylindrical stem.

**Seat cone angle** — Angle of seat opening  
120 deg (default) | positive scalar

Angle of the seat opening.

**Dependencies**

To enable this parameter, set either:

- **Poppet geometry** to `Cylindrical stem`
- **Poppet geometry** to `Round ball` and **Valve seat specification** to `Conical`

**Poppet position when in the seat** — Control member offset

0 m (default) | positive scalar

Poppet offset when valve is closed. A positive, nonzero value indicates a partially open valve. A negative, nonzero value indicates an overlapped valve that remains closed for an initial displacement set by the physical signal at port **S**.

**Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Cross-sectional area at ports A and B** — Area at conserving ports

inf m<sup>2</sup> (default) | positive scalar

Areas at the entry and exit ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Pressure recovery** — Whether to account for pressure increase in area expansions

off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Version History**

Introduced in R2020a

Poppet Valve (G) | Poppet Valve (TL) | Needle Valve (IL) | Gate Valve (IL)

# Poppet Valve (TL)

Poppet flow control valve in a thermal liquid network

## Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Flow Control Valves

## Description

The Poppet Valve (TL) block represents the flow control within a thermal liquid network. You can specify the seat geometry as either sharp-edged or conical. Set the poppet displacement with the physical signal at port **S**.

## Mass Balance

The mass conservation equation in the valve is

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate into the valve through port **A**.
- $\dot{m}_B$  is the mass flow rate into the valve through port **B**.

## Momentum Balance

The pressure differential over the valve is:

$$p_A - p_B = \frac{\dot{m}\sqrt{\dot{m}^2 + \dot{m}_{cr}^2}}{2\rho_{Avg}C_d^2S^2} \left[ 1 - \left( \frac{S_R}{S} \right)^2 \right] PR_{Loss},$$

where:

- $p_A$  is the pressure at port **A**.
- $p_B$  is the pressure at port **B**.
- $\dot{m}$  is the mass flow rate.
- $\rho_{Avg}$  is the average liquid density.

- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\dot{m}_{cr}$  is the critical mass flow rate:

$$\dot{m}_{cr} = Re_{cr} \mu_{Avg} \sqrt{\frac{\pi}{4} S_R}.$$

where:

- $Re_{cr}$  is the value of the **Critical Reynolds number** parameter.
- $\mu_{Avg}$  is the average fluid dynamic viscosity.
- $S$  is the value of the **Cross-sectional area at port A and B** parameter.
- $PR_{Loss}$  is the pressure ratio:

$$PR_{Loss} = \frac{\sqrt{1 - (S_R/S)^2(1 - C_d^2)} - C_d(S_R/S)}{\sqrt{1 - (S_R/S)^2(1 - C_d^2)} + C_d(S_R/S)}.$$

### Energy Balance

The energy conservation equation in the valve is

$$\phi_A + \phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate into the valve through port **A**.
- $\phi_B$  is the energy flow rate into the valve through port **B**.

### Opening Area With a Sharp-Edged Seat

When you set **Valve seat specification** to Sharp-edged, the block calculates the valve opening area using

$$A = \pi r_o \left( 1 - \left( \frac{r_p}{d_{OB}} \right)^2 \right) d_{OB}(h) + A_{leak},$$

where:

- $r_o$  is the valve orifice radius.
- $r_p$  is the valve poppet radius.
- $d_{OB}(h)$  is the distance between the center of the poppet and the edge of the orifice. This distance is a function of the valve lift,  $h$ .
- $A_{leak}$  is the leakage area.

The maximum displacement,  $h_{max}$ , is

$$h_{max} = \sqrt{\frac{2r_p^2 - r_o^2 + r_o \sqrt{r_o^2 + 4r_p^2}}{2}} - \sqrt{r_p^2 - r_o^2}.$$

The figure shows a schematic of a hard-edged seat.

### Opening Area With a Conical Seat

When you set **Valve seat specification** to `Conical`, the block calculates the valve opening area using a geometric relationship, such that

$$A = \pi r_p \sin(\theta) h + \frac{\pi}{2} \sin\left(\frac{\theta}{2}\right) \sin(\theta) h^2 + A_{leak}.$$

The maximum displacement,  $h_{max}$ , is:

$$h_{max} = \frac{\sqrt{r_p^2 + \frac{r_o^2}{\cos\left(\frac{\theta}{2}\right)} - r_p}}{\sin\left(\frac{\theta}{2}\right)},$$

where  $\theta$  is the **Cone angle**. The figure shows a schematic of a conical seat.

### Numerically Smoothed Displacement

The block calculates the poppet displacement,  $h$ , such that

$$h = \begin{cases} 0, & (S - S_{min}) \leq 0 \\ h_{Max}, & (S - S_{min}) \geq h_{Max} \\ (S - S_{min}), & \text{Else} \end{cases}$$

where:

- $S$  is the physical signal input.
- $S_{min}$  is the **Poppet position when in the seat** parameter.
- $h_{Max}$  is the maximum displacement.

If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the poppet displacement between  $\theta$  and  $h_{Max}$ .

For more information, see “Numerical Smoothing”.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet A.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet B.

### Input

**S** — Poppet displacement, m  
physical signal

Physical signal port associated with the displacement of the poppet, in m.

## Parameters

**Valve seat specification** — Geometry of valve seat  
Sharp-edged (default) | Conical

Geometry of the valve seat. The block uses this parameter to calculate the open area between the poppet and seat.

**Cone angle** — Angle of seat opening  
120 deg (default) | positive scalar

Angle of the seat opening.

### Dependencies

To enable this parameter, set **Valve seat specification** to Conical.

**Ball diameter** — Poppet diameter  
0.01 m (default) | positive scalar

Diameter of the poppet.

**Orifice diameter** — Seat orifice diameter  
7e-3 m (default) | positive scalar

Seat orifice diameter.

**Poppet position when in the seat** — Poppet offset  
0 m (default) | nonnegative scalar

Poppet offset when valve is shut. A positive, nonzero value indicates a partially open valve. A negative, nonzero value indicates an overlapped valve that remains shut for an initial displacement set by the physical signal at port **S**.

**Leakage area** — Gap area when in fully closed position

$1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in the fully shut position. The block saturates smaller numbers to this value. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Smoothing factor** — Gap area when in fully closed position

0.01 (default) | scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in the near-open or near-shut positions. Set this value to a nonzero number less than one to increase the stability of your simulation in these regimes.

**Cross-sectional area at ports A and B** — Area at conserving ports

$0.01 \text{ m}^2$  (default) | positive scalar

Area at ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

## Porting Plate Variable Orifice

(To be removed) Variable orifice between piston and porting plate

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see "Upgrading Hydraulic Models to Use Isothermal Liquid Blocks".

## Library

Pumps and Motors

## Description

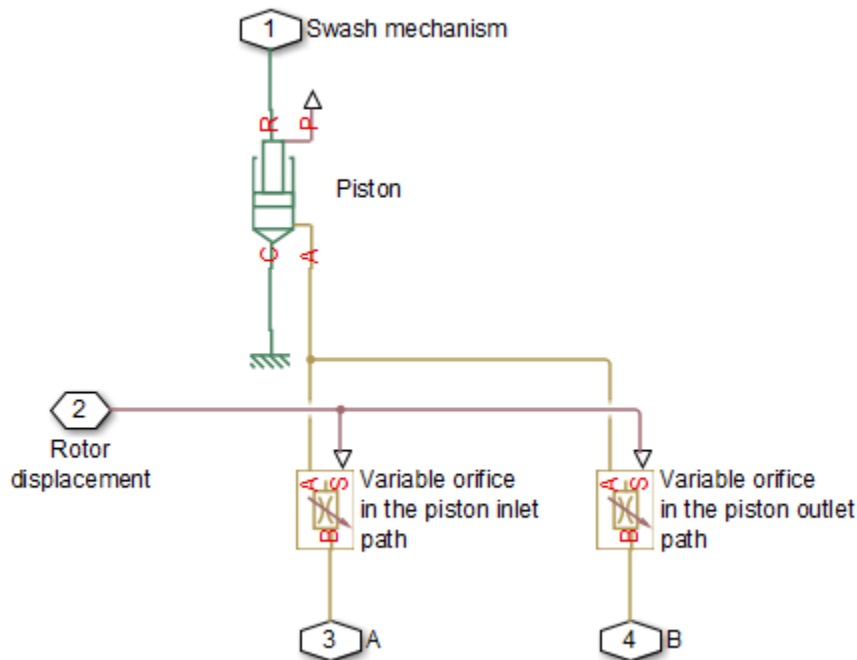

Porting plate is a key element of axial-piston machines. Its objective is to provide communication between pistons and pump ports during the rotor, or cylinder block, rotation. The porting plate is equipped with two crescent-shaped slots, one of which is connected to the intake port while the other is channeled to the discharge port. The pistons are carried along the porting plate slots, thus periodically connecting the piston to either the intake or the discharge port of the machine.

The preceding diagram shows an axial-piston machine with five pistons, where:

- 1 Porting plate
- 2 Rotor
- 3 Piston
- 4 Driving shaft
- 5 Swash plate

During rotor rotation, every piston gets connected to one of the porting slots. These piston connections, modeled as variable orifices, are reflected in the schematic model of a piston, shown in the following illustration.

The Porting Plate Variable Orifice block is a model of a variable orifice created between the piston chamber and a slot on a porting plate. Two Porting Plate Variable Orifice blocks are necessary in the model of a piston, to simulate connection to the intake and the discharge port, respectively.

The calculation diagram of the porting plate variable orifice is shown in the next illustration.

The model assumes that the slot is shifted by a pressure carryover angle  $\psi$  from the reference point in the direction of orifice rotation. Generally,  $r/R \leq \psi \leq 3 \cdot r/R$ , where  $r$  is the orifice radius and  $R$  is the piston pitch radius. A small triangular-shaped transition slot is placed at the beginning of the major slot, to avoid sudden pressure change. To avoid direct connection between the intake and discharge slots, the transition slot angle  $\theta$  must be less than  $\psi - r/R$ . The transition slot area is assumed to be linearly dependent on the rotation angle and characterized by its maximum area. There are six distinctive angles defining the relationship between the rotation angle  $\gamma$  and the orifice opening, as listed in the following table.

No	Nomenclature	Value	Description
1	$\gamma_1$	$\psi - \theta - r/R$	Opening of transition slot starts.
2	$\gamma_2$	$\psi - r/R$	Opening of the major slot starts. The orifice contacts with the transition slot.
3	$\gamma_3$	$\psi + r/R$	Major slot full opening starts.
4	$\gamma_4$	$\psi + r/R + 0.01$	Transition slot ends.
5	$\gamma_5$	$\pi - 2 \cdot r/R$	Major slot full opening ends.
6	$\gamma_6$	$\pi$	Major slot opening ends.

The variable orifice is fully opened in the  $\alpha_0$  region

$$\psi + r/R \leq \gamma \leq \pi - 2 \cdot r/R$$

where  $\gamma$  is the rotation angle.

The orifice area is computed with the following equations:

$$\begin{aligned}
 A &= A_{leak} && \text{for } \gamma_6 < \gamma \leq \gamma_1 \\
 A &= G \cdot (\gamma - \gamma_1) + A_{leak} && \text{for } \gamma_1 < \gamma \leq \gamma_2 \\
 A &= A_{tr} + r^2(\beta - \sin\beta) + A_{leak} && \text{for } \gamma_2 < \gamma \leq \gamma_3 \\
 A &= A_{tr} \cdot (1 - 100 \cdot (\gamma - \gamma_3)) + \pi \cdot r^2 + A_{leak} && \text{for } \gamma_3 < \gamma \leq \gamma_4 \\
 A &= \pi \cdot r^2 + A_{leak} && \text{for } \gamma_4 < \gamma \leq \gamma_5 \\
 A &= r^2(\beta - \sin\beta) + A_{leak} && \text{for } \gamma_5 < \gamma \leq \gamma_6 \\
 \beta &= \begin{cases} 2 \cdot \arccos(R/r \cdot \sin(0.5 \cdot (\gamma_3 - \gamma))) & \text{for } \gamma_2 < \gamma \leq \gamma_3 \\ 2 \cdot \arccos(R/r \cdot \sin(0.5 \cdot (2 \cdot r/R + \gamma - \pi))) & \text{for } \gamma_5 < \gamma \leq \gamma_6 \end{cases}
 \end{aligned}$$

where

$A$	Orifice area
$A_{tr}$	Transition slot maximum area
$A_{leak}$	Closed orifice leakage area

After the area has been determined, the flow rate through the orifice is computed with the following equations:

$$q = C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

$$\Delta p = p_A - p_B,$$

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$D_H$	Orifice hydraulic diameter
$\rho$	Fluid density
$\nu$	Fluid kinematic viscosity
$p_{cr}$	Minimum pressure for turbulent flow
$Re_{cr}$	Critical Reynolds number

The Porting Plate Variable Orifice block model is essentially a building block intended for use in various piston machines. The model accounts for the flow regime by computing the Reynolds number and comparing it with its critical value. No inertial effects are considered in the model.

Connections A and B are hydraulic conserving ports associated with the inlet and outlet of the orifice. Connection G is a physical signal port associated with the input signal for the cylinder block angle. The input signal at port G is treated as an angle, in radians, therefore it is essential that the input signal representing angular displacement is kept within the range from 0 to  $2\pi$ . Connect port G to the output port of an Angle Sensor block to meet this requirement.

The flow rate is considered positive if it flows from A to B. At initial position, the orifice is assumed to be shifted by the pressure carryover angle from the slot. When the block rotates in the positive direction, the orifice starts opening. To adjust the initial position of the orifice with respect to the slot, use the **Phase angle** parameter.

## Basic Assumptions and Limitations

- The model accounts for the viscous friction in the piston-plate contact.
- No inertial effects are considered.
- The plate angular displacements are considered to be small.
- The joint between the piston and the plate permanently maintains contact between the piston and the plate.

## Parameters

### Piston pitch radius

The radius of the pitch circle where the pistons are located. The parameter must be greater than zero. The default value is 0.05 m.

### Orifice diameter

The diameter of the orifice at the bottom of the piston chamber. The parameter must be greater than zero. The default value is 0.005 m.

### Pressure carryover angle

The angle introduced between to slot and the orifice to avoid abrupt pressure change and decrease leakage. This angle is marked  $\psi$  in the preceding calculation diagram. The angle is expected to be in the range  $r/R \leq \psi \leq 3 \cdot r/R$ , where  $r$  is the orifice radius and  $R$  is the piston pitch radius. The default value is 0.06 rad.

### Phase angle

This parameter sets the orifice initial angular position with respect to the slot. The default value is 0, which means that the orifice is shifted by the pressure carryover angle from the slot.

### Transition slot angle

The angle covered by a small, triangular-shaped transition slot placed before the major slot to avoid sudden pressure change, as shown in the preceding calculation diagram. To avoid direct connection between the intake and discharge slots, the transition slot angle  $\theta$  must be less than  $\psi - r/R$ . The default value is 0.01 rad.

### Transition slot maximum area

The maximum cross-sectional area of the transition slot. The slot area is assumed to be linearly-dependent on the rotation angle and reaches its maximum when the orifice approaches the major slot. The default value is  $1e-6$  m.

**Flow discharge coefficient**

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.6.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges.

**Leakage area**

The total area of possible leaks in the completely closed orifice. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-9 \text{ m}^2$ .

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the orifice inlet.

B

Hydraulic conserving port associated with the orifice outlet.

G

Physical signal input port that conveys the angular position of the orifice to the block. The signal applied to the port is treated as an angle, in radians, and must be in the range between 0 and  $2\pi$ .

**Examples**

The “Hydraulic Axial-Piston Pump with Load-Sensing and Pressure-Limiting Control” example models a test rig designed to investigate interaction between an axial-piston pump and a typical control unit, simultaneously performing the load-sensing and pressure-limiting functions. To assure required accuracy, the model of the pump must account for such features as interaction between pistons, swash plate, and porting plate, which makes it necessary to build a detailed pump model.

## Positive-Displacement Compressor (2P)

Two-phase fluid positive-displacement compressor in a thermodynamic cycle

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Fluid Machines

### Description

The Positive-Displacement Compressor (2P) block represents a positive-displacement compressor, such as reciprocating piston, rotary screw, rotary vane, and scroll, in a two-phase fluid network. You can control how the block parameterizes a positive displacement compressor by setting **Parameterization** to `Analytical` or `Tabulated`. Port **R** and port **C** are mechanical rotational conserving ports associated with the compressor shaft and casing, respectively. When there is positive rotation at port **R** with respect to port **C**, two-phase fluid flows from port **A** to port **B**. The block may not be accurate for reversed flow.

The block treats the positive displacement process as polytropic such that  $p v^n$  is constant, where  $p$  is pressure,  $v$  is specific volume, and  $n$  is the **Polytropic exponent** parameter. You can use the block to model isentropic processes by setting  $n$  equal to the isentropic exponent,  $k$ . The figure shows the steps of a positive-displacement compressor on a P-V diagram, which has these states:

- $a$  — The compressor cylinder is full at inlet pressure.
- $b$  — The pressure inside the compressor exceeds that of the outlet, which results in fluid discharge.
- $c$  — The compressor reaches the top of the piston stroke, and only the clearance volume remains in the cylinder.
- $d$  — The pressure inside the cylinder drops below the inlet pressure, which results in fluid intake.

### Efficiency

When you set **Volumetric efficiency parameterization** to Analytical, the block calculates the volumetric efficiency as

$$\eta_V = 1 + C - C \left( \frac{P_{out}}{P_{in}} \right)^{1/n},$$

where the block implements the polytropic pressure-volume relationship. The block calculates the clearance volume fraction,  $C$ , as

$$C = \frac{1 - \eta_{V,nominal}}{p_{ratio}^{1/n} - 1},$$

where  $\eta_{V,nominal}$  is the **Nominal volumetric efficiency** parameter, and  $p_{ratio}$  is the ratio of saturation pressures that correspond to **Nominal condensing temperature** and **Nominal evaporating temperature**.

When you set **Volumetric efficiency parameterization** to

Tabulated, the block interpolates the values of the **Volumetric efficiency table**,  $\eta_V(\text{pr}, \omega)$  parameter as a function of the shaft speed and the pressure ratio.

### Continuity Equations

The block calculates the mass flow rate as

$$\dot{m} = \eta_V \omega \frac{V_{disp}}{v_s},$$

where

- $\dot{m}$  is the mass flow rate.
- $\omega$  is the angular velocity of port **R** relative to port **C**.
- $v_s$  is the specific volume at the inlet.
- $V_{disp}$  is the displacement volume that the block uses.

When you set **Displacement specification** to Volumetric displacement, the block uses the **Displacement volume** parameter. When you set **Displacement specification** to Nominal mass flow rate and shaft speed, the block calculates the displacement volume as

$$V_{disp} = \frac{\dot{m}_{nominal} v_{s, nominal}}{\omega_{nominal} \eta_{V, nominal}},$$

where

- $\dot{m}_{nominal}$  is the **Nominal mass flow rate** parameter.
- $\omega_{nominal}$  is the **Nominal shaft speed** parameter.
- $\eta_{V, nominal}$  is the **Nominal volumetric efficiency** parameter.

The block calculates the nominal inlet specific volume,  $v_s$ , based upon the **Nominal conditions specification** parameter. When you select Nominal pressure ratio, the block uses the **Nominal inlet pressure** and **Nominal inlet temperature** parameters. When you select Nominal evaporating and condensing temperatures, the block uses the **Nominal evaporating temperature** and **Nominal evaporator superheat** parameters.

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}_A$  and  $\dot{m}_B$  are the mass flow rates of ports **A** and **B**, respectively. The block conserves energy such that

$$\phi_A + \phi_B + \dot{m}_A \Delta h_t = 0,$$

where  $\Delta h_t$  is the change in specific total enthalpy, and  $\dot{m}_A \Delta h_t$  is the fluid power.

The block equates the fluid power to the polytropic power such that

$$\eta_M \tau = \frac{n}{n-1} \eta_V p_{in} V_{disp} \left[ \left( \frac{p_{out}}{p_{in}} \right)^{\frac{n-1}{n}} - 1 \right],$$

where  $\eta_M$  is the **Mechanical efficiency** parameter, and  $\tau$  is the shaft torque.

### Visualizing the Volumetric Efficiency

To visualize the block volumetric efficiency, right-click the block and select **Fluids > Plot Volumetric Efficiency**.

Each time you modify the block settings, click **Reload Data** on the figure window.

When you set **Volumetric efficiency parameterization** to Analytical, the block plots compressor volumetric efficiency vs. pressure ratio.

Reload Data

#### Analytical Parameterization Default Volumetric Efficiency

When you set **Volumetric efficiency parameterization** to Tabulated, the block plots compressor volumetric efficiency vs. pressure ratio for each entry in the **Shaft speed vector, w**.

Reload Data

### Tabulated Parameterization Default Volumetric Efficiency

#### Assumptions and Limitations

- The block may not be accurate for flow from port **B** to port **A**.
- The block assumes that the flow is quasi-steady: the compressor does not accumulate mass.
- The block is designed to operate in superheated vapor. The block may not be accurate in two-phase mixture or subcooled liquid.

#### Ports

##### Conserving

**A** — Compressor inlet  
two-phase fluid

Two-phase fluid conserving port associated with the compressor inlet.

**B** — Compressor outlet  
two-phase fluid

Two-phase fluid conserving port associated with the compressor outlet.

**C** — Compressor casing  
mechanical rotational

Mechanical rotational conserving port associated with the compressor case.

**R** — Compressor shaft  
mechanical rotational

Mechanical rotational conserving port associated with the compressor shaft.

## Parameters

**Displacement specification** — Option to specify displacement by volume or nominal conditions  
Volumetric displacement (default) | Nominal mass flow rate and shaft speed

Whether to specify the fluid displacement according to volume per cycle or nominal condition values.

**Displacement volume** — Displacement volume  
130 cm<sup>3</sup>/rev (default) | positive scalar

Fluid volume displaced per cycle. The block defines a cycle as one compression stroke and one expansion stroke, which occur during a single crank shaft revolution. This volume is the difference between the maximum cylinder volume and the clearance volume, ( $V_a - V_c$ ). In general, the displacement volume is the volume swept out by the compressor over one shaft revolution.

### Dependencies

To enable this parameter, set **Displacement specification** to Volumetric displacement.

**Nominal conditions specification** — Option to specify pressure ratio or refrigeration cycle saturation temperatures  
Nominal pressure ratio (default) | Nominal evaporating and condensing temperatures

Whether to specify the nominal conditions that determine the displacement volume using the nominal outlet to inlet pressure ratio or the nominal evaporating and condensing temperatures.

### Dependencies

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed.

**Nominal mass flow rate** — Nominal mass flow rate  
0.01 kg/s (default) | positive scalar

Nominal mass flow rate that the block uses to find the displacement volume.

### Dependencies

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed.

**Nominal shaft speed** — Nominal shaft speed  
1000 rpm (default) | positive scalar

Nominal shaft speed that the block uses to find the displacement volume.

**Dependencies**

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed.

**Nominal inlet pressure** — Nominal inlet pressure  
0.101325 MPa (default) | positive scalar

Nominal inlet pressure that the block uses to find the displacement volume.

**Dependencies**

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed and **Nominal conditions specification** to Nominal pressure ratio.

**Nominal inlet temperature** — Nominal inlet temperature  
373.15 K (default) | positive scalar

Nominal inlet temperature that the block uses to find the displacement volume.

**Dependencies**

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed and **Nominal conditions specification** to Nominal pressure ratio.

**Nominal evaporating temperature** — Nominal evaporating temperature  
373.15 K (default) | positive scalar

Nominal evaporating temperature that the block uses to find the displacement volume. This is the saturation temperature in the evaporator. The block assumes the nominal compressor inlet pressure is the pressure that corresponds to this saturation temperature.

The evaporating temperature is also known as the saturated suction temperature, or SST.

**Dependencies**

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed and **Nominal conditions specification** to Nominal evaporating and condensing temperatures.

**Nominal condensing temperature** — Nominal condensing temperature  
398.15 K (default)

Nominal condensing temperature that the block uses to find the displacement volume. This is the saturation temperature in the condenser. The block assumes that the nominal compressor outlet pressure is the pressure that corresponds to this saturation temperature.

The condensing temperature is also known as the saturated discharge temperature, or SDT.

**Dependencies**

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed and **Nominal conditions specification** to Nominal evaporating and condensing temperatures.

**Nominal evaporator superheat** — Nominal saturation excess temperature  
10 deltaK (default) | scalar

Nominal excess temperature beyond the saturation point in the evaporator outlet, which the block assumes to be connected to the compressor inlet.

**Dependencies**

To enable this parameter, set **Nominal conditions specification** to Nominal evaporating and condensing temperatures.

**Volumetric efficiency parameterization** — Option to parameterize volumetric efficiency analytically or using tables

Analytical (default) | Tabulated

Whether to parameterize the displacement volumetric efficiency using analytical equations or tabulated data.

**Nominal volumetric efficiency** — Nominal volumetric efficiency

0.95 (default) | positive scalar

Nominal volumetric efficiency to compute the clearance volume fraction. The nominal volumetric efficiency is the volumetric efficiency when the compressor operates at nominal conditions.

**Dependencies**

To enable this parameter, set **Volumetric efficiency parameterization** to Analytical.

**Nominal pressure ratio** — Nominal pressure ratio

5 (default)

Nominal pressure ratio to compute the clearance volume fraction.

**Dependencies**

To enable this parameter, set **Nominal conditions specification** to Nominal pressure ratio and **Volumetric efficiency parameterization** to Analytical.

**Shaft speed vector,  $w$**  — Shaft speed vector

[800, 1500, 2800, 3300, 4000] rpm (default) | vector of length M

Vector of shaft speeds corresponding to the compressor volumetric efficiency. Each element corresponds to a row of the **Volumetric efficiency table,  $\eta(\mathbf{pr}, \mathbf{w})$**  parameter.

**Dependencies**

To enable this parameter, set **Nominal conditions specification** to Nominal pressure ratio and **Volumetric efficiency parameterization** to Tabulated.

**Pressure ratio vector,  $\mathbf{pr}$**  — Pressure ratio vector

[2, 4, 6, 8] (default) | vector of length N

Vector of pressure ratios corresponding to the compressor volumetric efficiency. Each element corresponds to a column of the **Volumetric efficiency table,  $\eta(\mathbf{pr}, \mathbf{w})$**  parameter.

**Dependencies**

To enable this parameter, set **Nominal conditions specification** to Nominal pressure ratio and **Volumetric efficiency parameterization** to Tabulated.

**Volumetric efficiency table, eta(pr,w)** — Volumetric efficiency

[.95, .9, .85, .8, .75; .925, .875, .825, .775, .725; .875, .825, .775, .725, .675; .75, .7, .65, .6, .55] (default) | M-by-N matrix

Volumetric efficiency for a given shaft speed and pressure ratio.

**Dependencies**

To enable this parameter, set **Nominal conditions specification** to Nominal pressure ratio and **Volumetric efficiency parameterization** to Tabulated.

**Polytropic exponent** — Polytropic exponent

1.2 (default) | positive scalar

Exponent that the block uses when implementing the polytropic pressure-volume relationship.

**Mechanical efficiency** — Compressor mechanical efficiency

0.9 (default) | positive scalar

Ratio of the fluid power to the mechanical shaft power.

**Inlet area at port A** — Inlet area

0.01 m<sup>2</sup> (default) | positive scalar

Inlet area associated with port **A**.

**Outlet area at port B** — Outlet area

0.01 m<sup>2</sup> (default) | positive scalar

Outlet area associated with port **B**.

**Report when fluid is not fully vapor** — Two-phase fluid condition check

None (default) | Warning | Error

Action to perform when the fluid at port **A** does not meet vapor conditions.

## Positive-Displacement Compressor (G)

Positive displacement compressor in a gas network

**Libraries:**

Simscape / Fluids / Gas / Turbomachinery

### Description

The Positive-Displacement Compressor (G) block represents a positive-displacement compressor, such as reciprocating piston, rotary screw, rotary vane, and scroll, in a gas network. You can control how the block parameterizes a positive displacement compressor by setting **Parameterization** to **Analytical** or **Tabulated**. Port **R** and port **C** are mechanical rotational conserving ports associated with the compressor shaft and casing, respectively. When there is positive rotation at port **R** with respect to port **C**, gas flows from port **A** to port **B**. The block may not be accurate for reversed flow.

The block treats the positive displacement process as polytropic such that  $pv^n$  is constant, where  $p$  is pressure,  $v$  is specific volume, and  $n$  is the **Polytropic exponent** parameter. You can use the block to model isentropic processes by setting  $n$  equal to the isentropic exponent,  $k$ . The figure shows the steps of a piston compressor on a P-V diagram, which has these states:

- $a$  — The compressor cylinder is full at inlet pressure.
- $b$  — The pressure inside the compressor exceeds that of the outlet, which results in fluid discharge.
- $c$  — The compressor reaches the top of the piston stroke, and only the clearance volume remains in the cylinder.
- $d$  — The pressure inside the cylinder drops below the inlet pressure, which results in fluid intake.

### Efficiency

When you set **Volumetric efficiency parameterization** to Analytical, the block calculates the volumetric efficiency as

$$\eta_V = 1 + C - C \left( \frac{p_{out}}{p_{in}} \right)^{1/n},$$

where the block implements the polytropic pressure-volume relationship. The block calculates the clearance volume fraction,  $C$ , as

$$C = \frac{1 - \eta_{V,nominal}}{p_{ratio}^{1/n} - 1},$$

where  $\eta_{V,nominal}$  is the **Nominal volumetric efficiency** parameter, and  $p_{ratio}$  is the ratio of saturation pressures that correspond to the **Nominal inlet pressure** and **Nominal inlet temperature** parameters.

When you set **Volumetric efficiency parameterization** to

Tabulated, the block interpolates the values of the **Volumetric efficiency table, eta(pr,w)** parameter as a function of the shaft speed and the pressure ratio.

### Continuity Equations

The block calculates the mass flow rate as

$$\dot{m} = \eta_V \omega \frac{V_{disp}}{v_s},$$

where

- $\dot{m}$  is the mass flow rate.
- $\omega$  is the angular velocity of port **R** relative to port **C**.
- $v_s$  is the specific volume at the inlet.
- $V_{disp}$  is the displacement volume that the block uses.

When you set **Displacement specification** to `Volumetric displacement`, the block uses the **Displacement volume** parameter. When you set **Displacement specification** to `Nominal mass flow rate and shaft speed`, the block calculates the displacement volume as

$$V_{disp} = \frac{\dot{m}_{nominal} v_{s,nominal}}{\omega_{nominal} \eta_{V,nominal}},$$

where

- $\dot{m}_{nominal}$  is the **Nominal mass flow rate** parameter.
- $\omega_{nominal}$  is the **Nominal shaft speed** parameter.
- $\eta_{V,nominal}$  is the **Nominal volumetric efficiency** parameter.

The block calculates the nominal inlet specific volume,  $v_s$ , based upon the **Nominal conditions specification** parameter. When you select `Nominal pressure ratio`, the block uses the **Nominal inlet pressure** and **Nominal inlet temperature** parameters.

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}_A$  and  $\dot{m}_B$  are the mass flow rates of ports **A** and **B**, respectively. The block conserves energy such that

$$\phi_A + \phi_B + \dot{m}_A \Delta h_t = 0,$$

where  $\Delta h_t$  is the change in specific total enthalpy, and  $\dot{m}_A \Delta h_t$  is the fluid power.

The block equates the fluid power to the polytropic power such that

$$\eta_M \tau = \frac{n}{n-1} \eta_V p_{in} V_{disp} \left[ \left( \frac{p_{out}}{p_{in}} \right)^{\frac{n-1}{n}} - 1 \right],$$

where  $\eta_M$  is the **Mechanical efficiency** parameter, and  $\tau$  is the shaft torque.

## Parameters

**Displacement specification** — Option to specify displacement by volume or nominal conditions  
Volumetric displacement (default) | Nominal mass flow rate and shaft speed

Whether to specify the fluid displacement according to volume per cycle or nominal condition values.

**Displacement volume** — Displacement volume  
130 cm<sup>3</sup>/rev (default) | positive scalar

Fluid volume displaced per cycle. The block defines a cycle as one compression stroke and one expansion stroke, which occur during a single crank shaft revolution. This volume is the difference between the maximum cylinder volume and the clearance volume, ( $V_a - V_c$ ). In general, the displacement volume is the volume swept out by the compressor over one shaft revolution.

### Dependencies

To enable this parameter, set **Displacement specification** to Volumetric displacement.

**Nominal mass flow rate** — Nominal mass flow rate  
0.01 kg/s (default) | positive scalar

Nominal mass flow rate that the block uses to find the displacement volume.

### Dependencies

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed.

**Nominal shaft speed** — Nominal shaft speed  
1000 rpm (default) | positive scalar

Nominal shaft speed that the block uses to find the displacement volume.

### Dependencies

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed.

**Nominal inlet pressure** — Nominal inlet pressure  
0.101325 MPa (default) | positive scalar

Nominal inlet pressure that the block uses the find the displacement volume.

**Dependencies**

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed.

**Nominal inlet temperature** — Nominal inlet temperature  
293.15 K (default) | positive scalar

Nominal inlet temperature that the block uses to find the displacement volume.

**Dependencies**

To enable this parameter, set **Displacement specification** to Nominal mass flow rate and shaft speed.

**Volumetric efficiency parameterization** — Option to parameterize volumetric efficiency analytically or using tables  
Analytical (default) | Tabulated

Whether to parameterize the displacement volumetric efficiency using analytical equations or tabulated data.

**Nominal volumetric efficiency** — Nominal volumetric efficiency  
0.95 (default) | positive scalar

Nominal volumetric efficiency to compute the clearance volume fraction. The nominal volumetric efficiency is the volumetric efficiency when the compressor operates at nominal conditions.

**Dependencies**

To enable this parameter, set **Volumetric efficiency parameterization** to Analytical.

**Nominal pressure ratio** — Nominal pressure ratio  
5 (default) | positive scalar

Nominal pressure ratio to compute the clearance volume fraction.

**Dependencies**

To enable this parameter, set **Nominal conditions specification** to Nominal pressure ratio and **Volumetric efficiency parameterization** to Analytical.

**Pressure ratio vector, pr** — Pressure ratio vector  
[2, 4, 6, 8] (default) | vector of length N

Vector of pressure ratios corresponding to the compressor volumetric efficiency. Each element corresponds to a column of the **Volumetric efficiency table, eta(pr,w)** parameter.

**Dependencies**

To enable this parameter, set **Volumetric efficiency parameterization** to Tabulated.

**Shaft speed vector, w** — Shaft speed vector  
[800, 1500, 2800, 3300, 4000] rpm (default) | vector of length M

Vector of shaft speeds corresponding to the compressor volumetric efficiency. Each element corresponds to a row of the **Volumetric efficiency table, eta(pr,w)** parameter.

**Dependencies**

To enable this parameter, set **Volumetric efficiency parameterization** to Tabulated.

**Volumetric efficiency table, eta(pr,w)** — Volumetric efficiency

[.95, .9, .85, .8, .75; .925, .875, .825, .775, .725; .875, .825, .775, .725, .675; .75, .7, .65, .6, .55] (default) | M-by-N matrix

Volumetric efficiency for a given shaft speed and pressure ratio.

**Dependencies**

To enable this parameter, set **Volumetric efficiency parameterization** to Tabulated.

**Polytropic exponent** — Polytropic exponent

1.2 (default) | positive scalar

Exponent that the block uses when implementing the polytropic pressure-volume relationship.

**Mechanical efficiency** — Compressor mechanical efficiency

0.9 (default) | positive scalar

Ratio of the fluid power to the mechanical shaft power.

**Inlet area at port A** — Inlet area

0.01 m<sup>2</sup> (default) | positive scalar

Inlet area associated with port **A**.

**Outlet area at port B** — Outlet area

0.01 m<sup>2</sup> (default) | positive scalar

Outlet area associated with port **B**.

## Library

Flow Control Valves

## Description

The Pressure-Compensated 3-Way Flow Control Valve block represents a 3-way pressure-compensated flow control valve as a data-sheet-based model. The valve model includes a variable orifice and a normally closed pressure-control valve, connected in parallel with the orifice. The purpose of the pressure-control valve is to maintain a preset pressure differential across the orifice by diverting some flow from port A to the tank (port R) if the pressure differential exceeds the preset value. Port C controls the orifice opening, as shown in the following figure.

Depending on data listed in the manufacturer's catalogs or data sheets for your particular valve, you can choose one of the following model parameterization options:

- **By maximum area and opening** — Use this option if the data sheet provides only the orifice maximum area and the control member maximum stroke.
- **By area vs. opening table** — Use this option if the catalog or data sheet provides a table of the orifice passage area based on the control member displacement  $A=A(h)$ .

In the first case, the passage area is assumed to be linearly dependent on the control member displacement, that is, the orifice is assumed to be closed if the initial orifice opening is set to zero and the control member position also equals zero. The maximum orifice opening takes place at the maximum displacement. In the second case, the passage area is determined by one-dimensional interpolation from the table  $A=A(h)$ .

The pressure-control valve representation does not account for inertia, friction, or hydraulic forces. The valve has the following area-pressure differential relationship:

$$A_{pc} = \begin{cases} A_{leak} & \text{for } p < p_{set} \\ (p - p_{set}) \frac{A_{max\_pc}}{p_{reg}} & \text{for } p_{set} \leq p \leq (p_{set} + p_{reg}) \\ A_{max\_pc} & \text{for } p > (p_{set} + p_{reg}) \end{cases}$$

where

$A_{pc}$	Pressure-control valve passage area
$p$	Pressure differential across the orifice
$p_{set}$	Preset pressure differential
$p_{reg}$	Regulation range
$A_{max\_pc}$	Pressure-control valve maximum area
$A_{leak}$	Closed orifice leakage area for pressure compensator

Both for the variable orifice and the pressure compensator, a small leakage area is assumed to exist even after the orifice is completely closed. Physically, it represents a possible clearance in the closed valve, but the main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. An isolated or “hanging” part of the system could affect computational efficiency and even cause failure of computation.

After the area has been determined, the block computes the flow rate for both the orifice and the pressure compensator according to the following equations:

$$q = C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

$$A = \begin{cases} A_{pc} & \text{for pressure compensator} \\ A_{or} & \text{for variable orifice} \end{cases}$$

$$A_{pc} = \begin{cases} h \cdot A_{max}/h_{max} + A_{leak} & \text{for } h > 0 \\ A_{leak} & \text{for } h < = 0 \end{cases}$$

$$h = x_0 + x$$

$$p = \begin{cases} p_A - p_R & \text{for pressure compensator} \\ p_A - p_B & \text{for variable orifice} \end{cases}$$

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B, p_R$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A$	Instantaneous orifice passage area
$A_{max}$	Orifice maximum area
$A_{leak}$	Closed orifice leakage area
$h_{max}$	Control member maximum displacement
$x_0$	Initial opening
$x$	Control member displacement from initial position
$h$	Orifice opening
$\rho$	Fluid density
$\nu$	Fluid kinematic viscosity
$p_{cr}$	Minimum pressure for turbulent flow
$Re_{cr}$	Critical Reynolds number
$D_H$	Instantaneous orifice hydraulic diameter

Connections A, B, and R are the conserving hydraulic ports associated with the valve inlet, outlet, and return, respectively. Connection C is a physical signal port through which the orifice opening is controlled. The block positive direction is from port A to port B. Positive signal at port C opens the valve.

## Assumptions and Limitations

Fluid inertia and pressure compensator loading are not taken into account.

## Parameters

- “Variable Orifice Tab” on page 1-1486
- “Pressure Compensator Tab” on page 1-1488

### Variable Orifice Tab

#### Orifice parameterization

Select one of the following methods for specifying the orifice:

- **By maximum opening and area** — Provide values for the maximum orifice area and the maximum orifice opening. The passage area is linearly dependent on the control member displacement, that is, the orifice is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By orifice area vs. orifice opening table** — Provide tabulated data of orifice openings and corresponding orifice areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

### **Orifice maximum area**

The area of a fully opened orifice. The parameter value must be greater than zero. The default value is  $1e-4 \text{ m}^2$ . This parameter is used if **Orifice parameterization** is set to **By maximum opening and area**.

### **Orifice maximum opening**

The maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $0.005 \text{ m}$ . This parameter is used if **Orifice parameterization** is set to **By maximum opening and area**.

### **Tabulated orifice openings**

Vector of input values for orifice openings, specified as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in mm, are [-6, 0, 1, 3, 6, 9, 15]. This parameter is used if **Orifice parameterization** is set to **By orifice area vs. orifice opening table**. **Tabulated orifice openings** values will be used together with **Tabulated orifice area** values for one-dimensional table lookup.

### **Tabulated orifice area**

Vector of orifice areas, specified as a one-dimensional array. The vector must be the same size as the orifice openings vector. All the values must be positive. The default values, in  $\text{cm}^2$ , are [ $1e-7$ ,  $1e-6$ , 0.08, 0.145, 0.96, 1, 1.001]. This parameter is used if **Orifice parameterization** is set to **By orifice area vs. orifice opening table**.

### **Interpolation method**

This parameter is used if **Orifice parameterization** is set to **By orifice area vs. orifice opening table**. Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) block reference page.

### **Extrapolation method**

This parameter is used if **Orifice parameterization** is set to **By orifice area vs. orifice opening table**. Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.

- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) block reference page.

### **Orifice initial opening**

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or 0 for zero-lap configuration. The default value is 0.

### **Orifice flow discharge coefficient**

Semi-empirical coefficient that is used in the computation of flow rate through the orifice. Its value depends on the geometrical properties of the orifice and usually is provided in textbooks or manufacturer data sheets. The default value is 0.6.

### **Orifice laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Orifice laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Orifice critical Reynolds number** parameter.

### **Orifice laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Orifice laminar transition specification** parameter is set to **Pressure ratio**.

### **Orifice critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12. This parameter is visible only if the **Orifice laminar transition specification** parameter is set to **Reynolds number**.

### **Orifice leakage area**

The total area of possible leaks in the completely closed orifice. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-9 \text{ m}^2$ .

## **Pressure Compensator Tab**

### **Pressure differential across orifice setting**

Pressure difference that must be maintained across the variable orifice by the pressure compensator. The default value is 6e5 Pa.

### **Pressure differential regulation range**

Pressure increase over the preset level needed to fully open the pressure compensator orifice. The lower the value of the range, the higher the valve sensitivity. The default value is 0.5e5 Pa.

### **Pressure compensator maximum area**

The area of a fully opened pressure compensator. The parameter value must be greater than zero. The default value is  $1e-4 \text{ m}^2$ .

**Pressure compensator flow discharge coefficient**

Semi-empirical coefficient that is used in the computation of flow rate through the pressure compensator. The default value is 0.6.

**Pressure compensator laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Pressure compensator laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Pressure compensator critical Reynolds number** parameter.

**Pressure compensator laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Pressure compensator laminar transition specification** parameter is set to **Pressure ratio**.

**Pressure compensator critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12. This parameter is visible only if the **Pressure compensator laminar transition specification** parameter is set to **Reynolds number**.

**Pressure compensator leakage area**

The total area of possible leaks in the completely closed orifice. Must be greater than 0. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The default value is  $1e-9$  m<sup>2</sup>.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Model parameterization**
- **Interpolation method**
- **Extrapolation method**
- **Orifice laminar transition specification**
- **Pressure compensator laminar transition specification**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Model parameterization** parameter at the time the model entered Restricted mode.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

R

Hydraulic conserving port that connects with the tank.

C

Physical signal control port.

## Version History

### Introduced in R2013b

#### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Extended Capabilities

Pressure-Compensated Flow Control Valve

# Pressure-Compensated 3-Way Flow Control Valve (IL)

3-way flow control in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Flow Control Valves

## Description

The Pressure-Compensated 3-Way Flow Control Valve (IL) block models constant-pressure flow control. When the control pressure,  $p_A - p_B$ , meets or exceeds the **Set orifice pressure differential**, the relief component of the underlying compensator valve opens to maintain the pressure in the block.

The flow control valve opening and closing is controlled by a physical signal received at port **S**, which determines the area of the underlying orifice block. A positive signal opens the valve. Port **R** vents liquid to another part of your network.

For pressure-compensated flow control without venting, see the Pressure-Compensated Flow Control Valve (IL) block.

## Orifice Parameterization

You can choose the valve model with the **Orifice parameterization** setting:

- **Linear - area vs. control member position** is an analytical formulation that assumes the valve opening area and the valve control member are related linearly.
- **Tabulated data - Area vs. control member position** is a user-supplied data sheet that relates orifice opening area and the control member position. The block queries between data points with linear interpolation and uses nearest extrapolation for points beyond the table boundaries.
- **Tabulated data - Volumetric flow rate vs. control member position and pressure drop** is a user-supplied data sheet that relates the control member position, orifice pressure drop, and orifice volumetric flow rate. The block queries between data points with linear interpolation and uses a nearest extrapolation for points beyond the table boundaries.

## Numerically-Smoothed Area and Pressure

When the orifice parameterization is linear, you can maintain numerical robustness at the extremes of the orifice area and valve pressure range by tuning the **Smoothing factor** parameter to a nonzero value less than 1. If the **Smoothing factor** parameter is nonzero, the block applies a smoothing function to all calculated areas and pressures, but it primarily influences the simulation at the extremes of these ranges.

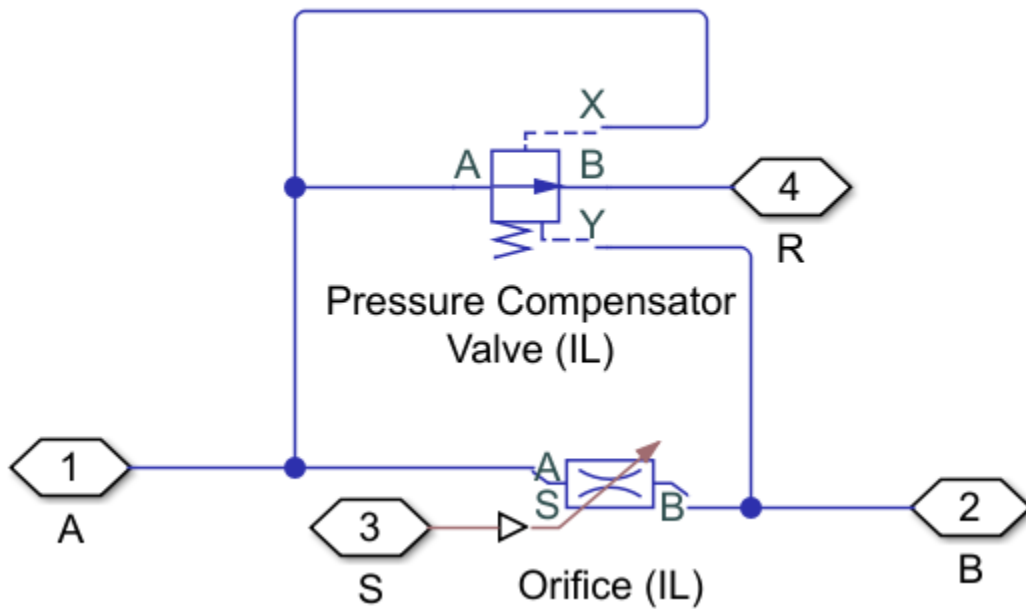

If you enable smoothing, the block smoothly saturates the orifice area between the **Leakage area** and **Maximum orifice area** parameters. The block smoothly saturates the valve pressure between

the **Set orifice pressure differential** parameter and the sum of the **Set orifice pressure differential** and the **Pressure compensator valve regulation range** parameters.

For more information, see “Numerical Smoothing”.

**Block Schematic**

**Three-Way Flow Control Valve Schematic**

**Ports**

**Conserving**

**A** — Valve liquid port  
isothermal liquid

Liquid entry or exit port to the three-way valve.

**B** — Orifice liquid port  
isothermal liquid

Liquid entry or exit port to the orifice.

**R** — Reducing valve liquid port  
isothermal liquid

Liquid exit port from the reducing valve.

## Input

**S** — Physical signal, in m  
physical signal

Orifice opening in m, set as a physical signal.

## Parameters

**Orifice parameterization** — Method of modeling orifice opening

Linear - area vs. control member position (default) | Tabulated data - Area vs. control member position | Tabulated data - Volumetric flow rate vs. control member position and pressure drop

Method of modeling the opening of the orifice. The opening is either parametrized linearly, which correlates the opening area to the control member position; by user-supplied data that correlate the orifice opening area to the control member position; or by an array of data that correlates the valve flow rate to the control member position and valve pressure drop.

**Control member position at closed orifice** — Control member offset

0 m (default) | scalar

Control member offset when the orifice is fully open. A positive, nonzero value indicates a partially closed orifice. A negative, nonzero value indicates an overlapped orifice that remains open for an initial displacement set by the physical signal at port **S**.

**Control member travel between closed and opened orifice** — Maximum control member stroke

5e-3 m (default) | positive scalar

Control member stroke that fully opens the orifice.

### Dependencies

To enable this parameter, set **Orifice parameterization** to Linear - area vs. control member position.

**Maximum orifice area** — Maximum orifice cross-sectional area

8e-5 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice in its fully open position. This parameter is used as an upper limit for area-pressure calculations during the simulation.

### Dependencies

To enable this parameter, set **Orifice parameterization** to Linear - area vs. control member position.

**Control member position vector** — Vector of opening position

[0, .002, .007] m (default) | 1-by-*n* vector

Vector of orifice opening distances for the tabular parameterization of the orifice opening area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The elements are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Orifice area vector** — Vector of opening areas

[1e-09, 4e-09, 1e-05] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of valve opening areas for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Control member position vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Control member position vector, s** — Vector of control member positions

[0, .002, .004, .007, .017] m (default) | 1-by-*n* vector

Vector of control member positions for the tabular parameterization of the volumetric flow rate. The control member position vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 3-D dependent **Volumetric flow rate table, q(s,dp)** parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Pressure drop vector, dp** — Vector of pressure differential values

[.3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of valve opening areas for the tabular parameterization of the valve opening area. The pressure drop vector forms an independent axis with the **Control member position vector, s** parameter for the 3-D dependent **Volumetric flow rate table, q(s,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Volumetric flow rate table, q(s,dp)** — Array of volumetric flow rate values

[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13] .\* 1e-3 m<sup>3</sup>/s (default) | *M*-by-*N* array

Array of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **Pressure drop vector, dp** parameter.
- *N* is the number of elements in the **Control member position vector, s** parameter.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Set orifice pressure differential** — Threshold for compensator valve operation

0.6 MPa (default) | positive scalar

Magnitude of pressure differential that triggers valve opening or closing.

**Pressure compensator valve regulation range** — Area of the fully opened pressure compensator valve

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the valve in its fully open position. This parameter is used as an upper limit for area-pressure calculations during the simulation.

**Pressure compensator valve maximum area** — Pressure operational region of the pressure compensating valve

0.1 MPa (default) | scalar

Operational pressure range of the valve. The pressure regulation range lies between the **Set orifice pressure differential** and the maximum valve operating pressure.

**Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is maintained at the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

## Library

Flow Control Valves

## Description

The Pressure-Compensated Flow Control Valve block represents a pressure-compensated flow control valve as a data-sheet-based model. This flow control valve is composed of a Pressure Compensator valve block and a Variable Orifice block.

Depending on data listed in the manufacturer's catalogs or data sheets for your particular valve, you can choose one of the following model parameterization options:

- By maximum area and opening — Use this option if the data sheet provides only the orifice maximum area and the control member maximum stroke.
- By area vs. opening table — Use this option if the catalog or data sheet provides a table of the orifice passage area based on the control member displacement  $A=A(h)$ .

In the first case, the passage area is assumed to be linearly dependent on the control member displacement, that is, the orifice is assumed to be closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement.

The *valve maximum area* is 1.5x the maximum area of the orifice. This is the **Orifice maximum area** if the parameterization is **By maximum area and opening**, or the final element of the **Tabulated orifice area** if the parameterization is **By area vs. opening table**.

In the second case, the passage area is determined by one-dimensional interpolation from the table  $A=A(h)$ . In both cases, a small leakage area is assumed to exist even after the orifice is completely closed. Physically, it represents a possible clearance in the closed valve, but the main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. An isolated or “hanging” part of the system could affect computational efficiency and even cause failure of computation.

The block positive direction is from port **A** to port **B**. This means that the flow rate is positive if it flows from **A** to **B**, and the pressure differential is determined as  $\Delta p = p_A - p_B$ . A positive signal at port **C** opens the valve.

## Assumptions and Limitations

Fluid inertia is not taken into account.

## Parameters

### Model parameterization

Select one of the following methods for specifying the orifice:

- **By maximum area and opening** — Provide values for the maximum orifice area and the maximum orifice opening. The passage area is linearly dependent on the control member displacement, that is, the orifice is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of orifice openings and corresponding orifice areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

### Orifice maximum area

Specify the area of a fully opened orifice. The parameter value must be greater than zero. The *valve maximum area* is 1.5x the **Orifice maximum area**. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

### Orifice maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-4 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

### Tabulated orifice openings

Specify the vector of input values for orifice openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters,

are  $[-2e-3, 0, 5e-3, 15e-3]$ . This parameter is used if **Model parameterization** is set to By area vs. opening table. **Tabulated orifice openings** values will be used together with **Tabulated orifice area** values for one-dimensional table lookup.

#### **Tabulated orifice area**

Specify the vector of orifice areas as a one-dimensional array. The vector must be of the same size as the orifice openings vector. All the values must be positive. The *valve maximum area* is 1.5x the last element of the **Tabulated orifice area**. The default values, in  $m^2$ , are  $[1e-12, 4e-12, 1.e-5, 1.02e-5]$ . This parameter is used if **Model parameterization** is set to By area vs. opening table.

#### **Interpolation method**

This parameter is used if **Model parameterization** is set to By area vs. opening table. Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) block reference page.

#### **Extrapolation method**

This parameter is used if **Model parameterization** is set to By area vs. opening table. Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) block reference page.

#### **Pressure differential across the orifice**

Pressure difference that must be maintained across the element by the pressure compensator. The default value is  $6e5$  Pa.

#### **Pressure reducing valve regulation range**

Pressure increase over the preset level needed to fully close the valve. Must be less than 0.2 of the **Pressure differential across the orifice** parameter value. The default value is  $5e4$  Pa.

#### **Flow discharge coefficient**

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.7$ .

#### **Initial opening**

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The value of initial opening does not depend on the orifice orientation. The default value is  $0$ .

#### **Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

### **Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Model parameterization**
- **Interpolation method**
- **Extrapolation method**
- **Laminar transition specification**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Model parameterization** parameter at the time the model entered Restricted mode.

### **Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

### **Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

C

Physical signal control port.

## Version History

### Introduced in R2006a

#### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

## Pressure-Compensated Flow Control Valve (IL)

Flow control with pressure regulation in an isothermal liquid system

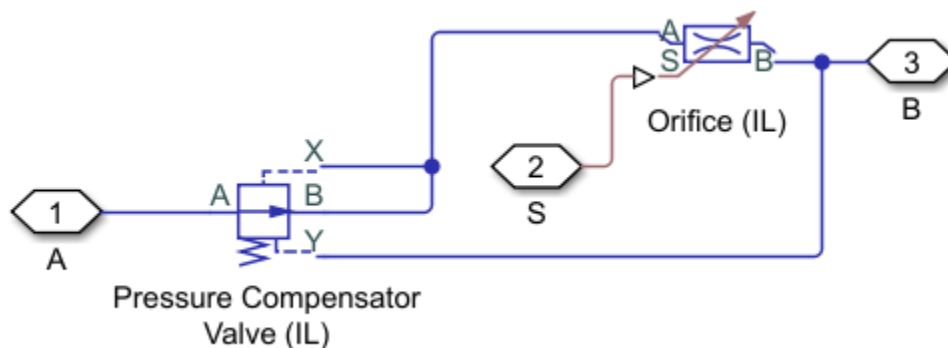

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Flow Control Valves

### Description

The Pressure-Compensated Flow Control Valve (IL) block provides constant-pressure flow control through an Orifice (IL) block via a Pressure Compensator Valve (IL) connected in series. When the control pressure over the orifice,  $p_A - p_B$ , meets or exceeds the **Set orifice pressure differential**, the reducing valve in the pressure compensator component begins to close, which maintains the pressure in the orifice. For systems with venting or redirection of fluid to another part of the system, see the Pressure-Compensated 3-Way Flow Control Valve (IL) block.

The valve opening and closing is controlled by a physical signal received at port **S**. A positive signal opens the valve.

### Flow Control Valve Schematic

#### Numerically-Smoothed Area and Pressure

When the orifice parameterization is linear, you can maintain numerical robustness at the extremes of the orifice area and valve pressure range by tuning the **Smoothing factor** parameter to a nonzero value less than 1. If the **Smoothing factor** parameter is nonzero, the block applies a smoothing function to all calculated areas and pressures, but it primarily influences the simulation at the extremes of these ranges.

If you enable smoothing, the block smoothly saturates the orifice area between the **Leakage area** and **Maximum orifice area** parameters and applies a smoothing function. The block smoothly saturates the valve pressure between the **Set orifice pressure differential** parameter and the sum of the **Set orifice pressure differential** and the **Pressure compensator valve regulation range** parameters.

For more information, see “Numerical Smoothing”.

### Orifice Parameterization

Setting **Orifice parameterization** to:

- **Linear - area vs. control member position** assumes that the spool position and the orifice opening area are related linearly.
- **Tabulated data - Area vs. control member position** interpolates user-provided data between the orifice opening area and the control member position with a potentially nonlinear relationship.
- **Tabulated data - Volumetric flow rate vs. control member position and pressure drop** interpolates the orifice volumetric flow rate directly from user-provided data between the control member position, orifice pressure drop, and orifice volumetric flow rate.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit point to the valve.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit point to the valve.

### Input

**S** — Physical signal, in m  
physical signal

Orifice opening in m, returned as a physical signal. A positive signal opens the orifice.

## Parameters

**Orifice parameterization** — Method of modeling orifice opening

Linear - area vs. control member position (default) | Tabulated data - Area vs. control member position | Tabulated data - Volumetric flow rate vs. control member position and pressure drop

Method of modeling the opening of the orifice. The opening is either parametrized linearly, which correlates the opening area to the control member position; by user-supplied data that correlate the orifice opening area to the control member position; or by an array of data that correlates the valve flow rate to the control member position and valve pressure drop.

**Control member travel between closed and open valve** — Maximum control member stroke  
5e-3 m (default) | positive scalar

Control member stroke that fully opens the orifice.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Linear - area vs. control member travel.

**Maximum orifice area** — Maximum orifice cross-sectional area  
8e-5 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice in its fully open position. This parameter is used as an upper limit for area-pressure calculations during the simulation.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Linear - area vs. control member travel.

**Control member position at closed valve** — Control member offset  
0 m (default) | positive scalar

Control member offset when the orifice is fully open. A positive, nonzero value indicates a partially closed orifice. A negative, nonzero value indicates an overlapped orifice that remains open for an initial displacement set by the physical signal at port **S**.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Linear - area vs. control member travel.

**Control member position vector** — Vector of control member travel distances  
[0, .002, .007] (default) | 1-by-*n* vector

Vector of orifice opening distances for the tabular parameterization of the orifice opening area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The elements are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Orifice area vector** — Vector of opening areas  
[1e-09, 4e-09, 1e-05] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of valve opening areas for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Control member position vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Control member position vector, s** — Vector of control member displacements  
[0, .002, .004, .007, .017] m (default) | 1-by-*n* vector

Vector of control member positions for the tabular parameterization of the volumetric flow rate. The control member position vector forms an independent axis with the **Pressure drop vector, dp**

parameter for the 3-D dependent **Volumetric flow rate table,  $q(s,dp)$**  parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Pressure drop vector,  $dp$**  — Vector of pressure differential values

[.3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of valve opening areas for the tabular parameterization of the valve opening area. The pressure drop vector forms an independent axis with the **Control member position vector,  $s$**  parameter for the 3-D dependent **Volumetric flow rate table,  $q(s,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Volumetric flow rate table,  $q(s,dp)$**  — Array of volumetric flow rate values

[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13]  $\cdot 1e-3$  m<sup>3</sup>/s (default) |  $M$ -by- $N$  array

Array of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of elements in the **Control member position vector,  $s$**  parameter.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Set orifice pressure differential** — Threshold for compensator valve operation

0.6 MPa (default) | scalar

Magnitude of pressure differential that triggers valve opening or closing.

**Pressure compensator valve regulation range** — Pressure operational region of the pressure compensating valve

0.1 MPa (default) | scalar

Operational pressure range of the valve. The pressure regulation range lies between the **Set orifice pressure differential** and the maximum valve operating pressure.

**Pressure compensator valve maximum area** — Area of the fully opened pressure compensator valve

$1.5 \cdot 8e-5$  m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the valve in its fully open position. This parameter is used as an upper limit for area-pressure calculations during the simulation.

**Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is maintained at the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

# Pressure Compensator

(To be removed) Valve used to regulate the pressure drop across a hydraulic component

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Pressure Control Valves

## Description

The Pressure Compensator block models the flow through a valve that constricts so as to maintain a preset pressure drop between a chosen two hydraulic nodes. The valve has four hydraulic ports, two being flow passages (the inlet, **A**, and the outlet, **B**) and two pressure sensors (**X** and **Y**). The normally open valve contracts when the pressure drop from **X** to **Y** rises above the valve pressure setting. The drop in opening area is a function of the pressure drop—proportional to it in a linear parameterization (the block default) or a general function of it in a tabulated parameterization. The valve serves its purpose until it hits the limit of its pressure regulation range—a point at which the valve is fully closed and the pressure drop can again rise unabated.

## Valve Opening

The opening area calculation depends on the valve parameterization selected for the block: either Linear area-opening relationship or Tabulated data - Area vs. pressure.

### Linear Parameterization

If the **Valve parameterization** block parameter is in the default setting of Linear area-opening relationship, the opening area is computed as:

$$S(\Delta p_{XY}) = S_{\text{Max}} - k(\Delta p_{XY} - \Delta p_{\text{Set}}),$$

where:

- $S_{\text{Max}}$  is the value specified in the **Maximum passage area** block parameter.
- $\Delta p_{\text{Set}}$  is the value specified in the **Valve pressure setting** block parameter.
- $\Delta p_{XY}$  is the pressure drop from port **X** to port **Y**:

$$\Delta p_{XY} = p_X - p_Y,$$

where  $p$  is the gauge pressure at the port indicated by the subscript (**X** or **Y**).

- $k$  is the linear constant of proportionality:

$$k = \frac{S_{\text{Max}} - S_{\text{Leak}}}{\Delta p_{\text{Reg}}},$$

where in turn:

- $S_{\text{Leak}}$  is the value specified in the **Leakage area** block parameter.
- $\Delta p_{\text{Reg}}$  is that specified in the **Valve regulation range** block parameter.

At and below the valve pressure setting, the opening area is that of a fully open valve:

$$S(\Delta p_{XY} \leq \Delta p_{\text{Set}}) = S_{\text{Max}}.$$

At and above a maximum pressure, the opening area is that due to internal leakage alone:

$$S(\Delta p \geq \Delta p_{\text{Max}}) = S_{\text{Leak}}$$

where the maximum pressure drop  $\Delta p_{\text{Max}}$  is the sum:

$$\Delta p_{\text{Max}} = \Delta p_{\text{Set}} + \Delta p_{\text{Reg}}.$$

### Opening area in the Linear area-opening relationship parameterization

#### Tabulated Parameterization

If the **Valve parameterization** block parameter is set to Tabulated data - Area vs. pressure, the opening area is computed as:

$$S = S(\Delta p_{XY}),$$

where  $S_{XY}$  is a tabulated function constructed from the **Pressure drop vector** and **Opening area vector** block parameters. The function is based on linear interpolation (for points within the data range) and nearest-neighbor extrapolation (for points outside the data range). The leakage and maximum opening areas are the minimum and maximum values of the **Valve opening area vector** block parameter.

## Opening area in the Tabulated data - Area vs. pressure parameterization

### Opening Dynamics

By default, the valve opening dynamics are ignored. The valve is assumed to respond instantaneously to changes in the pressure drop, without time lag between the onset of a pressure disturbance and the increased valve opening that the disturbance produces. If such time lags are of consequence in a model, you can capture them by setting the **Opening dynamics** block parameter to `Include valve opening dynamics`. The valves then open each at a rate given by the expression:

$$\dot{S} = \frac{S(\Delta p_{SS}) - S(\Delta p_{In})}{\tau},$$

where  $\tau$  is a measure of the time needed for the instantaneous opening area (subscript In) to reach a new steady-state value (subscript SS).

### Leakage Area

The primary purpose of the leakage area of a closed valve is to ensure that at no time does a portion of the hydraulic network become isolated from the remainder of the model. Such isolated portions reduce the numerical robustness of the model and can slow down simulation or cause it to fail. Leakage is generally present in minuscule amounts in real valves but in a model its exact value is less important than it being a small number greater than zero. The leakage area is obtained from the block parameter of the same name.

### Valve Flow Rate

The causes of the pressure losses incurred in the passages of the valve are ignored in the block. Whatever their natures—sudden area changes, flow passage contortions—only their cumulative effect is considered during simulation. This effect is captured in the block by the discharge coefficient, a measure of the flow rate through the valve relative to the theoretical value that it would have in an ideal valve. The flow rate through the valve is defined as:

$$q = C_D S \sqrt{\frac{2}{\rho} \frac{\Delta p_{AB}}{[(\Delta p_{AB})^2 + p_{Crit}^2]^{1/4}}},$$

where:

- $q$  is the volumetric flow rate through the valve.
- $C_D$  is the value of the **Flow discharge coefficient** block parameter.

- $S$  is the opening area of the valve.
- $\Delta p_{AB}$  is the pressure drop from port **A** to port **B**.
- $p_{\text{Crit}}$  is the pressure differential at which the flow shifts between the laminar and turbulent flow regimes.

The calculation of the critical pressure depends on the setting of the **Laminar transition specification** block parameter. If this parameter is in the default setting of By pressure ratio:

$$p_{\text{Crit}} = (p_{\text{Atm}} + p_{\text{Avg}})(1 - \beta_{\text{Crit}}),$$

where:

- $p_{\text{Atm}}$  is the atmospheric pressure (as defined for the corresponding hydraulic network).
- $p_{\text{Avg}}$  is the average of the gauge pressures at ports **A** and **B**.
- $\beta_{\text{Crit}}$  is the value of the **Laminar flow pressure ratio** block parameter.

If the **Laminar transition specification** block parameter is instead set to By Reynolds number:

$$p_{\text{Crit}} = \frac{\rho}{2} \left( \frac{Re_{\text{Crit}} \nu}{C_D D_H} \right)^2,$$

where:

- $Re_{\text{Crit}}$  is the value of the **Critical Reynolds number** block parameter.
- $\nu$  is the kinematic viscosity specified for the hydraulic network.
- $D_H$  is the instantaneous hydraulic diameter:

$$D_H = \sqrt{\frac{4S}{\pi}}.$$

## Ports

### Conserving

**A** — Valve inlet

hydraulic (isothermal liquid)

Opening through which the flow can enter the valve.

**B** — Valve outlet

hydraulic (isothermal liquid)

Opening through which the flow can exit the valve.

**X** — Pressure sensor

hydraulic (isothermal liquid)

Port at which pressure is measured for the purpose of setting the valve opening area.

**Y** — Pressure sensor

hydraulic (isothermal liquid)

Port at which pressure is measured for the purpose of setting the valve opening area.

## Parameters

**Opening area parameterization** — Method by which to calculate the opening area of the valve  
 Linear area-opening relationship (default) | Tabulated data - Area vs. pressure

Method by which to calculate the opening area of the valve. The default setting prescribes a linear relationship between the opening area of the valve and the pressure drop between its sensor ports. The alternative setting allows for a general, nonlinear relationship to be specified in tabulated form.

**Maximum passage area** — Opening area of the valve in the fully open position  
 $1e-4 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of the valve in the fully open position. The valve is fully open if the pressure drop from port **X** to port **Y** is less than the value specified in the **Valve pressure setting** block parameter.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve pressure setting** — Pressure drop to maintain from port X to port Y  
 $30e5 \text{ Pa}$  (default) | positive scalar in units of pressure

Pressure drop from port **X** to port **Y** that the valve is to maintain. The valve closes in proportion to the pressure drop if it should exceed the value specified here. If the pressure drop is less than this value, the opening area is that specified in the **Maximum passage area** block parameter.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve regulation range** — Pressure drop interval over which the valve is to designed to operate  
 $1.5e5 \text{ Pa}$  (default) | positive scalar in units of pressure

Pressure drop interval over which the valve is designed to operate. This interval stretches from the largest pressure drop at which the valve is fully open to the lowest pressure drop at which the valve is fully closed. Only within this range is the valve capable of maintaining the specified pressure setting.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Flow discharge coefficient** — Empirical factor defined as the ratio of actual to ideal mass flow rates  
 $0.7$  (default) | positive unitless scalar

Ratio of the actual flow rate through the valve to the theoretical value that it would have in an ideal valve. This semi-empirical parameter measures the flow allowed through the valve: the greater its value, the greater the flow rate. Refer to the valve data sheet, if available, for this parameter.

**Leakage area** — Opening area of the valve in the maximally closed position  
 $1e-10 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of the valve in the fully closed position, when only internal leakage between its ports remains. This parameter serves primarily to ensure that closure of the valve does not cause portions

of the thermal liquid network to become isolated. The exact value specified here is less important than its being a small number greater than zero.

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Pressure differential vector** — Vector of pressure drops at which to tabulate the valve opening areas

[30.15E5 : 15E3 : 31.35E5] Pa (default) | vector of positive numbers in units of pressure

Vector of pressure differentials from port **X** to port **Y** at which to specify the opening area of the valve. The vector elements must increase monotonically from left to right. This order is important when specifying the **Opening area vector** block parameter.

The block uses this data to construct a lookup table by which to determine from the pressure differential the valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Opening area vector** — Vector of opening areas at the specified pressure differential breakpoints

[9E-5 : -1 : 1E-5] m<sup>2</sup> (default) | vector of positive numbers in units of area

Vector of opening areas corresponding to the breakpoints defined in the **Pressure differential vector** block parameter. The vector elements must decrease monotonically from left to right (with increasing pressure). For best results, avoid regions of flattened slope.

The block uses this data to construct a lookup table by which to determine from the pressure differential the valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Laminar transition specification** — Parameter in terms of which to define the boundary between laminar and turbulent regimes

Pressure ratio (default) | Reynolds number

Parameter in terms of which to specify the boundary between the laminar and turbulent flow regimes. The pressure ratio of the default parameterization is defined as the gauge pressure at the outlet divided by the same at the inlet.

**Laminar flow pressure ratio** — Pressure ratio at which the flow transitions between laminar and turbulent regimes

0.999 (default) | positive unitless scalar

Pressure ratio at which the flow is assumed to transition between laminar and turbulent regimes. The pressure ratio is defined as the gauge pressure at the outlet divided by the same at the inlet. The transition is assumed to be smooth and centered on this value.

**Dependencies**

This parameter is active when the **Laminar transition specification** block parameter is set to `Pressure ratio`.

**Critical Reynolds number** — Reynolds number at the boundary between laminar and turbulent flow regimes

12 (default) | positive unitless scalar

Reynolds number at which the flow is assumed to transition between laminar and turbulent regimes.

**Dependencies**

This parameter is active when the **Laminar transition specification** block parameter is set to `Reynolds number`.

**Opening dynamics** — Choice of whether to capture the opening dynamics of the valve

`Do not include valve opening dynamics (default)` | `Include valve opening dynamics`

Choice of whether to capture the opening dynamics of the valve. Selecting `Include valve opening dynamics` causes the valve to open gradually, so as to approach its new steady-state area over a small time span. The characteristic time for such transitions is given in the **Opening time constant** block parameter.

Setting this parameter to the alternative `Do not include valve opening dynamics` is equivalent to specifying a value of 0 for the opening time constant. The opening area is in this case assumed to reach its new steady-state value instantaneously.

Include opening dynamics to more accurately capture the behavior of a real valve. For best real-time simulation performance, use with a local solver or disable valve opening dynamics altogether.

**Opening time constant** — Characteristic time scale of the valve opening transitions

0.1 s (default) | positive scalar in units of time

Measure of the time taken by the valve to transition from its current opening area to a new steady-state value. The block uses this parameter to calculate the rate at which a valve is opening and from it the instantaneous opening area at the next time step.

**Dependencies**

This parameter is active when the **Opening dynamics** block parameter is set to `Include valve opening dynamics`.

**Initial area** — Opening area at the start of simulation

1e-12 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the direction of flow within the valve at the start of simulation. The block uses this parameter to calculate the initial rate at which the valve is opening and from it the instantaneous opening area at the next time step.

**Dependencies**

This parameter is active when the **Opening dynamics** block parameter is set to `Include valve opening dynamics`.

Pressure Reducing 3-Way Valve | Pressure Reducing Valve | Pressure Relief Valve

# Pressure Compensator Valve (IL)

Pressure compensator valve in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Compensator Valve (IL) block represents a pressure compensator in an isothermal liquid network, such as a pressure relief valve or pressure-reducing valve. Use this valve to maintain the pressure at the valve based on signals from another part of the system.

The pressure differential between ports **X** and **Y** is the control pressure,  $P_{control}$ . When this value meets or exceeds the set pressure, the valve area opens or closes depending on the **Valve specification** parameter. The pressure regulation range begins at the set pressure,  $P_{set}$ . You can choose between constant and controlled set pressure regulation. A physical signal at port **Ps** provides a varying set pressure.

## Pressure Control

The block regulates pressure when  $P_{control}$  exceeds  $P_{set}$ . The block continues to regulate the pressure up to  $P_{max}$ , the sum of  $P_{set}$  and the pressure regulation range. The block supports two modes of regulation:

- When you set **Set pressure control** to **Controlled** and connect a pressure signal to port **Ps**, the block keeps the pressure regulation range constant. The valve regulates pressure when  $P_{control}$  is greater than the value of the signal at port **Ps** and less than  $P_{max}$ .
- When you set **Set pressure control** to **Constant**, the **Set pressure differential** parameter defines a constant set pressure.

## Conservation of Mass

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = 0.$$

The block calculates the mass flow rate through the valve as

$$\dot{m} = \frac{C_d A_{valve} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 \right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient** parameter.
- $A_{valve}$  is the instantaneous valve open area.

- $A_{port}$  is the **Cross-sectional area at ports A and B** parameter.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential specified by the **Critical Reynolds number** parameter,  $Re_{crit}$ . This parameter represents the flow regime transition point between laminar and turbulent flow. The block finds the critical pressure difference as

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{valve}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2.$$

The pressure loss,  $PR_{loss}$ , describes the reduction of pressure in the valve due to a decrease in area. The block calculates the pressure loss as:

$$PR_{loss} = \frac{\sqrt{1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 (1 - C_d^2)} - C_d \frac{A_{valve}}{A_{port}}}{\sqrt{1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 (1 - C_d^2)} + C_d \frac{A_{valve}}{A_{port}}}.$$

The pressure recovery describes the positive pressure change in the valve due to an increase in area. When you set **Pressure recovery** to **Off**, the block sets  $PR_{loss}$  to 1.

The block calculates  $A_{valve}$  using the opening parameterization and the valve opening dynamics.

### Valve Opening Parameterization

When you set **Opening parameterization** to **Linear**, the valve area for normally open valves is

$$A_{valve} = \hat{p}(A_{leak} - A_{max}) + A_{max}.$$

This figure demonstrates how the block controls the opening area for a normally open valve using the linear parameterization.

For normally closed valves, the block uses

$$A_{valve} = \hat{p}(A_{max} - A_{leak}) + A_{leak}.$$

This figure demonstrates how the block controls the opening area for a normally closed valve using the linear parameterization.

The normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{set}}{p_{max} - p_{set}}.$$

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{set}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

When you set **Opening parameterization** to **Tabulated data**,  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the **Opening area vector** parameter, respectively. The block calculates the opening area as

$$A_{valve} = \text{tablelookup}(p_{control, TLU, ref}, A_{TLU}, p_{control}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest}),$$

where:

- $p_{control}$  is the control pressure, the pressure differential between ports **X** and **Y**.
- $p_{control, TLU, ref} = p_{TLU} + p_{offset}$ .
- $p_{TLU}$  is the **Pressure differential vector** parameter.
- $p_{offset}$  is an internal pressure offset that causes the valve to start closing when  $p_{control, TLU, ref} = p_{set}$ .

- $A_{TLU}$  is the **Opening area vector** parameter.

This figure demonstrates how the block controls the opening area for a normally open valve using the tabulated parameterization.

This figure demonstrates how the block controls the opening area for a normally closed valve using the tabulated parameterization.

### Opening Dynamics

When you select **Opening dynamics**, the block introduces a control pressure lag where  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ . The block calculates the instantaneous change in dynamic control pressure based on the **Opening time constant** parameter,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}$$

By default, the block does not model **Opening dynamics**. For the linear parameterization, a nonzero value for the **Smoothing factor** parameter provides additional numerical stability when the orifice is in near-closed or near-open position.

The block calculates the steady-state dynamics according to the **Opening parameterization** parameter, and are based on the control pressure,  $p_{control}$ .

### Faults

When you set **Enable faults** to On, the valve open area stops at a specified value in response to one of these triggers:

- Simulation time — The fault occurs at a specified time during the simulation.
- Simulation behavior — The fault occurs in response to an external trigger.

You can set the **Opening area when faulted** parameter to:

- **Closed** — The valve area stops at its smallest value, depending on the **Opening parameterization** parameter setting:
  - **Linear** — The valve area stops at the value of the **Leakage area** parameter.
  - **Tabulated data** — The valve area stops at the smallest element of the **Opening area vector** parameter.
- **Open** — The valve stops at its largest value, depending on the **Opening parameterization** parameter setting:
  - **Linear** — The valve area stops at the value of the **Maximum opening area** parameter.
  - **Tabulated data** — The valve area stops at the largest element of the **Opening area vector** parameter.
- **Maintain last value** — The valve area stops at the valve open area when the trigger occurred.

Due to numerical smoothing at the extremes of the valve area, the minimum area applied is larger than the leakage area, and the maximum is smaller than the value of the **Maximum orifice area** parameter. This effect is in proportion to the amount of smoothing you apply.

After the fault triggers, the valve remains at the faulted area for the rest of the simulation.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the A side of the valve.

**B** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the B side of the valve.

**X** — Pressure reference  
isothermal liquid

Isothermal liquid conserving port associated with sensing the pressure at point X,  $P_x$ .

**Y** — Pressure reference  
isothermal liquid

Isothermal liquid conserving port associated with point Y,  $P_y$ .

### Input

**Ps** — Controlled pressure differential, Pa  
physical signal

Pressure differential for controlled valve operation, in Pa.

**Dependencies**

To enable this port, set **Set pressure control** to `Controlled`.

**Tr** — External fault trigger, unitless  
physical signal

Physical signal port for an external fault trigger, unitless. Triggering occurs when the value is greater than 0.5.

**Dependencies**

To enable this port, set **Enable faults** to `On` and **Fault trigger** to `External`.

**Parameters****Parameters**

**Valve specification** — Valve bias  
`Normally open (default) | Normally closed`

Normal operating condition of the pressure compensator valve. For a reducing valve, choose `Normally open valve`. For a relief valve, choose `Normally closed`.

**Set pressure control** — Constant or controlled valve operation  
`Constant (default) | Controlled`

Valve operation method. When you set this parameter to:

- `Controlled` and connect a pressure signal to port **Ps**, the block keeps the pressure regulation range constant. The valve regulates pressure when  $P_{control}$  is greater than the value of the signal at port **Ps** and less than  $P_{max}$ .
- `Constant`, the **Set pressure differential** parameter defines a constant set pressure.

**Opening parameterization** — Opening parameterization  
`Linear (default) | Tabulated data`

Method to parameterize the opening action of the valve.

**Set pressure differential** — Range outside of which constant valve operation is triggered  
`0 MPa (default) | scalar`

Magnitude of the pressure differential that triggers pressure compensation.

**Dependencies**

To enable this parameter, set **Set pressure control** to `Constant`.

**Pressure regulation range** — Valve operational pressure range  
`0.1 MPa (default) | scalar`

Operational pressure range of the valve. The pressure regulation range defines the difference between the **Set pressure differential** parameter and the maximum valve operating pressure.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Maximum opening area** — Area of fully open valve

$1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the valve in the fully open position.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Leakage area** — Gap area when in fully closed position

$1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value saturates to the specified leakage area. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Pressure differential vector** — Differential pressure values for tabulated parameterization

[0.2 : 0.2 : 1.2] MPa (default) | 1-by-n vector

Vector of pressure differential values for the tabulated parameterization of the opening area. The vector elements must correspond one-to-one to the values in the **Opening area vector** parameter. The pressures must be in ascending order.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data.

**Opening area vector** — Valve opening areas for tabulated parameterization

[ $1e-05$ ,  $8e-06$ ,  $6e-06$ ,  $4e-06$ ,  $2e-06$ ,  $1e-10$ ]  $\text{m}^2$  (default) | 1-by-n vector

Vector of opening area values for the tabulated parameterization of the opening area. The vector elements must correspond one-to-one to the values in the **Pressure differential vector** parameter. For normally open valves, list elements in descending order. For normally closed valves, list elements in ascending order.

The opening area vector must have the same number of elements as the **Pressure differential vector**. The block uses linear interpolation between table data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data.

**Cross-sectional area at ports A and B** — Area at valve entry or exit

$\text{inf } \text{m}^2$  (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. The block uses this area in the pressure-flow rate equation that determines mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Pressure recovery** — Option to include pressure recovery  
Off (default) | On

Whether to account for pressure increase when fluid flows from a region of a smaller cross-sectional area to a region of larger cross-sectional area.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range of [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### **Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Opening dynamics** — Option to simulate flow response to valve transitions  
off (default) | on

Whether to account for transient effects to the fluid system due to the valve opening. When you select **Opening dynamics**, the block approximates the opening conditions by introducing a first-order lag in the flow response.

**Opening time constant** — Valve opening time constant  
0.1 s (default) | positive scalar

Time constant by which to compute the lag in the opening dynamics.

#### **Dependencies**

To enable this parameter, select **Opening dynamics**.

#### **Faults**

**Enable faults** — Fault option  
Off (default) | On

Whether to enable externally or temporally triggered faults. After a fault, the block sets the valve area to the value specified in the **Opening area when faulted** parameter.

**Opening area when faulted** — Faulted valve position  
Closed (default) | Open | Maintain last value

Opening area that the valve assume following a fault. You can choose for the valve to seize when the valve is opened, closed, or at the area after a fault.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On.

**Fault trigger** — External or temporal trigger option  
Temporal (default) | External

Whether a fault trigger occurs due to an external event or at a specified time. When you select:

- **External** — The block enables port **Tr**. A physical signal at port **Tr** that is greater than 0.5 triggers faulting.
- **Temporal** — When the simulation time reaches the value of the **Simulation time for fault event** parameter, the block sets the valve area according to the **Opening area when faulted** parameter.

#### Dependencies

To enable this parameter, set **Enable faults** to On.

**Simulation time for fault event** — Time at which fault triggers  
5 s (default) | positive scalar

When the simulation time reaches the value of the **Simulation time for fault event** parameter, the block sets the valve area according to the **Opening area when faulted** parameter.

#### Dependencies

To enable this parameter, set **Enable faults** to On and **Fault trigger** to Temporal.

## Version History

# Pressure Compensator Valve (TL)

Pressure compensator valve in thermal liquid network

## Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Compensator Valve (TL) block represents a pressure compensator in a thermal liquid network, such as a pressure relief valve or pressure reducing valve. Use this block to maintain the pressure at the valve based on signals from another part of the system.

The pressure differential between ports **X** and **Y** is the control pressure,  $P_{control}$ . When this value meets or exceeds the set pressure, the valve area opens or closes depending on the **Valve specification** parameter. The pressure regulation range begins at the set pressure,  $P_{set}$ .

## Pressure Control

The block regulates pressure when  $P_{control}$  exceeds  $P_{set}$  and continues to regulate the pressure until  $P_{max}$ , the sum of  $P_{set}$  and the pressure regulation range. The **Set pressure differential** parameter defines the constant regulation range.

## Conservation of Mass

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = 0.$$

The block calculates the mass flow rate through the valve as

$$\dot{m} = \frac{C_d A_{valve} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 \right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $C_d$  is the value of the **Discharge coefficient** parameter.
- $A_{valve}$  is the instantaneous valve open area.
- $A_{port}$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential specified by the **Critical Reynolds number** parameter,  $Re_{crit}$ . This parameter represents the flow regime transition point between laminar and turbulent flow. The block finds the critical pressure difference as

$$\Delta p_{crit} = \frac{\pi}{8A_{valve}\bar{\rho}} \left( \frac{\mu Re_{crit}}{C_d} \right)^2,$$

where  $\mu$  is the dynamic viscosity of the thermal liquid.

The pressure loss,  $PR_{loss}$ , describes the reduction of pressure in the valve due to a decrease in area. The block calculates the pressure loss as:

$$PR_{loss} = \frac{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{valve}}{A_{port}}}{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{valve}}{A_{port}}}.$$

The pressure recovery describes the positive pressure change in the valve due to an increase in area. When you clear the **Pressure recovery** check box, the block sets  $PR_{loss}$  to 1.

The block calculates  $A_{valve}$  using the opening parameterization and the valve opening dynamics.

### Valve Opening Parameterization

When you set **Opening parameterization** to Linear, the valve area for normally open valves is

$$A_{valve} = \hat{p}(A_{leak} - A_{max}) + A_{max},$$

where  $A_{leak}$  is the value of the **Leakage Area** parameter and  $A_{max}$  is the value of the **Maximum opening area** parameter. This figure shows how the block controls the opening area for a normally open valve using the linear parameterization.

For normally closed valves, the block uses

$$A_{valve} = \hat{p}(A_{max} - A_{leak}) + A_{leak}.$$

This figure shows how the block controls the opening area for a normally closed valve using the linear parameterization.

The normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{\text{control}} - p_{\text{set}}}{p_{\text{max}} - p_{\text{set}}}$$

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{\text{set}}$  and  $p_{\text{max}}$ . For more information, see “Numerical Smoothing”.

When you set **Opening parameterization** to **Tabulated data**,  $A_{\text{leak}}$  and  $A_{\text{max}}$  are the first and last parameters of the **Opening area vector** parameter, respectively. The block calculates the opening area as

$$A_{\text{valve}} = \text{tablelookup}(p_{\text{control,TLU,ref}}, A_{\text{TLU}}, p_{\text{control}}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest}),$$

where:

- $p_{\text{control,TLU,ref}} = p_{\text{TLU}} + p_{\text{offset}}$ .
- $p_{\text{TLU}}$  is the **Pressure differential vector** parameter.
- $p_{\text{offset}}$  is an internal pressure offset that causes the valve to start closing when  $p_{\text{control,TLU,ref}} = p_{\text{set}}$ .
- $A_{\text{TLU}}$  is the **Opening area vector** parameter.

This figure demonstrates how the block controls the opening area for a normally open valve using the tabulated data parameterization.

This figure demonstrates how the block controls the opening area for a normally closed valve using the tabulated data parameterization.

### Opening Dynamics

When you select **Opening dynamics**, the block introduces a control pressure lag where  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ . The block calculates the instantaneous change in dynamic control pressure based on the **Opening time constant** parameter,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}$$

By default, the block clears the **Opening dynamics** check box. When **Opening parameterization** is **Linear**, a nonzero value for the **Smoothing factor** parameter provides additional numerical stability when the orifice is in near-closed or near-open position.

The block calculates the steady-state dynamics according to the **Opening parameterization** parameter based on the control pressure,  $p_{control}$ .

### Energy Balance

The energy conservation equation in the valve is

$$\phi_A + \phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate into the valve through port **A**.

- $\phi_B$  is the energy flow rate into the valve through port **B**.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the A side of the valve.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the B side of the valve.

**X** — Pressure reference  
thermal liquid

Thermal liquid conserving port associated with the pressure at point X,  $P_x$ .

**Y** — Pressure reference  
thermal liquid

Thermal liquid conserving port associated with point Y,  $P_y$ .

## Parameters

**Valve specification** — Valve bias  
Normally open (default) | Normally closed

Normal operating condition of the pressure compensator valve. For a reducing valve, choose **Normally open** valve. For a relief valve, choose **Normally closed**.

**Opening parameterization** — Opening parameterization  
Linear (default) | Tabulated data

Method used to parameterize the opening action of the valve.

**Set pressure differential** — Pressure differential that triggers pressure compensation  
0 MPa (default) | scalar

Magnitude of the pressure differential that triggers pressure compensation.

**Pressure regulation range** — Valve operational pressure range  
0.1 MPa (default) | scalar

Operational pressure range of the valve. The pressure regulation range defines the difference between the **Set pressure differential** parameter and the maximum valve operating pressure.

### Dependencies

To enable this parameter, set **Opening parameterization** to **Linear**.

**Maximum opening area** — Area of fully open valve

$1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the valve in the fully open position.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Leakage area** — Gap area when in fully closed position

$1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. An area smaller than this value saturates to the specified leakage area. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Pressure differential vector** — Differential pressure values for tabulated parameterization

[0.2 : 0.2 : 1.2] MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabulated parameterization of the opening area. The vector elements must correspond one-to-one to the values in the **Opening area vector** parameter. The pressures must be in ascending order.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data.

**Opening area vector** — Valve opening areas for tabulated parameterization

[ $1e-05$ ,  $8e-06$ ,  $6e-06$ ,  $4e-06$ ,  $2e-06$ ,  $1e-10$ ]  $\text{m}^2$  (default) | 1-by-*n* vector

Vector of opening area values for the tabulated parameterization of the opening area. The vector elements must correspond one-to-one to the values in the **Pressure differential vector** parameter. For normally open valves, list elements in descending order. For normally closed valves, list elements in ascending order.

The opening area vector must have the same number of elements as the **Pressure differential vector** parameter. The block uses linear interpolation between table data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data.

**Cross-sectional area at ports A and B** — Area at valve entry or exit

$0.01 \text{ m}^2$  (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. The block uses this area in the pressure-flow rate equation that determines mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that the block uses to account for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range of [0,1]

Continuous smoothing factor that the block uses to introduce a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### **Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Pressure recovery** — Option to include pressure recovery  
off (default) | on

Whether to account for pressure increase when fluid flows from a region of a smaller cross-sectional area to a region of larger cross-sectional area.

**Opening dynamics** — Option to simulate flow response to valve transitions  
off (default) | on

Whether to account for transient effects to the fluid system due to the valve opening. When you select this parameter, the block approximates the opening conditions by introducing a first-order lag in the flow response.

**Opening time constant** — Valve opening time constant  
0.1 s (default) | positive scalar

Time constant by which to compute the lag in the opening dynamics.

#### **Dependencies**

To enable this parameter, select **Opening dynamics**.

# Pressure Reducing 3-Way Valve

(To be removed) Composite valve comprising the functions of pressure reducing and relief valves

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Pressure Control Valves

## Description

The Pressure Reducing 3-Way Valve block models the flow through a valve that constricts and, if necessary, vents (via a separate line) so as to maintain a preset pressure differential between its outlet (port **A**) and its surroundings (**T**, the vent). The valve combines the functions of two more elementary valves, one a pressure-reducing valve, the other a pressure-relief valve.

The pressure-reducing valve runs between the inlet (**P**) and the outlet (**A**). It is normally open but closes as needed to combat pressure fluctuations upstream of the outlet. The pressure-relief valve runs between the outlet (**A**) and the vent (**T**). It is normally closed but opens if the outlet pressure should exceed (by a specified transition amount) the pressure regulation range of the pressure-reducing valve.

The valve opening areas are functions of the pressure differential from port **A** to port **T**—either directly proportional to it or general (tabulated) functions of it. The opening areas can each vary up to a point—the limit of the respective valve regulation range—beyond which the valve is saturated at full capacity and unable to counteract any additional pressure rises.

## Valve Opening

The opening area calculation depends on the valve parameterization selected for the block: either Linear area-opening relationship or Tabulated data - Area vs. pressure.

### Linear Parameterization

If the **Valve parameterization** block parameter is in the default setting of Linear area-opening relationship, the opening area of the pressure-reducing valve (**P-A**) is computed as:

$$S_{PA} = \frac{S_{Max} + S_{Leak}}{2} - \frac{S_{Max} - S_{Leak}}{2} \tanh \left[ \frac{\lambda(\Delta p_{AT} - \Delta p_{Rdn})}{\Delta p_{Reg}/2} \right],$$

where the  $\tanh$  term serves to smooth the transitions to the fully open and fully closed valve positions. In the equation:

- $S_{Max}$  is the value specified in the **Maximum passage area** block parameter.
- $S_{Leak}$  is the value specified in the **Leakage area** block parameter.
- $\lambda$  is the value of the **Valve opening adjustment coefficient** block parameter, a measure of the smoothing to apply to the valve transitions. The smaller the value, the smoother the transition.
- $\Delta p_{Reg}$  is the value specified in the **Valve regulation range** block parameter.
- $\Delta p_{Rdn}$  is the midpoint of the pressure regulation range of the pressure-reducing valve:

$$\Delta p_{Rdn} = \Delta p_{Set} + \frac{\Delta p_{Reg}}{2},$$

with  $\Delta p_{Set}$  being the value of the **Reducing valve pressure setting** block parameter.

The opening area of the pressure-relief valve (**A-T**) is likewise computed as:

$$S_{AT} = \frac{S_{Max} + S_{Leak}}{2} + \frac{S_{Max} - S_{Leak}}{2} \tanh\left(\frac{\lambda(\Delta p_{AT} - \Delta p_{Rlf})}{\Delta p_{Reg}/2}\right),$$

where  $\Delta p_{Rlf}$  is the midpoint of the pressure regulation range of the pressure-relief valve:

$$\Delta p_{Rlf} = \Delta p_{Set} + \Delta p_{Reg} + \Delta p_{Tran} + \frac{\Delta p_{Reg}}{2},$$

with  $\Delta p_{Tran}$  being the transition pressure differential—that required for the pressure-relief valve to open after the pressure-reducing valve has fully closed. This value is obtained from the **Transition pressure** block parameter.

### Opening area in the Linear area-opening relationship parameterization

#### Tabulated Parameterization

If the **Valve parameterization** block parameter is set to Tabulated data - Area vs. pressure, the valve opening areas are computed as:

$$S = S(\Delta p_{AT}),$$

where  $S_{AT}$  is a tabulated function constructed from the **Pressure drop vector** and **Opening area vector** block parameters. The function is based on linear interpolation (for points within the data range) and nearest-neighbor extrapolation (for points outside the data range). The leakage and maximum opening areas are the minimum and maximum values of the **Valve opening area vector** block parameter.

## Opening area in the Tabulated data - Area vs. pressure parameterization

### Opening Dynamics

By default, the valve opening dynamics are ignored. The valves are each assumed to respond instantaneously to changes in the pressure drop, without time lag between the onset of a pressure disturbance and the increased valve opening that the disturbance produces. If such time lags are of consequence in a model, you can capture them by setting the **Opening dynamics** block parameter to Include valve opening dynamics. The valves then open each at a rate given by the expression:

$$\dot{S} = \frac{S(\Delta p_{SS}) - S(\Delta p_{In})}{\tau},$$

where  $\tau$  is a measure of the time needed for the instantaneous opening area (subscript In) to reach a new steady-state value (subscript SS).

### Leakage Area

The primary purpose of the leakage area of a closed valve is to ensure that at no time does a portion of the hydraulic network become isolated from the remainder of the model. Such isolated portions reduce the numerical robustness of the model and can slow down simulation or cause it to fail. Leakage is generally present in minuscule amounts in real valves but in a model its exact value is less important than it being a small number greater than zero. The leakage area is obtained from the block parameter of the same name.

### Valve Flow Rates

The causes of the pressure losses incurred in the passages of the composite valve are ignored in the block. Whatever their natures—sudden area changes, flow passage contortions—only their cumulative effect is considered during simulation. This effect is captured in the block by the discharge coefficient, a measure of the flow rate through a valve relative to the theoretical value that it would have in the ideal case. The flow rates through each of the elementary valves are defined as:

$$q = C_D S \sqrt{\frac{2}{\rho} \frac{\Delta p}{[(\Delta p)^2 + p_{\text{crit}}^2]^{1/4}}},$$

where:

- $q$  is the volumetric flow rate through the valve (**P-A** or **A-T**).
- $C_D$  is the value of the **Discharge coefficient** block parameter.

- $S$  is the opening area of the valve ( $S_{PA}$  or  $S_{AT}$ ).
- $\Delta p$  is the pressure drop across the valve ( $\Delta p_{PA}$  or  $\Delta p_{AT}$ ).
- $p_{\text{Crit}}$  is the pressure differential at which the flow shifts between the laminar and turbulent flow regimes.

The calculation of the critical pressure depends on the setting of the **Laminar transition specification** block parameter. If this parameter is in the default setting of By pressure ratio:

$$p_{\text{Crit}} = (p_{\text{Atm}} + p_{\text{Avg}})(1 - \beta_{\text{Crit}}),$$

where:

- $p_{\text{Atm}}$  is the atmospheric pressure (as defined for the corresponding hydraulic network).
- $p_{\text{Avg}}$  is the average of the gauge pressures at the ports (**P** and **A** or **A** and **T**).
- $\beta_{\text{Crit}}$  is the value of the **Laminar flow pressure ratio** block parameter.

If the **Laminar transition specification** block parameter is instead set to By Reynolds number:

$$p_{\text{Crit}} = \frac{\rho}{2} \left( \frac{\text{Re}_{\text{Crit}} \nu}{C_D D_H} \right)^2,$$

where:

- $\text{Re}_{\text{Crit}}$  is the value of the **Critical Reynolds number** block parameter.
- $\nu$  is the kinematic viscosity specified for the hydraulic network.
- $D_H$  is the instantaneous hydraulic diameter:

$$D_H = \sqrt{\frac{4S}{\pi}}.$$

## Ports

### Conserving

#### **A** – Valve outlet

hydraulic (isothermal liquid)

Opening through which the flow can exit the valve.

#### **P** – Valve inlet

hydraulic (isothermal liquid)

Opening through which the flow can enter the valve.

#### **T** – Valve vent

hydraulic (isothermal liquid)

Opening through which the flow can vent from the valve.

## Parameters

**Opening area parameterization** — Method by which to calculate the opening area of the valve  
 Linear area-opening relationship (default) | Tabulated data - Area vs. pressure

Method by which to calculate the opening area of the valve. The default setting prescribes a linear relationship between the opening area of the valve and the pressure drop between the outlet and the vent opening. The alternative setting allows for a general, nonlinear relationship to be specified in tabulated form.

**Maximum passage area** — Opening areas of the P-A and A-T valves in the fully open position  
 $1e-4 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of each valve when fully open. The pressure-reducing and pressure-relief valves are assumed to be identical in size. See the block description for the pressure conditions under which the valves can each be said to be fully open.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Reducing valve pressure setting** — Pressure from port A to port T at which the reducing valve begins to close  
 $6e5 \text{ Pa}$  (default) | positive scalar in units of pressure

Pressure differential from port **A** to port **T** that the composite valve is to maintain. The pressure-reducing valve closes in proportion to the pressure differential if its value should exceed that specified here. The pressure-relief valve opens in proportion to the same if its value should exceed, by an amount given by the **Transition pressure** block parameter, that needed to fully close the reducing valve.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve regulation range** — Pressure drop interval over which the valves are each designed to operate  
 $1.5e5 \text{ Pa}$  (default) | positive scalar in units of pressure

Pressure differential interval over which the valves are each designed to operate. This interval spans those pressures over which the opening area changes between its minimum and maximum values. The value specified here applies to both the pressure-reducing and pressure-relief valves.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Transition pressure** — Pressure interval between the final closing of the reducing valve and the first opening of the relief valve  
 $2e5 \text{ Pa}$  (default) | positive scalar in units of pressure

Pressure differential in excess of that required to fully close the pressure-reducing valve at which the pressure-relief valve first opens. The greater the transition pressure, the greater the lag between the closing of the pressure-reducing valve and the opening of its pressure-relief counterpart.

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve flow discharge coefficient** — Empirical factor defined as the ratio of actual to ideal mass flow rates

0.7 (default) | positive unitless scalar

Ratio of the actual flow rate through the valve to the theoretical value that it would have in an ideal valve. This semi-empirical parameter measures the flow allowed through the valve: the greater its value, the greater the flow rate. Refer to the valve data sheet, if available, for this parameter. The value specified here is shared by both pressure-reducing and pressure-relief valves.

**Valve leakage area** — Opening area of the valve in the maximally closed position

$1e-10 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of a valve in the fully closed position, when only internal leakage between its respective ports remains. The leakage area is the same in the pressure-reducing and pressure-relief valves. This parameter serves primarily to ensure that closure of the valve does not cause portions of the hydraulic network to become isolated. The exact value specified here is less important than its being a small number greater than zero.

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve opening adjustment coefficient** — Smoothing factor for easing the transition to the fully open or fully closed position

1 (default) | positive unitless scalar

Smoothing factor for easing the transition to the fully open or fully closed valve position. The smoothing enhances the numerical robustness of the model, helping to avoid numerical errors due to discontinuities and simulation slowdowns due to zero crossings. Use this parameter to scale the widths of the smoothed regions. The smaller the value, the broader the transition.

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Pressure differential vector for reducing valve** — Vector of pressure drops at which to tabulate the valve opening areas

[6.06E5 : .06E5 : 6.24E5] Pa (default) | vector of positive numbers in units of pressure

Vector of pressure drops from port **P** to port **A** at which to specify the opening area of the valve. The vector elements must increase monotonically from left to right. This order is important when specifying the **Opening area vector for reducing valve** block parameter.

The block uses this data to construct a lookup table by which to determine from the pressure differential the reducing-valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Opening area vector for reducing valve** — Vector of opening areas at the specified pressure differential breakpoints

[.9168, .69, .31, .0832] E-4 m<sup>2</sup> (default) | vector of positive numbers in units of area

Vector of opening areas corresponding to the breakpoints defined in the **Pressure differential vector for reducing valve** block parameter. The vector elements must decrease monotonically from left to right (with increasing pressure). For best results, avoid regions of flattened slope.

The block uses this data to construct a lookup table by which to determine from the pressure differential the reducing-valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Pressure differential vector for relief valve** — Vector of pressure drops at which to tabulate the valve opening areas

[6.2, 6.26, 6.32, 6.38] E5 Pa (default) | vector of positive numbers in units of pressure

Vector of pressure drops from port **A** to port **T** at which to specify the opening area of the valve. The vector elements must increase monotonically from left to right. This order is important when specifying the **Opening area vector for relief valve** block parameter.

The block uses this data to construct a lookup table by which to determine from the pressure differential the reducing-valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Opening area vector for relief valve** — Vector of opening areas at the specified pressure differential breakpoints

[.9168, .69, .31, .0832] E-4 m<sup>2</sup> (default) | vector of positive numbers in units of area

Vector of opening areas corresponding to the breakpoints defined in the **Pressure differential vector for relief valve** block parameter. The vector elements must decrease monotonically from left to right (with increasing pressure). For best results, avoid regions of flattened slope.

The block uses this data to construct a lookup table by which to determine from the pressure differential the reducing-valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Laminar transition specification** — Parameter in terms of which to define the boundary between laminar and turbulent regimes

Pressure ratio (default) | Reynolds number

Parameter in terms of which to specify the boundary between the laminar and turbulent flow regimes. The pressure ratio of the default parameterization is defined as the gauge pressure at the outlet divided by the same at the inlet.

**Laminar flow pressure ratio** — Pressure ratio at which the flow transitions between laminar and turbulent regimes

0.999 (default) | positive unitless scalar

Pressure ratio at which the flow is assumed to transition between laminar and turbulent regimes. The pressure ratio is defined as the gauge pressure at the outlet divided by the same at the inlet. The transition is assumed to be smooth and centered on this value.

#### **Dependencies**

This parameter is active when the **Laminar transition specification** block parameter is set to Pressure ratio.

**Critical Reynolds number** — Reynolds number at the boundary between laminar and turbulent flow regimes

12 (default) | positive unitless scalar

Reynolds number at which the flow is assumed to transition between laminar and turbulent regimes.

#### **Dependencies**

This parameter is active when the **Laminar transition specification** block parameter is set to Reynolds number.

**Opening dynamics** — Choice of whether to capture the opening dynamics of the valve

Do not include valve opening dynamics (default) | Include valve opening dynamics

Choice of whether to capture the opening dynamics of the valve. Selecting Include valve opening dynamics causes the valve to open gradually, so as to approach its new steady-state area over a small time span. The characteristic time for such transitions is given in the **Opening time constant** block parameter.

Setting this parameter to the alternative Do not include valve opening dynamics is equivalent to specifying a value of 0 for the opening time constant. The opening area is in this case assumed to reach its new steady-state value instantaneously.

Include opening dynamics to more accurately capture the behavior of a real valve. For best real-time simulation performance, use with a local solver or disable valve opening dynamics altogether.

**Opening time constant** — Characteristic time scale of the valve opening transitions

0.1 s (default) | positive scalar in units of time

Measure of the time taken by the valve to transition from its current opening area to a new steady-state value. The block uses this parameter to calculate the rate at which a valve is opening and from it the instantaneous opening area at the next time step.

### Dependencies

This parameter is active when the **Opening dynamics** block parameter is set to `Include valve opening dynamics`.

**Initial reducing valve area** — Opening area of the reducing valve at the start of simulation  
`1e-9 m^2 (default)` | positive scalar in units of area

Area normal to the direction of flow within the pressure-reducing valve at the start of simulation. The block uses this parameter to calculate the initial rate at which the pressure-reducing valve is opening and from it the instantaneous opening area at the next time step.

### Dependencies

This parameter is active when the **Opening dynamics** block parameter is set to `Include valve opening dynamics`.

**Initial relief valve area** — Opening area of the relief valve at the start of simulation  
`1e-9 m^2 (default)` | positive scalar in units of area

Area normal to the direction of flow within the pressure-relief valve at the start of simulation. The block uses this parameter to calculate the initial rate at which the pressure-relief valve is opening and from it the instantaneous opening area at the next time step.

### Dependencies

This parameter is active when the **Opening dynamics** block parameter is set to `Include valve opening dynamics`.

### Description

The Pressure-Reducing 3-Way Valve (IL) is a combination of a pressure-relief and pressure-reducing valve. It maintains pressure at the valve outlet, port **A**, by restricting the inflow area at port **P** and venting the flow at port **T**.

### Valve Functionality

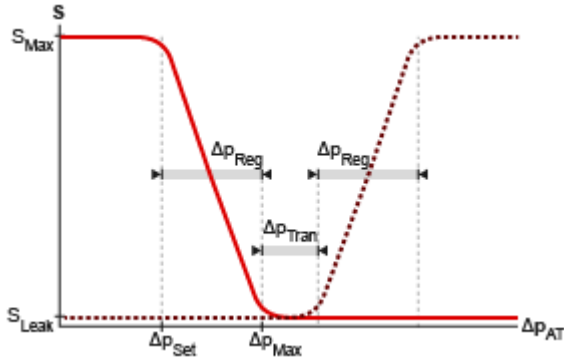

Valve operation is triggered by comparing the pressure difference between port **A** and port **T** to a threshold, the set pressure. When the pressure between **A** and **T**,  $P_{control}$ , exceeds this set pressure,  $P_{set, reducing}$ , port **P** begins to close. A transition pressure range defines the pressures the valve experiences when both valves at ports **P** and **T** are closed. When the pressure difference between ports **A** and **T** exceeds the pressure transition range, port **T** opens. That is,  $P_{set, relief} = P_{set, reducing} + P_{range} + P_{transition}$ . The **Pressure regulation range** is specified for both the pressure-reducing and the pressure-relief valves. The valve parameters, such as **Leakage Area** and **Maximum Opening Area**, are the same for all ports.

To simulate pressure relief or pressure reduction with respect to another system element, see Pressure Compensator Valve (IL). To simulate pressure reduction between the valve outlet and atmosphere, see the Pressure-Reducing Valve (IL). To simulate pressure relief with respect to a valve or between the valve outlet and atmospheric pressure, see Pressure Relief Valve (IL).

### Pressure Control

When  $P_{control}$ ,  $P_A - P_T$ , exceeds the threshold pressure,  $P_{set, reducing}$ , the valve at port **P** begins to close. When the **Pressure transition range** is exceeded, or when  $P_{control} > P_{set, relief}$ , the valve at port **T** begins to open. Both valve closing and opening are parameterized in two ways:

- When **Set Pressure control** is set to **Controlled**, connect a pressure signal to port **Ps**, set the constant **Pressure regulation range**, and set the constant **Pressure transition range**. The pressure-reducing valve begins to close when  $P_{control}$  is greater than  $P_{set, reducing}$  and below  $P_{max, reducing}$ . The relief valve response is triggered when  $P_{control}$  is greater than  $P_{set, relief}$  and below  $P_{max, relief}$ .  $P_{max, relief}$  is the sum of the **Pressure regulation range** and  $P_{set, relief}$ .
- When **Set Pressure control** is set to **Constant**, valve closing at port **P** is continuously regulated by either a linear or tabular parameterization. Similarly, relief valve opening at port **T** is parameterized linearly or by table lookup. An example of linear parameterization of the reduction valve (solid line) and relief valve (dotted line) is shown below.

When the Tabulated data option is selected,  $P_{set, reducing}$  and  $P_{max, reducing}$  are the first and last parameters of the **Pressure differential vector for reducing valve**, respectively, and  $P_{set, relief}$  and  $P_{max, relief}$  are the first and last parameters of the **Pressure differential vector for relief valve**, respectively. An example of tabular parameterization of both the reducing and relieving valves are shown below.

### Mass Flow Rate Equation

Momentum is conserved through the valve:

$$\dot{m}_A + \dot{m}_{reducing} + \dot{m}_{relief} = 0.$$

The mass flow rate through the valves is calculated as:

$$\dot{m}_{reducing} = \frac{C_d A_{PA} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss, reducing} \left(1 - \left(\frac{A_{PA}}{A_{port}}\right)^2\right)}} \frac{\Delta p_{reducing}}{[\Delta p_{reducing}^2 + \Delta p_{crit, reducing}^2]^{1/4}},$$

$$\dot{m}_{relief} = \frac{C_d A_{AT} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss, relief} \left(1 - \left(\frac{A_{AT}}{A_{port}}\right)^2\right)}} \frac{\Delta p_{relief}}{[\Delta p_{relief}^2 + \Delta p_{crit, relief}^2]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient**.

- $A$  is the instantaneous valve open area between ports **A** and **P** or **A** and **T**, as indicated by the subscript.
- $A_{port}$  is the **Cross-sectional area at ports A, P & T**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference:  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow, which corresponds to either the pressure-reducing or pressure relief component of the valve:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8A} \left( \frac{\nu Re_{crit}}{C_d} \right)^2,$$

where  $A$  is either  $A_{PA}$  or  $A_{AT}$ , corresponding to the reducing or relief component of the valve, respectively.

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area.  $PR_{loss}$  is calculated as:

$$PR_{loss} = \frac{\sqrt{1 - \left(\frac{A}{A_{port}}\right)^2 (1 - C_d^2)} - C_d \frac{A}{A_{port}}}{\sqrt{1 - \left(\frac{A}{A_{port}}\right)^2 (1 - C_d^2)} + C_d \frac{A}{A_{port}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{loss}$  is 1.

The opening area  $A$  is determined by the opening parameterization (for Constant valves only) of the reducing valve (**P** to **A**) or relief valve (**A** to **T**) and the valve opening dynamics.

### Opening and Closing Parameterization

When you set **Opening parameterization** to Linear, the valve area for the reducing valve is

$$A_{valve} = \hat{p}_{reducing}(A_{leak} - A_{max}) + A_{max},$$

and for the relief valve is

$$A_{valve} = \hat{p}_{relief}(A_{max} - A_{leak}) + A_{leak}.$$

The normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{set}}{p_{max} - p_{set}},$$

where the set and maximum pressures are the respective reducing or relief valve settings.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{set}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

When you set **Opening parameterization** to **Tabulated data**,  $A_{leak,PA}$  and  $A_{max,PA}$  are the first and last elements of the **Opening area vector reducing valve** parameter, respectively, and  $A_{leak,AT}$  and  $A_{max,AT}$  are the first and last elements of the **Opening area vector for relief valve** parameter, respectively. The block calculates the opening area as

$$A_{valve} = \text{tablelookup}(p_{control, TLU, ref}, A_{TLU}, p_{control}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest}).$$

For the reducing valve, the block calculates the opening area by using the table lookup method, where:

- $p_{control}$  is the control pressure, which is the pressure differential between ports **A** and **T**.
- $p_{control, TLU, ref} = p_{TLU} + p_{offset}$ .
- $p_{TLU}$  is the **Pressure differential vector for reducing valve** parameter
- $p_{offset}$  is an internal pressure offset that causes the valve to start closing when  $p_{control, TLU, ref} = p_{set, reducing}$ .
- $A_{TLU}$  is the **Opening area vector reducing valve** parameter.

For the relief valve, the block calculates the opening area by using the table lookup method, where:

- $p_{control}$  is the pressure differential between ports **A** and **T**.
- $p_{control, TLU, ref} = p_{TLU} + p_{offset}$ .
- $p_{TLU}$  is the **Pressure differential vector for relief valve** parameter.
- $p_{offset}$  is an internal pressure offset that causes the valve to start opening when  $p_{control, TLU, ref} = p_{set, relief}$ .
- $A_{TLU}$  is the **Opening area vector for relief valve** parameter.

### Opening Dynamics

If **Opening dynamics** are modeled, a lag is introduced to the flow response to valve opening.  $A_{valve}$  becomes the dynamic opening or closing area,  $A_{dyn}$ ; otherwise,  $A_{valve}$  is the steady-state opening area. This area is specific to the reducing and relief components of the valve,  $A_{PA}$  or  $A_{AT}$ , respectively. The instantaneous change in dynamic opening area is calculated based on the **Opening time constant**,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, **Opening dynamics** are not modeled.

### Faults

When faults are enabled, the reducing and relief valve open areas become stuck at a specified value in response to one of these triggers:

- Simulation time — Faulting occurs at a specified time.
- Simulation behavior — Faulting occurs in response to an external trigger. This exposes port **Tr**.

Three fault options are available in the **Valve areas when faulted** parameter:

- Reducing valve closed and relief valve open — The reducing valve freezes at its smallest value and the relief valve freezes at its largest value, depending on the **Opening parameterization**:
  - When **Opening parameterization** is set to **Linear**, the reducing valve area freezes at the **Leakage area** and the relief valve area freezes at the **Maximum opening area**.
  - When **Opening parameterization** is set to **Tabulated data**, the reducing valve area freezes at the first element of the **Opening area vector** and the relief valve area freezes at the last element of the **Opening area vector**.
- Reducing valve open and relief valve closed — The reducing valve freezes at its largest value and the relief valve freezes at its smallest value, depending on the **Opening parameterization**:
  - When **Opening parameterization** is set to **Linear**, the reducing valve area freezes at the **Maximum opening area** and the relief valve freezes at the **Leakage area**.
  - When **Orifice parameterization** is set to **Tabulated data**, the reducing valve area freezes at the last element of the **Opening area vector** and the relief valve area freezes at the first element of the **Opening area vector**.
- **Maintain last value** — The reducing and relief valve areas freeze at the open area when the trigger occurred.

Due to numerical smoothing at the extremes of the valve area, the minimum area applied is larger than the **Leakage area**, and the maximum is smaller than the **Maximum orifice area**, in proportion to the **Smoothing factor** value.

Once triggered, the valves remain at the faulted area for the rest of the simulation.

### **Assumptions and Limitations**

Friction between the valve and fluid, the hydraulic force of the fluid on the valve components, and the effect of fluid inertia are neglected.

## **Port**

### **Conserving**

**A** — Liquid port  
isothermal liquid

Liquid exit port of the valve.

**P** — Liquid port  
isothermal liquid

Liquid entry port to the valve.

**T** — Liquid port  
isothermal liquid

Liquid relief port of the valve.

## Input

**Ps** — Controlled pressure differential  
physical signal

Varying-signal set pressure for controlled valve operation.

### Dependencies

To enable this port, set **Set pressure control** to **Controlled**.

**Tr** — External fault trigger  
physical signal

Physical signal port for an external fault trigger. Triggering occurs when the value is greater than 0.5. There is no unit associated with the trigger value.

### Dependencies

This port is visible when **Enable faults** is set to **On** and **Fault trigger** is set to **External**.

## Parameters

### Parameters

**Set pressure control** — Valve operation method  
Constant (default) | Controlled

Valve operation method. A **Constant** valve opens or closes linearly over a fixed pressure regulation range and pressure transition or in accordance with tabulated pressure and opening area data that you provide. A **Controlled** valve opens or closes according to a variable set pressure signal at port **Pset** over a fixed pressure regulation and pressure transition range. The selected setting applies both to the reducing and relief valve operation.

**Opening parameterization** — Type of opening parameterization  
Linear (default) | Tabulated data

Method of modeling the valve opening or closing. Valve opening is either parametrized linearly, which correlates the opening area to the provided pressure range, or by a table of values you provide that correlate the valve opening area to pressure differential data.

### Dependencies

To enable this port, set **Set pressure control** to **Constant**.

**Set pressure differential for reducing valve** — Set pressure for valve closing at port P  
0.6 MPa (default) | scalar

Pressure differential between port **T** and port **A**. When this set pressure differential is surpassed, the valve at port **P** begins to close. The closing is parametrized linearly or by lookup table as defined in the **Opening parameterization**.

**Pressure regulation range** — Valve operational pressure range  
3e-2 MPa (default) | scalar

Operational pressure range of the reducing valve. The pressure regulation range lies between the **Set pressure differential** and the maximum valve operating pressure. At the end of the **Pressure regulation range**, the pressure-reducing valve is closed and the **Pressure transition range** begins.

**Dependencies**

To enable this parameter, set

- **Set pressure control** to Controlled, or
- **Set pressure control** to Constant and **Opening parameterization** to Linear.

**Pressure transition range** — Pressure range of valve with ports P and T closed

2e-2 MPa (default) | scalar

Pressure range of the 3-way valve. This parameter defines the pressure range, which begins at the end of the **Pressure regulation range**, over which both ports **P** and **T** are closed. Below this range, the reducing valve at port **P** is open to flow, and above this range, the relief valve at port **T** opens.

**Dependencies**

To enable this parameter, set either:

- **Set pressure control** to Controlled
- **Set pressure control** to Constant and **Opening parameterization** to Linear

**Maximum opening area** — Maximum opening area of ports

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the valve (**P-A** or **A-T**) in its fully-open position.

**Dependencies**

To enable this parameter, set either:

- **Set pressure control** to Controlled
- **Set pressure control** to Constant and **Opening parameterization** to Linear

**Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set either:

- **Set pressure control** to Controlled
- **Set pressure control** to Constant and **Opening parameterization** to Linear

**Pressure differential vector for reducing valve** — Differential pressure values for tabular parameterization of reducing valve

0.6 : 0.02 : 0.7 MPa (default) | 1-by-n vector

Vector of pressure differential values for the tabular parameterization of opening area. The vector elements correspond one-to-one to the values in the **Opening area vector reducing valve**

parameter. Pressure differential vector values are listed in ascending order and must have the same number of elements as the **Opening area vector reducing valve** parameter. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Set pressure control** to Constant and **Opening parameterization** to Tabulated data.

**Opening area vector reducing valve** — Vector of valve opening areas for tabular parameterization of reducing valve

[1e-05, 8e-06, 6e-06, 4e-06, 2e-06, 1e-10] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening area values for the tabular parameterization of opening area. The vector elements must correspond one-to-one to the values in the **Pressure differential vector for reducing valve** parameter. Areas are listed in descending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Set pressure control** to Constant and **Opening parameterization** to Tabulated data.

**Pressure differential vector for relief valve** — Differential pressure values for tabular parameterization of relief valve

0.68 : 0.02 : 0.78 MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabular parameterization of opening area. The vector elements correspond one-to-one to the values in the **Opening area vector relief valve** parameter. Pressure differential vector values are listed in ascending order and must have the same number of elements as the **Opening area vector relief valve** parameter. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Set pressure control** to Constant and **Opening parameterization** to Tabulated data.

**Opening area vector for relief valve** — Valve opening areas for tabular parameterization of relief valve

[1e-10, 2e-06, 4e-06, 6e-06, 8e-06, 1e-05] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening area values for the tabular parameterization of opening area. The vector elements must correspond one-to-one to the values in the **Pressure differential vector for relief valve** parameter. Areas are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Set pressure control** to Constant and **Opening parameterization** to Tabulated data.

**Cross-sectional area at ports A, P & T.** — Orifice area at conserving ports

inf m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A**, **P**, and **T**. This area is used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor accounting for discharge losses in theoretical flows. The default discharge coefficient for a valve in Simscape Fluids is 0.64.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range of [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### **Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Pressure recovery** — Whether to account for pressure increase in area expansions

off (default) | on

Accounts for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area. This increase in pressure is not captured when you clear the **Pressure recovery** check box.

**Opening dynamics** — Whether to introduce flow lag due to orifice opening

off (default) | on

Accounts for transient effects to the fluid system due to the valve opening. Selecting **Opening dynamics** approximates the opening conditions by introducing a first-order lag in the flow response. The **Opening time constant** also impacts the modeled opening dynamics.

**Reducing valve initial opening area** — Open area at port P at the start of the simulation

1e-4 m<sup>2</sup> (default) | positive scalar

Initial cross-sectional area at port **P** at the time of dynamic opening. This value is used to calculate the instantaneous opening area for the dynamic opening between **P** and **A** at the following time step.

#### **Dependencies**

To enable this parameter, select **Opening dynamics**.

**Relief valve initial opening area** — Open area at port T at the start of the simulation

1e-10 m<sup>2</sup> (default) | positive scalar

Initial cross-sectional area at port **T** of opening at the time of dynamic opening. This value is used to calculate the instantaneous opening area for the dynamic opening between **A** and **T** at the following time step.

#### **Dependencies**

To enable this parameter, select **Opening dynamics**.

**Opening time constant** — Valve opening time constant

0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state when opening or closing the valve from one position to another. This parameter impacts the modeled opening dynamics.

**Dependencies**

To enable this parameter, select **Opening dynamics**.

**Faults****Enable faults** — Fault option

Off (default) | On

Enable externally or temporally triggered faults. When faulting occurs, the valve area normally set by the opening parameterization will be set to the value specified in the **Opening area when faulted** parameter.

**Valve areas when faulted** — Set faulted characteristics

Reducing valve closed and relief valve open (default) | Reducing valve open and relief valve closed | Maintain last value

Sets the faulted valve type. You can choose for the valve to seize when the valves are opened, closed, or at the area when faulting is triggered.

**Dependencies**

To enable this parameter, set **Enable faults** to On.

**Fault trigger** — External or temporal trigger option

Temporal (default) | External

Whether a fault trigger occurs due to an external event or at a specified time.

When set to External, port **Tr** is enabled. A physical signal at port **Tr** that is greater than 0.5 triggers faulting.

When set to Temporal, when the **Simulation time for fault event** is reached, the valve area will be set to the value specified in the **Opening area when faulted** parameter.

**Dependencies**

To enable this parameter, set **Enable faults** to On.

**Simulation time for fault event** — Time at which faulting is triggered

5 s (default) | positive scalar

When the **Simulation time for fault event** is reached, the valve area is set to the value specified in the **Opening area when faulted** parameter.

**Dependencies**

To enable this parameter, set **Enable faults** to On and **Fault trigger** to Temporal.

# Pressure Reducing Valve

(To be removed) Valve used to reduce pressure to a specified value

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Pressure Control Valves

## Description

The Pressure Reducing Valve block models the flow through a valve that constricts so as to maintain a preset gauge pressure at its outlet (port **B**). The normally open valve contracts when the outlet pressure, measured against atmospheric pressure, exceeds the valve pressure setting. The drop in opening area is a function of the outlet pressure—proportional to it in a linear parameterization (the block default) or a general function of it in a tabulated parameterization. The valve serves its purpose until it hits the limit of its pressure regulation range—a point at which the valve is fully closed and the outlet pressure can again rise unabated.

## Valve Opening

The figures show the opening characteristics of the valve. In the default valve parameterization, the opening area ( $S$ ) drops linearly with the outlet pressure ( $p_B$ ) with its value ranging from a maximum in the fully open position ( $S_{Max}$ ) to a minimum in the fully closed position ( $S_{Leak}$ ). The drop occurs over a pressure range stretching from the valve pressure setting ( $p_{Set}$ ) to a maximum equal to the sum of the valve regulation range ( $p_{Reg}$ ) and the valve pressure setting.

## Opening area in the Linear area-opening relationship parameterization

In the optional tabulated parameterization, the opening area is a general function of the outlet pressure, with its value dropping from a maximum ( $S_{Max}$ ) to a minimum ( $S_{Min}$ ) contained in the tabulated data. The maximum opening occurs at the minimum pressure ( $p_{Min}$ ) contained in the data and the minimum opening at the maximum pressure ( $p_{Max}$ ). Calculations are based on linear interpolation (between the tabulated bounds) and nearest-neighbor extrapolation (outside of those bounds).

### Opening area in the Tabulated data - Area vs. pressure parameterization

#### Composite Diagram

This block is a composite component with a Pressure Compensator block connected as follows: its sensor port **X** connected to its outlet (port **B**) and its sensor port **Y** connected to a hydraulic reference. The hydraulic reference is by definition at atmospheric pressure as defined for the entire hydraulic network. For detailed block calculations see the Pressure Compensator block (noting that quantities at port **X** are defined at port **B** and those at port **Y** are defined at reference conditions).

#### Composite model of the pressure relief valve

### Ports

#### Conserving

**A** — Valve inlet  
hydraulic (isothermal liquid)

Opening through which the flow can enter the valve.

**B** — Valve outlet  
hydraulic (isothermal liquid)

Opening through which the flow can exit the valve.

## Parameters

**Opening area parameterization** — Method by which to calculate the opening area of the valve  
 Linear area-opening relationship (default) | Tabulated data - Area vs. pressure

Method by which to calculate the opening area of the valve. The default setting prescribes a linear relationship between the opening area of the valve and the pressure drop between its sensor ports. The alternative setting allows for a general, nonlinear relationship to be specified in tabulated form.

**Maximum passage area** — Opening area of the valve in the fully open position  
 $1e-4 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of the valve in the fully open position. The valve is fully open if the pressure at port **B** relative to a hydraulic reference at atmospheric pressure is less than the value specified in the **Valve pressure setting** block parameter.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve pressure setting** — Pressure drop to maintain at port B relative to a hydraulic reference  
 $30e5 \text{ Pa}$  (default) | positive scalar in units of pressure

Gauge pressure that the valve is to maintain at port **B**. The valve closes in proportion to the gauge pressure if it should exceed the value specified here. If the pressure drop is less than this value, the opening area is that specified in the **Maximum passage area** block parameter.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve regulation range** — Pressure interval over which the valve is designed to operate  
 $1.5e5 \text{ Pa}$  (default) | positive scalar in units of pressure

Pressure interval over which the valve is designed to operate. This interval stretches from the largest pressure at which the valve is fully open to the lowest pressure at which the valve is fully closed. Only within this range is the valve capable of maintaining the specified pressure setting.

### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Discharge coefficient** — Empirical factor defined as the ratio of actual to ideal mass flow rates  
 $0.7$  (default) | positive unitless scalar

Ratio of the actual flow rate through the valve to the theoretical value that it would have in an ideal valve. This semi-empirical parameter measures the flow allowed through the valve: the greater its value, the greater the flow rate. Refer to the valve data sheet, if available, for this parameter.

**Leakage area** — Opening area of the valve in the maximally closed position  
 $1e-10 \text{ m}^2$  (default) | positive scalar in units of area

Opening area of the valve in the fully closed position, when only internal leakage between its ports remains. This parameter serves primarily to ensure that closure of the valve does not cause portions

of the thermal liquid network to become isolated. The exact value specified here is less important than its being a small number greater than zero.

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Pressure differential vector** — Vector of pressure drops at which to tabulate the valve opening areas

[30.15E5 : 15E3 : 31.35E5] Pa (default) | vector of positive numbers in units of pressure

Vector of gauge pressures at port **B** at which to specify the opening area of the valve. The vector elements must increase monotonically from left to right. This order is important when specifying the **Opening area vector** block parameter.

The block uses this data to construct a lookup table by which to determine from the gauge pressure at port **B** the valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Opening area vector** — Vector of opening areas at the specified pressure differential breakpoints

[9E-5 : -1 : 1E-5] m<sup>2</sup> (default) | vector of positive numbers in units of area

Vector of opening areas corresponding to the breakpoints defined in the **Pressure differential vector** block parameter. The vector elements must decrease monotonically from left to right (with increasing pressure). For best results, avoid regions of flattened slope.

The block uses this data to construct a lookup table by which to determine from the gauge pressure at port **B** the valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

**Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Laminar transition specification** — Parameter in terms of which to define the boundary between laminar and turbulent regimes

Pressure ratio (default) | Reynolds number

Parameter in terms of which to specify the boundary between the laminar and turbulent flow regimes. The pressure ratio of the default parameterization is defined as the gauge pressure at the outlet divided by the same at the inlet.

**Laminar flow pressure ratio** — Pressure ratio at which the flow transitions between laminar and turbulent regimes

0.999 (default) | positive unitless scalar

Pressure ratio at which the flow is assumed to transition between laminar and turbulent regimes. The pressure ratio is defined as the gauge pressure at the outlet divided by the same at the inlet. The transition is assumed to be smooth and centered on this value.

**Dependencies**

This parameter is active when the **Laminar transition specification** block parameter is set to `Pressure ratio`.

**Critical Reynolds number** — Reynolds number at the boundary between laminar and turbulent flow regimes

12 (default) | positive unitless scalar

Reynolds number at which the flow is assumed to transition between laminar and turbulent regimes.

**Dependencies**

This parameter is active when the **Laminar transition specification** block parameter is set to `Reynolds number`.

**Opening dynamics** — Choice of whether to capture the opening dynamics of the valve

`Do not include valve opening dynamics (default)` | `Include valve opening dynamics`

Choice of whether to capture the opening dynamics of the valve. Selecting `Include valve opening dynamics` causes the valve to open gradually, so as to approach its new steady-state area over a small time span. The characteristic time for such transitions is given in the **Opening time constant** block parameter.

Setting this parameter to the alternative `Do not include valve opening dynamics` is equivalent to specifying a value of 0 for the opening time constant. The opening area is in this case assumed to reach its new steady-state value instantaneously.

Include opening dynamics to more accurately capture the behavior of a real valve. For best real-time simulation performance, use with a local solver or disable valve opening dynamics altogether.

**Opening time constant** — Characteristic time scale of the valve opening transitions

0.1 s (default) | positive scalar in units of time

Measure of the time taken by the valve to transition from its current opening area to a new steady-state value. The block uses this parameter to calculate the rate at which a valve is opening and from it the instantaneous opening area at the next time step.

**Dependencies**

This parameter is active when the **Opening dynamics** block parameter is set to `Include valve opening dynamics`.

**Initial area** — Opening area at the start of simulation

1e-12 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the direction of flow within the valve at the start of simulation. The block uses this parameter to calculate the initial rate at which the valve is opening and from it the instantaneous opening area at the next time step.

**Dependencies**

This parameter is active when the **Opening dynamics** block parameter is set to `Include valve opening dynamics`.

## **Version History**

**Introduced in R2016a**

### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

# Pressure-Reducing Valve (IL)

Pressure-reducing valve in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Pressure Control Valves

## Description

The Pressure-Reducing Valve (IL) block represents a pressure-reducing valve in an isothermal liquid network. The valve remains open when the pressure at port **B** is less than a specified pressure. When the pressure at port **B** meets or surpasses this pressure, the valve closes. The block operates based on the differential between the set pressure and the pressure at port **B**. The block contains a check valve portion that functions identically to the Check Valve (IL) block during flow reversals. For pressure control based on another location in the fluid network, see the Pressure Compensator Valve (IL) block.

## Set Pressure Control

The block regulates pressure between the set pressure and maximum pressure. When you set **Set pressure control** to:

- **Controlled** — You can connect a pressure signal to port **Ps**. The block regulates pressure when the pressure at port **B** is greater than the reference set pressure,  $P_{set}$ , and below  $P_{max}$ . The pressure at port **B** acts as the control pressure,  $P_{control}$ , for this valve.

$P_{max}$  is the sum of  $P_{set}$  and the pressure regulation range.

- **Constant** — The **Set pressure (gauge)** parameter defines a constant set pressure.

How the block determines the pressure regulation range depends on the **Opening parameterization** parameter:

- **Linear - Area vs. pressure** — The **Pressure regulation range** parameter defines the pressure regulation range.
- **Tabulated data - Area vs. Pressure** — The pressure regulation range is the difference between the last and first elements of the **Port B (gauge) vector** parameter.
- **Tabulated data - Volumetric flow rate vs. pressure** — The pressure regulation range is the difference between the first and last elements of the **Reference pressure at port B (gauge) vector** parameter.

## Area vs. Pressure Parameterizations

When you set **Opening parameterization** to **Linear - Area vs. pressure**, the block calculates the valve area as

$$A_{valve} = \hat{p}(A_{leak} - A_{max}) + A_{max}$$

where the normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{set}}{p_{max} - p_{set}}.$$

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{set}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

The figure demonstrates the opening characteristics of the valve when using the linear area parameterization. The opening area,  $A_{valve}$ , drops linearly with the outlet pressure,  $p_{B,gauge}$ . The opening area ranges from  $A_{leak}$  to  $A_{Max}$ , and the pressure operating range starts at  $p_{set}$  and goes to  $p_{max}$ .

When you set **Opening parameterization** to Tabulated data - Area vs. Pressure, the block calculates the opening area as

$$A_{valve} = \text{tablelookup}(p_{control, TLU}, A_{TLU}, p_{control}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest}),$$

where:

- $p_{control} = p_{B,gauge}$  is the control pressure.
- $p_{control, TLU} = p_{B, TLU} + p_{offset}$ .
- $p_{B, TLU}$  is the **Port B (gauge) vector** parameter.

- $p_{offset}$  is an internal pressure offset that causes the valve to start closing when  $p_{B,Gauge} = p_{set}$ , where  $p_{offset} = p_{set} - p_{B,TLU}(1)$ .
- $A_{TLU}$  is the **Opening area vector** parameter.

$A_{max}$  and  $A_{leak}$  are the first and last parameters of the **Opening area vector** parameter, respectively. The figure demonstrates the opening characteristics of the valve when using the tabulated area parameterization.

### Conservation of Mass

When you set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. Pressure, the block conserves mass such that:

$$\dot{m}_A + \dot{m}_B = 0.$$

The block calculates the mass flow rate as

$$\dot{m} = \frac{C_d A_{valve} \sqrt{2\rho}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 \right) [\Delta p^2 + \Delta p_{crit}^2]^{1/4}}}$$

where:

- $C_d$  is the **Discharge coefficient** parameter.

- $A_{valve}$  is the instantaneous valve open area.
- $A_{port}$  is the **Cross-sectional area at ports A and B** parameter.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number** parameter,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{valve}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area. The block calculates  $PR_{loss}$  as:

$$PR_{loss} = \frac{\sqrt{1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 (1 - C_d^2)} - C_d \frac{A_{valve}}{A_{port}}}{\sqrt{1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 (1 - C_d^2)} + C_d \frac{A_{valve}}{A_{port}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{loss}$  is 1.

The block determines the opening area,  $A_{valve}$ , using the valve opening dynamics.

### Opening Dynamics

For either area parameterization, you can choose to simulate the opening dynamics of the valve response. If you select **Opening dynamics**, the block adds a lag to the flow response when the valve opens, and  $A_{valve}$  becomes the dynamic opening area,  $A_{dyn}$ . Otherwise,  $A_{valve}$  is the steady-state opening area. The block calculates the instantaneous change in the dynamic opening area based on the **Opening time constant** parameter,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, the block ignores opening dynamics.

The block calculates the steady-state dynamics based on the control pressure,  $p_{control}$ , and using the same parameterization as the valve opening.

### Volumetric Flow Rate vs. Pressure Parameterization

The volumetric flow rate parameterization equations refer to these quantities:

- $\square_{TLU,ref}$  is the **Reference volumetric flow rate vector** parameter.
- $P_{A,gauge,ref}$  and  $P_{B,gauge,ref}$  are the **Reference pressure at port A (gauge) vector** and **Reference pressure at port B (gauge) vector** parameters, respectively.
- $p_{set,gauge}$  is either the **Set pressure (gauge)** parameter or the signal at port **Ps**.
- $K$  is the flow coefficient through the reducing stage, which the block calculates during the simulation.

- $\bar{\rho}$  is the average fluid density in the reducing valve.
- $\Delta p$  is the pressure drop across the valve for fluid flow.
- $\Delta p_{crit}$  is the critical pressure drop for fluid flow.
- $C_d$  is the discharge coefficient, which the block sets internally for the volumetric flow rate parameterization.
- $Re_{crit}$  is the critical Reynolds number, which the block sets internally.
- $\nu$  is the kinematic viscosity, which is constant for the isothermal liquid network.

When you set **Opening parameterization** to **Tabulated data - Volumetric flow rate vs. pressure**, the block calculates the smoothed mass flow rate of the reducing valve such that

$$\dot{m}_{valve} = \bar{\rho} K \frac{\Delta p}{(\Delta p^2 + \Delta p_{crit}^2)^{1/4}}$$

$$\Delta p = p_A - p_B$$

$$\Delta p_{crit} = \frac{\pi \sqrt{2} \bar{\rho}}{8 C_d K} (Re_{crit} \nu)^2$$

where the block computes  $K$  using a `tablelookup` function such that

$$K = \text{tablelookup}(\Delta p_{control, TLU, Ref}, K_{TLU, Ref}, \Delta p_{control}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest})$$

$$K_{TLU, Ref} = \frac{\dot{V}_{TLU, Ref}}{\sqrt{\Delta p_{TLU, Ref}}}$$

The block calculates the control pressure as

$$\Delta p_{control} = p_B - p_{drain},$$

where the block sets the drain pressure,  $p_{drain}$ , to 1 atm. The block calculates the reference control pressure vector as

$$\Delta p_{control, TLU, Ref} = p_{B, gauge, ref} + p_{offset},$$

where  $p_{offset}$  is an internally computed pressure offset that causes the valve to start shutting when  $p_{B, gauge, ref} = p_{set, gauge}$ . Thus,  $p_{offset} = p_{set, gauge} - p_{B, gauge, ref}$ . The figure shows how the block controls pressure using the tabulated volumetric flow rate parameterization.

## Faults

You can control the fault settings of the reducing valve separately from the check valve. However, the fault parameters are similar for either portion of the valve. You can set **Reducing valve fault trigger** or **Check valve fault trigger** to:

- **Temporal** — Faulting occurs at a specified time.
- **External** — Faulting occurs in response to an external trigger. This exposes port **Tr** or **Tc** for the reducing valve and the check valve, respectively.

Three fault options are available for the reducing valve and check valve. For the **Reducing valve opening when faulted** and **Check valve opening when faulted** parameters, you can choose:

- **Closed** — The valve shuts to its smallest opening value, depending on the **Opening parameterization** parameter. When you set **Opening parameterization** to:
  - **Linear - Area vs. pressure** — The valve area reduces to the value of the **Leakage area** parameter.
  - **Tabulated data - Area vs. pressure** — The valve area reduces to the value of the last element in the **Opening area vector** parameter.
  - **Tabulated data - Volumetric flow rate vs. pressure** — The flow coefficient reduces to the value of the last element of the derived flow coefficient lookup table,  $K_{TLU,Ref}$ .
- **Open** — The valve opens to its largest opening value, depending on the **Opening parameterization** parameter. When you set **Opening parameterization** to:

- **Linear - Area vs. pressure** — The valve area opens to the value of the **Maximum opening area**.
- **Tabulated data - Area vs. pressure** — The valve area opens to the value of the first element in the **Opening area vector**.
- **Tabulated data - Volumetric flow rate vs. pressure** — The flow coefficient reduces to the value of the first element of the derived flow coefficient lookup table,  $K_{TLU,Ref}$ .
- **Maintain last value** — The valve area remains at the valve opening area when the trigger occurred.

For the linear parameterization, numerical smoothing at the extremes of the valve area causes the minimum area applied to be larger than the **Leakage area** parameter, and the maximum is smaller than the **Maximum orifice area** parameter.

Once triggered, the valve remains at the faulted area for the rest of the simulation.

### Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see "List of Pre-Parameterized Components".

## Ports

### Input

**Ps** — Set pressure signal, Pa  
physical signal

Pressure threshold for controlled valve operation, in Pa.

### Dependencies

To enable this port, set **Set pressure control** to **Controlled**.

**Tr** — External reducing valve fault trigger, unitless  
physical signal

Physical signal port for a unitless external fault trigger in the reducing valve. Triggering occurs when the value is greater than 0.5.

#### **Dependencies**

To enable this port, set **Enable reducing valve faults** to On and **Reducing valve fault trigger** to External.

**Tc** — External check valve fault trigger, unitless  
physical signal

Physical signal port for a unitless external fault trigger in the check valve. Triggering occurs when the value is greater than 0.5.

#### **Dependencies**

To enable this port, set **Enable check valve faults** to On and **Check valve fault trigger** to External.

#### **Conserving**

**A** — Liquid port  
isothermal liquid

Entry or exit point to the valve.

**B** — Liquid port  
isothermal liquid

Entry or exit point to the valve.

### **Parameters**

#### **Parameters**

**Set pressure control** — Valve operation method  
Constant (default) | Controlled

Valve operation method. When you set this parameter to **Constant**, the valve closes linearly over a fixed pressure regulation range or in accordance with the tabulated pressure and opening area data that you provide. When you set this parameter to **Controlled**, the valve closes according to a variable set pressure signal at port **Ps** over a fixed pressure regulation range.

**Opening parameterization** — Opening parameterization

Linear - Area vs. pressure (default) | Tabulated data - Area vs. pressure |  
Tabulated data - Volumetric flow rate vs. pressure

Method of modeling the opening of the valve. When you select **Linear - Area vs. pressure** or **Tabulated data - Area vs. pressure**, the block relates the opening area to the control pressure. When you select **Tabulated data - Volumetric flow rate vs. pressure**, the block takes a reference flow rate and pressure differential curve of the reducing valve..

**Set pressure (gauge)** — Gauge pressure beyond which valve operation triggers  
0.1 MPa (default) | positive scalar

Gauge pressure beyond which valve operation triggers. When the pressure at port **B** reaches this value, the valve begins to shut. This parameter shifts the reference curve so the reducing valve begins to close when the pressure at port **B** equals the set pressure.

**Dependencies**

To enable this parameter, set **Set pressure control** to Constant.

**Pressure regulation range** — Valve operational pressure range  
1 MPa (default) | positive scalar

Operational pressure range of the valve. The pressure regulation range begins at the **Set pressure (gauge)** and the end of the range is the maximum valve operating pressure.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Maximum opening area** — Area of fully opened valve  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the valve in the fully open position.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Leakage area** — Valve gap area when in fully closed position  
 $1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value saturates to the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Port B (gauge) vector** — Vector of gauge pressure values for tabulated area parameterization  
[0.2 : 0.2 : 1.2] MPa (default) | 1-by-*n* vector

Vector of gauge pressure values for the tabulated parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. The elements must be positive and in ascending order. The block uses linear interpolation between the data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Area vs. pressure.

**Opening area vector** — Valve opening areas for tabulated parameterization  
[1e-05, 8e-06, 6e-06, 4e-06, 2e-06, 1e-10]  $\text{m}^2$  (default) | 1-by-*n* vector

Vector of valve opening areas for the tabulated parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Port B (gauge) vector** parameter. The elements must be positive and in ascending order. The block uses linear interpolation between the data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Area vs. pressure.

**Cross-sectional area at ports A and B** — Area at valve entry or exit  
inf m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. The block uses these areas in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure recovery** — Option to include pressure increase during area expansions  
off (default) | on

Whether to capture the increase in pressure when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Opening dynamics** — Option to include flow response to valve opening  
off (default) | on

Whether to approximate the transient effects to the fluid system due to valve opening. Selecting **Opening dynamics** approximates opening conditions by introducing a first-order lag in the flow response.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Opening time constant** — Valve opening time constant  
0.1 s (default) | positive scalar

Time constant by which to compute the lag in the opening dynamics.

**Dependencies**

To enable this parameter, select **Opening dynamics** and set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Reference pressure at port A (gauge)** — Reference pressure at port A  
1.5 MPa (default) | positive scalar

Constant pressure at port **A** that forms the basis of the reference curve. This value typically corresponds to the maximum operating pressure of the valve. The pressure at port **A** can be any value during simulation.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Reference pressure at port B (gauge) vector** — Reference pressure at port B  
[1.2, 1, .8, .6, .4, .2] MPa (default) | 1-by-*n* vector

Vector of monotonically decreasing pressure values at port **B** in the reference curve as the valve opening area changes. The first element is the reference maximum pressure, which is the pressure where the valve fully shuts. The last element is the reference set pressure.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Reference volumetric flow rate vector** — Reference volumetric flow rate  
[1e-09, 1.8e-05, 6.6e-05, .00013, .0002, .00028] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of monotonically increasing reference flow rates through the valve. The block uses this curve to generate a flow coefficient for the changing valve area.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Check Valve**

**Enable check valve** — Check valve option

off (default) | on

Whether the block simulates an internal check valve.

**Cracking pressure differential** — Set pressure for check valve operation

0.1 MPa (default) | positive scalar

Pressure differential that lifts the check valve.

**Dependencies**

To enable this parameter, set **Enable check valve** to On and **Valve parameterization** to Linear - Area vs. pressure.

**Maximum opening pressure differential** — Maximum pressure in valve

0.2 MPa (default) | positive scalar

Pressure differential when the check valve fully shuts.

**Dependencies**

To enable this parameter, set **Enable check valve** to On and **Valve parameterization** to Linear - Area vs. pressure.

**Maximum opening area** — Maximum open area

1e-4 m<sup>2</sup> (default) | positive scalar

Maximum open area of the check valve in the load line. Internally, the check valve is in parallel with the reducing stage.

**Dependencies**

To enable this parameter, set **Enable check valve** to On and **Valve parameterization** to Linear - Area vs. pressure.

**Pressure differential vector** — Pressure differential for check valve operation

[0.01 : 0.01 : 1] MPa (default) | 1-by-*n* vector

Vector of pressure differentials for the check valve stage. The block computes the check valve pressure differential as pressure at port **B** with respect to pressure at port **A**.

**Dependencies**

To enable this parameter, set **Enable check valve** to On and **Valve parameterization** to Tabulated data - Area vs. pressure or Tabulated data - Volumetric flow rate vs. pressure.

**Opening area vector** — Check stage opening areas

[1e-10, 1e-05, 2e-05, 3e-05, 4e-05, 5e-05, 6e-05, 7.5e-05, 8.5e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the check valve stage. The vector elements must correspond one-to-one with the elements in the **Pressure differential vector** parameter.

#### Dependencies

To enable this parameter, set **Enable check valve** to On and **Valve parameterization** to Tabulated data - Area vs. pressure.

**Volumetric flow rate vector** — Check stage volumetric flow rates

[.000358, .045, .11, .191, .284, .39, .505, .63, .764, .905] .\* 1e-3 m<sup>3</sup>/s  
(default) | 1-by-*n* vector

Vector of volumetric flow rates for the check valve stage. The elements of this vector must correspond to the elements in the **Pressure differential vector** parameter.

#### Dependencies

To enable this parameter, set **Enable check valve** to On and **Valve parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

#### Faults

**Enable reducing valve fault** — Reducing valve fault option

off (default) | on

Whether to enable the fault parameters for the reducing valve. When faulting occurs, the block sets the opening area to the position specified by the **Reducing valve opening when faulted** parameter.

**Reducing valve opening when faulted** — Reducing valve fault position

Closed (default) | Open | Maintain last value

Reducing valve position when the fault triggers. You can choose for the valve to fault open, shut, or in place.

#### Dependencies

To enable this parameter, set **Enable reducing valve fault** to On.

**Reducing valve fault trigger** — External or temporal reducing valve trigger option

Temporal (default) | External

Whether a reducing valve fault trigger occurs due to an external event or at a specified time. When you set this parameter to:

- **External**, the block enables port **Tr**. A physical signal at port **Tr** that is greater than 0.5 triggers faulting.
- **Temporal**, when the **Simulation time for reducing valve fault event** is reached, the block sets the valve area to the value specified in the **Reducing valve opening when faulted** parameter.

#### Dependencies

To enable this parameter, set **Enable reducing valve fault** to On.

**Simulation time for reducing valve fault event** — Time at which reducing valve fault triggers

5 s (default) | positive scalar

Simulation time at which the block sets the opening area to the position specified by the **Reducing valve opening when faulted** parameter.

**Dependencies**

To enable this parameter, set **Enable reducing valve fault** to On and **Reducing valve fault trigger** to Temporal.

**Enable check valve fault** — Check valve fault option  
off (default) | on

Whether to enable the fault parameters for the check valve. When faulting occurs, the block sets the opening area to the position specified by the **Check valve opening when faulted** parameter.

**Dependencies**

To enable this parameter, set **Enable check valve** to On.

**Check valve opening when faulted** — Check valve fault position  
Closed (default) | Open | Maintain last value

Check valve position when the fault triggers. You can choose for the valve to fault open, shut, or in place.

**Dependencies**

To enable this parameter, set **Enable check valve** to On and **Enable check valve fault** to On.

**Check valve fault trigger** — External or temporal check valve trigger option  
Temporal (default) | External

Whether a check valve fault trigger occurs due to an external event or at a specified time. When you set this parameter to:

- **External**, the block enables port **Tc**. A physical signal at port **Tc** that is greater than 0.5 triggers faulting.
- **Temporal**, when the **Simulation time for check valve fault event** is reached, the valve area will be set to the value specified in the **Check valve opening when faulted** parameter.

**Dependencies**

To enable this parameter, set **Enable check valve** to On and **Enable check valve fault** to On.

**Simulation time for check valve fault event** — Time at which check valve fault triggers  
5 s (default) | positive scalar

Simulation time at which the block sets the opening area to the position specified by the **Check valve opening when faulted** parameter.

**Dependencies**

To enable this parameter, set **Enable check valve** to On, **Enable check valve fault** to On, and **Check valve fault trigger** to Temporal.

## Version History

Introduced in R2020a

**R2022b: Parameterize by volumetric flow rate vs. pressure**

You can set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**R2022b: Access pre-parameterized block options**

The block supports pre-parameterization options. Suppliers include Hawe Hydraulik, Rexroth Bosch Group, and Sun Hydraulics.

# Pressure Reducing Valve (G)

Pressure reducing valve in a gas network

## Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Reducing Valve (G) block represents a valve that constricts to maintain a preset gauge pressure at its outlet, port **B**. The normally open valve begins to close when the outlet pressure, measured against atmospheric pressure, rises above the valve pressure setting. The opening area falls with the pressure drop down to a minimum, where the valve is fully closed and only leakage flow remains.

The relationship between the opening area and the pressure drop depends on the parameterization of the valve. That relationship can take the form of a linear analytical expression or a tabulated function.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

## Control and Other Pressures

The pressure at the outlet is the control signal of the valve. The more the outlet pressure rises over the pressure setting of the valve, the smaller the opening area becomes. The control pressure,  $P_{Ctl}$ , is

$$P_{Ctl} = P_B - P_{Atm}$$

where  $P_B$  is the instantaneous pressure at port **B** and  $P_{Atm}$  is the atmospheric pressure specified in the Gas Properties (G) block of the model. Both pressures are determined during simulation as absolute pressures.

The pressure setting,  $P_{Set}$ , of the valve is the value of the **Set pressure (gauge)** parameter when the **Opening characteristic** parameter is **Linear**. When the **Opening characteristic** parameter is **Tabulated**,  $P_{Set}$  is the first element of the **Port B pressure (gauge) vector** parameter.

The maximum pressure,  $P_{Max}$ , is  $P_{Max} = P_{Set} + \Delta P$ , where  $\Delta P$  is the pressure regulation range of the valve when the **Opening characteristic** parameter is **Linear**. When the **Opening characteristic** parameter is **Tabulated**,  $P_{Set}$  is the last element of the **Port B pressure (gauge) vector** parameter.

## Fraction of Valve Opening

The degree to which the control pressure exceeds the pressure setting determines how much the valve opens. When the **Opening characteristic** parameter is **Linear**, the block calculates the valve opening fraction to scale the flow characteristic parameters. The valve opening fraction is

$$\widehat{P} = 1 - \frac{P_{Ctl} - P_{Set}}{\Delta P},$$

where:

- $P_{Ctl}$  is the control pressure.
- $P_{Set}$  is the pressure setting specified by the **Set pressure (gauge)** parameter.
- $\Delta P$  is the pressure regulation range specified by the **Pressure regulation range** parameter.

The fraction is normalized so that it is 0 in the fully closed valve and 1 in the fully open valve. If the calculation returns a value outside of these bounds, the block saturates the value to the nearest of the two limits.

### Numerical Smoothing

When the **Opening characteristic** parameter is **Linear** and the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the normalized control pressure,  $\widehat{P}$ . Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area** — The size of the flow restriction determines the block parameterization.

### Opening Characteristics

The flow characteristic relates the opening of the valve to the input that produces it. The opening is expressed as a sonic conductance, flow coefficient, or restriction area, determined by the **Valve parameterization** parameter.

The flow characteristic is normally given at steady state, with the inlet at a constant, carefully controlled pressure. This inherent flow characteristic depends only on the valve and it can be linear or nonlinear, the most common examples of the latter being the quick-opening and equal-percentage types. To capture such flow characteristics, the block provides a choice for the **Opening characteristic** parameter:

- **Linear** — The measure of flow capacity is a linear function of the orifice opening fraction. As the opening fraction rises from 0 to 1, the measure of flow capacity scales from its specified minimum to its specified maximum.

- **Tabulated** — The measure of flow capacity is a general function, which can be linear or nonlinear, of the orifice opening fraction. The function is specified in tabulated form, with the independent variable specified by the **Port B pressure (gauge) vector**.

### Momentum Balance

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to Cv flow coefficient parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}},$$

where:

- $C_v$  is the flow coefficient.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.
- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3 p_{in} F_\gamma x_T},$$

where:

- $F_\gamma$  is the ratio of the isentropic exponent to 1.4.
- $x_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_v N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{\rho_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3 F_\gamma x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_{\gamma}x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3}C_v N_6 \sqrt{F_{\gamma} x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, see [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C\rho_{ref}p_{in}\sqrt{\frac{T_{ref}}{T_{in}}}\left[1 - \left(\frac{\frac{p_{out}}{p_{in}} - B_{crit}}{1 - B_{crit}}\right)^2\right]^m,$$

where:

- $C$  is the sonic conductance.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.
- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ ,

$$\dot{m} = C\rho_{ref}\sqrt{\frac{T_{ref}}{T_{avg}}}\left[1 - \left(\frac{B_{lam} - B_{crit}}{1 - B_{crit}}\right)^2\right]^m \left(\frac{p_{in} - p_{out}}{1 - B_{lam}}\right).$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C\rho_{ref}p_{in}\sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma - 1} p_{in} \rho_{in} \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}} \left[ \frac{1 - \left(\frac{p_{out}}{p_{in}}\right)^{\frac{\gamma - 1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}}}\right]}$$

where:

- $S_r$  is the orifice or valve area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \left[ \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 B_{lam}^{\frac{2}{\gamma}}} \right] \left( \frac{p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}}}{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}} \right)}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_R \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left(\frac{\gamma+1}{2}\right)^{\frac{2}{\gamma-1}} - \left(\frac{S_R}{S}\right)^2}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area parameterization, see [4].

### Mass Balance

The block assumes the volume and mass of fluid inside the valve is very small and ignores these values. As a result, no amount of fluid can accumulate in the valve. By the principle of conservation of mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

## Assumptions and Limitations

- The `Sonic conductance` setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the `Orifice area` parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Conserving

**A** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow must enter the valve.

**B** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow must exit the valve.

## Parameters

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice  
`Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area`

Method to calculate the mass flow rate.

- `Cv flow coefficient` — The flow coefficient  $C_v$  determines the block parameterization.
- `Kv flow coefficient` — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- `Sonic conductance` — The sonic conductance of the resistive element at steady state determines the block parameterization.
- `Orifice area` — The size of the flow restriction determines the block parameterization.

**Opening characteristic** — Method to calculate the opening characteristics of the valve  
`Linear (default) | Tabulated`

Method the block uses to calculate the opening area of the valve. The linear setting treats the opening area as a linear function of the orifice opening fraction. The tabulated setting allows for a general, nonlinear relationship you can specify in tabulated form.

**Set pressure (gauge)** — Outlet gauge pressure required to close valve  
`0.1 MPa (default) | scalar`

Outlet gauge pressure required to close the valve. This parameter marks the beginning of the pressure regulation range, over which the valve progressively closes in an effort to contain a pressure rise. The opening area of the valve depends on the difference between the actual outlet pressure to the value specified here.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Pressure regulation range** — Width of the pressure range over which the opening area is variable  
0.1 MPa (default) | scalar

Width of the pressure range over which the opening area of the valve is variable. The pressure range begins at the value of the **Set pressure (gauge)** parameter. It ends at the sum of the values of this parameter and the **Set pressure (gauge)** parameter. The smaller the pressure regulation range, the greater the impact of a unit pressure rise on the opening area of the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear.

**Port B pressure (gauge) vector** — Vector of control pressures at which to specify valve opening data  
0.2 : 0.2 : 1.2 MPa (default) | vector in units of pressure

Vector of control pressures at which to specify the chosen measure of valve opening—sonic conductance, flow coefficient, or opening area. This vector must be equal in size to those containing the valve opening data. The vector elements must be positive and increase monotonically in value from left to right.

The first vector element gives the pressure setting of the valve where the valve begins to close. This element is equivalent to the **Set pressure (gauge)** parameter of the Linear opening parameterizations. The last element gives the maximum pressure, at which the valve is maximally closed and only leakage flow remains. The difference between the two gives the pressure regulation range of the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Linear.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Leakage flow fraction** — Ratio of flow rates  
1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Cv flow coefficient vector** — Cv coefficients corresponding to values in opening fraction vector  
[1e-06, .8, 1.6, 2.4, 3.2, 4] (default) | vector of positive numbers

Vector of  $C_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector**.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component  
3.6 (default) | positive scalar

Value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Linear.

**Kv flow coefficient vector** — Kv coefficients corresponding to values in opening fraction vector  
[1e-06, .72, 1.44, 2.16, 2.88, 3.6] (default) | vector of positive numbers

Vector of  $K_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically

from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12  $\text{l}/(\text{bar}\cdot\text{s})$  (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference density** — ISO 8778 reference density  
1.185  $\text{kg}/\text{m}^3$  (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185  $\text{kg}/\text{m}^3$  in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Sonic conductance vector** — Sonic conductances corresponding to values in opening fraction vector  
[1e-05, 2.4, 4.8, 7.2, 9.6, 12]  $\text{l}/(\text{bar}\cdot\text{s})$  (default) | vector of positive values

Vector of sonic conductances inside the resistive element. Each conductance corresponds to a value in the **Opening fraction vector** parameter. The sonic conductances must increase monotonically from left to right, with greater opening fractions representing greater sonic conductances. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Valve parameterization** to `Sonic conductance`, and **Opening characteristic** to `Tabulated`.

**Critical pressure ratio vector** — Critical pressure ratios corresponding to values in opening fraction vector

0.3 \* ones(1,6) (default) | vector of positive numbers

Vector of critical pressure ratios at which the flow first chokes, with each critical pressure ratio corresponding to a value in the **Opening fraction vector** parameter. The critical pressure ratio is the fraction of downstream-to-upstream pressures at which the flow velocity reaches the local speed of sound. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Valve parameterization** to `Sonic conductance`, and **Opening characteristic** to `Tabulated`.

**Maximum orifice area** — Flow area corresponding to maximally open component

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

#### Dependencies

To enable this parameter, set **Valve parameterization** to `Orifice area`, and **Opening characteristic** to `Linear`.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

#### Dependencies

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Orifice area vector** — Vector of orifice opening area values

[1e-10, 2e-05, 4e-05, 6e-05, 8e-05, .0001] m<sup>2</sup> (default) | vector

Vector of cross-sectional areas of the orifice opening. The values in this vector correspond one-to-one with the elements in the **Opening fraction vector** parameter. The first element of this vector is the orifice leakage area and the last element is the maximum orifice area.

#### Dependencies

To enable this parameter, set **Valve parameterization** to `Orifice area`, and **Opening characteristic** to `Tabulated`.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes

0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports

0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

Introduced in R2018b

### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.
- The **Control pressure vector** parameter has been renamed to **Port B pressure (gauge) vector**.

# Pressure Reducing Valve (TL)

Pressure reducing valve in a thermal liquid network

## Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Reducing Valve (TL) block represents a valve that reduces downstream pressure in a thermal liquid network. The valve remains open when the pressure at port **B** is less than a specified pressure. When the pressure at port **B** meets or surpasses this pressure, the valve closes. The block operates based on the differential between the set pressure and the pressure at port **B**.

## Mass Balance

The mass conservation equation in the valve is

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate into the valve through port **A**.
- $\dot{m}_B$  is the mass flow rate into the valve through port **B**.

## Mass Flow Rate

The block calculates the mass flow rate as

$$\dot{m} = \frac{C_d A_{valve} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss} \left(1 - \left(\frac{A_{valve}}{A_{port}}\right)^2\right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $C_d$  is the value of the **Discharge coefficient** parameter.
- $A_{valve}$  is the instantaneous valve open area.
- $A_{port}$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\pi}{8A_{valve}\bar{\rho}} \left( \frac{\mu Re_{crit}}{C_d} \right)^2,$$

where  $\mu$  is the dynamic viscosity of the thermal liquid.

The pressure loss,  $PR_{loss}$ , describes the reduction of pressure in the valve due to a decrease in area. The block calculates  $PR_{loss}$  as

$$PR_{loss} = \frac{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{valve}}{A_{port}}}{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{valve}}{A_{port}}}$$

The pressure recovery describes the positive pressure change in the valve due to an increase in area. When you clear the **Pressure recovery** check box, the block sets  $PR_{loss}$  to 1.

### Opening Parameterization

When you set the **Opening parameterization** parameter to Linear - Area vs. pressure, the block calculates the opening area as

$$A_{valve} = \hat{p}(A_{leak} - A_{max}) + A_{max}$$

where  $A_{leak}$  is the value of the **Leakage Area** parameter and  $A_{max}$  is the value of the **Maximum opening area** parameter. The normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{set}}{p_{Max} - p_{set}}$$

where

- $p_{set}$  is the valve set pressure:

$$p_{set} = p_{set, gauge} + p_{Atm}$$

where  $p_{Atm}$  is the atmospheric pressure.

- $p_{Max}$  is the maximum pressure

$$p_{Max} = p_{set, gauge} + p_{range} + p_{Atm}$$

This figure shows how the block controls the opening area using the linear parameterization.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{set}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

When you set **Opening parameterization** to Tabulated data - Area vs. pressure, the block calculates the opening area as

$$A_{valve} = \text{tablelookup}(p_{control, TLU, ref}, A_{TLU}, p_{control}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest}),$$

where:

- $p_{control, TLU, ref} = p_{TLU} + p_{offset}$ .
- $p_{TLU}$  is the **Pressure differential vector** parameter.
- $p_{offset}$  is an internal pressure offset that causes the valve to start closing when  $p_{control, TLU, ref} = p_{set}$ .
- $A_{TLU}$  is the **Opening area vector** parameter.

This figure shows how the block controls the opening area when **Opening parameterization** is Tabulated data - Area vs. pressure.

When you set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure, the valve opens according to the user-provided tabulated data of volumetric flow rate and pressure differential between ports **A** and **B**.

The block calculates the mass flow rate as

$$\dot{m} = \bar{\rho} \dot{V},$$

where:

- $\dot{V}$  is the volumetric flow rate.
- $\bar{\rho}$  is the average fluid density.

The block calculates the relationship between the mass flow and pressure using

$$\dot{m} = K \bar{\rho} \sqrt{\Delta p},$$

where

$$K = \frac{\dot{V}}{\sqrt{|\Delta p|}}.$$

## Opening Dynamics

When you select **Opening dynamics**, the block introduces a control pressure lag where  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ . The instantaneous change in dynamic opening area is calculated based on the **Opening time constant** parameter,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, the block clears the **Opening dynamics** check box.

## Energy Balance

The energy conservation equation in the valve is

$$\phi_A + \phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate into the valve through port **A**.
- $\phi_B$  is the energy flow rate into the valve through port **B**.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet A.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet B.

## Parameters

**Opening parameterization** — Opening parameterization

Linear - Area vs. pressure (default) | Tabulated data - Area vs. pressure |  
Tabulated data - Volumetric flow rate vs. pressure

Method of modeling the opening of the valve. When you set this parameter to **Linear - Area vs. pressure** or **Tabulated data - Area vs. pressure**, the block relates the opening area to the control pressure. When you set this parameter to **Tabulated data - Volumetric flow rate vs. pressure**, the block takes the reference flow rate and pressure differential curve of the reducing valve.

**Set pressure (gauge)** — Gauge pressure at which the valve begins to shut  
0.1 MPa (default) | positive scalar

Pressure at which the valve begins to shut. The opening area remains variable throughout the pressure regulation range of the valve.

**Pressure regulation range** — Valve pressure range

0.01 MPa (default) | positive scalar

Pressure interval over which the valve opening area varies. The interval begins at the value of the **Set pressure (gauge)** parameter.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Maximum opening area** — Opening area in fully open position1e-4 m<sup>2</sup> (default) | positive scalar

Opening area of the valve in the fully open position due to sealing imperfections, when the valve is at the lower limit of the pressure regulation range. The block uses this parameter to scale the valve opening throughout the pressure regulation range.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Leakage area** — Gap area when in fully closed position1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully shut position. The block saturates smaller numbers to this value. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure at port B (gauge) vector** — Vector of gauge pressure values for tabulated area parameterization[0.2 : 0.2 : 1.2] MPa (default) | 1-by-*n* vector

Vector of gauge pressure values for the tabulated area parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. The elements must be positive and in ascending order. The block uses linear interpolation between the data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Area vs. pressure.

**Opening area vector** — Valve opening areas for tabulated area parameterization[1e-05, 8e-06, 6e-06, 4e-06, 2e-06, 1e-10] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of valve opening areas for the tabulated area parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Pressure at Port B (gauge) vector** parameter. The elements must be positive and in ascending order. The block uses linear interpolation between the data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Area vs. pressure.

**Reference pressure at port A (gauge)** — Reference pressure at port A

1.5 MPa (default) | positive scalar

Constant pressure at port **A** that forms the basis of the reference curve. This value typically corresponds to the maximum operating pressure of the valve. The pressure at port **A** can be any value during simulation.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Reference pressure at port B (gauge) vector** — Reference pressure at port B[1.2, 1, .8, .6, .4, .2] MPa (default) | 1-by-*n* vector

Vector of monotonically decreasing pressure values at port **B** in the reference curve as the valve opening area changes. The first element is the reference maximum pressure, which is the pressure where the valve fully shuts. The last element is the reference set pressure.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Reference volumetric flow rate vector** — Reference volumetric flow rate[1e-09, 1.8e-05, 6.6e-05, .00013, .0002, .00028] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of monotonically increasing reference flow rates through the valve. The block uses this curve to generate a flow coefficient for the changing valve area.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Cross-sectional area at ports A and B** — Area at conserving ports0.01 m<sup>2</sup> (default) | positive scalar

Area at ports **A** and **B**, which the block uses in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that the block uses to account for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure recovery** — Option to include pressure increase during area expansions

off (default) | on

Whether to capture the increase in pressure when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Opening dynamics** — Option to include flow response to valve opening

off (default) | on

Whether to approximate the transient effects to the fluid system due to valve opening. Selecting **Opening dynamics** approximates opening conditions by introducing a first-order lag in the flow response.

**Opening time constant** — Valve opening time constant

0.1 s (default) | positive scalar

Time constant by which to compute the lag in the opening dynamics.

**Dependencies**

To enable this parameter, select **Opening dynamics**.

Pressure Relief Valve (TL) | Pressure Compensator Valve (TL)

## Pressure-Reducing Valve (2P)

Pressure-reducing valve in a two-phase fluid network

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Valves & Orifices / Pressure Control Valves

### Description

The Pressure-Reducing Valve (2P) block models a pressure-controlling reducing valve in a two-phase fluid network. The valve is open when the pressure at port **B** is less than the set pressure, and closes when the pressure exceeds that value. The control pressure can be set as a constant in the **Set pressure (gauge)** parameter or, when you set **Set pressure control** to **Controlled**, the set pressure can vary according to the input signal at port **Ps**.

Fluid properties inside the valve are calculated from inlet conditions. There is no heat exchange between the fluid and the environment, and therefore phase change inside the valve only occurs due to a pressure drop or a propagated phase change from another part of the model.

A number of block parameters are based on nominal operating conditions, which correspond to the valve rated performance, such as a specification on a manufacturer datasheet.

### Pressure Control

The valve closes when the pressure in the valve,  $p_{control}$ , exceeds the set pressure,  $p_{set}$ . The valve is fully closed when the control pressure reaches the end of the **Pressure regulation range**,  $p_{range}$ .

When you set **Set pressure control** to **Constant**, the opening fraction of the valve,  $\lambda$ , is expressed as:

$$\lambda = 1 - (1 - f_{leak}) \frac{(p_{control} - p_{set})}{p_{range}},$$

where:

- $f_{leak}$  is the **Closed valve leakage as a fraction of nominal flow**.
- $p_{control}$  is the control pressure, which is the difference between the pressure at port **B** and atmospheric pressure.
- $p_{set}$  is the **Set pressure (gauge)**.

When you set **Set pressure control** to **Controlled**, the valve opening fraction is:

$$\lambda = 1 - (1 - f_{leak}) \frac{(p_{control} - p_s)}{p_{range}},$$

where  $p_s$  is the signal at port **Ps**. If the control pressure exceeds the valve pressure range, the valve opening fraction is 0.

### Mass Flow Rate

The mass flow rate depends on the pressure differential, and therefore the open area of the valve. It is calculated as:

$$\dot{m}_A = \lambda \dot{m}_{nom} \left[ \sqrt{\frac{v_{nom}}{2\Delta p_{nom}}} \right] \sqrt{\frac{2}{v_{in} (\Delta p^2 + \Delta p_{lam}^2)^{0.25}}},$$

where:

- $\Delta p$  is the pressure drop over the valve,  $p_A - p_B$ .
- $\Delta p_{lam}$  is the pressure transition threshold between laminar and turbulent flow, which is calculated from the **Laminar flow pressure ratio**,  $B_{lam}$ :

$$\Delta p_{lam} = \frac{(p_A + p_B)}{2} (1 - B_{lam}).$$

- $\dot{m}_{nom}$  is the **Nominal mass flow rate at maximum opening**.
- $\Delta p_{nom}$  is the **Nominal pressure drop rate at maximum opening**.
- $v_{nom}$  is the nominal inlet specific volume. This value is determined from the fluid properties tabulated data based on the **Nominal inlet specific enthalpy** and **Nominal inlet pressure** parameters.
- $v_{in}$  is the inlet specific volume.

### Fluid Specific Volume Dynamics

When the fluid at the valve inlet is a liquid-vapor mixture, the block calculates the specific volume as:

$$v_{in} = (1 - x_{dyn})v_{liq} + x_{dyn}v_{vap},$$

where:

- $x_{dyn}$  is the inlet vapor quality. The block applies a first-order lag to the inlet vapor quality of the mixture.
- $v_{liq}$  is the liquid specific volume of the fluid.
- $v_{vap}$  is the vapor specific volume of the fluid.

If the inlet fluid is liquid or vapor,  $v_{in}$  is the respective liquid or vapor specific volume.

### Vapor quality lag

If the inlet vapor quality is a liquid-vapor mixture, a first-order time lag is applied:

$$\frac{dx_{dyn}}{dt} = \frac{x_{in} - x_{dyn}}{\tau},$$

where:

- $x_{dyn}$  is the dynamic fluid vapor quality.
- $x_{in}$  is the current inlet vapor quality.
- $\tau$  is the **Inlet phase change time constant**.

If the inlet fluid is a subcooled liquid or superheated vapor,  $x_{dyn}$  is equal to  $x_{in}$ .

**Mass Balance**

Mass is conserved in the valve:

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

**Energy Balance**

Energy is conserved in the valve:

$$\Phi_A + \Phi_B = 0,$$

where:

- $\Phi_A$  is the energy flow at port **A**.
- $\Phi_B$  is the energy flow at port **B**.

**Assumptions and Limitations**

- The block does not model pressure recovery downstream of the valve.
- There is no heat exchange between the valve and the environment.
- The block does not model choked flow.

**Ports****Conserving**

**A** — Fluid port  
two-phase fluid

Fluid entry or exit port.

**B** — Fluid port  
two-phase fluid

Fluid entry or exit port.

**Input**

**Ps** — Set pressure  
physical signal

Input port for varying the set pressure signal.

**Dependencies**

To enable this port, set **Set pressure control** to **Controlled**.

## Parameters

**Set pressure control** — Varying or constant set pressure  
Constant (default) | Controlled

Whether the pressure threshold is constant or variable. Setting this parameter to `Controlled` exposes the physical signal port **Ps**.

**Set pressure (gauge)** — Pressure threshold  
0.1 MPa (default) | positive scalar

Valve pressure threshold. When the control pressure,  $p_B - p_{atm}$ , exceeds the set pressure, the valve begins to close.

### Dependencies

To enable this parameter, set **Set pressure control** to `Constant`.

**Pressure regulation range** — Valve operational range  
0.1 MPa (default) | positive scalar

Valve operational range. The valve begins to close at the set pressure value, and is fully closed at  $p_{max}$ , the end of the pressure regulation range:  $p_{max} = p_{set} + p_{range}$ .

**Nominal mass flow rate at maximum opening** — Rated mass flow rate  
0.1 kg/s (default) | positive scalar

Mass flow rate through a fully open valve under typical, design, or rated conditions.

**Nominal pressure drop at maximum opening** — Rated pressure drop  
0.001 MPa (default) | positive scalar

Pressure drop over a fully open valve under typical, design, or rated conditions.

**Nominal inlet condition specification** — Method of determining inlet fluid state  
Temperature (default) | Vapor quality | Vapor void fraction | Specific enthalpy | Specific internal energy

Method of determining inlet fluid state. The valve inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet pressure** — Pressure of fluid entering valve  
0.101325 MPa (default) | positive scalar

Inlet pressure in typical, design, or rated conditions. The valve inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet temperature** — Fluid temperature  
293.15 K (default) | positive scalar

Inlet fluid temperature in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Inlet vapor quality by mass fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet vapor quality of the mixture by mass fraction in open, nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor quality.

**Nominal inlet vapor void fraction** — Inlet vapor quality by volume fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet mixture volume fraction in nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor void fraction.

**Nominal inlet specific enthalpy** — Inlet fluid specific enthalpy

1500 kJ/kg (default) | positive scalar

Inlet specific enthalpy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific enthalpy.

**Nominal inlet specific internal energy** — Inlet specific internal energy

1500 kJ/kg (default) | positive scalar

Inlet specific internal energy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific internal energy.

**Cross-sectional area at ports A and B** — Valve port areas

0.01 m<sup>2</sup> (default) | positive scalar

Area of the valve ports **A** and **B**.

**Closed valve leakage as a fraction of nominal flow** — Fractional flow when valve is closed

1e-6 (default) | positive scalar

Fractional flow rate through the valve when it is fully closed. This parameter contributes to numerical stability by maintaining continuity in the fluid network.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Laminar-turbulent transition pressure ratio

0.999 (default) | positive scalar

Ratio of the valve outlet pressure to valve inlet pressure at which the fluid transitions between the laminar and turbulent regimes. The pressure loss corresponds to the mass flow rate linearly in laminar flows and quadratically in turbulent flows.

**Inlet phase change time constant** — Lag for mixture specific volume

0.1 s (default) | positive scalar

Time lag for liquid-vapor mixtures in computing the fluid specific volume. This parameter does not influence the specific volume when the inlet fluid is a fully supercooled liquid or fully superheated vapor.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Pressure Control Valves

## Description

The Pressure Relief Valve block models the flow through a valve that opens to vent so as to maintain a preset pressure drop between inlet (port **A**) and outlet (port **B**). The normally closed valve cracks open when the pressure drop from **A** to **B** exceeds the valve pressure setting. The valve opening area is computed as a function of the excess in the pressure drop, either a simple linear expression or a (generally nonlinear) tabulated function. The valve serves its purpose until its opening area reaches a maximum—a point at the limit of the valve regulation range, beyond which the pressure drop is again free to rise, unabated.

## Valve Opening

The opening area calculation depends on the valve parameterization selected for the block: either Linear area-opening relationship or Tabulated data - Area vs. pressure.

### Linear Parameterization

If the **Valve parameterization** block parameter is in the default setting of Linear area-opening relationship, the opening area is computed as:

$$S(\Delta p_{AB}) = S_{\text{Leak}} + k(\Delta p_{AB} - \Delta p_{\text{Set}}),$$

where:

- $S_{\text{Max}}$  is the value specified in the **Maximum passage area** block parameter.
- $\Delta p_{\text{Set}}$  is the value specified in the **Valve pressure setting** block parameter.
- $\Delta p_{AB}$  is the pressure drop from port **A** to port **B**:

$$\Delta p_{AB} = p_A - p_B,$$

where  $p$  is the gauge pressure at the port indicated by the subscript (**A** or **B**).

- $k$  is the linear constant of proportionality:

$$k = \frac{S_{\text{Max}} - S_{\text{Leak}}}{\Delta p_{\text{Reg}}},$$

where in turn:

- $S_{\text{Leak}}$  is the value specified in the **Leakage area** block parameter.
- $\Delta p_{\text{Reg}}$  is that specified in the **Valve regulation range** block parameter.

At and below the valve pressure setting, the opening area is that due to internal leakage alone:

$$S(\Delta p_{\text{AB}} \leq \Delta p_{\text{Set}}) = S_{\text{Leak}},$$

At and above a maximum pressure, the opening area is that of a fully open valve:

$$S(\Delta p_{\text{AB}} \geq \Delta p_{\text{Max}}) = S_{\text{Max}},$$

where the maximum pressure drop  $\Delta p_{\text{Max}}$  is the sum:

$$\Delta p_{\text{Max}} = \Delta p_{\text{Set}} + \Delta p_{\text{Reg}}.$$

## Opening area in the Linear area-opening relationship parameterization

### Tabulated Parameterization

If the **Valve parameterization** block parameter is set to Tabulated data - Area vs. pressure, the opening area is computed as:

$$S = S(\Delta p_{\text{AB}}),$$

where  $S_{\text{XY}}$  is a tabulated function constructed from the **Pressure drop vector** and **Opening area vector** block parameters. The function is based on linear interpolation (for points within the data range) and nearest-neighbor extrapolation (for points outside the data range). The leakage and maximum opening areas are the minimum and maximum values of the **Valve opening area vector** block parameter.

## Opening area in the Tabulated data - Area vs. pressure parameterization

### Opening Dynamics

By default, the valve opening dynamics are ignored. The valve is assumed to respond instantaneously to changes in the pressure drop, without time lag between the onset of a pressure disturbance and the increased valve opening that the disturbance produces. If such time lags are of consequence in a model, you can capture them by setting the **Opening dynamics** block parameter to `Include valve opening dynamics`. The valves then open each at a rate given by the expression:

$$\dot{S} = \frac{S(\Delta p_{SS}) - S(\Delta p_{In})}{\tau},$$

where  $\tau$  is a measure of the time needed for the instantaneous opening area (subscript In) to reach a new steady-state value (subscript SS).

### Leakage Area

The primary purpose of the leakage area of a closed valve is to ensure that at no time does a portion of the hydraulic network become isolated from the remainder of the model. Such isolated portions reduce the numerical robustness of the model and can slow down simulation or cause it to fail. Leakage is generally present in minuscule amounts in real valves but in a model its exact value is less important than its being a small number greater than zero. The leakage area is obtained from the block parameter of the same name.

### Valve Flow Rate

The causes of the pressure losses incurred in the passages of the valve are ignored in the block. Whatever their natures—sudden area changes, flow passage contortions—only their cumulative effect is considered during simulation. This effect is captured in the block by the discharge coefficient, a measure of the flow rate through the valve relative to the theoretical value that it would have in an ideal valve. The flow rate through the valve is defined as:

$$q = C_D S \sqrt{\frac{2}{\rho} \frac{\Delta p_{AB}}{[(\Delta p_{AB})^2 + p_{Crit}^2]^{1/4}}},$$

where:

- $q$  is the volumetric flow rate through the valve.
- $C_D$  is the value of the **Discharge coefficient** block parameter.

- $S$  is the opening area of the valve.
- $\Delta p_{AB}$  is the pressure drop from port **A** to port **B**.
- $p_{\text{Crit}}$  is the pressure differential at which the flow shifts between the laminar and turbulent flow regimes.

The calculation of the critical pressure depends on the setting of the **Laminar transition specification** block parameter. If this parameter is in the default setting of **By pressure ratio**:

$$p_{\text{Crit}} = (p_{\text{Atm}} + p_{\text{Avg}})(1 - \beta_{\text{Crit}}),$$

where:

- $p_{\text{Atm}}$  is the atmospheric pressure (as defined for the corresponding hydraulic network).
- $p_{\text{Avg}}$  is the average of the gauge pressures at ports **A** and **B**.
- $\beta_{\text{Crit}}$  is the value of the **Laminar flow pressure ratio** block parameter.

If the **Laminar transition specification** block parameter is instead set to **By Reynolds number**:

$$p_{\text{Crit}} = \frac{\rho}{2} \left( \frac{Re_{\text{Crit}} \nu}{C_D D_H} \right)^2,$$

where:

- $Re_{\text{Crit}}$  is the value of the **Critical Reynolds number** block parameter.
- $\nu$  is the kinematic viscosity specified for the hydraulic network.
- $D_H$  is the instantaneous hydraulic diameter:

$$D_H = \sqrt{\frac{4S}{\pi}}.$$

## Ports

### Conserving

**A** — Valve inlet

hydraulic (isothermal liquid)

Opening through which the flow can enter the valve.

**B** — Valve outlet

hydraulic (isothermal liquid)

Opening through which the flow can exit the valve.

## Parameters

**Opening area parameterization** — Method of calculating the opening area of the valve

Linear area-opening relationship (default) | Tabulated data - Area vs. pressure

Method by which to calculate the opening area of the valve. The default setting prescribes a linear relationship between the opening area of the valve and the pressure drop between its sensor ports. The alternative setting allows for a general, nonlinear relationship to be specified in tabulated form.

**Maximum passage area** — Opening area of the valve in the fully open position

1e-4 m<sup>2</sup> (default) | positive scalar in units of area

Opening area of the valve in the fully open position. The valve is fully open if the pressure drop from port **A** to port **B** is in excess of that given by the sum of the **Valve pressure setting** and **Valve regulation range** block parameters.

#### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve pressure setting** — Pressure drop to maintain from port A to port B

30e5 Pa (default) | positive scalar in units of pressure

Pressure drop from port **A** to port **B** that the valve is to maintain. The valve begins to open when the pressure drop exceeds the value specified here. If the pressure drop is less than this value, the valve is maximally closed and the opening area is that given in the **Leakage area** block parameter.

#### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Valve regulation range** — Pressure drop interval over which the valve is to designed to operate

1.5e5 Pa (default) | positive scalar in units of pressure

Pressure drop interval over which the valve is designed to operate. This interval stretches from the largest pressure drop at which the valve is maximally closed to the lowest pressure drop at which the valve is fully open. Only within this range is the valve capable of maintaining the specified pressure setting.

#### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Flow Discharge coefficient** — Empirical factor defined as the ratio of actual to ideal mass flow rates

0.7 (default) | positive unitless scalar

Ratio of the actual flow rate through the valve to the theoretical value that it would have in an ideal valve. This semi-empirical parameter measures the flow allowed through the valve: the greater its value, the greater the flow rate. Refer to the valve data sheet, if available, for this parameter.

**Leakage area** — Opening area of the valve in the maximally closed position

1e-10 m<sup>2</sup> (default) | positive scalar in units of area

Opening area of the valve in the fully closed position, when only internal leakage between its ports remains. This parameter serves primarily to ensure that closure of the valve does not cause portions of the thermal liquid network to become isolated. The exact value specified here is less important than its being a small number greater than zero.

#### Dependencies

This parameter is active when the **Opening area parameterization** block parameter is set to Linear area-pressure relationship.

**Pressure differential vector** — Vector of pressure drops at which to tabulate the valve opening areas

[30.15E5 : 15E3 : 31.35E5] Pa (default) | vector of positive numbers in units of pressure

Vector of pressure drops from port **A** to port **B** at which to specify the opening area of the valve. The vector elements must increase monotonically from left to right. This order is important when specifying the **Opening area vector** block parameter.

The block uses this data to construct a lookup table by which to determine from the gauge pressure at port **B** the valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

#### **Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Opening area vector** — Vector of opening areas at the specified pressure differential breakpoints

[9E-5 : -1 : 1E-5] m<sup>2</sup> (default) | vector of positive numbers in units of area

Vector of opening areas corresponding to the breakpoints defined in the **Pressure differential vector** block parameter. The vector elements must increase monotonically from left to right (the direction of increasing pressure). For best results, avoid regions of flattened slope.

The block uses this data to construct a lookup table by which to determine from the pressure differential the valve opening area. Data is handled with linear interpolation (within the tabulated data range) and nearest-neighbor extrapolation (outside of the range).

#### **Dependencies**

This parameter is active when the **Opening area parameterization** block parameter is set to Tabulated data - Area vs. pressure.

**Laminar transition specification** — Parameter in terms of which to define the boundary between laminar and turbulent regimes

Pressure ratio (default) | Reynolds number

Parameter in terms of which to specify the boundary between the laminar and turbulent flow regimes. The pressure ratio of the default parameterization is defined as the gauge pressure at the outlet divided by the same at the inlet.

**Laminar flow pressure ratio** — Pressure ratio at which the flow transitions between laminar and turbulent regimes

0.999 (default) | positive unitless scalar

Pressure ratio at which the flow is assumed to transition between laminar and turbulent regimes. The pressure ratio is defined as the gauge pressure at the outlet divided by the same at the inlet. The transition is assumed to be smooth and centered on this value.

#### **Dependencies**

This parameter is active when the **Laminar transition specification** block parameter is set to Reynolds number.

**Critical Reynolds number** — Reynolds number at the boundary between laminar and turbulent flow regimes

12 (default) | positive unitless scalar

Reynolds number at which the flow is assumed to transition between laminar and turbulent regimes.

#### Dependencies

This parameter is active when the **Laminar transition specification** block parameter is set to Pressure ratio.

**Opening dynamics** — Choice of whether to capture the opening dynamics of the valve

Do not include valve opening dynamics (default) | Include valve opening dynamics

Choice of whether to capture the opening dynamics of the valve. Selecting Include valve opening dynamics causes the valve to open gradually, so as to approach its new steady-state area over a small time span. The characteristic time for such transitions is given in the **Opening time constant** block parameter.

Setting this parameter to the alternative Do not include valve opening dynamics is equivalent to specifying a value of 0 for the opening time constant. The opening area is in this case assumed to reach its new steady-state value instantaneously.

Include opening dynamics to more accurately capture the behavior of a real valve. For best real-time simulation performance, use with a local solver or disable valve opening dynamics altogether.

**Opening time constant** — Characteristic time scale of the valve opening transitions

0.1 s (default) | positive scalar in units of time

Measure of the time taken by the valve to transition from its current opening area to a new steady-state value. The block uses this parameter to calculate the rate at which a valve is opening and from it the instantaneous opening area at the next time step.

#### Dependencies

This parameter is active when the **Opening dynamics** block parameter is set to Include valve opening dynamics.

**Initial area** — Opening area at the start of simulation

1e-12 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the direction of flow within the valve at the start of simulation. The block uses this parameter to calculate the initial rate at which the valve is opening and from it the instantaneous opening area at the next time step.

#### Dependencies

This parameter is active when the **Opening dynamics** block parameter is set to Include valve opening dynamics.

# Pressure Relief Valve (IL)

Pressure-relief valve in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Relief Valve (IL) block represents a pressure relief valve in an isothermal liquid network. The valve remains closed when the pressure is less than a specified value. When this pressure is met or surpassed, the valve opens. This set pressure is either a threshold pressure differential over the valve, between ports **A** and **B**, or between port **A** and atmospheric pressure. For pressure control based on another element in the fluid system, see the Pressure Compensator Valve (IL) block.

## Pressure Control

You can use a constant value or a physical signal to control the set pressure:

- When you set **Set pressure control** to **Controlled**, connect a pressure signal to port **Ps** and define the constant **Pressure regulation range**. The valve response will be triggered when  $P_{control}$ , the pressure differential between ports **A** and **B**, is greater than  $P_{set}$  and below  $P_{max}$ .  $P_{max}$  is the sum of  $P_{set}$  and the pressure regulation range.
- When you set **Set pressure control** to **Constant**, the valve opening is continuously regulated between  $P_{set}$  and  $P_{max}$ . There are two options for pressure regulation available in the **Opening pressure specification** parameter:  $P_{control}$  can be the pressure differential between ports **A** and **B** or the pressure differential between port **A** and atmospheric pressure. The opening area is then modeled by either linear or tabular parameterization. When the **Tabulated data** option is selected,  $P_{set}$  and  $P_{max}$  are the first and last parameters of the **Pressure differential vector**, respectively.

## Conservation of Mass

The block conserves mass through the valve such that

$$\dot{m}_A + \dot{m}_B = 0.$$

The block calculates the mass flow rate as

$$\dot{m} = \frac{C_d A_{valve} \sqrt{2\rho}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 \right) [\Delta p^2 + \Delta p_{crit}^2]^{1/4}}}, \Delta p$$

where:

- $C_d$  is the **Discharge coefficient**.

- $A_{valve}$  is the instantaneous valve open area.
- $A_{port}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{valve}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area.  $PR_{loss}$  is calculated as:

$$PR_{loss} = \frac{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{valve}}{A_{port}}}{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{valve}}{A_{port}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{loss}$  is 1.

The opening area  $A_{valve}$  is determined by the opening parameterization (for Constant valves only) and the valve opening dynamics.

### Opening Parameterization

When you set **Opening parameterization** to Linear - Area vs. pressure, the block calculates the opening area as

$$A_{valve} = \hat{p}(A_{max} - A_{leak}) + A_{leak},$$

where the normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{set}}{p_{max} - p_{set}}.$$

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{set}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

When you set **Opening parameterization** to Tabulated data - Area vs. pressure,  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the **Opening area vector**, respectively. The smoothed, normalized pressure is also used when the smoothing factor is nonzero with linear interpolation and nearest extrapolation.

When you set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure, the valve opens according to the user-provided tabulated data of volumetric flow rate and pressure differential between ports **A** and **B**.

Within the limits of the tabulated data, the block calculates the mass flow rate as:

$$\dot{m} = \bar{\rho}\dot{V},$$

where:

- $\dot{V}$  is the volumetric flow rate.
- $\bar{\rho}$  is the average fluid density.

When the simulation pressure falls below the first element of the **Pressure drop vector** parameter,  $\Delta p_{TLU}(1)$ , the block calculates the mass flow rate as:

$$\dot{m} = K_{Leak}\bar{\rho}\sqrt{\Delta p}.$$

$$K_{Leak} = \frac{V_{TLU}(1)}{\sqrt{|\Delta p_{TLU}(1)|}},$$

where  $V_{TLU}(1)$  is the first element of the **Volumetric flow rate vector** parameter.

When the simulation pressure rises above the last element of the **Pressure drop vector** parameter,  $\Delta p_{TLU}(end)$ , the block calculates the mass flow rate as

$$\dot{m} = K_{Max}\bar{\rho}\sqrt{\Delta p}$$

$$K_{Max} = \frac{V_{TLU}(end)}{\sqrt{|\Delta p_{TLU}(end)|}}$$

where  $V_{TLU}(end)$  is the last element of the **Volumetric flow rate vector** parameter.

### Opening Dynamics

When you select **Opening dynamics**, the block introduces lag in the flow response to the valve opening.  $A_{valve}$  becomes the dynamic opening area,  $A_{dyn}$ ; otherwise,  $A_{valve}$  is the steady-state opening area. The instantaneous change in dynamic opening area is calculated based on the **Opening time constant** parameter,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, the block clears the **Opening dynamics** check box.

Steady-state dynamics are set by the same parameterization as valve opening, and are based on the control pressure,  $p_{control}$ . A nonzero **Smoothing factor** can provide additional numerical stability when the orifice is in near-closed or near-open position.

### Faults

When faults are enabled, the valve open area becomes stuck at a specified value in response to one of these triggers:

- Simulation time — Faulting occurs at a specified time.
- Simulation behavior — Faulting occurs in response to an external trigger. This exposes port **Tr**.

Three fault options are available in the **Opening area when faulted** parameter:

- Closed — The valve freezes at its smallest value, depending on the **Opening parameterization** parameter:

- When you set **Opening parameterization** to Linear - Area vs. pressure, the valve area freezes at the **Leakage area** parameter.
- When you set **Opening parameterization** to Tabulated data - Area vs. pressure, the valve area freezes at the first element of the **Opening area vector** parameter.
- Open — The valve freezes at its largest value, depending on the **Opening parameterization** parameter:
  - When you set **Opening parameterization** to Linear - Area vs. pressure, the valve area freezes at the **Maximum opening area** parameter.
  - When you set **Orifice parameterization** to Tabulated data - Area vs. pressure, the valve area freezes at the last element of the **Opening area vector** parameter.
- Maintain last value — The valve area freezes at the valve open area when the trigger occurred.

Due to numerical smoothing at the extremes of the valve area, the minimum area applied is larger than the **Leakage area** parameter, and the maximum is smaller than the **Maximum orifice area** parameter, in proportion to the **Smoothing factor** parameter value.

Once triggered, the valve remains at the faulted area for the rest of the simulation.

When you set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure, the fault options are defined by the volumetric flow rate through the valve:

- Closed — The valve stops at the mass flow rate associated with the first elements of the **Volumetric flow rate vector** parameter and the **Pressure drop vector** parameter:

$$\dot{m} = K_{Leak} \bar{\rho} \sqrt{\Delta p}.$$

- Open — The valve stops at the mass flow rate associated with the last elements of the **Volumetric flow rate vector** parameter and the **Pressure drop vector** parameter:

$$\dot{m} = K_{Max} \bar{\rho} \sqrt{\Delta p}$$

- Maintain at last value — The valve stops at the mass flow rate and pressure differential when the trigger occurs:

$$\dot{m} = K_{Last} \bar{\rho} \sqrt{\Delta p},$$

where

$$K_{Last} = \frac{|\dot{m}|}{\bar{\rho} \sqrt{|\Delta p|}}.$$

### Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.

- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see “List of Pre-Parameterized Components”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry or exit point to the valve.

**B** — Liquid port  
isothermal liquid

Entry or exit point to the valve.

### Input

**Ps** — Set pressure signal  
physical signal

Varying-signal set pressure for controlled valve operation.

### Dependencies

To enable this port, set **Set pressure control** to **Controlled**.

**Tr** — External fault trigger  
physical signal

Physical signal port for an external fault trigger. Triggering occurs when the value is greater than 0.5. There is no unit associated with the trigger value.

### Dependencies

This port is visible when **Enable faults** is set to **On** and **Fault trigger** is set to **External**.

## Parameters

### Parameters

#### **Set pressure control** — Valve operation method

Constant (default) | Controlled

Valve operation method. A **Constant** valve opens linearly over a fixed pressure regulation range or in accordance with tabulated pressure and opening area data that you provide. A **Controlled** valve opens according to a variable set pressure signal at port **Ps** over a fixed pressure regulation range.

#### **Opening parameterization** — Method of modeling constant valve opening or closing

Linear - Area vs. pressure (default) | Tabulated data - Area vs. pressure |  
Tabulated data - Volumetric flow rate vs. pressure

Method of modeling valve opening or closing. The valve opening is either parametrized linearly or by a table of values that correlate area to pressure differential.

#### **Opening pressure specification** — Pressure differential used for valve control

Pressure differential (default) | Pressure at port A

Pressure differential used for the valve control. Selecting **Pressure differential** sets the pressure difference between port **A** and port **B** as the trigger for pressure control. Selecting **Pressure at port A** sets the gauge pressure at port **A**, or the difference between the pressure at port **A** and atmospheric pressure, as the trigger for pressure control.

#### **Set pressure (gauge)** — Threshold pressure

0.1 MPa (default) | positive scalar

Gauge pressure beyond which valve operation is triggered when the **Pressure control specification** is with respect to port **A**.

### Dependencies

To enable this parameter, set **Set pressure control** to **Constant** and **Pressure control specification** to **Pressure at port A**.

#### **Set pressure differential** — Threshold pressure

0 MPa (default) | positive scalar

Pressure beyond which valve operation is triggered. This is the set pressure when the **Pressure control specification** is with respect to the pressure differential between ports **A** and **B**.

### Dependencies

To enable this parameter, set **Set pressure control** to **Constant** and **Pressure control specification** to **Pressure differential**.

#### **Pressure regulation range** — Valve operational pressure range

0.1 MPa (default) | positive scalar

Operational pressure range of the valve. The pressure regulation range begins at the valve set pressure and the end of the range is the maximum valve operating pressure.

### Dependencies

To enable this parameter, set

- **Set pressure control** to Controlled
- **Set pressure control** to Constant and **Opening parameterization** to Linear - Area vs. pressure

**Maximum opening area** — Area of fully opened valve  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the valve in its fully open position.

#### Dependencies

To enable this parameter, set either:

- **Set pressure control** to Controlled
- **Set pressure control** to Constant and **Opening parameterization** to Linear - Area vs. pressure

**Leakage area** — Valve gap area when in fully closed position  
 $1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in fully closed position. Any area smaller than this value is maintained at the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

#### Dependencies

To enable this parameter, set either:

- **Set pressure control** to Controlled.
- **Set pressure control** to Constant and **Opening parameterization** to Linear - Area vs. pressure

**Opening pressure (gauge) vector** — Differential pressure values for tabular parameterization  
 $[0.2 : 0.2 : 1.2]$  MPa (default) | 1-by- $n$  vector

Vector of pressure differential values for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. The elements are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Set pressure control** to Constant, **Opening parameterization** to Tabulated data - Area vs. pressure, and **Opening pressure specification** to Pressure differential..

**Pressure differential vector** — Differential pressure values for tabular parameterization  
 $[0.2 : 0.2 : 1.2]$  MPa (default) | 1-by- $n$  vector

Vector of pressure differential values for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. The elements are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Set pressure control** to Constant, and set

- **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure, or
- **Opening parameterization** to Tabulated data - Area vs. pressure and **Opening pressure specification** to Pressure differential.

**Volumetric flow rate vector** — Vector of volumetric flow rate for tabulated data parameterization  
[1e-09, 3.6e-05, 8.9e-05, .00015, .00023, .00031] (default) | 1-by-*n* vector

Vector of volumetric flow rate values for the tabular parameterization of valve opening. This vector must have the same number of elements as the **Pressure drop vector** parameter. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Opening area vector** — Valve opening areas for tabular parameterization  
[1e-10, 2e-06, 4e-06, 6e-06, 8e-06, 1e-05] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of valve opening areas for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Pressure differential vector** parameter. The elements are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Set pressure control** to Constant and **Opening parameterization** to Tabulated data - Area vs. pressure.

**Cross-sectional area at ports A and B** — Area at valve entry or exit  
inf m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. These areas are used in the pressure-flow rate equation determining mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor accounting for discharge losses in theoretical flows. The default discharge coefficient for a valve in Simscape Fluids is 0.64.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### Dependencies

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
off (default) | on

Accounts for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area. This increase in pressure is not captured when you clear the **Pressure recovery** check box.

**Opening dynamics** — Whether to account for flow response to valve opening  
off (default) | on

Whether to account for transient effects to the fluid system due to valve opening. Selecting **Opening dynamics** approximates the opening conditions by introducing a first-order lag in the flow response. The **Opening time constant** also impacts the modeled opening dynamics.

#### Dependencies

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Opening time constant** — Valve opening time constant  
0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state when opening or closing the valve from one position to another. This parameter impacts the modeled opening dynamics.

#### Dependencies

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure and select **Opening dynamics**.

#### Faults

**Enable faults** — Fault option  
Off (default) | On

Enable externally or temporally triggered faults. When faulting occurs, the valve area normally set by the opening parameterization will be set to the value specified in the **Opening area when faulted** parameter.

**Opening area when faulted** — Set faulted characteristics  
Closed (default) | Open | Maintain last value

Sets the faulted valve type. You can choose for the valve to seize when the valve is opened, closed, or at the area when faulting is triggered.

#### Dependencies

To enable this parameter, set **Enable faults** to On.

**Fault trigger** — External or temporal trigger option  
Temporal (default) | External

Whether a fault trigger occurs due to an external event or at a specified time.

When set to External, port **Tr** is enabled. A physical signal at port **Tr** that is greater than 0.5 triggers faulting.

When set to Temporal, when the **Simulation time for fault event** is reached, the valve area will be set to the value specified in the **Opening area when faulted** parameter.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On.

**Simulation time for fault event** — Time at which faulting is triggered  
5 s (default) | positive scalar

When the **Simulation time for fault event** is reached, the valve area is set to the value specified in the **Opening area when faulted** parameter.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On and **Fault trigger** to Temporal.

## **Version History**

**Introduced in R2020a**

### **R2022b: Access pre-parameterized block options**

The block supports pre-parameterization options. Suppliers include Daikin, Kawasaki Heavy Industries, Parker, and Yuken.

## **Extended Capabilities**

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

# Pressure Relief Valve (G)

Pressure relief valve in a gas network

## Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Relief Valve (G) block represents an orifice that opens with inlet pressure to keep the pressure from reaching extreme levels. At normal pressures, the valve is closed and only releases leakage flow. Above a specified pressure setting, the valve begins to open, which allows the gas to vent from the region of high pressure. The opening area increases with inlet pressure up to a maximum value, at which point the valve is fully open and pressure rises unabated.

The valve responds to inlet pressure relative to the outlet or inlet pressure relative to the environment. The chosen pressure measurement is the *control pressure* of the valve. The **Control pressure specification** parameter determines which of the measurements the block uses during simulation.

The relationship between the opening area and the pressure drop depends on the parameterization of the valve. That relationship can take the form of a linear analytical expression or a tabulated function.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

## Control and Other Pressures

The pressure at the inlet is the control signal of the valve. The more the inlet pressure rises over the pressure setting of the valve, the greater the opening area becomes. The inlet pressure measurement can be relative to the outlet or the environment. You can select the control pressure by setting the **Opening pressure specification** parameter to Pressure difference of port A relative to port B or Gauge pressure at port A. The term *control pressure* refers to both measurements.

### Pressure Difference of Port A Relative to Port B

When the **Opening pressure specification** parameter is Pressure difference of port A relative to port B:

- The control pressure is

$$P_{\text{Ctl}} = P_A - P_B,$$

where  $P_A$  is the absolute pressure at port **A** and  $P_B$  is the absolute pressure at port **B**.

- The pressure setting,  $P_{Set}$ , is the value of the **Set pressure differential** parameter when the **Opening characteristic** parameter is **Linear**. When the **Opening characteristic** parameter is **Tabulated**,  $P_{Set}$  is the first element of the **Opening pressure differential vector** parameter.
- When the **Opening characteristic** parameter is **Linear** and the valve is fully open, the maximum pressure of the valve,  $P_{Max}$ , is

$$P_{Max} = P_{Set} + \Delta P,$$

where  $\Delta P$  is the pressure regulation range of the valve. When the **Opening characteristic** parameter is **Tabulated**,  $P_{Max}$  is the last element of the **Opening pressure differential vector** parameter.

### Gauge Pressure at Port A

When the **Opening pressure specification** parameter is **Gauge pressure at port A**:

- The control pressure is

$$P_{Ctl} = P_A - P_{Atm},$$

where  $P_{Atm}$  is the atmospheric pressure specified in the Gas Properties (G) block of the model.

- The pressure setting,  $P_{Set}$ , is the value of the **Set pressure (gauge)** parameter when the **Opening characteristic** parameter is **Linear**. When the **Opening characteristic** parameter is **Tabulated**,  $P_{Set}$  is the first element of the **Opening pressure (gauge) vector** parameter.
- When the **Opening characteristic** parameter is **Linear** and the valve is fully open, the maximum pressure of the valve,  $P_{Max}$ , is

$$P_{Max} = P_{Set} + \Delta P,$$

where  $\Delta P$  is the pressure regulation range of the valve. When the **Opening characteristic** parameter is **Tabulated**,  $P_{Max}$  is the last element of the **Opening pressure (gauge) vector** parameter.

### Fraction of Valve Opening

The degree to which the control pressure exceeds the pressure setting determines how much the valve opens. When the **Opening characteristic** parameter is **Linear**, the block calculates the valve opening fraction to scale the flow characteristic parameters. The valve opening fraction is

$$\hat{p} = \frac{P_{Ctl} - P_{Set}}{\Delta P},$$

where:

- $P_{Ctl}$  is the control pressure.
- $P_{Set}$  is the pressure specified by the **Set pressure differential** or **Set pressure (gauge)** parameters.
- $\Delta P$  is the pressure regulation range specified by the **Pressure regulation range** parameter.

The fraction is normalized so that it is 0 in the fully closed valve and 1 in the fully open valve. If the calculation returns a value outside of these bounds, the block saturates the value to the nearest of the two limits.

### Numerical Smoothing

When the **Opening characteristic** parameter is Linear and the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the normalized control pressure,  $\hat{p}$ . Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area** — The size of the flow restriction determines the block parametrization.

### Opening Characteristics

The flow characteristic relates the opening of the valve to the input that produces it. The opening is expressed as a sonic conductance, flow coefficient, or restriction area, determined by the **Valve parameterization** parameter.

The flow characteristic is normally given at steady state, with the inlet at a constant, carefully controlled pressure. The flow characteristic depends only on the valve and can be linear or nonlinear. To capture the flow characteristics, use the **Opening characteristic** parameter:

- **Linear** — The measure of flow capacity is a linear function of the valve opening fraction. As the opening fraction rises from 0 to 1, the measure of flow capacity scales from the specified minimum to the specified maximum.

- **Tabulated** — The measure of flow capacity is a general function, which can be linear or nonlinear, of the orifice opening fraction. The function is specified in tabulated form, with the independent variable specified by the **Opening pressure differential vector** or the **Opening pressure (gauge) vector**.

## Momentum Balance

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to Cv flow coefficient parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}},$$

where:

- $C_v$  is the flow coefficient.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.
- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3 p_{in} F_\gamma x_T},$$

where:

- $F_\gamma$  is the ratio of the isentropic exponent to 1.4.
- $x_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_v N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{\rho_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3 F_\gamma x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_\gamma x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3} C_v N_6 \sqrt{F_\gamma x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865 C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, see [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C\rho_{ref}p_{in}\sqrt{\frac{T_{ref}}{T_{in}}}\left[1 - \left(\frac{\frac{p_{out}}{p_{in}} - B_{crit}}{1 - B_{crit}}\right)^2\right]^m,$$

where:

- $C$  is the sonic conductance.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.
- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ ,

$$\dot{m} = C\rho_{ref}\sqrt{\frac{T_{ref}}{T_{avg}}}\left[1 - \left(\frac{B_{lam} - B_{crit}}{1 - B_{crit}}\right)^2\right]^m\left(\frac{p_{in} - p_{out}}{1 - B_{lam}}\right).$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C\rho_{ref}p_{in}\sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma - 1} p_{in} \rho_{in} \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}} \left[ \frac{1 - \left(\frac{p_{out}}{p_{in}}\right)^{\frac{\gamma - 1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}}}\right]},$$

where:

- $S_r$  is the orifice or valve area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_d S_R \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \left[ \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 B_{lam}^{\frac{2}{\gamma}}} \right] \left( \frac{p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}}}{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}} \right)}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_R \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left(\frac{\gamma+1}{2}\right)^{\frac{2}{\gamma-1}} - \left(\frac{S_R}{S}\right)^2}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area parameterization, see [4].

### Mass Balance

The block assumes the volume and mass of fluid inside the valve is very small and ignores these values. As a result, no amount of fluid can accumulate in the valve. By the principle of conservation of mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

### Assumptions and Limitations

- The **Sonic** conductance setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the **Orifice** area parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Conserving

**A** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow must enter the valve.

**B** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow must exit the valve.

## Parameters

**Opening pressure specification** — Choice of pressure measurement to use as valve control signal  
Pressure difference of port A relative to port B (default) | Gauge pressure at port A

Choice of pressure measurement to use as valve control signal. The block uses this setting to determine when the valve should begin to open. In the default setting, Pressure difference of port A relative to port B, the opening pressure of the valve is expressed as a pressure drop from inlet to outlet. In the alternative setting, Gauge pressure at port A, it is expressed as a gauge inlet pressure.

**Valve parameterization** — Parameterization used to specify flow characteristics of valve  
Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- Cv flow coefficient — The flow coefficient  $C_v$  determines the block parameterization.
- Kv flow coefficient — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- Sonic conductance — The sonic conductance of the resistive element at steady state determines the block parameterization.
- Orifice area — The size of the flow restriction determines the block parameterization.

**Opening characteristic** — Method to calculate the opening characteristics of the valve  
Linear (default) | Tabulated

Method the block uses to calculate the opening area of the valve. The linear setting treats the opening area as a linear function of the orifice opening fraction. The tabulated setting allows for a general, nonlinear relationship you can specify in tabulated form.

**Set pressure differential** — Threshold differential for valve operation  
0 MPa (default) | positive scalar

Pressure drop, from inlet to outlet, required to open the valve. This value marks the beginning of the pressure regulation range, over which the valve progressively opens in an effort to contain a pressure rise. The opening area of the valve depends on the difference between the actual pressure drop to the value specified here.

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Pressure difference at port A relative to port B and **Opening characteristic** to Linear.

**Pressure regulation range** — Width of the pressure range over which the opening area is variable  
0.1 MPa (default) | positive scalar

Width of the pressure range over which the opening area of the valve is variable. The pressure range begins at the set pressure measurement specified in the block: **Set pressure differential** or **Set pressure (gauge)**, depending on the setting of the **Opening pressure specification** parameter. It ends at the sum of the set pressure with the value specified here. The smaller the pressure regulation range, the faster the valve reaches its maximum opening area.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Set pressure (gauge)** — Inlet gauge pressure required to open the valve  
0.1 MPa (default) | positive scalar in units of pressure

Inlet gauge pressure required to open the valve. This parameter marks the beginning of the pressure regulation range, over which the valve progressively opens in an effort to contain a pressure rise. The opening area of the valve depends on the difference between the actual inlet pressure to the value specified here.

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Gauge pressure at port A and **Opening characteristic** to Linear.

**Opening pressure differential vector** — Vector of control pressures at which to specify valve opening data  
0.2 : 0.2 : 1.2 MPa (default) | vector

Vector of control pressures at which to specify the chosen measure of valve opening—sonic conductance, flow coefficient, or opening area. This vector must be equal in size to those containing the valve opening data. The vector elements must be positive and increase monotonically from left to right. These pressure values are the pressure drop from inlet to outlet.

The first vector element gives the pressure setting of the valve, at which the valve begins to open. This element is equivalent to the **Set pressure differential** parameter of the Linear opening parameterizations. The last element gives the maximum pressure, at which the valve is fully open. The difference between the two gives the pressure regulation range of the valve.

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Pressure difference at port A relative to port B and **Opening characteristic** to Tabulated.

**Opening pressure (gauge) vector** — Vector of control pressures at which to specify valve opening data  
0.2 : 0.2 : 1.2 MPa (default) | vector

Vector of control pressures at which to specify the chosen measure of valve opening—sonic conductance, flow coefficient, or opening area. This vector must be equal in size to those containing

the valve opening data. The vector elements must be positive and increase monotonically in value from left to right. These pressures are the gauge pressure at the inlet.

The first vector element gives the pressure setting of the valve, at which the valve begins to open. This element is equivalent to the **Set pressure (gauge)** parameter of the **Linear** opening parameterizations. The last element gives the maximum pressure, at which the valve is fully open. The difference between the two gives the pressure regulation range of the valve.

#### Dependencies

To enable this parameter, set **Opening pressure specification** to Gauge pressure at port A and **Opening characteristic** to Tabulated.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Linear.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Leakage flow fraction** — Ratio of flow rates  
1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

#### Dependencies

To enable this parameter, set **Opening characteristic** to Linear.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### Dependencies

To enable this parameter, set **Opening characteristic** to Linear.

**Cv flow coefficient vector** — Cv coefficients corresponding to values in opening fraction vector [1e-06, .8, 1.6, 2.4, 3.2, 4] (default) | vector of positive numbers

Vector of  $C_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector**.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component 3.6 (default) | positive scalar

Value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Linear.

**Kv flow coefficient vector** — Kv coefficients corresponding to values in opening fraction vector [1e-06, .72, 1.44, 2.16, 2.88, 3.6] (default) | vector of positive numbers

Vector of  $K_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component 12 l/(bar\*s) (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes 0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Sonic conductance vector** — Sonic conductances corresponding to values in opening fraction vector  
[1e-05, 2.4, 4.8, 7.2, 9.6, 12] l/(bar\*s) (default) | vector of positive values

Vector of sonic conductances inside the resistive element. Each conductance corresponds to a value in the **Opening fraction vector** parameter. The sonic conductances must increase monotonically from left to right, with greater opening fractions representing greater sonic conductances. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Tabulated.

**Critical pressure ratio vector** — Critical pressure ratios corresponding to values in opening fraction vector  
0.3 \* ones(1,6) (default) | vector of positive numbers

Vector of critical pressure ratios at which the flow first chokes, with each critical pressure ratio corresponding to a value in the **Opening fraction vector** parameter. The critical pressure ratio is the fraction of downstream-to-upstream pressures at which the flow velocity reaches the local speed of sound. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Tabulated.

**Maximum orifice area** — Flow area corresponding to maximally open component  
1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Orifice area, and **Opening characteristic** to Linear.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Orifice area.

**Orifice area vector** — Vector of orifice opening area values  
[1e-10, 2e-05, 4e-05, 6e-05, 8e-05, .0001] m<sup>2</sup> (default) | vector

Vector of cross-sectional areas of the orifice opening. The values in this vector correspond one-to-one with the elements in the **Opening fraction vector** parameter. The first element of this vector is the orifice leakage area and the last element is the maximum orifice area.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Orifice area, and **Opening characteristic** to Tabulated.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports  
0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

### Introduced in R2018b

### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.
- The **Pressure control specification** parameter has been renamed to **Opening pressure specification**. The options for this parameter have been renamed to **Pressure difference of port A relative to port B** and **Gauge pressure at port A**.
- The **Control pressure vector** parameter has been renamed to **Opening pressure differential vector** or **Opening pressure (gauge) vector**, depending on the choice for **Opening pressure specification**.

Orifice (G) | Pressure Reducing Valve (G)

# Pressure Relief Valve (TL)

Pressure relief valve in a thermal liquid network

## Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Relief Valve (TL) block represents a valve that relieves excess pressure in a thermal liquid network. The valve remains closed when the pressure is less than a specified value. When this pressure is met or surpassed, the valve opens. This set pressure is either a threshold pressure differential over the valve, between ports **A** and **B**, or between port **A** and atmospheric pressure. A control pressure above the set pressure causes the valve to gradually open, which allows the fluid network to relieve excess pressure.

## Mass Balance

The mass conservation equation in the valve is

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate into the valve through port **A**.
- $\dot{m}_B$  is the mass flow rate into the valve through port **B**.

## Mass Flow Rate

The block calculates the mass flow rate as

$$\dot{m} = \frac{C_d A_{valve} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{valve}}{A_{port}} \right)^2 \right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $C_d$  is the value of the **Discharge coefficient** parameter.
- $A_{valve}$  is the instantaneous valve open area.
- $A_{port}$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\pi}{8 A_{valve} \bar{\rho}} \left( \frac{\mu Re_{crit}}{C_d} \right)^2,$$

where  $\mu$  is the dynamic viscosity of the thermal liquid.

The pressure loss,  $PR_{loss}$ , describes the reduction of pressure in the valve due to a decrease in area. The block calculates  $PR_{loss}$  as

$$PR_{loss} = \frac{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{valve}}{A_{port}}}{\sqrt{1 - \left(\frac{A_{valve}}{A_{port}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{valve}}{A_{port}}}$$

The pressure recovery describes the positive pressure change in the valve due to an increase in area. When you clear the **Pressure recovery** check box, the block sets  $PR_{loss}$  to 1.

### Opening Parameterization

When you set **Opening parameterization** to Linear - Area vs. pressure, the block calculates the opening area as

$$A_{valve} = \hat{p}(A_{max} - A_{leak}) + A_{leak}$$

where  $A_{leak}$  is the value of the **Leakage Area** parameter and  $A_{max}$  is the value of the **Maximum opening area** parameter. The normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{set}}{p_{Max} - p_{set}}$$

where the expressions for  $p_{control}$ ,  $p_{set}$ , and  $p_{Max}$  depend whether the setting of the **Pressure control specification** parameter is Pressure at port A or Pressure differential.

$p_{control}$  is the valve control pressure:

$$p_{control} = \begin{cases} p_A - p_{Atm}, & \text{Pressure at port A} \\ p_A - p_B, & \text{Pressure differential} \end{cases}$$

where  $p_{Atm}$  is the atmospheric pressure.

$p_{set}$  is the set pressure:

$$p_{set} = \begin{cases} p_{set, gauge} + p_{Atm}, & \text{Pressure at port A} \\ p_{set, diff}, & \text{Pressure differential} \end{cases}$$

$p_{Max}$  is the maximum pressure:

$$p_{max} = \begin{cases} p_{set, gauge} + p_{range} + p_{Atm}, & \text{Pressure at port A} \\ p_{set, diff} + p_{range}, & \text{Pressure differential} \end{cases}$$

This figure shows how the block controls the opening area using the linear parameterization.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{set}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

When you set **Opening parameterization** to Tabulated data - Area vs. pressure, the block calculates the opening area as

$$A_{valve} = \text{tablelookup}(p_{control, TLU, ref}, A_{TLU}, p_{control}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest}),$$

where:

- $p_{control, TLU, ref} = p_{TLU} + p_{offset}$ .
- $p_{TLU}$  is the **Pressure differential vector** parameter.
- $p_{offset}$  is an internal pressure offset that causes the valve to start closing when  $p_{control, TLU, ref} = p_{set}$ .
- $A_{TLU}$  is the **Opening area vector** parameter.

This figure shows how the block controls the opening area when **Opening parameterization** is Tabulated data - Area vs. pressure.

When you set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure, the valve opens according to the user-provided tabulated data of volumetric flow rate and pressure differential between ports **A** and **B**.

The block calculates the mass flow rate as

$$\dot{m} = \bar{\rho} \dot{V},$$

where:

- $\dot{V}$  is the volumetric flow rate.
- $\bar{\rho}$  is the average fluid density.

The block calculates the relationship between the mass flow and pressure using

$$\dot{m} = K \bar{\rho} \sqrt{\Delta p},$$

where

$$K = \frac{\dot{V}}{\sqrt{|\Delta p|}}.$$

## Opening Dynamics

When you set **Opening dynamics** to On, the block introduces a control pressure lag where  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ . The instantaneous change in dynamic opening area is calculated based on the **Opening time constant** parameter,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, the block clears the **Opening dynamics** check box.

## Energy Balance

The energy conservation equation in the valve is

$$\phi_A + \phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate into the valve through port **A**.
- $\phi_B$  is the energy flow rate into the valve through port **B**.

## Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see "List of Pre-Parameterized Components".

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet A.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet B.

## Parameters

**Opening parameterization** — Method of modeling constant valve opening or closing  
Linear - Area vs. pressure (default) | Tabulated data - Area vs. pressure |  
Tabulated data - Volumetric flow rate vs. pressure

Method of modeling the valve opening or closing. You can parameterize the valve opening linearly or by using a table of values that correlate the area-to-pressure differential.

**Pressure control specification** — Method to evaluate pressure  
Pressure at port A (default) | Pressure differential

Specification method for the valve control pressure. When you set this parameter to **Pressure at port A**, the block uses only the pressure at port **A** to determine when the flow exceeds the value of the **Set pressure (gauge)** parameter. When you set this parameter **Pressure differential**, the block uses the value of the **Set pressure differential** parameter to determine whether the pressure differential from port **A** to port **B** exceeds the range.

### Dependencies

To enable this parameter, set **Opening parameterization** to **Linear - Area vs. pressure** or **Tabulated data - Area vs. pressure**.

**Set pressure (gauge)** — Gauge pressure when opening mechanism triggers  
0.1 MPa (default) | positive scalar

Pressure at which the opening mechanism triggers. The opening area remains variable throughout the pressure regulation range of the valve.

### Dependencies

To enable this parameter, set either:

- **Pressure control specification** to **Pressure at port A** and **Opening parameterization** to **Linear - Area vs. pressure**
- Set **Opening parameterization** to **Tabulated data - Volumetric flow rate vs. pressure**

**Set pressure differential** — Minimum opening pressure differential  
0 MPa (default) | nonnegative scalar

Minimum pressure differential between ports **A** and **B** required to open the valve. A pressure differential above this value causes the valve to gradually open until it reaches the fully open state.

### Dependencies

To enable this parameter, set **Pressure control specification** to **Pressure differential** and **Opening parameterization** to **Linear - Area vs. pressure**.

**Pressure regulation range** — Valve pressure range

0.15 MPa (default) | positive scalar

Pressure interval over which the valve opening area varies. The interval begins at the value of the **Set pressure (gauge)** parameter or when the difference between ports **A** and **B** exceeds the value of the **Set pressure differential** parameter.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Maximum opening area** — Opening area in fully open position1e-4 m<sup>2</sup> (default) | positive scalar

Opening area of the valve in the fully open position due to sealing imperfections, when the valve is at the upper limit of the pressure regulation range.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Leakage area** — Gap area when in fully shut position1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully shut position. The block saturates smaller numbers to this value. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure differential vector** — Differential pressure values for tabular parameterization[0.2 : 0.2 : 1.2] MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. The elements must be listed in ascending order and must be greater than 0. The block employs linear interpolation between table data points.

**Dependencies**

To enable this parameter, set either:

- **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure
- **Opening parameterization** to Tabulated data - Area vs. pressure and **Opening pressure specification** to Pressure differential

**Opening pressure (gauge) vector** — Differential pressure values for tabular area parameterization[0.2 : 0.2 : 1.2] MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabular area parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. The elements are must be in ascending order and must be greater than 0. The block employs linear interpolation between table data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Area vs. pressure, and **Opening pressure specification** to Pressure at port A.

**Opening area vector** — Valve opening areas for tabular area parameterization  
[1e-10, 2e-06, 4e-06, 6e-06, 8e-06, 1e-05] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of valve opening areas for the tabular area parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Pressure differential vector** parameter. The elements must be in ascending order and must be greater than 0. The block employs linear interpolation between table data points.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Area vs. pressure.

**Volumetric flow rate vector** — Vector of volumetric flow rate for tabulated data parameterization  
[1e-09, 3.6e-05, 8.9e-05, .00015, .00023, .00031]m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values for the tabular parameterization of the valve opening. This vector must have the same number of elements as the **Pressure drop vector** parameter. The vector elements must be in ascending order.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Cross-sectional area at ports A and B** — Area at conserving ports  
0.01 m<sup>2</sup> (default) | positive scalar

Area at ports **A** and **B**, which the block uses in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor that the block uses to account for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

A smoothing factor of 0 corresponds to a linear function that is discontinuous at the set and maximum-area pressures. A smoothing factor of 1 corresponds to a nonlinear function that changes continuously throughout the entire function domain.

A smoothing factor between 0 and 1 corresponds to a continuous function with smooth nonlinear transitions at the set and maximum-area pressures.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure recovery** — Whether to account for pressure increase in area expansions

off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area. To capture the increase in pressure, select this parameter.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Opening dynamics** — Whether to account for flow response to valve opening

off (default) | on

Whether to account for transient effects to the fluid system due to the valve opening. Selecting this parameter approximates the opening conditions by introducing a first-order lag in the flow response.

**Opening time constant** — Valve opening time constant

0.1 s (default) | positive scalar

Time constant by which to compute the lag in the opening dynamics .

**Dependencies**

To enable this parameter, select **Opening dynamics**.

## Version History

Introduced in R2016a

**R2023a: New Parameterization Options**

Use the **Opening parameterization** parameter to choose the block parameterization Linear - Area vs. pressure, Tabulated data - Area vs. pressure, or Tabulated data - Volumetric flow rate vs. pressure.

Pressure Reducing Valve (TL) | Pressure Compensator Valve (TL)

# Pressure Relief Valve (2P)

Pressure relief valve in a two-phase fluid network

## Libraries:

Simscape / Fluids / Two-Phase Fluid / Valves & Orifices / Pressure Control Valves

## Description

The Pressure Relief Valve (2P) block models a pressure-controlling relief valve in a two-phase fluid network. The valve opens when the pressure exceeds the set pressure. Specify the pressure differential that opens the valve in the **Set pressure specification** parameter, which can be the pressure difference between ports **A** and **B** or the gauge pressure at port **A**. When you set **Set pressure control** to **Controlled**, the set pressure varies according to the input signal at port **Ps**.

Fluid properties inside the valve are calculated from inlet conditions. There is no heat exchange between the fluid and the environment, and therefore phase change inside the valve only occurs due to a pressure drop or a propagated phase change from another part of the model.

A number of block parameters are based on nominal operating conditions, which correspond to the valve rated performance, such as a specification on a manufacturer datasheet.

## Pressure Control

The valve opens when the pressure in the valve,  $p_{control}$ , exceeds the **Set pressure differential**,  $p_{set}$ . The valve is fully open when the control pressure reaches the end of the **Pressure regulation range**,  $p_{range}$ .

When you set **Set pressure control** to **Constant**, the opening fraction of the valve,  $\lambda$ , is expressed as:

$$\lambda = (1 - f_{leak}) \frac{(p_{control} - p_{set})}{p_{range}} + f_{leak},$$

where:

- $f_{leak}$  is the **Closed valve leakage as a fraction of nominal flow**.
- $p_{control}$  is the control pressure, which depends on the **Set pressure specification** parameter.

When you set **Set pressure specification** to **Pressure differential**, the control pressure is  $P_A - P_B$ .

When you set **Set pressure specification** to **Gauge pressure at port A**, the control pressure is the difference between the pressure at port **A** and atmospheric pressure.

When you set **Set pressure control** to **Controlled**, the valve opening fraction is:

$$\lambda = (1 - f_{leak}) \frac{(p_{control} - p_s)}{p_{range}} + f_{leak},$$

where  $p_s$  is the signal at port **Ps**. If the control pressure exceeds the valve pressure regulation range, the valve opening fraction is 1.

### Mass Flow Rate

The mass flow rate depends on the pressure differential, and therefore the open area of the valve. It is calculated as:

$$\dot{m}_A = \lambda \dot{m}_{nom} \left[ \sqrt{\frac{v_{nom}}{2\Delta p_{nom}}} \right] \sqrt{\frac{2}{v_{in} (\Delta p^2 + \Delta p_{lam}^2)^{0.25}}}$$

where:

- $\Delta p$  is the pressure drop over the valve,  $p_A - p_B$ .
- $\Delta p_{lam}$  is the pressure transition threshold between laminar and turbulent flow, which is calculated from the **Laminar flow pressure ratio**,  $B_{lam}$ :

$$\Delta p_{lam} = \frac{(p_A + p_B)}{2} (1 - B_{lam}).$$

- $\dot{m}_{nom}$  is the **Nominal mass flow rate at maximum opening**.
- $\Delta p_{nom}$  is the **Nominal pressure drop rate at maximum opening**.
- $v_{nom}$  is the nominal inlet specific volume. This value is determined from the fluid properties tabulated data based on the **Nominal inlet specific enthalpy** and **Nominal inlet pressure** parameters.
- $v_{in}$  is the inlet specific volume.

### Fluid Specific Volume Dynamics

When the fluid at the valve inlet is a liquid-vapor mixture, the block calculates the specific volume as:

$$v_{in} = (1 - x_{dyn})v_{liq} + x_{dyn}v_{vap}$$

where:

- $x_{dyn}$  is the inlet vapor quality. The block applies a first-order lag to the inlet vapor quality of the mixture.
- $v_{liq}$  is the liquid specific volume of the fluid.
- $v_{vap}$  is the vapor specific volume of the fluid.

If the inlet fluid is liquid or vapor,  $v_{in}$  is the respective liquid or vapor specific volume.

### Vapor Quality Lag

If the inlet vapor quality is a liquid-vapor mixture, a first-order time lag is applied:

$$\frac{dx_{dyn}}{dt} = \frac{x_{in} - x_{dyn}}{\tau},$$

where:

- $x_{dyn}$  is the dynamic vapor quality.
- $x_{in}$  is the current inlet vapor quality.

- $\tau$  is the **Inlet phase change time constant**.

If the inlet fluid is a subcooled liquid or superheated vapor,  $x_{dyn}$  is equal to  $x_{in}$ .

### Mass Balance

Mass is conserved in the valve:

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

### Energy Balance

Energy is conserved in the valve:

$$\Phi_A + \Phi_B = 0,$$

where:

- $\Phi_A$  is the energy flow at port **A**.
- $\Phi_B$  is the energy flow at port **B**.

### Assumptions and Limitations

- The block does not model pressure recovery downstream of the valve.
- There is no heat exchange between the valve and the environment.
- The block does not model choked flow.

## Ports

### Conserving

**A** — Fluid port  
two-phase fluid

Fluid entry or exit port.

**B** — Fluid port  
two-phase fluid

Fluid entry or exit port.

### Input

**Ps** — Set pressure  
physical signal

Input port for varying set pressure signal.

**Dependencies**

To enable this port, set **Set pressure control** to `Controlled`.

**Parameters**

**Set pressure control** — Variable or constant set pressure  
`Constant (default) | Controlled`

Whether the pressure threshold is constant or variable. Setting this parameter to `Controlled` exposes the physical signal port **Ps**.

**Set pressure specification** — Control pressure  
`Pressure differential (default) | Gauge pressure at port A`

Control pressure specification:

- When set to `Pressure differential`, the valve opens when  $p_A - p_B$  exceeds the **Set pressure differential**.
- When set to `Gauge pressure at port A`, the valve opens when  $p_A - p_{atm}$  exceeds the **Set pressure (gauge)**.

**Set pressure differential** — Set pressure  
`0.01 MPa (default) | positive scalar`

Valve pressure threshold. When the control pressure,  $p_A - p_B$ , exceeds the set pressure, the valve begins to open.

**Dependencies**

To enable this parameter, set **Set pressure control** to `Constant` and **Set pressure specification** to `Pressure differential`.

**Set pressure (gauge)** — Set pressure  
`0.1 MPa (default) | positive scalar`

Valve pressure threshold. When the control pressure,  $p_A - p_{atm}$ , exceeds the set pressure, the valve begins to open.

**Dependencies**

To enable this parameter, set **Set pressure control** to `Constant` and **Set pressure specification** to `Gauge pressure at port A`.

**Pressure regulation range** — Valve operational range  
`0.1 MPa (default) | positive scalar`

Valve operational range. The valve begins to open at the set pressure value, and is fully open at  $p_{max}$ , the end of the pressure regulation range:  $p_{max} = p_{set} + p_{range}$ .

**Nominal mass flow rate at maximum opening** — Rated mass flow rate  
`0.1 kg/s (default) | positive scalar`

Mass flow rate through a fully open valve under typical, design, or rated conditions.

**Nominal pressure drop at maximum opening** — Rated pressure drop

0.001 MPa (default) | positive scalar

Pressure drop over a fully open valve under typical, design, or rated conditions.

**Nominal inlet condition specification** — Method of determining inlet fluid state

Temperature (default) | Vapor quality | Vapor void fraction | Specific enthalpy | Specific internal energy

Method of determining inlet fluid state. The valve inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet pressure** — Pressure of fluid entering valve

0.101325 MPa (default) | positive scalar

Inlet pressure to the valve in typical, design, or rated conditions. The valve inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet temperature** — Fluid temperature

293.15 K (default) | positive scalar

Inlet fluid temperature in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Inlet vapor quality by mass fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet vapor quality of the mixture by mass fraction in nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor quality.

**Nominal inlet vapor void fraction** — Inlet volume fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet mixture by volume fraction in nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor void fraction.

**Nominal inlet specific enthalpy** — Inlet fluid specific enthalpy

1500 kJ/kg (default) | positive scalar

Inlet specific enthalpy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific enthalpy.

**Nominal inlet specific internal energy** — Inlet specific internal energy  
1500 kJ/kg (default) | positive scalar

Inlet specific internal energy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific internal energy.

**Cross-sectional area at ports A and B** — Valve port areas  
0.01 m<sup>2</sup> (default) | positive scalar

Area of the valve ports **A** and **B**.

**Closed valve leakage as a fraction of nominal flow** — Fractional flow when valve is closed  
1e-6 (default) | positive scalar

Fractional flow rate through the valve when it is fully closed. This parameter contributes to numerical stability by maintaining continuity in the fluid network.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Laminar-turbulent transition pressure ratio  
0.999 (default) | positive scalar

Ratio of the valve outlet pressure to valve inlet pressure at which the fluid transitions between the laminar and turbulent regimes. The pressure loss corresponds to the mass flow rate linearly in laminar flows and quadratically in turbulent flows.

**Inlet phase change time constant** — Lag for mixture specific volume  
0.1 s (default) | positive scalar

Time lag for liquid-vapor mixtures in computing the fluid specific volume. This parameter does not influence the specific volume when the inlet fluid is a fully supercooled liquid or fully superheated vapor.

## Proportional and Servo-Valve Actuator

(To be removed) Continuous valve driver with output proportional to input signal

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

### Library

Valve Actuators

### Description

The Proportional and Servo-Valve Actuator block represents an electromagnetic actuator that is used in proportional and servo-valves to drive a spool or other working member. The block is intended to work with one of the directional valve models to form a desirable configuration of a proportional or servo-valve. The block is implemented as a data-sheet-based model and reproduces only the input/output relationship, or the actuator’s transient response, as presented in the catalog or data sheet.

The Proportional and Servo-Valve Actuator block is built using the blocks from the Simscape Physical Signals library. Both the input and the output of the block are physical signals. The block diagram of the model is shown in the following figure.

The model of the actuator is built of the Foundation Library Physical Signals blocks: PS Subtract, PS Saturation, PS Gain, PS Integrator. The first-order lag is arranged as a subsystem, as shown below,

and is also built of the Physical Signals blocks: PS Subtract, PS Gain, and PS Integrator. The transfer function of the lag is

$$H(s) = \frac{1}{Ts + 1}$$

where  $T$  is the **Time constant** of the lag. The value of this parameter is set through the parameter **Gain** of the PS Gain block in the First-Order Lag subsystem by setting it equal to  $1/T$ .

The typical transient responses of a servo-valve or a high-quality proportional valve are shown in the following figure. The only difference between the two responses in the figure is the value of the saturation.

You can adjust the block parameters, such as saturation, gain, and time constant, to make the transient responses close enough to those provided in the data sheet. The most effective way to adjust the parameters is to use the Simulink Design Optimization software.

**Note** This block is constructed out of blocks from the Simscape Physical Signals library (such as PS Add, PS Gain, and so on). Currently, the blocks in the Physical Signals library do not support unit propagation and checking. For more information, see “How to Work with Physical Units”.

---

## Parameters

### Gain

Gain of the PS Gain block in the top level of the block diagram of the actuator model. The default value is 377.

### Time constant

Time constant of the first-order lag. The **Gain** parameter of the PS Gain block in the First-Order Lag subsystem is equal to  $1/\mathbf{Time\ constant}$ . The default value is 0.002 s.

### Saturation

Saturation level of the PS Saturation block in the actuator model. The default value is 0.3.

## Ports

The block has one physical signal input port and one physical signal output port.

## Examples

The “Closed-Loop Actuator with Variable-Displacement Pressure-Compensated Pump” example illustrates the use of the Proportional and Servo-Valve Actuator block in hydraulic systems.

# Proportional Valve Actuator

Power-controlled valve actuator in any fluid domain

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Actuators

## Description

The Proportional Valve Actuator block models a power-controlled actuator used in conjunction with a valve block in any in any fluid domain. You can use it in combination with any valve block that takes a physical signal as input. The signal to open or close the valve is received at port **A**. The opening distance for a connected valve is returned as a physical signal at port **S**.

You can adjust the opening or closing magnitude with the **Actuator gain** parameter. A first-order lag in time is applied to the actuation distance:

$$\frac{(IG - d)}{\tau},$$

where:

- $IG$  is the signal received at port **A** multiplied by the **Actuator gain**. Outside of the valve stroke limits,  $IG$  is the **Valve stroke** if fully extended and the negative **Valve stroke** if fully retracted.
- $d$  is the current actuator position.
- $\tau$  is the **Time constant**.

## Ports

### Input

**A** — Valve opening signal  
physical signal

Physical signal that indicates valve opening or closing, specified as a physical signal. The signal is multiplied by the **Actuator gain** value.

### Output

**S** — Valve opening distance, m  
physical signal

Opening distance for the connected valve, in m, specified as a physical signal.

If you use the Proportional Valve Actuator block with a valve from the Gas Library, the gas block converts the actuator signal units of m to units of 1.

## Parameters

**Actuator gain** — Input signal multiplier  
5e-4 m (default) | positive scalar

Input signal multiplier for the valve opening distance.

**Time constant** — Opening signal time constant  
0.01 s (default) | positive scalar

Constant that captures the time required to reach steady-state conditions during actuation. This parameter impacts the response lag to the valve opening or closing signal.

**Valve stroke** — Maximum valve opening distance  
0.005 m (default) | positive scalar

Maximum opening distance of the connected valve.

## Receiver Accumulator (2P)

Tank with liquid and vapor volumes of variable proportion

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Tanks & Accumulators

### Description

The Receiver-Accumulator (2P) block represents a tank with fluid that can undergo phase change. The liquid and vapor phases, referred to as *zones*, are modeled as distinct volumes that can change in size during simulation, but do not mix. The relative amount of space a zone occupies in the system is called a *zone fraction*, which ranges from 0 to 1. The vapor-liquid mixture phase is not modeled.

In an HVAC system, when this tank is placed between a condenser and an expansion valve, it acts as a receiver. Liquid connections to the block are made at ports **AL** and **BL**. When the tank is placed between an evaporator and a compressor, it acts as an accumulator. Vapor connections to the block are made at ports **AV** and **BV**. A fluid of either phase can be connected to either port, however the fluid exiting from a V port is in the vapor zone and an L port is in the liquid zone. There is no mass flow through unconnected ports.

The temperature of the tank walls are set at port **H**.

The liquid level of the tank is reported as a zone fraction at port **L**. If the liquid level reports 0, the tank is fully filled with vapor. The tank is never empty.

### Heat Transfer

The total heat transfer,  $Q_H$ , is the sum of the heat transfer in the liquid and vapor phases:

$$Q_H = Q_L + Q_V.$$

The heat transfer between the liquid and the wall is:

$$Q_L = (S_c + z_L S_s) \alpha_L (T_H - T_L) + S_c \alpha_{LV} (T_V - T_L)$$

where:

- $z_L$  is the liquid volume fraction of the tank.
- $S_c$  is the **Tank cross sectional area** parameter.
- $S_s$  is surface area of the tank side, which the block calculates from the volume and tank cross-sectional area.
- $\alpha_L$  is the **Liquid heat transfer coefficient** parameter.
- $T_H$  is the temperature of the tank wall.
- $T_L$  is the temperature of the liquid.

The block calculates the heat transfer coefficient between the liquid and the vapor as

$$\alpha_{LV} = \frac{1}{\frac{1}{\alpha_L} + \frac{1}{\alpha_V}}.$$

The heat transfer between the vapor and the wall is:

$$Q_V = (S_c + (1 - z_L)S_s)\alpha_V(T_H - T_V) + S_c\alpha_{LV}(T_L - T_V),$$

where:

- $\alpha_V$  is the **Vapor heat transfer coefficient**.
- $T_V$  is the temperature of the vapor.

The liquid volume fraction is determined from the liquid mass fraction:

$$z_L = \frac{f_{M,L}\nu_L}{f_{M,L}\nu_L + (1 - f_{M,L})\nu_V},$$

where:

- $f_{M,L}$  is the mass fraction of the liquid.
- $\nu_L$  is the specific volume of the liquid.
- $\nu_V$  is the specific volume of the vapor.

### Energy Flow Rates Due To Phase Change

When the liquid specific enthalpy is greater than or equal to the saturated liquid specific enthalpy, the mass flow rate of the vaporizing fluid is:

$$\dot{m}_{\text{Vap}} = \frac{M_L(h_L - h_{L, \text{Sat}})/(h_V - h_{L, \text{Sat}})}{\tau}.$$

where:

- $M_L$  is the total liquid mass.
- $\tau$  is the **Vaporization and condensation time constant** parameter.
- $h_L$  is the specific enthalpy of the liquid at the internal node.
- $h_{L, \text{Sat}}$  is the saturated liquid specific enthalpy at the internal node.
- $h_V$  is the specific enthalpy of the vapor.
- $h_{V, \text{Sat}}$  is the saturated vapor specific enthalpy.

The energy flow associated with vaporization is:

$$\phi_{\text{Vap}} = \dot{m}_{\text{Vap}}h_{V, \text{Sat}},$$

When the liquid specific enthalpy is lower than the saturated liquid specific enthalpy, no vaporization occurs, and  $\dot{m}_{\text{Vap}} = 0$ .

Similarly, when the vapor specific enthalpy is less than or equal to the saturated vapor specific enthalpy, the mass flow rate of the condensing fluid is:

$$\dot{m}_{\text{Con}} = \frac{M_V(h_V - h_{V, \text{Sat}})/(h_V - h_{L, \text{Sat}})}{\tau}.$$

where  $M_V$  is the total vapor mass.

The energy flow associated with condensation is:

$$\phi_{\text{Con}} = \dot{m}_{\text{Con}} h_{L, \text{Sat}}$$

When the vapor specific enthalpy is higher than the saturated vapor specific enthalpy, no condensation occurs, and  $\dot{m}_{\text{Con}} = 0$ .

### Mass Balance

The total tank volume is constant. Due to phase change, the volume fraction and mass of the fluid changes. The mass balance in the liquid zone is:

$$\frac{dM_L}{dt} = \dot{m}_{L, \text{In}} - \dot{m}_{L, \text{Out}} + \dot{m}_{\text{Con}} - \dot{m}_{\text{Vap}}$$

where:

- $\dot{m}_{L, \text{In}}$  is the inlet liquid mass flow rate at all L and V ports.
- $\dot{m}_{L, \text{Out}}$  is the outlet liquid mass flow rate:

$$\dot{m}_{L, \text{Out}} = -(\dot{m}_{\text{AL}} + \dot{m}_{\text{BL}}),$$

- $\dot{m}_{\text{Con}}$  is the mass flow rate of the condensing fluid.
- $\dot{m}_{\text{Vap}}$  is the mass flow rate of the vaporizing fluid.

The mass balance in the vapor zone is:

$$\frac{dM_V}{dt} = \dot{m}_{V, \text{In}} - \dot{m}_{V, \text{Out}} - \dot{m}_{\text{Con}} + \dot{m}_{\text{Vap}}$$

where:

- $M_V$  is the total vapor mass.
- $\dot{m}_{V, \text{In}}$  is the inlet vapor mass flow rate at all L and V ports.
- $\dot{m}_{V, \text{Out}}$  is the outlet vapor mass flow rate:

$$\dot{m}_{V, \text{Out}} = -(\dot{m}_{\text{AV}} + \dot{m}_{\text{BV}}).$$

If there is only one zone present in the tank, the outlet mass flow rate of the fluid is the sum of the flow rate through all of the ports:

$$\dot{m}_{\text{phase, Out}} = -(\dot{m}_{\text{AL}} + \dot{m}_{\text{BL}} + \dot{m}_{\text{AV}} + \dot{m}_{\text{BV}}).$$

where  $\dot{m}_{\text{phase, Out}}$  is  $\dot{m}_{L, \text{Out}}$  if the fluid is entirely liquid, and  $\dot{m}_{V, \text{Out}}$  if the fluid is entirely vapor.

### Energy Balance

The fluid can heat or cool depending on the heat transfer between the tank and wall, which is set by the temperature at port **H**.

The energy balance in the liquid zone is:

$$M_L \frac{du_L}{dt} + \frac{dM_L}{dt} u_L = \phi_{L, \text{In}} - \phi_{L, \text{Out}} + \phi_{\text{Con}} - \phi_{\text{Vap}} + Q_L.$$

where:

- $u_L$  is the specific internal energy of the liquid.
- $\phi_{L,In}$  is the inlet liquid energy flow rate at all L and V ports.
- $\phi_{L,Out}$  is the outlet liquid energy flow rate:  

$$\phi_{L,Out} = -(\phi_{AL} + \phi_{BL}).$$
- $\phi_{Con}$  is the energy flow rate of the condensing vapor.
- $\phi_{Vap}$  is the energy flow rate of the vaporizing liquid.
- $Q_L$  is the heat transfer between the tank wall and the liquid.

The energy balance in the vapor zone is:

$$M_V \frac{du_V}{dt} + \frac{dM_V}{dt} u_V = \phi_{V,In} - \phi_{V,Out} - \phi_{Con} + \phi_{Vap} + Q_V.$$

- $u_V$  is the specific internal energy of the vapor.
- $\phi_{V,In}$  is the inlet vapor energy flow rate at all L and V ports.
- $\phi_{V,Out}$  is the outlet vapor energy flow rate:  

$$\phi_{V,Out} = -(\phi_{AV} + \phi_{BV}).$$
- $Q_V$  is the heat transfer between the tank wall and the vapor.

If there is only one zone present in the tank, the outlet energy flow rate is the sum of the flow rate through all of the ports:

$$\phi_{phase,Out} = -(\phi_{AL} + \phi_{BL} + \phi_{AV} + \phi_{BV}).$$

where  $\phi_{phase,Out}$  is  $\phi_{L,Out}$  if the fluid is entirely liquid, and  $\phi_{V,Out}$  if the fluid is entirely vapor.

### Momentum Balance

There are no pressure changes modeled in the tank, including hydrostatic pressure. The pressure at any port is equal to the internal tank pressure.

The Receiver Accumulator block models the vapor and liquid volumes separately. If you input vapor or liquid quickly, the block may compress the vapor volume and the pressure may rise faster than expected. The pressure rises because when there is a high vapor or liquid mass flow rate input, the temperature rise due to compression is faster than the heat transfer that cools the vapor. If you add the vapor slowly, the heat transfer between the vapor and the liquid brings the vapor temperature down, which allows it to condense into liquid, and the pressure will not spike. Additionally, if you wait until the block achieves equilibrium, adding vapor or liquid shifts the mass fraction and does not cause pressure spikes.

### Assumptions and Limitations

- Pressure must remain below the critical pressure.
- Hydrostatic pressure is not modeled.
- The container wall is rigid, therefore the total volume of fluid is constant.
- The thermal mass of the tank wall is not modeled.
- Flow resistance through the outlets is not modeled. To model pressure losses associated with the outlets, connect a Local Restriction (2P) block or a Flow Resistance (2P) block to the ports of the Receiver-Accumulator (2P) block.

- A liquid-vapor mixture is not modeled.

## Ports

### Output

**L** — Liquid level  
physical signal

Liquid level in the tank. Use this port to monitor the amount of liquid remaining inside.

### Conserving

**AV** — Tank opening  
two-phase fluid

Opening for the fluid to flow into or out of the tank. Both liquid and vapor can enter through this port. However, only vapor can exit through it—until the tank is depleted of vapor, in which event liquid too can flow out through this port.

**BV** — Tank opening  
two-phase fluid

Opening for the fluid to flow into or out of the tank. Both liquid and vapor can enter through this port. However, only vapor can exit through it—until the tank is depleted of vapor, in which event liquid too can flow out through this port.

**AL** — Tank opening  
two-phase fluid

Opening for the fluid to flow into or out of the tank. Both liquid and vapor can enter through this port. However, only liquid can exit through it—until the tank is depleted of liquid, in which event vapor too can flow out through this port.

**BL** — Tank opening  
two-phase fluid

Opening for the fluid to flow into or out of the tank. Both liquid and vapor can enter through this port. However, only liquid can exit through it—until the tank is depleted of liquid, in which event vapor too can flow out through this port.

**H** — Tank wall  
thermal

Thermal boundary between the fluid volume and the tank wall. Use this port to capture heat exchanges of various kinds—for example, conductive, convective, or radiative—between the fluid and the environment external to the tank.

## Parameters

### Main

**Total tank volume** — Aggregate volume of liquid and vapor phases in the tank  
1 m<sup>3</sup> (default) | positive scalar

Aggregate volume of liquid and vapor phases in the tank.

**Tank cross-sectional area** — Tank cross-sectional area  
0.5 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the tank.

**Cross-sectional area at port AV** — Area normal to the direction of flow at port AV  
0.01 m<sup>2</sup> (default) | positive scalar with units of area

Area normal to the direction of flow at port **AV**.

**Cross-sectional area at port BV** — Area normal to the direction of flow at port BV  
0.01 m<sup>2</sup> (default) | positive scalar with units of area

Area normal to the direction of flow at port **BV**.

**Cross-sectional area at port AL** — Area normal to the direction of flow at port AL  
0.01 m<sup>2</sup> (default) | positive scalar with units of area

Area normal to the direction of flow at port **AL**.

**Cross-sectional area at port BL** — Area normal to the direction of flow at port BL  
0.01 m<sup>2</sup> (default) | positive scalar with units of area

Area normal to the direction of flow at port **BL**.

**Liquid volume fraction out of range** — What happens when volume fractions are out of range  
No error (default) | Error | Warning

Select what happens when the block has volume fractions lower than the **Minimum liquid volume fraction** parameter or higher than the **Maximum liquid volume fraction** parameter. Select Warning to be notified when the volume fraction crosses a specified range. Select Error to stop simulation at such events.

**Minimum liquid volume fraction** — Value below which to trigger warning or error  
0.05 (default) | positive scalar between 0 and 1

Lower bound of the valid range for the liquid volume fraction in the tank. Fractions below this value will trigger a simulation warning or error (depending on the setting of the **Liquid volume fraction out of range** block parameter).

#### **Dependencies**

This parameter is active when the **Liquid volume fraction out of range** block parameter is set to Warning or Error.

**Maximum liquid volume fraction** — Value above which to trigger warning or error  
0.95 (default) | positive scalar between 0 and 1

Upper bound of the valid range for the liquid volume fraction in the tank. Fractions above this value will trigger a simulation warning or error (depending on the setting of the **Liquid volume fraction out of range** block parameter).

## Dependencies

This parameter is active when the **Liquid volume fraction out of range** block parameter is set to Warning or Error.

**Volume fraction threshold for transition to pure liquid or pure vapor** — Volume fraction of a phase below which to transition to a single-phase tank

20 W/(m<sup>2</sup>\*K) (default) | positive scalar with units of power/(area\*temperature)

Volume fraction of either phase below which to transition to a single-phase tank—either subcooled liquid or superheated vapor. This parameter determines how smooth the transition is. The larger its value, the smoother the transition and therefore the faster the simulation (though at the cost of lower accuracy).

## Heat Transfer

**Vapor heat transfer coefficient** — Coefficient for heat exchange between vapor and the tank wall

20 W/(m<sup>2</sup>\*K) (default) | positive scalar with units of power/(area\*temperature)

Coefficient for heat exchange between the vapor zone and its section of the tank wall. This parameter serves to calculate the rate of this heat exchange.

**Liquid heat transfer coefficient** — Coefficient for heat exchange between liquid and the tank wall

100 W/(m<sup>2</sup>\*K) (default) | positive scalar with units of power/(area\*temperature)

Coefficient for heat exchange between the liquid zone and its section of the tank wall. This parameter serves to calculate the rate of this heat exchange.

## Effects and Initial Conditions

**Initial fluid energy specification** — Thermodynamic variable whose initial value to set

Liquid volume fraction (default) | Temperature | Liquid mass fraction | Specific enthalpy | Specific internal energy

Thermodynamic variable in terms of which to define the initial conditions of the component.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- **Temperature** — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- **Liquid mass fraction**— Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Liquid volume fraction**— Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid volume fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Specific enthalpy** — Specify the specific enthalpy of the fluid. The block does not limit the initial state.
- **Specific internal energy** — Specify the specific internal energy of the fluid. The block does not limit the initial state.

**Initial pressure** — Absolute pressure at the start of simulation

0.101325 MPa (default) | scalar with units of pressure

Pressure in the tank at the start of simulation, specified against absolute zero.

**Initial temperature** — Absolute temperature at the start of simulation

293.15 K (default) | scalar with units of temperature

Temperature in the tank at the start of simulation, specified against absolute zero.

**Dependencies**

This parameter is active when the **Initial fluid energy specification** option is set to Temperature.

**Initial liquid mass fraction** — Mass fraction of liquid at the start of simulation

0.5 (default) | unitless scalar between 0 and 1

Mass fraction of liquid in the tank at the start of simulation.

**Dependencies**

This parameter is active when the **Initial fluid energy specification** option is set to Liquid mass fraction.

**Initial liquid volume fraction** — Volume fraction of liquid at the start of simulation

0.5 (default) | unitless scalar between 0 and 1

Volume fraction of liquid in the tank at the start of simulation.

**Dependencies**

This parameter is active when the **Initial fluid energy specification** option is set to Liquid volume fraction.

**Initial specific enthalpy** — Specific enthalpy at the start of simulation

1500 kJ/kg (default) | scalar with units of energy/mass

Specific enthalpy of the fluid in the tank at the start of simulation.

**Dependencies**

This parameter is active when the **Initial fluid energy specification** option is set to Specific enthalpy.

**Initial specific internal energy** — Specific internal energy at the start of simulation

1500 kJ/kg (default) | scalar with units of energy/mass

Specific internal energy of the fluid in the tank at the start of simulation.

**Dependencies**

This parameter is active when the **Initial fluid energy specification** option is set to Specific internal energy.

**Vaporization and condensation time constant** — Characteristic duration of a phase-change event

0.1 s (default) | scalar with units of time

Characteristic time to equilibrium of a phase-change event taking place in the tank. Increase this parameter to slow the rate of phase change or decrease it to speed up the rate.

## Library

Hydraulic Utilities

## Description

The Reservoir block represents a pressurized hydraulic reservoir, in which fluid is stored under a specified pressure. The pressure remains constant regardless of volume change. The block accounts for pressure loss in the return line that can be caused by a filter, fittings, or some other local resistance. The loss is specified with the pressure loss coefficient. The block computes the volume of fluid in the tank and exports it outside through the physical signal port V.

The fluid volume value does not affect the results of simulation. It is introduced merely for information purposes. It is possible for the fluid volume to become negative during simulation, which signals that the fluid volume is not enough for the proper operation of the system. By viewing the results of the simulation, you can determine the extent of the fluid shortage.

## Parameters

### Pressurization level

The pressure inside the reservoir. The default value is 0.

### Initial fluid volume

The initial volume of fluid in the tank. The default value is  $0.02 \text{ m}^3$ .

### Return line diameter

The diameter of the return line. The default value is  $0.02 \text{ m}$ .

### Pressure loss coefficient in return line

The value of the pressure loss coefficient, to account for pressure loss in the return line. This parameter must be greater than zero. The default value is 1.

For reasons of computational robustness, the loss is computed with the equation similar to that used in the Fixed Orifice block:

$$q = \frac{1}{\sqrt{K}} A_p \sqrt{\frac{2}{\rho} p_{loss}}$$

The Critical Reynolds number is set to 15.

## Ports

The block has the following ports:

P

Hydraulic conserving port associated with the pump line.

R

Hydraulic conserving port associated with the return line.

V

Physical signal port that outputs the volume of fluid in the tank.

## Library

Low-Pressure Blocks

## Description

The Resistive Pipe LP block models hydraulic pipelines with circular and noncircular cross sections and accounts for resistive property only. In other words, the block is developed with the basic assumption of the steady state fluid momentum conditions. Neither fluid compressibility nor fluid inertia is considered in the model, meaning that features such as water hammer cannot be investigated. If necessary, you can add fluid compressibility, fluid inertia, and other effects to your model using other blocks, thus producing a more comprehensive model.

The end effects are also not considered, assuming that the flow is fully developed along the entire pipe length. To account for local resistances, such as bends, fittings, inlet and outlet losses, and so on, convert the resistances into their equivalent lengths, and then sum up all the resistances to obtain their aggregate length. Then add this length to the pipe geometrical length.

Pressure loss due to friction is computed with the Darcy equation, in which losses are proportional to the flow regime-dependable friction factor and the square of the flow rate. The friction factor in turbulent regime is determined with the Haaland approximation (see [1] on page 1-1669). The friction factor during transition from laminar to turbulent regimes is determined with the linear interpolation between extreme points of the regimes. As a result of these assumptions, the tube is simulated according to the following equations:

$$p = f \frac{(L + L_{eq})}{D_H} \frac{\rho}{2A^2} q \cdot |q| + \rho \cdot g(z_B - z_A)$$

$$f = \begin{cases} K_s/Re & \text{for } Re < = Re_L \\ f_L + \frac{f_T - f_L}{Re_T - Re_L}(Re - Re_L) & \text{for } Re_L < Re < Re_T \\ \frac{1}{\left(-1.8 \log_{10} \left( \frac{6.9}{Re} + \left( \frac{r/D_H}{3.7} \right)^{1.11} \right)\right)^2} & \text{for } Re > = Re_T \end{cases}$$

$$Re = \frac{q \cdot D_H}{A \cdot \nu}$$

where

$p$	Pressure loss along the pipe due to friction
$q$	Flow rate through the pipe
$Re$	Reynolds number
$Re_L$	Maximum Reynolds number at laminar flow
$Re_T$	Minimum Reynolds number at turbulent flow
$K_s$	Shape factor that characterizes the pipe cross section
$f_L$	Friction factor at laminar border
$f_T$	Friction factor at turbulent border
$A$	Pipe cross-sectional area
$D_H$	Pipe hydraulic diameter
$L$	Pipe geometrical length
$L_{eq}$	Aggregate equivalent length of local resistances
$r$	Height of the roughness on the pipe internal surface
$\nu$	Fluid kinematic viscosity
$z_A, z_B$	Elevations of the pipe port A and port B, respectively
$g$	Gravity acceleration

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure loss is determined as  $p = p_A - p_B$ .

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Basic Assumptions and Limitations

- Flow is assumed to be fully developed along the pipe length.
- Fluid inertia, fluid compressibility, and wall compliance are not taken into account.

## Parameters

### Basic Parameters Tab

#### Pipe cross section type

The type of pipe cross section: **Circular** or **Noncircular**. For a circular pipe, you specify its internal diameter. For a noncircular pipe, you specify its hydraulic diameter and pipe cross-sectional area. The default value of the parameter is **Circular**.

#### Internal diameter

Pipe internal diameter. The parameter is used if **Pipe cross section type** is set to **Circular**. The default value is 0.01 m.

#### Noncircular pipe cross-sectional area

Pipe cross-sectional area. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is  $1e-4 \text{ m}^2$ .

#### Noncircular pipe hydraulic diameter

Hydraulic diameter of the pipe cross section. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is 0.0112 m.

#### Geometrical shape factor

Used for computing friction factor at laminar flow. The shape of the pipe cross section determines the value. For a pipe with a noncircular cross section, set the factor to an appropriate value, for example, 56 for a square, 96 for concentric annulus, 62 for rectangle (2:1), and so on [1 on page 1-1669]. The default value is 64, which corresponds to a pipe with a circular cross section.

#### Pipe length

Pipe geometrical length. The default value is 5 m.

#### Aggregate equivalent length of local resistances

This parameter represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. The default value is 1 m.

#### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer's catalogs. The default value is  $1.5e-5 \text{ m}$ , which corresponds to drawn tubing.

#### Laminar flow upper margin

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

#### Turbulent flow lower margin

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

## Vertical Position Tab

### Port A elevation wrt reference plane

The parameter specifies vertical position of the pipe port A with respect to the reference plane. The default value is 0.

### Port B elevation wrt reference plane

The parameter specifies vertical position of the pipe port B with respect to the reference plane. The default value is 0.

### Gravitational acceleration

Value of the gravitational acceleration constant ( $g$ ). The block uses this parameter to compute the effects of an elevation gradient between the ports on their pressure differential. The default value is 9.80665 m/s<sup>2</sup>.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Pipe cross section type**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Pipe cross section type** parameter at the time the model entered Restricted mode.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

### Library

Low-Pressure Blocks

### Description

The Resistive Pipe LP with Variable Elevation block models hydraulic pipelines with circular and noncircular cross sections and accounts for resistive property only. Use this block for low-pressure system simulation in which the pipe ends change their positions with respect to the reference plane. The elevations are provided through respective physical signal inputs.

To reduce model complexity, you can use this block to simulate not only a pipe itself, but also a combination of pipes and local resistances such as bends, fittings, inlet and outlet losses, associated with the pipe. You must convert the resistances into their equivalent lengths, and then sum up all the resistances to obtain their aggregate length. Then add this length to the pipe geometrical length.

Pressure loss due to friction is computed with the Darcy equation, in which losses are proportional to the flow regime-dependable friction factor and the square of the flow rate. The friction factor in turbulent regime is determined with the Haaland approximation (see [1] on page 1-1674). The friction factor during transition from laminar to turbulent regimes is determined with the linear interpolation between extreme points of the regimes. As a result of these assumptions, the tube is simulated according to the following equations:

$$p = f \frac{(L + L_{eq})}{D_H} \frac{\rho}{2A^2} q \cdot |q| + \rho \cdot g(z_B - z_A)$$

$$f = \begin{cases} K_s/Re & \text{for } Re < = Re_L \\ f_L + \frac{f_T - f_L}{Re_T - Re_L}(Re - Re_L) & \text{for } Re_L < Re < Re_T \\ \frac{1}{\left(-1.8 \log_{10} \left( \frac{6.9}{Re} + \left( \frac{r/D_H}{3.7} \right)^{1.11} \right)\right)^2} & \text{for } Re > = Re_T \end{cases}$$

$$Re = \frac{q \cdot D_H}{A \cdot \nu}$$

where

$p$	Pressure loss along the pipe due to friction
$q$	Flow rate through the pipe
$Re$	Reynolds number
$Re_L$	Maximum Reynolds number at laminar flow
$Re_T$	Minimum Reynolds number at turbulent flow
$K_s$	Shape factor that characterizes the pipe cross section
$f_L$	Friction factor at laminar border
$f_T$	Friction factor at turbulent border
$A$	Pipe cross-sectional area
$D_H$	Pipe hydraulic diameter
$L$	Pipe geometrical length
$L_{eq}$	Aggregate equivalent length of local resistances
$r$	Height of the roughness on the pipe internal surface
$\nu$	Fluid kinematic viscosity
$z_A, z_B$	Elevations of the pipe port A and port B, respectively
$g$	Gravity acceleration

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure loss is determined as  $p = p_A - p_B$ .

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

### Basic Assumptions and Limitations

- Flow is assumed to be fully developed along the pipe length.
- Fluid inertia, fluid compressibility, and wall compliance are not taken into account.

### Ports

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

el\_A

Physical signal input port that controls pipe elevation at port A.

el\_B

Physical signal input port that controls pipe elevation at port B.

## Parameters

### Basic Parameters

#### Pipe cross section type

The type of pipe cross section: **Circular** or **Noncircular**. For a circular pipe, you specify its internal diameter. For a noncircular pipe, you specify its hydraulic diameter and pipe cross-sectional area. The default value of the parameter is **Circular**.

#### Internal diameter

Pipe internal diameter. The parameter is used if **Pipe cross section type** is set to **Circular**. The default value is 0.01 m.

#### Noncircular pipe cross-sectional area

Pipe cross-sectional area. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is  $1e-4 \text{ m}^2$ .

#### Noncircular pipe hydraulic diameter

Hydraulic diameter of the pipe cross section. The parameter is used if **Pipe cross section type** is set to **Noncircular**. The default value is 0.0112 m.

#### Geometrical shape factor

Used for computing friction factor at laminar flow. The shape of the pipe cross section determines the value. For a pipe with a noncircular cross section, set the factor to an appropriate value, for example, 56 for a square, 96 for concentric annulus, 62 for rectangle (2:1), and so on [1 on page 1-1674]. The default value is 64, which corresponds to a pipe with a circular cross section.

#### Pipe length

Pipe geometrical length. The default value is 5 m.

#### Aggregate equivalent length of local resistances

This parameter represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. The default value is 1 m.

#### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer's catalogs. The default value is  $1.5e-5 \text{ m}$ , which corresponds to drawn tubing.

#### Laminar flow upper margin

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

**Turbulent flow lower margin**

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

**Gravitational acceleration**

Value of the gravitational acceleration constant ( $g$ ). The block uses this parameter to calculate time changes in pressure due to time changes in elevation. The default value is 9.80655 m/s<sup>2</sup>.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

# Rotating Channel (IL)

Rotating pipe with a fluid channel in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

## Description

The Rotating Channel (IL) block models a rotating pipe with a fluid channel in an isothermal liquid network. The pipe angular velocity is set by a physical signal at port **W**. Ports **A** and **B** are isothermal liquid inlet and outlet ports.

Fluid passing through a rotating channel experiences pressure changes due to resistance passing through the casing orifice and due to the fluid angular momentum. An internal connection to an Orifice (IL) block accounts for the local resistances. The pressure change in the block is modeled as:

$$P = \rho_A W^2 \frac{r_B^2}{2},$$

where:

- $\rho_A$  is the fluid density at port **A**.
- $W$  is the shaft angular velocity, received as a physical signal at port **W**.
- $r_B$  is the radius of rotation at port **B**.

The isothermal liquid outlet port can be connected to a Rotating Cylinder Force (IL) block to model components such as a Rotating Single-Acting Actuator (IL).

## Assumptions and Limitations

- The effects of fluid inertia are not calculated.
- The pipe angular velocity is assumed to be constant or changes very slowly.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port.

### **Input**

**W** — Angular velocity, rad/s  
physical signal

Rotating shaft angular velocity in rad/s, specified as a physical signal.

### **Parameters**

**Channel area** — Shaft channel cross-sectional area  
1e-3 m<sup>2</sup> (default) | positive scalar

Shaft channel cross-sectional area for liquid entry/exit.

**Port B radius of rotation** — Rotation radius  
0.01 m (default) | positive scalar

Radius of swept circle of pipe rotation, specified at port **B**.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

Simscape / Fluids / Isothermal Liquid / Actuators / Auxiliary Components

## Description

The Rotating Cylinder Force (IL) block models the axial force due to a centripetal pressure gradient in a rotating shaft about its symmetry axis, which is found in applications such as friction clutches, square-jaw positive clutches, dog clutches, and brakes. Connect this block in parallel to a Single-Acting Actuator (IL) or a Translational Mechanical Converter (IL) block to model a rotating actuator. The fluid density is recorded at the isothermal liquid port **X**. The angular velocity is received as a physical signal at port **W**. Port **R** is associated with the piston velocity, relative to the case at port **C**.

The angular velocity of the shaft is assumed to be constant or nearly-constant, and therefore the fluid is considered to be in rigid-body rotation.

The centripetal force is due solely to the fluid angular momentum induced by shaft rotation. Removing the contribution of the static pressure in the fluid channel, the contribution of the rotation of the shaft to the axial force is:

$$F_{rotational} = \frac{\rho\pi W^2}{4}(r_o^4 - r_i^4 - 2r_p^2(r_o^2 - r_i^2)),$$

where:

- $\rho$  is the fluid density at port **X**.
- $W$  is the angular velocity of the rotating pipe, received as a physical signal at port **W**.
- $r_o$  is the **Piston outer radius**.
- $r_i$  is the **Piston inner radius**.
- $r_p$  is the **Fluid entry radius**.

## Ports

### Conserving

**X** — Liquid density port  
isothermal liquid

Liquid port associated with fluid density. There is no mass flow through port **X**. Connect port **X** to port **A** of the Single-Acting Actuator (IL) or Translational Mechanical Converter (IL) blocks.

**C** — Cylinder casing  
mechanical translational

Mechanical translational conserving port associated with the cylinder casing reference velocity and force.

**R** — Piston  
mechanical translational

Mechanical translational conserving port associated with the piston velocity and force induced by the pressure differential.

### Input

**W** — Angular velocity, rad/s  
physical signal

Angular velocity in rad/s, specified as a physical signal.

## Parameters

**Piston outer radius** — Piston outer radius  
0.1 m (default) | positive scalar

Piston outer radius.

**Piston inner radius** — Piston inner radius  
0.05 m (default) | positive scalar

Piston inner radius.

**Fluid entry radius** — Fluid channel radius  
0.06 m (default) | positive scalar

Radius of the fluid opening in the cylinder casing, measured from the rotational axis. This value must be greater than or equal to the **Piston inner radius** and less than or equal to the **Piston outer radius**.

**Actuator mechanical orientation** — Piston displacement direction  
Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Piston displacement direction of the connected actuator block. Pressure at A causes positive displacement of R relative to C corresponds to positive displacement, or actuator shaft extension, when **R - C** is positive. Pressure at A causes negative displacement of R relative to C corresponds to negative displacement, or actuator shaft retraction, when **R - C** is positive.

---

## Library

Pipelines

### Description

The Rotating Pipe block models a hydraulic pipeline represented as a short bore drilled through a shaft at some angle to its axis, or as a short pipe that connects actuator or bearings, mounted on the shaft, with the channel inside the shaft. Such connections are typical for lubrication systems and for hydraulically-operated clutches and mechanisms. The shaft angular velocity is assumed to be constant or changing at very low speed. The block is implemented as a structural model, shown in the diagram below:

The Fixed Orifice block simulates pressure losses in the bore. The pipe is assumed to be short enough to be characterized by a flow-pressure relationship similar to that of the fixed orifice. The model accounts for the laminar and turbulent flow regimes by monitoring the Reynolds number ( $Re$ ) and comparing its value with the critical Reynolds number ( $Re_{cr}$ ). The Hydraulic Pressure Source block represents pumping action developed by a rotating pipe, which is calculated with the equation:

$$p = \rho \cdot \frac{\omega^2 \cdot r_B^2}{2}$$

where

$p$	Pressure at the pipe outlet
$\rho$	Fluid density
$\omega$	Shaft angular velocity
$r_B$	Radius of the pipe outlet

Connections A and B are conserving hydraulic ports associated with the pipe inlet and outlet, respectively. Connection W is the physical signal input port that provides the shaft angular velocity value.

## Basic Assumptions and Limitations

- The pipe is assumed to be short, to be simulated with the fixed orifice.
- Flow is assumed to be fully developed along the pipe length.
- The transition between laminar and turbulent regimes is assumed to be sharp and taking place exactly at  $Re=Re_{cr}$ .
- Fluid inertia is not taken into account.
- Fluid compressibility is not taken into account.

## Parameters

### Pipe cross-section area

Cross-sectional area of the pipe. The default value is  $1e-4 \text{ m}^2$ .

### Port B radius of rotation

Radius of rotation of the outer end of the pipe. The default value is  $0.03 \text{ m}$ .

### Flow discharge coefficient

Semi-empirical parameter for pipe capacity characterization. Its value depends on the geometrical properties of the pipe, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.6$ .

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The value of the parameter depends on the pipe geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is  $12$ , which corresponds to a round orifice in thin material with sharp edges.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Examples

For an example on page 1-451 of using the Rotating Pipe block to model a custom single-acting hydraulic cylinder, see the Centrifugal Force in Rotating Cylinder block reference page.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

W

Physical signal port providing the angular velocity value.

## Version History

# Rotating Single-Acting Actuator (IL)

Actuator on a rotating shaft in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Actuators

## Description

The Rotating Single-Acting Actuator (IL) block models an actuator that rotates around its central axis in an isothermal liquid network. Rotating actuators are used in rotating shaft control components such as friction clutches or brakes. The fluid enters the actuator at port **A**. The angular velocity is set at port **W**. Port **C** is associated with the actuator casing and the piston velocity and force are set at port **R**.

When the piston position is calculated internally, it is reported at port **p**, and when the position is set by a connection to a Simscape Multibody joint, it is received as a physical signal at port **p**. The motion of the piston when it is near full extension or full retraction is limited by one of four hard stop models. **Fluid dynamic compressibility** can optionally be modeled.

## Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Mechanical orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\Theta$ , when the chamber volume is equal to the **Dead volume**. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Translational Multibody Interface block connection to a Simscape Multibody joint.

## Hard Stop Model

To avoid mechanical damage to an actuator when it is fully extended or fully retracted, an actuator typically displays nonlinear behavior when the piston approaches these limits. The Double-Acting Actuator (IL) block models this behavior with a choice of four hard stop models, which model the material compliance through a spring-damper system. The hard stop models are:

- Stiffness and damping applied smoothly through transition region, damped rebound.
- Full stiffness and damping applied at bounds, undamped rebound.
- Full stiffness and damping applied at bounds, damped rebound.
- Based on coefficient of restitution

The hard stop force is modeled when the piston is at its upper or lower bound. The boundary region is within the **Transition region** of the **Piston stroke** or piston initial displacement. Outside of this region,  $F_{HardStop} = 0$ .

For more information about these settings, see the Translational Hard Stop block page.

### Block Subcomponents

The Rotating Single-Acting Actuator (IL) block comprises three Isothermal Liquid library blocks:

- Rotating Channel (IL)
- Single-Acting Actuator (IL)
- Rotating Cylinder Force (IL)

### Actuator Schematic

### Ports

#### Conserving

**A** — Liquid chamber inlet port  
isothermal liquid

Inlet port to the liquid chamber.

**C** — Actuator casing  
mechanical translational

Reference port for actuator velocity and force.

**R** — Rod velocity  
mechanical translational

Port associated with the piston velocity and force.

**Input**

**W** — Actuator rotational velocity  
physical signal

Actuator rotational velocity, received as a physical signal in rad/s.

**p** — Piston position, m  
physical signal

Piston position in m, received as a physical signal from a Simscape Multibody block.

**Dependencies**

To expose this port, set **Piston displacement** to Provide input signal from Multibody joint.

**Output**

**p** — Piston position, m  
physical signal

Piston position in m, returned as a physical signal.

**Dependencies**

To expose this port, set **Piston displacement** to Calculate from velocity of port R relative to port C.

**Parameters****Actuator**

**Piston outer radius** — Piston outer radius  
0.1 m (default) | positive scalar

Piston outer radius.

**Piston inner radius** — Piston inner radius  
0.05 m (default) | positive scalar

Piston inner radius.

**Mechanical orientation** — Piston displacement direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Sets the piston displacement direction. When you set this parameter to:

- Pressure at A causes positive displacement of R relative to C the piston displacement is positive when the volume of liquid at port **A** is expanding. This corresponds to rod extension.
- Pressure at A causes negative displacement of R relative to C the piston displacement is negative when the volume of liquid at port **A** is expanding. This corresponds to rod contraction.

**Piston stroke** — Maximum piston travel distance

0.1 m (default) | positive scalar

Maximum piston travel distance.

**Dead volume** — Fluid volume at full piston retraction

1e-5 m<sup>3</sup> (default) | positive scalar

Volume of liquid when the piston displacement is 0. This is the liquid volume when the piston is up against the actuator end cap.

**Environment pressure specification** — Reference environment pressure

Atmospheric pressure (default) | Specified pressure

Environment reference pressure. The `Atmospheric pressure` option sets the environmental pressure to 0.101325 MPa.

**Environment pressure** — User-defined environmental pressure

0.101325 MPa (default) | positive scalar

User-defined environmental pressure.

#### **Dependencies**

To enable this parameter, set **Environment pressure specification** to `Specified pressure`.

#### **Fluid Channel**

**Fluid entry radius** — Fluid channel radius

0.06 m (default) | positive scalar

Radius of the fluid opening in the rotating shaft. This value must be greater than or equal to the **Piston inner radius** and less than or equal to the **Piston outer radius**.

**Fluid channel cross-sectional area** — Fluid cross-sectional area

1e-3 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the fluid channel.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Flow discharge loss coefficient.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

#### **Hard Stop**

**Hard stop model** — Select the hard stop model

Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
 $1e10$  N/m (default) | positive scalar

Piston stiffness coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient  
 $150$  N\*s/m (default) | positive scalar

Piston damping coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model  
 $0.1$  mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

#### Dependencies

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision  
 $0.7$  (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

#### Dependencies

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision  
 $0.001$  m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Initial Conditions**

**Piston displacement** — Method for determining piston position

Calculate from velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the piston position. The block can receive the position from a Multibody block when set to Provide input signal from Multibody joint, or calculates the position internally and reports the position at port **p**. The position is between 0 and the **Piston stroke** when the mechanical orientation is positive and 0 and **-Piston stroke** when the mechanical orientation is negative.

**Initial piston displacement** — Piston position at start of simulation

0 m (default) | scalar

Piston position at the start of the simulation.

**Dependencies**

To enable this parameter, set **Piston displacement** to Calculate from velocity of port R relative to port C.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid dynamic compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid pressure** — Starting liquid pressure for compressible fluids

0.101325 MPa (default) | positive scalar

Starting liquid pressure for compressible fluids.

**Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

## Version History

Introduced in R2020a

### R2023a: New hard stop parameterization option

The block has a new option for the **Hard stop model** parameter. This option, called **Based on coefficient of restitution**, models the hard stop by using a mode chart.

# Segmented Pipeline

(To be removed) Hydraulic pipeline with resistive, fluid inertia, and fluid compressibility properties

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Library

Pipelines

## Description

The Segmented Pipeline block models hydraulic pipelines with circular cross sections. Hydraulic pipelines, which are inherently distributed parameter elements, are represented with sets of identical, connected in series, lumped parameter segments. It is assumed that the larger the number of segments, the closer the lumped parameter model becomes to its distributed parameter counterpart. The equivalent circuit of a pipeline adopted in the block is shown below, along with the segment configuration.

## Pipeline Equivalent Circuit

## Segment Configuration

The model contains as many Constant Volume Hydraulic Chamber blocks as there are segments. The chamber lumps fluid volume equal to

$$V = \frac{\pi \cdot d^2 L}{4 N}$$

where

$V$	Fluid volume
$d$	Pipe diameter
$L$	Pipe length
$N$	Number of segments

The Constant Volume Hydraulic Chamber block is placed between two branches, each consisting of a Hydraulic Resistive Tube block and a Fluid Inertia block. Every Hydraulic Resistive Tube block lumps  $(L+L_{ad})/(N+1)$ -th portion of the pipe length, while Fluid Inertia block has  $L/(N+1)$  length ( $L_{ad}$  denotes additional pipe length equal to aggregate equivalent length of pipe local resistances, such as fitting, elbows, bends, and so on).

The nodes to which Constant Volume Hydraulic Chamber blocks are connected are assigned names  $N_1, N_2, \dots, N_n$  ( $n$  is the number of segments). Pressures at these nodes are assumed to be equal to average pressure of the segment. Intermediate nodes between Hydraulic Resistive Tube and Fluid Inertia blocks are assigned names  $nn_0, nn_1, nn_2, \dots, nn_n$ . The Constant Volume Hydraulic Chamber blocks are named  $ch_1, ch_2, \dots, ch_n$ , Hydraulic Resistive Tube blocks are named  $tb_0, tb_1, tb_2, \dots, tb_n$ , and Fluid Inertia blocks are named  $fl\_in_0, fl\_in_1, fl\_in_2, \dots, fl\_in_n$ .

The number of segments determines the number of computational nodes associated with the block. A higher number increases model fidelity but decreases simulation speed. Experiment with different numbers to obtain a suitable trade-off between accuracy and speed. Use the following equation as a starting point in estimating a suitable number of segments:

$$N > \frac{4L}{\pi \cdot c} \omega$$

where:

$N$	Number of segments
$L$	Pipe length
$c$	Speed of sound in the fluid
$\omega$	Maximum frequency to be observed in the pipe response

The table contains an example of simulation of a pipeline where the first four true eigenfrequencies are 89.1 Hz, 267 Hz, 446 Hz, and 624 Hz.

Number of Segments	1st Mode	2nd Mode	3rd Mode	4th Mode
1	112.3	-	-	-
2	107.2	271.8	-	-

Number of Segments	1st Mode	2nd Mode	3rd Mode	4th Mode
4	97.7	284.4	432.9	689
8	93.2	271.9	435.5	628

The error between simulated and actual eigenfrequencies is less than 5% if an eight-segment model is used.

The flow rate through the pipeline is positive if it is directed from port A to port B. The pressure differential is positive if pressure is higher at port A than at port B.

## Basic Assumptions and Limitations

Flow is assumed to be fully developed along the pipe length.

## Parameters

### Pipe internal diameter

Internal diameter of the pipe. The default value is 0.01 m.

### Pipe length

Pipe geometrical length. The default value is 5 m.

### Number of segments

Number of lumped parameter segments in the pipeline model. The default value is 1.

### Aggregate equivalent length of local resistances

This parameter represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. This length is added to the geometrical pipe length only for hydraulic resistance computation. Both the fluid volume and fluid inertia are determined based on pipe geometrical length only. The default value is 1 m.

### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer's catalogs. The default value is  $1.5e-5$  m, which corresponds to drawn tubing.

### Laminar flow upper margin

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

### Turbulent flow lower margin

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

### Pipe wall type

The parameter can have one of two values: `Rigid Wall` or `Flexible Wall`. If the parameter is set to `Rigid Wall`, wall compliance is not taken into account, which can improve computational efficiency. The value `Flexible Wall` is recommended for hoses and metal pipes where wall compliance can affect the system behavior. The default value is `Rigid Wall`.

**Static pressure-diameter coefficient**

Coefficient that establishes relationship between the pressure and the internal diameter at steady-state conditions. This coefficient can be determined analytically for cylindrical metal pipes or experimentally for hoses. The parameter is used if the **Pipe wall type** parameter is set to **Flexible Wall**, and the default value is  $2e-10$  m/Pa.

**Viscoelastic process time constant**

Time constant in the transfer function that relates pipe internal diameter to pressure variations. By using this parameter, the simulated elastic or viscoelastic process is approximated with the first-order lag. The value is determined experimentally or provided by the manufacturer. The default value is  $0.008$  s.

**Specific heat ratio**

Gas-specific heat ratio for the Constant Volume Hydraulic Chamber block. The default value is  $1.4$ .

**Initial pressures at model nodes**

Lets you specify the initial condition for pressure inside the pipe segments. The parameter can have one of two values:

- **The same initial pressure for all nodes** — The initial pressure in all pipe segments is the same, and is specified by the **Initial pressure** parameter value. This is the default.
- **Custom** — Lets you specify initial pressure individually for each pipe segment, by using the **Initial pressure vector** parameter. The vector size must be equal to the number of pipe segments, defined by the **Number of segments** parameter value.

**Initial pressure**

Specifies the initial pressure in all pipe segments. The parameter is used if the **Initial pressures at model nodes** parameter is set to **The same initial pressure for all nodes**, and the default value is  $0$ .

**Initial pressure vector**

Lets you specify initial pressure individually for each pipe segment. The parameter is used if the **Initial pressures at model nodes** parameter is set to **Custom**. The vector size must be equal to the number of pipe segments, defined by the **Number of segments** parameter value.

**Initial flow rate**

Specifies the initial volumetric flow rate through the pipe. The default value is  $0$  m<sup>3</sup>/s.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Pipe wall type**
- **Initial pressures at model nodes**

All other block parameters are available for modification.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**

- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

## Version History

## Library

Low-Pressure Blocks

## Description

The Segmented Pipe LP block models hydraulic pipelines with circular cross sections. Hydraulic pipelines, which are inherently distributed parameter elements, are represented with sets of identical, connected in series, lumped parameter segments. It is assumed that the larger the number of segments, the closer the lumped parameter model becomes to its distributed parameter counterpart. The equivalent circuit of a pipeline adopted in the block is shown below, along with the segment configuration.

## Pipeline Equivalent Circuit

## Segment Configuration

The model contains as many Constant Volume Hydraulic Chamber blocks as there are segments. The chamber lumps fluid volume equal to

$$V = \frac{\pi \cdot d^2 L}{4 N}$$

where

$V$	Fluid volume
$d$	Pipe diameter
$L$	Pipe length
$N$	Number of segments

The Constant Volume Hydraulic Chamber block is placed between two branches, each consisting of a Resistive Pipe LP block and a Fluid Inertia block. Every Resistive Pipe LP block lumps  $(L+L_{ad}) / (N+1)$ -th portion of the pipe length, while Fluid Inertia block has  $L / (N+1)$  length ( $L_{ad}$  denotes additional pipe length equal to aggregate equivalent length of pipe local resistances, such as fitting, elbows, bends, and so on).

The nodes to which Constant Volume Hydraulic Chamber blocks are connected are assigned names  $N_1, N_2, \dots, N_n$  ( $n$  is the number of segments). Pressures at these nodes are assumed to be equal to average pressure of the segment. Intermediate nodes between Resistive Pipe LP and Fluid Inertia blocks are assigned names  $nn_0, nn_1, nn_2, \dots, nn_n$ . The Constant Volume Hydraulic Chamber blocks are named  $ch_1, ch_2, \dots, ch_n$ , Resistive Pipe LP blocks are named  $tb_0, tb_1, tb_2, \dots, tb_n$ , and Fluid Inertia blocks are named  $fl\_in_0, fl\_in_1, fl\_in_2, \dots, fl\_in_n$ .

The number of segments determines the number of computational nodes associated with the block. A higher number increases model fidelity but decreases simulation speed. Experiment with different numbers to obtain a suitable trade-off between accuracy and speed. Use the following equation as a starting point in estimating a suitable number of segments:

$$N > \frac{4L}{\pi \cdot c} \omega$$

where

$N$	Number of segments
$L$	Pipe length
$c$	Speed of sound in the fluid
$\omega$	Maximum frequency to be observed in the pipe response

The table below contains an example of simulation of a pipeline where the first four true eigenfrequencies are 89.1 Hz, 267 Hz, 446 Hz, and 624 Hz.

Number of Segments	1st Mode	2nd Mode	3rd Mode	4th Mode
1	112.3	-	-	-
2	107.2	271.8	-	-
4	97.7	284.4	432.9	689
8	93.2	271.9	435.5	628

As you can see, the error is less than 5% if an eight-segmented version is used.

The difference in elevation between ports A and B is distributed evenly between pipe segments.

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure loss is determined as  $\Delta p = p_A - p_B$ .

## Basic Assumptions and Limitations

Flow is assumed to be fully developed along the pipe length.

## Parameters

- “Basic Parameters Tab” on page 1-1697
- “Wall Compliance Tab” on page 1-1698
- “Vertical Position Tab” on page 1-1698

### Basic Parameters Tab

#### Pipe internal diameter

Internal diameter of the pipe. The default value is 0.01 m.

#### Pipe length

Pipe geometrical length. The default value is 5 m.

#### Number of segments

Number of lumped parameter segments in the pipeline model. The default value is 1.

#### Aggregate equivalent length of local resistances

This parameter represents total equivalent length of all local resistances associated with the pipe. You can account for the pressure loss caused by local resistances, such as bends, fittings, armature, inlet/outlet losses, and so on, by adding to the pipe geometrical length an aggregate equivalent length of all the local resistances. This length is added to the geometrical pipe length only for hydraulic resistance computation. Both the fluid volume and fluid inertia are determined based on pipe geometrical length only. The default value is 1 m.

#### Internal surface roughness height

Roughness height on the pipe internal surface. The parameter is typically provided in data sheets or manufacturer’s catalogs. The default value is  $1.5e-5$  m, which corresponds to drawn tubing.

#### Laminar flow upper margin

Specifies the Reynolds number at which the laminar flow regime is assumed to start converting into turbulent. Mathematically, this is the maximum Reynolds number at fully developed laminar flow. The default value is 2000.

#### Turbulent flow lower margin

Specifies the Reynolds number at which the turbulent flow regime is assumed to be fully developed. Mathematically, this is the minimum Reynolds number at turbulent flow. The default value is 4000.

#### Initial liquid pressure

Gauge pressure in the pipe segments at time zero. Enter a scalar for a single-segment pipeline and a vector for a multi-segment pipeline. The number of elements in the vector must match the number of segments in the pipe. The default value is 0 Pa.

## Wall Compliance Tab

### Pipe wall type

The parameter can have one of two values: **Rigid Wall** or **Flexible Wall**. If the parameter is set to **Rigid Wall**, wall compliance is not taken into account, which can improve computational efficiency. The value **Flexible Wall** is recommended for hoses and metal pipes where wall compliance can affect the system behavior. The default value is **Rigid Wall**.

### Static pressure-diameter coefficient

Coefficient that establishes relationship between the pressure and the internal diameter at steady-state conditions. This coefficient can be determined analytically for cylindrical metal pipes or experimentally for hoses. The parameter is used if the **Pipe wall type** parameter is set to **Flexible**. The default value is  $2e-12$  m/Pa.

### Viscoelastic process time constant

Time constant in the transfer function that relates pipe internal diameter to pressure variations. By using this parameter, the simulated elastic or viscoelastic process is approximated with the first-order lag. The value is determined experimentally or provided by the manufacturer. The parameter is used if the **Pipe wall type** parameter is set to **Flexible Wall**. The default value is 0.01 s.

### Specific heat ratio

Gas-specific heat ratio for the Constant Volume Hydraulic Chamber block. The default value is 1.4.

## Vertical Position Tab

### Port A elevation wrt reference plane

Vertical position of port **A** with respect to a reference plane. The reference plane is assumed to be the same as that used in the **Port B elevation from reference plane** parameter. The default value is 0m.

### Port B elevation wrt reference plane

Vertical position of port **B** with respect to a reference plane. The reference plane is assumed to be the same as that used in the **Port A elevation from reference plane** parameter. The default value is 0m.

### Gravitational acceleration

Value of the gravitational acceleration constant ( $g$ ). The block uses this parameter to compute the effects of an elevation gradient between the ports on their pressure differential. The default value is  $9.80655$  m/s<sup>2</sup>.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Pipe wall type**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Pipe wall type** parameter at the time the model entered Restricted mode.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the pipe inlet.

B

Hydraulic conserving port associated with the pipe outlet.

## Library

Directional Valves

## Description

The Shuttle Valve block represents a hydraulic shuttle valve as a data-sheet-based model. The valve has two inlet ports (A and A1) and one outlet port (B). The valve is controlled by pressure differential  $p_c = p_A - p_{A1}$ . The valve permits flow either between ports A and B or between ports A1 and B, depending on the pressure differential  $p_c$ . Initially, path A-B is assumed to be opened. To open path A1-B (and close A-B at the same time), pressure differential must be less than the valve cracking pressure ( $p_{cr} <= 0$ ).

When cracking pressure is reached, the valve control member (spool, ball, poppet, etc.) is forced off its seat and moves to the opposite seat, thus opening one passage and closing the other. If the flow rate is high enough and pressure continues to change, the control member continues to move until it reaches its extreme position. At this moment, one of the valve passage areas is at its maximum. The valve maximum area and the cracking and maximum pressures are generally provided in the catalogs and are the three key parameters of the block.

The relationship between the A-B, A1-B path openings and control pressure  $p_c$  is shown in the following illustration.

In addition to the maximum area, the leakage area is also required to characterize the valve. The main purpose of the parameter is not to account for possible leakage, even though this is also important, but to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. An isolated or “hanging” part of the system could affect computational efficiency and even cause failure of computation. Therefore, the parameter value must be greater than zero.

The flow rate through each of the orifices is determined according to the following equations:

$$q_{AB} = C_D \cdot A_{AB} \sqrt{\frac{2}{\rho}} \cdot \frac{p_{AB}}{(p_{AB}^2 + p_{cr}^2)^{1/4}}$$

$$q_{A1B} = C_D \cdot A_{A1B} \sqrt{\frac{2}{\rho}} \cdot \frac{p_{A1B}}{(p_{A1B}^2 + p_{cr}^2)^{1/4}}$$

$$A_{AB} = \begin{cases} A_{leak} & \text{for } p_c \leq p_{crack} \\ A_{leak} + k \cdot (p_c - p_{crack}) & \text{for } p_{crack} < p_c < p_{crack} + p_{op} \\ A_{max} & \text{for } p_c \geq p_{crack} + p_{op} \end{cases}$$

$$A_{A1B} = \begin{cases} A_{leak} & \text{for } p_c \geq p_{crack} + p_{op} \\ A_{max} - k \cdot (p_c - p_{crack}) & \text{for } p_{crack} < p_c < p_{crack} + p_{op} \\ A_{max} & \text{for } p_c \leq p_{crack} \end{cases}$$

$$k = \frac{A_{max} - A_{leak}}{p_{op}}$$

$$p_c = p_A - p_{A1}$$

where

$q_{AB}, q_{A1B}$	Flow rates through the AB and A1B orifices
$p_{AB}, p_{A1B}$	Pressure differentials across the AB and A1B orifices

$p_A, p_{A1}, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$\rho$	Fluid density
$A_{AB}, A_{A1B}$	Instantaneous orifice AB and A1B passage areas
$A_{max}$	Fully open orifice passage area
$A_{leak}$	Closed valve leakage area
$p_c$	Valve control pressure differential
$p_{crack}$	Valve cracking pressure differential
$p_{op}$	Pressure differential needed to fully shift the valve
$p_{crAB}, p_{crA1B}$	Minimum pressures for turbulent flow across the AB and A1B orifices

The minimum pressures for turbulent flow across the AB and A1B orifices,  $p_{crAB}$  and  $p_{crA1B}$ , are calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{crAB} = (p_{avgAB} + p_{atm})(1 - B_{lam})$$

$$p_{crA1B} = (p_{avgA1B} + p_{atm})(1 - B_{lam})$$

$$p_{avgAB} = (p_A + p_B)/2$$

$$p_{avgA1B} = (p_{A1} + p_B)/2$$

where

$p_{avgAB}$	Average pressure for orifice AB
$p_{avgA1B}$	Average pressure for orifice A1B
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{crAB} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_{HAB}} \right)^2$$

$$p_{crA1B} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_{HA1B}} \right)^2$$

$$D_{HAB} = \sqrt{\frac{4A_{AB}}{\pi}}$$

$$D_{HA1B} = \sqrt{\frac{4A_{A1B}}{\pi}}$$

where

$D_{HAB}, D_{HA1B}$	Instantaneous orifice hydraulic diameters
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

By default, the block does not include valve opening dynamics. Adding valve opening dynamics provides continuous behavior that is particularly helpful in situations with rapid valve opening and closing. The orifice passage areas  $A_{AB}$  and  $A_{A1B}$  in the equations above then become steady-state orifice AB and A1B passage areas, respectively. Instantaneous orifice AB and A1B passage areas with opening dynamics are determined as follows:

$$A_{AB\_dyn}(t = 0) = A_{AB\_init}$$

$$\frac{dA_{AB\_dyn}}{dt} = \frac{A_{AB} - A_{AB\_dyn}}{\tau}$$

$$A_{A1B\_dyn} = A_{max} + A_{leak} - A_{AB\_dyn}$$

where

$A_{AB\_dyn}$	Instantaneous orifice AB passage area with opening dynamics
$A_{A1B\_dyn}$	Instantaneous orifice A1B passage area with opening dynamics
$A_{AB\_init}$	Initial open area for orifice AB
$\tau$	Time constant for the first order response of the valve opening
$t$	Time

The block positive direction is from port A to port B and from port A1 to port B. Control pressure is determined as  $p_c = p_A - p_{A1}$ .

## Basic Assumptions and Limitations

- Valve opening is linearly proportional to the pressure differential.
- No loading on the valve, such as inertia, friction, spring, and so on, is considered.

## Parameters

### Maximum passage area

Valve passage maximum cross-sectional area. The default value is  $1e-4 \text{ m}^2$ .

### Cracking pressure

Pressure differential level at which the orifice of the valve starts to open. The default value is  $-1e4 \text{ Pa}$ .

### Opening pressure

Pressure differential across the valve needed to shift the valve from one extreme position to another. The default value is  $1e4 \text{ Pa}$ .

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.7$ .

### **Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

### **Opening dynamics**

Select one of the following options:

- **Do not include valve opening dynamics** — The valve sets its orifice passage area directly as a function of pressure. If the area changes instantaneously, so does the flow equation. This is the default.
- **Include valve opening dynamics** — Provide continuous behavior that is more physically realistic, by adding a first-order lag during valve opening and closing. Use this option in hydraulic simulations with the local solver for real-time simulation. This option is also helpful if you are interested in valve opening dynamics in variable step simulations.

### **Opening time constant**

The time constant for the first order response of the valve opening. This parameter is available only if **Opening dynamics** is set to **Include valve opening dynamics**. The default value is 0.1 s.

### **Initial area at port A**

The initial open area for orifice AB. This parameter is available only if **Opening dynamics** is set to **Include valve opening dynamics**. The default value is  $1e-4 \text{ m}^2$ .

### **Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Opening dynamics**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Opening dynamics** parameter at the time the model entered Restricted mode.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

A1

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

## Version History

## Shuttle Valve (IL)

One-way switching valve in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The Shuttle Valve (IL) block models a one-way pressure control valve or switching component in an isothermal liquid network. Flow through the valve travels from port **A** or port **A1** to port **B**. When the pressure differential between **A** and **A1**,  $p_{AA1}$ , is above a specified threshold pressure, the path between ports **A** and **B** is open to flow and the port at **A1** closes. The path has been fully changed when the pressure reaches the **Pressure at which A-B is fully open and A1-B is fully closed**. When  $p_{AA1}$  falls below the threshold pressure, the flow inlet switches to port **A1**.

### Mass Flow Rate Equation

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_{A1} + \dot{m}_B = 0.$$

There is no flow between ports **A** and **A1**.

The mass flow rate through the valve is calculated as:

$$\dot{m} = \frac{C_d A_{\text{valve}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left( 1 - \left( \frac{A_{\text{valve}}}{A_{\text{port}}} \right)^2 \right) [\Delta p^2 + \Delta p_{\text{crit}}^2]^{1/4}}} \Delta p$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{\text{valve}}$  is the valve open area, either between ports **A** and **B** or ports **A1** and **B**.
- $A_{\text{port}}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference. Depending on the flow path through the valve, this is either  $p_A - p_B$ ,  $p_{A1} - p_B$ , or the normalized pressure when switching between the two inlet ports,  $\hat{p}$ , defined below.

The critical pressure difference,  $\Delta p_{\text{crit}}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{\text{crit}}$ , and is also dependent on the flow path through the valve:

$$\Delta p_{\text{crit}} = \frac{\pi \bar{\rho}}{8 A_{\text{valve}}} \left( \frac{\nu Re_{\text{crit}}}{C_d} \right)^2.$$

The critical Reynolds number is the flow regime transition point between laminar and turbulent flow.

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area, and can change if different valve flow paths have different areas.  $PR_{\text{loss}}$  is calculated as:

$$PR_{\text{loss}} = \frac{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, set the **Pressure recovery** to Off. In this case,  $PR_{\text{loss}}$  is 1.

The opening area,  $A_{\text{valve}}$ , is also impacted by the valve opening dynamics.

### Opening Parameterization

The linear parameterization of the valve area depends on the flow path through the valve. The dynamic area is based on a normally open path between ports **A** and **B**:

$$A_{\text{valve}, AB} = \hat{p}(A_{\text{max}} - A_{\text{leak}}) + A_{\text{leak}}.$$

The normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{AA1} - p_{\text{open}, A1B}}{p_{\text{open}, AB} - p_{\text{open}, A1B}},$$

when  $p_{AA1}$  is between the parameters **Pressure at which A-B is fully closed and A1-B is fully open** and **Pressure at which A-B is fully open and A1-B is fully closed**. If  $p_{AA1}$  is below **Pressure at which A-B is fully closed and A1-B is fully open**,  $\hat{p}$  is 0. If  $p_{AA1}$  is above **Pressure at which A-B is fully open and A1-B is fully closed**,  $\hat{p}$  is 1.

When the valve inlet switches from port **A** to port **A1**, the valve opening area is:

$$A_{\text{valve}, A1B} = A_{\text{max}} + A_{\text{leak}} - A_{\text{valve}, AB}.$$

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the normalized control pressure between 0 and 1. For more information, see “Numerical Smoothing”.

### Opening Dynamics

If opening dynamics are modeled, a lag is introduced to the flow response to the modeled control pressure.  $p_{\text{control}}$  becomes the dynamic control pressure,  $p_{\text{dyn}}$ ; otherwise,  $p_{\text{control}}$  is the steady-state pressure. The instantaneous change in dynamic control pressure is calculated based on the **Opening time constant**,  $\tau$ :

$$\dot{p}_{\text{dyn}, AB} = \frac{p_{\text{control}} - p_{\text{dyn}, AB}}{\tau}.$$

By default, **Opening dynamics** is set to Off.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry port to the valve.

**A1** — Liquid port  
isothermal liquid

Entry port to the valve.

**B** — Liquid port  
isothermal liquid

Exit port from the valve.

## Parameters

**Pressure at which A-B is fully closed and A1-B is fully open** — Threshold pressure for fully open inlet A1

-0.01 MPa (default) | scalar

Pressure threshold between ports **A** and **A1**, below which the flow path between ports **A1** and **B** is fully open and the flow path between ports **A** and **B** is fully closed.

**Pressure at which A-B is fully open and A1-B is fully closed** — Threshold pressure for fully open inlet A

0.01 MPa (default) | scalar

Pressure threshold between ports **A** and **A1**, above which the flow path between ports **A** and **B** is fully open and the flow path between ports **A1** and **B** is fully closed.

**Maximum opening area** — Maximum valve area

1e-4 m<sup>2</sup> (default) | positive scalar

Maximum open area of the valve. This value is used to determine the normalized valve pressure and the valve opening area during operation.

**Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Cross-sectional area at ports A and B** — Area at conserving ports

inf m<sup>2</sup> (default) | positive scalar

Areas at the entry and exit ports **A**, **A1**, and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor accounting for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Pressure recovery** — Whether to account for pressure increase in area expansions

Off (default) | On

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Opening dynamics** — Whether to introduce flow lag due to valve opening

Off (default) | On

Whether to account for transient effects to the fluid system due to opening the valve. Setting **Opening dynamics** to On approximates the opening conditions by introducing a first-order lag in the flow response. The **Opening time constant** also impacts the modeled opening dynamics.

**Opening time constant** — Valve opening time constant

0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state conditions when opening or closing the valve from one position to another. This parameter impacts the modeled opening dynamics.

### Dependencies

To enable this parameter, set **Opening dynamics** to On.

## Simple Heat Exchanger Interface (G)

Thermal interface between a gas and its surroundings

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers / Fundamental Components

### Description

The Simple Heat Exchanger Interface (G) block models the pressure drop and temperature change in a gas as it traverses the length of a thermal interface such as that provided by a heat exchanger. Heat transfer across the thermal interface is ignored. See the composite block diagram of the Heat Exchanger (G-G) block for an example showing how to combine the two blocks.

The pressure drop is calculated as a function of mass flow rate from tabulated data specified at some reference pressure and temperature. The calculation is based on linear interpolation if the mass flow rate is within the bounds of the tabulated data and on nearest-neighbor extrapolation otherwise. In other words, neighboring data points connect through straight-line segments, with those at the mass flow rate bounds extending horizontally outward.

### Linear interpolation (left) and nearest-neighbor extrapolation (right)

The block calculations rely on the states and properties of the fluid—temperature, density, and specific internal energy—at the entrance to the thermal interface. The entrance changes abruptly from one port to the other during flow reversal, introducing discontinuities in the values of these variables. To eliminate these discontinuities, the block smooths the affected variables at mass flow rates below a specified threshold value.

### Smoothing of entrance temperature below mass flow rate threshold

#### Mass Balance

Mass can enter and exit the thermal interface through ports **A** and **B**. The volume of the interface is fixed but the compressibility of the fluid means that the mass inside the interface can change with pressure and temperature. The compressibility of the gas is always taken into account, with its value being that specified in the Gas Properties (G) block dialog box. The mass balance in the interface can then be expressed as:

$$\frac{\partial M}{\partial p} \frac{dp}{dt} + \frac{\partial M}{\partial T} \frac{dT}{dt} = \dot{m}_A + \dot{m}_B,$$

where:

- $M$  is the mass of the internal fluid volume of the thermal interface.
- $p$  is the internal fluid pressure.
- $T$  is the internal fluid temperature.
- $\dot{m}_*$  are the mass flow rates in through the gas ports.

#### Energy Balance

Energy can enter and exit the thermal interface in two ways: with fluid flow through ports **A** and **B** and with heat flow through port **H**. No work is done on or by the fluid inside the interface. The rate of energy accumulation in the internal fluid volume of the interface must therefore equal the sum of the energy flow rates through all three ports:

$$\frac{\partial E}{\partial p} \frac{dp}{dt} + \frac{\partial E}{\partial T} \frac{dT}{dt} = \phi_A + \phi_B + Q_H,$$

where:

- $E$  is the total energy in the internal fluid volume of the thermal interface.
- $\phi_*$  are the energy flow rates in through the gas ports.
- $Q$  is the heat flow rate in through the thermal port.

#### Momentum Balance

The pressure drop calculation is based entirely on tabulated data that you specify. The causes of the pressure drop are ignored, except in the effects that they might have on the specified data. The overall pressure drop from one gas port to the other is calculated from the individual pressure drops from each gas port to the internal fluid volume:

$$p_A - p_B = \Delta p_A - \Delta p_B,$$

where:

- $p_*$  are the fluid pressures at the gas ports.
- $\Delta p_*$  are the pressure drops from the gas ports to the internal fluid volume:

$$\Delta p_* = p_* - p,$$

with  $p$  as the pressure in the internal fluid volume.

The tabulated data is specified at a reference pressure and temperature from which a third reference parameter, the *reference density*, is calculated. The ratio of the reference density to the actual port density serves as a correction factor in the individual pressure drop equations, each defined as:

$$\Delta p_* = \Delta p(\dot{m}_*) \frac{\rho_R}{\rho_*},$$

where:

- $\Delta p(\dot{m})$  is the tabulated pressure drop function.
- $\rho_*$  are the fluid densities at the gas ports.

The asterisk denotes the gas port (**A** or **B**) at which a parameter or variable is defined. Subscript R denotes a reference value. The density at the interface entrance is smoothed below the mass flow rate threshold by introducing a hyperbolic term  $\alpha$ :

$$\rho^{*, \text{smooth}} = \rho_* \left( \frac{1 + \alpha}{2} \right) + \rho \left( \frac{1 - \alpha}{2} \right),$$

where  $\rho_{\text{smooth}}$  is the smoothed density at the entrance port,  $\rho_*$  is the unsmoothed density at the same port, and  $\rho$  is the density in the internal fluid volume. The hyperbolic smoothing term is defined as:

$$\alpha = \tanh \left( 4 \frac{\dot{m}_{\text{avg}}}{\dot{m}_{\text{th}}} \right),$$

where  $\dot{m}_{\text{avg}}$  is the average of the mass flow rates through the gas ports and  $\dot{m}_{\text{th}}$  is the mass flow rate threshold specified in the block dialog box. This threshold determines the width of the mass flow rate region over which to smooth the fluid density. The average mass flow rate is defined as:

$$\dot{m}_{\text{avg}} = \frac{\dot{m}_A + \dot{m}_B}{2}$$

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables” and “Initial Conditions for Blocks with Finite Gas Volume”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Output

**CP** — Isobaric specific heat of gas,  $\text{kJ}/(\text{kg}\cdot\text{K})$   
physical signal

Isobaric specific heat of the gas in the internal fluid volume of the thermal interface.

**M** — Mass flow rate of the thermal liquid,  $\text{kg}/\text{s}$   
physical signal

Mass flow rate of the gas in the internal fluid volume of the interface. The output signal is positive when the flow rate is directed from port **A** to port **B** and negative otherwise.

### Conserving

**A** — Fluid opening  
gas

Opening through which gas can enter and exit the thermal interface.

**B** — Fluid opening  
gas

Opening through which gas can enter and exit the thermal interface.

**H** — Thermal condition at the fluid entrance  
thermal

Thermal port used to set the thermal condition at the gas port serving as the gas entrance.

## Parameters

### Pressure Loss

**Mass flow rate vector** — Mass flow rates at which to specify pressure-drop data  
[.3, .5, 1, 1.5, 2, 2.5]  $\text{kg}/\text{s}$  (default) | *K*-element array with units of mass/time

Array of mass flow rates at which to specify the pressure drop tabulated data.

**Pressure drop vector** — Pressure-drop data corresponding to specified mass flow rates  
[3, 5, 10, 25, 35, 50] \*  $1\text{e-}3$  MPa (default) | *K*-element array with units of pressure

Array of pressure drops from inlet to outlet corresponding to the tabulated mass flow rate data.

**Reference inflow temperature** — Temperature at which pressure-drop data is specified  
293.15 K (default) | scalar with units of temperature

Temperature at which the tabulated pressure-drop data is specified.

**Reference inflow pressure** — Pressure at which pressure-drop tabulated data is specified  
0.101325 MPa (default) | scalar with units of pressure

Pressure at which the tabulated pressure-drop data is specified. The block uses this parameter to calculate a third reference parameter, the reference density. The reference that it uses to scale the

tabulated pressure drop data for pressures and temperatures deviating from the reference conditions.

**Mass flow rate threshold for flow reversal** — Mass flow rate below which to smooth numerical data

1e-6 kg/s (default) | scalar with units of mass/time

Mass flow rate below which to initiate a smooth flow reversal to prevent discontinuities in the simulation data.

**Gas volume** — Volume of gas inside the heat exchanger

0.01 m<sup>3</sup> (default) | scalar with units of volume

Volume of gas occupying the heat exchanger at any given time. The initial conditions specified in the **Effects and Initial Conditions** tab apply to this volume. The volume is constant during simulation.

**Cross-sectional area at ports A1 and B1** — Flow area at the gas inlets

0.01 m<sup>2</sup> (default) | scalar with units of area

Flow area at the gas inlets. Inlets **A1** and **B1** are assumed to be identical in size.

## Version History

# Simple Heat Exchanger Interface (TL)

Thermal interface between a thermal liquid and its surroundings

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers / Fundamental Components

## Description

The Simple Heat Exchanger Interface (TL) block models the pressure drop and temperature change in a thermal liquid as it traverses the length of a thermal interface such as that provided by a heat exchanger. Heat transfer across the thermal interface is ignored. See the composite block diagram of the Heat Exchanger (TL-TL) block for an example showing how to combine the two blocks.

The pressure drop is calculated as a function of mass flow rate from tabulated data specified at some reference pressure and temperature. The calculation is based on linear interpolation if the mass flow rate is within the bounds of the tabulated data and on nearest-neighbor extrapolation otherwise. In other words, neighboring data points connect through straight-line segments, with those at the mass flow rate bounds extending horizontally outward.

## Linear interpolation (left) and nearest-neighbor extrapolation (right)

The block calculations rely on the states and properties of the fluid—temperature, density, and specific internal energy—at the entrance to the thermal interface. The entrance changes abruptly from one port to the other during flow reversal, introducing discontinuities in the values of these variables. To eliminate these discontinuities, the block smooths the affected variables at mass flow rates below a specified threshold value.

### Smoothing of entrance temperature below mass flow rate threshold

#### Mass Balance

Mass can enter and exit the thermal interface through ports **A** and **B**. The volume of the interface is fixed but the compressibility of the fluid means that the mass inside the interface can change with pressure and temperature. Whether compressibility is factored into the block calculations depends on the setting of the **Thermal Liquid dynamic compressibility** parameter in the **Effects and Initial Conditions** tab:

$$\dot{m}_A + \dot{m}_B = \begin{cases} \left( \frac{dp}{dt} \frac{1}{\beta} - \frac{dT}{dt} \alpha \right) \rho V, & \text{if } ThermalLiquiddynamiccompressibility \text{ is On} \\ 0, & \text{otherwise} \end{cases}$$

where:

- $\dot{m}_*$  are the mass flow rates in through the thermal liquid ports.
- $p$  is the internal fluid pressure.
- $T$  is the internal fluid temperature.
- $\alpha$  is the isobaric thermal expansion coefficient.
- $\beta$  is the isothermal bulk modulus.
- $\rho$  is the internal fluid density.
- $V$  is the internal fluid volume.

If the **Thermal Liquid dynamic compressibility** parameter is set to **Off**, the fluid is treated as incompressible and the mass flow rate in through one thermal liquid port must exactly equal that out through the other thermal liquid port. The rate of mass accumulation is, in this case, zero.

#### Energy Balance

Energy can enter and exit the thermal interface in two ways: with fluid flow through ports **A** and **B** and with heat flow through port **H**. No work is done on or by the fluid inside the interface. The rate of energy accumulation in the internal fluid volume of the interface must therefore equal the sum of the energy flow rates through all three ports:

$$\frac{\partial E}{\partial p} \frac{dp}{dt} + \frac{\partial E}{\partial T} \frac{dT}{dt} = \phi_A + \phi_B + Q_H$$

where:

- $E$  is the total energy in the internal fluid volume of the thermal interface.

- $\phi_*$  are the energy flow rates in through the thermal liquid ports.
- $Q$  is the heat flow rate in through the thermal port.

### Momentum Balance

The pressure drop calculation is based entirely on tabulated data that you specify. The causes of the pressure drop are ignored, except in the effects that they might have on the specified data. The overall pressure drop from one thermal liquid port to the other is calculated from the individual pressure drops from each thermal liquid port to the internal fluid volume:

$$p_A - p_B = \Delta p_A - \Delta p_B,$$

where:

- $p_*$  are the fluid pressures at the thermal liquid ports.
- $\Delta p_*$  are the pressure drops from the thermal liquid ports to the internal fluid volume:

$$\Delta p_* = p_* - p,$$

with  $p$  as the pressure in the internal fluid volume.

The tabulated data is specified at a reference pressure and temperature from which a third reference parameter, the *reference density*, is calculated. The ratio of the reference density to the actual port density serves as a correction factor in the individual pressure drop equations, each defined as:

$$\Delta p_* = \Delta p(\dot{m}_*) \frac{\rho_R}{\rho_*},$$

where:

- $\Delta p(\dot{m})$  is the tabulated pressure drop function.
- $\rho_*$  are the fluid densities at the thermal liquid ports.

The asterisk denotes the thermal liquid port (**A** or **B**) at which a parameter or variable is defined. Subscript R denotes a reference value. The density at the interface entrance is smoothed below the mass flow rate threshold by introducing a hyperbolic term  $\alpha$ :

$$\rho_{*, \text{smooth}} = \rho_* \left( \frac{1 + \alpha}{2} \right) + \rho \left( \frac{1 - \alpha}{2} \right),$$

where  $\rho_{\text{smooth}}$  is the smoothed density at the entrance port,  $\rho_*$  is the unsmoothed density at the same port, and  $\rho$  is the density in the internal fluid volume. The hyperbolic smoothing term is defined as:

$$\alpha = \tanh \left( 4 \frac{\dot{m}_{\text{avg}}}{\dot{m}_{\text{th}}} \right),$$

where  $\dot{m}_{\text{avg}}$  is the average of the mass flow rates through the thermal liquid ports and  $\dot{m}_{\text{th}}$  is the mass flow rate threshold specified in the block dialog box. This threshold determines the width of the mass flow rate region over which to smooth the fluid density. The average mass flow rate is defined as:

$$\dot{m}_{\text{avg}} = \frac{\dot{m}_A + \dot{m}_B}{2}$$

## Ports

### Output

**CP** — Isobaric specific heat of the thermal liquid, kJ/(kg\*K)  
physical signal

Isobaric specific heat of the thermal liquid in the internal fluid volume of the thermal interface.

**M** — Mass flow rate of the thermal liquid, kg/s  
physical signal

Mass flow rate of the thermal liquid in the interior of the thermal interface. The output signal is positive when the flow rate is directed from port **A** to port **B** and negative otherwise.

### Conserving

**A** — Fluid opening  
thermal liquid

Opening through which thermal liquid can enter and exit the thermal interface.

**B** — Fluid opening  
thermal liquid

Opening through which thermal liquid can enter and exit the thermal interface.

**H** — Thermal condition at the fluid entrance  
thermal

Thermal port used to set the thermal condition at the thermal liquid port serving as the thermal liquid entrance.

## Parameters

### Pressure Loss Tab

**Mass flow rate vector** — Mass flow rates at which to specify pressure-drop data  
[.3, .5, 1, 1.5, 2, 2.5] kg/s (default) | *K*-element array with units of mass/time

Array of mass flow rates at which to specify the pressure drop tabulated data.

**Pressure drop vector** — Pressure-drop data corresponding to specified mass flow rates  
[3, 5, 10, 25, 35, 50] \* 1e-3 MPa (default) | *K*-element array with units of pressure

Array of pressure drops from inlet to outlet corresponding to the tabulated mass flow rate data.

**Reference inflow temperature** — Temperature at which pressure-drop data is specified  
293.15 K (default) | scalar with units of temperature

Temperature at which the tabulated pressure-drop data is specified.

**Reference inflow pressure** — Pressure at which pressure-drop tabulated data is specified  
0.101325 MPa (default) | scalar with units of pressure

Pressure at which the tabulated pressure-drop data is specified. The block uses this parameter to calculate a third reference parameter, the reference density. The reference that it uses to scale the tabulated pressure drop data for pressures and temperatures deviating from the reference conditions.

**Mass flow rate threshold for flow reversal** — Mass flow rate below which to smooth numerical data

1e-6 kg/s (default) | scalar with units of mass/time

Mass flow rate below which to initiate a smooth flow reversal to prevent discontinuities in the simulation data.

**Thermal Liquid volume** — Volume of thermal liquid inside the heat exchanger

0.01 m<sup>3</sup> (default) | scalar with units of volume

Volume of thermal liquid occupying the heat exchanger at any given time. The initial conditions specified in the **Effects and Initial Conditions** tab apply to this volume. The volume is constant during simulation.

**Cross-sectional area at ports A1 and B1** — Flow area at the thermal liquid inlets

0.01 m<sup>2</sup> (default) | scalar with units of area

Flow area at the thermal liquid inlets. Inlets **A1** and **B1** are assumed to be identical in size.

### Effects and Initial Conditions

**Thermal Liquid dynamic compressibility** — Option to model pressure dynamics inside the heat exchanger

On (default) | Off

Option to model the pressure dynamics inside the heat exchanger. Setting this parameter to **Off** removes the pressure derivative terms from the component energy and mass conservation equations. The pressure inside the heat exchanger is then reduced to the weighted average of the two port pressures.

**Thermal Liquid initial temperature** — Temperature inside the heat exchanger at the start of simulation

293.15 K (default) | scalar with units of temperature

Temperature of the internal volume of thermal liquid at the start of simulation.

**Thermal Liquid initial pressure** — Pressure inside the heat exchanger at the start of simulation

0.101325 MPa (default) | scalar with units of pressure

Pressure of the internal volume of thermal liquid at the start of simulation.

# Single-Acting Actuator (TL)

Single-acting linear actuator in a thermal liquid system

## Libraries:

Simscape / Fluids / Thermal Liquid / Actuators

## Description

The Single-Acting Actuator (TL) block represents a linear actuator with piston motion controlled by a single thermal liquid chamber. The actuator generates force in the extension and retraction strokes, but the actuation force depends on the gauge pressure at a single chamber.

The figure shows the key components of an actuator. Port **A** represents the thermal liquid chamber inlet. Port **R** represents the translating actuator piston, and port **C** represents the actuator case. Port **H** represents the thermal interface between the thermal liquid chamber and the environment.

## Single-Acting Actuator Schematic

### Displacement

The block measures the piston displacement as the position at port **R** relative to port **C**. The **Mechanical orientation** parameter identifies the direction of piston displacement. The piston displacement is neutral, or  $\theta$ , when the chamber volume is equal to the value of the **Dead volume** parameter. When you input the piston displacement using port **p**, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when you use a Translational Multibody Interface block connection to a Simscape Multibody joint.

The direction of the piston motion depends on the **Mechanical orientation** parameter. If the mechanical orientation is positive, then a positive gauge pressure at port **A** yields a positive piston translation relative to the actuator case. The direction of motion reverses for a negative mechanical orientation.

### Hard Stop

A set of hard stops limit the piston range of motion. The block uses an implementation of the Translational Hard Stop block, which treats hard stops like spring-damper systems. The spring stiffness coefficient controls the restorative component of the hard-stop contact force and the damping coefficient the dissipative component.

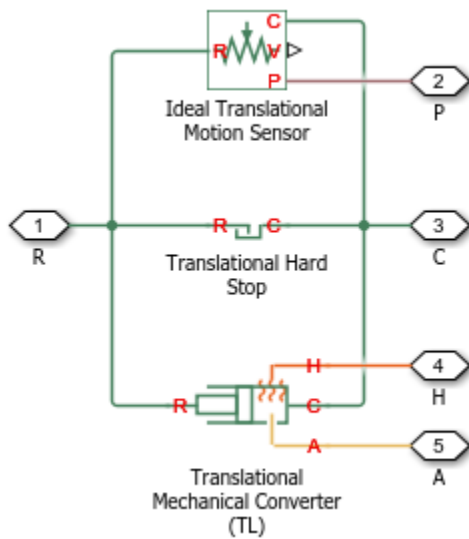

The hard stops are located at the distal ends of the piston stroke. If the mechanical orientation is positive, then the lower hard stop is at  $x = 0$ , and the upper hard stop is at  $x = +stroke$ . If the

mechanical orientation is negative, then the lower hard stop is at  $x = -stroke$ , and the upper hard stop is at  $x = 0$ .

### Block Composite

This block is a composite component based on the Simscape Foundation blocks:

- Translational Mechanical Converter (TL)
- Translational Hard Stop
- Ideal Translational Motion Sensor

### Composite Component Diagram

### Ports

#### Input

**p** — Multibody piston position input, m  
physical signal

Physical signal input associated with the piston position, in m. Connect this port to a Simscape Multibody network using a Translational Multibody Interface block.

#### Dependencies

To enable this port, set **Piston displacement** to Provide input signal from Multibody joint.

#### Output

**p** — Piston position, m  
physical signal

Physical signal output associated with the piston position, in m.

**Dependencies**

To enable this port, set **Piston displacement** to Calculate from velocity of port R relative to port C.

**Conserving**

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with chamber A.

**C** — Actuator casing  
translational mechanical

Translational mechanical conserving port associated with the actuator casing.

**R** — Actuator piston  
translational mechanical

Translational mechanical conserving port associated with the actuator piston.

**H** — Heat transfer  
thermal liquid

Thermal liquid conserving port associated with the thermal mass of the liquid volume.

**Parameters****Actuator**

**Mechanical orientation** — Piston displacement direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Sets the piston displacement direction. When you set this parameter to:

- Pressure at A causes positive displacement of R relative to C, the piston displacement is positive when the volume of liquid at port **A** is expanding. This corresponds to rod extension.
- Pressure at A causes negative displacement of R relative to C, the piston displacement is negative when the volume of liquid at port **A** is expanding. This corresponds to rod contraction.

**Piston cross-sectional area** — Cross-sectional area of piston rod  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the piston rod.

**Piston stroke** — Maximum piston travel distance  
0.1 m (default) | positive scalar

Maximum piston travel distance.

**Dead volume** — Fluid volume at full piston retraction

1e-5 m<sup>3</sup> (default) | positive scalar

Volume of liquid when the piston displacement is 0. This is the liquid volume when the piston is up against the actuator end cap.

**Environment pressure specification** — Reference environment pressure

Atmospheric pressure (default) | Specified pressure

Environment reference pressure. When you select Atmospheric pressure, the block assumes a pressure of 0.101325 MPa.

**Environment pressure** — User-defined environmental pressure

0.101325 MPa (default) | positive scalar

User-defined environmental pressure.

#### **Dependencies**

To enable this parameter, set **Environment pressure specification** to Specified pressure.

#### **Hard Stop**

**Hard stop model** — Select the hard stop model

Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient

1e10 N/m (default) | positive scalar

Piston stiffness coefficient.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient

150 N\*s/m (default) | positive scalar

Piston damping coefficient.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound

- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model

0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

#### Dependencies

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision

0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

#### Dependencies

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision

0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

#### Dependencies

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

#### Dependencies

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

#### Initial Conditions

**Piston displacement** — Method for determining piston position

Calculate from velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the piston position. The block can receive the position from a Multibody block when set to Provide input signal from Multibody joint, or calculates the position internally and reports the position at port **p**. The position is between 0 and the **Piston stroke** when

the mechanical orientation is positive and  $\theta$  and **-Piston stroke** when the mechanical orientation is negative.

**Initial piston displacement** — Piston position at start of simulation

$\theta$  m (default) | scalar

Piston position at the start of the simulation.

#### Dependencies

To enable this parameter, set **Piston displacement** to Calculate from velocity of port R relative to port C.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid temperature** — Starting liquid temperature

293.15 K (default)

Initial temperature of the liquid volume in the actuator.

**Initial liquid pressure** — Starting liquid pressure for compressible fluids

$0.101325$  MPa (default) | positive scalar

Starting liquid pressure for compressible fluids.

#### Dependencies

To enable this parameter, select **Fluid dynamic compressibility**.

## Version History

Introduced in R2016a

### R2023a: New hard stop parameterization option

The block has a new option for the **Hard stop model** parameter. This option, called **Based on coefficient of restitution**, models the hard stop by using a mode chart.

## Library

Hydraulic Cylinders

### Description

The Single-Acting Hydraulic Cylinder block models a device that converts hydraulic energy into mechanical energy in the form of translational motion. Hydraulic fluid pumped under pressure into the cylinder chamber forces the piston to move and exert force on the cylinder rod. Single-acting cylinders transfer force and motion in one direction only. Use an external device, such as a spring, weight, or another opposite installed cylinder, to move the rod in the opposite direction.

Ports **R** and **C** are mechanical translational conserving ports corresponding to the cylinder rod and cylinder clamping structure, respectively. Port **A** is a hydraulic conserving port associated with the cylinder inlet.

The energy through port **A** is directed to the Translational Hydro-Mechanical Converter block. The converter transforms hydraulic energy into mechanical energy and accounts for the fluid compressibility in the cylinder chamber. The rod motion is limited with the mechanical Translational Hard Stop block in such a way that the rod can travel only between cylinder caps. The piston position is conveyed to the physical signal port **p**.

### Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Cylinder orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\theta$ , when the chamber volume is equal to the chamber dead volume. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Translational Multibody Interface block connection to a Simscape Multibody joint.

When displacement is set by the cylinder, it is calculated as:

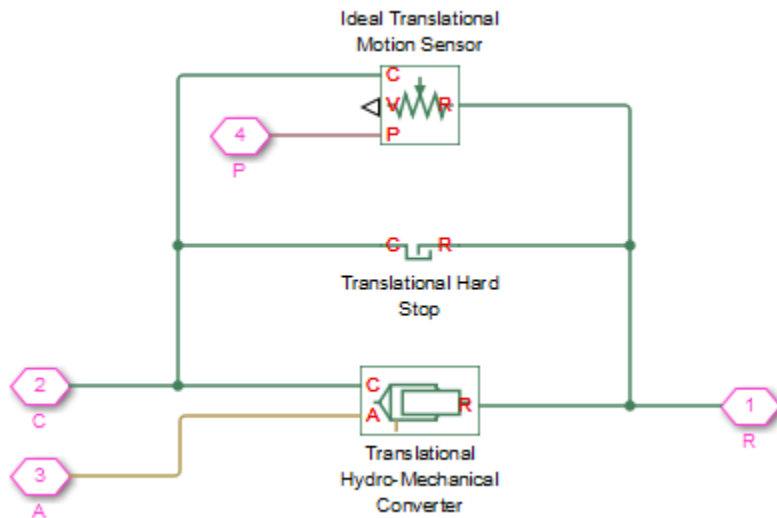

$$x_{\text{pst}} = x_0 + x_p \quad (1-11)$$

where

$x_{pst}$	Rod displacement output by the physical signal port
$x_0$	Initial distance between piston and cap
$x_p$	Rod displacement with respect to its initial position

### Composite Structure

The model of the cylinder is built of Simscape Foundation library blocks. The schematic diagram of the model is shown below.

### Basic Assumptions and Limitations

- No leakage, internal or external, is taken into account.
- No loading on piston rod, such as inertia, friction, spring, and so on, is taken into account. If necessary, you can easily add them by connecting an appropriate building block to cylinder port R.

### Parameters

#### Piston area

Effective piston area. The default value is  $0.001 \text{ m}^2$ .

#### Piston stroke

Piston maximum travel between caps. The default value is  $0.1 \text{ m}$ .

#### Piston displacement

Method for determining the piston position. The default value is `Calculate` from `velocity` of port R relative to port C, which calculates the position internally and reports the position at port **p**. The block can also receive the position at port **p** from a Multibody block when set to `Provide input signal from Multibody joint`.

#### Initial distance between piston and cap

The distance between the piston and cap at the beginning of simulation. This value cannot exceed the piston stroke. The default value is  $0$ , which corresponds to the fully retracted position. To

enable this parameter, set **Piston displacement** to Calculate from velocity of port R relative to port C.

**Dead volume**

Fluid volume that remains in the chamber after the rod is fully retracted. The default value is  $1e-4 \text{ m}^3$ .

**Chamber initial pressure**

Pressure in the cylinder chamber at the beginning of simulation. The default value is 0.

**Specific heat ratio**

Gas-specific heat ratio for the Hydraulic Piston Chamber block. The default value is 1.4.

**Contact stiffness**

Specifies the elastic property of colliding bodies for the Translational Hard Stop block. The greater the value of the parameter, the less the bodies penetrate into each other, the more rigid the impact becomes. Lesser value of the parameter makes contact softer, but generally improves convergence and computational efficiency. The default value is  $1e6 \text{ N/m}$ .

**Contact damping**

Specifies dissipating property of colliding bodies for the Translational Hard Stop block. At zero damping, the impact is close to an absolutely elastic one. The greater the value of the parameter, the more energy dissipates during an interaction. Keep in mind that damping affects slider motion as long as the slider is in contact with the stop, including the period when slider is pulled back from the contact. For computational efficiency and convergence reasons, MathWorks recommends that you assign a nonzero value to this parameter. The default value is  $150 \text{ N*s/m}$ .

**Hard stop model**

Modeling approach for hard stops. Options include:

- **Stiffness and damping applied smoothly through transition region (default)** — Scale the magnitude of the contact force from zero to its full value over a specified transition length. The scaling is polynomial in nature. The polynomial scaling function is numerically smooth and it produces no zero crossings of any kind.
- **Full stiffness and damping applied at bounds, undamped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during penetration and a spring force—without a damping component—during rebound. No smoothing is applied.
- **Full stiffness and damping applied at bounds, damped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during both penetration and rebound. No smoothing is applied. This is the hard-stop model used in previous releases.

**Transition region**

Distance below which scaling is applied to the hard-stop force. The contact force is zero when the distance to the hard stop is equal to the value specified here. It is at its full value when the distance to the hard stop is zero. The default value is 1 mm.

**Cylinder orientation**

Specifies cylinder orientation with respect to the globally assigned positive direction. The cylinder can be installed in two different ways, depending upon whether it exerts force in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port A exerts force in negative direction, set the parameter to **Pressure at A causes negative displacement of R relative to C**. The default value is **Pressure at A causes positive displacement of R relative to C**.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Cylinder orientation**

All other block parameters are available for modification.

## Global Parameters

Parameter determined by the type of working fluid:

- **Fluid bulk modulus**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the cylinder inlet.

R

Mechanical translational conserving port associated with the cylinder rod.

C

Mechanical translational conserving port associated with the cylinder clamping structure.

p

Physical signal input port that receives rod extension from a Multibody block. To expose this port, set **Piston displacement** to Provide input signal from Multibody joint.

p

Physical signal output port that returns the rod position with respect to port C. To expose this port, set **Piston displacement** to Calculate from velocity of port R relative to port C.

## Version History

# Single-Acting Actuator (IL)

Single-acting linear actuator in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Actuators

## Description

The Single-Acting Actuator (IL) block represents an actuator that converts the liquid pressure at port **A** into a mechanical force at port **R** via an extending-retracting piston. The piston motion is limited by a hard stop model. When the piston position is calculated internally, it is reported at port **p**, and when the position is set by a connection to a Simscape Multibody joint, it is received as a physical signal at port **p**.

The **Initial piston displacement**, **Fluid dynamic compressibility**, and reference environmental pressure can be modified. Fluid and mechanical inertia are not modeled.

## Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Mechanical orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\Theta$ , when the chamber volume is equal to the **Dead volume**. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Translational Multibody Interface block connection to a Simscape Multibody joint.

## Hard Stop Model

Four models are available to model the extension limit of the actuator piston. This block uses a similar formulation as the Translational Hard Stop block and models uniform damping and stiffness coefficients at both ends of the piston stroke. For more information on the hard stop model options, see the Translational Hard Stop block.

The hard stop force is modeled when the piston is at its upper or lower bound. The boundary region is within the **Transition region** of the **Piston stroke** or **Piston initial displacement**. Outside of this region,  $F_{HardStop} = 0$ .

## Cushion

You can optionally model cushioning toward the extremes of the piston stroke. Selecting **Cylinder end cushioning** slows the piston motion as it approaches its maximum extension, which is defined in **Piston stroke**. For more information on the functionality of a cylinder cushion, see the Cylinder Cushion (IL) block.

## Friction

You can optionally model friction against piston motion. When you select **Cylinder friction**, the resulting friction is a combination of Stribeck, Coulomb, and viscous effects. The pressure difference is measured between the chamber pressure and the environment pressure. For more information on the friction model and its limitations, see the Cylinder Friction block.

## Leakage

You can optionally model leakage between the liquid chamber and the piston reservoir. When you select **Leakage**, Poiseuille flow is modeled between the piston and cylinder. This block uses the Simscape Foundation Library Laminar Leakage (IL) block. The flow rate is calculated as:

$$\dot{m} = \frac{\frac{\pi}{128} \left( d_0^4 - d_i^4 - \frac{(d_0^2 - d_i^2)^2}{\log(d_0/d_i)} \right)}{\nu L} (p_A - p_{env}),$$

where:

- $\nu$  is the fluid kinematic viscosity.
- $L$  is the piston length,  $\mathbf{p} - P_0$ .
- $p_A$  is the pressure at port **A**.
- $p_{env}$  is the environmental pressure, which is selected in the **Environment pressure specification** parameter.

The cylinder diameter,  $d_0$ , is  $d_0 = d_i + 2c$ , where  $c$  is the **Piston-cylinder clearance**, and the piston diameter,  $d_i$ , is  $d_i = \sqrt{\frac{4A_p}{\pi}}$ , where  $A_p$  is the **Piston cross-sectional area**.

## Numerically-Smoothed Area and Pressure

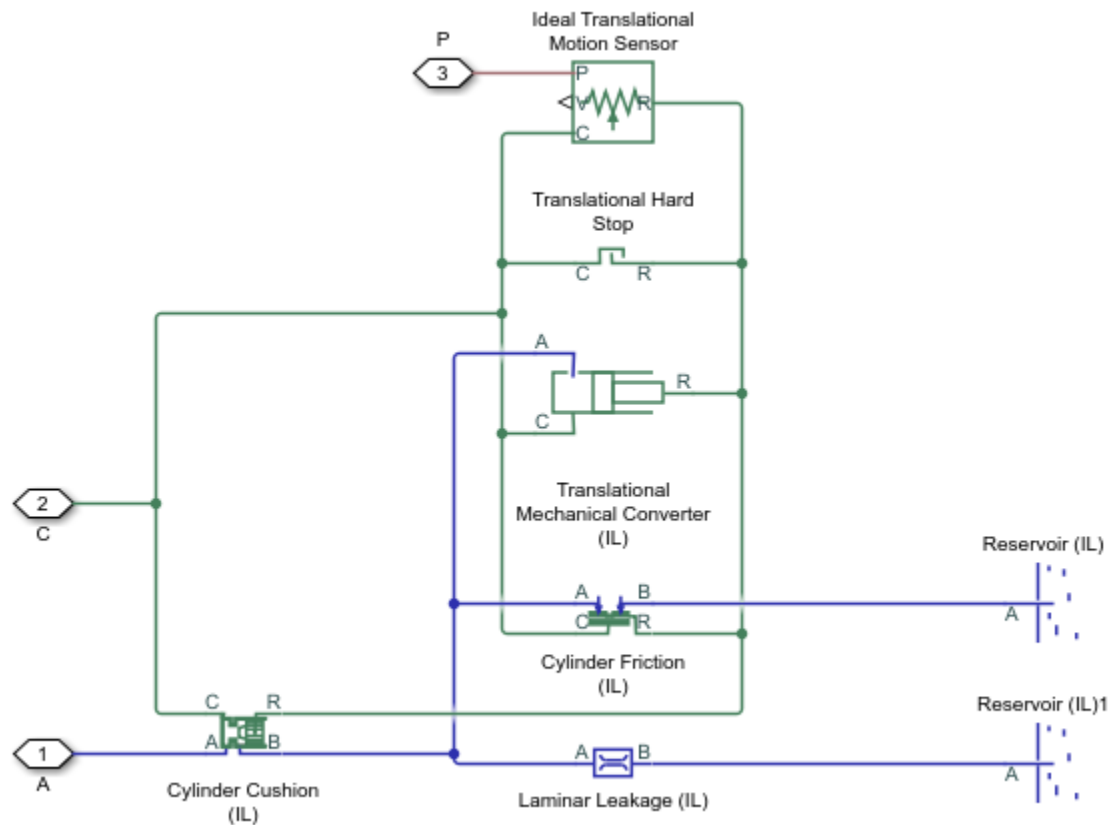

You can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smooths the cushion orifice area and the check valve pressure range. The orifice area is smoothly saturated between the **Leakage area between plunger and cushion sleeve** and **Cushion plunger cross-sectional area** parameters while the valve pressure is saturated between the **Check valve cracking pressure differential** and **Check valve maximum pressure differential** parameters. For more information, see “Numerical Smoothing”.

## Block Sub-Components

The Single-Acting Actuator (IL) block comprises four Simscape Foundation and two Fluids Library blocks:

- Translational Hard Stop
- Laminar Leakage (IL)
- Translational Mechanical Converter (IL)
- Ideal Translational Motion Sensor
- Cylinder Cushion (IL)
- Cylinder Friction (IL)

## Actuator Structural Diagram

## Ports

### Input

**p** — Multibody piston position input, m  
physical signal

Physical signal input port associated with the piston position, in m. Connect this port to a Simscape Multibody block.

### Dependencies

To enable this port, set **Piston displacement** to Provide input signal from Multibody joint.

### Output

**p** — Piston position, m  
physical signal

Piston position in m, returned as a physical signal.

### Dependencies

To expose this port, set **Piston displacement** to Calculate from velocity of port R relative to port C.

### Conserving

**A** — Liquid port  
isothermal liquid

Thermal liquid conserving port associated with chamber A.

**C** — Actuator casing  
translational mechanical

Translational mechanical conserving port associated with the actuator casing.

**R** — Actuator piston  
translational mechanical

Translational mechanical conserving port associated with the actuator piston.

### Parameters

#### Actuator

**Mechanical orientation** — Piston displacement direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Sets the piston displacement direction. When you set this parameter to:

- Pressure at A causes positive displacement of R relative to C the piston displacement is positive when the volume of liquid at port A is expanding. This corresponds to rod extension.
- Pressure at A causes negative displacement of R relative to C the piston displacement is negative when the volume of liquid at port A is expanding. This corresponds to rod contraction.

**Piston cross-sectional area** — Cross-sectional area of piston rod

$0.01 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the piston rod.

**Piston stroke** — Maximum piston travel distance

$0.1 \text{ m}$  (default) | positive scalar

Maximum piston travel distance.

**Dead volume** — Fluid volume at full piston retraction

$1 \text{e-}5 \text{ m}^3$  (default) | positive scalar

Volume of liquid when the piston displacement is 0. This is the liquid volume when the piston is up against the actuator end cap.

**Environment pressure specification** — Reference environment pressure  
 Atmospheric pressure (default) | Specified pressure

Environment reference pressure. The Atmospheric pressure option sets the environmental pressure to 0.101325 MPa.

**Environment pressure** — User-defined environmental pressure  
 0.101325 MPa (default) | positive scalar

User-defined environmental pressure.

#### Dependencies

To enable this parameter, set **Environment pressure specification** to Specified pressure.

#### Hard Stop

**Hard stop model** — Select the hard stop model  
 Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
 1e10 N/m (default) | positive scalar

Piston stiffness coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient  
 150 N\*s/m (default) | positive scalar

Piston damping coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model  
 0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

**Dependencies**

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision

0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision

0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Cushion**

**Cylinder end cushioning** — Whether to model piston slow-down at maximum extension

off (default) | on

Whether to model piston slow-down at maximum extension. See the Cylinder Cushion (IL) block for more information.

**Cushion plunger cross-sectional area** — Cylinder cushion plunger area

1e-4 m<sup>2</sup> (default) | positive scalar

Area of the plunger inside the actuator cushion element.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Cushion plunger length** — Length of cushion plunger

1e-3 m (default) | positive scalar

Length of the cushion plunger.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Cushion orifice area** — Area of orifice between cushion chambers

1e-6 m<sup>2</sup> (default) | positive scalar

Area of the orifice between cushion chambers.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Leakage area between plunger and cushion sleeve** — Gap between cushion plunger and sleeve

1e-7 m<sup>2</sup> (default) | positive scalar

Gap area between the cushion plunger and sleeve. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Check valve cracking pressure differential** — Cushion threshold pressure

0.01 MPa (default) | positive scalar

Pressure beyond which the valve operation is triggered. When the pressure difference between port **A** and  $P_{env}$  meets or exceeds the **Check valve cracking pressure differential**, the cushion valve begins to open.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Check valve maximum pressure differential** — Cushion differential pressure maximum

0.1 MPa (default) | positive scalar

Maximum cushion valve differential pressure. This parameter provides an upper limit to the pressure so that system pressures remain realistic.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Check valve maximum area** — Area of fully opened cushion valve

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the cushion valve in its fully open position.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Check valve leakage area** — Cushion valve gap area when in fully closed position  
1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the cushion check valve is in a fully closed position. Any area smaller than this value is saturated to the specified leakage area. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the variable orifice and check valve are in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, select **Cylinder end cushioning**.

**Friction**

**Cylinder friction** — Whether to model friction against piston motion  
off (default) | on

Whether to model friction against piston motion. The model accounts for Coulomb, Stribeck, and viscous friction. See the Cylinder Friction block for more information.

**Breakaway to Coulomb friction force ratio** — Ratio of breakaway force to Coulomb friction force  
1.2 (default) | positive scalar

Ratio of the breakaway force to the Coulomb friction force.

**Dependencies**

To enable this parameter, select **Cylinder friction**.

**Breakaway friction velocity** — Threshold for motion  
0.1 m/s (default) | positive scalar

Threshold velocity for motion against friction force to begin.

**Dependencies**

To enable this parameter, select **Cylinder friction**.

**Preload force** — Initial force in cylinder due to seal assembly  
20 N (default) | scalar

Initial force in the cylinder due to seal assembly.

**Dependencies**

To enable this parameter, select **Cylinder friction**.

**Coulomb friction force coefficient** — Coulomb friction force coefficient  
1e-6 N/Pa (default) | positive scalar

Coulomb force coefficient of friction.

**Dependencies**

To enable this parameter, select **Cylinder friction**.

**Viscous friction coefficient** — Viscous friction coefficient  
100 N/(m/s) (default) | positive scalar

Viscous friction coefficient.

**Dependencies**

To enable this parameter, select **Cylinder friction**.

**Leakage**

**Leakage** — Whether to model annular leakage  
off (default) | on

Whether to model annular leakage between the fluid chamber and the piston reservoir at reference environment conditions. The leakage is considered laminar. See the Laminar Leakage (IL) block for more information.

**Piston-cylinder clearance** — Radial clearance  
1e-4 m (default) | positive scalar

Radial distance between the piston rod and cylinder casing.

**Dependencies**

To enable this parameter, select **Leakage**.

**Piston head length** — Annular length of piston mounting  
0.01 m (default) | positive scalar

Annular length of the piston mounting, not including the piston rod.

**Dependencies**

To enable this parameter, select **Leakage**.

**Initial conditions**

**Piston displacement** — Method for determining piston position  
Calculate from velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the piston position. The block can receive the position from a Multibody block when set to Provide input signal from Multibody joint, or calculates the position internally and reports the position at port **p**. The position is between 0 and the **Piston stroke** when the mechanical orientation is positive and 0 and **-Piston stroke** when the mechanical orientation is negative.

**Initial piston displacement** — Piston position at start of simulation

0 m (default) | scalar

Piston position at the start of the simulation.

#### **Dependencies**

To enable this parameter, set **Piston displacement** to Calculate from velocity of port R relative to port C.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid dynamic compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid pressure** — Starting liquid pressure for compressible fluids

0.101325 MPa (default) | positive scalar

Starting liquid pressure for compressible fluids.

#### **Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

## **Version History**

---

## Library

Hydraulic Cylinders

## Description

The Single-Acting Hydraulic Cylinder (Simple) block represents a simplified version of a hydraulic cylinder, developed for applications where only the basic cylinder functionality must be reproduced, in exchange for better numerical efficiency. For these reasons, such factors as fluid compressibility, friction, and leakages are assumed to be negligible. The hard stops are assumed to be fully inelastic, to eliminate any possible oscillations at the end of the stroke. The model is especially suitable for real-time and HIL (hardware-in-the-loop) simulation, if such simplifications are acceptable.

The model is described with the following equations:

$$F = A \cdot p - F_c$$

$$q = A \cdot v$$

$$\frac{dx}{dt} = v$$

$$v = v_R - v_C$$

$$F_c = \begin{cases} (x - x_E) \cdot K_p \cdot v & \text{if } x > x_E, v > 0 \\ (x - x_R) \cdot K_p \cdot v & \text{if } x < x_R, v < 0 \\ 0 & \text{otherwise} \end{cases}$$

$$x_E = S - x_0$$

$$x_R = -x_0$$

where

$F$	Force developed by the cylinder
$v$	Cylinder rod velocity
$v_R, v_C$	Absolute velocities of cylinder rod and cylinder case, respectively
$A$	Piston area
$p$	Pressure at the cylinder inlet
$q$	Flow rate at the cylinder inlet
$x$	Piston position
$x_0$	Initial distance between piston and the cap
$F_c$	Hard stop force
$x_E$	Distance the piston can travel to fully extend from initial position
$x_R$	Distance the piston can travel to fully retract from initial position
$K_p$	Penetration coefficient
$S$	Piston stroke

The main difference between this block and the Single-Acting Hydraulic Cylinder block is the representation of the hard stop:

- The Single-Acting Hydraulic Cylinder block utilizes the elastic model of the stop, which is essentially a combination of a spring and a damper, connected in parallel. The stiffness of the spring, which represents contact stiffness of colliding bodies, is very high, resulting in high-frequency, low-magnitude oscillations at the moment the bodies collide. These oscillations can hardly be noticed experimentally, but they are difficult to process by a numerical simulation and generally decrease numerical efficiency.
- The hard stop in the Single-Acting Hydraulic Cylinder (Simple) block is represented with the inelastic model, which is essentially a viscous damper with the penetration-dependent damping coefficient. This coefficient is referred to as the penetration coefficient. With inelastic model, no oscillation is generated during an impact, resulting in improved numerical robustness and efficiency. But inelastic stop model has a feature that you must consider while selecting the model: colliding bodies continue slowly moving into each other as long as the contact is loaded with the compressing force. In real life, this phenomenon is similar to collision of two bodies separated by a sizable layer of viscous liquid. It takes some time to squeeze the liquid before bodies themselves come into contact.

Connections R and C are mechanical translational conserving ports corresponding to the cylinder rod and cylinder clamping structure, respectively. Connection A is a hydraulic conserving port associated with the cylinder inlet. The physical signal output port P shows current rod extension.

Pressure at port A generates force in the direction specified by the **Cylinder orientation** parameter.

## Basic Assumptions and Limitations

- Friction between moving parts is not taken into account.
- Inertia effects are not taken into account.
- Fluid compressibility is not taken into account.
- Leakage flows are assumed to be negligible.
- The hard stops are assumed to be fully inelastic, as explained above.

## Parameters

### Piston area

Effective piston area. The default value is  $5e-4 \text{ m}^2$ .

### Piston stroke

Piston maximum travel between caps. The default value is  $0.1 \text{ m}$ .

### Initial distance between piston and cap

The distance between the piston and cap at the beginning of simulation. This value cannot exceed the piston stroke. The default value is  $0$ , which corresponds to the fully retracted position.

### Penetration coefficient

Specifies the penetration property of colliding bodies. The higher the value of the coefficient, the less the bodies penetrate into each other, but the sharper the increase of the impact force. To find out the value of the coefficient for a particular application, it is recommended to run the same model with different hard stop models (or with different cylinder models) until they show close results. The default value of the coefficient is  $1e12 \text{ N/m/(m/s)}$ .

### Cylinder orientation

Specifies cylinder orientation with respect to the globally assigned positive direction. The cylinder can be installed in two different ways, depending upon whether it exerts force in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port A exerts force in negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

### Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Cylinder orientation**

All other block parameters are available for modification.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the cylinder inlet.

R

Mechanical translational conserving port associated with the cylinder rod.

C

Mechanical translational conserving port associated with the cylinder clamping structure.

P

Physical signal output port that outputs rod extension.

# Single-Acting Rotary Actuator (IL)

Double-acting rotary actuator in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Actuators

## Description

The Single-Acting Rotary Actuator (IL) block models a rotary actuator that converts liquid pressure into mechanical torque in an isothermal liquid network. The motion of the piston when it is near full extension or full retraction is limited by one of four hard stop models.

Port **A** is the isothermal liquid conserving port associated with inlet of the liquid chamber. Ports **R** and **C** are the mechanical rotational conserving ports associated with the rotating shaft and the actuator casing, respectively. If **Mechanical orientation** is set to **Pressure at A causes positive rotation of R relative to C**, the pressure in the liquid chamber causes a positive rotation of the shaft at port **R** relative to port **C**. When the shaft angle is calculated internally, the physical signal port **q** reports the angle. When the angle is set by a connection to a Simscape Multibody joint, it is received as a physical signal at port **q**.

## Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Mechanical orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\theta$ , when the chamber volume is equal to the **Dead volume**. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Rotational Multibody Interface block connection to a Simscape Multibody joint.

## Hard Stop Model

To avoid mechanical damage to an actuator when it is fully extended or fully retracted, an actuator typically displays nonlinear behavior when the piston approaches these limits. The Single-Acting Rotary Actuator (IL) block models this behavior with a choice of four hard stop models, which model the material compliance through a spring-damper system. The hard stop models are:

- Stiffness and damping applied smoothly through transition region, damped rebound.
- Full stiffness and damping applied at bounds, undamped rebound.
- Full stiffness and damping applied at bounds, damped rebound.
- Based on coefficient of restitution

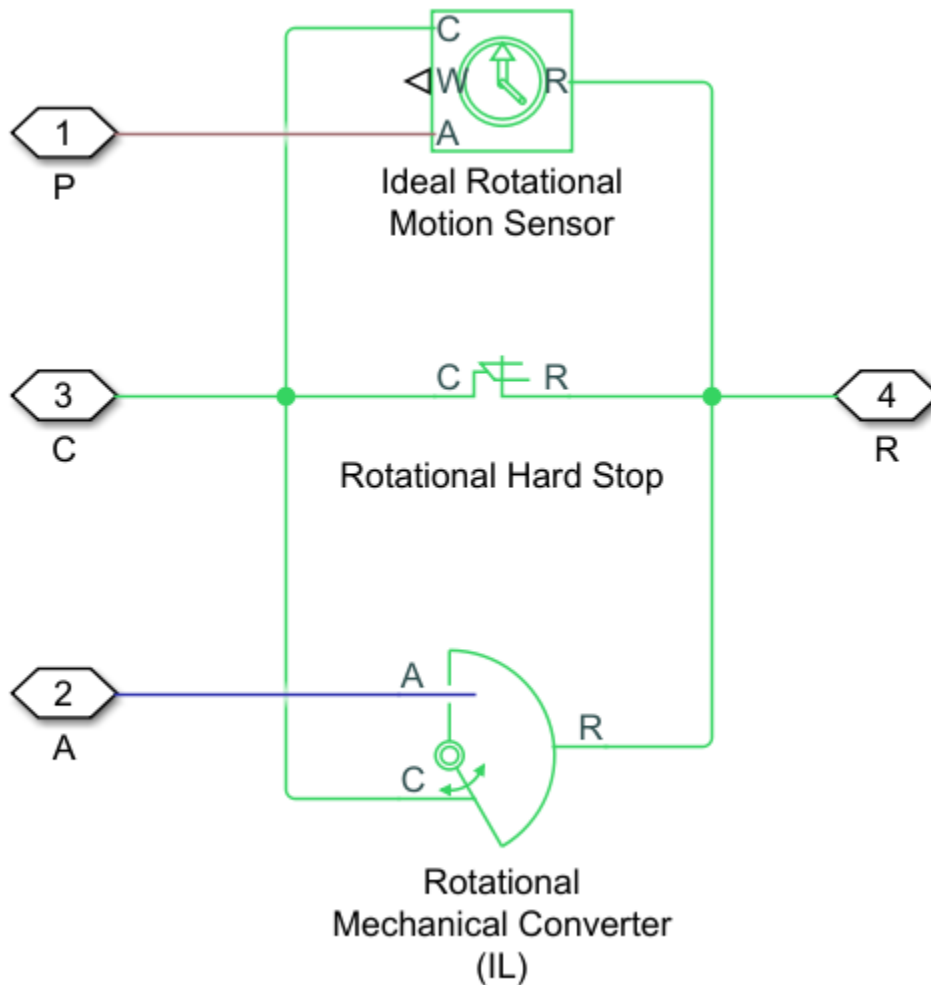

The hard stop force is modeled when the piston is at its upper or lower bound. The boundary region is within the **Transition region** of the **Stroke** or piston initial displacement. Outside of this region,  $F_{HardStop} = 0$ .

For more information about these settings, see the Rotational Hard Stop block page.

### Block Schematics

The actuator block comprises three Foundation Library blocks:

- Ideal Rotational Motion Sensor
- Rotational Hard Stop
- Rotational Mechanical Converter (IL)

### Underlying Block Components

#### Leakage

Laminar leakage is not accounted for in the Single-Acting Rotary Actuator (IL) block. To include leakage in your simulation, set the **Cross-sectional geometry** parameter to **Custom** and connect port **A** to port **A** of the Laminar Leakage (IL) block. Connect port **B** of the Laminar Leakage (IL) block to a Reservoir (IL) block.

### Adding Leakage to the Simulation

#### Ports

##### Conserving

**A** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the actuator.

**R** — Actuator  
mechanical translational

Mechanical rotational conserving port associated with the shaft angular velocity and torque.

**C** — Casing  
mechanical translational

Mechanical rotational conserving port associated with the actuator casing.

##### Input

**q** — Shaft angle  
physical signal

Shaft angle, received as a physical signal from a Simscape Multibody block.

##### Dependencies

To expose this port, set **Shaft rotation from chamber A** to Provide input signal from Multibody joint.

## Output

**q** — Shaft angle  
physical signal

Shaft angle, reported as a physical signal.

## Dependencies

To expose this port, set **Shaft rotation from chamber A** to Calculate from angular velocity of port R relative to port C.

## Parameters

### Actuator

**Mechanical orientation** — Piston displacement direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Sets the piston displacement direction. When you set this parameter to:

- Pressure at A causes positive displacement of R relative to C the piston displacement is positive when the volume of liquid at port **A** is expanding. This corresponds to rod extension.
- Pressure at A causes negative displacement of R relative to C the piston displacement is negative when the volume of liquid at port **A** is expanding. This corresponds to rod contraction.

**Volume displacement** — Volume displacement

$1e-4 \text{ m}^3/\text{rad}$  (default) | positive scalar

Effective displacement of the actuator.

**Stroke** — Angle

$5.0 \text{ rad}$  (default) | positive scalar

Shaft maximum travel between stops.

**Dead volume** — Fluid volume

$1e-5 \text{ m}^3$  (default) | positive scalar

Volume of liquid when the piston displacement is 0. This is the liquid volume when the piston is up against the actuator end cap.

**Environment pressure specification** — Pressure reference source

Atmospheric pressure (default) | Specified pressure

Choice of environment pressure. Options include Atmospheric pressure and Specified pressure.

**Environment pressure** — User-defined pressure reference

$0.101325 \text{ MPa}$  (default)

Pressure outside the actuator casing. This pressure acts against the pressures inside the actuator chambers. A value of zero corresponds to a vacuum.

#### Dependencies

To enable this parameter, set **Environment pressure specification** to Specified pressure.

#### Hard Stop

**Hard stop model** — Select the hard stop model

Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Rotational Hard Stop block for more information.

**Hard stop stiffness coefficient** — Stiffness coefficient

$1e6 \text{ N}\cdot\text{m}/\text{rad}$  (default) | positive scalar

Specifies the elastic property of colliding bodies for the Rotational Hard Stop block. The greater the value of the parameter, the more rigid the impact between the piston and the stop becomes. Lower values make contact softer and generally improve convergence and computational efficiency.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard stop damping coefficient** — Damping coefficient

$150 \text{ N}\cdot\text{m}/(\text{rad}/\text{s})$  (default) | positive scalar

Specifies the dissipating property of colliding bodies for the Rotational Hard Stop block. At zero damping, the impact is elastic. The greater the value of the parameter, the greater the energy dissipation during piston-stop interaction. Damping affects slider motion as long as the slider is in contact with the stop, including the period when slider is pulled back from the contact. Set this parameter to a nonzero value to improve the efficiency and convergence of your simulation.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Transition region

$0.001 \text{ rad}$  (default) | positive scalar

Distance below which scaling is applied to the hard-stop force. The contact force is zero when the distance to the hard stop is equal to the value of this parameter. The contact force is at its full value when the distance to the hard stop is zero.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Stiffness and damping applied smoothly through transition region, damped rebound`.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision

0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision

0.1 rad/s (default) | nonnegative scalar

Threshold relative speed between the slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

**Static contact release torque threshold** — Threshold torque needed to transition from contact mode to free mode

0.001 N\*m (default) | positive scalar

Minimum torque needed to release the slider from a static contact mode.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

**Initial Conditions**

**Shaft rotation from chamber A** — Method for determining shaft angle

Calculate from angular velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the shaft angle. The block can receive the angle from a Multibody block when set to `Provide input signal from Multibody joint`, or calculates the angle internally, which is reported at port **q**.

**Initial shaft rotation** — Initial rotation

0 rad (default) | scalar

The position of the actuator at the beginning of simulation. This value falls between 0 and the value of the **Stroke** in the positive orientation, and 0 and the negative value of the **Stroke** in the negative orientation.

### Dependencies

To enable this parameter, set **Shaft rotation from chamber A** to Calculate from angular velocity of port R relative to port C.

### Fluid dynamic compressibility — Fluid compressibility

On (default) | Off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid dynamic compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

### Initial liquid pressure — Liquid pressure

0.101325 MPa (default) | positive scalar

Pressure in actuator chamber A at the start of simulation.

### Dependencies

To enable this parameter, select **Fluid dynamic compressibility**.

## Version History

### Introduced in R2020a

### R2023a: New hard stop parameterization option

The block has a new option for the **Hard stop model** parameter. This option, called Based on coefficient of restitution, models the hard stop by using a mode chart.

## Library

Hydraulic Cylinders

## Description

The Single-Acting Rotary Actuator block models a single-acting hydraulic rotary actuator, which directly converts hydraulic energy into mechanical rotational energy without employing intermediary transmissions such as rack-and-pinion, sliding spline, chain, and so on. Single-acting actuators generate torque and motion in a single direction only. Use an external device, such as a spring or another opposite installed actuator, to move the shaft in the opposite direction.

The model of the actuator is built of Simscape Foundation library blocks. The schematic diagram of the model is shown below.

The blocks in the diagram perform the following functions:

Rotational Hydro-Mechanical Converter	Converts hydraulic energy into mechanical rotational energy and vice versa, while accounting for fluid compressibility.
---------------------------------------	---

Rotational Hard Stop	Imposes limits on shaft rotation.
Linear Hydraulic Resistance	Accounts for leakages.

Connection A is a hydraulic conserving port corresponding to the actuator chamber. Connection S is a mechanical rotational conserving port associated with the actuator shaft.

The block directionality is adjustable and can be controlled with the **Actuator orientation** parameter.

## Basic Assumptions and Limitations

No loading, such as inertia, friction, spring, and so on, is taken into account. If necessary, you can easily add them by connecting an appropriate building block to port S.

## Parameters

### Actuator displacement

Effective displacement of the actuator. The default value is  $4.5 \times 10^{-5} \text{ m}^3/\text{rad}$ .

### Shaft stroke

Shaft maximum travel between stops. The default value is  $5.1 \text{ rad}$ .

### Shaft initial angle

The position of the shaft at the beginning of simulation. You can set the shaft position to any angle within its stroke. The default value is  $0$ , which corresponds to the shaft position at the very beginning of the stroke.

### Dead volume

Fluid volume that remains in the chamber when the shaft is positioned at the very beginning of the stroke. The default value is  $1 \times 10^{-4} \text{ m}^3$ .

### Leak coefficient

Leak coefficient for the Linear Hydraulic Resistance block. The default value is  $1 \times 10^{-14} \text{ (m}^3/\text{s)/Pa}$ .

### Specific heat ratio

Gas-specific heat ratio for the Hydraulic Piston Chamber block. The default value is  $1.4$ .

### Contact stiffness

Specifies the elastic property of colliding bodies for the Rotational Hard Stop block. The greater the value of the parameter, the less the bodies penetrate into each other, the more rigid the impact becomes. Lesser value of the parameter makes contact softer, but generally improves convergence and computational efficiency. The default value is  $1 \times 10^6 \text{ N}\cdot\text{m}/\text{rad}$ .

### Contact damping

Specifies dissipating property of colliding bodies for the Rotational Hard Stop block. At zero damping, the impact is close to an absolutely elastic one. The greater the value of the parameter, the more energy dissipates during an interaction. Keep in mind that damping affects slider motion as long as the slider is in contact with the stop, including the period when slider is pulled back from the contact. For computational efficiency and convergence reasons, MathWorks recommends that you assign a nonzero value to this parameter. The default value is  $150 \text{ N}\cdot\text{m}/(\text{rad}/\text{s})$ .

### **Hard stop model**

Modeling approach for hard stops. Options include:

- **Stiffness and damping applied smoothly through transition region (default)** — Scale the magnitude of the contact force from zero to its full value over a specified transition length. The scaling is polynomial in nature. The polynomial scaling function is numerically smooth and it produces no zero crossings of any kind.
- **Full stiffness and damping applied at bounds, undamped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during penetration and a spring force—without a damping component—during rebound. No smoothing is applied.
- **Full stiffness and damping applied at bounds, damped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during both penetration and rebound. No smoothing is applied. This is the hard-stop model used in previous releases.

### **Transition region**

Distance below which scaling is applied to the hard-stop force. The contact force is zero when the distance to the hard stop is equal to the value specified here. It is at its full value when the distance to the hard stop is zero. The default value is 1 mm..

### **Actuator orientation**

Specifies actuator orientation with respect to the globally assigned positive direction. The actuator can be installed in two different ways, depending upon whether it generates torque in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port A generates torque in the negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

### **Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Actuator orientation**

All other block parameters are available for modification.

### **Global Parameters**

Parameter determined by the type of working fluid:

- **Fluid bulk modulus**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

### **Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the actuator inlet.

S

Mechanical rotational conserving port associated with the actuator shaft.

## Version History

**Introduced in R2007a**

# Specific Dissipation Heat Transfer

Simple heat transfer model between two general fluids

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers / Fundamental Components

## Description

The Specific Dissipation Heat Transfer block models the heat transfer between two fluids given only minimal knowledge of component parameters. The fluids are controlled by physical signals, with these providing the entrance mass flow rate and isobaric specific heat for each. Thermal ports set the entrance temperatures of the fluids.

The rate of heat transfer is calculated from the specific dissipation, a parameter specified in tabulated form as a function of the entrance mass flow rates. The specific dissipation quantifies the amount of heat exchanged between the fluids per unit of time when the entrance temperatures differ by one degree.

Pressure losses and other aspects of flow mechanics are ignored. To capture such effects, use the heat exchanger interface blocks provided in the same library. Combine heat transfer and heat exchanger blocks to model a custom heat exchanger. See the composite block diagrams of the heat exchanger blocks for examples.

## Heat Transfer Rate

Heat flows from the warmer fluid to the cooler fluid, at a rate proportional to the difference between the fluid entrance temperatures. The heat flow rate is positive if fluid 1 enters at a higher temperature than fluid 2—and therefore if heat flows from fluid 1 to fluid 2:

$$Q = SD(T_{1,in} - T_{2,in}),$$

where  $T_{*,in}$  are the fluid entrance temperatures, determined by the conditions at thermal port **H1** for fluid 1 and **H2** for fluid 2.  $SD$  is the specific dissipation obtained from the specified tabulated data at the given mass flow rates:

$$SD = SD(\dot{m}_1, \dot{m}_2),$$

where  $\dot{m}$  are the entrance mass flow rates, specified through physical signal port **M1** for fluid 1 and **M2** for fluid 2. The specific dissipation can be calculated for a set of entrance mass flow rates ( $\dot{m}_1$ ,  $\dot{m}_2$ ) given the experimental values of the heat transfer rate and the corresponding entrance temperature difference:

$$SD = \frac{Q}{T_{1,in} - T_{2,in}}.$$

### Maximum Heat Transfer Rate

The heat transfer rate is constrained so that the specific dissipation used in the calculations can never exceed the maximum value:

$$SD_{\max} = \min(C_1, C_2),$$

where  $C_*$  are the thermal capacity rates of the controlled fluids, each defined as:

$$C_* = \dot{m}_* c_{p,*},$$

with  $c_{p,*}$  denoting the isobaric specific heat of the fluid, specified through physical signal port **CP1** for fluid 1 and **CP2** for fluid 2. The constraint on the maximum heat transfer rate is implemented in the form of a piecewise function:

$$Q = \begin{cases} SD_{\max}(T_{1,in} - T_{2,in}), & \text{if } SD > SD_{\max} \\ SD(T_{1,in} - T_{2,in}), & \text{otherwise} \end{cases},$$

A warning is issued whenever the heat flow rate exceeds the maximum value,  $SD_{\max}(T_{1,in} - T_{2,in})$ , if the **Check if violating maximum specific dissipation** block parameter is set to **Warning**.

## Ports

### Input

**CP1** — Isobaric specific heat of controlled fluid 1  
physical signal

Isobaric specific heat of controlled fluid 1.

**CP2** — Isobaric specific heat of controlled fluid 2  
physical signal

Isobaric specific heat of controlled fluid 2.

**M1** — Entrance mass flow rate of controlled fluid 1  
physical signal

Entrance mass flow rate of controlled fluid 1. Positive values indicate flow into the heat exchanger. Negative values indicate flow out of the heat exchanger.

**M2** — Entrance mass flow rate of controlled fluid 2  
physical signal

Entrance mass flow rate of controlled fluid 2. Positive values indicate flow into the heat exchanger. Negative values indicate flow out of the heat exchanger.

### Conserving

**H1** — Entrance temperature of controlled fluid 1  
thermal

Entrance temperature of controlled fluid 1.

**H2** — Entrance temperature of controlled fluid 2  
thermal

Entrance temperature of controlled fluid 2.

## Parameters

**Thermal Liquid mass flow rate vector, *mdot1*** — Entrance mass flow rate at which to specify specific-dissipation data  
[.3, .5, .6, .7, 1, 1.4, 1.9, 2.3] kg/s (default) | *M*-element array with units of mass/time

Array of mass flow rates at the inlet for controlled fluid 1. Each value corresponds to a row in the specific dissipation lookup table. Positive values indicate flow into the heat exchanger and negative values indicate flow out of the heat exchanger.

**Controlled fluid mass flow rate vector, *mdot2*** — Entrance mass flow rate at which to specify specific-dissipation data  
[.3, .5, 1, 1.3, 1.7, 2, 2.6, 3.3] kg/s (default) | *N*-element array with units of mass/time

Array of mass flow rates at the inlet for controlled fluid 2. Each value corresponds to a row in the specific dissipation lookup table. Positive values indicate flow into the heat exchanger and negative values indicate flow out of the heat exchanger.

**Specific dissipation table, *SD(mdot1, mdot2)*** — Specific dissipation values corresponding to specified mass flow rates  
8-by-8 matrix with units of kW/K (default) | *M*-by-*N* matrix with units of power/temperature

Matrix of specific dissipation values corresponding to the specified mass flow rate arrays for controlled fluids 1 and 2. The block uses the tabulated data to calculate the heat transfer at the simulated operating conditions.

**Mass flow rate threshold for flow reversal** — Mass flow rate below which to smooth numerical data  
1e-3 kg/s (default) | scalar with units of mass/time

Mass flow rate below which to initiate a smooth flow reversal to prevent discontinuities in the simulation data.

**Check if violating maximum specific dissipation** — Option to warn if the specific dissipation exceeds the maximum allowed value  
Warning (default) | None

Option to warn if the specific dissipation exceeds the maximum value described in the block description.

# Spool Orifice (IL)

Variable-area spool orifice in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Orifices

## Description

The Spool Orifice (IL) block models a variable-area orifice between a spool and a sleeve with holes. The sleeve holes can be either a series of round or rectangular holes. The flow rate is based on the total opening area between the sleeve, holes, and spool, which extends or retracts according to the signal received at port **S**. Multiple Spool Orifice (IL) blocks can be connected for multiple sets of holes along a spool-sleeve pair.

If the spool displacement in your system is supplied by an external source or custom block and you would like the axial flow force to be transmitted to the system, you can use the Spool Orifice Flow Force (IL) block, which applies the same equations for force as the Spool Orifice (IL) block.

## Flow Force

The force on the spool is calculated as:

$$F = \frac{-\dot{m}_A^2}{\rho A} \cos(\alpha) \varepsilon,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\rho$  is the fluid density.
- $A$  is the orifice open area, which is determined by the spool position and orifice parameterization.
- $\alpha$  is the jet angle, which is calculated from an approximation of the Von Mises formula:

$$\alpha_{jet} = 0.3663 + 0.8373 \left( 1 - e^{\frac{-h}{1.848c}} \right),$$

where  $c$  is the **Radial clearance**, and  $h$  is the orifice opening.

- $\varepsilon$  is the **Orifice orientation**, which indicates orifice opening that is associated with a positive or negative signal at **S**.

## Orifice Opening Area

For variable orifices, setting **Orifice orientation** to **Positive** spool displacement opens the orifice indicates that the orifice opens when the control member extends, while **Negative** spool displacement opens the orifice indicates that the orifice opens when the control member retracts.

The **Leakage area**,  $A_{leak}$ , is considered a small area open to flow when the orifice is closed, which maintains numerical continuity. Additionally, a nonzero **Smoothing factor** can provide increased numerical stability when the orifice is in near-closed or near-open position.

### Round Holes

Setting **Orifice parameterization** to Round holes evenly distributes a user-defined number of holes along the sleeve perimeter with the equal diameters and centers aligned in the same plane.

The open area is calculated as:

$$A_{orifice} = n_0 \frac{d_0^2}{8} (\theta - \sin(\theta)) + A_{leak}.$$

The orifice opening angle,  $\theta$ , is set by the control signal at **S**:

$$\theta = 2 \cos^{-1} \left( \theta - \frac{2\Delta S}{d_0} \right),$$

where:

- $n_0$  is the number of holes.
- $d_0$  is the diameter of the holes.
- $A_{leak}$  is  $A_{leak} = cd_0n_0$ .
- $\Delta S$  is the control member travel distance,  $\varepsilon(S - S_{min})$ , where  $S_{min}$  is the **Control member position at closed orifice**.

The maximum open area is:

$$A_{max} = \frac{\pi}{4} d_0^2 n_0 + A_{leak}.$$

### Rectangular Slot

Setting **Orifice parameterization** to Rectangular slot models one rectangular slot in the tube sleeve.

For an orifice with a slot in a rectangular sleeve, the open area is

$$A_{orifice} = w\Delta S + A_{leak},$$

where  $w$  is the orifice width.

The maximum opening distance between the sleeve and case is:

$$A_{max} = w\Delta S_{max} + A_{leak}.$$

where  $\Delta S_{max}$  is the slot orifice **Spool travel between closed and open orifice** distance.

At the minimum orifice opening area, the leakage area is:

$$A_{leak} = cw.$$

### Numerically-Smoothed Displacement

At the extremes of the orifice opening range, you can maintain numerical robustness in your simulation by adjusting the block **Smoothing factor**. The block applies a smoothing function to every calculated displacement, but primarily influences the simulation at the extremes of this range.

If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the orifice opening between  $\theta$  and  $\Delta S_{max}$  where  $\Delta S_{max}$  is the:

- Value of the **Diameter of round holes** parameter, when **Orifice parameterization** is set to Round holes.
- Value of the **Spool travel between closed and open orifice** parameter, when **Orifice parameterization** is set to Rectangular slot.

For more information, see “Numerical Smoothing”.

### The Mass Flow Rate Equation

The flow through a spool orifice is calculated by the pressure-flow rate equation:

$$\dot{m} = \frac{C_d A_{orifice} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{orifice}}{A} \right)^2 \right) [\Delta p^2 + \Delta p_{crit}^2]^{1/4}} \Delta p,$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $A_{orifice}$  is the orifice open area, unless:
  - The opening is larger than or equal to the area at the **Spool travel between closed and open orifice** distance. The orifice area is then  $A_{max}$ .
  - The orifice opening is less than or equal to the minimum opening distance. The orifice area is then  $A_{leak}$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , which is the point of transition between laminar and turbulent flow in the fluid:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{orifice}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the orifice due to a decrease in area.  $PR_{loss}$  is calculated as:

$$PR_{loss} = \frac{\sqrt{1 - \left( \frac{A_{orifice}}{A_{port}} \right)^2 (1 - C_d^2)} - C_d \frac{A_{orifice}}{A_{port}}}{\sqrt{1 - \left( \frac{A_{orifice}}{A_{port}} \right)^2 (1 - C_d^2)} + C_d \frac{A_{orifice}}{A_{port}}}.$$

*Pressure recovery* describes the positive pressure change in the orifice due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{loss}$  is 1.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry or exit port of the liquid to or from the orifice.

**B** — Liquid port  
isothermal liquid

Entry or exit port of the liquid to or from the orifice.

### Input

**S** — Control member displacement, m  
physical signal

Control member displacement for a variable-area orifice, in m.

### Output

**F** — Flow force, N  
physical signal

Axial flow force, in N.

## Parameters

**Orifice parameterization** — Type of orifice  
Round holes (default) | Rectangular slot

Hole geometry in the sleeve. The round holes are spaced evenly about the cross-sectional circumference. There is only one hole in the Rectangular slot setting.

**Diameter of round holes** — Diameter of round holes  
5e-3 m (default) | positive scalar

Diameter of all holes on the sleeve.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Round holes.

**Number of round holes** — Number of round holes  
6 (default) | positive integer

Number of holes along the sleeve circumference.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Round holes.

**Orifice width** — Rectangular slot width  
0.01 m (default) | positive scalar

Rectangular slot width.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Rectangular slot.

**Spool travel between closed and open orifice** — Control member maximum stroke  
5e-3 m (default) | positive scalar

Maximum distance of the control member travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Rectangular slot.

**Flow force output** — Whether to model axial hydraulic force on the spool  
off (default) | on

Whether to model the axial hydraulic force on the spool. When you select this parameter, port **F** is enabled and outputs the axial force as a physical signal, in N.

**Radial clearance** — Spool-sleeve clearance  
1e-5 m (default) | positive scalar

Radial distance between the spool and the sleeve.

**Dependencies**

To enable this parameter, select **Flow force output**.

**Leakage area** — Gap area when valve is in fully closed position  
1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Spool position at closed orifice** — Spool offset  
0 (default) | scalar

Spool offset when the orifice is fully open. A positive, nonzero value indicates a partially closed orifice. A negative, nonzero value indicates an overlapped orifice that remains open for an initial displacement set by the physical signal at port **S**.

**Cross-sectional area at ports A and B** — Orifice area at conserving ports

`inf m^2` (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. This area is used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

**Opening orientation** — Direction of changing orifice area

`Positive spool displacement opens the orifice` (default) | `Negative spool displacement opens the orifice`

Direction of the area change for variable orifices. A positive opening orientation indicates an increase in the orifice opening. A negative orientation indicates a decrease in the orifice opening. The magnitude is always positive.

**Discharge coefficient** — Discharge coefficient

`0.64` (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

`150` (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Smoothing factor** — Numerical smoothing factor

`0.01` (default) | positive scalar

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Pressure recovery** — Whether to account for pressure increase in area expansions

`off` (default) | `on`

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

Spool Orifice Flow Force (IL) | Variable Overlapping Orifice (IL) | Annular Leakage (IL) | Orifice (IL)

## Spool Orifice Flow Force (IL)

Axial fluid force on spool orifice in an isothermal liquid system

### Libraries:

Simscape / Fluids / Valve Actuators & Forces

### Description

The Spool Orifice Flow Force (IL) block models the hydraulic axial force on a spool orifice. It receives the spool position as a physical signal at port **S**. You can also model the flow through a spool orifice with round or rectangular holes. A positive force acts to close the orifice.

If you would like to model the spool and axial force in one block, use the Spool Orifice (IL) block. The axial force is output as a physical signal at port **F**.

### Flow Force

The force on the spool is calculated as:

$$F = \frac{-\dot{m}_A^2}{\rho A} \cos(\alpha) \varepsilon,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\rho$  is the fluid density.
- $A$  is the orifice open area, which is determined by the spool position and orifice parameterization.
- $\alpha$  is the jet angle, which is calculated from an approximation of the Von Mises formula:

$$\alpha_{jet} = 0.3663 + 0.8373 \left( 1 - e^{\frac{-h}{1.848c}} \right),$$

where  $c$  is the **Radial clearance** and  $h$  is the orifice opening.

- $\varepsilon$  is the opening orientation, which indicates orifice opening that is associated with a positive or negative signal at **S**.

### Opening Area

The orifice opening is based on the open area created by the displaced spool:

$$\Delta S = (S - S_{\min}) \varepsilon,$$

where:

- $S_{\min}$  is the **Spool position at closed orifice**.
- $S$  is the displacement signal at port **S**.

If  $\Delta s$  falls below 0, the orifice leakage area is used. If  $\Delta S$  is greater than the **Spool travel between closed and open orifice**, the maximum orifice area is used.

### Round Holes

Setting **Orifice geometry** to Round holes evenly distributes a user-defined number of holes along the sleeve perimeter that have equal diameters and centers aligned in the same plane.

The open area is calculated as:

$$A_{orifice} = n_0 \frac{d_0^2}{8} \left( \theta - \sin\left(\frac{\theta}{2}\right) \right) + A_{leak},$$

where:

- $n_0$  is the number of holes.
- $d_0$  is the diameter of the holes.
- $\theta$  is the orifice opening angle:

$$\theta = \cos^{-1}\left(1 - 2\frac{\Delta S}{d_0}\right).$$

If  $\theta$  is greater than  $2\pi$ ,  $\theta$  remains at  $2\pi$ .

- $A_{leak}$  is the **Leakage area**.

The maximum open area is:

$$A_{max} = \frac{\pi}{4} d_0^2 n_0 + A_{leak}.$$

### Rectangular Slot

Setting **Orifice geometry** to Rectangular slot models one rectangular slot in the tube sleeve.

For an orifice with a slot in a rectangular sleeve, the open area is

$$A_{orifice} = w\Delta S + A_{leak},$$

where  $w$  is the orifice width.

The maximum opening distance between the sleeve and case is:

$$A_{max} = w\Delta S_{max} + A_{leak}.$$

where  $\Delta S_{max}$  is the **Spool travel between closed and open orifice**.

### Numerically-Smoothed Displacement

At the extremes of the orifice opening range, you can maintain numerical robustness in your simulation by adjusting the block **Smoothing factor**. The block applies a smoothing function to every calculated displacement, but primarily influences the simulation at the extremes of this range.

If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the orifice opening between  $\theta$  and  $\Delta S_{max}$  where  $\Delta S_{max}$  is the:

- Value of the **Diameter of round holes** parameter, when **Orifice parameterization** is set to Round holes.
- Value of the **Spool travel between closed and open orifice** parameter, when **Orifice parameterization** is set to Rectangular slot.

For more information, see “Numerical Smoothing”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the block.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the block.

### Input

**S** — Control member displacement, m  
physical signal

Spool displacement in m, specified as a physical signal.

### Output

**F** — Flow force, N  
physical signal

Axial flow force in N, specified as a physical signal.

## Parameters

**Orifice geometry** — Type of orifice  
Round holes (default) | Rectangular slot

Whether the modeled spool has round holes or a rectangular slot in the sleeve.

**Diameter of round holes** — Diameter of round holes  
5e-3 m (default) | positive scalar

Diameter of all holes on the sleeve.

### Dependencies

To enable this parameter, set **Orifice geometry** to Round holes.

**Number of round holes** — Number of round holes  
6 (default) | positive integer

Number of holes along the sleeve circumference.

**Dependencies**

To enable this parameter, set **Orifice geometry** to Round holes.

**Orifice width** — Rectangular slot width

0.01 m (default) | positive scalar

Rectangular slot width.

**Dependencies**

To enable this parameter, set **Orifice geometry** to Rectangular slot.

**Spool travel between closed and open orifice** — Maximum spool stroke

1 m (default) | positive scalar

Maximum orifice opening, including the **Spool position at maximum orifice area**.

**Dependencies**

To enable this parameter, set **Orifice geometry** to Rectangular slot.

**Radial clearance** — Spool-sleeve clearance

1e-5 m (default) | positive scalar

Radial distance between the spool and the sleeve.

**Spool position at closed orifice** — Initial spool offset

0 m (default) | scalar

Initial offset if the spool is extended or retracted in its neutral position.

**Opening orientation** — Direction of changing orifice area

Positive spool displacement opens orifice (default) | Negative spool displacement closes orifice

Direction of member movement that opens the orifice. A positive orientation indicates that positive control member displacement increases the orifice opening. A negative orientation indicates that negative control member displacement increases the orifice opening. The magnitude is always positive.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

# Spool Orifice Hydraulic Force

(To be removed) Axial hydraulic force exerted on spool

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Library

Valve Forces

## Description

The Spool Orifice Hydraulic Force block simulates the steady-state axial hydraulic force exerted on the spool by fluid flowing through the orifice. The spool is assumed to be sharp-edged. You have two parameterization options:

- A rectangular slot, to be used with the Orifice with Variable Area Slot block
- A round hole, or a set of round holes, to be used with the Orifice with Variable Area Round Holes block

The width of the slot, or the diameter of the holes, must be considerably larger than the radial clearance between the spool and the sleeve. Connect the Spool Orifice Hydraulic Force block in series with the respective orifice block to monitor the flow rate.

The force is simulated according to the following equations:

$$F = \rho \frac{q^2}{A} \cos\theta \cdot or$$

$$\theta = 0.3663 + 0.8373(1 - \exp(-x/1.848))$$

$$x = x_0 + s \cdot or$$

For rectangular slot,

$$A = \begin{cases} b \cdot \sqrt{x^2 + \delta^2} & \text{for } x > 0 \\ b \cdot \delta & \text{for } x \leq 0 \end{cases}$$

For round holes,

$$A = \begin{cases} A_{\min} + Z \frac{d^2}{8} (\alpha - \sin\alpha) & \text{for } d \geq x \geq 0 \\ A_{\min} & \text{for } x < 0 \\ A_{\min} + A_{\max} & \text{for } x > d \end{cases}$$

$$\alpha = 2 \cdot \arccos\left(1 - 2\frac{x}{d}\right)$$

$$A_{\min} = Z \cdot d \cdot \delta$$

$$A_{\max} = \pi d^2/4$$

where

$F$	Axial hydraulic force
$q$	Flow rate through the orifice
$\rho$	Fluid density
$A$	Orifice area
$\Theta$	Jet angle (rad)
$x_0$	Orifice initial opening
$s$	Spool displacement
$b$	Orifice width, for rectangular slot
$D$	Orifice diameter, for round holes
$Z$	Number of round holes
$\delta$	Radial clearance
$or$	Orientation parameter with respect to the globally assigned positive direction. If the orifice is opened while the spool is shifted in positive direction, $or$ equals 1. If the orifice is opened while the spool is shifted in negative direction, $or$ equals -1.

Connections A and B are hydraulic conserving ports that should be connected in series with the orifice block to monitor the flow rate. Connection S is a physical signal port that provides the spool displacement. Connection F is a physical signal port that outputs the hydraulic axial force value. This port should be connected to the control port of an Ideal Force Source block. The force computed in the block always acts to close the orifice.

## Basic Assumptions and Limitations

- The transient effects are assumed to be negligible.
- The jet angle approximation is based on the Richard von Mises equation.
- The jet angle variation with the orifice opening is identical for the rectangular slot and the round holes orifices.
- The block can be used with orifices whose width or diameter is considerably larger than the axial opening.

## Parameters

### Orifice type

Select the type of orifice:

- **Rectangular slot** — Orifice created by the sharp-edged spool and a rectangular slot in the sleeve. This is the default.

- **Round holes** — Orifice created by the sharp-edged spool and a set of round holes evenly distributed along the sleeve perimeter.

#### **Orifice width**

Orifice width. The parameter must be greater than zero. The default value is 0.01 m. The parameter is used if **Orifice type** is set to **Rectangular slot**.

#### **Diameter of round holes**

Orifice diameter. If multiple orifices are used, all of them must be of the same diameter, identically aligned with respect to the spool edge, and spaced evenly among the sleeve perimeter. The parameter must be greater than zero. The default value is 0.005 m. The parameter is used if **Orifice type** is set to **Round holes**.

#### **Number of round holes**

Number of round holes in the sleeve. The parameter must be greater than zero. The default value is 4. The parameter is used if **Orifice type** is set to **Round holes**.

#### **Radial clearance**

The radial clearance between the spool and the sleeve. The default value is 1e-5 m.

#### **Initial opening**

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The default value is 0.

#### **Orifice orientation**

The parameter is introduced to specify the effect of the force on the orifice opening. The parameter can be set to one of two options: **Opens in positive direction** or **Opens in negative direction**. The value **Opens in positive direction** specifies an orifice that opens when the spool moves in the globally assigned positive direction. The default value is **Opens in positive direction**.

#### **Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Orifice type**
- **Orifice orientation**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Orifice type** parameter at the time the model entered Restricted mode.

#### **Ports**

The block has the following ports:

A

Hydraulic conserving port associated with an orifice inlet.

B

Hydraulic conserving port associated with an orifice outlet.

S

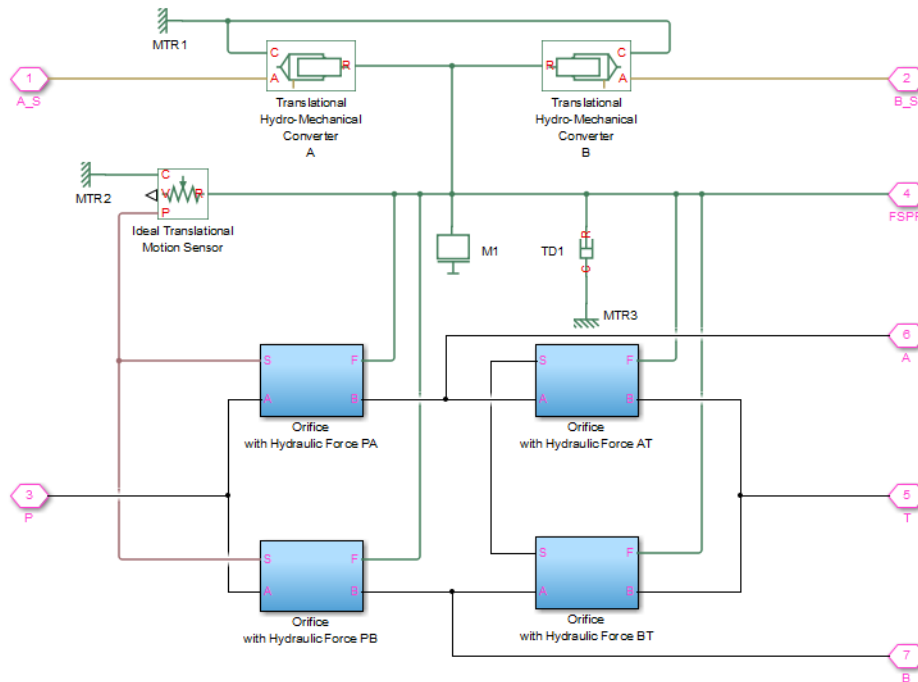

Physical signal port that provides the spool displacement.

F

Physical signal port that outputs hydraulic axial force.

## Examples

The following example shows a model of a 4-way, 3-position, hydraulically-operated directional valve where the hydraulic axial forces acting on the spool are being taken into consideration.

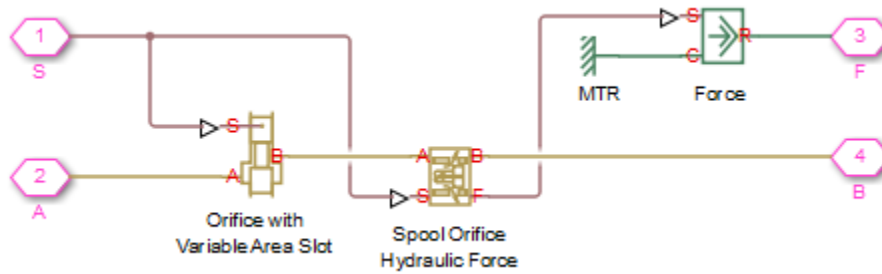

The spool (mass M1, viscous friction TD1) is shifted by the servo-actuator simulated by two Translational Hydro-Mechanical Converter blocks. Connections A\_S and B\_S are hydraulic ports for applying pilot control pressure.

Four variable orifices are represented by subsystems:

- Orifice with Hydraulic Force PA
- Orifice with Hydraulic Force PB
- Orifice with Hydraulic Force AT
- Orifice with Hydraulic Force BT

The structure of a subsystem is shown in the following illustration.

It consists of an Orifice with Variable Area Slot block, which simulates hydraulic properties of the orifice, connected in series with a Spool Orifice Hydraulic Force block. The force value computed in the block is exported through its port F and passed to the Force block.

The forces on all four orifices ( $F_{PA}$ ,  $F_{PB}$ ,  $F_{AT}$ ,  $F_{BT}$ ) are applied to the valve spool as it is shown in the first schematic.

For more details and for parameter settings, see the “Servo-Valve Controlling Hydraulic Actuator” example.

## Version History

## Spring-Loaded Accumulator (IL)

Accumulator with a spring used for energy storage in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Tanks & Accumulators

### Description

This block models a spring-charged accumulator in an isothermal liquid network. The accumulator consists of a preloaded spring and a liquid chamber.

As the liquid pressure at the accumulator inlet becomes greater than the preload pressure, liquid enters the accumulator and compresses the spring. A decrease in the liquid pressure causes the spring to decompress and discharge stored liquid into the system. The separator motion is restricted by a hard stop when the liquid volume is zero and when the liquid volume is at the liquid chamber capacity.

The inlet liquid resistance and spring properties, such as the spring inertia and damping, are not modeled. The spring pressure is assumed to be linear with respect to the liquid volume. The flow rate is positive if liquid flows into the accumulator.

This diagram represents a spring-loaded accumulator.

$V_L$	Volume of the liquid in the accumulator.
$V_C$	Liquid chamber capacity
$p_{\max}$	Pressure at full capacity
$p_I$	Liquid pressure in the liquid chamber, which is equal to the pressure at the accumulator inlet.
$p_{HS}$	Hard-stop contact pressure.
$K_{stiff}$	Hard-stop stiffness coefficient.
$K_{spring}$	Spring gain.
$\dot{m}_A$	Mass flow rate of liquid coming into port A.

$\rho_I$	Density of the liquid in the liquid chamber.
----------	--

### Conservation of Mass

Conservation of mass is represented by the following equation.

$$\begin{cases} \dot{p}_I \frac{d\rho_I}{dp_I} V_L + \rho_I \dot{V}_L = \dot{m}_A, & \text{compressibility on} \\ \rho_I \dot{V}_L = \dot{m}_A, & \text{compressibility off} \end{cases}$$

where

$$\dot{V}_L = \begin{cases} \frac{\dot{p}_I}{K_{spring}}, & \text{if } 0 < V_L < V_C \\ \frac{\dot{p}_I}{K_{spring} + K_{stiff}}, & \text{else} \end{cases}$$

### Conservation of Momentum

Conservation of momentum is represented by the following equation.

$$p_I = p_{spring} + p_{HS}$$

where

$$\begin{aligned} p_{spring} &= p_{pr} + K_{spring} V_L \\ p_{HS} &= \begin{cases} (V_L - V_C) K_{stiff}, & \text{if } V_L \geq V_C \\ V_L K_{stiff}, & \text{if } V_L \leq 0 \\ 0, & \text{else} \end{cases} \end{aligned}$$

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

### Ports

#### Conserving

**A** — Hydraulic conserving port  
hydraulic conserving

Hydraulic conserving port associated with the accumulator inlet. The flow rate is positive if liquid flows into the accumulator.

## Parameters

**Liquid capacity** — Liquid capacity  
8e-3 m<sup>3</sup> (default) | positive scalar

Amount of liquid that the accumulator can hold.

**Preload pressure** — Spring pressure  
1.01325 MPa (default) | positive scalar

Spring pressure when the liquid chamber is empty.

**Pressure at full capacity** — Spring pressure  
3.01325 MPa (default) | positive scalar

Spring pressure when the liquid chamber is at capacity.

**Hard stop stiffness coefficient** — Proportionality constant  
1e4 MPa/m<sup>3</sup> (default) | positive scalar

Proportionality constant of the hard-stop contact pressure with respect to the liquid volume penetrated into the hard stop. The hard stops are used to restrict the liquid volume between zero and liquid chamber capacity.

**Fluid dynamic compressibility** — Fluid compressibility  
on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid dynamic compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

## Library

Accumulators

## Description

This block models a spring-loaded hydraulic fluid accumulator. The accumulator consists of a preloaded spring and a fluid chamber. The fluid chamber is connected to a hydraulic system.

As the fluid pressure at the accumulator inlet becomes greater than the preload pressure, fluid enters the accumulator and compresses the spring, storing hydraulic energy. A decrease in the fluid pressure causes the spring to decompress and discharge stored fluid into the system.

During typical operations, the spring pressure is equal to the pressure in the fluid chamber. However, if the pressure at the accumulator inlet drops below the preload pressure, the spring becomes isolated from the system. In this situation, the fluid chamber is empty and the spring pressure remains constant and equal to the preload pressure while the pressure at the accumulator inlet depends on the hydraulic system to which the accumulator is connected. If the pressure at the accumulator inlet builds up to the preload pressure or higher, fluid enters the accumulator again.

The motion of the spring is restricted by two hard stops that limit the expansion and contraction of the fluid volume. The fluid volume is limited when the fluid chamber is at capacity and when the fluid chamber is empty. The hard stops are modeled with finite stiffness and damping. This means that it is possible for the fluid volume to become negative or greater than the fluid chamber capacity, depending on the values of the hard-stop stiffness coefficient and the accumulator inlet pressure.

The diagram represents a spring-loaded accumulator. The fluid chamber is on the left and the spring is on the right. The distance between the left side and the spring defines the fluid volume ( $V_F$ ).

The hard stop contact pressure is modeled with a stiffness term and a damping term. The accumulator spring is assumed to have a linear relationship between the spring pressure and the fluid volume, with pressure balanced at the end of the spring:

$$p_{spr} - p_{pr} = K_{spr}V_F$$

$$p_F = p_{spr} + p_{HS}$$

$$K_{spr} = \frac{p_{max} - p_{pr}}{V_C}$$

$$p_{HS} = \begin{cases} K_S(V_F - V_C) + K_d q_F^{\pm}(V_F - V_C) & \text{if } V_F \geq V_C \\ K_S V_F - K_d q_F^- V_F & \text{if } V_F \leq 0 \\ 0 & \text{otherwise} \end{cases}$$

$$q_F^{\pm} = \begin{cases} q_F & \text{if } q_F \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

$$q_F^- = \begin{cases} q_F & \text{if } q_F \leq 0 \\ 0 & \text{otherwise} \end{cases}$$

where

$V_F$	Volume of fluid in the accumulator
$V_{init}$	Initial volume of fluid in the accumulator
$V_C$	Fluid chamber capacity
$p_F$	Pressure at the accumulator inlet (gauge)
$p_{pr}$	Preload pressure (gauge)
$K_{spr}$	Spring gain coefficient
$p_{max}$	Pressure needed to fully fill the accumulator
$p_{spr}$	Pressure developed by the spring
$p_{HS}$	Hard-stop contact pressure
$K_s$	Hard-stop stiffness coefficient
$K_d$	Hard-stop damping coefficient

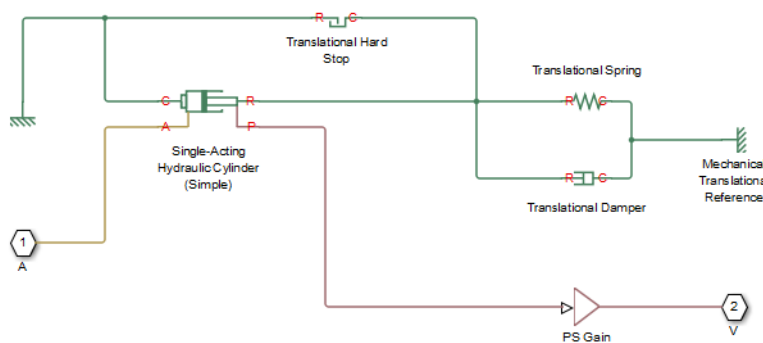

$q_F$	Fluid flow rate into the accumulator, which is positive if fluid flows into the accumulator
-------	---

The flow rate into the accumulator is the rate of change of the fluid volume:

$$q_F = \frac{dV_F}{dt}$$

At  $t = 0$ , the initial condition is  $V_F = V_{init}$ , where  $V_{init}$  is the value you assign to the **Initial fluid volume** parameter.

The Spring-Loaded Accumulator block does not consider loading on the separator. To model additional effects, such as the separator inertia and friction, you can construct a spring-loaded accumulator as a subsystem or a composite component, similar to the block diagram below.

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Basic Assumptions and Limitations

- The accumulator spring is assumed to behave linearly.
- Loading on the separator, such as inertia or friction, is not considered.
- Inlet hydraulic resistance is not considered.
- Fluid compressibility is not considered.

## Parameters

### Parameters Tab

#### Fluid chamber capacity

Amount of fluid that the accumulator can hold. The default value is  $8e-3 \text{ m}^3$ .

**Preload pressure (gauge)**

Spring pressure (gauge) when the fluid chamber is empty. The default value is 10e5 Pa.

**Pressure at full capacity (gauge)**

Spring pressure (gauge) when the fluid chamber is at capacity. The default value is 30e5 Pa.

**Hard-stop stiffness coefficient**

Proportionality constant of the hard-stop contact pressure with respect to the fluid volume penetrated into the hard stop. The hard stops are used to restrict the fluid volume between zero and fluid chamber capacity. The default value is 1e10 Pa/m<sup>3</sup>.

**Hard-stop damping coefficient**

Proportionality constant of the hard-stop contact pressure with respect to the flow rate and the fluid volume penetrated into the hard stop. The hard stops are used to restrict the fluid volume between zero and fluid chamber capacity. The default value is 1e10 Pa\*s/m<sup>6</sup>.

**Ports**

The block has one hydraulic conserving port associated with the accumulator inlet.

The flow rate is positive if fluid flows into the accumulator.

# Solenoid Valve (IL)

Solenoid valve in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

## Description

The Solenoid Valve (IL) block models flow through a solenoid valve in an isothermal liquid network. The valve consists of a two-way directional control valve with a solenoid actuator. The physical signal at port **S** controls the solenoid. When the signal at port **S** is above 0.5, the solenoid turns on and the valve opens. When the signal at port **S** falls below 0.5, the solenoid turns off, closing the valve.

A solenoid valve consists of a valve body with a spring-loaded plunger that is operated by an electric solenoid. When the solenoid is on, the magnetic force lifts the spool, allowing fluid to flow. When the solenoid is off, the spring pushes the plunger back in place, stopping flow. The block does not model the mechanics of the solenoid explicitly, but characterizes the opening and closing of the valve using the opening and closing switching times.

## Opening Dynamics

The block assumes that the solenoid behaves as a resistor-inductor series circuit, represented as

$$V = iR + L \frac{\partial i}{\partial t},$$

where:

- $V$  is the voltage across solenoid inductor.
- $R$  is the resistance of the solenoid inductor.
- $L$  is the inductance of the solenoid.
- $i$  is the current through the solenoid inductor.

The solenoid generates a force proportional to the current squared,  $F_{mag} \propto i^2$ .

The expression for the cross-sectional area of the valve,  $A(t)$ , depends on whether the valve is opening or closing. When the valve is opening,

$$A(t) = \frac{A_{max} - A_{leak}}{7} \left( e^{-2\frac{t-t_0}{\tau_{open}}} - 8e^{-\frac{t-t_0}{\tau_{open}}} \right) + A_{max}$$

$$t_0 = t_{start} + \log \left( 4 - \sqrt{16 - 7 \frac{A_{max} - A_0}{A_{max} - A_{leak}}} \right) \tau_{open}.$$

When the valve is closing,

$$A(t) = (A_{max} - A_{leak}) e^{-\frac{t-t_0}{\tau_{close}}} + A_{leak}$$

$$t_0 = t_{start} + \log \left( \frac{A_0 - A_{leak}}{A_{max} - A_{leak}} \right) \tau_{close},$$

where:

- $A_{max}$  is the value of the **Maximum opening area** parameter.
- $A_{leak}$  is the value of the **Leakage area** parameter.
- $t_{start}$  is the time that the solenoid turns on or off.
- $A_0$  is the valve area at the time the solenoid turns on or off.
- $\tau_{open} = \frac{-t_{switch_{open}}}{\log(4 - \sqrt{15.3})}$ , where  $t_{switch_{open}}$  is the value of the **Opening switching time** parameter.
- $\tau_{close} = \frac{t_{switch_{close}}}{\log(0.1)}$ , where  $t_{switch_{close}}$  is the value of the **Closing switching time** parameter.

### Switching Time

The block characterizes the solenoid valve by using the valve opening and closing switching times specified by the **Opening switching time** and **Closing switching time** parameters, respectively. The **Opening switching time** parameter is the time from the solenoid being turned on to the flow rate rising to 90% of the way between its maximum and minimum values.

The **Closing switching time** parameter is the time from the solenoid being turned off to the flow rate falling to 10% of the way between its maximum and minimum values.

### Assumptions and Limitations

- The maximum force of the solenoid is the same as the force generated by the spring. The block does not include a hard stop.
- The damping inside the solenoid and the pressure flow forces are negligible.
- The spool is balanced.

### Ports

#### Input

**S** — Signal that controls valve, unitless  
physical signal

Physical signal that controls the valve. When the signal at port **S** is above 0.5, the solenoid turns on and the valve opens. When the signal at port **S** falls below 0.5 the solenoid turns off, and the valve closes.

#### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port.

### Parameters

**Valve initial position** — Initial position for valve  
Closed (default) | Open

Whether the initial position of the valve is open or closed.

**Opening switching time** — Time for flow rate to rise when opening  
0.05 s (default) | positive scalar

Time from the solenoid turning on to the flow rate reaching 90% of the way between its maximum and minimum values.

**Closing switching time** — Time for flow rate to fall when closing  
0.1 s (default) | positive scalar

Time from the solenoid turning off to the flow rate falling to 10% of the way between its maximum and minimum values.

**Maximum opening area** — Area of fully opened valve  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the valve in the fully open position.

**Leakage area** — Valve gap area when in fully closed position  
 $1e-10 \text{ m}^2$  (default)

Sum of all the gaps when the valve is in the fully closed position. The block saturates any valve area smaller than this value to the specified leakage area. The leakage area contributes to numerical stability by maintaining continuity in the flow.

**Cross-sectional area at ports A and B** — Area at valve entry or exit  
 $\text{inf m}^2$  (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. The block uses this area in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
off (default) | on

Whether the block accounts for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

## Library

Local Hydraulic Resistances

### Description

The Sudden Area Change block represents a local hydraulic resistance, such as a sudden cross-sectional area change. The resistance represents a sudden enlargement if fluid flows from inlet to outlet, or a sudden contraction if fluid flows from outlet to inlet. The block is based on the Local Resistance block. It determines the pressure loss coefficient and passes its value to the underlying Local Resistance block. The block offers two methods of parameterization: by applying semi-empirical formulas (with a constant value of the pressure loss coefficient) or by table lookup for the pressure loss coefficient based on the Reynolds number.

If you choose to apply the semi-empirical formulas, you provide geometric parameters of the resistance, and the pressure loss coefficient is determined automatically according to the following equations (see [1] on page 1-1794):

$$K_{SE} = K_{cor} \left( 1 - \frac{A_S}{A_L} \right)^2$$

$$K_{SC} = K_{cor} \cdot 0.5 \left( 1 - \frac{A_S}{A_L} \right)^{0.75}$$

where

$K_{SE}$	Pressure loss coefficient for the sudden enlargement, which takes place if fluid flows from inlet to outlet
$K_{SC}$	Pressure loss coefficient for the sudden contraction, which takes place if fluid flows from outlet to inlet
$K_{cor}$	Correction factor

$A_S$	Small area
$A_L$	Large area

If you choose to specify the pressure loss coefficient by a table, you have to provide a tabulated relationship between the loss coefficient and the Reynolds number. In this case, the loss coefficient is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

The pressure loss coefficient, determined by either of the two methods, is then passed to the underlying Local Resistance block, which computes the pressure loss according to the formulas explained in the reference documentation for that block. The flow regime is checked in the underlying Local Resistance block by comparing the Reynolds number to the specified critical Reynolds number value, and depending on the result, the appropriate formula for pressure loss computation is used.

The Sudden Area Change block is bidirectional and computes pressure loss for both the direct flow (sudden enlargement) and return flow (sudden contraction). If the loss coefficient is specified by a table, the table must cover both the positive and the negative flow regions.

Connections A and B are conserving hydraulic ports associated with the block inlet and outlet, respectively.

The block positive direction is from port A to port B. This means that the flow rate is positive if fluid flows from A to B, and the pressure loss is determined as  $p = p_A - p_B$ .

## Basic Assumptions and Limitations

- Fluid inertia is not taken into account.
- If you select parameterization by the table-specified relationship  $K=f(Re)$ , the flow is assumed to be turbulent.

## Parameters

### Model parameterization

Select one of the following methods for block parameterization:

- **By semi-empirical formulas** — Provide geometrical parameters of the resistance. This is the default method.
- **Tabulated data – Loss coefficient vs. Reynolds number** — Provide tabulated relationship between the loss coefficient and the Reynolds number. The loss coefficient is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods. The table must cover both the positive and the negative flow regions.

### Small diameter

Internal diameter of the small port, **A**. The default value is 0.01 m.

### Large diameter

Internal diameter of the large port, **B**. The default value is 0.02 m. This parameter is used if **Model parameterization** is set to **By semi-empirical formulas**.

**Correction coefficient**

Correction factor used in the formula for computation of the loss coefficient. The default value is 1. This parameter is used if **Model parameterization** is set to `By semi-empirical formulas`.

**Laminar transition specification**

If **Model parameterization** is set to `By semi-empirical formulas`, select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to `Pressure ratio`.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 110. This parameter is visible only if the **Laminar transition specification** parameter is set to `Reynolds number`.

**Reynolds number vector**

Specify the vector of input values for Reynolds numbers as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values are [-4000, -3000, -2000, -1000, -500, -200, -100, -50, -40, -30, -20, -15, -10, 10, 20, 30, 40, 50, 100, 200, 500, 1000, 2000, 4000, 5000, 10000]. This parameter is used if **Model parameterization** is set to `By loss coefficient vs. Re table`.

**Loss coefficient vector**

Specify the vector of the loss coefficient values as a one-dimensional array. The loss coefficient vector must be of the same size as the Reynolds numbers vector. The default values are [0.25, 0.3, 0.65, 0.9, 0.65, 0.75, 0.90, 1.15, 1.35, 1.65, 2.3, 2.8, 3.10, 5, 2.7, 1.8, 1.46, 1.3, 0.9, 0.65, 0.42, 0.3, 0.20, 0.40, 0.42, 0.25]. This parameter is used if **Model parameterization** is set to `By loss coefficient vs. Re table`.

**Interpolation method**

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) block reference page. This parameter is used if **Model parameterization** is set to `By loss coefficient vs. Re table`.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) block reference page. This parameter is used if **Model parameterization** is set to `By loss coefficient vs. Re table`.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Model parameterization**
- **Interpolation method**
- **Extrapolation method**
- **Laminar transition specification**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Model parameterization** parameter at the time the model entered Restricted mode.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the resistance inlet.

B

Hydraulic conserving port associated with the resistance outlet.

# Sudden Area Change (TL)

Sudden expansion or contraction in flow area

## Libraries:

Simscape / Fluids / Thermal Liquid / Pipes & Fittings

## Description

The Sudden Area Change (TL) block models the minor pressure losses due to a sudden change in flow cross-sectional area. The area change is a contraction from port **A** to port **B** and an expansion from port **B** to port **A**. This component is adiabatic. It does not exchange heat with its surroundings.

## Sudden Area Change Schematic

The pressure drop across a sudden expansion is primarily due to turbulence mixing in the expansion zone. Across a sudden contraction, it is primarily due to flow detachment at the contraction zone entrance. The figure shows the expansion and contraction zones of the sudden area change.

## Mass Balance

The mass conservation equation in the sudden area change is

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  and  $\dot{m}_B$  are the mass flow rates into the sudden area change through ports A and B.

### Momentum Balance

The momentum conservation equation in the sudden area change is

$$p_A - p_B = \frac{\dot{m}^2}{2\rho} \left( \frac{1}{S_B^2} - \frac{1}{S_A^2} \right) + \phi_{Loss},$$

where:

- $p_A$  and  $p_B$  are the pressures at ports A and B.
- $\dot{m}$  is the average mass flow rate.
- $\rho$  is the average fluid density.
- $S_A$  and  $S_B$  are the flow cross-sectional areas at ports A and B.
- $\phi_{Loss}$  is the mechanical energy loss due to the sudden area change.

The mechanical energy loss is

$$\phi_{Loss} = K_{Loss} \frac{\dot{m}^2}{2\rho S_B^2},$$

where:

- $K_{Loss}$  is the loss coefficient.

If the **Loss coefficient specification** parameter is set to Semi-empirical formulation, the loss coefficient for a sudden expansion is computed as

$$K_{Loss} = K_e \left( 1 - \frac{S_B}{S_A} \right)^2,$$

while for a sudden contraction it is computed as

$$K_{Loss} = \frac{K_c}{2} \left( 1 - \frac{S_B}{S_A} \right),$$

where:

- $K_e$  is the correction factor in the expansion zone.
- $K_c$  is the correction factor in the contraction zone.

In the transition zone between sudden expansion and sudden contraction behavior, the loss coefficient is smoothed through a cubic polynomial function:

$$K_{Loss} = K_e \left( 1 - \frac{S_B}{S_A} \right)^2 + \lambda \left[ \frac{K_c}{2} \left( 1 - \frac{S_B}{S_A} \right) - K_e \left( 1 - \frac{S_B}{S_A} \right)^2 \right],$$

where

$$\lambda = 3\bar{m}^{-2} - 2\bar{m}^{-3},$$

and

$$\dot{m}_{Cr} = \text{Re}_{Cr} \sqrt{\frac{\pi}{4} S_B \mu}.$$

If the **Loss coefficient specification** parameter is set to **Tabulated data – Loss coefficient vs. Reynolds number**, the block obtains the loss coefficient from tabular data provided as a function of the Reynolds number.

### Energy Balance

The energy conservation equation in the sudden area change is

$$\phi_A + \phi_B = 0,$$

where:

- $\Phi_A$  and  $\Phi_B$  are the energy flow rates into the sudden area change through ports A and B.

### Assumptions and Limitations

- The flow is incompressible. The fluid density is assumed constant in the sudden area change.

### Ports

#### Conserving

**A** — Section inlet  
thermal liquid

Fluid entry or exit point to the area change section.

**B** — Section inlet  
thermal liquid

Fluid entry or exit point to the area change section.

### Parameters

**Local loss parameterization** — Method of flow loss calculating

Semi-empirical (default) | Tabulated data - loss coefficient vs. Reynolds number

Parameterization for calculating the loss coefficient due to the sudden area change. Select **Semi-empirical formulation** to automatically compute the loss coefficient from the cross-sectional areas at ports **A** and **B**. Select **Tabulated data - Loss coefficient vs. Reynolds number** to specify a 1-D lookup table for the loss coefficient with respect to the flow Reynolds number.

**Cross-sectional area at port A** — Inlet area at A

0.02 m<sup>2</sup> (default) | positive scalar

Area normal to the direction of flow at inlet **A**. This value must be greater than the cross-sectional area at **B**.

**Cross-sectional area at port B** — Inlet area at B

0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the direction of flow at **B**. This value must be smaller than the cross-sectional area at **A**.

**Critical Reynolds number** — Transitional Reynolds number associated with smallest area in section  
150 (default) | positive scalar

Reynolds number at which flow transitions between laminar and turbulent regimes in the contraction portion of the sudden area change. This parameter is visible only when the **Loss coefficient specification** parameter is set to `Semi-empirical formulation`.

**Contraction correction factor** — Loss coefficient scaling factor  
1 (default) | positive scalar

Scaling factor for adjusting the loss coefficient value in the contraction portion of the sudden area change. The block multiplies the loss coefficient factor calculated from the semi-empirical expression by this factor. This parameter is visible only when the **Loss coefficient specification** parameter is set to `Semi-empirical formulation`.

**Expansion correction factor** — Loss coefficient scaling factor  
1 (default) | positive scalar

Scaling factor for adjusting the loss coefficient value in the expansion portion of the sudden area change. The block multiplies the loss coefficient factor calculated from the semi-empirical expression by this factor. This parameter is visible only when the **Loss coefficient specification** parameter is set to `Semi-empirical formulation`.

**Reynolds number vector** — Vector of Reynolds numbers for tabular parameterization  
[10, 20, 30, 40, 50, 100, 200, 500, 1000, 2000] (default) | vector

Vector of Reynolds numbers for the tabular parameterization of loss coefficients. You specify the **Contraction loss coefficient vector** and **Expansion loss coefficient vector** parameters at these Reynolds numbers.

This parameter is visible only when the **Loss coefficient specification** parameter is set to `Tabulated data - Loss coefficient vs. Reynolds number`.

**Contraction loss coefficient vector** — Vector of loss coefficients for tabular parameterization  
[4, 2.7, 1.8, 1.46, 1.3, .9, .65, .42, .3, .2] (default) | 1-by-*n* vector

Vector of loss coefficients for the contraction portion of the area change. Specify the loss coefficients at the Reynolds numbers in the **Reynolds number vector** parameter. The block uses the Reynolds number and loss coefficient vectors to construct a 1-D lookup table.

This parameter is visible only when the **Loss coefficient specification** parameter is set to `Tabulated data - Loss coefficient vs. Reynolds number`.

**Expansion loss coefficient vector** — Vector of loss coefficients for tabular parameterization  
[4, 2.3, 1.65, 1.35, 1.15, .9, .75, .65, .9, .65] (default) | 1-by-*n* vector

Vector of loss coefficients for the expansion portion of the area change. Specify the loss coefficients at the Reynolds numbers in the **Reynolds number vector** parameter. The block uses the Reynolds number and loss coefficient vectors to construct a 1-D lookup table.

This parameter is visible only when the **Loss coefficient specification** parameter is set to `Tabulated data - Loss coefficient vs. Reynolds number`.

## Library

Pumps and Motors

## Description

Note that this reference page is for the Hydraulics (Isothermal) Liquid library block. For the Isothermal Liquid library block, see Swash Plate.

The Swash Plate block is a model of a swash plate mechanism used in axial-piston hydraulic pumps and motors to convert translational motion of a piston into rotational motion of a drive shaft. The mechanism is a combination of a cylinder block or rotor, with the piston fitted inside, and an angled swash plate.

The angular position of the plate is controlled by an actuator, usually a servo cylinder, acting along the actuator action line (marked in the preceding diagram). The distance between the actuator line and the swash plate at zero angle is equal to the actuator arm length  $r_A$ . The pistons are offset by  $h_{\text{off}}$  from the swash plate. The swash plate angle can be changed to increase or decrease the piston stroke. As the rotor turns, the piston slides on the swash plate, which causes the piston to reciprocate. The sliding contact between the piston and the swash plate is maintained by the guideway shown in the diagram.

In a hydraulic machine, the piston moves along the slots in the porting plate (not shown in the preceding diagram) thus being periodically connected to either the intake or the discharge port of the machine. The model simulates a single piston interacting with the swash plate. Mechanically, the mechanism performs summation of two motions, caused by rotation of the swash plate with respect to its axis and rotation of the rotor, and converts them into displacement of the piston.

The following illustration shows the calculation diagram of the mechanism.

The positive direction of the actuator is assumed to be directed to the left from the vertical axis, while the positive direction of the piston motion is directed upward, as it is shown in the diagram. The reference point for both motions corresponds to the plate being perpendicular to the rotor axis. As far as the angular motion of the rotor is concerned, the clockwise rotation (looking from the top) is assumed to be positive.

The piston displacement at arbitrary rotor rotation angle  $\gamma$  and actuator displacement  $x_A$  is determined from the relationship:

$$x_P = -(AB - h_{off} + BC + DE \cdot \operatorname{tg} \alpha)$$

$$\operatorname{tg} \alpha = \frac{x_A}{r_A}$$

which, after minor rearrangement, yields:

$$x_P = -\frac{r_P}{r_A}x_A \cos(\gamma + \beta) - h_{off} \left( \sqrt{1 + \frac{x_A^2}{r_A^2}} - 1 \right) \quad (1-12)$$

$$\gamma = \omega \cdot t$$

where

$x_P$	Piston displacement
$x_A$	Actuator displacement
$r_P$	Cylinder block pitch radius
$r_A$	Actuator arm
$\gamma$	Rotor angle of rotation
$h_{off}$	Piston offset
$\beta$	Piston phase angle
$\omega$	Rotor angular velocity
$t$	Time

The kinematic relationship between piston and actuator displacement must be converted into a relationship between the basic Across variables for the physical network representation, that is, velocities:

$$V_P = \frac{dx_P}{dt} = -\frac{r_P}{r_A}V_A \cos(\gamma + \beta) + \frac{r_P}{r_A}x_A \omega \sin(\gamma + \beta) - \frac{h_{off}}{r_A^2} \frac{x_A V_A}{\sqrt{1 + \frac{x_A^2}{r_A^2}}}$$

where

$V_P$	Piston velocity
$V_A$	Actuator velocity

The inertia properties of the mechanism are assumed to be negligible. Therefore, any state of the mechanism can be considered as equilibrium. According to the principle of virtual work, if the system is in equilibrium the aggregate work of all the applied forces and torques on the system virtual displacements is equal to zero. For the mechanism under consideration, the principle of virtual work yields:

$$F_P \delta x_P + F_A \delta x_A + (T - T_{res}) \delta \gamma = 0 \quad (1-13)$$

where

$F_P$	Piston force
$F_A$	Actuator force
$T$	Rotor torque
$T_{res}$	Resistance torque acting on the rotor due to viscous friction

Virtual displacements  $\delta x_P$ ,  $\delta x_A$ , and  $\delta \gamma$  are determined from “Equation 1-12” and substituted into “Equation 1-13”. Since virtual displacements  $\delta x_A$  and  $\delta \gamma$  are independent, any of them can be equal to zero. As a result, we obtain two more equations of the mechanism:

$$F_A = \frac{r_P}{r_A} F_P \cos(\gamma + \beta) + \frac{h_{off}}{r_A^2} \frac{x_A}{\sqrt{1 + \frac{x_A^2}{r_A^2}}} F_P$$

$$T = -\frac{r_P}{r_A} x_A \cdot F_P \cdot \sin(\gamma + \beta) + T_{res}$$

The resistance torque is:

$$T_{res} = \mu \cdot r_P \cdot \omega$$

where  $\mu$  is the viscous friction coefficient in the contact between the piston and the plate.

The final set of equations describing the swash plate mechanism takes the form:

$$V_P = \frac{dx_P}{dt} = -\frac{r_P}{r_A} V_A \cos(\gamma + \beta) + \frac{r_P}{r_A} x_A \omega \sin(\gamma + \beta) - \frac{h_{off}}{r_A^2} \frac{x_A V_A}{\sqrt{1 + \frac{x_A^2}{r_A^2}}}$$

$$F_A = \frac{r_P}{r_A} F_P \cos(\gamma + \beta) + \frac{h_{off}}{r_A^2} \frac{x_A}{\sqrt{1 + \frac{x_A^2}{r_A^2}}} F_P$$

$$T = -\frac{r_P}{r_A} x_A \cdot F_P \cdot \sin(\gamma + \beta) + \mu \cdot r_P \cdot F_P$$

Connection P is a mechanical translational conserving port associated with the tip of the piston. Connection S is a mechanical rotational conserving port associated with the drive shaft, which is connected to the cylinder block. Connection A is a mechanical translational conserving port associated with the swash plate actuator.

## Basic Assumptions and Limitations

- The model accounts for the viscous friction in the piston-plate contact.
- No inertial effects are considered.
- The plate angular displacements are considered to be small.
- The joint between the piston and the plate permanently maintains contact between the piston and the plate.

## Parameters

### Swash plate actuator arm

The distance between the actuator line of action and the center of the rotor rotation. The parameter must be greater than zero. The default value is 0.065 m.

**Piston pitch radius**

The radius of the pitch circle where the pistons are located, that is, the cylinder block pitch radius. The parameter must be greater than zero. The default value is 0.05 m.

**Piston offset from the plate**

The offset between the piston tip and the swash plate. The parameter must be greater than or equal to zero. The default value is 0.

**Phase angle**

Parameter sets the piston initial angular position with respect to the reference point which corresponds to the zero angle. The default value is 0.

**Actuator initial displacement**

Parameter sets the initial position of the actuator with respect to the reference point which corresponds to the plate being perpendicular to the axis of rotor rotation. The default value is 0.

**Viscous friction coefficient**

The parameter specifies the coefficient of viscous friction in the contact between the piston and the plate. The parameter must be greater than zero. The default value is 50 N/(m/s).

**Ports**

The block has the following ports:

A

Mechanical translational conserving port associated with the actuator joint.

P

Mechanical translational conserving port associated with the tip of the piston.

S

Mechanical rotational conserving port associated with the drive shaft.

**Examples**

The “Hydraulic Axial-Piston Pump with Load-Sensing and Pressure-Limiting Control” example models a test rig designed to investigate interaction between an axial-piston pump and a typical control unit, simultaneously performing the load-sensing and pressure-limiting functions. To assure required accuracy, the model of the pump must account for such features as interaction between pistons, swash plate, and porting plate, which makes it necessary to build a detailed pump model.

**Version History****Introduced in R2011a****R2023a: To be removed**

Porting Plate Variable Orifice

# Swash Plate

Swash plate in a single-piston, isothermal axial piston pump

**Libraries:**

Simscape / Fluids / Isothermal Liquid / Pumps & Motors / Auxiliary Components

## Description

The Swash Plate block models a single, piston-actuated swash plate within an axial-piston pump. It translates linear actuation into rotational motion that, when connected to the Valve Plate Orifice (IL) block, periodically connects the piston with the pump intake and discharge. You can connect multiple swash plate blocks to multiple pistons.

### Schematic of a Swash Plate Within an Axial-Piston Pump Unit

#### Force Balance

The plate is in dynamic equilibrium if the net work by the piston, actuator, and plate is zero:

$$F_P \delta_P + F_A \delta_A + (\tau - \tau_{res}) \delta_y = 0,$$

where:

- $F_P \delta_P$  is the work done due to piston displacement.
- $F_A \delta_A$  is the work done due to actuator displacement.
- $(\tau - \tau_{res}) \delta_y$  is the work done due to the net plate torque tangent to plate motion.

The plate torque is:

$$\tau = -\frac{r_P}{r_A}x_A F_P \sin\gamma + \tau_{res},$$

where:

- $r_P$  is the **Cylinder block pitch radius**.
- $r_A$  is the **Swash plate actuator arm**.
- $X_A$  is the actuator displacement.
- $F_P$  is the piston force.
- $\gamma$  is the plate angular displacement.

The viscous friction torque, or the resistance to motion due to plate-piston contact, is:

$$\tau_{res} = \mu_{viscous}\omega r_P^2,$$

where:

- $\mu_{viscous}$  is the **Viscous friction coefficient**.
- $\omega$  is the rotor angular velocity.

### Piston Dynamics

The piston displacement,  $x$ , is proportional to the actuator displacement:

$$x = -h_{off}\left(\sqrt{1 + \frac{x_A^2}{r_A^2}} - 1\right) - \frac{r_P}{r_A}x_A \cos\gamma,$$

where  $h_{off}$  is the **Piston offset from the plate**. Displacement is positive if it moves toward the cylinder block.

The piston velocity is:

$$V_P = \frac{r_P}{r_A}x_A\omega\sin(\gamma) - \frac{r_P}{r_A}V_A\cos\gamma - \frac{h_{off}}{r_A^2}\frac{x_A V_A}{\sqrt{1 + \frac{x_A^2}{r_A^2}}},$$

where  $V_A$  is the actuator velocity.

### Assumptions and Limitations

This block accounts for the effect of viscous friction between the piston and plate, but neglects plate and fluid inertia.

---

**Note** This reference page is for the Isothermal Liquid library block. For the Hydraulics (Isothermal) Liquid library block, see Swash Plate.

---

## Ports

### Conserving

**A** — Mechanical port associated with actuator  
mechanical translational

Swash plate actuator velocity and force.

**P** — Mechanical port associated with piston  
mechanical translational

Piston end velocity and force.

**S** — Mechanical port associated with shaft  
mechanical rotational

Drive shaft angular velocity and torque. Rotation is relative to the environment.

## Parameters

**Swash plate actuator arm** — Length of actuator extension  
0.065 m (default) | positive scalar

Length of fully extended actuator arm.

**Cylinder block pitch radius** — Cylinder pitch radius  
0.05 m (default) | positive scalar

Pitch radius of the rotating cylinder.

**Piston offset from the plate** — Resting piston offset  
0 m (default) | scalar

Piston offset when the actuator is in neutral position. A positive, nonzero value indicates a partially retracted piston. A negative, nonzero value indicates an extended piston that remains within the cylinder block during an initial actuator displacement away from the cylinder.

**Viscous friction coefficient** — Torque viscous friction coefficient  
50 N/(m/s) (default) | positive scalar

Coefficient used in the equation for torque due to viscous friction.

## System-Level Condenser Evaporator (2P-MA)

Heat exchanger between two-phase fluid and moist air networks, with model based on performance data

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

### Description

The System-Level Condenser Evaporator (2P-MA) block models a heat exchanger between a two-phase fluid network and a moist air network.

The block can act as a condenser or as an evaporator in a refrigeration system, depending on the direction of heat transfer. The block model is based on performance data from the heat exchanger datasheet, rather than on the detailed geometry of the exchanger, and therefore lets you easily adjust the size and performance of the heat exchanger during design iterations, or model heat exchangers with uncommon geometries. You can also use this block to model heat exchangers with a certain level of performance at an early design stage, when detailed geometry data is not yet available.

You parameterize the block by the nominal operating condition. The heat exchanger is sized to match the specified performance at the nominal operating condition at steady state.

The Two-Phase Fluid 1 side approximates the liquid zone, mixture zone, and vapor zone based on the change in enthalpy along the flow path. The Moist Air 2 side models water vapor condensation based on convective water vapor mass transfer with the heat transfer surface. Condensed water is removed from the moist air flow.

This block is similar to the Condenser Evaporator (2P-MA) block but uses a different parameterization model. The table provides a comparison of the two blocks, to help you choose the right block for your application.

Condenser Evaporator (2P-MA)	System-Level Condenser Evaporator (2P-MA)
Block parameters are based on the heat exchanger geometry	Block parameters are based on performance and operating conditions
Heat exchanger geometry may be limited by the available geometry parameter options	Model is independent of the specific heat exchanger geometry
You can adjust the block for different performance requirements by tuning geometry parameters, such as fin sizes and tube lengths	You can adjust the block for different performance requirements by directly specifying the desired heat and mass flow rates
Lets you select between parallel, counter, or cross flow configurations	Lets you select between parallel, counter, or cross flow arrangement at nominal operating conditions, to help with sizing

Condenser Evaporator (2P-MA)	System-Level Condenser Evaporator (2P-MA)
Predictively accurate results over a wide range of operating conditions, subject to the applicability of the E-NTU equations and the heat transfer coefficient correlations	Very accurate results around the specified operating condition; accuracy may decrease far away from the specified operating conditions
Heat transfer calculations account for the variation of temperature along the flow path by using the E-NTU model	Heat transfer calculations approximate the variation of temperature along the flow path by dividing it into three segments
Accounts for different fluid properties and heat transfer coefficients for subcooled liquid, liquid-vapor mixture, and superheated vapor	Accounts for different fluid properties and heat transfer coefficients for subcooled liquid, liquid-vapor mixture, and superheated vapor
Keeps track of variable zone length fractions for subcooled liquid, liquid-vapor mixture, and superheated vapor regions based on the geometry	Approximates the effect of subcooled liquid, liquid-vapor mixture, and superheated vapor regions using weighting factors based on the difference in enthalpy between inlet and outlet
Accounts for water vapor condensation and the latent heat on the moist air flow	Accounts for water vapor condensation and the latent heat on the moist air flow
Does not model the wall thermal mass; you can approximate the effect by connecting a pipe block with a thermal mass downstream	Includes an option to model the wall thermal mass

### Heat Transfer

The two-phase fluid flow and the moist air flow are each divided into three segments of equal size. Heat transfer between the fluids is calculated in each segment. For simplicity, the equation for one segment is shown here.

If the wall thermal mass is off, then the heat balance in the heat exchanger is

$$Q_{seg, 2P} + Q_{seg, MA} = 0,$$

where:

- $Q_{seg, 2P}$  is the heat flow rate from the wall (that is, the heat transfer surface) to the two-phase fluid in the segment.
- $Q_{seg, MA}$  is the heat flow rate from the wall to the moist air in the segment.

If the wall thermal mass is on, then the heat balance in the heat exchanger is

$$Q_{seg, 2P} + Q_{seg, MA} = - \frac{M_{wall} c_{p, wall}}{N} \frac{dT_{seg, wall}}{dt},$$

where:

- $M_{wall}$  is the mass of the wall.
- $c_{p, wall}$  is the specific heat of the wall.
- $N = 3$  is the number of segments.
- $T_{seg, wall}$  is the average wall temperature in the segment.
- $t$  is time.

The heat flow rate from the wall to the two-phase fluid in the segment is

$$Q_{seg, 2P} = UA_{seg, 2P}(T_{seg, wall} - T_{seg, 2P}),$$

where:

- $UA_{seg, 2P}$  is the weighted-average heat transfer conductance for the two-phase fluid in the segment.
- $T_{seg, 2P}$  is the weighted-average fluid temperature for the two-phase fluid in the segment.

The heat flow rate from the wall to the moist air in the segment is

$$Q_{seg, MA} = \frac{UA_{seg, MA}}{\bar{c}_{pseg, MA}}(\bar{h}_{seg, wall} - \bar{h}_{seg, MA}) + \dot{m}_{w, seg, cond}h_{l, wall}$$

where:

- $UA_{seg, MA}$  is the heat transfer conductance for the moist air in the segment.
- $\bar{c}_{pseg, MA}$  is the moist air mixture specific heat per unit mass of dry air and trace gas in the segment.
- $\bar{h}_{seg, wall}$  is the moist air mixture enthalpy per unit mass of dry air and trace gas at the average wall segment temperature.
- $\bar{h}_{seg, MA}$  is the moist air mixture enthalpy per unit mass of dry air and trace gas in the segment.
- $\dot{m}_{w, seg, cond}$  is the rate of water vapor condensation on the wall surface.
- $h_{l, wall}$  is the specific enthalpy of liquid water at the average wall segment temperature.

Using mixture enthalpy in this equation accounts for both differences in temperature and differences in moisture due to condensation [3].

---

**Note** For the moist air quantities, the bar above the symbols indicates that they are quantities for mixture divided by the mass of dry air and trace gas only, as opposed to dividing by the mass of the whole mixture. The whole mixture includes dry air, water vapor, and trace gas.

---

### Two-Phase Fluid Heat Transfer Correlation

If the segment is subcooled liquid, then the heat transfer conductance is

$$UA_{seg, L, 2P} = a_{L, 2P}(Re_{seg, L, 2P})^{b_{2P}}(Pr_{seg, L, 2P})^{c_{2P}}k_{seg, L, 2P}\frac{G_{2P}}{N},$$

where:

- $a_{L, 2P}$ ,  $b_{2P}$ , and  $c_{2P}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg, L, 2P}$  is the average liquid Reynolds number for the segment.
- $Pr_{seg, L, 2P}$  is the average liquid Prandtl number for the segment.
- $k_{seg, L, 2P}$  is the average liquid thermal conductivity for the segment.
- $G_{2P}$  is the geometry scale factor for the two-phase fluid side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average liquid Reynolds number is

$$Re_{seg,L,2P} = \frac{\dot{m}_{seg,2P} D_{ref,2P}}{\mu_{seg,L,2P} S_{ref,2P}},$$

where:

- $\dot{m}_{seg,2P}$  is the mass flow rate through the segment.
- $\mu_{seg,L,2P}$  is the average liquid dynamic viscosity for the segment.
- $D_{ref,2P}$  is an arbitrary reference diameter.
- $S_{ref,2P}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref,2P}$  and  $S_{ref,2P}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg,L,2P}$  nondimensional. The values of  $D_{ref,2P}$  and  $S_{ref,2P}$  are arbitrary because the  $G_{2P}$  calculation overrides these values.

---

Similarly, if the segment is superheated vapor, then the heat transfer conductance is

$$UA_{seg,V,2P} = a_{V,2P} (Re_{seg,V,2P})^{b_{2P}} (Pr_{seg,V,2P})^{c_{2P}} k_{seg,V,2P} \frac{G_{2P}}{N},$$

where:

- $a_{V,2P}$ ,  $b_{2P}$ , and  $c_{2P}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,V,2P}$  is the average vapor Reynolds number for the segment.
- $Pr_{seg,V,2P}$  is the average vapor Prandtl number for the segment.
- $k_{seg,V,2P}$  is the average vapor thermal conductivity for the segment.

The average vapor Reynolds number is

$$Re_{seg,V,2P} = \frac{\dot{m}_{seg,2P} D_{ref,2P}}{\mu_{seg,V,2P} S_{ref,2P}},$$

where  $\mu_{seg,V,2P}$  is the average vapor dynamic viscosity for the segment.

If the segment is liquid-vapor mixture, then the heat transfer conductance is

$$UA_{seg,M,2P} = a_{M,2P} (Re_{seg,SL,2P})^{b_{2P}} CZ (Pr_{seg,SL,2P})^{c_{2P}} k_{seg,SL,2P} \frac{G_{2P}}{N},$$

where:

- $a_{M,2P}$ ,  $b_{2P}$ , and  $c_{2P}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,SL,2P}$  is the saturated liquid Reynolds number for the segment.
- $Pr_{seg,SL,2P}$  is the saturated liquid Prandtl number for the segment.
- $k_{seg,SL,2P}$  is the saturated liquid thermal conductivity for the segment.
- CZ is the Cavallini and Zecchin term.

The saturated liquid Reynolds number is

$$Re_{seg, SL, 2P} = \frac{\dot{m}_{seg, 2P} D_{ref, 2P}}{\mu_{seg, SL, 2P} S_{ref, 2P}},$$

where  $\mu_{seg, SL, 2P}$  is the saturated liquid dynamic viscosity for the segment.

The Cavallini and Zecchin term is

$$CZ = \frac{\left( \left( \sqrt{\frac{\nu_{seg, SV, 2P}}{\nu_{seg, SL, 2P}}} - 1 \right) (x_{seg, out, 2P} + 1) \right)^{1 + b_{2P}} - \left( \left( \sqrt{\frac{\nu_{seg, SV, 2P}}{\nu_{seg, SL, 2P}}} - 1 \right) (x_{seg, in, 2P} + 1) \right)^{1 + b_{2P}}}{(1 + b_{2P}) \left( \sqrt{\frac{\nu_{seg, SV, 2P}}{\nu_{seg, SL, 2P}}} - 1 \right) (x_{seg, out, 2P} - x_{seg, in, 2P})},$$

where:

- $\nu_{seg, SL, 2P}$  is the saturated liquid specific volume for the segment.
- $\nu_{seg, SV, 2P}$  is the saturated vapor specific volume for the segment.
- $x_{seg, in, 2P}$  is the vapor quality at the segment inlet.
- $x_{seg, out, 2P}$  is the vapor quality at the segment outlet.

The expression is based on the work of Cavallini and Zecchin [5], which derives a heat transfer coefficient correlation at a local vapor quality  $x$ . Equations for the liquid-vapor mixture are obtained by averaging Cavallini and Zecchin's correlation over the segment from  $x_{seg, in, 2P}$  to  $x_{seg, out, 2P}$ .

### Two-Phase Fluid Weighted Average

The two-phase fluid flow through a segment may not be entirely represented as either subcooled liquid, superheated vapor, or liquid-vapor mixture. Instead, each segment may consist of a combination of these. The block approximates this condition by computing weighting factors ( $w_L$ ,  $w_V$ , and  $w_M$ ) based on the change in specific enthalpy across the segment and the saturated liquid and vapor specific enthalpies. The block assumes that the specific enthalpy across the segment varies piecewise linearly from inlet to outlet, with the breakpoints corresponding to the saturation boundaries for liquid and vapor. The zone with a larger heat transfer coefficient has a steeper slope than the zone with a lower heat transfer coefficient.

$$w_L = \frac{\Delta_L}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_V = \frac{\Delta_V}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_M = 1 - w_L - w_V$$

$$\Delta_L = |\min(h_{seg, out, 2P}, h_{seg, SL, 2P}) - \min(h_{seg, in, 2P}, h_{seg, SL, 2P})| \cdot UA_{seg, M, 2P} \cdot UA_{seg, V, 2P}$$

$$\Delta_M = |\min(\max(h_{seg, out, 2P}, h_{seg, SL, 2P}), h_{seg, SV, 2P}) - \min(\max(h_{seg, in, 2P}, h_{seg, SL, 2P}), h_{seg, SV, 2P})| \cdot UA_{seg, L, 2P} \cdot U$$

$$\Delta_V = |\max(h_{seg, out, 2P}, h_{seg, SV, 2P}) - \max(h_{seg, in, 2P}, h_{seg, SV, 2P})| \cdot UA_{seg, L, 2P} \cdot UA_{seg, M, 2P}$$

where:

- $h_{seg, in, 2P}$  is the specific enthalpy at the segment inlet.
- $h_{seg, out, 2P}$  is the specific enthalpy at the segment outlet.

- $h_{\text{seg,SL,2P}}$  is the saturated liquid specific enthalpy for the segment.
- $h_{\text{seg,SV,2P}}$  is the saturated vapor specific enthalpy for the segment.

The weighted-average two-phase fluid heat transfer conductance for the segment is therefore

$$UA_{\text{seg,2P}} = w_L(UA_{\text{seg,L,2P}}) + w_V(UA_{\text{seg,V,2P}}) + w_M(UA_{\text{seg,M,2P}}).$$

The weighted-average fluid temperature for the segment is

$$T_{\text{seg,2P}} = \frac{w_L(UA_{\text{seg,L,2P}})T_{\text{seg,L,2P}} + w_V(UA_{\text{seg,V,2P}})T_{\text{seg,V,2P}} + w_M(UA_{\text{seg,M,2P}})T_{\text{seg,M,2P}}}{UA_{\text{seg,2P}}},$$

where:

- $T_{\text{seg,L,2P}}$  is the average liquid temperature for the segment.
- $T_{\text{seg,V,2P}}$  is the average vapor temperature for the segment.
- $T_{\text{seg,M,2P}}$  is the average mixture temperature for the segment, which is the saturated liquid temperature.

### Moist Air Heat Transfer Correlation

The heat transfer conductance is

$$UA_{\text{seg,MA}} = a_{\text{MA}}(\text{Re}_{\text{seg,MA}})^{b_{\text{MA}}}(\text{Pr}_{\text{seg,MA}})^{c_{\text{MA}}}k_{\text{seg,MA}}\frac{G_{\text{MA}}}{N},$$

where:

- $a_{\text{MA}}$ ,  $b_{\text{MA}}$ , and  $c_{\text{MA}}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $\text{Re}_{\text{seg,MA}}$  is the average Reynolds number for the segment.
- $\text{Pr}_{\text{seg,MA}}$  is the average Prandtl number for the segment.
- $k_{\text{seg,MA}}$  is the average thermal conductivity for the segment.
- $G_{\text{MA}}$  is the geometry scale factor for the moist air side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average Reynolds number is

$$\text{Re}_{\text{seg,MA}} = \frac{\dot{m}_{\text{seg,MA}}D_{\text{ref,MA}}}{\mu_{\text{seg,MA}}S_{\text{ref,MA}}},$$

where:

- $\dot{m}_{\text{seg,MA}}$  is the mass flow rate through the segment.
- $\mu_{\text{seg,MA}}$  is the average dynamic viscosity for the segment.
- $D_{\text{ref,MA}}$  is an arbitrary reference diameter.
- $S_{\text{ref,MA}}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref,MA}$  and  $S_{ref,MA}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg,MA}$  nondimensional. The values of  $D_{ref,MA}$  and  $S_{ref,MA}$  are arbitrary because the  $G_{MA}$  calculation overrides these values.

---

### Moist Air Condensation

The equation describing the heat flow rate from the wall to the moist air in the segment (the last equation in the “Heat Transfer” on page 1-1813 section) uses the average moist air mixture enthalpy,  $\bar{h}_{seg,MA}$ , and the wall segment moist air mixture enthalpy,  $\bar{h}_{seg,wall}$ .

The average moist air mixture enthalpy is based on the temperature and humidity of the moist air flow through the segment:

$$\bar{h}_{seg,MA} = h_{seg,ag,MA} + W_{seg,MA}h_{seg,w,MA},$$

where:

- $h_{seg,ag,MA}$  is the average specific enthalpy of dry air and trace gas for the segment.
- $h_{seg,w,MA}$  is the average specific enthalpy of water vapor for the segment.
- $W_{seg,MA}$  is the humidity ratio of the segment.

The wall segment moist air mixture enthalpy is based on the temperature and humidity at the wall segment:

$$\bar{h}_{seg,wall} = h_{seg,ag,wall} + W_{seg,wall}h_{seg,w,wall},$$

where:

- $h_{seg,ag,wall}$  is the specific enthalpy of dry air and trace gas at the wall segment temperature.
- $h_{seg,w,wall}$  is the specific enthalpy of water vapor at the wall segment temperature.
- $W_{seg,wall}$  is the humidity ratio at the wall segment:

$$W_{seg,wall} = \min(W_{seg,MA}, W_{seg,s,wall}),$$

where  $W_{seg,s,wall}$  is the saturated humidity ratio at the wall segment temperature. In other words, the humidity ratio at the wall is the same as the humidity ratio of the moist air flow but not more than the maximum that can be supported at the wall segment temperature.

When  $W_{seg,s,wall} < W_{seg,MA}$ , water vapor condensation occurs on the wall surface. The rate of water vapor condensation is

$$\dot{m}_{w,seg,cond} = \frac{UA_{seg,MA}}{c_{pseg,MA}}(W_{seg,MA} - W_{seg,wall}).$$

The condensed water is assumed to be drained from the wall surface and is thus removed from the moist air flow downstream.

### Pressure Loss

The pressure losses on the two-phase fluid side are

$$p_{A,2P} - p_{2P} = \frac{K_{2P} \dot{m}_{A,2P} \sqrt{\dot{m}_{A,2P}^2 + \dot{m}_{thres,2P}^2}}{2 \rho_{avg,2P}}$$

$$p_{B,2P} - p_{2P} = \frac{K_{2P} \dot{m}_{B,2P} \sqrt{\dot{m}_{B,2P}^2 + \dot{m}_{thres,2P}^2}}{2 \rho_{avg,2P}}$$

where:

- $p_{A,2P}$  and  $p_{B,2P}$  are the pressures at ports **A1** and **B1**, respectively.
- $p_{2P}$  is internal two-phase fluid pressure at which the heat transfer is calculated.
- $\dot{m}_{A,2P}$  and  $\dot{m}_{B,2P}$  are the mass flow rates into ports **A1** and **B1**, respectively.
- $\rho_{avg,2P}$  is the average two-phase fluid density over all segments.
- $\dot{m}_{thres,2P}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{2P}$ , so that  $p_{A,2P} - p_{B,2P}$  matches the nominal pressure loss at the nominal mass flow rate.

The pressure losses on the moist air side are

$$p_{A,MA} - p_{MA} = \frac{K_{MA} \dot{m}_{A,MA} \sqrt{\dot{m}_{A,MA}^2 + \dot{m}_{thres,MA}^2}}{2 \rho_{avg,2P}}$$

$$p_{B,MA} - p_{MA} = \frac{K_{MA} \dot{m}_{B,MA} \sqrt{\dot{m}_{B,MA}^2 + \dot{m}_{thres,MA}^2}}{2 \rho_{avg,MA}}$$

where:

- $p_{A,MA}$  and  $p_{B,MA}$  are the pressures at ports **A2** and **B2**, respectively.
- $p_{MA}$  is internal moist air pressure at which the heat transfer is calculated.
- $\dot{m}_{A,MA}$  and  $\dot{m}_{B,MA}$  are the mass flow rates into ports **A2** and **B2**, respectively.
- $\rho_{avg,MA}$  is the average moist air density over all segments.
- $\dot{m}_{thres,MA}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{MA}$ , so that  $p_{A,MA} - p_{B,MA}$  matches the nominal pressure loss at the nominal mass flow rate.

### Two-Phase Fluid Mass and Energy Conservation

The mass conservation equation for the overall two-phase fluid flow is

$$\left( \frac{dp_{2P}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg,2P}}{\partial p} \right) + \sum_{segments} \left( \frac{du_{seg,2P}}{dt} \frac{\partial \rho_{seg,2P}}{\partial u} \right) \right) \frac{V_{2P}}{N} = \dot{m}_{A,2P} + \dot{m}_{B,2P},$$

where:

- $\frac{\partial \rho_{seg,2P}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg,2P}}{\partial u}$  is the partial derivative of density with respect to specific internal energy for the segment.

- $u_{seg,2P}$  is the specific internal energy for the segment.
- $V_{2P}$  is the total two-phase fluid volume.

The summation is over all segments.

---

**Note** Although the two-phase fluid flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{2P}$ . That is why  $p_{2P}$  is outside of the summation.

---

The energy conservation equation for each segment is

$$\frac{du_{seg,2P}}{dt} \frac{M_{2P}}{N} + u_{seg,2P}(\dot{m}_{seg,in,2P} - \dot{m}_{seg,out,2P}) = \Phi_{seg,in,2P} - \Phi_{seg,out,2P} + Q_{seg,2P},$$

where:

- $M_{2P}$  is the total two-phase fluid mass.
- $\dot{m}_{seg,in,2P}$  and  $\dot{m}_{seg,out,2P}$  are the mass flow rates into and out of the segment.
- $\Phi_{seg,in,2P}$  and  $\Phi_{seg,out,2P}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A,2P}$  and  $\dot{m}_{B,2P}$ .

### Moist Air Mass and Energy Conservation

The mass conservation for the overall moist air mixture flow is

$$\left( \frac{dp_{MA}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg,MA}}{\partial p} \right) + \sum_{segments} \left( \frac{dT_{seg,MA}}{dt} \frac{\partial \rho_{seg,MA}}{\partial T} + \frac{dx_{w,seg,MA}}{dt} \frac{\partial \rho_{seg,MA}}{\partial x_w} + \frac{dx_{g,seg,MA}}{dt} \frac{\partial \rho_{seg,MA}}{\partial x_g} \right) \right) \frac{V_{MA}}{N} = \dot{m}_{A,MA} + \dot{m}_{B,MA} - \sum_{segments} (\dot{m}_{w,seg,cond}),$$

where:

- $\frac{\partial \rho_{seg,MA}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg,MA}}{\partial T}$  is the partial derivative of density with respect to temperature for the segment.
- $\frac{\partial \rho_{seg,MA}}{\partial x_w}$  is the partial derivative of density with respect to specific humidity for the segment.
- $\frac{\partial \rho_{seg,MA}}{\partial x_g}$  is the partial derivative of density with respect to trace gas mass fraction for the segment.
- $x_{w,seg,MA}$  is the specific humidity, that is, the water vapor mass fraction, for the segment.
- $x_{g,seg,MA}$  is the trace gas mass fraction for the segment.
- $V_{MA}$  is the total moist air volume.

The summation is over all segments.

**Note** Although the moist air flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{MA}$ . That is why  $p_{MA}$  is outside of the summation.

The energy conservation equation for each segment is

$$\left( \frac{dT_{seg,MA}}{dt} \frac{\partial u_{seg,MA}}{\partial T} + \frac{dx_{w,seg,MA}}{dt} \frac{\partial u_{seg,MA}}{\partial x_w} + \frac{dx_{g,seg,MA}}{dt} \frac{\partial u_{seg,MA}}{\partial x_g} \right) \frac{M_{MA}}{N} + u_{seg,MA} (\dot{m}_{seg,in,MA} - \dot{m}_{seg,out,MA}) - \Phi_{seg,in,MA} + \Phi_{seg,out,MA} + Q_{seg,MA} - \dot{m}_{w,seg,cond} h_{l,wall},$$

where:

- $\frac{\partial u_{seg,MA}}{\partial T}$  is the partial derivative of specific internal energy with respect to temperature for the segment.
- $\frac{\partial u_{seg,MA}}{\partial x_w}$  is the partial derivative of specific internal energy with respect to specific humidity for the segment.
- $\frac{\partial u_{seg,MA}}{\partial x_g}$  is the partial derivative of specific internal energy with respect to trace gas mass fraction for the segment.
- $u_{seg,2P}$  is the specific internal energy for the segment.
- $M_{MA}$  is the total moist air mass.
- $\dot{m}_{seg,in,MA}$  and  $\dot{m}_{seg,out,MA}$  are the mass flow rates into and out of the segment.
- $\Phi_{seg,in,MA}$  and  $\Phi_{seg,out,MA}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A,MA}$  and  $\dot{m}_{B,MA}$ .

The water vapor mass conservation equation for each segment is

$$\frac{dx_{w,seg,MA}}{dt} \frac{M_{MA}}{N} + x_{w,seg,MA} (\dot{m}_{seg,in,MA} - \dot{m}_{seg,out,MA}) = \dot{m}_{w,seg,in,MA} - \dot{m}_{w,seg,out,MA} - \dot{m}_{w,seg,cond},$$

where  $\dot{m}_{w,seg,in,MA}$  and  $\dot{m}_{w,seg,out,MA}$  are the water vapor mass flow rates into and out of the segment.

The trace gas mass conservation equation for each segment is

$$\frac{dx_{g,seg,MA}}{dt} \frac{M_{MA}}{N} + x_{g,seg,MA} (\dot{m}_{seg,in,MA} - \dot{m}_{seg,out,MA}) = \dot{m}_{g,seg,in,MA} - \dot{m}_{g,seg,out,MA},$$

where  $\dot{m}_{g,seg,in,MA}$  and  $\dot{m}_{g,seg,out,MA}$  are the trace gas mass flow rates into and out of the segment.

## Ports

### Output

**Q1** — Rate of heat transfer to two-phase fluid, W  
physical signal

Rate of heat transfer to two-phase fluid, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to **On**, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

**Q2** — Rate of heat transfer to moist air, W  
physical signal

Rate of heat transfer to moist air, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to **On**, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

**W** — Moist air condensation rate, kg/s  
physical signal

Water condensation rate in the moist air flow, returned as a physical signal. The condensate does not accumulate on the heat transfer surface.

### Conserving

**A1** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**B1** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**A2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

**B2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

## Parameters

### Configuration

#### Flow arrangement at nominal operating condition — Flow path alignment

Counter flow - Two-Phase Fluid 1 flows from A to B, Moist Air 2 flows from B to A (default) | Parallel flow - Both fluids flow from A to B | Cross flow - Both fluids flow from A to B

Flow path alignment between the heat exchanger sides at nominal operating condition. The available flow arrangements are:

- Counter flow - Two-Phase Fluid 1 flows from A to B, Moist Air 2 flows from B to A — The flows run parallel to each other, in the opposite directions.
- Parallel flow - Both fluids flow from A to B — The flows run in the same direction.
- Cross flow - Both fluids flow from A to B — The flows run perpendicular to each other.

The choice between parallel flow and counter flow affects how the block determines the size of the heat exchanger. Counter flow is the most effective, therefore it will need the smallest size to meet the specified performance. Conversely, parallel flow is the least effective, therefore it will need the biggest size to meet the specified performance.

Flow direction at nominal condition (from A to B, or from B to A) affects only the model initialization, in case if you set the **Initial condition specification** parameter to Same as nominal operating condition. If you set up different initial operating conditions, the flow directions can be different.

Once the size is determined, the choice between parallel and counter does not play a role in how the block calculates the heat transfer during simulation. Instead, the heat transfer depends on the flow directions during simulation. If you set the parameter to parallel flow but set up the model to run in counter flow (or the other way around), then the rate of heat transfer during simulation will not match the specified performance, even if the rest of the boundary conditions are the same.

If you set the parameter to cross flow, then the flow paths are modeled as perpendicular inside the heat exchanger, so the flow directions during simulation do not matter.

#### Wall thermal mass — Enable or disable effect of thermal mass on heat transfer surface

Off (default) | On

Enable or disable the effect of thermal mass on the heat transfer surface. Setting this parameter to On introduces additional dynamics to the simulation, so that it takes longer to reach steady state, but does not affect the results at steady-state simulation.

#### Wall mass — Mass of heat transfer surface

1 kg (default) | positive scalar

Mass of the heat transfer surface.

### Dependencies

To enable this parameter, set **Wall thermal mass** to On.

#### Wall specific heat — Specific heat of heat transfer surface

490 J/(K\*kg) (default) | positive scalar

Specific heat of the heat transfer surface.

**Dependencies**

To enable this parameter, set **Wall thermal mass** to 0n.

**Cross-sectional area at port A1** — Flow area at port A1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **A1**.

**Cross-sectional area at port B1** — Flow area at port B1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **B1**.

**Cross-sectional area at port A2** — Flow area at port A2  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air port **A2**.

**Cross-sectional area at port B2** — Area normal to flow at port B2  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air port **B2**.

**Two-Phase Fluid 1**

**Nominal operating condition** — Select whether nominal operating condition corresponds to condenser or evaporator

Condenser - heat transfer from two-phase fluid to moist air (default) | Evaporator  
- heat transfer from moist air to two-phase fluid

Select the nominal operating condition:

- Condenser - heat transfer from two-phase fluid to moist air — The two-phase fluid is being cooled and the moist air is being heated.
- Evaporator - heat transfer from moist air to two-phase fluid — The moist air is being cooled and the two-phase fluid is being heated.

This choice relates only to specifying the nominal operating condition parameters. It does not mean that heat transfer can only happen in the specified direction during simulation.

**Nominal mass flow rate** — Mass flow rate between two-phase ports during nominal operating condition

0.001 kg/s (default) | positive scalar

Mass flow rate from port **A1** to port **B1** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between two-phase ports during nominal operating condition

0.01 MPa (default) | positive scalar

Pressure drop from port **A1** to port **B1** during the nominal operating condition.

**Pressure specification** — Select method of pressure specification

Inlet pressure (default) | Saturation pressure at specified condensing temperature  
| Saturation pressure at specified evaporating temperature

Select the method of pressure specification:

- Inlet pressure — Specify the nominal inlet pressure.
- Saturation pressure at specified condensing temperature — Specify the nominal condensing temperature. This option is available if you set **Nominal operating condition** to Condenser - heat transfer from two-phase fluid to moist air.
- Saturation pressure at specified evaporating temperature — Specify the nominal evaporating temperature. This option is available if you set **Nominal operating condition** to Evaporator - heat transfer from moist air to two-phase fluid.

**Nominal inlet pressure** — Pressure at the two-phase fluid side inlet

1 MPa (default) | positive scalar

Pressure at the inlet of the two-phase fluid side of the heat exchanger during nominal operating condition.

#### Dependencies

To enable this parameter, set **Pressure specification** to Inlet pressure.

**Nominal condensing temperature** — Use nominal condensing temperature to specify pressure

313.15 K (default) | positive scalar

Liquid saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during nominal operating condition. The pressure in the heat exchanger is the corresponding saturation pressure. The nominal condensing temperature must be less than the critical temperature.

#### Dependencies

To enable this parameter, set **Nominal operating condition** to Condenser - heat transfer from two-phase fluid to moist air and **Pressure specification** to Saturation pressure at specified condensing temperature.

**Nominal evaporating temperature** — Use nominal evaporating temperature to specify pressure

243.15 K (default) | positive scalar

Vapor saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during nominal operating condition. The pressure in the heat exchanger is the corresponding saturation pressure. The nominal evaporating temperature must be less than the critical temperature.

#### Dependencies

To enable this parameter, set **Nominal operating condition** to Evaporator - heat transfer from moist air to two-phase fluid and **Pressure specification** to Saturation pressure at specified evaporating temperature.

**Inlet condition specification** — Select quantity to describe the inlet condition of the two-phase fluid

Specific enthalpy (default) | Temperature | Vapor quality

Quantity used to describe the inlet condition of the fluid at the nominal operating condition: temperature, specific enthalpy, or vapor quality.

**Nominal inlet specific enthalpy** — Specific enthalpy at the two-phase fluid side inlet  
440 kJ/kg (default) | positive scalar

Specific enthalpy at the inlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Specific enthalpy.

**Nominal inlet temperature** — Temperature at the two-phase fluid side inlet  
313.15 K (default) | positive scalar

Temperature at the inlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Vapor quality at the two-phase fluid side inlet  
1 (default) | positive scalar

Vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the inlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Vapor quality.

**Heat transfer capacity specification** — Select how to specify heat transfer capacity of the two-phase fluid  
Rate of heat transfer (default) | Outlet condition

Select whether to specify the performance of the heat exchanger at the nominal operating condition directly, by the rate of heat transfer, or indirectly, by the outlet condition.

**Nominal rate of heat transfer** — Specify performance by rate of heat transfer  
0.1 kW (default) | positive scalar

Rate of heat transfer, depending on the nominal operating condition:

- If **Nominal operating condition** is Condenser - heat transfer from two-phase fluid to moist air, rate of heat transfer from the two-phase fluid to the moist air during the nominal operating condition.
- If **Nominal operating condition** is Evaporator - heat transfer from moist air to two-phase fluid, rate of heat transfer from the moist air to the two-phase fluid during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Heat transfer capacity specification** to Rate of heat transfer.

**Outlet condition specification** — Select quantity for outlet condition specification  
Specific enthalpy (default) | Subcooling | Superheating | Vapor quality

Select the quantity for outlet condition specification:

- **Specific enthalpy** — Specify the nominal specific enthalpy.
- **Subcooling** — Specify the nominal subcooling. This option is available if you set **Nominal operating condition** to Condenser - heat transfer from two-phase fluid to moist air.
- **Superheating** — Specify the nominal superheating. This option is available if you set **Nominal operating condition** to Evaporator - heat transfer from moist air to two-phase fluid.
- **Vapor quality** — Specify the nominal vapor quality.

#### Dependencies

To enable this parameter, set **Heat transfer capacity specification** to Outlet condition.

**Nominal outlet specific enthalpy** — Specific enthalpy at the two-phase fluid side outlet  
250 kJ/kg (default) | positive scalar | two-element vector

Specific enthalpy at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Specific enthalpy.

**Nominal subcooling** — Degree of temperature below the liquid saturation temperature at the two-phase fluid side outlet  
5 deltaK (default) | positive scalar

Degree of temperature below the liquid saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Subcooling.

**Nominal superheating** — Degree of temperature above the vapor saturation temperature at the two-phase fluid side outlet  
5 deltaK (default) | positive scalar

Degree of temperature above the vapor saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Superheating.

**Nominal outlet vapor quality** — Vapor mass fraction at the two-phase fluid side outlet  
0 (default) | scalar in the range [0,1]

Two-phase fluid vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Vapor quality.

**Two-phase fluid volume** — Total volume of two-phase fluid  
0.001 m<sup>3</sup> (default) | positive scalar

Total volume of two-phase fluid inside the heat exchanger.

**Initial condition specification** — Select how to specify initial state of two-phase fluid  
Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of two-phase fluid:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.
- Specify initial condition — Specify a different set of initial conditions using additional parameters.

**Initial fluid energy specification** — Initial state of the two-phase fluid  
Specific enthalpy (default) | Temperature | Vapor quality | Vapor void fraction |  
Specific internal energy

Quantity used to describe the initial state of the fluid.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- Temperature — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- Vapor quality — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- Vapor void fraction — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- Specific enthalpy — Specify the specific enthalpy of the fluid. The block does not limit the initial state.
- Specific internal energy — Specify the specific internal energy of the fluid. The block does not limit the initial state.

### Dependencies

To enable this parameter, set **Initial condition specification** to Specify initial condition.

**Initial two-phase fluid pressure** — Fluid pressure at start of simulation  
0.101325 MPa (default) | positive scalar

Two-phase fluid pressure at the start of the simulation.

**Initial two-phase fluid specific enthalpy** — Enthalpy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid specific enthalpy at the start of simulation. If the value is a scalar, then the initial specific enthalpy is assumed uniform. If the value is a two-element vector, then the initial specific

enthalpy is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific enthalpy.

**Initial two-phase fluid temperature** — Temperature at start of simulation

293.15 K (default) | positive scalar | two-element vector

Two-phase fluid temperature at the start of simulation. If the value is a scalar, then the initial temperature is assumed uniform. If the value is a two-element vector, then the initial temperature is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Temperature.

**Initial two-phase fluid vapor quality** — Vapor mass fraction at start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor quality is assumed uniform. If the value is a two-element vector, then the initial vapor quality is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

If using this option, the initial pressure cannot be higher than the critical pressure.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor quality.

**Initial two-phase fluid vapor void fraction** — Vapor volume fraction at start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid vapor void fraction, defined as the volume fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor void fraction is assumed uniform. If the value is a two-element vector, then the initial vapor void fraction is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

If using this option, the initial pressure cannot be higher than the critical pressure.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor void fraction.

**Initial two-phase fluid specific internal energy** — Internal energy per unit mass at start of simulation

1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid specific internal energy at the start of simulation. If the value is a scalar, then the initial specific internal energy is assumed uniform. If the value is a two-element vector, then the initial specific internal energy is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

**Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Specific internal energy.

**Moist Air 2**

**Nominal mass flow rate** — Mass flow rate between moist air ports during nominal operating condition

0.1 kg/s (default) | positive scalar

Mass flow rate from port **A2** to port **B2** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between moist air ports during nominal operating condition

0.001 MPa (default) | positive scalar

Pressure drop from port **A2** to port **B2** during the nominal operating condition.

**Nominal inlet pressure** — Pressure at the moist air side inlet

0.101325 MPa (default) | positive scalar

Pressure at the inlet of the moist air side of the heat exchanger during nominal operating condition.

**Nominal inlet temperature** — Temperature at the moist air side inlet

293.15 K (default) | positive scalar

Temperature at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

**Inlet moisture specification** — Quantity used to describe the moisture level at the moist air side inlet

Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Select quantity used to describe the moisture level at the inlet during the nominal operating condition: relative humidity, specific humidity, water vapor mole fraction, or humidity ratio.

**Nominal inlet relative humidity** — Relative humidity at the inlet

0.5 (default) | scalar in the range [0,1]

Relative humidity at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet moisture specification** to Relative humidity.

**Nominal inlet specific humidity** — Specific humidity at the inlet

0.01 (default) | scalar in the range [0,1]

Specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet moisture specification** to Specific humidity.

**Nominal inlet water vapor mole fraction** — Mole fraction of water vapor at the inlet

0.01 (default) | scalar in the range [0,1]

Mole fraction of water vapor in a moist air mixture at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Inlet moisture specification** to Mole fraction.

**Nominal inlet humidity ratio** — Humidity ratio at the inlet

0.01 (default) | positive scalar in the range [0,1]

Humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Inlet moisture specification** to Humidity ratio.

**Inlet trace gas specification** — Quantity used to describe trace gas level at the inlet

Mass fraction (default) | Mole fraction

Select quantity used to describe the trace gas level at the inlet during the nominal operating condition: mass fraction or mole fraction.

**Nominal inlet trace gas mass fraction** — Mass fraction of trace gas at the inlet

0.001 (default) | scalar in the range [0,1]

Mass fraction of trace gas in a moist air mixture at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to None.

#### Dependencies

To enable this parameter, set **Inlet trace gas specification** to Mass fraction.

**Nominal inlet trace gas mole fraction** — Mole fraction of trace gas at the inlet

0.001 (default) | scalar in the range [0,1]

Mole fraction of trace gas in a moist air mixture at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to None.

#### Dependencies

To enable this parameter, set **Inlet trace gas specification** to Mole fraction.

**Moist air volume** — Total volume of moist air in the heat exchanger

0.1 m<sup>3</sup> (default) | positive scalar

Total volume of moist air in the heat exchanger.

**Initial condition specification** — Select how to specify initial state of moist air

Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of moist air:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.
- Specify initial condition — Specify a different set of initial conditions using additional parameters.

**Initial moist air pressure** — Moist air pressure at start of simulation  
0.101325 MPa (default) | positive scalar

Moist air pressure at the start of the simulation.

**Initial moist air temperature** — Moist air temperature at start of simulation  
293.15 K (default) | positive scalar | two-element vector

Moist air temperature at the start of simulation. If the value is a scalar, then the initial temperature is assumed uniform. If the value is a two-element vector, then the initial temperature is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

**Initial moisture specification** — Quantity used to describe the initial moisture level  
Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Select quantity used to describe the initial moisture level: relative humidity, specific humidity, water vapor mole fraction, or humidity ratio.

**Initial moist air relative humidity** — Relative humidity at the start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Moist air relative humidity at the start of simulation. If the value is a scalar, then the initial relative humidity is assumed uniform. If the value is a two-element vector, then the initial relative humidity is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

#### **Dependencies**

To enable this parameter, set **Initial moisture specification** to Relative humidity.

**Initial moist air specific humidity** — Specific humidity at the start of simulation  
0.01 (default) | scalar in the range [0,1] | two-element vector

Moist air specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the start of simulation. If the value is a scalar, then the initial specific humidity is assumed uniform. If the value is a two-element vector, then the initial specific humidity is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

#### **Dependencies**

To enable this parameter, set **Initial moisture specification** to Specific humidity.

**Initial moist air water vapor mole fraction** — Mole fraction of water vapor at the start of simulation  
0.01 (default) | scalar in the range [0,1] | two-element vector

Mole fraction of water vapor in a moist air mixture at the start of simulation. If the value is a scalar, then the initial mole fraction is assumed uniform. If the value is a two-element vector, then the initial

mole fraction is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

#### Dependencies

To enable this parameter, set **Initial moisture specification** to `Mole fraction`.

**Initial moist air humidity ratio** — Humidity ratio at the start of simulation  
`0.01` (default) | positive scalar in the range `[0,1]` | two-element vector

Moist air humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the start of simulation. If the value is a scalar, then the initial humidity ratio is assumed uniform. If the value is a two-element vector, then the initial humidity ratio is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

#### Dependencies

To enable this parameter, set **Initial moisture specification** to `Humidity ratio`.

**Initial trace gas specification** — Quantity used to describe initial trace gas level  
`Mass fraction` (default) | `Mole fraction`

Select quantity used to describe the trace gas level at the start of simulation: mass fraction or mole fraction.

**Initial moist air trace gas mass fraction** — Mass fraction of trace gas at the start of simulation  
`0.001` (default) | scalar in the range `[0,1]` | two-element vector

Mass fraction of trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the initial mass fraction is assumed uniform. If the value is a two-element vector, then the initial mass fraction is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

#### Dependencies

To enable this parameter, set **Initial trace gas specification** to `Mass fraction`.

**Initial moist air trace gas mole fraction** — Mole fraction of trace gas at the start of simulation  
`0.001` (default) | scalar in the range `[0,1]` | two-element vector

Mole fraction of trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the initial mole fraction is assumed uniform. If the value is a two-element vector, then the initial mole fraction is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

#### Dependencies

To enable this parameter, set **Initial trace gas specification** to `Mole fraction`.

**Relative humidity at saturation** — Relative humidity point of condensation

1 (default) | nonnegative scalar

Relative humidity point of condensation. Condensation occurs above this value. In most cases, this value is 1, that is, 100%. A value greater than 1 indicates a supersaturated vapor.

**Correlation Coefficients****a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid liquid** — Correlation coefficient for subcooled liquid in two-phase fluid

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for subcooled liquid in two-phase fluid. The default value is based on the Colburn equation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid mixture** — Correlation coefficient for liquid-vapor mixture in two-phase fluid

0.005 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for liquid-vapor mixture in two-phase fluid. The default value is based on the Cavallini and Zecchin correlation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid vapor** — Correlation coefficient for superheated vapor in two-phase fluid

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for superheated vapor in two-phase fluid. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid** — Reynolds number exponent in correlation for two-phase fluid

0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid** — Prandtl number exponent in correlation for two-phase fluid

0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for moist air** — Correlation coefficient for moist air

0.005 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for moist air. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for moist air** — Reynolds number exponent in correlation for moist air  
0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for moist air. The default value is based on the Colburn equation.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for moist air** — Prandtl number exponent in correlation for moist air  
0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for moist air. The default value is based on the Colburn equation.

## System-Level Condenser Evaporator (2P-TL)

Heat exchanger between two-phase fluid and thermal liquid networks, with model based on performance data

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

### Description

The System-Level Condenser Evaporator (2P-TL) block models a heat exchanger between a two-phase fluid network and a thermal liquid network.

The block can act as a condenser or as an evaporator in a refrigeration system, depending on the direction of heat transfer. The block model is based on performance data from the heat exchanger datasheet, rather than on the detailed geometry of the exchanger, and therefore lets you easily adjust the size and performance of the heat exchanger during design iterations, or model heat exchangers with uncommon geometries. You can also use this block to model heat exchangers with a certain level of performance at an early design stage, when detailed geometry data is not yet available.

You parameterize the block by the nominal operating condition. The heat exchanger is sized to match the specified performance at the nominal operating condition at steady state.

The Two-Phase Fluid 1 side approximates the liquid zone, mixture zone, and vapor zone based on the change in enthalpy along the flow path.

This block is similar to the Condenser Evaporator (TL-2P) block but uses a different parameterization model. The table provides a comparison of the two blocks, to help you choose the right block for your application.

Condenser Evaporator (TL-2P)	System-Level Condenser Evaporator (2P-TL)
Block parameters are based on the heat exchanger geometry	Block parameters are based on performance and operating conditions
Heat exchanger geometry may be limited by the available geometry parameter options	Model is independent of the specific heat exchanger geometry
You can adjust the block for different performance requirements by tuning geometry parameters, such as fin sizes and tube lengths	You can adjust the block for different performance requirements by directly specifying the desired heat and mass flow rates
Lets you select between parallel, counter, or cross flow configurations	Lets you select between parallel, counter, or cross flow arrangement at nominal operating conditions, to help with sizing
Predictively accurate results over a wide range of operating conditions, subject to the applicability of the E-NTU equations and the heat transfer coefficient correlations	Very accurate results around the specified operating condition; accuracy may decrease far away from the specified operating conditions

Condenser Evaporator (TL-2P)	System-Level Condenser Evaporator (2P-TL)
Heat transfer calculations account for the variation of temperature along the flow path by using the E-NTU model	Heat transfer calculations approximate the variation of temperature along the flow path by dividing it into three segments
Accounts for different fluid properties and heat transfer coefficients for subcooled liquid, liquid-vapor mixture, and superheated vapor	Accounts for different fluid properties and heat transfer coefficients for subcooled liquid, liquid-vapor mixture, and superheated vapor
Keeps track of variable zone length fractions for subcooled liquid, liquid-vapor mixture, and superheated vapor regions based on the geometry	Approximates the effect of subcooled liquid, liquid-vapor mixture, and superheated vapor regions using weighting factors based on the difference in enthalpy between inlet and outlet
Does not model the wall thermal mass; you can approximate the effect by connecting a pipe block with a thermal mass downstream	Includes an option to model the wall thermal mass

### Heat Transfer

The two-phase fluid flow and the thermal liquid flow are each divided into three segments of equal size. Heat transfer between the fluids is calculated in each segment. For simplicity, the equation for one segment is shown here.

If the wall thermal mass is off, then the heat balance in the heat exchanger is

$$Q_{seg, 2P} + Q_{seg, TL} = 0,$$

where:

- $Q_{seg, 2P}$  is the heat flow rate from the wall (that is, the heat transfer surface) to the two-phase fluid in the segment.
- $Q_{seg, TL}$  is the heat flow rate from the wall to the thermal liquid in the segment.

If the wall thermal mass is on, then the heat balance in the heat exchanger is

$$Q_{seg, 2P} + Q_{seg, TL} = - \frac{M_{wall} c_{pwall}}{N} \frac{dT_{seg, wall}}{dt},$$

where:

- $M_{wall}$  is the mass of the wall.
- $c_{pwall}$  is the specific heat of the wall.
- $N = 3$  is the number of segments.
- $T_{seg, wall}$  is the average wall temperature in the segment.
- $t$  is time.

The heat flow rate from the wall to the two-phase fluid in the segment is

$$Q_{seg, 2P} = UA_{seg, 2P}(T_{seg, wall} - T_{seg, 2P}),$$

where:

- $UA_{seg,2P}$  is the weighted-average heat transfer conductance for the two-phase fluid in the segment.
- $T_{seg,2P}$  is the weighted-average fluid temperature for the two-phase fluid in the segment.

The heat flow rate from the wall to the thermal liquid in the segment is

$$Q_{seg,TL} = UA_{seg,TL}(T_{seg,wall} - T_{seg,TL}),$$

where:

- $UA_{seg,TL}$  is the heat transfer conductance for the thermal liquid in the segment.
- $T_{seg,TL}$  is the average liquid temperature in the segment.

### Two-Phase Fluid Heat Transfer Correlation

If the segment is subcooled liquid, then the heat transfer conductance is

$$UA_{seg,L,2P} = a_{L,2P}(Re_{seg,L,2P})^{b_{2P}}(Pr_{seg,L,2P})^{c_{2P}}k_{seg,L,2P}\frac{G_{2P}}{N},$$

where:

- $a_{L,2P}$ ,  $b_{2P}$ , and  $c_{2P}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,L,2P}$  is the average liquid Reynolds number for the segment.
- $Pr_{seg,L,2P}$  is the average liquid Prandtl number for the segment.
- $k_{seg,L,2P}$  is the average liquid thermal conductivity for the segment.
- $G_{2P}$  is the geometry scale factor for the two-phase fluid side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average liquid Reynolds number is

$$Re_{seg,L,2P} = \frac{\dot{m}_{seg,2P}D_{ref,2P}}{\mu_{seg,L,2P}S_{ref,2P}},$$

where:

- $\dot{m}_{seg,2P}$  is the mass flow rate through the segment.
- $\mu_{seg,L,2P}$  is the average liquid dynamic viscosity for the segment.
- $D_{ref,2P}$  is an arbitrary reference diameter.
- $S_{ref,2P}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref,2P}$  and  $S_{ref,2P}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg,L,2P}$  nondimensional. The values of  $D_{ref,2P}$  and  $S_{ref,2P}$  are arbitrary because the  $G_{2P}$  calculation overrides these values.

---

Similarly, if the segment is superheated vapor, then the heat transfer conductance is

$$UA_{seg,V,2P} = a_{V,2P}(Re_{seg,V,2P})^{b_{2P}}(Pr_{seg,V,2P})^{c_{2P}}k_{seg,V,2P}\frac{G_{2P}}{N},$$

where:

- $a_{V,2P}$ ,  $b_{2P}$ , and  $c_{2P}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,V,2P}$  is the average vapor Reynolds number for the segment.
- $Pr_{seg,V,2P}$  is the average vapor Prandtl number for the segment.
- $k_{seg,V,2P}$  is the average vapor thermal conductivity for the segment.

The average vapor Reynolds number is

$$Re_{seg,V,2P} = \frac{\dot{m}_{seg,2P} D_{ref,2P}}{\mu_{seg,V,2P} S_{ref,2P}}$$

where  $\mu_{seg,V,2P}$  is the average vapor dynamic viscosity for the segment.

If the segment is liquid-vapor mixture, then the heat transfer conductance is

$$UA_{seg,M,2P} = a_{M,2P} (Re_{seg,SL,2P})^{b_{2P}} CZ (Pr_{seg,SL,2P})^{c_{2P}} k_{seg,SL,2P} \frac{G_{2P}}{N}$$

where:

- $a_{M,2P}$ ,  $b_{2P}$ , and  $c_{2P}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,SL,2P}$  is the saturated liquid Reynolds number for the segment.
- $Pr_{seg,SL,2P}$  is the saturated liquid Prandtl number for the segment.
- $k_{seg,SL,2P}$  is the saturated liquid thermal conductivity for the segment.
- $CZ$  is the Cavallini and Zecchin term.

The saturated liquid Reynolds number is

$$Re_{seg,SL,2P} = \frac{\dot{m}_{seg,2P} D_{ref,2P}}{\mu_{seg,SL,2P} S_{ref,2P}}$$

where  $\mu_{seg,SL,2P}$  is the saturated liquid dynamic viscosity for the segment.

The Cavallini and Zecchin term is

$$CZ = \frac{\left( \left( \sqrt{\frac{\nu_{seg,SV,2P}}{\nu_{seg,SL,2P}}} - 1 \right) (\chi_{seg,out,2P} + 1) \right)^{1+b_{2P}} - \left( \left( \sqrt{\frac{\nu_{seg,SV,2P}}{\nu_{seg,SL,2P}}} - 1 \right) (\chi_{seg,in,2P} + 1) \right)^{1+b_{2P}}}{(1+b_{2P}) \left( \sqrt{\frac{\nu_{seg,SV,2P}}{\nu_{seg,SL,2P}}} - 1 \right) (\chi_{seg,out,2P} - \chi_{seg,in,2P})}$$

where:

- $\nu_{seg,SL,2P}$  is the saturated liquid specific volume for the segment.
- $\nu_{seg,SV,2P}$  is the saturated vapor specific volume for the segment.
- $\chi_{seg,in,2P}$  is the vapor quality at the segment inlet.
- $\chi_{seg,out,2P}$  is the vapor quality at the segment outlet.

The expression is based on the work of Cavallini and Zecchin [5], which derives a heat transfer coefficient correlation at a local vapor quality  $x$ . Equations for the liquid-vapor mixture are obtained by averaging Cavallini and Zecchin's correlation over the segment from  $x_{seg,in,2P}$  to  $x_{seg,out,2P}$ .

### Two-Phase Fluid Weighted Average

The two-phase fluid flow through a segment may not be entirely represented as either subcooled liquid, superheated vapor, or liquid-vapor mixture. Instead, each segment may consist of a combination of these. The block approximates this condition by computing weighting factors ( $w_L$ ,  $w_V$ , and  $w_M$ ) based on the change in specific enthalpy across the segment and the saturated liquid and vapor specific enthalpies. The block assumes that the specific enthalpy across the segment varies piecewise linearly from inlet to outlet, with the breakpoints corresponding to the saturation boundaries for liquid and vapor. The zone with a larger heat transfer coefficient has a steeper slope than the zone with a lower heat transfer coefficient.

$$w_L = \frac{\Delta_L}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_V = \frac{\Delta_V}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_M = 1 - w_L - w_V$$

$$\Delta_L = |\min(h_{seg,out,2P}, h_{seg,SL,2P}) - \min(h_{seg,in,2P}, h_{seg,SL,2P})| \cdot UA_{seg,M,2P} \cdot UA_{seg,V,2P}$$

$$\Delta_M = |\min(\max(h_{seg,out,2P}, h_{seg,SL,2P}), h_{seg,SV,2P}) - \min(\max(h_{seg,in,2P}, h_{seg,SL,2P}), h_{seg,SV,2P})| \cdot UA_{seg,L,2P} \cdot UA_{seg,M,2P}$$

$$\Delta_V = |\max(h_{seg,out,2P}, h_{seg,SV,2P}) - \max(h_{seg,in,2P}, h_{seg,SV,2P})| \cdot UA_{seg,L,2P} \cdot UA_{seg,M,2P}$$

where:

- $h_{seg,in,2P}$  is the specific enthalpy at the segment inlet.
- $h_{seg,out,2P}$  is the specific enthalpy at the segment outlet.
- $h_{seg,SL,2P}$  is the saturated liquid specific enthalpy for the segment.
- $h_{seg,SV,2P}$  is the saturated vapor specific enthalpy for the segment.

The weighted-average two-phase fluid heat transfer conductance for the segment is therefore

$$UA_{seg,2P} = w_L(UA_{seg,L,2P}) + w_V(UA_{seg,V,2P}) + w_M(UA_{seg,M,2P}).$$

The weighted-average fluid temperature for the segment is

$$T_{seg,2P} = \frac{w_L(UA_{seg,L,2P})T_{seg,L,2P} + w_V(UA_{seg,V,2P})T_{seg,V,2P} + w_M(UA_{seg,M,2P})T_{seg,M,2P}}{UA_{seg,2P}},$$

where:

- $T_{seg,L,2P}$  is the average liquid temperature for the segment.
- $T_{seg,V,2P}$  is the average vapor temperature for the segment.
- $T_{seg,M,2P}$  is the average mixture temperature for the segment, which is the saturated liquid temperature.

### Thermal Liquid Heat Transfer Correlation

The heat transfer conductance is

$$UA_{seg, TL} = a_{TL} (Re_{seg, TL})^{b_{TL}} (Pr_{seg, TL})^{c_{TL}} k_{seg, TL} \frac{G_{TL}}{N},$$

where:

- $a_{TL}$ ,  $b_{TL}$ , and  $c_{TL}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg, TL}$  is the average Reynolds number for the segment.
- $Pr_{seg, TL}$  is the average Prandtl number for the segment.
- $k_{seg, TL}$  is the average thermal conductivity for the segment.
- $G_{TL}$  is the geometry scale factor for the thermal liquid side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average Reynolds number is

$$Re_{seg, TL} = \frac{\dot{m}_{seg, TL} D_{ref, TL}}{\mu_{seg, TL} S_{ref, TL}},$$

where:

- $\dot{m}_{seg, TL}$  is the mass flow rate through the segment.
- $\mu_{seg, TL}$  is the average dynamic viscosity for the segment.
- $D_{ref, TL}$  is an arbitrary reference diameter.
- $S_{ref, TL}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref, TL}$  and  $S_{ref, TL}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg, TL}$  nondimensional. The values of  $D_{ref, TL}$  and  $S_{ref, TL}$  are arbitrary because the  $G_{TL}$  calculation overrides these values.

---

## Pressure Loss

The pressure losses on the two-phase fluid side are

$$p_{A, 2P} - p_{2P} = \frac{K_{2P} \dot{m}_{A, 2P} \sqrt{\dot{m}_{A, 2P}^2 + \dot{m}_{thres, 2P}^2}}{2 \rho_{avg, 2P}}$$

$$p_{B, 2P} - p_{2P} = \frac{K_{2P} \dot{m}_{B, 2P} \sqrt{\dot{m}_{B, 2P}^2 + \dot{m}_{thres, 2P}^2}}{2 \rho_{avg, 2P}}$$

where:

- $p_{A, 2P}$  and  $p_{B, 2P}$  are the pressures at ports **A1** and **B1**, respectively.
- $p_{2P}$  is internal two-phase fluid pressure at which the heat transfer is calculated.
- $\dot{m}_{A, 2P}$  and  $\dot{m}_{B, 2P}$  are the mass flow rates into ports **A1** and **B1**, respectively.
- $\rho_{avg, 2P}$  is the average two-phase fluid density over all segments.

- $\dot{m}_{thres, 2P}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{2P}$ , so that  $p_{A,2P} - p_{B,2P}$  matches the nominal pressure loss at the nominal mass flow rate.

The pressure losses on the thermal liquid side are

$$p_{A, TL} - p_{TL} = \frac{K_{TL} \dot{m}_{A, TL} \sqrt{\dot{m}_{A, TL}^2 + \dot{m}_{thres, TL}^2}}{2 \rho_{avg, 2P}}$$

$$p_{B, TL} - p_{TL} = \frac{K_{TL} \dot{m}_{B, TL} \sqrt{\dot{m}_{B, TL}^2 + \dot{m}_{thres, TL}^2}}{2 \rho_{avg, TL}}$$

where:

- $p_{A, TL}$  and  $p_{B, TL}$  are the pressures at ports **A2** and **B2**, respectively.
- $p_{TL}$  is internal thermal liquid pressure at which the heat transfer is calculated.
- $\dot{m}_{A, TL}$  and  $\dot{m}_{B, TL}$  are the mass flow rates into ports **A2** and **B2**, respectively.
- $\rho_{avg, TL}$  is the average thermal liquid density over all segments.
- $\dot{m}_{thres, TL}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{TL}$ , so that  $p_{A, TL} - p_{B, TL}$  matches the nominal pressure loss at the nominal mass flow rate.

### Two-Phase Fluid Mass and Energy Conservation

The mass conservation equation for the overall two-phase fluid flow is

$$\left( \frac{dp_{2P}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg, 2P}}{\partial p} \right) + \sum_{segments} \left( \frac{du_{seg, 2P}}{dt} \frac{\partial \rho_{seg, 2P}}{\partial u} \right) \right) \frac{V_{2P}}{N} = \dot{m}_{A, 2P} + \dot{m}_{B, 2P},$$

where:

- $\frac{\partial \rho_{seg, 2P}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg, 2P}}{\partial u}$  is the partial derivative of density with respect to specific internal energy for the segment.
- $u_{seg, 2P}$  is the specific internal energy for the segment.
- $V_{2P}$  is the total two-phase fluid volume.

The summation is over all segments.

---

**Note** Although the two-phase fluid flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{2P}$ . That is why  $p_{2P}$  is outside of the summation.

---

The energy conservation equation for each segment is

$$\frac{du_{seg, 2P}}{dt} \frac{M_{2P}}{N} + u_{seg, 2P} (\dot{m}_{seg, in, 2P} - \dot{m}_{seg, out, 2P}) = \Phi_{seg, in, 2P} - \Phi_{seg, out, 2P} + Q_{seg, 2P},$$

where:

- $M_{2P}$  is the total two-phase fluid mass.
- $\dot{m}_{seg, in, 2P}$  and  $\dot{m}_{seg, out, 2P}$  are the mass flow rates into and out of the segment.
- $\Phi_{seg, in, 2P}$  and  $\Phi_{seg, out, 2P}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A, 2P}$  and  $\dot{m}_{B, 2P}$ .

### Thermal Liquid Mass and Energy Conservation

The mass conservation for the overall thermal liquid flow is

$$\left( \frac{dp_{TL}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg, TL}}{\partial p} \right) + \sum_{segments} \left( \frac{dT_{seg, TL}}{dt} \frac{\partial \rho_{seg, TL}}{\partial T} \right) \right) \frac{V_{TL}}{N} = \dot{m}_{A, TL} + \dot{m}_{B, TL},$$

where:

- $\frac{\partial \rho_{seg, TL}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg, TL}}{\partial T}$  is the partial derivative of density with respect to temperature for the segment.
- $T_{seg, TL}$  is the temperature for the segment.
- $V_{TL}$  is the total thermal liquid volume.

The summation is over all segments.

---

**Note** Although the thermal liquid flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{TL}$ . That is why  $p_{TL}$  is outside of the summation.

---

The energy conservation equation for each segment is

$$\left( \frac{dp_{TL}}{dt} \frac{\partial u_{seg, TL}}{\partial p} + \frac{dT_{seg, TL}}{dt} \frac{\partial u_{seg, TL}}{\partial T} \right) \frac{M_{TL}}{N} + u_{seg, TL} (\dot{m}_{seg, in, TL} - \dot{m}_{seg, out, TL}) = \Phi_{seg, in, TL} - \Phi_{seg, out, TL} + Q_{seg, TL},$$

where:

- $\frac{\partial u_{seg, TL}}{\partial p}$  is the partial derivative of specific internal energy with respect to pressure for the segment.
- $\frac{\partial u_{seg, TL}}{\partial T}$  is the partial derivative of specific internal energy with respect to temperature for the segment.
- $M_{TL}$  is the total thermal liquid mass.
- $\dot{m}_{seg, in, TL}$  and  $\dot{m}_{seg, out, TL}$  are the mass flow rates into and out of the segment.

- $\Phi_{\text{seg,in,TL}}$  and  $\Phi_{\text{seg,out,TL}}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A,TL}$  and  $\dot{m}_{B,TL}$ .

## Ports

### Output

**Q1** — Rate of heat transfer to two-phase fluid, W  
physical signal

Rate of heat transfer to two-phase fluid, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to On, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

**Q2** — Rate of heat transfer to thermal liquid, W  
physical signal

Rate of heat transfer to thermal liquid, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to On, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

### Conserving

**A1** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**B1** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**A2** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

**B2** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

## Parameters

### Configuration

#### Flow arrangement at nominal operating condition — Flow path alignment

Counter flow - Two-Phase Fluid 1 flows from A to B, Thermal Liquid 2 flows from B to A (default) | Parallel flow - Both fluids flow from A to B | Cross flow - Both fluids flow from A to B

Flow path alignment between the heat exchanger sides at nominal operating condition. The available flow arrangements are:

- Counter flow - Two-Phase Fluid 1 flows from A to B, Thermal Liquid 2 flows from B to A — The flows run parallel to each other, in the opposite directions.
- Parallel flow - Both fluids flow from A to B — The flows run in the same direction.
- Cross flow - Both fluids flow from A to B — The flows run perpendicular to each other.

The choice between parallel flow and counter flow affects how the block determines the size of the heat exchanger. Counter flow is the most effective, therefore it will need the smallest size to meet the specified performance. Conversely, parallel flow is the least effective, therefore it will need the biggest size to meet the specified performance.

Flow direction at nominal condition (from A to B, or from B to A) affects only the model initialization, in case if you set the **Initial condition specification** parameter to Same as nominal operating condition. If you set up different initial operating conditions, the flow directions can be different.

Once the size is determined, the choice between parallel and counter does not play a role in how the block calculates the heat transfer during simulation. Instead, the heat transfer depends on the flow directions during simulation. If you set the parameter to parallel flow but set up the model to run in counter flow (or the other way around), then the rate of heat transfer during simulation will not match the specified performance, even if the rest of the boundary conditions are the same.

If you set the parameter to cross flow, then the flow paths are modeled as perpendicular inside the heat exchanger, so the flow directions during simulation do not matter.

#### Wall thermal mass — Enable or disable effect of thermal mass on heat transfer surface

Off (default) | On

Enable or disable the effect of thermal mass on the heat transfer surface. Setting this parameter to On introduces additional dynamics to the simulation, so that it takes longer to reach steady state, but does not affect the results at steady-state simulation.

#### Wall mass — Mass of heat transfer surface

1 kg (default) | positive scalar

Mass of the heat transfer surface.

### Dependencies

To enable this parameter, set **Wall thermal mass** to On.

#### Wall specific heat — Specific heat of heat transfer surface

490 J/(K\*kg) (default) | positive scalar

Specific heat of the heat transfer surface.

**Dependencies**

To enable this parameter, set **Wall thermal mass** to 0n.

**Cross-sectional area at port A1** — Flow area at port A1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **A1**.

**Cross-sectional area at port B1** — Flow area at port B1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **B1**.

**Cross-sectional area at port A2** — Flow area at port A2  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **A2**.

**Cross-sectional area at port B2** — Area normal to flow at port B2  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **B2**.

**Two-Phase Fluid 1**

**Nominal operating condition** — Select whether nominal operating condition corresponds to condenser or evaporator  
Condenser - heat transfer from two-phase fluid to thermal liquid (default) |  
Evaporator - heat transfer from thermal liquid to two-phase fluid

Select the nominal operating condition:

- Condenser - heat transfer from two-phase fluid to thermal liquid — The two-phase fluid is being cooled and the thermal liquid is being heated.
- Evaporator - heat transfer from thermal liquid to two-phase fluid — The thermal liquid is being cooled and the two-phase fluid is being heated.

This choice relates only to specifying the nominal operating condition parameters. It does not mean that heat transfer can only happen in the specified direction during simulation.

**Nominal mass flow rate** — Mass flow rate between two-phase ports during nominal operating condition  
0.001 kg/s (default) | positive scalar

Mass flow rate from port **A1** to port **B1** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between two-phase ports during nominal operating condition  
0.01 MPa (default) | positive scalar

Pressure drop from port **A1** to port **B1** during the nominal operating condition.

**Pressure specification** — Select method of pressure specification

Inlet pressure (default) | Saturation pressure at specified condensing temperature  
| Saturation pressure at specified evaporating temperature

Select the method of pressure specification:

- Inlet pressure — Specify the nominal inlet pressure.
- Saturation pressure at specified condensing temperature — Specify the nominal condensing temperature. This option is available if you set **Nominal operating condition** to Condenser - heat transfer from two-phase fluid to thermal liquid.
- Saturation pressure at specified evaporating temperature — Specify the nominal evaporating temperature. This option is available if you set **Nominal operating condition** to Evaporator - heat transfer from thermal liquid to two-phase fluid.

**Nominal inlet pressure** — Pressure at the two-phase fluid side inlet

1 MPa (default) | positive scalar

Pressure at the inlet of the two-phase fluid side of the heat exchanger during nominal operating condition.

#### Dependencies

To enable this parameter, set **Pressure specification** to Inlet pressure.

**Nominal condensing temperature** — Use nominal condensing temperature to specify pressure

313.15 K (default) | positive scalar

Liquid saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during nominal operating condition. The pressure in the heat exchanger is the corresponding saturation pressure. The nominal condensing temperature must be less than the critical temperature.

#### Dependencies

To enable this parameter, set **Nominal operating condition** to Condenser - heat transfer from two-phase fluid to thermal liquid and **Pressure specification** to Saturation pressure at specified condensing temperature.

**Nominal evaporating temperature** — Use nominal evaporating temperature to specify pressure

243.15 K (default) | positive scalar

Vapor saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during nominal operating condition. The pressure in the heat exchanger is the corresponding saturation pressure. The nominal evaporating temperature must be less than the critical temperature.

#### Dependencies

To enable this parameter, set **Nominal operating condition** to Evaporator - heat transfer from thermal liquid to two-phase fluid and **Pressure specification** to Saturation pressure at specified evaporating temperature.

**Inlet condition specification** — Select quantity to describe the inlet condition of the two-phase fluid

Specific enthalpy (default) | Temperature | Vapor quality

Quantity used to describe the inlet condition of the fluid at the nominal operating condition: temperature, specific enthalpy, or vapor quality.

**Nominal inlet specific enthalpy** — Specific enthalpy at the two-phase fluid side inlet  
440 kJ/kg (default) | positive scalar

Specific enthalpy at the inlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Specific enthalpy.

**Nominal inlet temperature** — Temperature at the two-phase fluid side inlet  
313.15 K (default) | positive scalar

Temperature at the inlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Vapor quality at the two-phase fluid side inlet  
1 (default) | positive scalar

Vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the inlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Vapor quality.

**Heat transfer capacity specification** — Select how to specify heat transfer capacity of the two-phase fluid  
Rate of heat transfer (default) | Outlet condition

Select whether to specify the performance of the heat exchanger at the nominal operating condition directly, by the rate of heat transfer, or indirectly, by the outlet condition.

**Nominal rate of heat transfer** — Specify performance by rate of heat transfer  
0.1 kW (default) | positive scalar

Rate of heat transfer, depending on the nominal operating condition:

- If **Nominal operating condition** is Condenser - heat transfer from two-phase fluid to thermal liquid, rate of heat transfer from the two-phase fluid to the thermal liquid during the nominal operating condition.
- If **Nominal operating condition** is Evaporator - heat transfer from thermal liquid to two-phase fluid, rate of heat transfer from the thermal liquid to the two-phase fluid during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Heat transfer capacity specification** to Rate of heat transfer.

**Outlet condition specification** — Select quantity for outlet condition specification  
Specific enthalpy (default) | Subcooling | Superheating | Vapor quality

Select the quantity for outlet condition specification:

- **Specific enthalpy** — Specify the nominal specific enthalpy.
- **Subcooling** — Specify the nominal subcooling. This option is available if you set **Nominal operating condition** to Condenser - heat transfer from two-phase fluid to thermal liquid.
- **Superheating** — Specify the nominal superheating. This option is available if you set **Nominal operating condition** to Evaporator - heat transfer from thermal liquid to two-phase fluid.
- **Vapor quality** — Specify the nominal vapor quality.

#### Dependencies

To enable this parameter, set **Heat transfer capacity specification** to Outlet condition.

**Nominal outlet specific enthalpy** — Specific enthalpy at the two-phase fluid side outlet  
250 kJ/kg (default) | positive scalar | two-element vector

Specific enthalpy at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Specific enthalpy.

**Nominal subcooling** — Degree of temperature below the liquid saturation temperature at the two-phase fluid side outlet  
5 deltaK (default) | positive scalar

Degree of temperature below the liquid saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Subcooling.

**Nominal superheating** — Degree of temperature above the vapor saturation temperature at the two-phase fluid side outlet  
5 deltaK (default) | positive scalar

Degree of temperature above the vapor saturation temperature at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Superheating.

**Nominal outlet vapor quality** — Vapor mass fraction at the two-phase fluid side outlet  
0 (default) | scalar in the range [0,1]

Two-phase fluid vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the outlet of the two-phase fluid side of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Outlet condition specification** to Vapor quality.

**Two-phase fluid volume** — Total volume of two-phase fluid  
0.001 m<sup>3</sup> (default) | positive scalar

Total volume of two-phase fluid inside the heat exchanger.

**Initial condition specification** — Select how to specify initial state of two-phase fluid  
Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of two-phase fluid:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.
- Specify initial condition — Specify a different set of initial conditions using additional parameters.

**Initial fluid energy specification** — Initial state of the two-phase fluid  
Specific enthalpy (default) | Temperature | Vapor quality | Vapor void fraction |  
Specific internal energy

Quantity used to describe the initial state of the fluid.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- Temperature — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- Vapor quality — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- Vapor void fraction — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- Specific enthalpy — Specify the specific enthalpy of the fluid. The block does not limit the initial state.
- Specific internal energy — Specify the specific internal energy of the fluid. The block does not limit the initial state.

### Dependencies

To enable this parameter, set **Initial condition specification** to Specify initial condition.

**Initial two-phase fluid pressure** — Fluid pressure at start of simulation  
0.101325 MPa (default) | positive scalar

Two-phase fluid pressure at the start of the simulation.

**Initial two-phase fluid specific enthalpy** — Enthalpy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid specific enthalpy at the start of simulation. If the value is a scalar, then the initial specific enthalpy is assumed uniform. If the value is a two-element vector, then the initial specific

enthalpy is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific enthalpy.

**Initial two-phase fluid temperature** — Temperature at start of simulation

293.15 K (default) | positive scalar | two-element vector

Two-phase fluid temperature at the start of simulation. If the value is a scalar, then the initial temperature is assumed uniform. If the value is a two-element vector, then the initial temperature is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Temperature.

**Initial two-phase fluid vapor quality** — Vapor mass fraction at start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor quality is assumed uniform. If the value is a two-element vector, then the initial vapor quality is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

If using this option, the initial pressure cannot be higher than the critical pressure.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor quality.

**Initial two-phase fluid vapor void fraction** — Vapor volume fraction at start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid vapor void fraction, defined as the volume fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor void fraction is assumed uniform. If the value is a two-element vector, then the initial vapor void fraction is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

If using this option, the initial pressure cannot be higher than the critical pressure.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor void fraction.

**Initial two-phase fluid specific internal energy** — Internal energy per unit mass at start of simulation

1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid specific internal energy at the start of simulation. If the value is a scalar, then the initial specific internal energy is assumed uniform. If the value is a two-element vector, then the initial specific internal energy is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

**Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Specific internal energy.

**Thermal Liquid 2**

**Nominal mass flow rate** — Mass flow rate between thermal liquid ports during nominal operating condition

0.1 kg/s (default) | positive scalar

Mass flow rate from port **A2** to port **B2** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between thermal liquid ports during nominal operating condition

0.01 MPa (default) | positive scalar

Pressure drop from port **A2** to port **B2** during the nominal operating condition.

**Nominal inlet pressure** — Pressure at the thermal liquid side inlet

0.101325 MPa (default) | positive scalar

Pressure at the inlet of the thermal liquid side of the heat exchanger during nominal operating condition.

**Nominal inlet temperature** — Temperature at the thermal liquid side inlet

293.15 K (default) | positive scalar

Temperature at the inlet of the thermal liquid side of the heat exchanger during the nominal operating condition.

**Thermal liquid volume** — Total volume of thermal liquid in the heat exchanger

0.001 m<sup>3</sup> (default) | positive scalar

Total volume of thermal liquid in the heat exchanger.

**Initial condition specification** — Select how to specify initial state of thermal liquid

Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of thermal liquid:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.
- Specify initial condition — Specify a different set of initial conditions using additional parameters.

**Initial thermal liquid pressure** — Thermal liquid pressure at start of simulation

0.101325 MPa (default) | positive scalar

Thermal liquid pressure at the start of the simulation.

**Initial thermal liquid temperature** — Thermal liquid temperature at start of simulation

293.15 K (default) | positive scalar | two-element vector

Thermal liquid temperature at the start of simulation. If the value is a scalar, then the initial temperature is assumed uniform. If the value is a two-element vector, then the initial temperature is

assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

### Correlation Coefficients

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid liquid** — Correlation coefficient for subcooled liquid in two-phase fluid

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for subcooled liquid in two-phase fluid. The default value is based on the Colburn equation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid mixture** — Correlation coefficient for liquid-vapor mixture in two-phase fluid

0.005 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for liquid-vapor mixture in two-phase fluid. The default value is based on the Cavallini and Zecchin correlation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid vapor** — Correlation coefficient for superheated vapor in two-phase fluid

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for superheated vapor in two-phase fluid. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid** — Reynolds number exponent in correlation for two-phase fluid

0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid** — Prandtl number exponent in correlation for two-phase fluid

0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for thermal liquid** — Correlation coefficient for thermal liquid

0.005 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for thermal liquid. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for thermal liquid** — Reynolds number exponent in correlation for thermal liquid

0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for thermal liquid. The default value is based on the Colburn equation.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for thermal liquid** — Prandtl number exponent in correlation for thermal liquid

0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for thermal liquid. The default value is based on the Colburn equation.

Heat exchanger between two two-phase fluid networks, with model based on performance data

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

### Description

The System-Level Heat Exchanger (2P-2P) block models a heat exchanger between two distinct two-phase fluid networks. Each network has its own set of fluid properties.

The block model is based on performance data from the heat exchanger datasheet, rather than on the detailed geometry of the exchanger, and therefore you can use this block when geometry data is unavailable. Either or both sides of the heat exchanger can condense or vaporize fluid as a result of the heat exchange. You can also use this block as an internal heat exchanger in a refrigeration system. An internal heat exchanger improves refrigeration system efficiency by providing additional heat exchange between the outlet of the condenser and the outlet of the evaporator.

You parameterize the block by the nominal operating condition. The heat exchanger is sized to match the specified performance at the nominal operating condition at steady state.

Each side of the heat exchanger approximates the liquid zone, mixture zone, and vapor zone based on the change in enthalpy along the flow path.

### Heat Transfer

The two-phase fluid 1 flow and the two-phase fluid 2 flow are each divided into three segments of equal size. Heat transfer between the fluids is calculated in each segment. For simplicity, the equation for one segment is shown here.

If the wall thermal mass is off, then the heat balance in the heat exchanger is

$$Q_{seg, 2P1} + Q_{seg, 2P2} = 0,$$

where:

- $Q_{seg, 2P1}$  is the heat flow rate from the wall (that is, the heat transfer surface) to the two-phase fluid 1 in the segment.
- $Q_{seg, 2P2}$  is the heat flow rate from the wall to the two-phase fluid 2 in the segment.

If the wall thermal mass is on, then the heat balance in the heat exchanger is

$$Q_{seg, 2P1} + Q_{seg, 2P2} = - \frac{M_{wall} c_{pwall}}{N} \frac{dT_{seg, wall}}{dt},$$

where:

- $M_{\text{wall}}$  is the mass of the wall.
- $c_{\text{pwall}}$  is the specific heat of the wall.
- $N = 3$  is the number of segments.
- $T_{\text{seg,wall}}$  is the average wall temperature in the segment.
- $t$  is time.

The heat flow rate from the wall to the two-phase fluid 1 in the segment is

$$Q_{\text{seg}, 2P1} = UA_{\text{seg}, 2P1}(T_{\text{seg}, \text{wall}} - T_{\text{seg}, 2P1}),$$

where:

- $UA_{\text{seg}, 2P1}$  is the weighted-average heat transfer conductance for the two-phase fluid 1 in the segment.
- $T_{\text{seg}, 2P1}$  is the weighted-average fluid temperature for the two-phase fluid 1 in the segment.

The heat flow rate from the wall to the two-phase fluid 2 in the segment is

$$Q_{\text{seg}, 2P2} = UA_{\text{seg}, 2P2}(T_{\text{seg}, \text{wall}} - T_{\text{seg}, 2P2}),$$

where:

- $UA_{\text{seg}, 2P2}$  is the weighted-average heat transfer conductance for the two-phase fluid 2 in the segment.
- $T_{\text{seg}, 2P2}$  is the weighted-average fluid temperature for the two-phase fluid 2 in the segment.

### Two-Phase Fluid 1 Heat Transfer Correlation

If the segment is subcooled liquid, then the heat transfer conductance is

$$UA_{\text{seg}, L, 2P1} = a_{L, 2P1}(\text{Re}_{\text{seg}, L, 2P1})^{b_{2P1}}(\text{Pr}_{\text{seg}, L, 2P1})^{c_{2P1}}k_{\text{seg}, L, 2P1}\frac{G_{2P1}}{N},$$

where:

- $a_{L, 2P1}$ ,  $b_{2P1}$ , and  $c_{2P1}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $\text{Re}_{\text{seg}, L, 2P1}$  is the average liquid Reynolds number for the segment.
- $\text{Pr}_{\text{seg}, L, 2P1}$  is the average liquid Prandtl number for the segment.
- $k_{\text{seg}, L, 2P1}$  is the average liquid thermal conductivity for the segment.
- $G_{2P1}$  is the geometry scale factor for the two-phase fluid 1 side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average liquid Reynolds number is

$$\text{Re}_{\text{seg}, L, 2P1} = \frac{\dot{m}_{\text{seg}, 2P1}D_{\text{ref}, 2P1}}{\mu_{\text{seg}, L, 2P1}S_{\text{ref}, 2P1}},$$

where:

- $\dot{m}_{seg, 2P1}$  is the mass flow rate through the segment.
- $\mu_{seg,L,2P1}$  is the average liquid dynamic viscosity for the segment.
- $D_{ref,2P1}$  is an arbitrary reference diameter.
- $S_{ref,2P1}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref,2P1}$  and  $S_{ref,2P1}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg,L,2P1}$  nondimensional. The values of  $D_{ref,2P1}$  and  $S_{ref,2P1}$  are arbitrary because the  $G_{2P1}$  calculation overrides these values.

---

Similarly, if the segment is superheated vapor, then the heat transfer conductance is

$$UA_{seg, V, 2P1} = a_{V, 2P1} (Re_{seg, V, 2P1})^{b_{2P1}} (Pr_{seg, V, 2P1})^{c_{2P1}} k_{seg, V, 2P1} \frac{G_{2P1}}{N},$$

where:

- $a_{V,2P1}$ ,  $b_{2P1}$ , and  $c_{2P1}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,V,2P1}$  is the average vapor Reynolds number for the segment.
- $Pr_{seg,V,2P1}$  is the average vapor Prandtl number for the segment.
- $k_{seg,V,2P1}$  is the average vapor thermal conductivity for the segment.

The average vapor Reynolds number is

$$Re_{seg, V, 2P1} = \frac{\dot{m}_{seg, 2P1} D_{ref, 2P1}}{\mu_{seg, V, 2P1} S_{ref, 2P1}},$$

where  $\mu_{seg,V,2P1}$  is the average vapor dynamic viscosity for the segment.

If the segment is liquid-vapor mixture, then the heat transfer conductance is

$$UA_{seg, M, 2P1} = a_{M, 2P1} (Re_{seg, SL, 2P1})^{b_{2P1}} CZ (Pr_{seg, SL, 2P1})^{c_{2P1}} k_{seg, SL, 2P1} \frac{G_{2P1}}{N},$$

where:

- $a_{M,2P1}$ ,  $b_{2P1}$ , and  $c_{2P1}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,SL,2P1}$  is the saturated liquid Reynolds number for the segment.
- $Pr_{seg,SL,2P1}$  is the saturated liquid Prandtl number for the segment.
- $k_{seg,SL,2P1}$  is the saturated liquid thermal conductivity for the segment.
- $CZ$  is the Cavallini and Zecchin term.

The saturated liquid Reynolds number is

$$Re_{seg, SL, 2P1} = \frac{\dot{m}_{seg, 2P1} D_{ref, 2P1}}{\mu_{seg, SL, 2P1} S_{ref, 2P1}},$$

where  $\mu_{seg,SL,2P1}$  is the saturated liquid dynamic viscosity for the segment.

The Cavallini and Zecchin term is

$$CZ = \frac{\left( \left( \sqrt{\frac{\nu_{seg,SV,2P1}}{\nu_{seg,SL,2P1}}} - 1 \right) (x_{seg,out,2P1} + 1) \right)^{1+b_{2P1}} - \left( \left( \sqrt{\frac{\nu_{seg,SV,2P1}}{\nu_{seg,SL,2P1}}} - 1 \right) (x_{seg,in,2P1} + 1) \right)^{1+b_{2P1}}}{(1+b_{2P1}) \left( \sqrt{\frac{\nu_{seg,SV,2P1}}{\nu_{seg,SL,2P1}}} - 1 \right) (x_{seg,out,2P1} - x_{seg,in,2P1})}$$

where:

- $\nu_{seg,SL,2P1}$  is the saturated liquid specific volume for the segment.
- $\nu_{seg,SV,2P1}$  is the saturated vapor specific volume for the segment.
- $x_{seg,in,2P1}$  is the vapor quality at the segment inlet.
- $x_{seg,out,2P1}$  is the vapor quality at the segment outlet.

The expression is based on the work of Cavallini and Zecchin [5], which derives a heat transfer coefficient correlation at a local vapor quality  $x$ . Equations for the liquid-vapor mixture are obtained by averaging Cavallini and Zecchin's correlation over the segment from  $x_{seg,in,2P1}$  to  $x_{seg,out,2P1}$ .

### Two-Phase Fluid 1 Weighted Average

The two-phase fluid flow through a segment may not be entirely represented as either subcooled liquid, superheated vapor, or liquid-vapor mixture. Instead, each segment may consist of a combination of these. The block approximates this condition by computing weighting factors ( $w_L$ ,  $w_V$ , and  $w_M$ ) based on the change in specific enthalpy across the segment and the saturated liquid and vapor specific enthalpies. The block assumes that the specific enthalpy across the segment varies piecewise linearly from inlet to outlet, with the breakpoints corresponding to the saturation boundaries for liquid and vapor. The zone with a larger heat transfer coefficient has a steeper slope than the zone with a lower heat transfer coefficient.

$$w_L = \frac{\Delta_L}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_V = \frac{\Delta_V}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_M = 1 - w_L - w_V$$

$$\Delta_L = \left| \min(h_{seg,out,2P1}, h_{seg,SL,2P1}) - \min(h_{seg,in,2P1}, h_{seg,SL,2P1}) \right| \cdot UA_{seg,M,2P1} \cdot UA_{seg,V,2P1}$$

$$\Delta_M = \left| \min(\max(h_{seg,out,2P1}, h_{seg,SL,2P1}), h_{seg,SV,2P1}) - \min(\max(h_{seg,in,2P1}, h_{seg,SL,2P1}), h_{seg,SV,2P1}) \right| \cdot UA_{seg,L,2P1} \cdot UA_{seg,M,2P1}$$

$$\Delta_V = \left| \max(h_{seg,out,2P1}, h_{seg,SV,2P1}) - \max(h_{seg,in,2P1}, h_{seg,SV,2P1}) \right| \cdot UA_{seg,L,2P1} \cdot UA_{seg,M,2P1}$$

where:

- $h_{seg,in,2P1}$  is the specific enthalpy at the segment inlet.
- $h_{seg,out,2P1}$  is the specific enthalpy at the segment outlet.
- $h_{seg,SL,2P1}$  is the saturated liquid specific enthalpy for the segment.
- $h_{seg,SV,2P1}$  is the saturated vapor specific enthalpy for the segment.

The weighted-average two-phase fluid 1 heat transfer conductance for the segment is therefore

$$UA_{seg,2P1} = w_L(UA_{seg,L,2P1}) + w_V(UA_{seg,V,2P1}) + w_M(UA_{seg,M,2P1}).$$

The weighted-average fluid 1 temperature for the segment is

$$T_{seg, 2P1} = \frac{w_L(UA_{seg, L, 2P1})T_{seg, L, 2P1} + w_V(UA_{seg, V, 2P1})T_{seg, V, 2P1} + w_M(UA_{seg, M, 2P1})T_{seg, M, 2P1}}{UA_{seg, 2P1}},$$

where:

- $T_{seg, L, 2P1}$  is the average liquid temperature for the segment.
- $T_{seg, V, 2P1}$  is the average vapor temperature for the segment.
- $T_{seg, M, 2P1}$  is the average mixture temperature for the segment, which is the saturated liquid temperature.

### Two-Phase Fluid 2 Heat Transfer Correlation

If the segment is subcooled liquid, then the heat transfer conductance is

$$UA_{seg, L, 2P2} = a_{L, 2P2}(Re_{seg, L, 2P2})^{b_{2P2}}(Pr_{seg, L, 2P2})^{c_{2P2}}k_{seg, L, 2P2}\frac{G_{2P2}}{N},$$

where:

- $a_{L, 2P2}$ ,  $b_{L, 2P2}$ , and  $c_{L, 2P2}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg, L, 2P2}$  is the average liquid Reynolds number for the segment.
- $Pr_{seg, L, 2P2}$  is the average liquid Prandtl number for the segment.
- $k_{seg, L, 2P2}$  is the average liquid thermal conductivity for the segment.
- $G_{2P2}$  is the geometry scale factor for the two-phase fluid 2 side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average liquid Reynolds number is

$$Re_{seg, L, 2P2} = \frac{\dot{m}_{seg, 2P2}D_{ref, 2P2}}{\mu_{seg, L, 2P2}S_{ref, 2P2}},$$

where:

- $\dot{m}_{seg, 2P2}$  is the mass flow rate through the segment.
- $\mu_{seg, L, 2P2}$  is the average liquid dynamic viscosity for the segment.
- $D_{ref, 2P2}$  is an arbitrary reference diameter.
- $S_{ref, 2P2}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref, 2P2}$  and  $S_{ref, 2P2}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg, L, 2P2}$  nondimensional. The values of  $D_{ref, 2P2}$  and  $S_{ref, 2P2}$  are arbitrary because the  $G_{2P2}$  calculation overrides these values.

---

Similarly, if the segment is superheated vapor, then the heat transfer conductance is

$$UA_{seg, V, 2P2} = a_{V, 2P2}(Re_{seg, V, 2P2})^{b_{2P2}}(Pr_{seg, V, 2P2})^{c_{2P2}}k_{seg, V, 2P2}\frac{G_{2P2}}{N},$$

where:

- $a_{V,2P2}$ ,  $b_{V,2P2}$ , and  $c_{V,2P2}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,V,2P2}$  is the average vapor Reynolds number for the segment.
- $Pr_{seg,V,2P2}$  is the average vapor Prandtl number for the segment.
- $k_{seg,V,2P2}$  is the average vapor thermal conductivity for the segment.

The average vapor Reynolds number is

$$Re_{seg,V,2P2} = \frac{\dot{m}_{seg,2P2} D_{ref,2P2}}{\mu_{seg,V,2P2} S_{ref,2P2}},$$

where  $\mu_{seg,V,2P2}$  is the average vapor dynamic viscosity for the segment.

If the segment is liquid-vapor mixture, then the heat transfer conductance is

$$UA_{seg,M,2P2} = a_{M,2P2} (Re_{seg,SL,2P2})^{b_{2P2}} CZ (Pr_{seg,SL,2P2})^{c_{2P2}} k_{seg,SL,2P2} \frac{G_{2P2}}{N},$$

where:

- $a_{M,2P2}$ ,  $b_{L,2P2}$ , and  $c_{L,2P2}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,SL,2P2}$  is the saturated liquid Reynolds number for the segment.
- $Pr_{seg,SL,2P2}$  is the saturated liquid Prandtl number for the segment.
- $k_{seg,SL,2P2}$  is the saturated liquid thermal conductivity for the segment.
- $CZ$  is the Cavallini and Zecchin term.

The saturated liquid Reynolds number is

$$Re_{seg,SL,2P2} = \frac{\dot{m}_{seg,2P2} D_{ref,2P2}}{\mu_{seg,SL,2P2} S_{ref,2P2}},$$

where  $\mu_{seg,SL,2P2}$  is the saturated liquid dynamic viscosity for the segment.

The Cavallini and Zecchin term is

$$CZ = \frac{\left( \left( \sqrt{\frac{\nu_{seg,SV,2P2}}{\nu_{seg,SL,2P2}}} - 1 \right) (x_{seg,out,2P2} + 1) \right)^{1+b_{2P2}} - \left( \left( \sqrt{\frac{\nu_{seg,SV,2P2}}{\nu_{seg,SL,2P2}}} - 1 \right) (x_{seg,in,2P2} + 1) \right)^{1+b_{2P2}}}{(1+b_{2P2}) \left( \sqrt{\frac{\nu_{seg,SV,2P2}}{\nu_{seg,SL,2P2}}} - 1 \right) (x_{seg,out,2P2} - x_{seg,in,2P2})},$$

where:

- $\nu_{seg,SL,2P2}$  is the saturated liquid specific volume for the segment.
- $\nu_{seg,SV,2P2}$  is the saturated vapor specific volume for the segment.
- $x_{seg,in,2P2}$  is the vapor quality at the segment inlet.
- $x_{seg,out,2P2}$  is the vapor quality at the segment outlet.

The expression is based on the work of Cavallini and Zecchin [5], which derives a heat transfer coefficient correlation at a local vapor quality  $x$ . Equations for the liquid-vapor mixture are obtained by averaging Cavallini and Zecchin's correlation over the segment from  $x_{\text{seg,in},2P2}$  to  $x_{\text{seg,out},2P2}$ .

### Two-Phase Fluid 2 Weighted Average

The two-phase fluid flow through a segment may not be entirely represented as either subcooled liquid, superheated vapor, or liquid-vapor mixture. Instead, each segment may consist of a combination of these. The block approximates this condition by computing weighting factors ( $w_L$ ,  $w_V$ , and  $w_M$ ) based on the change in specific enthalpy across the segment and the saturated liquid and vapor specific enthalpies. The block assumes that the specific enthalpy across the segment varies piecewise linearly from inlet to outlet, with the breakpoints corresponding to the saturation boundaries for liquid and vapor. The zone with a larger heat transfer coefficient has a steeper slope than the zone with a lower heat transfer coefficient.

$$w_L = \frac{\Delta_L}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_V = \frac{\Delta_V}{\Delta_L + \Delta_M + \Delta_V}$$

$$w_M = 1 - w_L - w_V$$

$$\Delta_L = |\min(h_{\text{seg,out},2P2}, h_{\text{seg,SL},2P2}) - \min(h_{\text{seg,in},2P2}, h_{\text{seg,SL},2P2})| \cdot UA_{\text{seg},M,2P2} \cdot UA_{\text{seg},V,2P2}$$

$$\Delta_M = |\min(\max(h_{\text{seg,out},2P2}, h_{\text{seg,SL},2P2}), h_{\text{seg,SV},2P2}) - \min(\max(h_{\text{seg,in},2P2}, h_{\text{seg,SL},2P2}), h_{\text{seg,SV},2P2})| \cdot UA_{\text{seg},L,2P2} \cdot UA_{\text{seg},M,2P2}$$

$$\Delta_V = |\max(h_{\text{seg,out},2P2}, h_{\text{seg,SV},2P2}) - \max(h_{\text{seg,in},2P2}, h_{\text{seg,SV},2P2})| \cdot UA_{\text{seg},L,2P2} \cdot UA_{\text{seg},M,2P2}$$

where:

- $h_{\text{seg,in},2P2}$  is the specific enthalpy at the segment inlet.
- $h_{\text{seg,out},2P2}$  is the specific enthalpy at the segment outlet.
- $h_{\text{seg,SL},2P2}$  is the saturated liquid specific enthalpy for the segment.
- $h_{\text{seg,SV},2P2}$  is the saturated vapor specific enthalpy for the segment.

The weighted-average two-phase fluid 2 heat transfer conductance for the segment is therefore

$$UA_{\text{seg},2P2} = w_L(UA_{\text{seg},L,2P2}) + w_V(UA_{\text{seg},V,2P2}) + w_M(UA_{\text{seg},M,2P2}).$$

The weighted-average fluid 2 temperature for the segment is

$$T_{\text{seg},2P2} = \frac{w_L(UA_{\text{seg},L,2P2})T_{\text{seg},L,2P2} + w_V(UA_{\text{seg},V,2P2})T_{\text{seg},V,2P2} + w_M(UA_{\text{seg},M,2P2})T_{\text{seg},M,2P2}}{UA_{\text{seg},2P2}},$$

where:

- $T_{\text{seg},L,2P2}$  is the average liquid temperature for the segment.
- $T_{\text{seg},V,2P2}$  is the average vapor temperature for the segment.
- $T_{\text{seg},M,2P2}$  is the average mixture temperature for the segment, which is the saturated liquid temperature.

### Pressure Loss

The pressure losses on the two-phase fluid 1 side are

$$p_{A,2P1} - p_{2P1} = \frac{K_{2P1} \dot{m}_{A,2P1} \sqrt{\dot{m}_{A,2P1}^2 + \dot{m}_{thres,2P1}^2}}{2 \rho_{avg,2P1}}$$

$$p_{B,2P1} - p_{2P1} = \frac{K_{2P1} \dot{m}_{B,2P1} \sqrt{\dot{m}_{B,2P1}^2 + \dot{m}_{thres,2P1}^2}}{2 \rho_{avg,2P1}}$$

where:

- $p_{A,2P1}$  and  $p_{B,2P1}$  are the pressures at ports **A1** and **B1**, respectively.
- $p_{2P1}$  is internal two-phase fluid 1 pressure at which the heat transfer is calculated.
- $\dot{m}_{A,2P1}$  and  $\dot{m}_{B,2P1}$  are the mass flow rates into ports **A1** and **B1**, respectively.
- $\rho_{avg,2P1}$  is the average two-phase fluid 1 density over all segments.
- $\dot{m}_{thres,2P1}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{2P1}$ , so that  $p_{A,2P1} - p_{B,2P1}$  matches the nominal pressure loss at the nominal mass flow rate.

The pressure losses on the two-phase fluid 2 side are

$$p_{A,2P2} - p_{2P2} = \frac{K_{2P2} \dot{m}_{A,2P2} \sqrt{\dot{m}_{A,2P2}^2 + \dot{m}_{thres,2P2}^2}}{2 \rho_{avg,2P2}}$$

$$p_{B,2P2} - p_{2P2} = \frac{K_{2P2} \dot{m}_{B,2P2} \sqrt{\dot{m}_{B,2P2}^2 + \dot{m}_{thres,2P2}^2}}{2 \rho_{avg,2P2}}$$

where:

- $p_{A,2P2}$  and  $p_{B,2P2}$  are the pressures at ports **A2** and **B2**, respectively.
- $p_{2P2}$  is internal two-phase fluid 2 pressure at which the heat transfer is calculated.
- $\dot{m}_{A,2P2}$  and  $\dot{m}_{B,2P2}$  are the mass flow rates into ports **A2** and **B2**, respectively.
- $\rho_{avg,2P2}$  is the average two-phase fluid 2 density over all segments.
- $\dot{m}_{thres,2P2}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{2P2}$ , so that  $p_{A,2P2} - p_{B,2P2}$  matches the nominal pressure loss at the nominal mass flow rate.

### Two-Phase Fluid 1 Mass and Energy Conservation

The mass conservation equation for the overall two-phase fluid 1 flow is

$$\left( \frac{dp_{2P1}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg,2P1}}{\partial p} \right) + \sum_{segments} \left( \frac{du_{seg,2P1}}{dt} \frac{\partial \rho_{seg,2P1}}{\partial u} \right) \right) \frac{V_{2P1}}{N} = \dot{m}_{A,2P1} + \dot{m}_{B,2P1},$$

where:

- $\frac{\partial \rho_{seg,2P1}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg,2P1}}{\partial u}$  is the partial derivative of density with respect to specific internal energy for the segment.

- $u_{seg,2P1}$  is the specific internal energy for the segment.
- $V_{2P1}$  is the total two-phase fluid 1 volume.

The summation is over all segments.

---

**Note** Although the two-phase fluid 1 flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{2P1}$ . That is why  $p_{2P1}$  is outside of the summation.

---

The energy conservation equation for each segment is

$$\frac{du_{seg,2P1}}{dt} \frac{M_{2P1}}{N} + u_{seg,2P1}(\dot{m}_{seg,in,2P1} - \dot{m}_{seg,out,2P1}) = \Phi_{seg,in,2P1} - \Phi_{seg,out,2P1} + Q_{seg,2P1},$$

where:

- $M_{2P1}$  is the total two-phase fluid 1 mass.
- $\dot{m}_{seg,in,2P1}$  and  $\dot{m}_{seg,out,2P1}$  are the mass flow rates into and out of the segment.
- $\Phi_{seg,in,2P1}$  and  $\Phi_{seg,out,2P1}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A,2P1}$  and  $\dot{m}_{B,2P1}$ .

### Two-Phase Fluid 2 Mass and Energy Conservation

The mass conservation equation for the overall two-phase fluid 2 flow is

$$\left( \frac{dp_{2P2}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg,2P2}}{\partial p} \right) + \sum_{segments} \left( \frac{du_{seg,2P2}}{dt} \frac{\partial \rho_{seg,2P2}}{\partial u} \right) \right) \frac{V_{2P2}}{N} = \dot{m}_{A,2P2} + \dot{m}_{B,2P2},$$

where:

- $\frac{\partial \rho_{seg,2P2}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg,2P2}}{\partial u}$  is the partial derivative of density with respect to specific internal energy for the segment.
- $u_{seg,2P2}$  is the specific internal energy for the segment.
- $V_{2P2}$  is the total two-phase fluid 2 volume.

The summation is over all segments.

---

**Note** Although the two-phase fluid 2 flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{2P2}$ . That is why  $p_{2P2}$  is outside of the summation.

---

The energy conservation equation for each segment is

$$\frac{du_{seg, 2P2}}{dt} \frac{M_{2P2}}{N} + u_{seg, 2P2}(\dot{m}_{seg, in, 2P2} - \dot{m}_{seg, out, 2P2}) = \Phi_{seg, in, 2P2} - \Phi_{seg, out, 2P2} + Q_{seg, 2P2},$$

where:

- $M_{2P2}$  is the total two-phase fluid 2 mass.
- $\dot{m}_{seg, in, 2P2}$  and  $\dot{m}_{seg, out, 2P2}$  are the mass flow rates into and out of the segment.
- $\Phi_{seg, in, 2P2}$  and  $\Phi_{seg, out, 2P2}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A, 2P2}$  and  $\dot{m}_{B, 2P2}$ .

## Ports

### Output

**Q1** — Rate of heat transfer to two-phase fluid 1, W  
physical signal

Rate of heat transfer to the first two-phase fluid network, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to On, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

**Q2** — Rate of heat transfer to two-phase fluid 2, W  
physical signal

Rate of heat transfer to the second two-phase fluid network, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to On, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

### Conserving

**A1** — Two-phase fluid port on side 1  
two-phase fluid

Inlet or outlet port associated with the first two-phase fluid network.

**B1** — Two-phase fluid port on side 1  
two-phase fluid

Inlet or outlet port associated with the first two-phase fluid network.

**A2** — Two-phase fluid port on side 2  
moist air

Inlet or outlet port associated with the second two-phase fluid network.

**B2** — Two-phase fluid port on side 2  
moist air

Inlet or outlet port associated with the second two-phase fluid network.

## Parameters

### Configuration

#### Flow arrangement at nominal operating condition — Flow path alignment

Counter flow - Two-Phase Fluid 1 flows from A to B, Two-Phase Fluid 2 flows from B to A (default) | Parallel flow - Both fluids flow from A to B | Cross flow - Both fluids flow from A to B

Flow path alignment between the heat exchanger sides at nominal operating condition. The available flow arrangements are:

- Counter flow - Two-Phase Fluid 1 flows from A to B, Two-Phase Fluid 2 flows from B to A — The flows run parallel to each other, in the opposite directions.
- Parallel flow - Both fluids flow from A to B — The flows run in the same direction.
- Cross flow - Both fluids flow from A to B — The flows run perpendicular to each other.

The choice between parallel flow and counter flow affects how the block determines the size of the heat exchanger. Counter flow is the most effective, therefore it will need the smallest size to meet the specified performance. Conversely, parallel flow is the least effective, therefore it will need the biggest size to meet the specified performance.

Flow direction at nominal condition (from A to B, or from B to A) affects only the model initialization, in case if you set the **Initial condition specification** parameter to `Same as nominal operating condition`. If you set up different initial operating conditions, the flow directions can be different.

Once the size is determined, the choice between parallel and counter does not play a role in how the block calculates the heat transfer during simulation. Instead, the heat transfer depends on the flow directions during simulation. If you set the parameter to parallel flow but set up the model to run in counter flow (or the other way around), then the rate of heat transfer during simulation will not match the specified performance, even if the rest of the boundary conditions are the same.

If you set the parameter to cross flow, then the flow paths are modeled as perpendicular inside the heat exchanger, so the flow directions during simulation do not matter.

#### Wall thermal mass — Enable or disable effect of thermal mass on heat transfer surface

Off (default) | On

Enable or disable the effect of thermal mass on the heat transfer surface. Setting this parameter to `On` introduces additional dynamics to the simulation, so that it takes longer to reach steady state, but does not affect the results at steady-state simulation.

#### Wall mass — Mass of heat transfer surface

1 kg (default) | positive scalar

Mass of the heat transfer surface.

### Dependencies

To enable this parameter, set **Wall thermal mass** to `On`.

#### Wall specific heat — Specific heat of heat transfer surface

490 J/(K\*kg) (default) | positive scalar

Specific heat of the heat transfer surface.

**Dependencies**

To enable this parameter, set **Wall thermal mass** to 0n.

**Cross-sectional area at port A1** — Flow area at port A1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid 1 port **A1**.

**Cross-sectional area at port B1** — Flow area at port B1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid 1 port **B1**.

**Cross-sectional area at port A2** — Flow area at port A2  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid 2 port **A2**.

**Cross-sectional area at port B2** — Area normal to flow at port B2  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid 2 port **B2**.

**Two-Phase Fluid 1**

**Nominal operating condition** — Select whether nominal operating condition corresponds to condenser or evaporator

Heat transfer from two-phase fluid 1 to two-phase fluid 2 (default) | Heat transfer from two-phase fluid 2 to two-phase fluid 1

Select the nominal operating condition:

- Heat transfer from two-phase fluid 1 to two-phase fluid 2 — Side 1 is being cooled and side 2 is being heated.
- Heat transfer from two-phase fluid 2 to two-phase fluid 1 — Side 2 is being cooled and side1 is being heated.

This choice relates only to specifying the nominal operating condition parameters. It does not mean that heat transfer can only happen in the specified direction during simulation.

**Nominal mass flow rate** — Mass flow rate between two-phase fluid side 1 ports during nominal operating condition

0.001 kg/s (default) | positive scalar

Mass flow rate from port **A1** to port **B1** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between two-phase fluid side 1 ports during nominal operating condition

0.01 MPa (default) | positive scalar

Pressure drop from port **A1** to port **B1** during the nominal operating condition.

**Pressure specification** — Select method of pressure specification

Inlet pressure (default) | Saturation pressure at specified condensing temperature  
| Saturation pressure at specified evaporating temperature

Select the method of pressure specification:

- Inlet pressure — Specify the nominal inlet pressure.
- Saturation pressure at specified saturation temperature — Specify the nominal saturation temperature.

**Nominal inlet pressure** — Pressure at the two-phase fluid side 1 inlet

1 MPa (default) | positive scalar

Pressure at the inlet of the two-phase fluid side 1 of the heat exchanger during nominal operating condition.

#### Dependencies

To enable this parameter, set **Pressure specification** to Inlet pressure.

**Nominal saturation temperature** — Use nominal saturation temperature to specify pressure

313.15 K (default) | positive scalar

Saturation temperature at the outlet of the two-phase fluid side 1 of the heat exchanger during nominal operating condition. The pressure in the heat exchanger is the corresponding saturation pressure. The nominal saturation temperature must be less than the critical temperature.

#### Dependencies

To enable this parameter, set **Pressure specification** to Saturation pressure at specified saturation temperature.

**Inlet condition specification** — Select quantity to describe the inlet condition of the two-phase fluid side 1

Specific enthalpy (default) | Temperature | Vapor quality

Quantity used to describe the inlet condition of the fluid at the nominal operating condition: temperature, specific enthalpy, or vapor quality.

**Nominal inlet specific enthalpy** — Specific enthalpy at the two-phase fluid side 1 inlet

440 kJ/kg (default) | positive scalar

Specific enthalpy at the inlet of the two-phase fluid side 1 of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Inlet condition specification** to Specific enthalpy.

**Nominal inlet temperature** — Temperature at the two-phase fluid side 1 inlet

313.15 K (default) | positive scalar

Temperature at the inlet of the two-phase fluid side 1 of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Vapor quality at the two-phase fluid side 1 inlet  
1 (default) | positive scalar

Vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the inlet of the two-phase fluid side 1 of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet condition specification** to Vapor quality.

**Heat transfer capacity specification** — Select how to specify heat transfer capacity of the two-phase fluid side 1  
Rate of heat transfer (default) | Outlet condition

Select whether to specify the performance of the heat exchanger at the nominal operating condition directly, by the rate of heat transfer, or indirectly, by the outlet condition.

**Nominal rate of heat transfer** — Specify performance by rate of heat transfer  
0.1 kW (default) | positive scalar

Rate of heat transfer, depending on the nominal operating condition:

- If **Nominal operating condition** is Heat transfer from two-phase fluid 1 to two-phase fluid 2, rate of heat transfer from the two-phase fluid side 1 to side 2 during the nominal operating condition.
- If **Nominal operating condition** is Heat transfer from two-phase fluid 2 to two-phase fluid 1, rate of heat transfer from the two-phase fluid side 2 to side 1 during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Heat transfer capacity specification** to Rate of heat transfer.

**Outlet condition specification** — Select quantity for outlet condition specification  
Specific enthalpy (default) | Subcooling | Superheating | Vapor quality

Select the quantity for outlet condition specification:

- Specific enthalpy — Specify the nominal specific enthalpy.
- Subcooling — Specify the nominal subcooling. This option is available if you set **Nominal operating condition** to Heat transfer from two-phase fluid 1 to two-phase fluid 2.
- Superheating — Specify the nominal superheating. This option is available if you set **Nominal operating condition** to Heat transfer from two-phase fluid 2 to two-phase fluid 1.
- Vapor quality — Specify the nominal vapor quality.

**Dependencies**

To enable this parameter, set **Heat transfer capacity specification** to Outlet condition.

**Nominal outlet specific enthalpy** — Specific enthalpy at the two-phase fluid side 1 outlet  
250 kJ/kg (default) | positive scalar | two-element vector

Specific enthalpy at the outlet of the two-phase fluid side 1 of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Outlet condition specification** to Specific enthalpy.

**Nominal subcooling** — Degree of temperature below the liquid saturation temperature at the two-phase fluid side 1 outlet

5 deltaK (default) | positive scalar

Degree of temperature below the liquid saturation temperature at the outlet of the two-phase fluid side 1 of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Outlet condition specification** to Subcooling.

**Nominal superheating** — Degree of temperature above the vapor saturation temperature at the two-phase fluid side 1 outlet

5 deltaK (default) | positive scalar

Degree of temperature above the vapor saturation temperature at the outlet of the two-phase fluid side 1 of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Outlet condition specification** to Superheating.

**Nominal outlet vapor quality** — Vapor mass fraction at the two-phase fluid side 1 outlet

0 (default) | scalar in the range [0,1]

Two-phase fluid vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the outlet of the two-phase fluid side 1 of the heat exchanger during the nominal operating condition.

If using this option, the initial pressure cannot be higher than the critical pressure.

**Dependencies**

To enable this parameter, set **Outlet condition specification** to Vapor quality.

**Two-phase fluid 1 volume** — Total volume of two-phase fluid 1

0.001 m<sup>3</sup> (default) | positive scalar

Total volume of two-phase fluid 1 inside the heat exchanger.

**Initial condition specification** — Select how to specify initial state of two-phase fluid 1  
Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of two-phase fluid 1:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.

- **Specify initial condition** — Specify a different set of initial conditions using additional parameters.

**Initial fluid energy specification** — Initial state of the two-phase fluid 1

Specific enthalpy (default) | Temperature | Vapor quality | Vapor void fraction | Specific internal energy

Quantity used to describe the initial state of the side 1 fluid: temperature, vapor quality, vapor void fraction, specific enthalpy, or specific internal energy.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- **Temperature** — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- **Vapor quality** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Vapor void fraction** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Specific enthalpy** — Specify the specific enthalpy of the fluid. The block does not limit the initial state.
- **Specific internal energy** — Specify the specific internal energy of the fluid. The block does not limit the initial state.

#### Dependencies

To enable this parameter, set **Initial condition specification** to **Specify initial condition**.

**Initial two-phase fluid 1 pressure** — Fluid 1 pressure at start of simulation

0.101325 MPa (default) | positive scalar

Two-phase fluid 1 pressure at the start of the simulation.

**Initial two-phase fluid 1 specific enthalpy** — Enthalpy per unit mass at start of simulation

1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid 1 specific enthalpy at the start of simulation. If the value is a scalar, then the initial specific enthalpy is assumed uniform. If the value is a two-element vector, then the initial specific enthalpy is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to **Specific enthalpy**.

**Initial two-phase fluid 1 temperature** — Temperature at start of simulation

293.15 K (default) | positive scalar | two-element vector

Two-phase fluid 1 temperature at the start of simulation. If the value is a scalar, then the initial temperature is assumed uniform. If the value is a two-element vector, then the initial temperature is

assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Temperature.

**Initial two-phase fluid 1 vapor quality** — Vapor mass fraction at start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid 1 vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor quality is assumed uniform. If the value is a two-element vector, then the initial vapor quality is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

If using this option, the initial pressure cannot be higher than the critical pressure.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor quality.

**Initial two-phase fluid 1 vapor void fraction** — Vapor volume fraction at start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid 1 vapor void fraction, defined as the volume fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor void fraction is assumed uniform. If the value is a two-element vector, then the initial vapor void fraction is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

If using this option, the initial pressure cannot be higher than the critical pressure.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor void fraction.

**Initial two-phase fluid 1 specific internal energy** — Internal energy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid 1 specific internal energy at the start of simulation. If the value is a scalar, then the initial specific internal energy is assumed uniform. If the value is a two-element vector, then the initial specific internal energy is assumed to vary linearly between ports **A1** and **B1**, with the first element corresponding to port **A1** and the second element corresponding to port **B1**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific internal energy.

### Two-Phase Fluid 2

**Nominal mass flow rate** — Mass flow rate between two-phase fluid side 2 ports during nominal operating condition  
0.001 kg/s (default) | positive scalar

Mass flow rate from port **A2** to port **B2** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between two-phase fluid side 2 ports during nominal operating condition

0.01 MPa (default) | positive scalar

Pressure drop from port **A2** to port **B2** during the nominal operating condition.

**Pressure specification** — Select method of pressure specification

Inlet pressure (default) | Saturation pressure at specified condensing temperature  
| Saturation pressure at specified evaporating temperature

Select the method of pressure specification:

- Inlet pressure — Specify the nominal inlet pressure.
- Saturation pressure at specified saturation temperature — Specify the nominal saturation temperature.

**Nominal inlet pressure** — Pressure at the two-phase fluid side inlet

1 MPa (default) | positive scalar

Pressure at the inlet of the two-phase fluid side 2 of the heat exchanger during nominal operating condition.

#### **Dependencies**

To enable this parameter, set **Pressure specification** to Inlet pressure.

**Nominal saturation temperature** — Use nominal saturation temperature to specify pressure

243.15 K (default) | positive scalar

Saturation temperature at the outlet of the two-phase fluid side 2 of the heat exchanger during nominal operating condition. The pressure in the heat exchanger is the corresponding saturation pressure. The nominal saturation temperature must be less than the critical temperature.

#### **Dependencies**

To enable this parameter, set **Pressure specification** to Saturation pressure at specified saturation temperature.

**Inlet condition specification** — Select quantity to describe the inlet condition of the two-phase fluid side 2

Specific enthalpy (default) | Temperature | Vapor quality

Quantity used to describe the inlet condition of the fluid at the nominal operating condition: temperature, specific enthalpy, or vapor quality.

**Nominal inlet specific enthalpy** — Specific enthalpy at the two-phase fluid side 2 inlet

250 kJ/kg (default) | positive scalar

Specific enthalpy at the inlet of the two-phase fluid side 2 of the heat exchanger during the nominal operating condition.

#### **Dependencies**

To enable this parameter, set **Inlet condition specification** to Specific enthalpy.

**Nominal inlet temperature** — Temperature at the two-phase fluid side 2 inlet

237.15 K (default) | positive scalar

Temperature at the inlet of the two-phase fluid side 2 of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Vapor quality at the two-phase fluid side 2 inlet  
0.1 (default) | positive scalar

Vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the inlet of the two-phase fluid side 2 of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Inlet condition specification** to Vapor quality.

**Two-phase fluid 2 volume** — Total volume of two-phase fluid 2  
0.001 m<sup>3</sup> (default) | positive scalar

Total volume of two-phase fluid 2 inside the heat exchanger.

**Initial condition specification** — Select how to specify initial state of two-phase fluid 2  
Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of two-phase fluid 2:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.
- Specify initial condition — Specify a different set of initial conditions using additional parameters.

**Initial fluid energy specification** — Initial state of the two-phase fluid 2  
Specific enthalpy (default) | Temperature | Vapor quality | Vapor void fraction | Specific internal energy

Quantity used to describe the initial state of the side 2 fluid.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- Temperature — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- Vapor quality — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- Vapor void fraction — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- Specific enthalpy — Specify the specific enthalpy of the fluid. The block does not limit the initial state.

- **Specific internal energy** — Specify the specific internal energy of the fluid. The block does not limit the initial state.

**Dependencies**

To enable this parameter, set **Initial condition specification** to Specify initial condition.

**Initial two-phase fluid 2 pressure** — Fluid 2 pressure at start of simulation

0.101325 MPa (default) | positive scalar

Two-phase fluid 2 pressure at the start of the simulation.

**Initial two-phase fluid 2 specific enthalpy** — Enthalpy per unit mass at start of simulation

1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid 2 specific enthalpy at the start of simulation. If the value is a scalar, then the initial specific enthalpy is assumed uniform. If the value is a two-element vector, then the initial specific enthalpy is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

**Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Specific enthalpy.

**Initial two-phase fluid 2 temperature** — Temperature at start of simulation

293.15 K (default) | positive scalar | two-element vector

Two-phase fluid 2 temperature at the start of simulation. If the value is a scalar, then the initial temperature is assumed uniform. If the value is a two-element vector, then the initial temperature is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

**Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Temperature.

**Initial two-phase fluid 2 vapor quality** — Vapor mass fraction at start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid 2 vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor quality is assumed uniform. If the value is a two-element vector, then the initial vapor quality is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

If using this option, the initial pressure cannot be higher than the critical pressure.

**Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Vapor quality.

**Initial two-phase fluid 2 vapor void fraction** — Vapor volume fraction at start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Two-phase fluid 2 vapor void fraction, defined as the volume fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the initial vapor void fraction is assumed uniform. If the value is a two-element vector, then the initial vapor void fraction is assumed

to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

If using this option, the initial pressure cannot be higher than the critical pressure.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor void fraction.

**Initial two-phase fluid 2 specific internal energy** — Internal energy per unit mass at start of simulation

1500 kJ/kg (default) | positive scalar | two-element vector

Two-phase fluid 2 specific internal energy at the start of simulation. If the value is a scalar, then the initial specific internal energy is assumed uniform. If the value is a two-element vector, then the initial specific internal energy is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific internal energy.

#### Correlation Coefficients

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 1 liquid** — Correlation coefficient for subcooled liquid in two-phase fluid 1

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for subcooled liquid in two-phase fluid 1. The default value is based on the Colburn equation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 1 mixture** — Correlation coefficient for liquid-vapor mixture in two-phase fluid 1

0.005 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for liquid-vapor mixture in two-phase fluid 1. The default value is based on the Cavallini and Zecchin correlation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 1 vapor** — Correlation coefficient for superheated vapor in two-phase fluid 1

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for superheated vapor in two-phase fluid 1. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 1** — Reynolds number exponent in correlation for two-phase fluid 1

0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid 1. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 1** — Prandtl number exponent in correlation for two-phase fluid 1

0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid 1. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 2 liquid** — Correlation coefficient for subcooled liquid in two-phase fluid 2

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for subcooled liquid in two-phase fluid 2. The default value is based on the Colburn equation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 2 mixture** — Correlation coefficient for liquid-vapor mixture in two-phase fluid 2

0.005 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for liquid-vapor mixture in two-phase fluid 2. The default value is based on the Cavallini and Zecchin correlation.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 2 vapor** — Correlation coefficient for superheated vapor in two-phase fluid 2

0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for superheated vapor in two-phase fluid 2. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 2** — Reynolds number exponent in correlation for two-phase fluid 2

0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid 2. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for two-phase fluid 2** — Prandtl number exponent in correlation for two-phase fluid 2

0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for two-phase fluid 2. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

## System-Level Heat Exchanger (TL-MA)

Heat exchanger between thermal liquid and moist air networks, with model based on performance data

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

### Description

The System-Level Heat Exchanger (TL-MA) block models a heat exchanger between a thermal liquid network and a moist air network.

The block model is based on performance data from the heat exchanger datasheet, rather than on the detailed geometry of the exchanger, and therefore lets you easily adjust the size and performance of the heat exchanger during design iterations, or model heat exchangers with uncommon geometries. You can also use this block to model heat exchangers with a certain level of performance at an early design stage, when detailed geometry data is not yet available.

You parameterize the block by the nominal operating condition. The heat exchanger is sized to match the specified performance at the nominal operating condition at steady state.

The Moist Air 2 side models water vapor condensation based on convective water vapor mass transfer with the heat transfer surface. Condensed water is removed from the moist air flow.

This block is similar to the Heat Exchanger (TL-MA) block but uses a different parameterization model. The table provides a comparison of the two blocks, to help you choose the right block for your application.

Heat Exchanger (TL-MA)	System-Level Heat Exchanger (TL-MA)
Block parameters are based on the heat exchanger geometry	Block parameters are based on performance and operating conditions
Heat exchanger geometry may be limited by the available geometry parameter options	Model is independent of the specific heat exchanger geometry
You can adjust the block for different performance requirements by tuning geometry parameters, such as fin sizes and tube lengths	You can adjust the block for different performance requirements by directly specifying the desired heat and mass flow rates
Lets you select between parallel, counter, or cross flow configurations	Lets you select between parallel, counter, or cross flow arrangement at nominal operating conditions, to help with sizing
Predictively accurate results over a wide range of operating conditions, subject to the applicability of the E-NTU equations and the heat transfer coefficient correlations	Very accurate results around the specified operating condition; accuracy may decrease far away from the specified operating conditions

Heat Exchanger (TL-MA)	System-Level Heat Exchanger (TL-MA)
Heat transfer calculations account for the variation of temperature along the flow path by using the E-NTU model	Heat transfer calculations approximate the variation of temperature along the flow path by dividing it into three segments
Accounts for water vapor condensation and the latent heat on the moist air flow	Accounts for water vapor condensation and the latent heat on the moist air flow
Does not model the wall thermal mass; you can approximate the effect by connecting a pipe block with a thermal mass downstream	Includes an option to model the wall thermal mass

### Heat Transfer

The thermal liquid flow and the moist air flow are each divided into three segments of equal size. Heat transfer between the fluids is calculated in each segment. For simplicity, the equation for one segment is shown here.

If the wall thermal mass is off, then the heat balance in the heat exchanger is

$$Q_{seg, TL} + Q_{seg, MA} = 0,$$

where:

- $Q_{seg, TL}$  is the heat flow rate from the wall (that is, the heat transfer surface) to the thermal liquid in the segment.
- $Q_{seg, MA}$  is the heat flow rate from the wall to the moist air in the segment.

If the wall thermal mass is on, then the heat balance in the heat exchanger is

$$Q_{seg, TL} + Q_{seg, MA} = - \frac{M_{wall} c_{pwall}}{N} \frac{dT_{seg, wall}}{dt},$$

where:

- $M_{wall}$  is the mass of the wall.
- $c_{pwall}$  is the specific heat of the wall.
- $N = 3$  is the number of segments.
- $T_{seg, wall}$  is the average wall temperature in the segment.
- $t$  is time.

The heat flow rate from the wall to the thermal liquid in the segment is

$$Q_{seg, TL} = UA_{seg, TL} (T_{seg, wall} - T_{seg, TL}),$$

where:

- $UA_{seg, TL}$  is the heat transfer conductance for the thermal liquid in the segment.
- $T_{seg, TL}$  is the average liquid temperature in the segment.

The heat flow rate from the wall to the moist air in the segment is

$$Q_{seg, MA} = \frac{UA_{seg, MA}}{\bar{c}_{pseg, MA}} (\bar{h}_{seg, wall} - \bar{h}_{seg, MA}) + \dot{m}_{w, seg, cond} h_{l, wall}$$

where:

- $UA_{seg,MA}$  is the heat transfer conductance for the moist air in the segment.
- $\bar{c}_{pseg,MA}$  is the moist air mixture specific heat per unit mass of dry air and trace gas in the segment.
- $\bar{h}_{seg,wall}$  is the moist air mixture enthalpy per unit mass of dry air and trace gas at the average wall segment temperature.
- $\bar{h}_{seg,MA}$  is the moist air mixture enthalpy per unit mass of dry air and trace gas in the segment.
- $\dot{m}_{w,seg,cond}$  is the rate of water vapor condensation on the wall surface.
- $h_{l,wall}$  is the specific enthalpy of liquid water at the average wall segment temperature.

Using mixture enthalpy in this equation accounts for both differences in temperature and differences in moisture due to condensation [3].

---

**Note** For the moist air quantities, the bar above the symbols indicates that they are quantities for mixture divided by the mass of dry air and trace gas only, as opposed to dividing by the mass of the whole mixture. The whole mixture includes dry air, water vapor, and trace gas.

---

### Thermal Liquid Heat Transfer Correlation

The heat transfer conductance is

$$UA_{seg,TL} = a_{TL}(Re_{seg,TL})^{b_{TL}}(Pr_{seg,TL})^{c_{TL}}k_{seg,TL}\frac{G_{TL}}{N},$$

where:

- $a_{TL}$ ,  $b_{TL}$ , and  $c_{TL}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,TL}$  is the average Reynolds number for the segment.
- $Pr_{seg,TL}$  is the average Prandtl number for the segment.
- $k_{seg,TL}$  is the average thermal conductivity for the segment.
- $G_{TL}$  is the geometry scale factor for the thermal liquid side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average Reynolds number is

$$Re_{seg,TL} = \frac{\dot{m}_{seg,TL}D_{ref,TL}}{\mu_{seg,TL}S_{ref,TL}},$$

where:

- $\dot{m}_{seg,TL}$  is the mass flow rate through the segment.
- $\mu_{seg,TL}$  is the average dynamic viscosity for the segment.
- $D_{ref,TL}$  is an arbitrary reference diameter.
- $S_{ref,TL}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref,TL}$  and  $S_{ref,TL}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg,TL}$  nondimensional. The values of  $D_{ref,TL}$  and  $S_{ref,TL}$  are arbitrary because the  $G_{TL}$  calculation overrides these values.

---

### Moist Air Heat Transfer Correlation

The heat transfer conductance is

$$UA_{seg,MA} = a_{MA}(Re_{seg,MA})^{b_{MA}}(Pr_{seg,MA})^{c_{MA}}k_{seg,MA}\frac{G_{MA}}{N},$$

where:

- $a_{MA}$ ,  $b_{MA}$ , and  $c_{MA}$  are the coefficients of the Nusselt number correlation. These coefficients appear as block parameters in the **Correlation Coefficients** section.
- $Re_{seg,MA}$  is the average Reynolds number for the segment.
- $Pr_{seg,MA}$  is the average Prandtl number for the segment.
- $k_{seg,MA}$  is the average thermal conductivity for the segment.
- $G_{MA}$  is the geometry scale factor for the moist air side of the heat exchanger. The block calculates the geometry scale factor so that the total heat transfer over all segments matches the specified performance at the nominal operating conditions.

The average Reynolds number is

$$Re_{seg,MA} = \frac{\dot{m}_{seg,MA}D_{ref,MA}}{\mu_{seg,MA}S_{ref,MA}},$$

where:

- $\dot{m}_{seg,MA}$  is the mass flow rate through the segment.
- $\mu_{seg,MA}$  is the average dynamic viscosity for the segment.
- $D_{ref,MA}$  is an arbitrary reference diameter.
- $S_{ref,MA}$  is an arbitrary reference flow area.

---

**Note** The  $D_{ref,MA}$  and  $S_{ref,MA}$  terms are included in this equation for unit calculation purposes only, to make  $Re_{seg,MA}$  nondimensional. The values of  $D_{ref,MA}$  and  $S_{ref,MA}$  are arbitrary because the  $G_{MA}$  calculation overrides these values.

---

### Moist Air Condensation

The equation describing the heat flow rate from the wall to the moist air in the segment (the last equation in the “Heat Transfer” on page 1-1879 section) uses the average moist air mixture enthalpy,  $\bar{h}_{seg,MA}$ , and the wall segment moist air mixture enthalpy,  $\bar{h}_{seg,wall}$ .

The average moist air mixture enthalpy is based on the temperature and humidity of the moist air flow through the segment:

$$\bar{h}_{seg,MA} = h_{seg,ag,MA} + W_{seg,MA}h_{seg,w,MA}$$

where:

- $h_{seg,ag,MA}$  is the average specific enthalpy of dry air and trace gas for the segment.
- $h_{seg,w,MA}$  is the average specific enthalpy of water vapor for the segment.
- $W_{seg,MA}$  is the humidity ratio of the segment.

The wall segment moist air mixture enthalpy is based on the temperature and humidity at the wall segment:

$$\bar{h}_{seg,wall} = h_{seg,ag,wall} + W_{seg,wall}h_{seg,w,wall},$$

where:

- $h_{seg,ag,wall}$  is the specific enthalpy of dry air and trace gas at the wall segment temperature.
- $h_{seg,w,wall}$  is the specific enthalpy of water vapor at the wall segment temperature.
- $W_{seg,wall}$  is the humidity ratio at the wall segment:

$$W_{seg,wall} = \min(W_{seg,MA}, W_{seg,s,wall}),$$

where  $W_{seg,s,wall}$  is the saturated humidity ratio at the wall segment temperature. In other words, the humidity ratio at the wall is the same as the humidity ratio of the moist air flow but not more than the maximum that can be supported at the wall segment temperature.

When  $W_{seg,s,wall} < W_{seg,MA}$ , water vapor condensation occurs on the wall surface. The rate of water vapor condensation is

$$\dot{m}_{w,seg,cond} = \frac{UA_{seg,MA}}{\bar{c}p_{seg,MA}}(W_{seg,MA} - W_{seg,wall}).$$

The condensed water is assumed to be drained from the wall surface and is thus removed from the moist air flow downstream.

### Pressure Loss

The pressure losses on the thermal liquid side are

$$p_{A,TL} - p_{TL} = \frac{K_{TL} \dot{m}_{A,TL} \sqrt{\dot{m}_{A,TL}^2 + \dot{m}_{thres,TL}^2}}{2 \rho_{avg,2P}}$$

$$p_{B,TL} - p_{TL} = \frac{K_{TL} \dot{m}_{B,TL} \sqrt{\dot{m}_{B,TL}^2 + \dot{m}_{thres,TL}^2}}{2 \rho_{avg,TL}}$$

where:

- $p_{A,TL}$  and  $p_{B,TL}$  are the pressures at ports **A2** and **B2**, respectively.
- $p_{TL}$  is internal thermal liquid pressure at which the heat transfer is calculated.
- $\dot{m}_{A,TL}$  and  $\dot{m}_{B,TL}$  are the mass flow rates into ports **A2** and **B2**, respectively.
- $\rho_{avg,TL}$  is the average thermal liquid density over all segments.
- $\dot{m}_{thres,TL}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{TL}$ , so that  $p_{A,TL} - p_{B,TL}$  matches the nominal pressure loss at the nominal mass flow rate.

The pressure losses on the moist air side are

$$p_{A,MA} - p_{MA} = \frac{K_{MA} \dot{m}_{A,MA} \sqrt{\dot{m}_{A,MA}^2 + \dot{m}_{thres,MA}^2}}{2 \rho_{avg,2P}}$$

$$p_{B,MA} - p_{MA} = \frac{K_{MA} \dot{m}_{B,MA} \sqrt{\dot{m}_{B,MA}^2 + \dot{m}_{thres,MA}^2}}{2 \rho_{avg,MA}}$$

where:

- $p_{A,MA}$  and  $p_{B,MA}$  are the pressures at ports **A2** and **B2**, respectively.
- $p_{MA}$  is internal moist air pressure at which the heat transfer is calculated.
- $\dot{m}_{A,MA}$  and  $\dot{m}_{B,MA}$  are the mass flow rates into ports **A2** and **B2**, respectively.
- $\rho_{avg,MA}$  is the average moist air density over all segments.
- $\dot{m}_{thres,MA}$  is the laminar threshold for pressure loss, approximated as 1e-4 of the nominal mass flow rate. The block calculates the pressure loss coefficient,  $K_{MA}$ , so that  $p_{A,MA} - p_{B,MA}$  matches the nominal pressure loss at the nominal mass flow rate.

### Thermal Liquid Mass and Energy Conservation

The mass conservation for the overall thermal liquid flow is

$$\left( \frac{dp_{TL}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg,TL}}{\partial p} \right) + \sum_{segments} \left( \frac{dT_{seg,TL}}{dt} \frac{\partial \rho_{seg,TL}}{\partial T} \right) \right) \frac{V_{TL}}{N} = \dot{m}_{A,TL} + \dot{m}_{B,TL}$$

where:

- $\frac{\partial \rho_{seg,TL}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg,TL}}{\partial T}$  is the partial derivative of density with respect to temperature for the segment.
- $T_{seg,TL}$  is the temperature for the segment.
- $V_{TL}$  is the total thermal liquid volume.

The summation is over all segments.

---

**Note** Although the thermal liquid flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{TL}$ . That is why  $p_{TL}$  is outside of the summation.

---

The energy conservation equation for each segment is

$$\left( \frac{dp_{TL}}{dt} \frac{\partial u_{seg,TL}}{\partial p} + \frac{dT_{seg,TL}}{dt} \frac{\partial u_{seg,TL}}{\partial T} \right) \frac{M_{TL}}{N} + u_{seg,TL} (\dot{m}_{seg,in,TL} - \dot{m}_{seg,out,TL}) = \Phi_{seg,in,TL} - \Phi_{seg,out,TL} + Q_{seg,TL}$$

where:

- $\frac{\partial u_{seg, TL}}{\partial p}$  is the partial derivative of specific internal energy with respect to pressure for the segment.
- $\frac{\partial u_{seg, TL}}{\partial T}$  is the partial derivative of specific internal energy with respect to temperature for the segment.
- $M_{TL}$  is the total thermal liquid mass.
- $\dot{m}_{seg, in, TL}$  and  $\dot{m}_{seg, out, TL}$  are the mass flow rates into and out of the segment.
- $\Phi_{seg, in, TL}$  and  $\Phi_{seg, out, TL}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A, TL}$  and  $\dot{m}_{B, TL}$ .

### Moist Air Mass and Energy Conservation

The mass conservation for the overall moist air mixture flow is

$$\left( \frac{dp_{MA}}{dt} \sum_{segments} \left( \frac{\partial \rho_{seg, MA}}{\partial p} \right) + \sum_{segments} \left( \frac{dT_{seg, MA}}{dt} \frac{\partial \rho_{seg, MA}}{\partial T} + \frac{dx_{w, seg, MA}}{dt} \frac{\partial \rho_{seg, MA}}{\partial x_w} + \frac{dx_{g, seg, MA}}{dt} \frac{\partial \rho_{seg, MA}}{\partial x_g} \right) \right) \frac{V_{MA}}{N} = \dot{m}_{A, MA} + \dot{m}_{B, MA} - \sum_{segments} (\dot{m}_{w, seg, cond}),$$

where:

- $\frac{\partial \rho_{seg, MA}}{\partial p}$  is the partial derivative of density with respect to pressure for the segment.
- $\frac{\partial \rho_{seg, MA}}{\partial T}$  is the partial derivative of density with respect to temperature for the segment.
- $\frac{\partial \rho_{seg, MA}}{\partial x_w}$  is the partial derivative of density with respect to specific humidity for the segment.
- $\frac{\partial \rho_{seg, MA}}{\partial x_g}$  is the partial derivative of density with respect to trace gas mass fraction for the segment.
- $x_{w, seg, MA}$  is the specific humidity, that is, the water vapor mass fraction, for the segment.
- $x_{g, seg, MA}$  is the trace gas mass fraction for the segment.
- $V_{MA}$  is the total moist air volume.

The summation is over all segments.

---

**Note** Although the moist air flow is divided into  $N=3$  segments for heat transfer calculations, all segments are assumed to be at the same internal pressure,  $p_{MA}$ . That is why  $p_{MA}$  is outside of the summation.

---

The energy conservation equation for each segment is

$$\left( \frac{dT_{seg, MA}}{dt} \frac{\partial u_{seg, MA}}{\partial T} + \frac{dx_{w, seg, MA}}{dt} \frac{\partial u_{seg, MA}}{\partial x_w} + \frac{dx_{g, seg, MA}}{dt} \frac{\partial u_{seg, MA}}{\partial x_g} \right) \frac{M_{MA}}{N} + u_{seg, MA} (\dot{m}_{seg, in, MA} - \dot{m}_{seg, out, MA}) - \Phi_{seg, in, MA} - \Phi_{seg, out, MA} + Q_{seg, MA} - \dot{m}_{w, seg, cond} h_{l, wall},$$

where:

- $\frac{\partial u_{seg,MA}}{\partial T}$  is the partial derivative of specific internal energy with respect to temperature for the segment.
- $\frac{\partial u_{seg,MA}}{\partial x_w}$  is the partial derivative of specific internal energy with respect to specific humidity for the segment.
- $\frac{\partial u_{seg,MA}}{\partial x_g}$  is the partial derivative of specific internal energy with respect to trace gas mass fraction for the segment.
- $u_{seg,2P}$  is the specific internal energy for the segment.
- $M_{MA}$  is the total moist air mass.
- $\dot{m}_{seg,in,MA}$  and  $\dot{m}_{seg,out,MA}$  are the mass flow rates into and out of the segment.
- $\Phi_{seg,in,MA}$  and  $\Phi_{seg,out,MA}$  are the energy flow rates into and out of the segment.

The mass flow rates between segments are assumed to be linearly distributed between the values of  $\dot{m}_{A,MA}$  and  $\dot{m}_{B,MA}$ .

The water vapor mass conservation equation for each segment is

$$\frac{dx_{w,seg,MA}}{dt} \frac{M_{MA}}{N} + x_{w,seg,MA}(\dot{m}_{seg,in,MA} - \dot{m}_{seg,out,MA}) = \dot{m}_{w,seg,in,MA} - \dot{m}_{w,seg,out,MA} - \dot{m}_{w,seg,cond}$$

where  $\dot{m}_{w,seg,in,MA}$  and  $\dot{m}_{w,seg,out,MA}$  are the water vapor mass flow rates into and out of the segment.

The trace gas mass conservation equation for each segment is

$$\frac{dx_{g,seg,MA}}{dt} \frac{M_{MA}}{N} + x_{g,seg,MA}(\dot{m}_{seg,in,MA} - \dot{m}_{seg,out,MA}) = \dot{m}_{g,seg,in,MA} - \dot{m}_{g,seg,out,MA}$$

where  $\dot{m}_{g,seg,in,MA}$  and  $\dot{m}_{g,seg,out,MA}$  are the trace gas mass flow rates into and out of the segment.

## Ports

### Output

**Q1** — Rate of heat transfer to thermal liquid, W  
physical signal

Rate of heat transfer to thermal liquid, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to On, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

**Q2** — Rate of heat transfer to moist air, W  
physical signal

Rate of heat transfer to moist air, returned as a physical signal. Physical signals **Q1** and **Q2** are usually equal in value with opposite sign. However, if the **Wall thermal mass** parameter is set to On, then these two signals may have different values because the wall may absorb and release some of the heat being transferred.

**W** — Moist air condensation rate, kg/s  
physical signal

Water condensation rate in the moist air flow, returned as a physical signal. The condensate does not accumulate on the heat transfer surface.

### Conserving

**A1** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

**B1** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

**A2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

**B2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

## Parameters

### Configuration

**Flow arrangement at nominal operating condition** — Flow path alignment

Counter flow - Thermal Liquid 1 flows from A to B, Moist Air 2 flows from B to A (default) | Parallel flow - Both fluids flow from A to B | Cross flow - Both fluids flow from A to B

Flow path alignment between the heat exchanger sides at nominal operating condition. The available flow arrangements are:

- Counter flow - Thermal Liquid 1 flows from A to B, Moist Air 2 flows from B to A — The flows run parallel to each other, in the opposite directions.
- Parallel flow - Both fluids flow from A to B — The flows run in the same direction.
- Cross flow - Both fluids flow from A to B — The flows run perpendicular to each other.

The choice between parallel flow and counter flow affects how the block determines the size of the heat exchanger. Counter flow is the most effective, therefore it will need the smallest size to meet the

specified performance. Conversely, parallel flow is the least effective, therefore it will need the biggest size to meet the specified performance.

Flow direction at nominal condition (from A to B, or from B to A) affects only the model initialization, in case if you set the **Initial condition specification** parameter to `Same as nominal operating condition`. If you set up different initial operating conditions, the flow directions can be different.

Once the size is determined, the choice between parallel and counter does not play a role in how the block calculates the heat transfer during simulation. Instead, the heat transfer depends on the flow directions during simulation. If you set the parameter to parallel flow but set up the model to run in counter flow (or the other way around), then the rate of heat transfer during simulation will not match the specified performance, even if the rest of the boundary conditions are the same.

If you set the parameter to cross flow, then the flow paths are modeled as perpendicular inside the heat exchanger, so the flow directions during simulation do not matter.

**Wall thermal mass** — Enable or disable effect of thermal mass on heat transfer surface  
Off (default) | On

Enable or disable the effect of thermal mass on the heat transfer surface. Setting this parameter to `On` introduces additional dynamics to the simulation, so that it takes longer to reach steady state, but does not affect the results at steady-state simulation.

**Wall mass** — Mass of heat transfer surface  
1 kg (default) | positive scalar

Mass of the heat transfer surface.

#### Dependencies

To enable this parameter, set **Wall thermal mass** to `On`.

**Wall specific heat** — Specific heat of heat transfer surface  
490 J/(K\*kg) (default) | positive scalar

Specific heat of the heat transfer surface.

#### Dependencies

To enable this parameter, set **Wall thermal mass** to `On`.

**Cross-sectional area at port A1** — Flow area at port A1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **A1**.

**Cross-sectional area at port B1** — Flow area at port B1  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **B1**.

**Cross-sectional area at port A2** — Flow area at port A2  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air port **A2**.

**Cross-sectional area at port B2** — Area normal to flow at port B2

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air port **B2**.

### **Thermal Liquid 1**

**Nominal operating condition** — Select nominal operating condition

Heat transfer from thermal liquid to moist air (default) | Heat transfer from moist air to thermal liquid

Select the nominal operating condition:

- Heat transfer from thermal liquid to moist air — The thermal liquid is being cooled and the moist air is being heated.
- Heat transfer from moist air to thermal liquid — The moist air is being cooled and the thermal liquid is being heated.

This choice relates only to specifying the nominal operating condition parameters. It does not mean that heat transfer can only happen in the specified direction during simulation.

**Nominal mass flow rate** — Mass flow rate between thermal liquid ports during nominal operating condition

0.1 kg/s (default) | positive scalar

Mass flow rate from port **A1** to port **B1** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between thermal liquid ports during nominal operating condition

0.01 MPa (default) | positive scalar

Pressure drop from port **A1** to port **B1** during the nominal operating condition.

**Nominal inlet pressure** — Pressure at the thermal liquid inlet

0.101325 MPa (default) | positive scalar

Pressure at the inlet of the thermal liquid of the heat exchanger during nominal operating condition.

**Nominal inlet temperature** — Temperature at the thermal liquid inlet

333.15 K (default) | positive scalar

Temperature at the inlet of the thermal liquid of the heat exchanger during the nominal operating condition.

**Heat transfer capacity specification** — Select how to specify heat transfer capacity of the thermal liquid

Rate of heat transfer (default) | Outlet condition

Select whether to specify the performance of the heat exchanger at the nominal operating condition directly, by the rate of heat transfer, or indirectly, by the outlet condition.

**Nominal rate of heat transfer** — Specify performance by rate of heat transfer

1 kW (default) | positive scalar

Rate of heat transfer, depending on the nominal operating condition:

- If **Nominal operating condition** is Heat transfer from thermal liquid to moist air, rate of heat transfer from the thermal liquid to the moist air during the nominal operating condition.
- If **Nominal operating condition** is Heat transfer from moist air to thermal liquid, rate of heat transfer from the moist air to the thermal liquid during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Heat transfer capacity specification** to Rate of heat transfer.

**Nominal outlet temperature** — Specify performance by outlet temperature  
323.15 K (default) | positive scalar

Temperature at the outlet of the thermal liquid of the heat exchanger during the nominal operating condition.

#### Dependencies

To enable this parameter, set **Heat transfer capacity specification** to Outlet condition.

**Thermal liquid volume** — Total volume of thermal liquid  
0.001 m<sup>3</sup> (default) | positive scalar

Total volume of thermal liquid inside the heat exchanger.

**Initial condition specification** — Select how to specify initial state of thermal liquid  
Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of thermal liquid:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.
- Specify initial condition — Specify a different set of initial conditions using additional parameters.

**Initial thermal liquid pressure** — Thermal liquid pressure at the start of simulation  
0.101325 MPa (default) | positive scalar

Thermal liquid pressure at the start of simulation.

#### Dependencies

To enable this parameter, set **Initial condition specification** to Specify initial condition.

**Initial thermal liquid temperature** — Thermal liquid temperature at the start of simulation  
293.15 K (default) | positive scalar

Thermal liquid temperature at the start of simulation.

#### Dependencies

To enable this parameter, set **Initial condition specification** to Specify initial condition.

## Moist Air 2

**Nominal mass flow rate** — Mass flow rate between moist air ports during nominal operating condition

0.1 kg/s (default) | positive scalar

Mass flow rate from port **A2** to port **B2** during the nominal operating condition.

**Nominal pressure drop** — Pressure drop between moist air ports during nominal operating condition

0.001 MPa (default) | positive scalar

Pressure drop from port **A2** to port **B2** during the nominal operating condition.

**Nominal inlet pressure** — Pressure at the moist air side inlet

0.101325 MPa (default) | positive scalar

Pressure at the inlet of the moist air side of the heat exchanger during nominal operating condition.

**Nominal inlet temperature** — Temperature at the moist air side inlet

293.15 K (default) | positive scalar

Temperature at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

**Inlet moisture specification** — Quantity used to describe the moisture level at the moist air side inlet

Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Select quantity used to describe the moisture level at the inlet during the nominal operating condition: relative humidity, specific humidity, water vapor mole fraction, or humidity ratio.

**Nominal inlet relative humidity** — Relative humidity at the inlet

0.5 (default) | scalar in the range [0,1]

Relative humidity at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

### Dependencies

To enable this parameter, set **Inlet moisture specification** to Relative humidity.

**Nominal inlet specific humidity** — Specific humidity at the inlet

0.01 (default) | scalar in the range [0,1]

Specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

### Dependencies

To enable this parameter, set **Inlet moisture specification** to Specific humidity.

**Nominal inlet water vapor mole fraction** — Mole fraction of water vapor at the inlet

0.01 (default) | scalar in the range [0,1]

Mole fraction of water vapor in a moist air mixture at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet moisture specification** to Mole fraction.

**Nominal inlet humidity ratio** — Humidity ratio at the inlet

0.01 (default) | positive scalar in the range [0,1]

Humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set **Inlet moisture specification** to Humidity ratio.

**Inlet trace gas specification** — Quantity used to describe trace gas level at the inlet

Mass fraction (default) | Mole fraction

Select quantity used to describe the trace gas level at the inlet during the nominal operating condition: mass fraction or mole fraction.

**Nominal inlet trace gas mass fraction** — Mass fraction of trace gas at the inlet

0.001 (default) | scalar in the range [0,1]

Mass fraction of trace gas in a moist air mixture at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to None.

**Dependencies**

To enable this parameter, set **Inlet trace gas specification** to Mass fraction.

**Nominal inlet trace gas mole fraction** — Mole fraction of trace gas at the inlet

0.001 (default) | scalar in the range [0,1]

Mole fraction of trace gas in a moist air mixture at the inlet of the moist air side of the heat exchanger during the nominal operating condition.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to None.

**Dependencies**

To enable this parameter, set **Inlet trace gas specification** to Mole fraction.

**Moist air volume** — Total volume of moist air in the heat exchanger

0.1 m<sup>3</sup> (default) | positive scalar

Total volume of moist air in the heat exchanger.

**Initial condition specification** — Select how to specify initial state of moist air

Same as nominal operating condition (default) | Specify initial condition

Select how to specify initial state of moist air:

- Same as nominal operating condition — Start the simulation at the nominal operating condition.

- `Specify initial condition` — Specify a different set of initial conditions using additional parameters.

**Initial moist air pressure** — Moist air pressure at start of simulation

0.101325 MPa (default) | positive scalar

Moist air pressure at the start of the simulation.

**Initial moist air temperature** — Moist air temperature at start of simulation

293.15 K (default) | positive scalar | two-element vector

Moist air temperature at the start of simulation. If the value is a scalar, then the initial temperature is assumed uniform. If the value is a two-element vector, then the initial temperature is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

**Initial moisture specification** — Quantity used to describe the initial moisture level

Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Select quantity used to describe the initial moisture level: relative humidity, specific humidity, water vapor mole fraction, or humidity ratio.

**Initial moist air relative humidity** — Relative humidity at the start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Moist air relative humidity at the start of simulation. If the value is a scalar, then the initial relative humidity is assumed uniform. If the value is a two-element vector, then the initial relative humidity is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

#### **Dependencies**

To enable this parameter, set **Initial moisture specification** to `Relative humidity`.

**Initial moist air specific humidity** — Specific humidity at the start of simulation

0.01 (default) | scalar in the range [0,1] | two-element vector

Moist air specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the start of simulation. If the value is a scalar, then the initial specific humidity is assumed uniform. If the value is a two-element vector, then the initial specific humidity is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

#### **Dependencies**

To enable this parameter, set **Initial moisture specification** to `Specific humidity`.

**Initial moist air water vapor mole fraction** — Mole fraction of water vapor at the start of simulation

0.01 (default) | scalar in the range [0,1] | two-element vector

Mole fraction of water vapor in a moist air mixture at the start of simulation. If the value is a scalar, then the initial mole fraction is assumed uniform. If the value is a two-element vector, then the initial mole fraction is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to `Mole fraction`.

**Initial moist air humidity ratio** — Humidity ratio at the start of simulation

0.01 (default) | positive scalar in the range [0,1] | two-element vector

Moist air humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the start of simulation. If the value is a scalar, then the initial humidity ratio is assumed uniform. If the value is a two-element vector, then the initial humidity ratio is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to `Humidity ratio`.

**Initial trace gas specification** — Quantity used to describe initial trace gas level

`Mass fraction` (default) | `Mole fraction`

Select quantity used to describe the trace gas level at the start of simulation: mass fraction or mole fraction.

**Initial moist air trace gas mass fraction** — Mass fraction of trace gas at the start of simulation

0.001 (default) | scalar in the range [0,1] | two-element vector

Mass fraction of trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the initial mass fraction is assumed uniform. If the value is a two-element vector, then the initial mass fraction is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

**Dependencies**

To enable this parameter, set **Initial trace gas specification** to `Mass fraction`.

**Initial moist air trace gas mole fraction** — Mole fraction of trace gas at the start of simulation

0.001 (default) | scalar in the range [0,1] | two-element vector

Mole fraction of trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the initial mole fraction is assumed uniform. If the value is a two-element vector, then the initial mole fraction is assumed to vary linearly between ports **A2** and **B2**, with the first element corresponding to port **A2** and the second element corresponding to port **B2**.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

**Dependencies**

To enable this parameter, set **Initial trace gas specification** to `Mole fraction`.

**Relative humidity at saturation** — Relative humidity point of condensation

1 (default) | nonnegative scalar

Relative humidity point of condensation. Condensation occurs above this value. In most cases, this value is 1, that is, 100%. A value greater than 1 indicates a supersaturated vapor.

### Correlation Coefficients

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for thermal liquid** — Correlation coefficient for thermal liquid  
0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for thermal liquid. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for thermal liquid** — Reynolds number exponent in correlation for thermal liquid  
0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for thermal liquid.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for thermal liquid** — Prandtl number exponent in correlation for thermal liquid  
0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for thermal liquid.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for moist air** — Correlation coefficient for moist air  
0.023 (default) | positive scalar

Proportionality constant in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for moist air. The default value is based on the Colburn equation.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for moist air** — Reynolds number exponent in correlation for moist air  
0.8 (default) | positive scalar

Reynolds number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for moist air. The default value is based on the Colburn equation.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for moist air** — Prandtl number exponent in correlation for moist air  
0.33 (default) | positive scalar

Prandtl number exponent in the correlation of Nusselt number as a function of Reynolds number and Prandtl number for moist air. The default value is based on the Colburn equation.

## System-Level Refrigeration Cycle (2P)

System-level, two-phase refrigeration block in a moist air, thermal liquid, or two-phase fluid network

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Thermodynamic Cycles

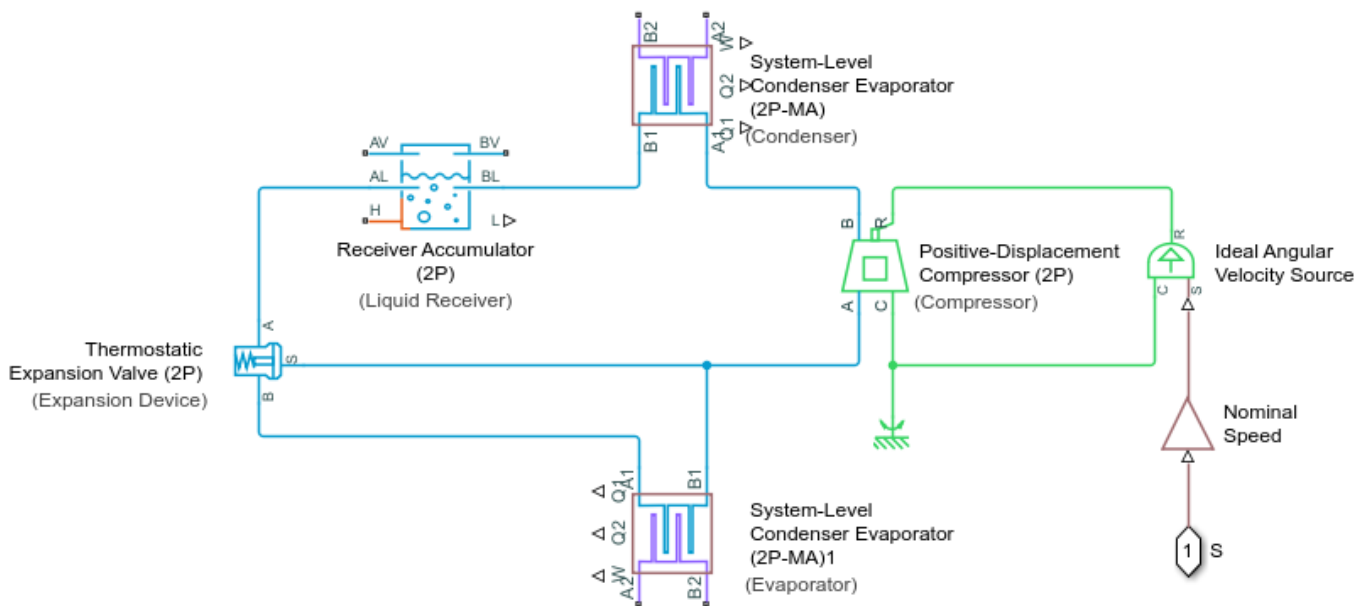

### Description

The System-Level Refrigeration Cycle (2P) block models a basic refrigeration cycle consisting of a compressor, a condenser, a liquid receiver, a thermostatic expansion valve, and an evaporator. The block models the refrigerant loop within the block in the two-phase fluid domain using the fluid properties specified at port **F**. The condenser and evaporator external fluids can be part of a moist air, thermal liquid, or two-phase fluid network. The external fluids are the fluids in the condenser and evaporator opposite the refrigerant.

When the compressor is on, the refrigeration cycle consumes power to transfer heat from the evaporator external fluid to the condenser external fluid. The subcomponents provide the specified nominal heat transfer under nominal operating conditions.

### Block Structure

This block behaves as a simplified version of this refrigeration cycle made from Simscape Fluids blocks that model the condenser, compressor, evaporator, expansion device, and liquid receiver:

The refrigerant flows through the loop counterclockwise. The compressor, which is controlled by the signal at port **S**, sucks in refrigerant vapor and produces a hot, high-pressure vapor, which moves to

the condenser. The condenser rejects heat from the refrigerant to the external fluid to condense the refrigerant. The liquid receiver acts as a storage tank for the refrigerant and only allows liquid flow to exit, which helps maintain normal operation even if fluctuating external conditions cause the condenser output to vary. From the tank, the refrigerant flows to the expansion device, which is typically a valve or capillary tube that produces a large pressure loss. The drop in pressure partially vaporizes the refrigerant, which chills it. The refrigerant moves to the evaporator, which absorbs heat from the external fluid to the cold refrigerant to vaporize the refrigerant.

The subcomponents of the System-Level Refrigeration Cycle (2P) block behave the same as these Simscape Fluids blocks in this model, but the equations for the positive displacement compressor, expansion valve, receiver component, and condenser and evaporator subcomponents vary. For more information on the individual components of a refrigeration system, see:

- Compressor (2P)
- Thermostatic Expansion Valve (2P)
- Receiver Accumulator (2P)

The compressor and evaporator components depend on the **External fluid for condenser heat transfer** and **External fluid for evaporator heat transfer** parameters. For more information, see:

- System-Level Condenser Evaporator (2P-MA)
- System-Level Condenser Evaporator (2P-TL)
- System-Level Heat Exchanger (2P-2P)

#### Positive Displacement Compressor Subcomponent

The compressor subcomponent determines the refrigerant mass flow rate for the system. The physical signal input port **S** controls the compressor operation. When the value at port **S** is 0, the compressor is off and the mass flow rate is 0. When the value at port **S** is 1, the compressor runs at the nominal shaft speed, which produces the nominal mass flow rate under nominal operating conditions. To prevent reverse flow, the value of **S** must be greater than or equal to 0.

The mass flow rate in the compressor is

$$\dot{m} = \frac{\eta_v \dot{V}_{nominal} S}{v_{in}},$$

where:

- $\eta_v$  is the volumetric efficiency.
- $S$  is the value of the signal at port **S**.
- $v_{in}$  is the inlet specific volume.
- $\dot{V}_{nominal}$  is the nominal volumetric flow rate, which the block determines from the nominal mass flow rate,  $\dot{m}_{nominal}$ , which depends on the setting of the **Capacity specification** parameter:
  - When the **Capacity specification** parameter is Cooling load,

$$\dot{m}_{nominal} = \frac{Q_{cooling}}{h_1 - h_4},$$

where  $Q_{cooling}$  is the **Nominal evaporator heat transfer** parameter,  $h_1$  is the evaporator outlet specific enthalpy, and  $h_4$  is the valve outlet specific enthalpy.

- When the **Capacity specification** parameter is Heating load,

$$\dot{m}_{nominal} = \frac{Q_{heating}}{h_2 - h_3},$$

where  $Q_{cooling}$  is the **Nominal condenser heat transfer** parameter,  $h_2$  is the compressor outlet specific enthalpy, and  $h_3$  is the condenser outlet specific enthalpy.

- When the **Capacity specification** parameter is Refrigerant mass flow rate,  $\dot{m}_{nominal}$  is the value of the **Nominal mass flow rate** parameter.

The fluid power that the compressor adds to the flow is

$$\Phi_{fluid} = \dot{m} \frac{h_{out, isen} - h_{in}}{\eta_s},$$

where:

- $h_{out, isen}$  is the specific enthalpy evaluated at the output pressure for an isentropic process.
- $h_{in}$  is the inlet specific enthalpy.
- $\eta_s$  is the isentropic efficiency.
- When **Performance specification** is Coefficient of performance for cooling or Coefficient of performance for heating, the block solves for  $\eta_s$  by calculating  $h_2$  and using the relation

$$h_2 = \frac{h_2^{isen} - h_1}{\eta_s} + h_1,$$

where  $h_2^{isen}$  is the compressor outlet specific enthalpy assuming an isentropic process.

- When **Performance specification** is Coefficient of performance for cooling, the block solves for  $h_2$  with  $CoP_{cooling} = \frac{h_1 - h_4}{h_2 - h_1}$ , where  $CoP_{cooling}$  is the **Coefficient of performance at nominal conditions** parameter.
- When **Performance specification** is Coefficient of performance for heating, the block solves for  $h_2$  with  $CoP_{heating} = \frac{h_2 - h_3}{h_2 - h_1} = \frac{h_2 - h_4}{h_2 - h_1} = CoP_{cooling} + 1$ , where  $CoP_{heating}$  is the **Coefficient of performance at nominal conditions** parameter.
- When **Performance specification** is Compressor isentropic efficiency,  $\eta_s$  is the value of the **Compressor isentropic efficiency** parameter.

The block calculates the volumetric efficiency directly from the inlet and outlet specific volumes

$$\eta_v = 1 + C - C \frac{v_{in}}{v_{out}},$$

where:

- $C$  is the clearance volume fraction that the block determines from the nominal operating conditions.
- $v_{in}$  and  $v_{out}$  are the inlet and outlet specific volumes evaluated at the inlet and outlet pressures.

The compressor subcomponent does not have mechanical rotational ports and does not need to calculate shaft torque. The mechanical power is

$$\Phi_{mech} = \frac{\Phi_{fluid}}{\eta_m},$$

where  $\eta_m$  is the mechanical efficiency.

### Expansion Valve Subcomponent

The relationship between mass flow rate, which the compressor determines, and the pressure drop across the thermostatic expansion valve subcomponent is

$$\dot{m} = S_{eff} \sqrt{\frac{2}{v_{in}}} \frac{\Delta p}{(\Delta p^2 - \Delta p_{lam}^2)^{0.25}},$$

where:

- $v_{in}$  is the inlet specific volume.
- $\Delta p$  is the pressure differential over the valve.
- $\Delta p_{lam}$  is the pressure threshold for transitional flow. Below this value, the flow is laminar.

The effective valve area depends on the pressure difference between the measured pressure,  $p_{bulb}$ , and the equalization pressure,  $p_{eq}$

$$S_{eff} = \beta [(p_{bulb} - p_{eq}) - (p_{sat}(T_{evap} + \Delta T_{static}) - p_{sat}(T_{evap}))],$$

where:

- $\beta$  is a valve constant the block determines from the nominal operating conditions.
- $T_{evap}$  is the evaporating temperature, which depends on the **Pressure specification** setting:
  - When **Pressure specification** is Pressure at specified saturation temperature,  $T_{evap}$  is the value of the **Nominal evaporating (saturation) temperature** parameter.
  - When **Pressure specification** is Specified pressure,  $T_{evap}$  is the saturation temperature that corresponds to the value of the **Nominal evaporator pressure** parameter.
- $\Delta T_{static}$  is the **Static (minimum) evaporator superheat** parameter.
- $p_{sat}(T_{evap})$  is the fluid saturation pressure as a function of  $T_{evap}$ .
- $p_{sat}(T_{evap} + \Delta T_{static})$  is the fluid saturation pressure as a function of  $T_{evap} + \Delta T_{static}$ .
- $p_{bulb}$  is the fluid pressure of the bulb. This pressure is the saturation pressure at the evaporator outlet temperature.
- $p_{eq}$  is the equalization pressure, which is the evaporator pressure for this block.

The effective valve area has limits. The minimum effective valve area,  $S_{eff,min}$ , is

$$S_{eff,min} = f_{leak} S_{eff,nom},$$

where  $f_{leak}$  is the value of the **Ratio of leakage to nominal expansion valve opening** parameter. The maximum effective valve area,  $S_{eff,max}$ , is

$$S_{eff,max} = f_{max} S_{eff,nom},$$

where  $f_{max}$  is the value of the **Ratio of maximum to nominal expansion valve opening** parameter.

### Receiver Subcomponent

Excluding the receiver, the block assumes that the refrigerant mass flow rate is the same value through the loop. In the receiver, the total mass is based on the balance between the mass flow rate produced by the compressor and the mass flow rate metered by the expansion valve. The outflow from the receiver subcomponent is always liquid and perfectly insulated from the environment.

The liquid mass fraction in the receiver subcomponent is

$$M \frac{dx_{liq}}{dt} = \dot{m}_{liq,in} - \dot{m}_{out} - \dot{m}_{vaporization} + \dot{m}_{condensation},$$

where:

- $x_{liq}$  is the liquid mass fraction.
- $\dot{m}_{liq,in}$  is the portion of the flow in that is liquid.
- $\dot{m}_{out}$  is the mass flow rate out of the receiver.
- $\dot{m}_{vaporization}$  is the rate of vaporization from the liquid volume to the vapor volume.
- $\dot{m}_{condensation}$  is the rate of condensation from the vapor volume to the liquid volume.

The pressure relates to the total mass via the specific volume using the relation

$$M(x_{liq}v_{liq} + (1 - x_{liq})v_{vap}) = V,$$

where:

- $V$  is the total receiver volume.
- $v_{liq}$  is the is the specific volume of the liquid volume.
- $v_{vap}$  is the is the specific volume of the vapor volume.

### Condenser and Evaporator Subcomponents

The condenser and evaporator subcomponents model the refrigerant thermal mass, but do not model fluid volume. For the condenser and evaporator, the energy conservation equation is

$$M \frac{dh_I}{dt} = \dot{m}(h_{in} - h_{out}) + Q,$$

where:

- $M$  is the constant mass of refrigerant in the component.
- $h_I$  is the refrigerant specific enthalpy at the component internal node.
- $\dot{m}$  is the refrigerant mass flow rate.
- $Q$  is the rate of heat transfer from the external fluid to the refrigerant.
- $h_{in}$  and  $h_{out}$  are the refrigerant specific enthalpy in and out of the component.

### Visualize the P-H Diagram

To visualize the refrigeration cycle, use a Probe block from the Simscape > Utilities library to output the variables `p_cycle` and `h_cycle`. These variables contain the four pressure and specific enthalpy

points of the refrigeration cycle. Connect the variables to the P-H Diagram (2P) block to visualize the refrigeration cycle.

This diagram shows the fluid attributes throughout the system for the refrigerant R-410a. Segment 1 to 2 is the compressor, segment 2 to 3 is the condenser, point 3 is the receiver, segment 3 to 4 is the expansion valve, and segment 4 to 1 is the evaporator.

### Assumptions and Limitations

- The block does not model reverse flow and limits the refrigeration cycle to zero and forward flow only. To prevent reverse flow, the block limits the compressor control to zero or forward operation and only models fluid volume in the liquid receiver subcomponent.
- Excluding the liquid receiver, the subcomponents do not model refrigerant fluid volume, which prevents the accumulation of mass in subcomponents. As a result, the refrigerant mass flow rate is the same through the evaporator, compressor, and condenser subcomponents.
- There is no refrigerant pressure loss in the evaporator or condenser.
- The block does not model kinetic energy changes in the refrigerant flow.
- The evaporator subcomponent models approximate pressure dynamics to maintain numerical robustness. However, the condenser subcomponent does not model approximate pressure dynamics, because the condenser pressure is equal to the receiver pressure, which does model pressure dynamics.
- The condenser and evaporator subcomponents only model counter flow because the refrigerant is primarily in the two-phase mixture state within the condenser and evaporator. Consequently, the temperature is uniform across most of the condenser and evaporator, and there is no significant difference between counter flow and cross flow.

### Ports

#### Input

**S** — Signal that operates compressor, unitless  
physical signal

Physical signal input that operates the compressor. A value of 0 means the compressor is off. A value of 1 means the compressor is operating at the nominal capacity.

#### Conserving

**F** — Refrigerant properties  
two-phase fluid

Two-phase fluid conserving port associated with the refrigerant properties. Connect a Two-Phase Fluid Properties (2P) or Two-Phase Fluid Predefined Properties (2P) block to this port. Do not connect any other Two-Phase Fluid blocks to port **F** because this port acts as an absolute reference.

**Ac** — Condenser external fluid inlet

moist air | thermal liquid | two-phase fluid

Moist air, thermal liquid, or two-phase fluid conserving port associated with the condenser external fluid inlet. The block assumes that the condenser external fluid flows from port **Ac** to port **Bc**. The **External fluid for condenser heat transfer** parameter controls the port fluid.

**Bc** — Condenser external fluid outlet

moist air | thermal liquid | two-phase fluid

Moist air, thermal liquid, or two-phase fluid conserving port associated with the condenser external fluid outlet. The block assumes that the condenser external fluid flows from port **Ac** to port **Bc**. The **External fluid for condenser heat transfer** parameter controls the port fluid.

**Ae** — Evaporator external fluid inlet

moist air | thermal liquid | two-phase fluid

Moist air, thermal liquid, or two-phase fluid conserving port associated with the evaporator external fluid inlet. The block assumes that the evaporator external fluid flows from port **Ae** to port **Be**. The **External fluid for evaporator heat transfer** parameter controls the port fluid.

**Be** — Evaporator external fluid outlet

moist air | thermal liquid | two-phase fluid

Moist air, thermal liquid, or two-phase fluid conserving port associated with the evaporator external fluid outlet. The block assumes that the evaporator external fluid flows from port **Ae** to port **Be**. The **External fluid for evaporator heat transfer** parameter controls the port fluid.

## Output

**Qc** — Heat rejected in condenser, W

physical signal

Physical signal output port that measures the heat rejected by the refrigerant in the condenser, in W.

**Qe** — Heat absorbed in evaporator, W

physical signal

Physical signal output port that measures the heat absorbed by the refrigerant in the evaporator, in W.

**Pwr** — Mechanical power consumed by the compressor, W

physical signal

Physical signal output port that measures the mechanical power consumed by the compressor, in W.

**W** — Rate of condensation in evaporator, kg/s

physical signal

Physical signal output port that measures rate of condensation in the evaporator external fluid, in kg/s, if the **External fluid for evaporator heat transfer** parameter is **Moist air**. If the **External fluid for evaporator heat transfer** parameter is not moist air, this port outputs 0.

## Parameters

### Refrigeration Cycle

**Capacity specification** — Method for specifying size of system  
Cooling load (default) | Heating load | Refrigerant mass flow rate

Method for specifying the size of the system. You can specify the cooling load, heating load, or the refrigerant mass flow rate.

**Nominal condenser heat transfer** — Rate of heat transfer in condenser  
15 kW (default) | positive scalar

Rate of heat transfer from the refrigerant to the external fluid in the condenser.

#### Dependencies

To enable this parameter, set **Capacity specification** to Heating load.

**Nominal evaporator heat transfer** — Rate of heat transfer in evaporator  
15 kW (default) | positive scalar

Rate of heat transfer from the external fluid to the refrigerant in the evaporator.

#### Dependencies

To enable this parameter, set **Capacity specification** to Cooling load.

**Nominal mass flow rate** — Refrigerant mass flow rate  
0.005 kg/s (default) | positive scalar

Refrigerant mass flow rate through the cycle.

#### Dependencies

To enable this parameter, set **Capacity specification** to Refrigerant mass flow rate.

**Pressure specification** — Method for specifying condenser and evaporator pressure  
Specified pressure (default) | Pressure at specified saturation temperature

Method for providing condenser and evaporator pressures. Select whether to directly provide the pressures or provide the corresponding saturation temperatures.

**Nominal condenser pressure** — Refrigerant pressure in condenser  
1 MPa (default) | positive scalar

Pressure of refrigerant in the condenser.

#### Dependencies

To enable this parameter, set **Pressure specification** to Specified pressure.

**Nominal evaporator pressure** — Refrigerant pressure in evaporator  
0.1 MPa (default) | positive scalar

Pressure of refrigerant in the evaporator.

**Dependencies**

To enable this parameter, set **Pressure specification** to Specified pressure.

**Nominal condensing (saturation) temperature** — Condenser refrigerant saturation temperature  
333.15 K (default) | positive scalar

Saturation temperature of refrigerant in the condenser.

**Dependencies**

To enable this parameter, set **Pressure specification** to Pressure at specified saturation temperature.

**Nominal evaporating (saturation) temperature** — Evaporator refrigerant saturation temperature  
273.15 K (default) | positive scalar

Saturation temperature of refrigerant in the evaporator.

**Dependencies**

To enable this parameter, set **Pressure specification** to Pressure at specified saturation temperature.

**Nominal condenser subcooling** — Operational condenser outlet temperature differential  
5 de1taK (default) | positive scalar

Degrees of temperature below saturation temperature at the condenser outlet.

**Nominal (static + opening) evaporator superheat** — Operational evaporator outlet temperature differential  
10 de1taK (default) | positive scalar

Degrees of temperature above saturation temperature at the evaporator outlet. The expansion valve adjusts its valve area to try to maintain this superheat.

**Static (minimum) evaporator superheat** — Minimum allowable temperature differential at evaporator outlet  
5 de1taK (default) | positive scalar

Superheat threshold to close the expansion valve.

**Performance specification** — Method to specify refrigeration cycle efficiency  
Coefficient of performance for cooling (default) | Coefficient of performance for heating | Compressor isentropic efficiency

Method to specify the refrigeration cycle efficiency. Choose based on the coefficient of performance of the cycle for heating, cooling, or the compressor efficiency.

**Coefficient of performance at nominal conditions** — Ratio of cooling or heating to power consumed for compressor  
3 (default) | positive scalar

Ratio of useful cooling or heating by the refrigeration cycle to the power consumed by the compressor.

**Dependencies**

To enable this parameter, set **Performance specification** to Coefficient of performance for cooling or Coefficient of performance for heating.

**Compressor isentropic efficiency** — Ratio of ideal-to-actual change in specific enthalpy across compressor

0.8 (default) | positive scalar

Ratio of ideal, or isentropic, change in specific enthalpy to the actual change in specific enthalpy across the compressor.

**Dependencies**

To enable this parameter, set **Performance specification** to Compressor isentropic efficiency.

**Compressor volumetric efficiency at nominal conditions** — Ratio of volumetric flow rate to displacement rate

0.95 (default) | positive scalar

Ratio of actual volumetric flow rate to the displacement rate of the compressor.

**Compressor mechanical efficiency** — Efficiency of conversion to torque

0.95 (default) | positive scalar

Ratio of the power delivered to the fluid flow to the power driving the mechanical shaft.

**Ratio of maximum to nominal expansion valve opening** — Ratio of open valve areas to maintain superheat

1.5 (default) | positive scalar

Ratio of the fully opened valve area to the valve area needed to maintain superheat at nominal conditions.

**Ratio of leakage to nominal expansion valve opening** — Ratio of closed valve areas to maintain superheat

1e-6 (default) | positive scalar

Ratio of the closed valve area to the valve area needed to maintain superheat at nominal conditions

**Expansion valve smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar

Smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Condenser refrigerant volume** — Volume of condenser refrigerant

0.001 m<sup>3</sup> (default) | positive scalar

Volume of refrigerant in the condenser.

**Evaporator refrigerant volume** — Volume of evaporator refrigerant

0.001 m<sup>3</sup> (default) | positive scalar

Volume of refrigerant in the evaporator.

**Liquid receiver tank volume** — Volume of liquid and vapor phases in receiver tank  
0.01 m<sup>3</sup> (default) | positive scalar

Total physical volume of liquid receiver tank, including both the volume of liquid and vapor phases.

**Initial receiver liquid level** — Initial liquid volume fraction in tank  
0.5 (default) | positive scalar

Liquid volume fraction in the receiver tank at the start of simulation.

**Initialize refrigerant to nominal operating conditions** — Whether to specify refrigerant initial conditions  
on (default) | off

Whether refrigerant in the cycle starts simulation at the nominal operating conditions based on the nominal operating parameters or specified explicitly with initial condition parameters.

**Initial condenser pressure** — Initial refrigerant pressure in condenser  
1 MPa (default) | positive scalar

Pressure of the refrigerant in the condenser and liquid receiver at the start of simulation.

#### **Dependencies**

To enable this parameter, clear the **Initialize refrigerant to nominal operating conditions** check box.

**Initial evaporator pressure** — Initial refrigerant pressure in evaporator  
0.1 MPa (default) | positive scalar

Pressure of the refrigerant in the evaporator at the start of simulation.

#### **Dependencies**

To enable this parameter, clear the **Initialize refrigerant to nominal operating conditions** check box.

**Initial condenser specific enthalpy [inlet, outlet]** — Initial refrigerant specific energy in condenser  
[450, 250] kJ/kg (default) | positive scalar | two-element vector

Specific enthalpy of the refrigerant in the condenser at the start of simulation. If you specify this parameter as a vector of two values, the first element is the inlet specific enthalpy value and the second element is the outlet specific enthalpy value. If you enter a scalar, the block assumes that the inlet and outlet specific enthalpy are the same value.

#### **Dependencies**

To enable this parameter, clear the **Initialize refrigerant to nominal operating conditions** check box.

**Initial evaporator specific enthalpy [inlet, outlet]** — Initial refrigerant specific energy in evaporator  
[250, 400] kJ/kg (default) | positive scalar | two-element vector

Specific enthalpy of the refrigerant in the evaporator at the start of simulation. If you specify this parameter as a vector of two values, the first element is the inlet specific enthalpy value and the second element is the outlet specific enthalpy value. If you enter a scalar, the block assumes that the inlet and outlet specific enthalpy are the same value.

#### Dependencies

To enable this parameter, clear the **Initialize refrigerant to nominal operating conditions** check box.

**Initial receiver liquid and vapor fully saturated** — Whether to specify receiver initial conditions  
on (default) | off

Whether the receiver starts the simulation at the saturation equilibrium, meaning the liquid and vapor volumes are both at the saturated state, or uses explicitly specified initial conditions.

#### Dependencies

To enable this parameter, clear the **Initialize refrigerant to nominal operating conditions** check box.

**Initial receiver liquid specific enthalpy** — Receiver initial liquid specific enthalpy  
500 kJ/kg (default) | positive scalar

Specific enthalpy of the liquid portion of the refrigerant in the receiver at the start of simulation.

#### Dependencies

To enable this parameter, clear the **Initialize refrigerant to nominal operating conditions** and **Initial receiver liquid and vapor fully saturated** check boxes.

**Initial receiver vapor specific enthalpy** — Receiver initial vapor specific enthalpy  
3500 kJ/kg (default) | positive scalar

Specific enthalpy of the vapor portion of the refrigerant in the receiver at the start of simulation.

#### Dependencies

To enable this parameter, clear the **Initialize refrigerant to nominal operating conditions** and **Initial receiver liquid and vapor fully saturated** check boxes.

### Condenser External Fluid

**External fluid for condenser heat transfer** — External fluid for heat transfer in condenser  
Moist air (default) | Thermal liquid | Two-phase fluid

External fluid for heat transfer in the condenser.

**Nominal mass flow rate** — Mass flow rate between condenser ports  
0.5 kg/s (default) | positive scalar

Mass flow rate from port **Ac** to port **Bc** during nominal operating conditions.

**Nominal pressure drop** — Pressure drop between condenser ports  
0.001 MPa (default) | positive scalar

Pressure drop from port **Ac** to port **Bc** during nominal operating conditions.

**Pressure specification** — Method of pressure specification

Specified pressure (default) | Pressure at specified saturation temperature

Method of pressure specification:

- **Specified pressure** — Specify the nominal inlet pressure.
- **Pressure at specified saturation temperature** — Specify the nominal saturation temperature that corresponds to the inlet pressure.

#### **Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid.

**Nominal inlet pressure** — Pressure at external fluid side inlet of condenser

0.101325 MPa (default) | positive scalar

Pressure at the inlet of the condenser on the external fluid side of the heat exchanger during the nominal operating condition.

#### **Dependencies**

To enable this parameter, set either:

- **External fluid for condenser heat transfer** to Moist air or Thermal liquid.
- **External fluid for condenser heat transfer** to Two-phase fluid, and set **Pressure specification** to Specific pressure.

**Nominal saturation temperature** — Nominal saturation temperature to specify pressure

400 K (default) | positive scalar

Saturation temperature at the outlet of the condenser external fluid side of the heat exchanger during the nominal operating condition. The pressure in the condenser is the corresponding saturation pressure.

#### **Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid and **Pressure specification** to Pressure at specified saturation temperature.

**Inlet condition specification** — Method to describe inlet condition of fluid

Specific enthalpy (default) | Temperature | Vapor quality

Method the block uses to describe the inlet condition of the condenser external fluid at the nominal operating condition.

#### **Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid.

**Nominal inlet temperature** — Temperature at condenser external fluid side inlet

400 K (default) | positive scalar

Temperature at the inlet of the external fluid side of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid and **Initial condition specification** to Temperature.

**Nominal inlet specific enthalpy** — Specific enthalpy at condenser external fluid side inlet  
500 kJ/kg (default) | positive scalar

Specific enthalpy at the inlet of the external fluid side of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid and **Initial condition specification** to Specific enthalpy.

**Nominal inlet vapor quality** — Vapor quality at condenser external fluid side inlet  
1 (default) | positive scalar

Vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the inlet of the external fluid side of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid and **Initial condition specification** to Vapor quality.

**Inlet moisture specification** — Method to describe moisture level at condenser external fluid side inlet  
Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Method the block uses to describe the moisture level at the inlet during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Moist air.

**Nominal inlet relative humidity** — Relative humidity at inlet  
0.1 (default) | scalar in the range [0,1]

Relative humidity at the inlet of the external fluid side of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Moist air and **Inlet moisture specification** to Relative humidity.

**Nominal inlet specific humidity** — Specific humidity at inlet  
0.01 (default) | scalar in the range [0,1]

Specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the inlet of the external fluid side of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air` and **Inlet moisture specification** to `Specific humidity`.

**Nominal inlet water vapor mole fraction** — Mole fraction of water vapor at inlet  
`0.01` (default) | scalar in the range `[0,1]`

Mole fraction of the water vapor in a moist air mixture at the inlet of the external fluid side of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air` and **Inlet moisture specification** to `Mole fraction`.

**Nominal inlet humidity ratio** — Humidity ratio at inlet  
`0.01` (default) | scalar in the range `[0,1]`

Humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the inlet of the external fluid side of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air` and **Inlet moisture specification** to `Humidity ratio`.

**Inlet trace gas specification** — Method to describe trace gas level at inlet  
`Mass fraction` (default) | `Mole fraction`

Method the block uses to describe the trace gas level at the external fluid side inlet of the condenser during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air`.

**Nominal inlet trace gas mass fraction** — Mass fraction of trace gas at inlet  
`0.001` (default) | scalar in the range `[0,1]`

Mass fraction of trace gas in a moist air mixture at the inlet of the external fluid side of the condenser during the nominal operating condition.

The block ignores this parameter if the **Trace gas model** parameter in the `Moist Air Properties (MA)` block is `None`.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air` and **Inlet trace gas specification** to `Mass fraction`.

**Nominal inlet trace gas mole fraction** — Mole fraction of trace gas at inlet  
`0.001` (default) | scalar in the range `[0,1]`

Mole fraction of the trace gas in a moist air mixture at the inlet of the external fluid side of the condenser during the nominal operating condition.

The block ignores this parameter if the **Trace gas model** parameter in the Moist Air Properties (MA) block is None.

#### Dependencies

To enable this parameter, set **External fluid for condenser heat transfer** to Moist air and **Inlet trace gas specification** to Mole fraction.

**External fluid volume** — Volume of fluid in condenser  
 $0.1 \text{ m}^3$  (default) | positive scalar

Total volume of external fluid in the condenser.

**Cross-sectional area at port Ac** — Flow area at port Ac  
 $0.01 \text{ m}^2$  (default) | positive scalar

Flow area at the condenser external fluid port **Ac**.

**Cross-sectional area at port Bc** — Flow area at port Bc  
 $0.01 \text{ m}^2$  (default) | positive scalar

Flow area at the condenser external fluid port **Bc**.

**Condenser wall thermal mass** — Option to model condenser wall heat transfer  
 Off (default) | On

Whether to include the temperature dynamics of the heat transfer surface.

**Condenser wall mass** — Condenser heat transfer mass  
 1 kg (default) | positive scalar

Total mass of the condenser heat transfer surface.

#### Dependencies

To enable this parameter, select **Condenser wall thermal mass**.

**Condenser wall specific heat** — Specific heat of condenser transfer surface  
 $490 \text{ J}/(\text{K}\cdot\text{kg})$  (default) | positive scalar

Specific heat of the condenser heat transfer surface.

#### Dependencies

To enable this parameter, select **Condenser wall thermal mass**.

**Initialize to nominal operating conditions** — Whether to specify condenser initial conditions  
 On (default) | Off

Whether to start the simulation at the nominal operating condition or specify a different set of initial conditions using additional parameters.

**Initial pressure** — Fluid pressure at start of simulation  
 $0.101325 \text{ MPa}$  (default) | positive scalar

Condenser external fluid pressure at the start of the simulation.

**Dependencies**

To enable this parameter, clear the **Initialize to nominal operating conditions** check box.

**Initial fluid energy specification** — Initial state of the condenser external fluid  
Specific enthalpy (default) | Temperature | Vapor quality | Vapor void fraction |  
Specific internal energy

Quantity used to describe the initial state of the condenser external fluid.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid and clear the **Initialize to nominal operating conditions** check box.

**Initial temperature** — Temperature at start of simulation  
293.15 K (default) | positive scalar | two-element vector

Temperature at the start of simulation. If the value is a scalar, then the block assumes that the initial temperature is uniform. If the value is a two-element vector, then the block assumes that the initial temperature varies linearly between the ports condenser ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set either:

- **External fluid for condenser heat transfer** to Moist air or Thermal liquid and clear the **Initialize to nominal operating conditions** check box.
- **External fluid for condenser heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Temperature.

**Initial vapor quality** — Vapor mass fraction at start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Condenser external fluid vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the block assumes that the initial vapor quality is uniform. If the value is a two-element vector, then the block assumes that the initial vapor quality varies between the condenser ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Vapor quality.

**Initial vapor void fraction** — Vapor volume fraction at start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Condenser external fluid vapor void fraction, defined as the volume fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the block assumes that the initial vapor void fraction is uniform. If the value is a two-element vector, then the block assumes that the initial vapor void quality varies between the condenser ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Vapor void fraction.

**Initial specific enthalpy** — Enthalpy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Condenser external fluid specific enthalpy at the start of simulation. If the value is a scalar, then the block assumes that the initial specific enthalpy is uniform. If the value is a two-element vector, then the block assumes that the initial specific enthalpy varies between the condenser ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Specific enthalpy.

**Initial specific internal energy** — Internal energy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Condenser external fluid specific internal energy at the start of simulation. If the value is a scalar, then the block assumes that the initial specific internal energy is uniform. If the value is a two-element vector, then the block assumes that the initial specific internal energy varies between the condenser ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Specific internal energy.

**Initial moisture specification** — Method used to describe initial moisture level  
Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Method used to describe the initial moisture level in condenser external fluid.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to Moist air and clear the **Initialize to nominal operating conditions** check box.

**Initial relative humidity** — Relative humidity at start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Condenser external fluid relative humidity at the start of simulation. If the value is a scalar, then the block assumes that the initial relative humidity is uniform. If the value is a two-element vector, then the block assumes that the initial relative humidity varies linearly between the ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Relative humidity.

**Initial specific humidity** — Specific humidity at start of simulation  
0.01 (default) | scalar in the range [0,1] | two-element vector

Condenser external fluid specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the start of simulation. If the value is a scalar, then the block assumes that the initial specific humidity is uniform. If the value is a two-element vector, then the block assumes that the initial specific humidity varies linearly between the ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Specific humidity.

**Initial water vapor mole fraction** — Mole fraction of water vapor at start of simulation  
0.01 (default) | scalar in the range [0,1] | two-element vector

Mole fraction of the water vapor in the condenser external fluid at the start of simulation. If the value is a scalar, then the block assumes that the initial water vapor mole fraction is uniform. If the value is a two-element vector, then the block assumes that the initial water vapor mole fraction varies linearly between the ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Mole fraction.

**Initial humidity ratio** — Humidity ratio at start of simulation  
0.01 (default) | scalar in the range [0,1] | two-element vector

Condenser external fluid humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the start of simulation. If the value is a scalar, then the block assumes that the initial humidity ratio is uniform. If the value is a two-element vector, then the block assumes that the initial humidity ratio varies linearly between the ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Humidity ratio.

**Initial trace gas specification** — Method to describe initial trace gas level  
Mass fraction (default) | Mole fraction

Method used to describe the trace gas level at the start of simulation.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air` and clear the **Initialize to nominal operating conditions** check box.

**Initial trace gas mass fraction** — Mass fraction of trace gas at start of simulation  
`0.001` (default) | scalar in the range `[0,1]` | two-element vector

Mass fraction of trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the block assumes that the initial mass fraction is uniform. If the value is a two-element vector, then the block assumes that the initial mass fraction varies linearly between the ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

The block ignores this parameter if the **Trace gas model** parameter in the Moist Air Properties (MA) block is `None`.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial trace gas specification** Mass fraction.

**Initial trace gas mole fraction** — Mole fraction of trace gas at start of simulation  
`0.001` (default) | scalar in the range `[0,1]` | two-element vector

Mole fraction of the trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the block assumes that the initial mole fraction is uniform. If the value is a two-element vector, then the block assumes that the initial mole fraction varies linearly between the ports, with the first element corresponding to port **Ac** and the second element corresponding to port **Bc**.

The block ignores this parameter if the **Trace gas model** parameter in the Moist Air Properties (MA) block is `None`.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial trace gas specification** Mole fraction.

**Initial condenser wall temperature** — Condenser surface temperature at simulation start  
`293.15 K` (default) | positive scalar | two-element vector

Heat transfer surface temperature at the start of simulation. If this value is a scalar, the block assumes that the initial temperature is uniform. If this value is a two-element vector, then the block assumes that the temperature varies linearly between ports **Ac** and **Bc** with the first element corresponding to **Ac** and second element corresponding to **Bc**.

**Dependencies**

To enable this parameter, clear the **Initialize to nominal operating conditions** check box.

**Relative humidity at saturation** — Relative humidity point of condensation  
`1` (default) | nonnegative scalar

Relative humidity point of condensation. Condensation occurs above this value. In most cases, this value is 1, which is equivalent to 100%. A value greater than 1 indicates a supersaturated vapor.

**Dependencies**

To enable this parameter, set **External fluid for condenser heat transfer** to `Moist air` and clear the **Initialize to nominal operating conditions** check box.

**Evaporator External Fluid**

**External fluid for evaporator heat transfer** — External fluid for heat transfer in evaporator  
`Moist air` (default) | `Thermal liquid` | `Two-phase fluid`

External fluid for heat transfer in the evaporator.

**Nominal mass flow rate** — Mass flow rate between evaporator ports  
`0.5 kg/s` (default) | positive scalar

Mass flow rate from port **Ae** to port **Be** during nominal operating conditions.

**Nominal pressure drop** — Pressure drop between evaporator ports  
`0.001 MPa` (default) | positive scalar

Pressure drop from port **Ae** to port **Be** during nominal operating conditions.

**Pressure specification** — Method of pressure specification  
`Specified pressure` (default) | `Pressure at specified saturation temperature`

Method of pressure specification:

- **Specified pressure** — Specify the nominal inlet pressure.
- **Pressure at specified saturation temperature** — Specify the nominal saturation temperature that corresponds to the inlet pressure.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Two-phase fluid`.

**Nominal inlet pressure** — Pressure at external fluid side inlet of evaporator  
`0.101325 MPa` (default) | positive scalar

Pressure at the inlet of the evaporator on the external fluid side of the heat exchanger during the nominal operating condition.

**Dependencies**

To enable this parameter, set either:

- **External fluid for evaporator heat transfer** to `Moist air` or `Thermal liquid`.
- **External fluid for evaporator heat transfer** to `Two-phase fluid`, and set **Pressure specification** to `Specific pressure`.

**Nominal saturation temperature** — Nominal saturation temperature to specify pressure  
`400 K` (default) | positive scalar

Saturation temperature at the outlet of the evaporator external fluid side of the heat exchanger during the nominal operating condition. The pressure in the evaporator is the corresponding saturation pressure.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid and **Pressure specification** to Pressure at specified saturation temperature.

**Inlet condition specification** — Method to describe inlet condition of fluid  
Specific enthalpy (default) | Temperature | Vapor quality

Method the block uses to describe the inlet condition of the evaporator external fluid at the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid.

**Nominal inlet temperature** — Temperature at evaporator external fluid side inlet  
400 K (default) | positive scalar

Temperature at the inlet of the external fluid side of the evaporator during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid and **Initial condition specification** to Temperature.

**Nominal inlet specific enthalpy** — Specific enthalpy at evaporator external fluid side inlet  
500 kJ/kg (default) | positive scalar

Specific enthalpy at the inlet of the external fluid side of the evaporator during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid and **Initial condition specification** to Specific enthalpy.

**Nominal inlet vapor quality** — Vapor quality at evaporator external fluid side inlet  
1 (default) | positive scalar

Vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the inlet of the external fluid side of the evaporator during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid and **Initial condition specification** to Vapor quality.

**Inlet moisture specification** — Method to describe moisture level at evaporator external fluid side inlet  
Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Method the block uses to describe the moisture level at the inlet during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Moist air.

**Nominal inlet relative humidity** — Relative humidity at inlet

0.1 (default) | scalar in the range [0,1]

Relative humidity at the inlet of the external fluid side of the evaporator during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air` and **Inlet moisture specification** to `Relative humidity`.

**Nominal inlet specific humidity** — Specific humidity at inlet

0.01 (default) | scalar in the range [0,1]

Specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the inlet of the external fluid side of the evaporator during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air` and **Inlet moisture specification** to `Specific humidity`.

**Nominal inlet water vapor mole fraction** — Mole fraction of water vapor at the inlet

0.01 (default) | scalar in the range [0,1]

Mole fraction of the water vapor in a moist air mixture at the inlet of the external fluid side of the evaporator during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air` and **Inlet moisture specification** to `Mole fraction`.

**Nominal inlet humidity ratio** — Humidity ratio at inlet

0.01 (default) | scalar in the range [0,1]

Humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the inlet of the external fluid side of the evaporator during the nominal operating condition.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air` and **Inlet moisture specification** to `Humidity ratio`.

**Inlet trace gas specification** — Method to describe trace gas level at inlet

Mass fraction (default) | Mole fraction

Method the block uses to describe the trace gas level at the external fluid side inlet of the evaporator during the nominal operating condition.

**Nominal inlet trace gas mass fraction** — Mass fraction of trace gas at inlet

0.001 (default) | scalar in the range [0,1]

Mass fraction of the trace gas in a moist air mixture at the inlet of the external fluid side of the evaporator during the nominal operating condition.

The block ignores this parameter if the **Trace gas model** parameter in the Moist Air Properties (MA) block is None.

#### Dependencies

To enable this parameter, set **External fluid for evaporator heat transfer** to Moist air and **Inlet trace gas specification** to Mass fraction.

**Nominal inlet trace gas mole fraction** — Mole fraction of trace gas at inlet

0.001 (default) | scalar in the range [0,1]

Mole fraction of the trace gas in a moist air mixture at the inlet of the external fluid side of the evaporator during the nominal operating condition.

The block ignores this parameter if the **Trace gas model** parameter in the Moist Air Properties (MA) block is None.

#### Dependencies

To enable this parameter, set **External fluid for evaporator heat transfer** to Moist air and **Inlet trace gas specification** to Mole fraction.

**External fluid volume** — Volume of fluid in evaporator

0.1 m<sup>3</sup> (default) | positive scalar

Total volume of external fluid in the evaporator.

**Cross-sectional area at port Ae** — Flow area at port Ae

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the evaporator external fluid port **Ae**.

**Cross-sectional area at port Be** — Flow area at port Be

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the evaporator external fluid port **Be**.

**Evaporator wall thermal mass** — Option to model evaporator wall heat transfer

Off (default) | On

Whether to include the temperature dynamics of the heat transfer surface.

**Evaporator wall mass** — Evaporator heat transfer mass

1 kg (default) | positive scalar

Total mass of the evaporator heat transfer surface.

#### Dependencies

To enable this parameter, select **Evaporator wall thermal mass**.

**Evaporator wall specific heat** — Specific heat of evaporator transfer surface

490 J/(K\*kg) (default) | positive scalar

Specific heat of the evaporator heat transfer surface.

**Dependencies**

To enable this parameter, select **Evaporator wall thermal mass**.

**Initialize to nominal operating conditions** — Whether to specify evaporator initial conditions  
On (default) | Off

Whether to start the simulation at the nominal operating condition or specify a different set of initial conditions using additional parameters.

**Initial pressure** — Fluid pressure at start of simulation  
0.101325 MPa (default) | positive scalar

Evaporator external fluid pressure at the start of the simulation.

**Dependencies**

To enable this parameter, clear the **Initialize to nominal operating conditions** check box.

**Initial fluid energy specification** — Initial state of the evaporator external fluid  
Specific enthalpy (default) | Temperature | Vapor quality | Vapor void fraction |  
Specific internal energy

Quantity used to describe the initial state of the evaporator external fluid.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Two-phase fluid` and clear the **Initialize to nominal operating conditions** check box.

**Initial temperature** — Temperature at start of simulation  
293.15 K (default) | positive scalar | two-element vector

Temperature at the start of simulation. If the value is a scalar, then the block assumes that the initial temperature is uniform. If the value is a two-element vector, then the block assumes that the initial temperature varies linearly between the ports evaporator ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set either:

- **External fluid for evaporator heat transfer** to `Moist air` or `Thermal liquid` and clear the **Initialize to nominal operating conditions** check box.
- **External fluid for evaporator heat transfer** to `Two-phase fluid`, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to `Temperature`.

**Initial vapor quality** — Vapor mass fraction at start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Evaporator external fluid vapor quality, defined as the mass fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the block assumes that the initial vapor quality is uniform. If the value is a two-element vector, then the block assumes that the initial vapor quality varies between the evaporator ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Vapor quality.

**Initial vapor void fraction** — Vapor volume fraction at start of simulation  
0.5 (default) | scalar in the range [0,1] | two-element vector

Evaporator external fluid vapor void fraction, defined as the volume fraction of vapor in a liquid-vapor mixture, at the start of simulation. If the value is a scalar, then the block assumes that the initial vapor void fraction is uniform. If the value is a two-element vector, then the block assumes that the initial vapor void quality varies between the evaporator ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Vapor void fraction.

**Initial specific enthalpy** — Enthalpy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Evaporator external fluid specific enthalpy at the start of simulation. If the value is a scalar, then the block assumes that the initial specific enthalpy is uniform. If the value is a two-element vector, then the block assumes that the initial specific enthalpy varies between the evaporator ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Specific enthalpy.

**Initial specific internal energy** — Internal energy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Evaporator external fluid specific internal energy at the start of simulation. If the value is a scalar, then the block assumes that the initial specific internal energy is uniform. If the value is a two-element vector, then the block assumes that the initial specific internal energy varies between the evaporator ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to Two-phase fluid, clear the **Initialize to nominal operating conditions** check box, and set **Initial fluid energy specification** to Specific internal energy.

**Initial moisture specification** — Method used to describe initial moisture level  
Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Method used to describe the initial moisture level in evaporator external fluid.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air` and clear the **Initialize to nominal operating conditions** check box.

**Initial relative humidity** — Relative humidity at start of simulation

0.5 (default) | scalar in the range [0,1] | two-element vector

Evaporator external fluid relative humidity at the start of simulation. If the value is a scalar, then the block assumes that the initial relative humidity is uniform. If the value is a two-element vector, then the block assumes that the initial relative humidity varies linearly between the ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Relative humidity.

**Initial specific humidity** — Specific humidity at start of simulation

0.01 (default) | scalar in the range [0,1] | two-element vector

Evaporator external fluid specific humidity, defined as the mass fraction of water vapor in a moist air mixture, at the start of simulation. If the value is a scalar, then the block assumes that the initial specific humidity is uniform. If the value is a two-element vector, then the block assumes that the initial specific humidity varies linearly between the ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Specific humidity.

**Initial water vapor mole fraction** — Mole fraction of water vapor at start of simulation

0.01 (default) | scalar in the range [0,1] | two-element vector

Mole fraction of the water vapor in the evaporator external fluid at the start of simulation. If the value is a scalar, then the block assumes that the initial water vapor mole fraction is uniform. If the value is a two-element vector, then the block assumes that the initial water vapor mole fraction varies linearly between the ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

**Dependencies**

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Mole fraction.

**Initial humidity ratio** — Humidity ratio at start of simulation

0.01 (default) | scalar in the range [0,1] | two-element vector

Evaporator external fluid humidity ratio, defined as the mass ratio of water vapor to dry air and trace gas, at the start of simulation. If the value is a scalar, then the block assumes that the initial humidity ratio is uniform. If the value is a two-element vector, then the block assumes that the initial humidity

ratio varies linearly between the ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

#### Dependencies

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial moisture specification** Humidity ratio.

**Initial trace gas specification** — Method to describe initial trace gas level  
Mass fraction (default) | Mole fraction

Method used to describe the trace gas level at the start of simulation.

#### Dependencies

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air` and clear the **Initialize to nominal operating conditions** check box.

**Initial trace gas mass fraction** — Mass fraction of trace gas at start of simulation  
0.001 (default) | scalar in the range [0,1] | two-element vector

Mass fraction of trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the block assumes that the initial mass fraction is uniform. If the value is a two-element vector, then the block assumes that the initial mass fraction varies linearly between the ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

The block ignores this parameter if the **Trace gas model** parameter in the Moist Air Properties (MA) block is `None`.

#### Dependencies

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial trace gas specification** Mass fraction.

**Initial trace gas mole fraction** — Mole fraction of trace gas at start of simulation  
0.001 (default) | scalar in the range [0,1] | two-element vector

Mole fraction of the trace gas in a moist air mixture at the start of simulation. If the value is a scalar, then the block assumes that the initial mole fraction is uniform. If the value is a two-element vector, then the block assumes that the initial mole fraction varies linearly between the ports, with the first element corresponding to port **Ae** and the second element corresponding to port **Be**.

The block ignores this parameter if the **Trace gas model** parameter in the Moist Air Properties (MA) block is `None`.

#### Dependencies

To enable this parameter, set **External fluid for evaporator heat transfer** to `Moist air`, clear the **Initialize to nominal operating conditions** check box, and set **Initial trace gas specification** Mole fraction.

**Initial evaporator wall temperature** — Evaporator surface temperature at simulation start  
293.15 K (default) | positive scalar | two-element vector

Heat transfer surface temperature at the start of simulation. If it this value is a scalar, the block assumes that the initial temperature is uniform. If this value is a two-element vector, then the block assumes that the temperature varies linearly between ports **Ae** and **Be** with the first element corresponding to **Ae** and second element corresponding to **Be**.

#### Dependencies

To enable this parameter, clear the **Initialize to nominal operating conditions** check box.

**Relative humidity at saturation** — Relative humidity point of condensation

1 (default) | nonnegative scalar

Relative humidity point of condensation. Condensation occurs above this value. In most cases, this value is 1, which is equivalent to 100%. A value greater than 1 indicates a supersaturated vapor.

#### Dependencies

To enable this parameter, set **External fluid for evaporator heat transfer** to **Moist air** and clear the **Initialize to nominal operating conditions** check box.

#### Correlation Coefficients

**Modify condenser Nusselt number correlation coefficients** — Whether to modify condenser Nusselt number correlation coefficients

Off (default) | On

Whether to manually modify the condenser Nusselt number correlation coefficients. Select this parameter to adjust the off-design performance of the condenser.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant, liquid regime** — Correlation coefficient for refrigerant subcooled liquid

0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for a subcooled liquid for the condenser. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients**.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant, mixture regime** — Correlation coefficient for refrigerant liquid-vapor mixture

0.005 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the liquid-vapor mixture for the condenser. The default value is based on the Cavallini and Zecchin correlation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients**.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant, vapor regime** — Correlation coefficient for refrigerant superheated vapor

0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the superheated vapor for the condenser. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients**.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant** — Reynolds number exponent in correlation for refrigerant  
0.8 (default) | positive scalar

Reynolds number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the condenser refrigerant. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients**.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant** — Prandtl number exponent in correlation for refrigerant  
0.33 (default) | positive scalar

Prandtl number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for condenser refrigerant. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients**.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid, liquid regime** — Correlation coefficient for subcooled liquid in two-phase fluid  
0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the subcooled condenser external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients** and set **External fluid for condenser heat transfer** to Two-phase fluid.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid, mixture regime** — Correlation coefficient for liquid-vapor mixture in two-phase fluid  
0.005 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for liquid-vapor mixture in the condenser external fluid. The default value is based on the Cavallini and Zecchin correlation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients** and set **External fluid for condenser heat transfer** to Two-phase fluid.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid, vapor regime** — Correlation coefficient for superheated vapor in two-phase fluid  
 0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for superheated vapor in the condenser external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients** and set **External fluid for condenser heat transfer** to Two-phase fluid.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid** — Correlation coefficient for condenser external fluid  
 0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the condenser external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients** and set **External fluid for condenser heat transfer** to Moist air or Thermal liquid.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid** — Reynolds number exponent in correlation for condenser external fluid  
 0.8 (default) | positive scalar

Reynolds number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the condenser external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients**.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid** — Prandtl number exponent in correlation for condenser external fluid  
 0.33 (default) | positive scalar

Prandtl number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the condenser external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify condenser Nusselt number correlation coefficients**.

**Modify evaporator Nusselt number correlation coefficients** — Whether to modify evaporator Nusselt number correlation coefficients  
 Off (default) | On

Whether to manually modify the evaporator Nusselt number correlation coefficients. Select this parameter to adjust the off-design performance of the evaporator.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant, liquid regime** — Correlation coefficient for refrigerant subcooled liquid

0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for a subcooled liquid for the evaporator. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients**.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant, mixture regime** — Correlation coefficient for refrigerant liquid-vapor mixture

0.005 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the liquid-vapor mixture for the evaporator. The default value is based on the Cavallini and Zecchin correlation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients**.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant, vapor regime** — Correlation coefficient for refrigerant superheated vapor

0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the superheated vapor for the condenser. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients**.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant** — Reynolds number exponent in correlation for refrigerant

0.8 (default) | positive scalar

Reynolds number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the evaporator refrigerant. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients**.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for refrigerant** — Prandtl number exponent in correlation for refrigerant

0.33 (default) | positive scalar

Prandtl number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for evaporator refrigerant. The same value applies to subcooled liquid, liquid-vapor mixture, and superheated vapor.

#### Dependencies

To enable this parameter, select **External fluid for evaporator heat transfer**.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid, liquid regime** — Correlation coefficient for subcooled liquid in two-phase fluid

0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the subcooled evaporator external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients** and set **External fluid for evaporator heat transfer** to Two-phase fluid.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid, mixture regime** — Correlation coefficient for liquid-vapor mixture in two-phase fluid

0.005 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for liquid-vapor mixture in the evaporator external fluid. The default value is based on the Cavallini and Zecchin correlation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients** and set **External fluid for evaporator heat transfer** to Two-phase fluid.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid, vapor regime** — Correlation coefficient for superheated vapor in two-phase fluid

0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for superheated vapor in the evaporator external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients** and set **External fluid for evaporator heat transfer** to Two-phase fluid.

**a in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid** — Correlation coefficient for evaporator external fluid

0.023 (default) | positive scalar

Proportionality constant in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the evaporator external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients** and set **External fluid for evaporator heat transfer** to Moist air or Thermal liquid.

**b in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid** — Reynolds number exponent in correlation for evaporator external fluid

0.8 (default) | positive scalar

Reynolds number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the evaporator external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients**.

**c in  $Nu = a \cdot Re^b \cdot Pr^c$  for external fluid** — Prandtl number exponent in correlation for evaporator external fluid

0.33 (default) | positive scalar

Prandtl number exponent in the correlation of the Nusselt number as a function of the Reynolds number and Prandtl number for the evaporator external fluid. The default value is based on the Colburn equation.

#### Dependencies

To enable this parameter, select **Modify evaporator Nusselt number correlation coefficients**.

## Version History

## T-junction

(To be removed) Hydraulic resistance of T-junction in pipe

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

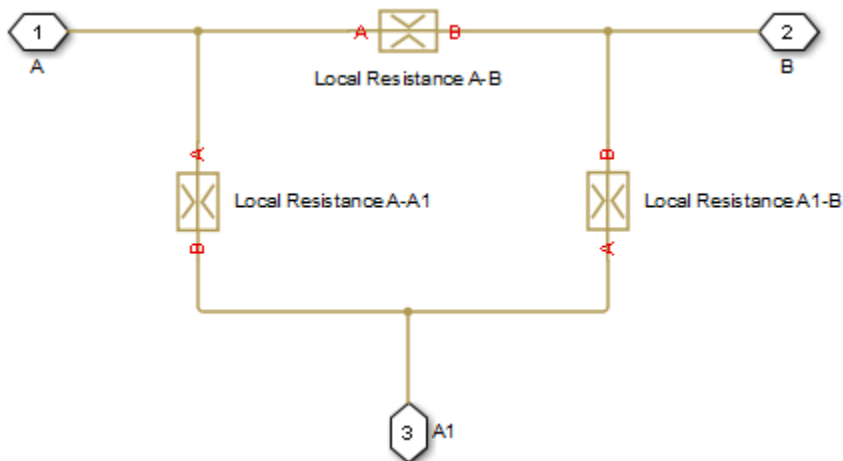

## Library

Local Hydraulic Resistances

### Description

The T-junction block represents a T-junction (wye connection) consisting, in general, of a main run and a branch merging to the main run. The junction as a hydraulic resistance is built of three Local Resistance blocks, as shown in the following diagram.

To specify pressure loss for all possible flow directions, you have to provide six pressure loss coefficients. The flow regime is checked in the underlying Local Resistance blocks by comparing the Reynolds number to the specified critical Reynolds number value, and depending on the result, the appropriate formula for pressure loss computation is used. For more information, see the reference documentation for the Local Resistance block.

The block positive direction is from port A to port B, from port A to port A1, and from port A1 to port B.

## Basic Assumptions and Limitations

- Fluid inertia is not taken into account.

## Parameters

### Geometry Tab

#### Main pipe diameter

The internal pipe diameter of the main run. The default value is 0.01 m.

#### Branch pipe diameter

The internal pipe diameter of the branch. The default value is 0.01 m.

#### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

#### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

#### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 120. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### Pressure Loss Tab

#### A-B pressure loss coefficient

The pressure loss coefficient between ports A and B when fluid flows in the direction from A to B. The default value is 1.12.

#### B-A pressure loss coefficient

The pressure loss coefficient between ports A and B when fluid flows in the direction from B to A. The default value is 1.12.

#### A-A1 pressure loss coefficient

The pressure loss coefficient between ports A and A1 when fluid flows in the direction from A to A1. The default value is 1.36.

**A1-A pressure loss coefficient**

The pressure loss coefficient between ports A and A1 when fluid flows in the direction from A1 to A. The default value is 1.65.

**A1-B pressure loss coefficient**

The pressure loss coefficient between ports A1 and B when fluid flows in the direction from A1 to B. The default value is 1.6.

**B-A1 pressure loss coefficient**

The pressure loss coefficient between ports A1 and B when fluid flows in the direction from B to A1. The default value is 1.8.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the main run inlet.

B

Hydraulic conserving port associated with the main run outlet.

A1

Hydraulic conserving port associated with the branch inlet.

**Version History****Introduced in R2006b****R2023a: To be removed**

## T-Junction (IL)

Three-way junction in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

### Description

The T-Junction (IL) block models a three-way pipe junction with a branch line at port **C** connected at a 90° angle to the main pipe line, between ports **A** and **B**. You can specify a custom junction or a junction that uses a Rennels correlation or Crane correlation loss coefficient. When **Loss coefficient model** is set to **Custom**, you can specify the loss coefficients of each pipe segment for converging and diverging flows.

### Flow Direction

The flow is *converging* when the flow through port **C** merges into the main flow. The flow is *diverging* when the branch flow splits from the main flow. The flow direction between **A** and **I**, the point where the branch meets the main, and **B** and **I** must be consistent for all loss coefficients to be applied. If they are not, as shown in the last two diagrams in the figure below, the losses in the junction are approximated with the main branch loss coefficient for converging or diverging flows.

### Converging Flows

### Diverging Flows

### Approximated Flow Losses

#### Flow Scenarios

The block uses mode charts to determine each loss coefficient for a given flow configuration. This table describes the conditions and coefficients for each operational mode.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Stagnant	-	-	-	1 or last valid value	1 or last valid value	1 or last valid value
Diverging from node A	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	0	$K_{main,div}$	$K_{side,div}$
Diverging from node B	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$K_{main,div}$	0	$K_{side,div}$
Converging to node A	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	0	$K_{main,conv}$	$K_{side,conv}$
Converging to node B	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$K_{main,conv}$	0	$K_{side,conv}$

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Converging to node C (branch) when the <b>Loss coefficient model</b> parameter is Crane correlation or Custom	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$(K_{main,conv} + K_{side,conv})/2$	$(K_{main,conv} + K_{side,conv})/2$	0
Diverging from node C (branch) when the <b>Loss coefficient model</b> parameter is Crane correlation or Custom	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$(K_{main,div} + K_{side,div})/2$	$(K_{main,div} + K_{side,div})/2$	0

When the **Loss coefficient model** parameter `Rennels correlation`, the values for converging to node C (branch) and diverging from node C (branch) are calculated directly.

The flow is stagnant when the mass flow rate conditions do not match any defined flow scenario. Stagnant flow is permitted at the start of the simulation, but the block does not revert to stagnant flow after it has achieved another mode. The mass flow rate threshold, which is the point at which the flow in the pipe begins to reverse direction, is

$$\dot{m}_{thresh} = Re_c \nu \bar{\rho} \sqrt{\frac{\pi}{4} A_{min}}$$

where:

- $Re_c$  is the **Critical Reynolds number** parameter, beyond which the transitional flow regime begins.
- $\nu$  is the fluid viscosity.
- $\bar{\rho}$  is the average fluid density.
- $A_{min}$  is the smallest cross-sectional area in the pipe junction.

### Crane Correlation Coefficient Model

When you set the **Loss coefficient model** parameter to `Crane correlation`, the pipe loss coefficients,  $K_{main}$  and  $K_{side}$ , and the pipe friction factor,  $f_T$ , are calculated according to Crane [1]:

$$K_{main,div} = K_{main,conv} = 20f_{T,main}$$

$$K_{side,div} = K_{side,conv} = 60f_{T,side}$$

In contrast to the custom junction type, the standard junction loss coefficient is the same for both converging and diverging flows.  $K_A$ ,  $K_B$ , and  $K_C$  are then calculated in the same manner as custom junctions.

**PIPE FRICTION DATA FOR CLEAN COMMERCIAL STEEL PIPE  
WITH FLOW IN ZONE OF COMPLETE TURBULENCE**

Nominal Size	1/2"	3/4"	1"	1 1/4"	1 1/2"	2"	2 1/2, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction Factor ( $f_r$ )	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

### Friction Factor per Nominal Pipe Diameter

#### Rennels Correlation Coefficient Model

When you set the **Loss coefficient model** parameter to Rennels correlation, the block calculates the pipe loss coefficients according to [2].

#### Diverging Flow on Main Branch

The main branch diverging loss coefficient is

$$K_{main,div} = 0.62 - 0.98 \frac{\dot{m}_1}{\dot{m}_2} + 0.36 \left( \frac{\dot{m}_1}{\dot{m}_2} \right)^2 + 0.03 \left( \frac{\dot{m}_2}{\dot{m}_1} \right)^6,$$

where:

- $\dot{m}_1$  is the mass flow rate at the inflow of the main branch.
- $\dot{m}_2$  is the mass flow rate at the outflow of the main branch.

The value of  $K_{main,div}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

The side branch diverging loss coefficient is

$$K_{side,div} = \left( 0.81 - 1.13 \frac{\dot{m}_1}{\dot{m}_3} + \left( \frac{\dot{m}_1}{\dot{m}_3} \right)^2 \right) \left( \frac{d_3}{d_1} \right)^4 + 1.12 \frac{d_3}{d_1} - 1.08 \left( \frac{d_3}{d_1} \right)^3 + K_*,$$

where

- $\dot{m}_3$  is the mass flow rate at the outflow of the side branch.
- $d_1$  is the diameter of the main branch.
- $d_3$  is the diameter of the side branch.
- $K_* = 0.57 - 1.07 \left( \frac{r}{d_3} \right)^{1/2} - 2.13 \frac{r}{d_3} + 8.24 \left( \frac{r}{d_3} \right)^{3/2} - 8.48 \left( \frac{r}{d_3} \right)^2 + 2.90 \left( \frac{r}{d_3} \right)^{5/2}$ .
- $r$  is the value of the **Junction radius of curvature** parameter.

The value of  $K_{side,div}$  saturates when  $\dot{m}_3/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

#### Converging Flow on Main Branch

The main branch converging loss coefficient is

$$K_{main,conv} = \left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 - 0.95 - 2C_{xC}\left(\frac{\dot{m}_1}{\dot{m}_2} - 1\right) - 2C_M\left(\left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 - \frac{\dot{m}_1}{\dot{m}_2}\right),$$

where

$$C_M = 0.23 + 1.46\left(\frac{r}{d_3}\right) - 2.75\left(\frac{r}{d_3}\right)^2 + 1.65\left(\frac{r}{d_3}\right)^3$$

$$C_{xC} = 0.08 + 0.56\left(\frac{r}{d_3}\right) - 1.75\left(\frac{r}{d_3}\right)^2 + 1.83\left(\frac{r}{d_3}\right)^3$$

The value of  $K_{main,conv}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

The side branch converging loss coefficient is

$$K_{side,conv} = (2C_{yC} - 1) + \left(\frac{d_3}{d_1}\right)^4 \left[ 2(C_{xC} - 1) + 2(2 - C_{xC} - C_M)\frac{\dot{m}_1}{\dot{m}_3} - 0.92\left(\frac{\dot{m}_1}{\dot{m}_3}\right)^2 \right],$$

where:

$$C_{yC} = 1 - 0.25\left(\frac{d_3}{d_1}\right)^{1.3} - \left[ 0.11\frac{r}{d_3} - 0.65\left(\frac{r}{d_3}\right) + 0.83\left(\frac{r}{d_3}\right)^3 \right] \left(\frac{d_3}{d_1}\right)^2.$$

The value of  $K_{side,conv}$  saturates when  $\dot{m}_3/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

#### Converging or Diverging flow from Side Branch

The loss coefficient when the flow is converging to the side branch is

$$K_{conv\ to\ side} = \left(0.81 - 1.16\sqrt{\frac{r}{d}} + 0.5\frac{r}{d}\right)\left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 - \left(0.95 - 1.65\frac{r}{d}\right)\frac{\dot{m}_1}{\dot{m}_2} + 1.34 - 1.69\frac{r}{d},$$

where  $d$  is the diameter of the side branch. The value of  $K_{conv\ to\ side}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

The loss coefficient when the flow is diverging from the side branch is

$$K_{div\ from\ side} = 0.59\left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 + \left(1.18 - 1.84\sqrt{\frac{r}{d}} + 1.16\frac{r}{d}\right)\frac{\dot{m}_1}{\dot{m}_2} - 0.68 + 1.04\sqrt{\frac{r}{d}} - 1.16\frac{r}{d}.$$

The value of  $K_{div\ from\ side}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

#### Custom T-Junction

When you set the **Loss coefficient model** parameter to Custom, the block calculates the pipe loss coefficient at each port,  $K$ , based on the user-defined loss parameters for converging and diverging flow and mass flow rate at each port. You must specify  $K_{main,conv}$ ,  $K_{main,div}$ ,  $K_{side,conv}$ , and  $K_{side,div}$  as the **Main branch converging loss coefficient**, **Main branch diverging loss coefficient**, **Side branch converging loss coefficient**, and **Side branch diverging loss coefficient** parameters, respectively.

## Mass and Momentum Balance

The block conserves mass in the junction such that

$$\dot{m}_A + \dot{m}_B + \dot{m}_C = 0.$$

The block calculates the flow through the pipe junction using the momentum conservation equations between ports **A**, **B**, and **C**:

$$p_A - p_I = I_A + \frac{K_A}{2\bar{\rho}A_{main}^2} \dot{m}_A \sqrt{\dot{m}_A^2 + \dot{m}_{thresh}^2}$$

$$p_B - p_I = I_B + \frac{K_B}{2\bar{\rho}A_{main}^2} \dot{m}_B \sqrt{\dot{m}_B^2 + \dot{m}_{thresh}^2}$$

$$p_C - p_I = I_C + \frac{K_C}{2\bar{\rho}A_{side}^2} \dot{m}_C \sqrt{\dot{m}_C^2 + \dot{m}_{thresh}^2}$$

where  $I$  represents the fluid inertia, and

$$I_A = \ddot{m}_A \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_B = \ddot{m}_B \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_C = \ddot{m}_C \frac{\sqrt{\pi \cdot A_{main}}}{A_{side}}$$

$A_{main}$  is the **Main branch area (A-B)** parameter and  $A_{side}$  is the **Side branch area (A-C, B-C)** parameter.

## Energy Balance

The block balances energy such that

$$\phi_A + \phi_B + \phi_C = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.
- $\phi_C$  is the energy flow rate at port **C**.

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**C** — Liquid port  
isothermal liquid

Liquid entry or exit port.

## Parameters

**Main branch area (A-B)** — Cross-sectional area between ports A and B  
0.01 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between ports **A** and **B**.

**Side branch area (A-C, B-C)** — Cross-sectional area of the side branch  
0.01 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between ports **A** and **C** and between ports **B** and **C**.

**Loss coefficient model** — Loss coefficient type  
Crane correlation (default) | Rennels correlation | Custom

The junction loss coefficient model. Set this parameter to `Custom` to specify individual diverging and converging loss coefficients for each flow path segment.

**Main branch converging loss coefficient** — Converging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for converging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to `Custom`.

**Main branch diverging loss coefficient** — Diverging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for diverging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to `Custom`.

**Side branch converging loss coefficient** — Converging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port C and the main line for converging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Side branch diverging loss coefficient** — Diverging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port C and the main line for diverging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Junction radius of curvature** — Radius of curvature of the junction  
0.001 m (default) | positive scalar

Radius of the curvature of the junction used to calculate the loss coefficients when **Loss coefficient model** is set to Rennels correlation.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Rennels correlation.

**Minimum valid flow ratio for coefficient calculation** — Minimum flow ration allowed in Rennels correlation flow calculation  
0.2 (default) | positive scalar

Minimum flow ratio allowed when calculating the loss coefficients in the Rennels correlation parameterization. If the flow ratio is below this limit, it will saturate at this value.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Rennels correlation.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the junction.

## Version History

Introduced in R2020a

### R2023a: New Pipe Loss Coefficient Models

The **Three-way junction type** parameter is renamed to the **Loss coefficient model** parameter. Set **Three-way junction type** to Rennels correlation to use the new loss coefficient model. The Standard option for this parameter is renamed to Crane correlation and the Custom option remains unchanged.

**R2022b: Conversion to Mode Charts**

*Behavior change in future release*

The block uses mode charts to handle the different flow configurations. Results during flow scenario transitions may be different than in previous releases. Results during flow scenario transitions are not steady state and are not necessarily accurate.

“Mode Chart Modeling”

## T-Junction (TL)

Three-way junction in a thermal liquid system

### Libraries:

Simscape / Fluids / Thermal Liquid / Pipes & Fittings

### Description

The T-Junction (TL) block represents a three-way pipe junction with a branch line at port **C** connected at a 90° angle to the main pipe line, between ports **A** and **B**. You can specify a custom junction or a junction that uses a Rennels correlation or Crane correlation loss coefficient. When **Loss coefficient model** is set to **Custom**, you can specify the loss coefficients of each pipe segment for converging and diverging flows.

### Flow Direction

The flow is *converging* when the flow through port **C** merges into the main flow. The flow is *diverging* when the branch flow splits from the main flow. The flow direction between **A** and **I**, the point where the branch meets the main, and **B** and **I** must be consistent for all loss coefficients to be applied. If they are not, as shown in the last two diagrams in the figure below, the losses in the junction are approximated with the main branch loss coefficient for converging or diverging flows.

### Converging Flows

### Diverging Flows

### Approximated Flow Losses

#### Flow Scenarios

The block uses mode charts to determine each loss coefficient for a given flow configuration. This table describes the conditions and coefficients for each operational mode.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Stagnant	-	-	-	1 or last valid value	1 or last valid value	1 or last valid value
Diverging from node A	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	0	$K_{main,div}$	$K_{side,div}$
Diverging from node B	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$K_{main,div}$	0	$K_{side,div}$
Converging to node A	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	0	$K_{main,conv}$	$K_{side,conv}$
Converging to node B	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$K_{main,conv}$	0	$K_{side,conv}$

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Converging to node C (branch) when the <b>Loss coefficient model</b> parameter is Crane correlation or Custom	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$(K_{main,conv} + K_{side,conv})/2$	$(K_{main,conv} + K_{side,conv})/2$	0
Diverging from node C (branch) when the <b>Loss coefficient model</b> parameter is Crane correlation or Custom	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$(K_{main,div} + K_{side,div})/2$	$(K_{main,div} + K_{side,div})/2$	0

When the **Loss coefficient model** parameter is **Rennels correlation**, the values for converging to node C (branch) and diverging from node C (branch) are calculated directly.

The flow is stagnant when the mass flow rate conditions do not match any defined flow scenario. Stagnant flow is permitted at the start of the simulation, but the block does not revert to stagnant flow after it has achieved another mode. The mass flow rate threshold, which is the point at which the flow in the pipe begins to reverse direction, is

$$\dot{m}_{thresh} = Re_c \nu \bar{\rho} \sqrt{\frac{\pi}{4} A_{min}}$$

where:

- $Re_c$  is the **Critical Reynolds number**, beyond which the transitional flow regime begins.
- $\nu$  is the fluid viscosity.
- $\bar{\rho}$  is the average fluid density.
- $A_{min}$  is the smallest cross-sectional area in the pipe junction.

### Crane Correlation Coefficient Model

When you set the **Loss coefficient model** parameter to **Crane correlation**, the pipe loss coefficients,  $K_{main}$  and  $K_{side}$ , and the pipe friction factor,  $f_T$ , are calculated according to Crane [1] :

$$K_{main,div} = K_{main,conv} = 20f_{T,main}$$

$$K_{side,div} = K_{side,conv} = 60f_{T,side}$$

In contrast to the custom junction type, the standard junction loss coefficient is the same for both converging and diverging flows.  $K_A$ ,  $K_B$ , and  $K_C$  are then calculated in the same manner as custom junctions.

**PIPE FRICTION DATA FOR CLEAN COMMERCIAL STEEL PIPE  
WITH FLOW IN ZONE OF COMPLETE TURBULENCE**

Nominal Size	½"	¾"	1"	1¼"	1½"	2"	2½, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction Factor ( $f_r$ )	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

### Friction Factor per Nominal Pipe Diameter

#### Rennels Correlation Coefficient Model

When you set the **Loss coefficient model** parameter to Rennels correlation, the block calculates the pipe loss coefficients according to [2].

#### Diverging Flow on Main Branch

The main branch diverging loss coefficient is

$$K_{main,div} = 0.62 - 0.98 \frac{\dot{m}_1}{\dot{m}_2} + 0.36 \left( \frac{\dot{m}_1}{\dot{m}_2} \right)^2 + 0.03 \left( \frac{\dot{m}_2}{\dot{m}_1} \right)^6,$$

where:

- $\dot{m}_1$  is the mass flow rate at the inflow of the main branch.
- $\dot{m}_2$  is the mass flow rate at the outflow of the main branch.

The value of  $K_{main,div}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

The side branch diverging loss coefficient is

$$K_{side,div} = \left( 0.81 - 1.13 \frac{\dot{m}_1}{\dot{m}_3} + \left( \frac{\dot{m}_1}{\dot{m}_3} \right)^2 \right) \left( \frac{d_3}{d_1} \right)^4 + 1.12 \frac{d_3}{d_1} - 1.08 \left( \frac{d_3}{d_1} \right)^3 + K_*,$$

where

- $\dot{m}_3$  is the mass flow rate at the outflow of the side branch.
- $d_1$  is the diameter of the main branch.
- $d_3$  is the diameter of the side branch.
- $K_* = 0.57 - 1.07 \left( \frac{r}{d_3} \right)^{1/2} - 2.13 \frac{r}{d_3} + 8.24 \left( \frac{r}{d_3} \right)^{3/2} - 8.48 \left( \frac{r}{d_3} \right)^2 + 2.90 \left( \frac{r}{d_3} \right)^{5/2}$ .
- $r$  is the value of the **Junction radius of curvature** parameter.

The value of  $K_{side,div}$  saturates when  $\dot{m}_3/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

#### Converging Flow on Main Branch

The main branch converging loss coefficient is

$$K_{main,conv} = \left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 - 0.95 - 2C_{xC}\left(\frac{\dot{m}_1}{\dot{m}_2} - 1\right) - 2C_M\left(\left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 - \frac{\dot{m}_1}{\dot{m}_2}\right),$$

where

$$C_M = 0.23 + 1.46\left(\frac{r}{d_3}\right) - 2.75\left(\frac{r}{d_3}\right)^2 + 1.65\left(\frac{r}{d_3}\right)^3$$

$$C_{xC} = 0.08 + 0.56\left(\frac{r}{d_3}\right) - 1.75\left(\frac{r}{d_3}\right)^2 + 1.83\left(\frac{r}{d_3}\right)^3$$

The value of  $K_{main,conv}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

The side branch converging loss coefficient is

$$K_{side,conv} = (2C_{yC} - 1) + \left(\frac{d_3}{d_1}\right)^4 \left[ 2(C_{xC} - 1) + 2(2 - C_{xC} - C_M)\frac{\dot{m}_1}{\dot{m}_3} - 0.92\left(\frac{\dot{m}_1}{\dot{m}_3}\right)^2 \right],$$

where:

$$C_{yC} = 1 - 0.25\left(\frac{d_3}{d_1}\right)^{1.3} - \left[ 0.11\frac{r}{d_3} - 0.65\left(\frac{r}{d_3}\right) + 0.83\left(\frac{r}{d_3}\right)^3 \right] \left(\frac{d_3}{d_1}\right)^2.$$

The value of  $K_{side,conv}$  saturates when  $\dot{m}_3/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

#### Converging or Diverging flow from Side Branch

The loss coefficient when the flow is converging to the side branch is

$$K_{conv\ to\ side} = \left(0.81 - 1.16\sqrt{\frac{r}{d}} + 0.5\frac{r}{d}\right)\left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 - \left(0.95 - 1.65\frac{r}{d}\right)\frac{\dot{m}_1}{\dot{m}_2} + 1.34 - 1.69\frac{r}{d},$$

where  $d$  is the diameter of the side branch. The value of  $K_{conv\ to\ side}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

The loss coefficient when the flow is diverging from the side branch is

$$K_{div\ from\ side} = 0.59\left(\frac{\dot{m}_1}{\dot{m}_2}\right)^2 + \left(1.18 - 1.84\sqrt{\frac{r}{d}} + 1.16\frac{r}{d}\right)\frac{\dot{m}_1}{\dot{m}_2} - 0.68 + 1.04\sqrt{\frac{r}{d}} - 1.16\frac{r}{d}.$$

The value of  $K_{div\ from\ side}$  saturates when  $\dot{m}_2/\dot{m}_1$  is equal to the value of the **Minimum valid flow ratio for coefficient calculation** parameter.

#### Custom T-Junction

When you set the **Loss coefficient model** parameter to Custom, the block calculates the pipe loss coefficient at each port,  $K$ , based on the user-defined loss parameters for converging and diverging flow and mass flow rate at each port. You must specify  $K_{main,conv}$ ,  $K_{main,div}$ ,  $K_{side,conv}$ , and  $K_{side,div}$  as the **Main branch converging loss coefficient**, **Main branch diverging loss coefficient**, **Side branch converging loss coefficient**, and **Side branch diverging loss coefficient** parameters, respectively.

### Mass and Momentum Balance

The block conserves mass in the junction such that

$$\dot{m}_A + \dot{m}_B + \dot{m}_C = 0.$$

The block calculates the flow through the pipe junction using the momentum conservation equations between ports **A**, **B**, and **C**:

$$p_A - p_I = I_A + \frac{K_A}{2\bar{\rho}A_{main}^2} \dot{m}_A \sqrt{\dot{m}_A^2 + \dot{m}_{thresh}^2}$$

$$p_B - p_I = I_B + \frac{K_B}{2\bar{\rho}A_{main}^2} \dot{m}_B \sqrt{\dot{m}_B^2 + \dot{m}_{thresh}^2}$$

$$p_C - p_I = I_C + \frac{K_C}{2\bar{\rho}A_{side}^2} \dot{m}_C \sqrt{\dot{m}_C^2 + \dot{m}_{thresh}^2}$$

where  $I$  represents the fluid inertia, and

$$I_A = \ddot{m}_A \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_B = \ddot{m}_B \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_C = \ddot{m}_C \frac{\sqrt{\pi \cdot A_{main}}}{A_{side}}$$

$A_{main}$  is the **Main branch area (A-B)** parameter and  $A_{side}$  is the **Side branch area (A-C, B-C)** parameter.

### Energy Balance

The block balances energy such that

$$\phi_A + \phi_B + \phi_C = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.
- $\phi_C$  is the energy flow rate at port **C**.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the liquid entrance or exit of the junction.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the liquid entrance or exit of the junction.

**C** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the liquid entrance or exit of the junction.

## Parameters

**Main branch area (A-B)** — Cross-sectional area between ports A and B  
0.01 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between ports **A** and **B**.

**Side branch area (A-C, B-C)** — Cross-sectional area of the side branch  
0.01 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between ports **A** and **C** and between ports **B** and **C**.

**Loss coefficient model** — Loss coefficient type  
Crane correlation (default) | Rennels correlation | Custom

The junction loss coefficient model. Set this parameter to **Custom** to specify individual diverging and converging loss coefficients for each flow path segment.

**Main branch converging loss coefficient** — Converging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for converging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Custom**.

**Main branch diverging loss coefficient** — Diverging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for diverging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Custom**.

**Side branch converging loss coefficient** — Converging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port C and the main line for converging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Side branch diverging loss coefficient** — Diverging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port C and the main line for diverging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Junction radius of curvature** — Radius of curvature of the junction  
0.001 m (default) | positive scalar

Radius of the curvature of the junction used to calculate the loss coefficients when **Loss coefficient model** is set to Rennels correlation.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Rennels correlation.

**Minimum valid flow ratio for coefficient calculation** — Minimum flow ration allowed in Rennels correlation flow calculation  
0.2 (default) | positive scalar

Minimum flow ratio allowed when calculating the loss coefficients in the Rennels correlation parameterization. If the flow ratio is below this limit, it will saturate at this value.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Rennels correlation.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the junction.

## Version History

Introduced in R2022a

### R2023a: New Pipe Loss Coefficient Models

The **Three-way junction type** parameter is renamed to the **Loss coefficient model** parameter. Set **Three-way junction type** to Rennels correlation to use the new loss coefficient model. The Standard option for this parameter is renamed to Crane correlation and the Custom option remains unchanged.

**R2022b: Conversion to Mode Charts**

*Behavior change in future release*

The block uses mode charts to handle the different flow configurations. Results during flow scenario transitions may be different than in previous releases. Results during flow scenario transitions are not steady state and are not necessarily accurate.

# Tank

(To be removed) Pressurized fluid container with variable fluid level

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Low-Pressure Blocks

## Description

The Tank block models a pressurized fluid container with a variable fluid level. The tank has an optional number of ports ranging from one to three, with each number corresponding to a block variant. The tank pressurization is fixed regardless of changes to fluid volume or fluid level. The tank is vented if the pressurization is set to zero—a setting corresponding to an internal pressure equal to atmospheric pressure.

## Tank Ports and Port Elevations

The block accounts for differences in port elevation. Hydrostatic pressure is computed separately for each port from the fluid level and port elevation. The hydrostatic pressure adds to the pressurization of the tank—increasing the port pressure as the fluid level rises. The block accounts also for minor pressure losses at the ports due to filters, fittings, and other local flow resistances. To modulate these losses, the block provides a pressure loss coefficient for each port.

## Changing the Number of Ports

To change the number of ports in the tank, use the **Modeling option** parameter to change the active block variant. Variant options include:

- One inlet (default) — Exposes one hydraulic conserving port, **T**.
- Two inlets — Exposes hydraulic conserving ports **A** and **B**.

- **Three inlets** — Exposes hydraulic conserving ports **A**, **B**, and **C**.

Port **A** in the **Two inlets** and **Three inlets** variants is a direct replacement of port **T** in the **One inlet** variant.

### Port Depth and Fluid Level

Port **T** in the **One inlet** variant—or port **A**, its replacement in the **Two inlets** and **Three inlets** variants—is by default located at the bottom of the tank. The depth of this port relative to the top of the fluid volume is equal to the fluid level—the height of the fluid volume:

$$y_{T/A} = H,$$

where:

- $y_{T/A}$  is the depth of port **T** or **A**.
- $H$  is the fluid level in the tank.

Ports **B** and **C** in the **Two inlets** and **Three inlets** variants are assumed to be located above port **A**. The depths of these ports are each computed as the difference between the fluid level and the port elevation above port **A**:

$$y_B = H - H_{AB},$$

and

$$y_C = H - H_{AC},$$

where:

- $y_B$  and  $y_C$  are the depths of ports **B**, and **C**.
- $H_{AB}$  and  $H_{AC}$  are the elevations of ports **B** and **C** above port **A**.

The fluid level,  $H$ , is computed during simulation from the instantaneous fluid volume. This calculation depends on the **Tank volume parameterization** setting. If the parameterization is set to **Constant cross-sectional area** (the default setting), the fluid level is:

$$H = \frac{V}{S},$$

where:

- $V$  is the instantaneous fluid volume in the tank.
- $S$  is the internal cross-sectional area of the tank, specified in the **Tank cross-section area** parameter.

If the **Tank volume parameterization** is set to **Tabulated data – Volume vs. level**, the fluid level is computed by interpolation or extrapolation of tabulated fluid level data specified as a function of fluid volume:

$$H = f(V)$$

The instantaneous fluid volume varies with the volumetric flow rates through the exposed ports. This volume increases if the sum of all flow rates is positive. A flow rate is positive if it is directed from the

port to the interior of the tank, that is, if fluid enters the tank. The time rate of change of the fluid volume is defined as:

$$\frac{dV}{dt} = \sum_i q_i,$$

where  $q_i$  is the flow rate into the tank through the port denoted by  $i$ —**T/A**, **B**, or **C**.

### Flow Rate and Pressure Drop

The volumetric flow rate through a port is a function of the pressure drop from that port to the interior of the tank. The flow rate is positive if the pressure drop is positive—that is, if pressure is higher at the port than in the tank—and negative otherwise:

$$q_i = A_i \sqrt{\frac{2}{K_i \rho}} \frac{\Delta p_i}{(\Delta p_i^2 + p_{Cr,i}^2)^{1/4}},$$

where:

- $A_i$  is the internal cross-sectional area of the port denoted by  $i$  (**T/A**, **B**, or **C**):

$$A_i = \frac{\pi d_i^2}{4},$$

with  $d_i$  as the internal diameter of the port.

- $K_i$  is the pressure loss coefficient specified for the port.
- $\rho$  is the hydraulic fluid density.
- $\Delta p_i$  is the pressure drop from the port to the interior of the tank.
- $p_{Cr,i}$  is the critical pressure at which the flow through the port switches between laminar and turbulent.

The critical pressure at a port is computed from the critical Reynolds number, internally set to a value of 15, and from the respective port diameter. The critical pressure is modulated by the pressure loss coefficient specified for the port—with this parameter serving as a gain for the critical pressure:

$$p_{Cr,i} = K_i \frac{\rho}{2} \left( \frac{Re_{Cr} \nu}{d_i} \right),$$

where:

- $Re_{Cr}$  is the critical Reynolds number.
- $\nu$  ( $nu$ ) is the hydraulic fluid dynamic viscosity.
- $d_i$  is the internal diameter of the port denoted by  $i$ .

The pressure drop from a port to the interior of the tank is computed from the specified **Pressurization** value, the hydrostatic pressure, and the pressure at the port:

$$\Delta p_i = p_{port,i} - (p_{press} + p_{elev,i}),$$

where:

- $p_{port,i}$  is the pressure at the port denoted by  $i$ .

- $p_{\text{press}}$  is the specified tank **Pressurization** value.
- $p_{\text{elev},i}$  is the hydrostatic pressure at the port.

The hydrostatic pressure at a port is a function of the port elevation above the bottom of the tank (zero for port **T/A**):

$$p_{\text{elev},i} = \rho g y_i$$

where

- $g$  is the value of the gravitational acceleration at the mean elevation of the system.
- $y_i$  is the elevation of the port denoted by  $i$  relative to the bottom of the port.

### C/C++ Code Generation

This block supports code generation for real-time simulation tasks. Certain blocks and block settings may be more suitable for simulation on a real-time device. For suggestions on how to improve real-time simulation performance, use the Simulink Performance Advisor function. Suggestions include ways to reduce model complexity and decrease numerical stiffness.

In the Simulink Editor, click the **Debug** tab and select **Performance Advisor** from **Performance Advisor**. Set the **Activity** parameter to `Execute real-time application` to view suggestions specific to real-time simulation performance. Expand the **Real-Time** node in the tree view pane to select performance checks specific to Simscape products.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Output

**V** — Fluid volume, m<sup>3</sup>  
physical signal

Physical signal output port reporting the volume of fluid in the tank.

### Conserving

**T** — Tank inlet  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing the tank inlet.

### Dependencies

To enable this port, set **Modeling option** to `One inlet`.

**A — Tank inlet**

hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing one of multiple tank inlets.

**B — Tank inlet**

hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing one of multiple tank inlets.

**Dependencies**To enable this port, set **Modeling option** to `Two inlets` or `Three inlets`.**C — Tank inlet**

hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing one of multiple tank inlets.

**Dependencies**To enable this port, set **Modeling option** to `Three inlets`.**Parameters****Modeling option** — Number of ports`One inlet` | `Two inlets` | `Three inlets`

Set the number of ports for the block.

**Main****Pressurization** — Gauge pressure of the tank volume`0 Pa` (default) | scalar number in units of pressureGauge pressure of the tank volume. The tank pressure is held constant at this value during simulation. The default value, `0 Pa`, corresponds to a vented tank—one whose internal pressure is equal to the atmospheric pressure of the system.**Tank volume parameterization** — Choice of parameterization for the tank volume`Constant cross-sectional area` (default) | `Tabulated data – volume vs. level`Choice of parameterization for the tank volume. Select `Constant cross-sectional area` to compute the tank volume from the variable fluid level and a constant cross-sectional area. Select `Tabulated data – volume vs. level` to compute the tank volume by interpolation or extrapolation of tabulated data on the fluid volume at discrete fluid levels.**Tank cross-section area** — Area of the (constant) tank cross-section`0.8 m2` (default) | scalar number in units of area

Area of the tank cross-section, assumed constant over the allowed range of fluid levels. The block uses this parameter to compute the volume of fluid inside the tank.

**Fluid volume vector** — Fluid volumes at which to specify the tank fluid levels`16-element row vector with values ranging from 0 to 0.727 m3` (default) | `N-element vector with elements in units of volume`

Array of fluid volumes for the 1-D lookup table used to compute the tank fluid level. The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

#### Dependencies

This parameter is active when the **Tank volume parameterization** parameter is set to **Tabulated data – volume vs. level**.

**Fluid level vector** — Fluid levels corresponding to the specified fluid volumes  
16-element row vector with values ranging from 0 to 0.3 m (default) |  $N$ -element vector with elements in units of length

Array of fluid levels corresponding to the specified orifice openings. The number of elements in the array must match the number of elements in the **Opening vector** parameter.

#### Dependencies

This parameter is active when the **Tank volume parameterization** parameter is set to **Tabulated data – volume vs. level**.

**Interpolation method** — Method of computing values inside the lookup table range  
Linear (default) | Smooth

Method of computing values inside the tabulated data range. The **Linear** method joins adjacent data points with straight line or surface segments with generally discontinuous slope at the segment boundaries. Surface segments are used in the 2-D lookup table specified in the **Pressure-flow characteristic model parameterization**.

The **Smooth** method replaces the straight segments with curved versions that have continuous slope everywhere inside the tabulated data range. The segments form a smooth line or surface passing through all of the tabulated data points without the discontinuities in first-order derivatives characteristic of the **Linear** interpolation method.

### Dependencies

This parameter is active when the **Tank volume parameterization** parameter is set to **Tabulated data – Volume vs. level**.

**Extrapolation method** — Method of computing values outside of the lookup table range

Linear (default) | Nearest

Method of computing values outside of the tabulated data range. The **Linear** method extends the line segment drawn between the last two data points at each end of the data range outward with a constant slope.

The **Nearest** method extends the last data point at each end of the data range outward as a horizontal line with constant value.

### Dependencies

This parameter is active when the **Tank volume parameterization** parameter is set to **Tabulated data – Volume vs. level**.

**Inlet pipeline diameter** — Diameter of the tank inlet

0.02 m (default) | scalar number in units of length

Diameter of the tank inlet. The tank has a single port when this parameter is exposed.

### Dependencies

This parameter is active when the block variant is set to **One inlet**.

**Port A/B/C pipeline diameter** — Diameter of tank port A/B/C

0.02 m (default) | scalar number in units of length

Diameter of tank port **A/B/C**.

### Dependencies

This parameter is active when the block variant is set to **Two inlets** or **Three inlets**.

**Pipeline pressure loss coefficient** — Coefficient used to account for pressure loss at the inlet  
1.2 (default) | unitless scalar number

Empirical coefficient used to account for pressure losses at the tank inlet. This parameter must be greater than zero. The block has a single port when this parameter is exposed.

#### Dependencies

This parameter is active when the block variant is set to `One inlet`.

**Port A/B/C pressure loss coefficient** — Coefficient used to account for pressure loss at port A/B/C  
1.2 (default) | unitless scalar number

Empirical coefficient used to account for pressure losses at port **A/B/C**. This parameter must be greater than zero.

#### Dependencies

This parameter is active when the block variant is set to `Two inlets` or `Three inlets`.

**Port B/C height above port A** — Elevation of port B/C above port A  
0.8 m (default) | scalar number in units of length

Elevation of port **B/C** above port **A**. The block uses this parameter to account for differences in port elevation.

#### Dependencies

This parameter is active when the block variant is set to `Two inlets` or `Three inlets`.

**Acceleration due to gravity** — Gravitational acceleration constant  
9.80665 m/s<sup>2</sup> (default) | scalar number in units of acceleration

Gravitational acceleration constant at the mean elevation of the hydraulic system. Changes in gravitational acceleration are assumed negligible over the height of the system.

**Minimum level of fluid** — Lowest fluid level allowed during simulation  
1e-3 m (default) | scalar number in units of length

Lowest fluid level allowed during simulation. The block triggers a simulation warning if the fluid level falls below the specified value.

**Check if fluid level violating minimum valid condition** — Simulation warning mode for minimum valid fluid level  
None (default) | Warning

Simulation warning mode for invalid fluid levels in the tank. Select `Warning` to be notified when the fluid level falls below a minimum specified value.

## Version History

### R2023a: To be removed

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

# Tank (IL)

Tank in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Tanks & Accumulators

## Description

The Tank (IL) block models a container with up to six input ports, **A** through **F**, within an isothermal liquid system. The tank outputs fluid volume at port **V** and fluid level at port **L** as physical signals. The block models the hydrostatic pressure difference between the liquid surface and the inlet height level. The tank can be pressurized to a constant, user-specified value or to atmospheric pressure.

## Fluid Volume

The volume of fluid in the tank is determined from the total mass flow into the tank:

$$V = \frac{M}{\rho},$$

where:

- $M$  is the total mass in the tank supplied by all ports.
- $\rho$  is the fluid density.

Due to the constant pressure in the tank, the liquid volume inside the tank changes based on mass flow rate. Note that the converse is true for pipes, where pressure is a function of fixed fluid volumes.

If the tank fluid volume exceeds the specified capacity of the tank, you can choose to be notified. Set the **Liquid volume above max capacity** parameter to **Warning** if you would like to receive a warning when this occurs during simulation. Set the parameter to **Error** if you would like the simulation to stop when this occurs.

## Fluid Level

If **Tank volume parameterization** is set to **Constant cross-section area**, the fluid level in the tank is determined from the fluid volume  $V$ , due to the constant cross-sectional area of the tank. Otherwise, the fluid level can be specified as tabulated data in the **Tabulated data - volume vs. level** option.

When the level in the tank falls below the inlet height, the assumption that fluid entirely fills the volume of the connecting blocks may not be valid. Connections to a Pipe (IL) block, which is based on this assumption, may in this case return unphysical results. If you expect to model tank fluid levels below tank inlet height(s), connect the Tank (IL) block to your system with a Partially Filled Pipe (IL) block instead.

Like the **Liquid volume above max capacity** parameter, you can be notified if the tank fluid level falls below the height of the inlet port(s) during your simulation by changing the **Liquid level below inlet height** parameter setting.

### Mass Flow Rate

If you have more than one port enabled, the equations below apply to each port. The mass flow rate at the inlet port is:

$$\dot{m}_{port} = A_{port} \frac{\sqrt{2\rho}}{\sqrt{\zeta}} \frac{\Delta p_{port}}{[\Delta p_{port}^2 + \Delta p_{port,crit}^2]^{1/4}},$$

where:

- $A_{port}$  is the **Inlet cross-sectional area**.
- $\rho$  is the fluid density.
- $\zeta$  is the **Inlet pressure loss coefficient**.

The inlet pressure difference due to inlet losses is:

$$\Delta p_{port} = p_{port} - (P + \Delta p_{elev, port}),$$

where:

- $p_{port}$  is the pressure at the inlet port.
- $P$  is the **Tank pressurization** if the **Pressurization specification** parameter is set to **Specified pressure**. Otherwise,  $P$  is the atmospheric pressure.
- $\Delta p_{elev, port}$  is the hydrostatic pressure difference at the specified port **Inlet height**:  
 $\Delta p_{elev, port} = \rho g L$ , where  $L$  is either the difference in height between the fluid level and the inlet height or zero, whichever is larger.

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the *critical Reynolds number*,  $Re_{crit}$ , which is the point of transition between laminar and turbulent flow in the fluid:

$$\Delta p_{crit} = \frac{\pi \rho P R_{loss}}{8 A_{port}} (\nu Re_{crit})^2,$$

where  $\nu$  is the fluid kinematic viscosity.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Tank inlet.

**B** — Liquid port  
isothermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 2, 3, 4, 5, or 6.

**C** — Liquid port  
isothermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 3, 4, 5, or 6.

**D** — Liquid port  
isothermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 4, 5, or 6.

**E** — Liquid port  
isothermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 5 or 6.

**F** — Liquid port  
isothermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 6.

## Output

**V** — Liquid volume, m<sup>3</sup>  
physical signal

Liquid volume inside the tank in  $m^3$ , specified as a physical signal.

**L** — Liquid level, m  
physical signal

Liquid level inside the tank in m, specified as a physical signal.

## Parameters

**Number of inlets** — Number of inlet ports  
1 (default) | positive integer between 1 and 6

Number of inlet ports. Setting this parameter to 2 or more exposes additional input ports.

**Pressurization specification** — Tank pressure  
Atmospheric pressure (default) | Specified pressure

Specifies a constant tank pressure. You can define a non-atmospheric pressure by selecting Specified pressure and defining the value in **Tank pressurization**.

**Tank pressurization** — User-defined tank pressure  
0.101325 MPa (default) | positive scalar

User-defined tank pressure.

**Tank volume parameterization** — Tank area characteristics  
Constant cross-section area (default) | Tabulated data - volume vs. level

Specifies tank area characteristics. This parameter is used to determine the fluid level in the tank. If you would like to model a tank with a variable cross-sectional area, you can provide data for tank volume and fluid level in the Tabulated data - volume vs. level option.

**Tank cross-sectional area** — Tank cross-sectional area  
1  $m^2$  (default) | positive scalar

Tank cross-sectional area.

### Dependencies

To enable this parameter, set **Tank volume parameterization** to Constant cross-section area.

**Liquid level vector** — Vector of tank fluid levels  
[0, 3, 5] m (default) | 1-by- $n$  vector

Vector of tank fluid levels for the tabular parameterization of a non-constant tank area. The values in this vector correspond one-to-one to values in the **Volumetric flow rate vector** parameter. Its elements are listed in ascending order. The elements must be positive and the first element must be 0.

### Dependencies

To enable this parameter, set **Tank volume parameterization** to Tabulated data - volume vs. level.

**Liquid volume vector** — Vector of tank fluid volumes[0, 4, 6] m<sup>3</sup> (default) | 1-by-*n* vector

Vector of tank fluid volumes for the tabular parameterization of a non-constant tank area. The values in this vector correspond one-to-one to values in the **Liquid level vector** parameter. Its elements are listed in ascending order. The elements must be positive and the first element must be 0.

**Dependencies**

To enable this parameter, set **Tank volume parameterization** to Tabulated data - volume vs. level.

**Inlet height** — Height of inlet port

0.1 m (default) | positive scalar

Height of inlet port. The value must be greater than or equal to 0.

**Dependencies**

To enable this parameter, set **Number of inlets** to 1.

**Inlet cross-sectional area** — Cross-sectional area of the port inlet0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the port inlet. This value must be greater than 0.

**Inlet pressure loss coefficient** — Loss coefficient for pressure at inlet port

1.2 (default) | positive scalar

Loss coefficient for pressure at inlet port. This value is used for calculating the hydrostatic pressure at the inlet and determining the fluid level minimum conditions.

**Height vector for inlets A and B** — Vector of port heights for multiple enabled ports[.1, .1] m (default) | 1-by-*n* vector

Vector of port heights for multiple enabled ports. If you have two or more ports enabled, the **Inlet height** parameter becomes a vector of values that correspond to the height of each inlet port, starting with port **A**. The parameter name and vector length depend on the value of the **Number of inlets** parameter. The default height for each inlet is .1 m. Each element of this vector must be greater than or equal to 0.

**Dependencies**

To enable this parameter, set **Number of inlets** to 2, 3, 4, 5, or 6.

**Cross-sectional area vector for inlets A and B** — Vector of inlet areas for two enabled ports[.01, .01] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of cross-sectional areas for multiple enabled ports. If you have two or more ports enabled, the **Inlet cross-sectional area** parameter becomes a vector of values that correspond to the cross-sectional area of each inlet, starting with port **A**. The parameter name will include all enabled ports. Each element of this vector must be greater than 0.

**Dependencies**

To enable this parameter, set **Number of inlets** to 2, 3, 4, 5, or 6.

**Pressure loss coefficient vector for inlets A and B** — Vector of pressure loss coefficients for tank inlets

[1.2, 1.2] (default) | 1-by- $n$  vector

Vector of pressure loss coefficients for multiple enabled ports. If you have two or more ports enabled, the **Pressure loss coefficient** parameter becomes a vector of values corresponding to the loss coefficient for each inlet port, starting with port **A**. The parameter name will include all enabled ports. Each element of this vector must be greater than 0.

#### Dependencies

To enable this parameter, set **Number of inlets** to 2, 3, 4, 5, or 6.

**Liquid level below inlet height** — Whether to be notified of low tank levels

Error (default) | None | Warning

Whether to be notified if the tank fluid level falls below the port inlet height during simulation. Set this parameter to **Warning** if you would like to receive a warning when this occurs during simulation. Set the parameter to **Error** if you would like the simulation to stop when this occurs.

**Liquid volume above max capacity** — Whether to be notified of high tank volume

None (default) | Warning | Error

Whether to be notified if the tank fluid volume rises above the tank maximum capacity during simulation. Set this parameter to **Warning** if you would like to receive a warning when this occurs during simulation. Set the parameter to **Error** if you would like the simulation to stop when this occurs.

**Maximum tank capacity** — Fill limit of the tank

10 m<sup>3</sup> (default) | positive scalar

Fill limit of the tank.

#### Dependencies

To enable this parameter, set **Liquid volume above max capacity** to either:

- Warning
- Error

**Gravitational acceleration** — Acceleration of gravity constant

9.81 m/s<sup>2</sup> (default) | positive scalar

Constant for the acceleration of gravity.

## Tank (G-TL)

Pressurized tank with variable gas and thermal liquid volumes

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Tanks & Accumulators

### Description

The Tank (G-TL) block models the accumulation of mass and energy in a chamber with separate gas and thermal liquid volumes. The total fluid volume is fixed but the individual gas and thermal liquid volumes are free to vary. Two gas ports allow for gas flow and a variable number of thermal liquid ports, ranging from one to three, allow for thermal liquid flow. The thermal liquid ports can be at different elevations.

### Tank Inlets and Inlet Heights ( $y$ )

The tank is pressurized but the pressurization is not fixed. It changes during simulation with the pressure in the gas volume. It rises when the pressure of the gas volume rises and it falls when the pressure of the gas volume falls. The thermal liquid volume is assumed to be at equilibrium with the gas volume and its pressure is therefore the same as that of the gas.

The fluid volumes can exchange energy with other fluid components and with the environment but not with each other. The fluid volumes behave as if they were isolated from each other by an insulated membrane. Energy exchanges with other components occur through gas or thermal liquid ports, while exchanges with the environment occur, strictly in the form of heat, through thermal ports.

Use this block to model components such as drain tanks, in which water condensed from a compressed gas system is trapped at the bottom by gravity and expelled through a drain outlet. Note, however, that neither gas nor thermal liquid domains capture the effects of phase change—and therefore that this block cannot capture the effects of condensation.

### Inlet Variants

The number of thermal liquid ports depends on the block variant that is active. To view or change the active variant, use the **Modeling option** parameter. The `One inlet` variant exposes thermal liquid port **A2**, the `Two inlets` variant adds port **B2**, and the `Three inlets` variant adds port **C2**.

## Fluid Volumes

The total volume of the tank is equal to the sum of the gas and thermal liquid volumes that it contains:

$$V_T = V_L + V_G,$$

where  $V$  is volume and T, L, and G stand for *total*, *liquid*, and *gas*. Because the total volume is fixed, the time rate of change of the gas volume must be the reverse of that measured for the thermal liquid volume:

$$\dot{V}_G = -\dot{V}_L.$$

The time rate of change of the thermal liquid volume is calculated by differentiating the expression:

$$M_L = \rho_L V_L,$$

where  $M$  is mass and  $\rho$  is density. The differentiation gives the mass flow rate into the thermal liquid volume:

$$\dot{M}_L = V_L \dot{\rho}_L + \dot{V}_L \rho_L,$$

The time rate of change of the thermal liquid density is:

$$\dot{\rho}_L = \frac{\rho_L}{\beta_L} \dot{p}_L - \alpha_L \rho_L \dot{T}_L,$$

where:

- $\beta$  is the isothermal bulk modulus.
- $\alpha$  is the isobaric thermal expansion coefficient.
- $p$  is the fluid pressure.
- $T$  is the fluid temperature.

Rearranging terms gives the rate of change of the thermal liquid volume and, by extension, of the gas volume:

$$\dot{V}_G = -\dot{V}_L \approx V_L \left( \frac{\dot{p}_L}{\beta_L} - \alpha_L \dot{T}_L \right) - \frac{\dot{M}_L}{\rho_L}$$

## Mass Balance

The rate of mass accumulation in each fluid volume is equal to the net mass flow rate into that fluid volume. In the thermal liquid volume:

$$\dot{M}_L = \sum_{i=A2, B2, C2} \dot{m}_i,$$

where  $\dot{M}_L$  is the rate of mass accumulation in the thermal liquid volume and  $\dot{m}_i$  are the individual mass flow rates into that volume through the thermal liquid ports (**A2**, **B2**, and **C2** in the case of the Three inlets variant). The rate of mass accumulation contains contributions from pressure, temperature, and volume change:

$$\dot{M}_L = V_L \left( \frac{\rho_L}{\beta_L} \dot{p}_G - \alpha_L \rho_L \dot{T}_L \right) + \dot{V}_L \rho_L,$$

where the pressure of the thermal liquid volume is by definition equal to the pressure of the gas volume and the equation is therefore written in terms of the gas pressure. In the gas volume:

$$\dot{M}_G = \sum_{i = A1, B1} \dot{m}_i,$$

where  $M_G$  is the rate of mass accumulation in the gas volume and  $\dot{m}_i$  are the individual mass flow rates into that volume through the gas ports (**A2** and **B2**). As with the thermal liquid volume, the rate of mass accumulation contains contributions from pressure, temperature, and volume change:

$$\dot{M}_G = \left. \frac{dM}{dp} \right|_G \dot{p}_G + \left. \frac{dM}{dT} \right|_G \dot{T}_G + \dot{V}_G \rho_G,$$

where the pressure and temperature derivatives depend on the type of gas specified in the Gas Properties (G) block. The derivatives are defined in the equations section of the Translational Mechanical Converter (G) block reference page. Replacing  $V_G$  with the expression previously obtained for this variable and combining the two expressions for  $M_G$ :

$$\left. \frac{dM}{dp} \right|_G \dot{p}_G + \left. \frac{dM}{dT} \right|_G \dot{T}_G + \left[ V_L \left( \frac{\dot{p}_G}{\beta_L} - \alpha_L \dot{T}_L \right) - \frac{\dot{M}_L}{\rho_L} \right] \rho_G = \sum_{i = A1, B1} \dot{m}_i.$$

Rearranging terms gives the final expression for the mass balance in the gas volume:

$$\dot{p}_G \left( \left. \frac{dM}{dp} \right|_G + \frac{\rho_G V_L}{\beta_L} \right) + \left( \dot{T}_G \left. \frac{dM}{dT} \right|_G - \dot{T}_L \rho_G V_L \alpha_L \right) = \sum_{i = A1, B1} \dot{m}_i + \frac{\rho_G}{\rho_L} \sum_{i = A2, B2, C2} \dot{m}_i,$$

where  $\dot{M}_L$  has been replaced with the summation of the mass flow rates into the thermal liquid volume.

### Energy Balance

The rate of energy accumulation in each fluid volume is the sum of the energy flow rates through the fluid inlets, the heat flow rate through the corresponding thermal port, and the energy flow rate due to volume changes. For the gas volume:

$$\dot{p}_G \left( \left. \frac{dU}{dp} \right|_G + \rho_G h_G \frac{V_L}{\beta_L} \right) + \left( \dot{T}_G \left. \frac{dU}{dT} \right|_G - \dot{T}_L \rho_G h_G V_L \alpha_L \right) = Q_{H1} + \sum_{i = A1, B1} \phi_i + \frac{\rho_G}{\rho_L} h_G \sum_{i = A2, B2, C2} \dot{m}_i,$$

where:

- $U$  is the total energy of the fluid volume.
- $h$  is the fluid enthalpy.
- $Q$  is the heat flow rate through the thermal port.
- $\phi_i$  are the energy flow rates through the fluid inlets.

As before, the pressure and temperature derivatives depend on the type of gas specified in the Gas Properties (G) block. See the equations section of the Translational Mechanical Converter (G) block reference page for their definitions. For the thermal liquid volume:

$$\dot{p}_L \left. \frac{dU}{dp} \right|_L + \dot{T}_L \left. \frac{dU}{dT} \right|_L = Q_{H2} + \sum_{i = A2, B2, C2} \phi_i + \sum_{i = A2, B2, C2} \dot{m}_i g(y(i) - y) - h_L \sum_{i = A2, B2, C2} \dot{m}_i,$$

where the pressure derivative is:

$$\left. \frac{dU}{dp} \right|_L = -T_L \alpha_L V_L,$$

and the temperature derivative is:

$$\left. \frac{dU}{dT} \right|_L = c_{p,L} \rho_L V_L,$$

in which  $c_p$  is the isobaric specific heat of the thermal liquid inside the tank.

### Momentum Balance

Flow resistance due to friction or other causes is ignored in both fluid volumes. The effect of elevation on inlet pressure is also ignored, but only on the gas side. The gas inlet pressures are therefore equal to each other and to the internal pressure of the gas volume:

$$p_{A1} = p_{B1} = p_G.$$

The thermal liquid inlet pressures are each a function of inlet depth. The internal pressure of the thermal liquid volume is equal to that of the gas volume ( $p_L = p_G$ ). Including the dynamic pressures ( $p_{i,dyn}$ ) at the inlets:

$$p_i + p_{i,dyn} = p_G + \rho_L (y - y_i) g,$$

where  $y$  is the elevation of the thermal liquid surface,  $y_i$  is the elevation of the thermal liquid inlet, and  $g$  is the gravitational constant. The term  $(y - y_i)$  gives the depth of the thermal liquid inlet with respect to the gas-thermal liquid boundary. The dynamic pressure at each thermal liquid inlet depends on the direction of flow at that inlet:

$$p_{i,dyn} = \begin{cases} \frac{1}{2} \rho_i v_i^2, & \text{if } \dot{m}_i < 0 \\ 0, & \text{if } \dot{m}_i \geq 0 \end{cases}$$

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables” and “Initial Conditions for Blocks with Finite Gas Volume”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

### Assumptions and Limitations

- Fluid momentum is lost at the tank inlet due to the sudden expansion into the tank volume.

### Ports

#### Output

**V** — Thermal liquid volume, m<sup>3</sup>  
physical signal

Physical signal output port reporting the volume of thermal liquid in the tank.

**L** — Thermal liquid level, m  
physical signal

Physical signal output port reporting the height of the thermal liquid volume relative to the bottom of the tank.

### **Conserving**

**A1** — Gas inlet  
gas

Opening through which gas can flow into or out of the tank.

**B1** — Gas inlet  
gas

Opening through which gas can flow into or out of the tank.

**A2** — Thermal liquid inlet  
thermal liquid

Opening through which thermal liquid can flow into or out of the tank.

**B2** — Thermal liquid inlet  
thermal liquid

Opening through which thermal liquid can flow into or out of the tank.

### **Dependencies**

To enable this port, set **Modeling option** to `Two inlets` or `Three inlets`.

**C2** — Thermal liquid inlet  
thermal liquid

Opening through which thermal liquid can flow into or out of the tank.

### **Dependencies**

To enable this port, set **Modeling option** to `Three inlets`.

## **Parameters**

**Modeling option** — Number of thermal liquid ports  
`One inlet` | `Two inlets` | `Three inlets`

Set the number of thermal liquid ports for the block.

### **Main**

**Total tank volume** — Combined gas and thermal liquid volume  
`10 m3` (default) | positive scalar with units of volume

Aggregate volume of the gas and thermal liquid portions of the tank.

**Tank volume parameterization** — Choice of parameterization for the thermal liquid volume  
Constant cross-sectional area (default) | Tabulated data – volume vs. level

Choice of parameterization for the thermal liquid volume. Select **Tabulated data – volume vs. level** to compute the thermal liquid volume by interpolation or extrapolation of tabulated data.

**Tank cross-sectional area** — Area of the (constant) tank cross-section  
1 m<sup>2</sup> (default) | scalar number in units of area

Area of the tank cross-section, assumed constant over the allowed range of fluid levels. The block uses this parameter to compute the volume of thermal liquid inside the tank.

**Liquid level vector** — Thermal liquid levels at which to specify the thermal liquid volume  
[0, 3, 5] m (default) | scalar number in units of length

Vector of thermal liquid levels at which to specify the thermal liquid volume in the tank. The block uses this vector to construct a one-way lookup table for the thermal liquid volume as a function of the thermal liquid level.

#### Dependencies

This parameter is active when the **Tank volume parameterization** parameter is set to **Tabulated data - volume vs. level**.

**Liquid volume vector** — Thermal liquid volume corresponding to the specified thermal liquid levels  
[0, 4, 6] m<sup>3</sup> (default) | scalar number in units of volume

Vector of thermal liquid volumes corresponding to the values specified in the **Liquid level vector** parameter. The block uses this vector to construct a one-way lookup table for the thermal liquid volume as a function of the thermal liquid level.

#### Dependencies

This parameter is active when the **Tank volume parameterization** parameter is set to **Tabulated data - volume vs. level**.

**Inlet height at port A2** — Height of the thermal liquid inlet  
0.1 m (default) | positive scalar with units of length

Height of the thermal liquid inlet.

#### Dependencies

This parameter is active when the block variant is set to **One inlet**.

**Height vector for inlets A2 and B2** — Heights of the thermal liquid inlets  
[.1, .1] m (default) | vector with number of elements equal to the number of thermal liquid ports

Vector of heights of the thermal liquid ports relative to the bottom of the tank.

#### Dependencies

This parameter is active when the block variant is set to **Two inlets**.

**Height vector for inlets A2, B2, and C2** — Heights of the thermal liquid inlets  
[.1, .1, .1] m (default) | vector with number of elements equal to the number of thermal liquid ports

Vector of heights of the thermal liquid ports relative to the bottom of the tank.

**Dependencies**

This parameter is active when the block variant is set to `Three inlets`.

**Cross-sectional area vector for inlets A1 and B1** — Flow areas of the gas inlets  
[.01, .01] m<sup>2</sup> (default) | vector with two elements

Vector with flow areas of the gas inlets.

**Cross-sectional area at port A2** — Flow area of the thermal liquid inlet  
0.01 m<sup>2</sup> (default) | positive scalar with units of area

Flow area of the thermal liquid inlet.

**Dependencies**

This parameter is active when the block variant is set to `One inlet`.

**Cross-sectional area vector for inlets A2 and B2** — Flow areas of the thermal liquid inlets  
[0.01, 0.01] m<sup>2</sup> (default) | vector with number of elements equal to the number of thermal liquid ports

Flow areas of the thermal liquid inlets.

**Dependencies**

This parameter is active when the block variant is set to `Two inlets`.

**Cross-sectional area vector for inlets A2, B2, and C2** — Flow areas of the thermal liquid inlets  
[0.01, 0.01, 0.01] m<sup>2</sup> (default) | vector with number of elements equal to the number of thermal liquid ports

Flow areas of the thermal liquid inlets.

**Dependencies**

This parameter is active when the block variant is set to `Three inlets`.

**Gravitational acceleration** — Gravitational acceleration constant  
9.81 m/s<sup>2</sup> (default) | scalar number with units of length/time<sup>2</sup>

Value of the gravitational acceleration at the elevation of the tank. This constant is assumed constant over the height of the tank.

## Tank (TL)

Thermal liquid container with variable fluid volume

### Libraries:

Simscape / Fluids / Thermal Liquid / Tanks & Accumulators

## Description

The Tank (TL) block models a thermal liquid container with a variable fluid volume. The absolute pressure of the tank fluid volume is assumed constant and equal to the value specified in the block dialog box. In the special case that the tank pressurization is equal to atmospheric pressure, the block represents a vented tank.

The tank can exchange energy with its surroundings, allowing its internal temperature and pressure to evolve over time. Heat transfer occurs via convection, as liquid enters or exits the chamber, and conduction, as thermal energy flows through the tank walls and the liquid itself at the tank inlets.

### Tank Schematic

The tank can have up to six input ports, **A** through **F**. The pressure at the tank inlets is the sum of the constant tank pressurization specified in the block dialog box and the hydrostatic pressure due to the inlet height.

The tank model accounts for heat transfer through the tank wall, associated with thermal conserving port **H**. The temperature defined at this port is the temperature of the tank fluid volume.

### Tank Volume

The tank fluid volume is computed from the total fluid mass at each time step:

$$V = \frac{M}{\rho},$$

where:

- $V$  is the tank fluid volume.
- $M$  is the tank fluid mass.
- $\rho$  is the tank fluid density.

### Mass Balance

The mass conservation equation in the tank fluid volume is

$$\dot{M} = \dot{m}_A + \dot{m}_B + \dot{m}_C + \dot{m}_D + \dot{m}_E + \dot{m}_F,$$

where:

- $\dot{M}$  is the change in fluid mass.
- $\dot{m}_\eta$  denotes the mass flow rates into the tank fluid volume through port  $\eta$ .

### Momentum Balance

The momentum conservation equation in the tank fluid volume for port  $\eta$  with  $\eta=A,B,C,D,E,F$  is

$$p_\eta + p_{dyn} = p_{Ref} + \rho g(y - y_\eta),$$

where:

- $p_\eta$  is the fluid pressure at inlet  $\eta$ .
- $p_{Ref}$  is the constant tank pressurization.
- $p_{dyn}$  is the dynamic pressure:

$$p_{dyn} = \begin{cases} 0, & \dot{m}_\eta \geq 0 \\ \frac{\dot{m}_\eta^2}{2\rho_\eta S_{IA}^2}, & \dot{m}_\eta < 0 \end{cases}$$

When the flow direction is into tank, the incoming jet dissipates into the large fluid volume, loses momentum, and causes  $p_{dyn}$  to be  $\Theta$ . When the fluid flows out of the tank, the fluid in the volume accelerates into the port and causes  $p_{dyn}$  to be greater than  $\Theta$ .

- $\rho_\eta$  is the liquid density at port  $\eta$ .
- $S_{IA}$  is the tank inlet area.
- $g$  is the gravitational constant.
- $y$  is the tank level, or height, relative to the tank bottom.
- $y_\eta$  is the tank inlet elevation relative to the tank bottom.

### Energy Balance

The energy conservation equation in the tank fluid volume is

$$M(C_p - h\alpha)\dot{T} = \phi_A + \phi_B + \phi_C + \phi_D + \phi_E + \phi_F - (\dot{m}_A + \dot{m}_B + \dot{m}_C + \dot{m}_D + \dot{m}_E + \dot{m}_F + M\alpha\dot{T})h + Q,$$

where:

- $C_p$  is the fluid thermal capacity.
- $\alpha$  is the fluid isobaric bulk modulus.
- $T$  is the fluid temperature.
- $\Phi_\eta$  denotes the energy flow rates into the tank through port  $\eta$ .
- $h$  is the fluid enthalpy.

- $Q$  is the thermal energy flow rate into the tank through port **H**.

## Assumptions and Limitations

- The tank pressure is constant and uniform throughout the tank volume. The tank elevation head affects only the inlet pressure calculations.
- Fluid momentum is lost at the tank inlet due to the sudden expansion into the tank volume.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Tank inlet.

**B** — Liquid port  
thermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 2, 3, 4, 5, or 6.

**C** — Liquid port  
thermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 3, 4, 5, or 6.

**D** — Liquid port  
thermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 4, 5, or 6.

**E** — Liquid port  
thermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 5, or 6.

**F** — Liquid port  
thermal liquid

Optional tank inlet.

### Dependencies

To enable this port, set **Number of inlets** to 6.

**H** — Heat transfer  
thermal liquid

Heat transfer at the tank wall.

### Output

**V** — Liquid volume, m<sup>3</sup>  
physical signal

Liquid volume inside the tank in m<sup>3</sup>, specified as a physical signal.

**L** — Liquid level, m  
physical signal

Liquid level inside the tank in m, specified as a physical signal.

**T** — Fluid temperature, K  
physical signal

Tank fluid temperature in K, specified as a physical signal.

## Parameters

**Number of inlets** — Number of inlet ports  
1 (default) | 2 | 3 | 4 | 5 | 6

Number of inlet ports. Setting this parameter to 2 or more exposes additional input ports.

**Pressurization specification** — Tank pressure  
Atmospheric pressure (default) | Specified pressure

Specifies a constant tank pressure. You can define a non-atmospheric pressure by selecting **Specified pressure** and defining the value in **Tank pressurization**.

**Tank pressurization** — User-defined tank pressure  
0.101325 MPa (default) | positive scalar

User-defined tank pressure.

**Tank volume parameterization** — Tank area characteristics  
Constant cross-section area (default) | Tabulated data - volume vs. level

Specifies tank area characteristics. This parameter is used to determine the fluid level in the tank. If you would like to model a tank with a variable cross-sectional area, you can provide data for tank volume and fluid level in the **Tabulated data - volume vs. level** option.

**Tank cross-sectional area** — Tank cross-sectional area  
1 m<sup>2</sup> (default) | positive scalar

Tank cross-sectional area.

**Dependencies**

To enable this parameter, set **Tank volume parameterization** to Constant cross-section area.

**Liquid level vector** — Vector of tank fluid levels

[0, 3, 5] m (default) | 1-by-*n* vector

Vector of tank fluid levels for the tabular parameterization of a non-constant tank area. The values in this vector correspond one-to-one to values in the **Volumetric flow rate vector** parameter. Its elements are listed in ascending order. The elements must be positive and the first element must be 0.

**Dependencies**

To enable this parameter, set **Tank volume parameterization** to Tabulated data - volume vs. level.

**Liquid volume vector** — Vector of tank fluid levels

[0, 4, 6] m<sup>3</sup> (default) | 1-by-*n* vector

Vector of tank fluid levels for the tabular parameterization of a non-constant tank area. The values in this vector correspond one-to-one to values in the **Volumetric flow rate vector** parameter. Its elements are listed in ascending order. The elements must be positive and the first element must be 0.

**Dependencies**

To enable this parameter, set **Tank volume parameterization** to Tabulated data - volume vs. level.

**Inlet height** — Height of inlet port

0.1 m (default) | positive scalar

Height of inlet port. The value must be greater than or equal to 0.

**Dependencies**

To enable this parameter, set **Number of inlets** to 1.

**Inlet cross-sectional area** — Cross-sectional area of the port inlet

0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the port inlet. This value must be greater than 0.

**Height vector for inlets A and B** — Vector of port heights for multiple enabled ports

[.1, .1] m (default) | 1-by-*n* vector

Vector of port heights for multiple enabled ports. If you have two or more ports enabled, the **Inlet height** parameter becomes a vector of values that correspond to the height of each inlet port, starting with port **A**. The parameter name and vector length depend on the value of the **Number of inlets** parameter. The default height for each inlet is .1 m. Each element of this vector must be greater than or equal to 0.

**Dependencies**

To enable this parameter, set **Number of inlets** to 2, 3, 4, 5, or 6.

**Cross-sectional area vector for inlets A and B** — Vector of inlet areas for two enabled ports  
[.01, .01] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of cross-sectional areas for multiple enabled ports. If you have two or more ports enabled, the **Inlet cross-sectional area** parameter becomes a vector of values that correspond to the cross-sectional area of each inlet, starting with port **A**. The parameter name will include all enabled ports. Each element of this vector must be greater than 0.

**Dependencies**

To enable this parameter, set **Number of inlets** to 2, 3, 4, 5, or 6.

**Liquid level below inlet height** — Whether to be notified of low tank levels  
Error (default) | Warning | None

Whether to be notified if the tank fluid level falls below the port inlet height during simulation. Set this parameter to **Warning** if you would like to receive a warning when this occurs during simulation. Set the parameter to **Error** if you would like the simulation to stop when this occurs.

**Liquid volume above max capacity** — Whether to be notified of high tank volume  
None (default) | Warning | Error

Whether to be notified if the tank fluid volume rises above the tank maximum capacity during simulation. Set this parameter to **Warning** if you would like to receive a warning when this occurs during simulation. Set the parameter to **Error** if you would like the simulation to stop when this occurs.

**Maximum tank capacity** — Fill limit of the tank  
10 m<sup>3</sup> (default) | positive scalar

Fill limit of the tank.

**Dependencies**

To enable this parameter, set **Liquid volume above max capacity** to either:

- Warning
- Error

**Gravitational acceleration** — Acceleration of gravity constant  
9.81 m/s<sup>2</sup> (default) | positive scalar

Constant for the acceleration of gravity.

Gas-Charged Accumulator (TL)

# Temperature Control Valve (G)

Temperature control valve in a gas network

## Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Flow Control Valves

## Description

The Temperature Control Valve (G) block represents an orifice with a thermostat as a flow control mechanism. The thermostat contains a temperature sensor and an opening mechanism. The sensor is at the inlet and responds with a slight delay, captured by a first-order time lag, to variations in temperature.

When the sensor reads a temperature in excess of a preset activation value, the opening mechanism actuates and the valve begins to open or close, depending on the operation mode specified by the **Valve operation** parameter. The change in opening area continues up to the limit of the temperature range of the valve, beyond which the opening area is a constant. Within the temperature range, the opening area is a linear function of temperature.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

## Control Temperature

The temperature reading at the inlet is the control signal for the valve. The more the temperature reading rises over the activation temperature, the more the opening area diverges from maximally closed when **Valve operation** is **Opens above activation temperature**, or from fully open when **Valve operation** is **Closes above activation temperature**.

The difference between the sensor temperature reading and the activation temperature is the temperature overshoot. The block normalizes this variable against the temperature regulation range of the valve. The fraction of valve opening is

$$\hat{T} = \frac{T_S - T_{Act}}{\Delta T},$$

where  $T_S$  is the inlet sensor temperature reading and  $T_{Act}$  is the value of the **Activation temperature** parameter.

The difference,  $\Delta T$ , is the value of the **Temperature regulation range** parameter.

## Numerical Smoothing

When the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the fraction of valve opening,  $\hat{T}$ . Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Sensor Dynamics

To emulate a real temperature sensor, which can only register a shift in temperature gradually, the block adds a first-order time lag to the temperature reading,  $T_S$ . The lag gives the sensor a transient response to variations in temperature. This expression for  $T_S$  is

$$\frac{d}{dt}T_S = \frac{T_{In} - T_S}{\tau},$$

where  $T_{In}$  is the actual inlet temperature at the current time step of the simulation and  $\tau$  is the value of the **Sensor time constant** parameter. The smaller this parameter is, the faster the sensor responds.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area** — The size of the flow restriction determines the block parameterization.

The block scales the specified flow capacity by the fraction of valve opening. As the fraction of valve opening rises from 0 to 1, the measure of flow capacity scales from its specified minimum to its specified maximum.

### Momentum Balance

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to Cv flow coefficient parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}},$$

where:

- $C_v$  is the flow coefficient.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.
- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3p_{in}F_{\gamma}x_T},$$

where:

- $F_{\gamma}$  is the ratio of the isentropic exponent to 1.4.
- $x_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_v N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{\rho_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3F_{\gamma}x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_{\gamma}x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3} C_v N_6 \sqrt{F_{\gamma} x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, see [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}} \left[ 1 - \left( \frac{p_{out} - B_{crit}}{1 - B_{crit}} \right)^2 \right]^m,$$

where:

- $C$  is the sonic conductance.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.
- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ ,

$$\dot{m} = C\rho_{ref}\sqrt{\frac{T_{ref}}{T_{avg}}}\left[1 - \left(\frac{B_{lam} - B_{crit}}{1 - B_{crit}}\right)^2\right]^m \left(\frac{p_{in} - p_{out}}{1 - B_{lam}}\right).$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C\rho_{ref}p_{in}\sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{in} \rho_{in} \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}} \left[ \frac{1 - \left(\frac{p_{out}}{p_{in}}\right)^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}}}\right]}$$

where:

- $S_r$  is the orifice or valve area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \left[ \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 B_{lam}^{\frac{2}{\gamma}}}\right] \left( \frac{p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}}}{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}\right)}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_R \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left(\frac{\gamma+1}{2}\right)^{\frac{2}{\gamma-1}} - \left(\frac{S_R}{S}\right)^2}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area parameterization, see [4].

### Mass Balance

The block assumes the volume and mass of fluid inside the valve is very small and ignores these values. As a result, no amount of fluid can accumulate in the valve. By the principle of conservation of

mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

### Assumptions and Limitations

- The **Sonic** conductance setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the **Orifice** area parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

### Ports

#### Conserving

**A** — Valve entrance

gas

Gas conserving port associated with the opening through which the flow enters or exits the valve. The direction of flow depends on the pressure differential established across the valve. The block allows both forward and backward directions.

**B** — Valve entrance

gas

Opening through which the working fluid can enter or exit the valve. The direction of flow depends on the pressure differential established across the valve. The block allows both forward and backward directions.

## Parameters

**Valve operation** — Sign of change in opening area

Opens above activation temperature (default) | Closes above activation temperature

Sign of the change in opening area that is induced by warming. The opening area can expand with a rise in temperature or it can contract. The change begins at an activation temperature and continues with warming conditions throughout the temperature regulation range of the valve.

The default setting corresponds to a normally closed valve that opens with rising temperature. The alternative setting corresponds to a normally open valve that closes with the same.

**Activation temperature** — Temperature at which opening mechanism is triggered

330 K (default) | scalar

Temperature at which the opening mechanism is triggered. Warming above this temperature will either open or close the valve, depending on the setting of the **Valve operation** parameter. The opening area remains variable throughout the temperature regulation range of the valve.

**Temperature regulation range** — Span of temperature interval over which opening area is variable

8 K (default) | positive scalar

Span of the temperature interval over which the valve opening area varies with temperature. The interval begins at the activation temperature of the valve. It ends at the sum of the same with the regulation range specified here.

**Sensor time constant** — Time for temperature change to register at inlet sensor

1.5 s (default) | positive scalar in units of time

Characteristic time for a temperature change to register at the inlet sensor. This parameter determines the delay between the onset of a change and a stable measurement of the same, taken as the sensor nears its new steady state. A value of 0 means that the sensor responds instantaneously to a temperature change.

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice

Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- Cv flow coefficient — The flow coefficient  $C_v$  determines the block parameterization.
- Kv flow coefficient — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- Sonic conductance — The sonic conductance of the resistive element at steady state determines the block parameterization.
- Orifice area — The size of the flow restriction determines the block parameterization.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component

4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to  $C_v$  flow coefficient.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Valve parameterization** to  $C_v$  flow coefficient or  $K_v$  flow coefficient.

**Maximum  $K_v$  flow coefficient** —  $K_v$  coefficient that corresponds to maximally open component  
3.6 (default) | positive scalar

Maximum value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to  $K_v$  flow coefficient.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12  $l/(bar*s)$  (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`.

**Maximum orifice area** — Flow area corresponding to maximally open component  
1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Leakage flow fraction** — Ratio of flow rates  
1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports  
0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

Introduced in R2018b

### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.

# Temperature Control Valve (TL)

Flow control valve with temperature-based actuation

## Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Flow Control Valves

## Description

The Temperature Control Valve (TL) block models an orifice with a thermostat as a flow control mechanism. The thermostat contains a temperature sensor and a black-box opening mechanism—one whose geometry and mechanics matter less than its effects. The sensor responds with a slight delay, captured by a first-order time lag, to variations in temperature.

When the sensor reads a temperature in excess of a preset activation value, the opening mechanism is actuated. The valve begins to open or close, depending on the chosen operation mode—the first case corresponding to a normally closed valve and the second to a normally open valve. The change in opening area continues up to the limit of the valve's temperature regulation range, beyond which the opening area is a constant.

A smoothing function allows the valve opening area to change smoothly between the fully closed and fully open positions. The smoothing function does this by removing the abrupt opening area changes at the zero and maximum ball positions.

## Mass Balance

The mass conservation equation in the valve is

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate into the valve through port **A**.
- $\dot{m}_B$  is the mass flow rate into the valve through port **B**.

## Momentum Balance

The momentum conservation equation in the valve is

$$p_A - p_B = \frac{\dot{m}\sqrt{\dot{m}^2 + \dot{m}_{cr}^2}}{2\rho_{Avg}C_d^2S^2} \left[ 1 - \left( \frac{S_R}{S} \right)^2 \right] PR_{Loss},$$

where:

- $p_A$  and  $p_B$  are the pressures at port A and port B.
- $\dot{m}$  is the mass flow rate.
- $\dot{m}_{cr}$  is the critical mass flow rate:

$$\dot{m}_{cr} = Re_{cr} \rho_{Avg} \sqrt{\frac{\pi}{4}} S_R.$$

- $\rho_{Avg}$  is the average liquid density.
- $C_d$  is the discharge coefficient.
- $S$  is the valve inlet area.
- $PR_{Loss}$  is the pressure ratio:

$$PR_{Loss} = \frac{\sqrt{1 - (S_R/S)^2(1 - C_d^2)} - C_d(S_R/S)}{\sqrt{1 - (S_R/S)^2(1 - C_d^2)} + C_d(S_R/S)}.$$

### Energy Balance

The energy conservation equation in the valve is

$$\phi_A + \phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate into the valve through port A.
- $\phi_B$  is the energy flow rate into the valve through port B.

### Valve Opening Area

The valve opening area calculation is based on the linear expression

$$S_{Linear} = \left( \frac{S_{End} - S_{Start}}{T_{Range}} \right) (T_{Sensor} - T_{Activation}) + S_{Start}.$$

where:

- $S_{Linear}$  is the linear valve opening area.
- $S_{Start}$  is the valve opening area at the beginning of the temperature actuation range. This area depends on the **Valve operation** parameter setting:

$$S_{Start} = \begin{cases} S_{Leak}, & \text{Valve opens above activation temperature} \\ S_{Max}, & \text{Valve closes above activation temperature} \end{cases}$$

- $S_{End}$  is the valve opening area at the end of the temperature actuation range. This area depends on the **Valve operation** parameter setting:

$$S_{End} = \begin{cases} S_{Max}, & \text{Valve opens above activation temperature} \\ S_{Leak}, & \text{Valve closes above activation temperature} \end{cases}$$

- $S_{Max}$  is the valve opening area in the fully open position.
- $S_{Leak}$  is the valve opening area in the fully closed position. Only leakage flow remains in this position.
- $T_{Range}$  is the temperature regulation range.
- $T_{Activation}$  is the minimum temperature required to operate the valve.
- $T_{Sensor}$  is the measured valve temperature.

The valve model accounts for a first-order lag in the measured valve temperature through the differential equation:

$$\frac{d}{dt}(T_{Sensor}) = \frac{T_{Avg} - T_{Sensor}}{\tau},$$

where:

- $T_{Avg}$  is the arithmetic average of the valve port temperatures,

$$T_{Avg} = \frac{T_A + T_B}{2},$$

where  $T_A$  and  $T_B$  are the temperatures at ports A and B.

- $\tau$  is the **Sensor time constant** value specified in the block dialog box.

When the valve is in a near-open or near-closed position you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the valve area between  $S_{Leak}$  and  $S_{Max}$ . For more information, see “Numerical Smoothing”.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port representing valve inlet A.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port representing valve inlet B.

## Parameters

**Valve operation** — Sign of the change in opening area induced by warming

Opens above activation temperature (default) | Closes above activation temperature

Sign of the change in opening area induced by warming. The opening area can expand with a rise in temperature or it can contract. The change begins at an activation temperature and continues with warming conditions throughout the temperature regulation range of the valve.

The default setting corresponds to a normally closed valve that opens with rising temperature; the alternative setting corresponds to a normally open valve that closes with the same.

**Activation temperature** — Temperature at which the opening mechanism triggers

330 K (default) | positive scalar

Temperature at which the opening mechanism triggers. Warming above this temperature will either open or close the valve, depending on the setting of the **Valve operation** parameter. The opening area remains variable throughout the temperature regulation range of the valve.

**Temperature regulation range** — Valve temperature range

8 K (default) | positive scalar

Temperature interval over which the valve opening area varies. The interval begins at the value of the **Activation temperature** parameter.

**Sensor time constant** — Time for a temperature change to register at the inlet sensor

1.5 s (default) | nonnegative scalar

Characteristic time for a temperature change to register at the inlet sensor. This parameter determines the delay between the onset of a change and a stable measurement of the change. A value of 0 means that the sensor responds instantaneously to a temperature change.

**Maximum opening area** — Opening area in the fully open position due to sealing imperfections $1e-4 \text{ m}^2$  (default) | positive scalar

Opening area of the valve in the fully open position, when the valve is at the upper limit of the pressure regulation range. The block uses this parameter to scale the valve opening throughout the pressure regulation range.

**Leakage area** — Opening area in the maximally closed position due to sealing imperfections $1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions.

**Cross-sectional area at ports A and B** — Orifice area at conserving ports $0.01 \text{ m}^2$  (default) | positive scalar

Areas at the entry and exit ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor accounting for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

# Thermal Liquid Properties (TL)

Preset fluid properties for the simulation of a thermal liquid network

**Libraries:**

Simscape / Fluids / Thermal Liquid / Utilities

## Description

The Thermal Liquid Properties (TL) block set predefined fluid properties to a thermal liquid network. The available fluids include pure water, aqueous mixtures, diesel, aviation fuel Jet A, and SAE 5W-30. You can use this block as a preset alternative to the Thermal Liquid Settings (TL) block. If your network does not have a connected liquid properties block, or the liquid defaults will apply. See “Specify Fluid Properties” for more details

The preset fluid properties are defined in tabular form as functions of temperature and pressure. During simulation, the network properties are set by linear interpolation between data points. Tabular data for aqueous mixtures is provided for concentration by mass or volume.

All the fluid properties commonly specified in the Thermal Liquid Settings (TL) block are defined in the block. These properties include density, the bulk modulus and thermal expansion coefficient, the specific internal energy and specific heat, as well as the kinematic viscosity and thermal conductivity. The properties are valid over a limited region of temperatures and pressures specific to the fluid selected and dependent, in the cases of mixtures, on the concentration specified. Simulation is allowed within this validity region only.

## Data Visualization

You can visualize the fluid properties defined in the block and the pressure and temperature regions of validity. To open the visualization utility, right-click the block and select **Fluids > Plot Fluid Properties**. The plot updates automatically upon selection of a fluid property from the drop-down list. Use the **Reload Data** button to regenerate the plot whenever the fluid selection or fluid parameters change.

### Visualization of density data for a 10% glycerol aqueous mixture

#### Validity Regions

The validity regions are defined in the block as matrices of zeros and ones. Each row corresponds to a tabulated temperature and each column to a tabulated pressure. A zero denotes an invalid breakpoint and a one a valid breakpoint. These validity matrices are internal to the block and cannot be modified; they can only be checked (using the data visualization utility of the block).

In most cases, the validity matrices are extracted directly from the tabulated data. The glycol and glycerol mixtures pressure boundaries are not available from the data, and are obtained explicitly from block parameters. The figure below shows an example of the validity region for water. The shaded squares indicate temperature and pressure regions outside of the validity region.

### Water

The properties of water are valid at temperatures above the triple-point value (273.160 K) up to the critical-point value (647.096 K). They are valid at pressures above the greater of the triple-point value (611.657 Pa) on one hand and the temperature-dependent saturation value on the other, up to the critical-point value (22.064 MPa). Pressures below the saturation point for a given temperature row are assigned a value of 0 in the validity matrix.

### Seawater (MIT model)

The properties of seawater are valid at temperatures above 0°C up to 120°C (273.15 K to 393.15 K); they are valid at pressures above the saturation point up to a maximum value of 12 MPa. Pressures below the saturation point for a given temperature row (and at the specified concentration level) are assigned a value of 0 in the validity matrix. Mixture concentrations can range in value from 0 to 0.12 on a mass fraction basis.

### Ethylene glycol and water mixture

The properties of an aqueous ethylene glycol mixture are valid over a temperature domain determined from the mixture concentration; they are valid at pressures within the minimum and maximum bounds specified in the block dialog box (extended horizontally to span the width of the temperature rows).

The lower temperature bound is always the lesser of the minimum temperature extracted from the available data and the freezing point of the mixture (the mixture must be in the liquid state). The upper temperature bound is always the maximum temperature extracted from the data. Mixture concentrations can range in value from 0 to 0.6 if a mass-fraction basis is used, or from 0 to 1 if a volume fraction basis is used.

### Propylene glycol and water mixture

The properties of an aqueous propylene glycol mixture are valid over the temperature and pressure ranges described for the case of Ethylene glycol and water mixture. Mixture concentrations can range in value from 0 to 0.6 if a mass-fraction basis is used, or from 0.1 to 0.6 if a volume fraction basis is used.

**Glycerol and water mixture**

The properties of an aqueous glycerol mixture are valid over the temperature and pressure ranges as described for the case of Ethylene glycol and water mixture. Mixture concentrations can range in value from 0 to 0.6 on a mass-fraction basis. The properties are all extended to 100 degC as:

- Density — quadratic fit
- Alpha (density thermal derivative) — linear fit
- Specific heat — linear fit
- Specific internal energy — linear fit
- Kinematic viscosity — exponential fit based on the upper half of the original temperature range
- Dynamic viscosity — exponential fit based on the upper half of the original temperature range
- Prandtl number — exponential fit based on the upper half of the original temperature range

**Aviation fuel Jet-A**

The properties of Jet A fuel are valid at temperatures above -50.93°C up to 372.46°C (222.22 K to 645.61 K); they are valid at pressures above the saturation point up to a maximum value of 2.41 MPa. Pressures below the saturation point for a given temperature row are assigned a value of 0 in the validity matrix.

**Diesel fuel**

The properties of diesel fuel are valid at temperatures above -34.95°C up to 417.82°C (238.20 K to 690.97 K); they are valid at pressures above the saturation point up to a maximum value of 2.29 MPa. Pressures below the saturation point for a given temperature row are assigned a value of 0 in the validity matrix.

**SAE 5W-30**

The properties of SAE 5W-30 fuel derive from data that cover temperature and pressure ranges for each property. The block uses measured properties between 29.85°C and 74.85°C (303 K to 348 K) and 7 MPa and 82 MPa. The block extrapolates data outside of this region to -38°C and 200°C (235.15 K and 473.15 K) and to 0.01 MPa and 100 MPa. The way the block smooths and extrapolates the data depends on the type of data:

- Density — The block uses a quadratic fit. The block fits extrapolated regions to the bulk modulus and alpha fundamental relationships.
- Bulk modulus — The block uses fundamental relationship with density based on the density quadratic fit. The block uses linear extrapolation in the extrapolation region.
- Alpha (density thermal derivative) — The block uses the fundamental relationship with density based on density quadratic fit. The block uses linear extrapolation in the extrapolation region.
- Specific heat — The block uses linear extrapolation in the extrapolation region. There is no dependency on pressure.
- Thermal conductivity — The block uses linear extrapolation in the extrapolation region. There is no dependency on pressure.
- Kinematic viscosity — The block uses the fundamental relationship with the fits of dynamic viscosity and density.
- Dynamic viscosity — The block uses an exponential fit with temperature and a linear fit with pressure.

- Prandtl number — The block uses the fundamental relationship with the fits of specific heat, dynamic viscosity, and thermal conductivity.

### Calculated Properties

The density and thermal expansion coefficients of the aqueous mixtures of glycol and glycerol compounds are obtained from the block parameters. The fluid density, with respect to pressure and temperature, is calculated as:

$$\rho(T, p) = \rho(T) \exp\left(\frac{p - p_R}{\beta}\right),$$

where:

- $T$  is the network temperature.
- $p$  is the network pressure.
- $\rho$  is the fluid density.
- $p_R$  is the reference pressure associated with the fluid property tables.
- $\beta$  is the isothermal bulk modulus.

where the change in fluid density is evaluated as:

$$\left(\frac{\partial \rho(T, p)}{\partial T}\right)_p = \left(\frac{\partial \rho(T)}{\partial T}\right)_T \exp\left(\frac{p - p_R}{\beta}\right).$$

The thermal expansion coefficient is calculated as:

$$\alpha(T, p) = -\frac{1}{\rho(T, p)} \left(\frac{\partial \rho(T)}{\partial T}\right)_T \exp\left(\frac{p - p_R}{\beta}\right).$$

## Ports

### Conserving

**R** — Thermal liquid network for which to define the working fluid  
thermal liquid

Node identifying the thermal liquid network for which to define the necessary fluid properties. The fluid selected in this block applies to the entire network. No other Thermal Liquid Properties (TL) or Thermal Liquid Settings (TL) block may be connected to the same network.

## Parameters

**Thermal liquid fluid list** — Available working fluids

Water (default) | Seawater (MIT model) | Ethylene glycol and water mixture |  
Propylene glycol and water mixture | Glycerol and water mixture | Diesel Fuel |  
Aviation fuel Jet-A | SAE 5W-30

Sets the fluid properties of your liquid network. The available fluids include pure water, aqueous mixtures, motor oils, and fuels.

**Dissolved salt mass fraction (salinity)** — Mass of salt divided by the total mass of the saline mixture

3.5e-3 (default) | positive unitless scalar valued between 0 and 1

Ratio of the mass of salt present in the saline mixture to the total mass of that mixture.

**Dependencies**

This parameter is active only when `Seawater (MIT model)` is selected as the working fluid.

**Concentration type** — Quantity in terms of which the mixture concentration is defined

`Volume fraction` (default) | `Mass fraction`

Quantity in terms of which to specify the concentration of ethylene glycol in its aqueous mixture. This parameter is active only when either `Ethylene glycol and water mixture` or `Propylene glycol and water mixture` is selected as the working fluid.

**Ethylene glycol volume fraction** — Volume of ethylene glycol divided by that of the aqueous mixture

0.1 (default) | positive unitless scalar valued between 0 and 1

Volume of ethylene glycol present in the aqueous mixture divided by the total volume of that mixture.

**Dependencies**

This parameter is active when `Ethylene glycol and water mixture` is selected as the working fluid and `Volume fraction` is selected as the concentration type.

**Ethylene glycol mass fraction** — Mass of ethylene glycol divided by that of the aqueous mixture

0.1 (default) | positive unitless scalar valued between 0 and 1

Mass of ethylene glycol present in the aqueous mixture divided by the total mass of that mixture.

**Dependencies**

This parameter is active when `Ethylene glycol and water mixture` is selected as the working fluid and `Mass fraction` is selected as the concentration type.

**Propylene glycol volume fraction** — Mass of propylene glycol divided by that of the aqueous mixture

0.1 (default) | positive unitless scalar valued between 0 and 1

Volume of propylene glycol present in the aqueous mixture divided by the total volume of that mixture.

**Dependencies**

This parameter is active when `Propylene glycol and water mixture` is selected as the working fluid and `Volume fraction` is selected as the concentration type.

**Propylene glycol mass fraction** — Mass of propylene glycol divided by that of the aqueous mixture

0.1 (default) | positive unitless scalar valued between 0 and 1

Mass of propylene glycol present in the aqueous mixture divided by the total mass of that mixture.

**Dependencies**

This parameter is active when `Propylene glycol and water mixture` is selected as the working fluid and `Mass fraction` is selected as the concentration type.

**Isothermal bulk modulus** — Measure of fluid compressibility specified at constant temperature  
2.1791 GPa (default) | positive scalar with units of pressure

Bulk modulus of the aqueous mixture at constant temperature. The bulk modulus measures the change in pressure required to produce a fractional change in fluid volume.

**Dependencies**

This parameter is active when either `Ethylene glycol and water mixture`, `Propylene glycol and water mixture`, or `Glycerol and water mixture` is selected as the working fluid.

**Minimum valid pressure** — Lower bound of the allowed pressure range for the thermal liquid network  
0.01 MPa (default) | positive scalar with units of pressure

Lower bound of the pressure range allowed in the thermal liquid network connected to this block.

**Dependencies**

This parameter is active when either `Ethylene glycol and water mixture`, `Propylene glycol and water mixture`, or `Glycerol and water mixture` is selected as the working fluid.

**Maximum valid pressure** — Upper bound of the allowed pressure range for the thermal liquid network  
50 MPa (default) | positive scalar with units of pressure

Upper bound of the pressure range allowed in the thermal liquid network connected to this block.

**Dependencies**

This parameter is active when either `Ethylene glycol and water mixture`, `Propylene glycol and water mixture`, or `Glycerol and water mixture` is selected as the working fluid.

**Atmospheric pressure** — Absolute pressure in the environment of the thermal liquid network  
0.101325 MPa (default) | positive scalar with units of pressure

Absolute pressure of the external environment in which the thermal liquid network is assumed to run. The default value is the standard atmospheric pressure measured at sea level on Earth.

**Pressure and temperature outside valid range** — Whether to notify when pressure or temperature are outside valid range  
Error (default) | Warning | None

Select what happens if the fluid pressure or temperature go beyond the valid range during simulation:

- **None** — The block does not return an error if the properties go out of range.
- **Warning** — The block issues a warning, but continues the simulation.
- **Error** — The block returns an error and stops the simulation.

## Version History

Introduced in R2018a

### R2023a: Numerical adjustments for SAE 5W-30

When the **Thermal liquid fluid** parameter is SAE 5W-30, the block includes numerical adjustments to the density, bulk modulus, thermal expansion coefficient, and specific internal energy to make the data more closely match experimental data.

### R2023a: Control block behavior when fluid properties go out of range during simulation

Previously, if fluid properties went beyond the valid range during simulation, the block would return an error. You can now use the new **Pressure and temperature outside valid range** parameter to control the block behavior if fluid properties go out of range during simulation

## Thermostatic Expansion Valve (2P)

Flow control valve that maintains evaporator superheat

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Valves & Orifices / Flow Control Valves

### Description

The Thermostatic Expansion Valve (2P) block models a valve with a pressure drop that maintains an evaporator superheat in a two-phase fluid network. You typically place this valve between a condenser and an evaporator in a refrigeration system to maintain a specific temperature differential by moderating the flow into the evaporator.

The valve behavior depends on the *superheat*, which is the difference in temperature between the vapor at the evaporator outlet and the fluid evaporating temperature. The valve opens if the superheat increases to let more flow through, and the valve closes if the superheat decreases to let less flow through. When the superheat drops to or below the value of the **Static (minimum) evaporator superheat** parameter, then the valve is fully closed. The closed valve reduces the flow through the evaporator, which reduces the heat transfer and increases the outlet temperature. When you use the **MOP limit** parameter to enable a maximum pressure or temperature limit, the valve closes when the temperature or pressure exceeds the limit.

The bulb sensor at port **S** measures the evaporator outlet temperature. If you set the **Pressure equalization** parameter to External pressure equalization, the block uses data from the evaporator at port **E** for internal pressure equalization. Otherwise, the block uses the pressure at port **B** for internal pressure equalization. The block balances the bulb pressure, which acts to open the valve, with the valve equalization pressure, which acts to close the valve.

### Analytical Parameterization

When you set **Valve parameterization** to Nominal capacity, superheat, and operating conditions, the block uses an analytical model. In this setting, the block fits the analytical model to the performance data so that when the refrigeration system operates at the specified nominal evaporating temperature, condensing temperature, and condenser subcooling, the block meters enough flow into the evaporator to maintain the evaporator superheat while the block transfers heat at the evaporator capacity. Subcooling is the difference in temperature between the condenser outlet and the condensing temperature.

For this parameterization, the block assumes a straight-charged bulb and assumes that the sensing bulb contains the same fluid as the refrigerant. To model a cross-charged bulb, set **Valve parameterization** to Tabulated data - quadrant diagram.

### Opening Area

The valve operates to control the mass flow rate between a condenser and an evaporator by regulating the effective opening area,  $S_{eff}$ . The mass flow rate is

$$\dot{m} = S_{eff} \sqrt{\frac{2}{v_{in}} \frac{\Delta p}{(\Delta p^2 - \Delta p_{lam}^2)^{0.25}}}$$

where:

- $v_{in}$  is the inlet specific volume, or the fluid volume per unit mass.
- $\Delta p$  is the pressure differential over the valve,  $p_A - p_B$ .
- $\Delta p_{lam}$  is the pressure threshold for transitional flow. Below this value, the flow is laminar

$$\Delta p_{lam} = \frac{p_A + p_B}{2} (1 - B_{lam}),$$

where  $B_{lam}$  is the value of the **Laminar flow pressure ratio** parameter.

The effective valve area depends on the pressure difference between the measured pressure,  $p_{bulb}$  and the equalization pressure,  $p_{eq}$

$$S_{eff} = \beta [(p_{bulb} - p_{eq}) - (p_{sat}(T_{evap} + \Delta T_{static}) - p_{sat}(T_{evap}))],$$

where:

- $\beta$  is a valve constant determined from the nominal operating conditions. See “Determining  $\beta$  from Nominal Conditions” on page 1-2008.
- $T_{evap}$  is the evaporating temperature.

When **Nominal pressure specification** is Pressure at specified saturation temperature,  $T_{evap}$  is the value of the **Nominal evaporating (saturation) temperature** parameter.

When **Nominal pressure specification** is Specified pressure,  $T_{evap}$  is the saturation temperature that corresponds to the value of the **Nominal evaporator outlet pressure** parameter.

- $\Delta T_{static}$  is the **Static (minimum) evaporator superheat** parameter.
- $p_{sat}(T_{evap})$  is the fluid saturation pressure as a function of  $T_{evap}$ . The block uses the `tablelookup` function to identify this value.
- $p_{sat}(T_{evap} + \Delta T_{static})$  is the saturation pressure as a function of  $T_{evap} + \Delta T_{static}$ . The block uses the `tablelookup` function to identify this value.
- $p_{bulb}$  is the fluid pressure of the bulb. The bulb pressure is the saturation pressure,  $p_{bulb} = p_{sat}(T_{bulb})$ , unless you set **MOP limit** to On - Specify maximum operating pressure and the pressure reaches the maximum pressure. See “Maximum Outlet Pressure Limit” on page 1-2009 for more information.  $T_{bulb}$  is the bulb fluid temperature.
- $p_{eq}$  depends on the valve pressure equalization setting:
  - When you set **Pressure equalization** to Internal pressure equalization,  $p_{eq}$  is the pressure at port **B**.
  - When you set **Pressure equalization** to External pressure equalization,  $p_{eq}$  is the pressure at port **E**.

The effective valve area has limits. The minimum effective valve area,  $S_{eff,min}$ , is

$$S_{eff,min} = f_{leak} S_{eff,nom}$$

where  $f_{leak}$  is the value of the **Closed valve leakage as a fraction of nominal flow** parameter. To see how the block calculates the nominal effective valve area,  $S_{eff,nom}$  and maximum effective valve area, see “Determining  $\beta$  from Nominal Conditions” on page 1-2008.

#### Determining $\beta$ from Nominal Conditions

$\beta$  represents the relationship between the nominal evaporator superheat and the nominal evaporator capacity, the rate of heat transfer between the two fluids in the evaporator:

$$\beta = \frac{S_{eff,nom}}{[p_{sat}(T_{evap} + \Delta T_{nom}) - p_{sat}(T_{evap})]}$$

where  $p_{sat}(T_{evap} + \Delta T_{nom})$  is the saturation pressure at the sum of the evaporator outlet temperature and the **Nominal (static + opening) evaporator superheat** parameter.

The block calculates the nominal effective valve area,  $S_{eff,nom}$ , as a function of the nominal condenser and evaporator thermodynamics. When **Capacity specification** is Evaporator heat transfer, the nominal effective valve area is

$$S_{eff,nom} = \frac{\left[ \frac{Q_{nom}}{c_{p,evap}\Delta T_{nom} + h_{evap} - h_{cond} + c_{p,cond}\Delta T_{sub}} \right]}{\sqrt{\frac{2}{v_{cond}}(p_{sat}(T_{cond}) - p_{sat}(T_{evap}))}}$$

When **Capacity specification** is Mass flow rate, the nominal effective valve area is

$$S_{eff,nom} = \frac{\dot{m}_{nom}}{\sqrt{\frac{2}{v_{cond}}(p_{sat}(T_{cond}) - p_{sat}(T_{evap}))}}$$

where:

- $T_{cond}$  is the condensing saturation temperature.

When **Nominal pressure specification** is Pressure at specified saturation temperature,  $T_{cond}$  is the value of the **Nominal condensing (saturation) temperature** parameter.

When **Nominal pressure specification** is Specified pressure,  $T_{cond}$  is the saturation temperature that corresponds to the value of the **Nominal condenser outlet pressure** parameter.

- $v_{cond}$  is the liquid specific volume at  $T_{cond}$ .
- $Q_{nom}$  is the **Nominal evaporator heat transfer** parameter.
- $c_{p,evap}$  is the vapor specific heat at  $T_{evap}$ .
- $h_{evap}$  is the vapor specific enthalpy at  $T_{evap}$ .
- $c_{p,cond}$  is the liquid specific heat at  $T_{cond}$ .
- $h_{cond}$  is the liquid specific enthalpy at  $T_{cond}$ .
- $\Delta T_{sub}$  is the **Nominal condenser subcooling** parameter.
- $\dot{m}_{nom}$  is the **Nominal mass flow rate** parameter.

When **Capacity specification** is Evaporator heat transfer, the block determines the maximum effective area of the valve in the same way as  $S_{eff,nom}$ , but uses the value of **Maximum evaporator**

**heat transfer** parameter instead of the **Nominal evaporator heat transfer** parameter. When **Capacity specification** is Mass flow rate, the block uses the value of the **Maximum mass flow rate** parameter instead of the **Nominal mass flow rate** parameter.

#### Maximum Outlet Pressure Limit

You can limit the maximum outlet pressure (MOP) in the evaporator by setting the **MOP limit** parameter to On - Specify maximum operating pressure or On - Specify maximum operating temperature. When you use one of these settings, the valve closes when the bulb temperature or pressure exceeds the temperature or pressure associated with maximum bulb pressure, and opens once the pressure reduces. If you set **MOP limit** to Off, or the measured pressure is below the limit,  $p_{bulb} = p_{sat}(T_{bulb})$ . Otherwise, when the measurement exceeds the limit, the bulb pressure remains at

$$p_{bulb} = \frac{p_{bulb,MOP}}{T_{bulb,MOP}} T_{bulb},$$

where:

- $p_{bulb,MOP}$  is a function of the **Maximum evaporator outlet pressure** parameter,  $p_{eq,MOP}$ , or the pressure specified by the **Maximum evaporating (saturation) temperature** parameter, and the nominal evaporator temperature:

$$p_{bulb,MOP} = p_{eq,MOP} + p_{sat}(T_{evap} + \Delta T_{static}) - p_{sat}(T_{evap}).$$

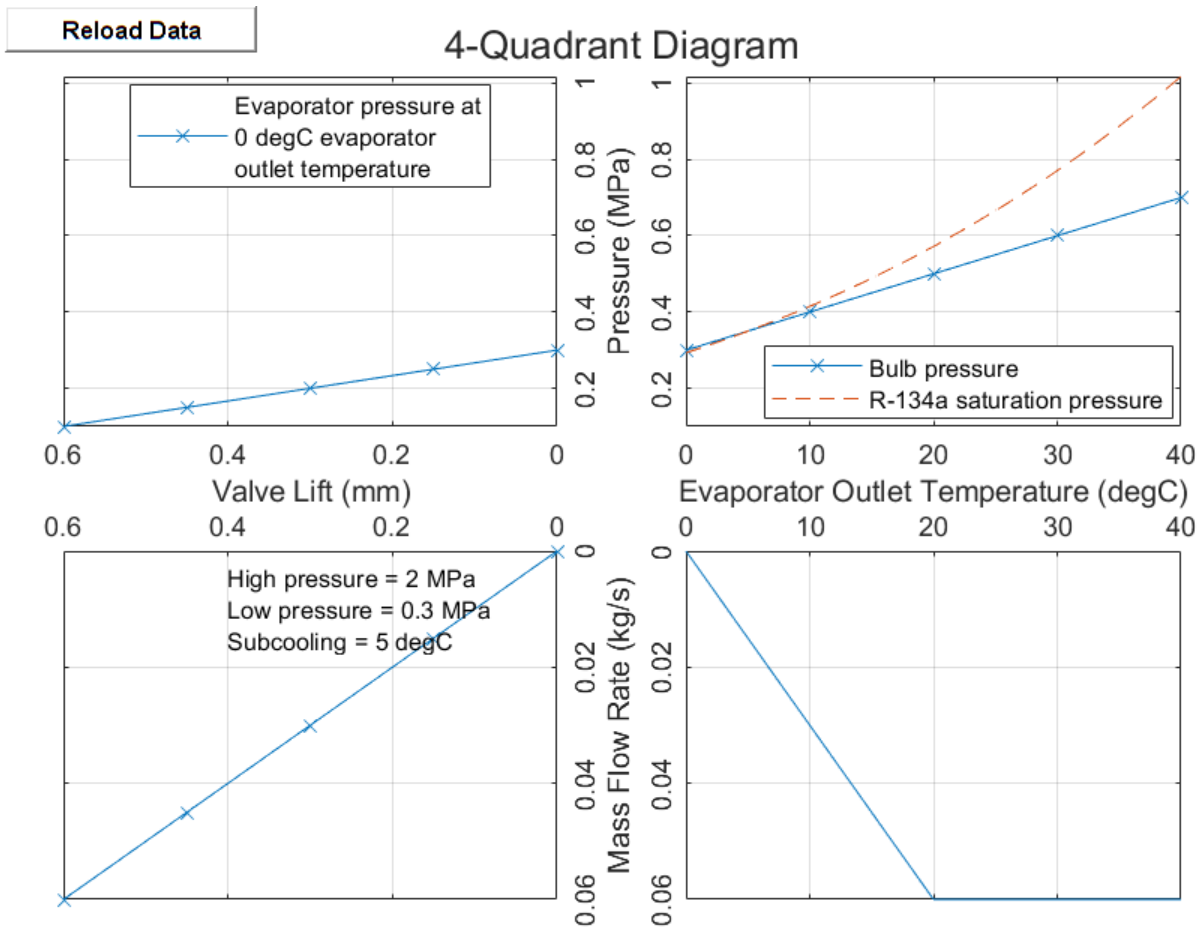

- $T_{bulb}$  is the bulb fluid temperature. This value is the temperature at port **S** if **Bulb temperature dynamics** is set to Off. The block applies a first-order delay to the bulb temperature if **Bulb temperature dynamics** is set to On.
- $T_{bulb,MOP}$  is the associated temperature at the pressure  $p_{bulb,MOP}$ .

#### Four-Quadrant Diagram

To visualize the four-quadrant diagram, right-click the block and select **Fluids > Plot 4-Quadrant Diagram**.

When **Valve parameterization** is Tabulated data - quadrant diagram, the block uses user-provided data to plot in all quadrants. See "Tabulated Data Parameterization" on page 1-2011.

When **Valve parameterization** is Nominal capacity, superheat, and operating conditions, the block calculates the data in all quadrants by using the analytical valve model, described in "Analytical Parameterization" on page 1-2006. Because the analytical model assumes a straight-charged bulb, the diagram plots the two curves in quadrant 1 on top of each other.

The diagram shows the four quadrants:

- **Quadrant 1:** Plot of the fluid pressure of the sensing bulb versus the evaporator outlet temperature when the sensing bulb is attached to the evaporator outlet. In this image, the graph includes a second line that represents the vapor saturation curve of the refrigerant in the cycle, which is a plot of saturation pressure versus saturation temperature.
- **Quadrant 2:** Plot of the valve lift versus the evaporator outlet pressure. The valve lift is the position of the needle of the valve. As the evaporator outlet pressure decreases, the valve opens and valve lift increases.

When **Valve parameterization** is Tabulated data - quadrant diagram, the plot holds the evaporator outlet temperature constant at the **Reference evaporator outlet temperature** parameter value.

- **Quadrant 3:** Plot of the mass flow rate through the valve versus valve lift.

When **Valve parameterization** is Tabulated data - quadrant diagram, the plot holds the inlet pressure of the valve constant at the **Reference condenser outlet pressure** parameter, the inlet temperature constant at the **Reference condenser subcooling** parameter, and the outlet pressure constant at the **Reference evaporator outlet pressure parameter**.

- **Quadrant 4:** Plot of the mass flow rate through the valve versus evaporator outlet temperature.

When **Valve parameterization** is Tabulated data - quadrant diagram, the plot holds the inlet pressure of the valve constant at the **Reference condenser outlet pressure** parameter, the inlet temperature constant at the **Reference condenser subcooling** parameter, and the outlet pressure constant at the **Reference evaporator outlet pressure** parameter.

### Tabulated Data Parameterization

When you set **Valve parameterization** to Tabulated data - quadrant diagram, the block uses tabulated data. Three of the four curves in the thermostatic expansion valve quadrant diagram specify the valve characteristics. The supplier typically provides this diagram.

To determine block characteristics, the block performs interpolation on the data you provide in the parameters **Quadrant 1 - Evaporator outlet temperature vector**, **Quadrant 1 - Bulb pressure vector**, **Quadrant 2 - Valve lift vector**, **Quadrant 2 - Evaporator outlet pressure vector**, **Quadrant 3 - Valve lift vector**, and **Quadrant 3 - Mass flow rate vector**.

The block determines the mass flow rate through the valve from the inlet pressure, outlet pressure, equalization pressure, and sensing bulb temperature by using the data from quadrant 1 to quadrant 3 and a series of interpolations. The block first calculates the quadrant 2 evaporator outlet pressure as

$$p_{evap,Q2} = p_{eq} - p_{bulb}(T_{bulb}) + p_{bulb}(T_{evap,ref})$$

where:

- $p_{eq}$  depends on the valve pressure equalization setting:
  - When you set **Pressure equalization** to Internal pressure equalization,  $p_{eq}$  is the pressure at port **B**.
  - When you set **Pressure equalization** to External pressure equalization,  $p_{eq}$  is the pressure at port **E**.
- $p_{bulb}(T_{bulb})$  is the bulb fluid pressure interpolated at the bulb fluid temperature  $T_{bulb}$ . You specify the bulb fluid pressure data in the parameter **Quadrant 1 - Bulb pressure vector**.
- $p_{bulb}(T_{evap,ref})$  is the bulb fluid pressure interpolated at the reference evaporator outlet temperature  $T_{evap,ref}$ .

The block uses the valve lift data,  $L$ , from the **Quadrant 2 - Valve lift vector** parameter to interpolate the valve lift at the values in **Quadrant 2 - Evaporator outlet pressure vector**, which gives  $L = L(p_{evap,Q2})$ . The block then uses the reference mass flow rate,  $\dot{m}_{ref}$ , from the **Quadrant 3 - Mass flow rate vector**, to interpolate the mass flow rate at the valve lift values  $\dot{m}_{ref} = \dot{m}_{ref}(L)$ . The block scales the reference mass flow rate to the actual mass flow rate with

$$\dot{m} = \dot{m}_{ref} \frac{\sqrt{\frac{2}{v_{in}} \frac{\Delta p}{(\Delta p^2 - \Delta p_{lam}^2)^{0.25}}}}{\sqrt{\frac{2}{v_{ref}} (p_{cond,ref} - p_{evap,ref})}}$$

where:

- $p_{cond,ref}$  is the **Reference condenser outlet pressure** parameter.
- $p_{evap,ref}$  is the **Reference evaporator outlet pressure** parameter.
- $v_{ref}$  is the specific volume that corresponds to the **Reference condenser outlet pressure** and **Reference condenser subcooling** parameters.

- $v_{in}$  is the inlet specific volume, or the fluid volume per unit mass.
- $\Delta p$  is the pressure differential over the valve,  $p_A - p_B$ .
- $\Delta p_{lam}$  is the pressure threshold for transitional flow. Below this value, the flow is laminar. The block calculates this value as:

$$\Delta p_{lam} = \frac{p_A + p_B}{2}(1 - B_{lam}),$$

where  $B_{lam}$  is the value of the **Laminar flow pressure ratio** parameter.

### Pressure Equalization

The equalization pressure is the pressure at the evaporator outlet that governs valve operability. In physical systems with low pressure loss in the evaporator due to viscous friction, pressure equalization can occur internally with the pressure at port **B**. This is *internal pressure equalization*. In systems with larger losses, connect the evaporator outlet port to the valve block at port **E**.

### Bulb Temperature Dynamics

You can model the bulb dynamic response to changing temperatures by setting **Bulb temperature dynamics** to On. This introduces a first-degree lag in the measured temperature

$$\frac{dT_{bulb}}{dt} = \frac{T_S - T_{bulb}}{\tau_{bulb}},$$

where:

- $T_S$  is the temperature at port **S**. If you do not model bulb dynamics, this value is  $T_{bulb}$ .
- $\tau_{bulb}$  is the value of the **Bulb thermal time constant** parameter.

### Fluid Specific Volume Dynamics

When the fluid at the valve inlet is a liquid-vapor mixture, the block calculates the specific volume as

$$v_{in} = (1 - x_{dyn})v_{liq} + x_{dyn}v_{vap},$$

where:

- $x_{dyn}$  is the inlet vapor quality. The block applies a first-order lag to the inlet vapor quality of the mixture.
- $v_{liq}$  is the liquid specific volume of the fluid.
- $v_{vap}$  is the vapor specific volume of the fluid.

If the inlet fluid is liquid or vapor,  $v_{in}$  is the respective liquid or vapor specific volume.

### Vapor Quality Lag

If the inlet vapor quality is a liquid-vapor mixture, the block applies a first-order time lag

$$\frac{dx_{dyn}}{dt} = \frac{x_{in} - x_{dyn}}{\tau},$$

where:

- $x_{dyn}$  is the dynamic vapor quality.
- $x_{in}$  is the current inlet vapor quality.
- $\tau$  is the value of the **Inlet phase change time constant** parameter.

If the inlet fluid is a subcooled liquid,  $x_{dyn}$  is equal to  $x_{in}$ .

### Conservation Equations

Mass is conserved through the valve

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

The block supports reversed flows numerically, however, the valve block is not designed for flows from port **B** to port **A**.

The block conserves energy flow through the valve

$$\Phi_A + \Phi_B = 0,$$

where:

- $\Phi_A$  is the energy flow rate at port **A**.
- $\Phi_B$  is the energy flow rate at port **B**.

### Ports

#### Conserving

**A** — Fluid inlet  
two-phase fluid

Valve inlet port. Connect this port to the outlet of a condenser or liquid receiver in a refrigeration cycle model.

**B** — Fluid outlet  
two-phase fluid

Valve outlet port. Connect this port to the inlet of an evaporator in a refrigeration cycle model.

**S** — Sensing bulb temperature measurement  
two-phase fluid

Two-phase fluid conserving port associated with the temperature of the sensing bulb. Connect this port to the outlet port of the evaporator. The valve operation depends on the comparison of the sensed temperature at **S** to the fluid saturation temperature.

There is no mass or energy flow rate through port **S**.

**E** — Equalization line pressure measurement  
two-phase fluid

Two-phase fluid port associated with the pressure of the equalization line. Connect this port to the outlet port of the evaporator.

There is no mass or energy flow rate through port **E**.

#### **Dependencies**

To enable this port, set **Pressure equalization** to External pressure equalization.

## **Parameters**

**Valve parameterization** — Parameterization method  
Nominal capacity, superheat, and operating conditions (default) | Tabulated data - quadrant diagram

Method to determine valve characteristics. When you select **Nominal capacity, superheat, and operating conditions**, the valve provides the specified nominal capacity and superheat at the specified nominal operating conditions. When you select **Tabulated data - quadrant diagram**, you can specify the valve characteristics by using three of the four curves in a thermostatic expansion valve quadrant diagram.

**Capacity specification** — Capacity specification method  
Evaporator heat transfer (default) | Mass flow rate

Method to specify capacity for the evaporator. When you select **Evaporator heat transfer**, you can specify the nominal and maximum evaporator heat transfer values. When you select **Mass flow rate**, the block calculates the heat transfer based on the mass flow rate.

#### **Dependencies**

To enable this parameter, set **Valve parameterization** to **Nominal capacity, superheat, and operating conditions**.

**Nominal evaporator heat transfer** — Evaporator heat transfer rate in nominal conditions  
15 kW (default) | positive scalar

Rate of heat transfer in the system evaporator under nominal operating conditions. This parameter sets the operational conditions of the thermostatic expansion valve.

#### **Dependencies**

To enable this parameter, set **Valve parameterization** to **Nominal capacity, superheat, and operating conditions** and **Capacity specification** to **Evaporator Heat transfer**.

**Maximum evaporator heat transfer** — Maximum evaporator heat transfer rate  
20 kW (default) | positive scalar

Maximum rate of heat transfer in the system evaporator. In most refrigeration cycles, this value is 20% to 50% larger than the value of the **Nominal evaporator heat transfer** parameter. This parameter sets the maximum operating conditions for the thermostatic expansion valve.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and **Capacity specification** to Evaporator Heat transfer.

**Nominal mass flow rate** — Mass flow rate in nominal conditions  
0.005 kg/s (default) | positive scalar

Mass flow rate in the system evaporator under nominal operating conditions. The block uses this parameter to set the operational conditions of the thermostatic expansion valve.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and **Capacity specification** to Mass flow rate.

**Maximum mass flow rate** — Maximum evaporator heat transfer rate  
0.008 kg/s (default) | positive scalar

Maximum rate of mass flow in the system evaporator. The block uses this parameter to set the maximum operating conditions for the thermostatic expansion valve.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and **Capacity specification** to Mass flow rate.

**Nominal pressure specification** — Method to specify nominal pressure  
Specified pressure (default) | Pressure at specified saturation temperature

Method to specify nominal pressure for the evaporator and condenser. When you select **Specified pressure**, you can specify the evaporator and condenser outlet pressure. When you select **Pressure at specified saturation temperature**, you specify the saturation temperature in the condenser and evaporator. The block calculates the corresponding saturation temperatures by using the refrigerant property tables.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions.

**Nominal condenser outlet pressure** — Condenser outlet pressure in nominal conditions  
1.5 MPa (default) | positive scalar

Refrigerant pressure in the condenser under nominal operating conditions. The block calculates the corresponding saturation temperatures by using the refrigerant property tables.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and **Nominal pressure specification** to Specific pressure.

**Nominal evaporator outlet pressure** — Evaporator outlet pressure in nominal conditions  
0.3 MPa (default) | positive scalar

Refrigerant pressure in the evaporator under nominal operating conditions. The block calculates the corresponding saturation temperatures by using the refrigerant property tables.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and **Nominal pressure specification** to Specific pressure.

**Nominal condensing (saturation) temperature** — Refrigerant saturation temperature in the condenser

313.15 K (default) | positive scalar

Refrigerant saturation temperature in the condenser under nominal operating conditions.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and **Nominal pressure specification** to Pressure at specified saturation temperature.

**Nominal evaporating (saturation) temperature** — Evaporator saturation temperature in nominal conditions

273.15 K (default) | positive scalar

Refrigerant saturation temperature in the evaporator under nominal operating conditions.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and **Nominal pressure specification** to Pressure at specified saturation temperature.

**Nominal condenser subcooling** — Operational condenser outlet temperature differential

5 deltaK (default) | positive scalar

Difference between the value of the **Nominal condensing (saturation) temperature** parameter and the liquid temperature at the condenser outlet under nominal operating conditions.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions.

**Nominal (static + opening) evaporator superheat** — Operational evaporator outlet temperature differential

10 deltaK (default) | positive scalar

Difference between the superheated vapor temperature at the evaporator outlet and the value of the **Nominal evaporating (saturation) temperature** parameter under nominal operating conditions. The valve maintains this value by adjusting the open area to allow more or less fluid into the evaporator.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions.

**Static (minimum) evaporator superheat** — Minimum allowable temperature differential at evaporator outlet

5 deltaK (default) | positive scalar

Minimum allowed difference between the superheated vapor temperature at the evaporator outlet and the value of the **Nominal evaporating (saturation) temperature** parameter. If the operational difference falls below this value, the valve is closes.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions.

**MOP limit** — Whether to enable pressure or temperature limits

Off (default) | On - Specify maximum operating pressure | On - Specify maximum operating temperature

Whether to enable pressure limits in the evaporator. The options are:

- **Off:** There is no pressure limit. The valve opens and closes based only on the evaporator superheat.
- **On - Specify maximum operating pressure:** This setting places an upper limit on the evaporating pressure and temperature. The valve closes when the evaporator pressure reaches this limit.
- **On - Specify maximum operating temperature:** This setting places an upper limit on the evaporating pressure and temperature. The valve closes when the evaporator temperature reaches this limit.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions.

**Maximum evaporator outlet pressure** — Maximum pressure

0.5 MPa (default) | positive scalar

Maximum permissible saturation pressure in the evaporator when evaporator pressure limiting is on.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and set **MOP limit** to On - Specify maximum operating pressure.

**Maximum evaporating (saturation) temperature** — Maximum temperature

288.15 K (default) | positive scalar

Maximum permissible saturation temperature in the evaporator when evaporator temperature limiting is on.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions and set **MOP limit** to On - Specify maximum operating temperature.

**Closed valve leakage as a fraction of nominal flow** — Minimum flow through valve at all times

1e-6 (default) | positive scalar

Fraction of leakage-to-nominal flow through the valve when the valve is closed. A nonzero value enhances numerical stability in the fluid network.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Nominal capacity, superheat, and operating conditions.

**Quadrant 1 - Evaporator outlet temperature vector** — Vector of temperature values at evaporator outlet

0 : 10 : 40 degC (default) | vector

Temperature of the sensing bulb, which is typically placed at the evaporator outlet. Therefore, this parameter is equivalent to the evaporator outlet temperature. The block uses this data on the x-axis in quadrant 1 of the four-quadrant diagram. This parameter must be the same length as the **Quadrant 1 - Bulb pressure vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Quadrant 1 - Bulb pressure vector** — Vector of pressure values of fluid inside sensing bulb

0.3 : 0.1 : 0.7 MPa (default) | vector

Pressure of the fluid inside the sensing bulb at the evaporator outlet. The refrigerant pressure at the evaporator outlet is independent of the internal fluid pressure of the sensing bulb. The valve uses the bulb pressure to open. The block interpolates this data for the y-axis in quadrant 1 of the four-quadrant diagram. This parameter must be the same length as the **Quadrant 1 - Evaporator outlet temperature vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Quadrant 2 - Valve lift vector** — Vector of valve lift values

0 : 0.15 : 0.6 mm (default) | vector

Vector of the valve lift, or the position of the needle of the valve. The block uses this data on the x-axis in quadrant 2 of the four-quadrant diagram. The valve lift must be defined consistently between quadrants 2 and 3. The block uses valve lift to relate the pressure in quadrant 2 and flow rate in quadrant 3. If data is unavailable, you can construct valve lift values, such as 0 for fully closed and 1 for fully open. This parameter must be the same length as the **Quadrant 2 - Evaporator outlet pressure vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Quadrant 2 - Evaporator outlet pressure vector** — Vector of values of evaporator outlet pressure  
0.3 : -0.05 : 0.1 MPa (default) | vector

Vector of the equalization pressure, which is the measure of the evaporator outlet pressure of the valve. The valve uses the equalization pressure to close:

- If the valve has internal pressure equalization, this parameter is the pressure at the outlet of the valve, which is connected to the evaporator inlet. In this case, the block assumes that the pressure loss in the evaporator is small.
- If the valve has external pressure equalization, this is the value measured by the external pilot line connected to the evaporator outlet.

The block interpolates this data for the y-axis in quadrant 2 of the four-quadrant diagram. This parameter must be the same length as the **Quadrant 2 - Valve lift vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Quadrant 3 - Valve lift vector** — Vector of valve lift values  
0 : 0.15 : 0.6 mm (default) | vector

Vector of the valve lift, or the position of the needle of the valve. The block uses this data on the x-axis in quadrant 3 of the four-quadrant diagram. The valve lift must be defined consistently between quadrants 2 and 3. The block uses valve lift to relate the pressure in quadrant 2 and flow rate in quadrant 3. If data is unavailable, you can construct valve lift values, such as 0 for fully closed and 1 for fully open. This parameter must be the same length as the **Quadrant 3 - Mass flow rate vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Quadrant 3 - Mass flow rate vector** — Vector of values of mass flow rate through the valve  
[1e-7, 0.015 : 0.015 : 0.06] kg/s (default) | vector

Values of mass flow rate through the valve in relation to different values of the valve opening. The block interpolates this data for the y-axis in quadrant 3 of the four-quadrant diagram. This parameter must be the same length as the **Quadrant 3 - Valve lift vector** parameter. The first element corresponds to the leakage mass flow rate when the valve is closed. This value must be a positive, small value for numerical robustness.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Reference condenser outlet pressure** — Reference pressure of condenser outlet  
2 MPa (default) | scalar

Reference valve inlet pressure. The block holds the valve inlet pressure at this value in quadrant 3 of the four-quadrant diagram.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Reference evaporator outlet pressure** — Reference pressure of evaporator outlet  
0.3 MPa (default) | scalar

Reference evaporator outlet pressure. The block holds the evaporator outlet pressure at this value in quadrant 3 of the four-quadrant diagram.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Reference evaporator outlet temperature** — Reference temperature of evaporator outlet  
0 degC (default) | scalar

Reference evaporator outlet temperature. The block holds the evaporator outlet temperature at this value in quadrant 2 of the four-quadrant diagram.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Reference condenser subcooling** — Reference condenser outlet temperature differential  
5 de1taK (default) | scalar

Difference in temperature between the condenser outlet and the condensing temperature. The block holds the valve inlet temperature at this value in quadrant 3 of the four-quadrant diagram.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data – quadrant diagram.

**Pressure equalization** — Pressure measurement location  
Internal pressure equalization (default) | External pressure equalization

Pressure measurement location. Set this parameter to **Internal pressure equalization** to measure the evaporator pressure at port **B**. Set this parameter to **External pressure equalization** to expose the evaporator pressure port, **E**. Connect this port to an evaporator outlet. Choose the setting for this parameter depending on the design of your thermostatic expansion valve.

**Bulb temperature dynamics** — Whether to model thermal lag  
Off (default) | On

Whether to model thermal dynamics in temperature measurement. When you set this parameter to **On**, the bulb fluid temperature lags the refrigeration temperature. The **Bulb thermal time constant** parameter determines the lag response.

**Bulb thermal time constant** — Thermal lag time constant  
20 s (default) | positive scalar

First-order time constant for the bulb fluid temperature delay. The block delays the measured temperature relative to the refrigerant temperature at port **S**. The time constant is proportional to the thermal mass of the bulb, including any ballast, and is inversely proportional to the thermal conductance across the thermal contact surface.

#### Dependencies

To enable this parameter, set **Bulb temperature dynamics** to On.

**Cross-sectional area at ports A and B** — Port area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of connecting pipes at ports **A** and **B**.

**Laminar flow pressure ratio** — Ratio of evaporator pressures at flow regime transition  
0.999 (default) | positive scalar

Ratio of the evaporator outlet pressure to evaporator inlet pressure at which the fluid transitions between the laminar and turbulent regimes. The pressure loss corresponds to the mass flow rate linearly in laminar flows and quadratically in turbulent flows.

**Inlet phase change time constant** — Lag for mixture specific volume  
0.1 s (default) | positive scalar

Time lag for liquid-vapor mixtures in computing the fluid specific volume. This parameter does not influence the specific volume when the inlet fluid is a fully supercooled liquid.

## Version History

**Introduced in R2020b**

**R2022b: Block supports parameterization by tabulated data from a 4-Quadrant diagram**

You can set the new **Valve parameterization** parameter to:

- **Nominal capacity, superheat, and operating conditions** — The block behaves as in previous releases.
- **Tabulated data - quadrant diagram** — The block enables parameters that you use to specify the curves in a 4-Quadrant diagram.

Additionally, you can generate a plot of the diagram by right-clicking the block and selecting **Fluids > Plot 4-Quadrant Diagram**.

# Turbine (G)

Gas turbine in a thermodynamic cycle

## Libraries:

Simscape / Fluids / Gas / Turbomachinery

## Description

The Turbine (G) block models a turbine in a gas network. You can parameterize the block as a tabulated turbine map that is either a 1-D function of pressure ratio or 2-D function of pressure ratio and corrected mass flow rate. Fluid flowing from port **A** to port **B** generates torque. Port **R** reports shaft torque and angular velocity relative to port **C**, which represents the turbine casing.

When enabled, port **VN** represents the nozzle opening fraction. This value linearly scales the corrected mass flow rate but does not influence the turbine efficiency. A value of **1** corresponds to the data in the turbine map.

## Turbine Map

To visualize the block map, right-click the block and select **Fluids > Plot Turbine Map**.

Each time you modify the block settings, click **Reload Data** on the figure window.

The turbine map relates turbine performance, as a function of pressure ratio, to the corrected mass flow rate and isentropic efficiency. The pressure ratio is the ratio between the turbine inlet pressure and outlet pressure.

The turbine map plots two separate graphs: corrected mass flow rate versus pressure ratio and isentropic efficiency versus pressure ratio. When you set the **Turbine map parameterization** to **Tabulated data - flow rate and efficiency vs. corrected speed and pressure ratio**, the plots also depend on the corrected rotor speed,  $N$ . The indexing variable  $\beta$  does not need to be the same between the mass flow rate and efficiency tables.

## Corrected Mass Flow Rate

Due to the large changes in pressure and temperature inside a turbine, the turbine map plots performance in terms of the corrected mass flow rate. The block adjusts the corrected mass flow rate from the inlet mass flow rate by using a corrected pressure and temperature

$$\dot{m}_A \sqrt{\frac{T_A}{T_{corr}}} = \dot{m}_{corr} \frac{p_A}{p_{corr}},$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $T_A$  is the temperature at port **A**.
- $T_{corr}$  is the **Reference temperature for corrected flow** parameter. Refer to the data sheet for your turbine for this value.

- $\dot{m}_{corr}$  is the corrected mass flow rate.

When **Turbine map parameterization** is Analytical - nominal pressure ratio and corrected mass flow rate, this is the value of the **Nominal corrected mass flow rate** parameter.

When **Turbine map parameterization** is Tabulated data - Flow rate and efficiency vs. pressure ratio, this is the value of the **Corrected mass flow rate vector,  $\dot{m}(\text{pr})$**  parameter.

When **Turbine map parameterization** is Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio, this is the value of the **Corrected mass flow rate table,  $\dot{m}(N,\beta)$**  parameter.

- $p_A$  is the pressure at port **A**.
- $p_{corr}$  is the **Reference pressure for corrected flow** parameter. Refer to the data sheet for your turbine for this value.

### Corrected Speed

The block also adjusts the shaft speed,  $\omega$ , according to the reference temperature, such that the corrected shaft speed is

$$\omega_{corr} = \frac{\omega}{\sqrt{\frac{T_A}{T_{ref}}}}$$

### Shaft Torque

The block calculates the shaft torque,  $\tau$ , as

$$\tau = \frac{\eta_m \dot{m}_A \Delta h_{total}}{\omega}$$

where:

- $\Delta h_{total}$  is the total change in the fluid specific enthalpy.
- $\eta_m$  is the value of the **Mechanical efficiency** parameter.
- $\omega$  is the relative shaft angular velocity,  $\omega_R - \omega_C$ .

Reversed flow, from port **B** to port **A**, is outside of the typical turbine operation mode and may not return accurate results. A threshold region when flow approaches zero ensures the block generates no torque when the flow rate is near zero or reversed.

### Analytical Parametrization

Use the analytical parametrization to create a turbine based on the expected nominal operating conditions. When **Turbine map parameterization** is Analytical – nominal pressure ratio and corrected mass flow rate, the turbine isentropic efficiency is constant and the mass flow rate is a function of the pressure ratio.

This image shows the default turbine map when you use the analytical parameterization.

### Parameterization by Pressure Ratio

When **Turbine map parameterization** is Tabulated data - Flow rate and efficiency vs. pressure ratio, the turbine isentropic efficiency and mass flow rate are a function of the pressure ratio and do not account for any changes in the turbine rotational speed.

The last element of the **Corrected mass flow rate vector,  $\dot{m}(\mathbf{pr})$**  and the **Pressure ratio vector,  $\mathbf{pr}$**  parameters represents the corrected mass flow rate and pressure ratio at choked flow conditions.

This image shows the default turbine map when you use the 1-D parameterization.

### Parameterization by Pressure Ratio and Corrected Mass Flow Rate

When **Turbine map parameterization** is Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio, the turbine isentropic efficiency, pressure ratio, and corrected mass flow rate are a function of the corrected speed,  $N$ , and the map index,  $\beta$ . The block uses linear interpolation between data points for the efficiency, pressure ratio, and corrected mass flow rate parameters.

The last column of the **Corrected mass flow rate table,  $\dot{m}(N,\beta)$**  and the **Pressure ratio table,  $pr(N,\beta)$**  parameters represents the corrected mass flow rate and pressure ratio at choked flow conditions.

This image shows the default turbine map when you use the 2-D parameterization.

### Continuity Equations

Mass is preserved over the block:

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}_B$  is the mass flow rate at port **B**.

The block calculates the energy balance as

$$\Phi_A + \Phi_B - P_{fluid} = 0,$$

where:

- $\Phi_A$  is the energy flow rate at port **A**.
- $\Phi_B$  is the energy flow rate at port **B**.
- $P_{fluid}$  is the work done by the fluid, which the block determines from the change in total fluid specific enthalpy,  $P_{fluid} = \dot{m}_A \Delta h_{total}$ .

## Assumptions and Limitations

- The shaft does not rotate under reversed flow conditions. Results during reversed flows may not be accurate.

## Ports

### Input

**VN** — Nozzle opening fraction, unitless  
physical signal

Variable nozzle opening fraction, specified as a unitless physical signal. The corrected mass flow rate scales linearly with the value of **VN**. A fraction of 1 corresponds to the tabulated data. The nozzle opening fraction does not influence the isentropic efficiency.

### Dependencies

To enable this port, select the **Enable variable nozzle input port** parameter.

### Conserving

**A** — Gas inlet  
gas

Gas conserving port associated with the fluid entry port.

**B** — Gas outlet  
gas

Gas conserving port associated with the fluid exit port.

**C** — Turbine case  
mechanical translational

Port associated with the turbine casing.

**R** — Turbine shaft  
mechanical translational

Port associated with the turbine shaft torque and angular velocity.

## Parameters

### Parameterization

**Turbine map parameterization** — Performance parameterization

Analytical - Nominal pressure ratio and corrected mass flow rate (default) |  
Tabulated data - Flow rate and efficiency vs. pressure ratio | Tabulated data -  
Flow rate and efficiency vs. corrected speed and pressure ratio

Performance parameterization specification:

- Analytical - Nominal pressure ratio and corrected mass flow rate: Parameterize turbine isentropic efficiency and corrected mass flow rate analytically.

- Tabulated data - Flow rate and efficiency vs. pressure ratio: Parameterize turbine isentropic efficiency and corrected mass flow rate by pressure ratio.
- Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio: Parameterize turbine isentropic efficiency and corrected mass flow rate by corrected speed and pressure ratio.

**Enable variable nozzle input port** — Whether to enable the variable nozzle input port  
Off (default) | On

Whether to enable the variable nozzle input port **VN**. When you do not enable the **VN** port, the nozzle remains constant at 1.

**Minimum nozzle opening fraction** — Minimum opening fraction  
1e-3 (default) | positive scalar in the range (0,1]

Minimum nozzle opening fraction. This value is the lower boundary to the signal at **VN**. The block multiplies the value of this parameter by the mass flow rate to obtain the minimum corrected mass flow rate through the turbine.

#### Dependencies

To enable this parameter, select **Enable variable nozzle input port**.

**Maximum nozzle opening fraction** — Maximum opening fraction  
1 (default) | positive scalar in the range (0,1]

Maximum nozzle opening fraction. This value is the upper boundary to the signal at **VN**. The block multiplies the value of this parameter by the mass flow rate to obtain the maximum corrected mass flow rate through the turbine.

#### Dependencies

To enable this parameter, select **Enable variable nozzle input port**.

**Corrected speed index vector, N** — Tabulated data shaft speed indices  
100 .\* [50, 60, 70, 80, 90, 100, 110] rpm (default) | vector of positive scalars

Vector of constant shaft speeds for tabular parameterization of corrected mass flow rate and isentropic efficiency.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

#### Flow Rate Data

**Nominal pressure ratio** — Pressure ratio value  
2 (default) | positive scalar

Pressure ratio value under nominal operating conditions for the analytical parameterization.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Analytical - Nominal pressure ratio and corrected mass flow rate.

**Nominal corrected mass flow rate** — Corrected mass flow rate value  
48 kg/s (default) | positive scalar

Corrected mass flow rate value under nominal operating conditions for the analytical parameterization.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Analytical - Nominal pressure ratio and corrected mass flow rate.

**Pressure ratio vector, pr** — Vector of pressure ratios  
[1.251, 1.345, 1.442, 1.521, 1.596, 1.692, 1.849, 1.972, 2.1, 2.173, 2.259, 2.3424] (default) | vector of positive scalars

Vector of pressure ratio values for the tabulated parameterization of corrected mass flow rate. This vector must have the same number of elements as the **Corrected mass flow rate vector, mdot(pr)** parameter and all elements must be greater than 1. The last element must be the pressure ratio at choked conditions.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Corrected mass flow rate vector, mdot(pr)** — Vector of corrected mass flow rate values  
[39.439, 43.01, 45.556, 46.801, 47.792, 48.388, 48.634, 48.67, 48.689, 48.747, 48.825, 48.912] kg/s (default) | vector of positive scalars

Vector of corrected mass flow rate values for the tabulated parameterization of corrected mass flow rate. This vector must have the same number of elements as the **Pressure ratio vector, pr** parameter and all elements must be greater than 0. The last element must be the corrected mass flow rate at choked conditions.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Pressure ratio table, pr(N,beta)** — Turbine map pressure ratio data  
*M*-by-*N* matrix (default)

*M*-by-*N* matrix of turbine outlet-to-inlet pressure ratios at the specified corrected shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Corrected speed index vector, N** parameter.
- *N* is the number of  $\beta$  indices in the table.

The default table values are:

[1.217, 1.285, 1.323, 1.363, 1.402, 1.427, 1.495, 1.545, 1.6, 1.687, 1.747, 1.8074; 1.231, 1.302, 1.356, 1.404, 1.443, 1.473, 1.525, 1.577, 1.635, 1.709, 1.782, 1.845; 1.242, 1.328, 1.388, 1.437, 1.528, 1.617, 1.704, 1.811, 1.915, 1.979, 2.053, 2.1226; 1.244, 1.339, 1.417, 1.465, 1.528, 1.584, 1.692, 1.787, 1.899, 2, 2.075, 2.1492; 1.245, 1.34, 1.425, 1.492, 1.546, 1.684, 1.748,

1.882, 1.987, 2.084, 2.167, 2.2458; 1.251, 1.345, 1.442, 1.521, 1.596, 1.692, 1.849, 1.972, 2.1, 2.173, 2.259, 2.3424; 1.248, 1.348, 1.447, 1.516, 1.581, 1.651, 1.749, 1.839, 1.93, 2.024, 2.154, 2.242]

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

**Corrected mass flow rate table,  $\dot{m}(N, \beta)$**  — Turbine map corrected mass flow rate data  $M$ -by- $N$  matrix (default)

$M$ -by- $N$  matrix of corrected mass flow rates at the specified corrected shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Constant speed index vector,  $N$**  parameter.
- $N$  is the number of  $\beta$  indices in the table.

The default table values are:

[40.403, 44.417, 46.653, 47.966, 48.97, 49.544, 50.001, 50.081, 50.086, 50.095, 50.09, 50.0922; 40.044, 43.754, 46.125, 47.626, 48.513, 49.105, 49.481, 49.58, 49.597, 49.624, 49.638, 49.633; 39.941, 43.795, 46.017, 47.335, 48.795, 49.199, 49.279, 49.27, 49.248, 49.23, 49.255, 49.2428; 39.896, 43.512, 45.914, 47.061, 48.011, 48.558, 48.943, 49.042, 49.069, 49.01, 49.046, 49.0266; 39.524, 42.934, 45.686, 46.743, 47.715, 48.67, 48.777, 48.836, 48.876, 48.836, 48.845, 48.8184; 39.439, 43.01, 45.556, 46.801, 47.792, 48.388, 48.634, 48.67, 48.639, 48.647, 48.625, 48.5912; 39.502, 42.849, 45.336, 46.385, 47.312, 47.877, 48.222, 48.397, 48.459, 48.482, 48.455, 48.414] kg/s

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

### Efficiency Data

**Constant isentropic efficiency** — Isentropic efficiency value

0.8 (default) | positive scalar

Isentropic efficiency under nominal operating conditions for the analytical parametrization.

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Analytical - Nominal pressure ratio and corrected mass flow rate.

**Pressure ratio vector,  $pr$**  — Vector of pressure ratios

[1.252, 1.328, 1.425, 1.544, 1.642, 1.757, 1.873, 2.005, 2.1, 2.204, 2.248, 2.28] (default) | vector of positive scalars

Vector of pressure ratio values for the tabulated parameterization of isentropic efficiency. This vector must have the same number of elements as the **Isentropic efficiency vector,  $\eta(pr)$**  parameter and all elements must be greater than 1.

**Dependencies**

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Isentropic efficiency vector, eta(pr)** — Vector of isentropic efficiencies

[.559, .61, .673, .741, .788, .835, .869, .895, .908, .899, .854, .751]  
(default) | vector of elements in the range (0,1]

Vector of isentropic efficiency values for the tabulated parameterization of isentropic efficiency. This vector must have the same number of elements as the **Pressure ratio vector, pr** parameter and all elements must be greater than 0 and less than or equal to 1.

**Dependencies**

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Pressure ratio table, pr(N,beta)** — Turbine map pressure ratio data

*M*-by-*N* matrix (default)

*M*-by-*N* matrix of turbine outlet-to-inlet pressure ratios at the specified corrected shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Constant speed index vector, N** parameter.
- *N* is the number of  $\beta$  indices in the table.

The default table values are:

[1.224, 1.246, 1.292, 1.387, 1.457, 1.534, 1.61, 1.686, 1.743, 1.79, 1.871, 1.914; 1.237, 1.25, 1.28, 1.369, 1.459, 1.553, 1.629, 1.716, 1.799, 1.846, 1.927, 1.97; 1.241, 1.255, 1.283, 1.326, 1.401, 1.509, 1.591, 1.704, 1.806, 1.913, 1.994, 2.037; 1.25, 1.265, 1.308, 1.364, 1.456, 1.532, 1.637, 1.739, 1.851, 1.934, 2.042, 2.085; 1.281, 1.314, 1.371, 1.425, 1.498, 1.574, 1.647, 1.749, 1.878, 1.979, 2.091, 2.18; 1.252, 1.328, 1.425, 1.544, 1.642, 1.757, 1.873, 2.005, 2.1, 2.204, 2.248, 2.28; 1.382, 1.43, 1.495, 1.586, 1.688, 1.791, 1.887, 1.99, 2.079, 2.158, 2.249, 2.217]

**Dependencies**

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

**Isentropic efficiency table, eta(N,beta)** — Turbine map isentropic efficiency data

*M*-by-*N* matrix (default)

*M*-by-*N* matrix of turbine isentropic efficiencies at the specified constant shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Constant speed index vector, N** parameter.
- *N* is the number of  $\beta$  indices in the table.

The default table values are:

[.72, .754, .759, .739, .714, .679, .643, .603, .554, .524, .494, .48; .716, .757, .794, .819, .812, .788, .761, .728, .692, .662, .632, .618; .629, .691, .775, .831, .858, .869, .859, .842, .816, .782, .752, .738; .594, .668, .757, .804, .857, .883, .892, .893, .884, .865, .835, .821; .664, .72, .779, .823, .858, .883, .897, .905, .904, .896, .883, .868; .559, .61, .673, .741, .788, .835, .869, .895, .908, .899, .854, .751; .718, .785, .824, .855, .882, .9, .908, .906, .884, .857, .804, .701]

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

### Reference Data

**Reference pressure for corrected flow** — Correcting pressure

0.101325 MPa (default) | positive scalar

Pressure at which the turbine data consolidates to a corrected trend line.

**Reference temperature for corrected flow** — Correcting temperature

288.15 K (default) | positive scalar

Temperature at which the turbine data the turbine data consolidates to a corrected trend line.

**Mechanical efficiency** — Efficiency of conversion to torque

0.9 (default) | positive scalar in the range [0,1]

Efficiency of the conversion from reduction in specific enthalpy to shaft torque.

**Inlet area at port A** — Turbine inlet area

1 m<sup>2</sup> (default) | positive scalar

Turbine inlet cross-sectional area.

**Outlet area at port B** — Turbine outlet area

1 m<sup>2</sup> (default) | positive scalar

Turbine outlet cross-sectional area.

## Version History

Introduced in R2021a

### R2023a: Control visibility of port VN

Use the **Enable variable nozzle input port** parameter to enable the variable nozzle control port VN.

### R2022b: Block supports nominal parameterization

Now you can parameterize the block using nominal values. Set **Turbine map parameterization** to **Analytical** - nominal pressure ratio and corrected mass flow rate. This selection enables these new parameters:

- **Nominal pressure ratio**
- **Nominal corrected mass flow rate**

## Turbine (2P)

Two-phase turbine in a thermodynamic cycle

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Fluid Machines

## Description

The Turbine (2P) block models a turbine in a two-phase fluid network. You can parameterize the block as a tabulated turbine map that is either a 1-D function of pressure ratio or 2-D function of pressure ratio and corrected mass flow rate. Fluid flowing from port **A** to port **B** generates torque. Port **R** reports shaft torque and angular velocity relative to port **C**, which represents the turbine casing.

When enabled, port **VN** represents the nozzle opening fraction. This value linearly scales the corrected mass flow rate but does not influence the turbine efficiency. A value of 1 corresponds to the data in the turbine map.

The Turbine (2P) block assumes that superheated fluid enters the inlet. You can use the **Report when fluid is not fully vapor** parameter to choose what the block does when the fluid does not meet superheated conditions.

### Turbine Map

To visualize the block map, right-click the block and select **Fluids > Plot Turbine Map**.

Each time you modify the block settings, click **Reload Data** on the figure window.

The turbine map relates turbine performance, as a function of pressure ratio, to the corrected mass flow rate and isentropic efficiency. The pressure ratio is the ratio between the turbine inlet pressure and outlet pressure.

The turbine map plots two separate graphs: corrected mass flow rate versus pressure ratio and isentropic efficiency versus pressure ratio. When you set the **Turbine map parameterization** to **Tabulated data - flow rate and efficiency vs. corrected speed and pressure ratio**, the plots also depend on the corrected rotor speed,  $N$ . The indexing variable  $\beta$  does not need to be the same between the mass flow rate and efficiency tables.

### Corrected Mass Flow Rate

Due to the large changes in pressure and temperature inside a turbine, the turbine map plots performance in terms of the corrected mass flow rate. The block adjusts the corrected mass flow rate from the inlet mass flow rate by using a corrected pressure and temperature

$$\dot{m}_A \sqrt{\frac{T_A}{T_{corr}}} = \dot{m}_{corr} \frac{p_A}{p_{corr}},$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.

- $T_A$  is the temperature at port **A**.
- $T_{corr}$  is the **Reference temperature for corrected flow** parameter. Refer to the data sheet for your turbine for this value.
- $\dot{m}_{corr}$  is the corrected mass flow rate.

When **Turbine map parameterization** is Analytical - nominal pressure ratio and corrected mass flow rate, this is the value of the **Nominal corrected mass flow rate** parameter.

When **Turbine map parameterization** is Tabulated data - Flow rate and efficiency vs. pressure ratio, this is the value of the **Corrected mass flow rate vector, mdot(pr)** parameter.

When **Turbine map parameterization** is Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio, this is the value of the **Corrected mass flow rate table, mdot(N,beta)** parameter.

- $p_A$  is the pressure at port **A**.
- $p_{corr}$  is the **Reference pressure for corrected flow** parameter. Refer to the data sheet for your turbine for this value.

### Corrected Speed

The block also adjusts the shaft speed,  $\omega$ , according to the reference temperature, such that the corrected shaft speed is

$$\omega_{corr} = \frac{\omega}{\sqrt{\frac{T_A}{T_{ref}}}}$$

### Shaft Torque

The block calculates the shaft torque,  $\tau$ , as

$$\tau = \frac{\eta_m \dot{m}_A \Delta h_{total}}{\omega}$$

where:

- $\Delta h_{total}$  is the total change in the fluid specific enthalpy.
- $\eta_m$  is the value of the **Mechanical efficiency** parameter.
- $\omega$  is the relative shaft angular velocity,  $\omega_R - \omega_C$ .

Reversed flow, from port **B** to port **A**, is outside of the typical turbine operation mode and may not return accurate results. A threshold region when flow approaches zero ensures the block generates no torque when the flow rate is near zero or reversed.

### Analytical Parametrization

Use the analytical parametrization to create a turbine based on the expected nominal operating conditions. When **Turbine map parameterization** is Analytical – nominal pressure ratio and corrected mass flow rate, the turbine isentropic efficiency is constant and the mass flow rate is a function of the pressure ratio.

This image shows the default turbine map when you use the analytical parameterization.

### Parameterization by Pressure Ratio

When **Turbine map parameterization** is Tabulated data - Flow rate and efficiency vs. pressure ratio, the turbine isentropic efficiency and mass flow rate are a function of the pressure ratio and do not account for any changes in the turbine rotational speed.

The last element of the **Corrected mass flow rate vector,  $\mathbf{mdot}(\mathbf{pr})$**  and the **Pressure ratio vector,  $\mathbf{pr}$**  parameters represents the corrected mass flow rate and pressure ratio at choked flow conditions.

This image shows the default turbine map when you use the 1-D parameterization.

### Parameterization by Pressure Ratio and Corrected Mass Flow Rate

When **Turbine map parameterization** is set to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio, the turbine isentropic efficiency, pressure ratio, and corrected mass flow rate are a function of the corrected speed,  $N$ , and the map index,  $\beta$ . The block uses linear interpolation between data points for the efficiency, pressure ratio, and corrected mass flow rate parameters.

The last column of the **Corrected mass flow rate table,  $\dot{m}(N,\beta)$**  and the **Pressure ratio table,  $pr(N,\beta)$**  represent the corrected mass flow rate and pressure ratio at choked flow conditions.

This image shows the default turbine map when you use the 2-D parameterization.

### Continuity Equations

Mass is preserved over the block:

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}_B$  is the mass flow rate at port **B**.

The block calculates the energy balance as

$$\Phi_A + \Phi_B - P_{fluid} = 0,$$

where:

- $\Phi_A$  is the energy flow rate at port **A**.
- $\Phi_B$  is the energy flow rate at port **B**.
- $P_{fluid}$  is the work done by the fluid, which the block determines from the change in total fluid specific enthalpy,  $P_{fluid} = \dot{m}_A \Delta h_{total}$ .

## Assumptions and Limitations

- The shaft does not rotate under reversed flow conditions. Results during reversed flows may not be accurate.

## Ports

### Input

**VN** — Nozzle opening fraction, unitless  
physical signal

Variable nozzle opening fraction, specified as a unitless physical signal. The corrected mass flow rate scales linearly with the value of **VN**. A fraction of 1 corresponds to the tabulated data. The nozzle opening fraction does not influence the isentropic efficiency.

### Dependencies

To enable this port, select the **Enable variable nozzle input port** parameter.

### Conserving

**A** — Two-phase fluid inlet  
two-phase fluid

Two-phase fluid conserving port associated with the fluid entry port.

**B** — Two-phase fluid outlet  
two-phase fluid

Two-phase fluid conserving port associated with the fluid exit port.

**C** — Turbine case  
mechanical translational

Port associated with the turbine casing.

**R** — Turbine shaft  
mechanical translational

Port associated with the turbine shaft torque and angular velocity.

## Parameters

### Parameterization

**Turbine map parameterization** — Performance parameterization

Analytical - Nominal pressure ratio and corrected mass flow rate (default) |  
Tabulated data - Flow rate and efficiency vs. pressure ratio | Tabulated data -  
Flow rate and efficiency vs. corrected speed and pressure ratio

Performance parameterization specification:

- Analytical - Nominal pressure ratio and corrected mass flow rate: Parameterize turbine isentropic efficiency and corrected mass flow rate analytically.

- **Tabulated data - Flow rate and efficiency vs. pressure ratio:** Parameterize turbine isentropic efficiency and corrected mass flow rate by pressure ratio.
- **Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio:** Parameterize turbine isentropic efficiency and corrected mass flow rate by corrected speed and pressure ratio.

**Enable variable nozzle input port** — Whether to enable the variable nozzle input port  
Off (default) | On

Whether to enable the variable nozzle input port **VN**. When you do not enable the **VN** port, the nozzle remains constant at 1.

**Minimum nozzle opening fraction** — Minimum opening fraction  
1e-3 (default) | positive scalar in the range (0,1]

Minimum nozzle opening fraction. This value is the lower boundary to the signal at **VN**. The block multiplies the value of this parameter by the mass flow rate to obtain the minimum corrected mass flow rate through the turbine.

#### Dependencies

To enable this parameter, select **Enable variable nozzle input port**.

**Maximum nozzle opening fraction** — Maximum opening fraction  
1 (default) | positive scalar in the range (0,1]

Maximum nozzle opening fraction. This value is the upper boundary to the signal at **VN**. The block multiplies the value of this parameter by the mass flow rate to obtain the maximum corrected mass flow rate through the turbine.

#### Dependencies

To enable this parameter, select **Enable variable nozzle input port**.

**Report when fluid is not fully vapor** — Fluid not fully vapor notification  
None (default) | Warning | Error

Whether the block does nothing, generates a warning, or generates an error when the block detects fluid that is not fully vapor.

**Corrected speed index vector, N** — Tabulated data shaft speed indices  
250 .\* [50, 60, 70, 80, 90, 100, 110] rpm (default) | vector of positive scalars

Vector of constant shaft speeds for tabular parameterization of corrected mass flow rate and isentropic efficiency.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

#### Flow Rate Data

**Nominal pressure ratio** — Pressure ratio value  
2 (default) | positive scalar

Pressure ratio value under nominal operating conditions for the analytical parameterization.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Analytical - Nominal pressure ratio and corrected mass flow rate.

**Nominal corrected mass flow rate** — Corrected mass flow rate value

0.48 kg/s (default) | positive scalar

Corrected mass flow rate value under nominal operating conditions for the analytical parameterization.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Analytical - Nominal pressure ratio and corrected mass flow rate.

**Pressure ratio vector, pr** — Vector of pressure ratios

[1.251, 1.345, 1.442, 1.521, 1.596, 1.692, 1.849, 1.972, 2.1, 2.173, 2.259, 2.3424] (default) | vector of positive scalars

Vector of pressure ratio values for the tabulated parameterization of corrected mass flow rate. This vector must have the same number of elements as the **Corrected mass flow rate vector, mdot(pr)** parameter and all elements must be greater than 1. The last element must be the pressure ratio at choked conditions.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Corrected mass flow rate vector, mdot(pr)** — Vector of corrected mass flow rate values

0.01.\*[39.439, 43.01, 45.556, 46.801, 47.792, 48.388, 48.634, 48.67, 48.689, 48.747, 48.825, 48.912] kg/s (default) | vector of positive scalars

Vector of corrected mass flow rate values for the tabulated parameterization of corrected mass flow rate. This vector must have the same number of elements as the **Pressure ratio vector, pr** parameter and all elements must be greater than 0. The last element must be the corrected mass flow rate at choked conditions.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Pressure ratio table, pr(N,beta)** — Turbine map pressure ratio data

*M*-by-*N* matrix (default)

*M*-by-*N* matrix of turbine outlet-to-inlet pressure ratios at the specified corrected shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Corrected speed index vector, N** parameter.
- *N* is the number of  $\beta$  indices in the table.

The default table values are:

[1.217, 1.285, 1.323, 1.363, 1.402, 1.427, 1.495, 1.545, 1.6, 1.687, 1.747, 1.8074; 1.231, 1.302, 1.356, 1.404, 1.443, 1.473, 1.525, 1.577, 1.635, 1.709, 1.782, 1.845; 1.242, 1.328, 1.388, 1.437, 1.528, 1.617, 1.704, 1.811, 1.915, 1.979, 2.053, 2.1226; 1.244, 1.339, 1.417, 1.465, 1.528, 1.584, 1.692, 1.787, 1.899, 2, 2.075, 2.1492; 1.245, 1.34, 1.425, 1.492, 1.546, 1.684, 1.748, 1.882, 1.987, 2.084, 2.167, 2.2458; 1.251, 1.345, 1.442, 1.521, 1.596, 1.692, 1.849, 1.972, 2.1, 2.173, 2.259, 2.3424; 1.248, 1.348, 1.447, 1.516, 1.581, 1.651, 1.749, 1.839, 1.93, 2.024, 2.154, 2.242]

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

**Corrected mass flow rate table,  $\dot{m}(N, \beta)$**  — Turbine map corrected mass flow rate data  
*M*-by-*N* matrix (default)

*M*-by-*N* matrix of corrected mass flow rates at the specified corrected shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Constant speed index vector, *N*** parameter.
- *N* is the number of  $\beta$  indices in the table.

The default table values are:

0.01.\*[40.403, 44.417, 46.653, 47.966, 48.97, 49.544, 50.001, 50.081, 50.086, 50.095, 50.09, 50.0922; 40.044, 43.754, 46.125, 47.626, 48.513, 49.105, 49.481, 49.58, 49.597, 49.624, 49.638, 49.633; 39.941, 43.795, 46.017, 47.335, 48.795, 49.199, 49.279, 49.27, 49.248, 49.23, 49.255, 49.2428; 39.896, 43.512, 45.914, 47.061, 48.011, 48.558, 48.943, 49.042, 49.069, 49.01, 49.046, 49.0266; 39.524, 42.934, 45.686, 46.743, 47.715, 48.67, 48.777, 48.836, 48.876, 48.836, 48.845, 48.8184; 39.439, 43.01, 45.556, 46.801, 47.792, 48.388, 48.634, 48.67, 48.639, 48.647, 48.625, 48.5912; 39.502, 42.849, 45.336, 46.385, 47.312, 47.877, 48.222, 48.397, 48.459, 48.482, 48.455, 48.414] kg/s

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

### Efficiency Data

**Constant isentropic efficiency** — Isentropic efficiency value  
0.8 (default) | positive scalar

Isentropic efficiency under nominal operating conditions for the analytical parametrization.

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Analytical - Nominal pressure ratio and corrected mass flow rate.

**Pressure ratio vector, pr** — Vector of pressure ratios

[1.252, 1.328, 1.425, 1.544, 1.642, 1.757, 1.873, 2.005, 2.1, 2.204, 2.248, 2.28] (default) | vector of positive scalars

Vector of pressure ratio values for the tabulated parameterization of isentropic efficiency. This vector must have the same number of elements as the **Isentropic efficiency vector, eta(pr)** parameter and all elements must be greater than 1.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Isentropic efficiency vector, eta(pr)** — Vector of isentropic efficiencies

[.559, .61, .673, .741, .788, .835, .869, .895, .908, .899, .854, .751] (default) | vector of elements in the range (0,1)

Vector of isentropic efficiency values for the tabulated parameterization of isentropic efficiency. This vector must have the same number of elements as the **Pressure ratio vector, pr** parameter and all elements must be greater than 0 and less than or equal to 1.

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. pressure ratio.

**Pressure ratio table, pr(N,beta)** — Turbine map pressure ratio data

*M*-by-*N* matrix (default)

*M*-by-*N* matrix of turbine outlet-to-inlet pressure ratios at the specified corrected shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Constant speed index vector, N** parameter.
- *N* is the number of  $\beta$  indices in the table.

The default table values are:

[1.224, 1.246, 1.292, 1.387, 1.457, 1.534, 1.61, 1.686, 1.743, 1.79, 1.871, 1.914; 1.237, 1.25, 1.28, 1.369, 1.459, 1.553, 1.629, 1.716, 1.799, 1.846, 1.927, 1.97; 1.241, 1.255, 1.283, 1.326, 1.401, 1.509, 1.591, 1.704, 1.806, 1.913, 1.994, 2.037; 1.25, 1.265, 1.308, 1.364, 1.456, 1.532, 1.637, 1.739, 1.851, 1.934, 2.042, 2.085; 1.281, 1.314, 1.371, 1.425, 1.498, 1.574, 1.647, 1.749, 1.878, 1.979, 2.091, 2.18; 1.252, 1.328, 1.425, 1.544, 1.642, 1.757, 1.873, 2.005, 2.1, 2.204, 2.248, 2.28; 1.382, 1.43, 1.495, 1.586, 1.688, 1.791, 1.887, 1.99, 2.079, 2.158, 2.249, 2.217]

#### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

**Isentropic efficiency table, eta(N,beta)** — Turbine map isentropic efficiency data

*M*-by-*N* matrix (default)

$M$ -by- $N$  matrix of turbine isentropic efficiencies at the specified constant shaft speed and  $\beta$  value. The block employs linear interpolation between the table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Constant speed index vector**,  $N$  parameter.
- $N$  is the number of  $\beta$  indices in the table.

The default table values are:

```
[.72, .754, .759, .739, .714, .679, .643, .603, .554, .524, .494, .48; .716,
.757, .794, .819, .812, .788, .761, .728, .692, .662, .632, .618; .629, .691,

```

### Dependencies

To enable this parameter, set **Turbine map parameterization** to Tabulated data - Flow rate and efficiency vs. corrected speed and pressure ratio.

### Reference Data

**Reference pressure for corrected flow** — Correcting pressure

0.101325 MPa (default) | positive scalar

Pressure at which the turbine data consolidates to a corrected trend line.

**Reference temperature for corrected flow** — Correcting temperature

373.15 K (default) | positive scalar

Temperature at which the turbine data consolidates to a corrected trend line.

**Mechanical efficiency** — Efficiency of conversion to torque

0.9 (default) | positive scalar in the range [0,1]

Efficiency of the conversion from reduction in specific enthalpy to shaft torque.

**Inlet area at port A** — Turbine inlet area

0.01 m<sup>2</sup> (default) | positive scalar

Turbine inlet cross-sectional area.

**Outlet area at port B** — Turbine outlet area

0.01 m<sup>2</sup> (default) | positive scalar

Turbine outlet cross-sectional area.

## Version History

Introduced in R2022b

**R2023a: Control visibility of port VN**

Use the **Enable variable nozzle input port** parameter to enable the variable nozzle control port VN.

- R-1234yf
- R-404a
- R-410a
- R-407c
- R-22
- Ammonia (R-717)
- CO<sub>2</sub> (R-744)
- Isobutane (R-600a)

If you would like to specify your own working fluid properties, use the Foundation Library Two-Phase Fluid Properties (2P) block. If you do not specify a fluid, the system defaults will apply. See “Specify Fluid Properties” for more details.

## Fluid Properties Range

### Water (R-718)

The fluid properties are provided for a pressure range of 0.001 to 95 MPa, and temperature range (at 1 atmosphere) of 273.16 to 1,245.8 K.

### R-134a

The fluid properties are provided for a pressure range of 0.001 to 5.5 MPa, and temperature range (at 1 atmosphere) of 177.08 to 424.4 K.

### R-1234yf

The fluid properties are provided for a pressure range of 0.04 to 3.2 MPa, and temperature range (at 1 atmosphere) of 223.52 to 387.45 K.

### R-404a

The fluid properties are provided for a pressure range of 0.003 to 12 MPa, and temperature range (at 1 atmosphere) of 171.6 to 550.94 K.

**R-410a**

The fluid properties are provided for a pressure range of 0.001 to 6 MPa, and temperature range (at 1 atmosphere) of 146.19 to 427.25 K.

**R-407c**

The fluid properties are provided for a pressure range of 0.001 to 6 MPa, and temperature range (at 1 atmosphere) of 158.85 to 427.92 K.

**R-22**

The fluid properties are provided for a pressure range of 0.001 to 8 MPa, and temperature range (at 1 atmosphere) of 120.77 to 519.49 K.

**Ammonia (R-717)**

The fluid properties are provided for a pressure range of 0.008 to 95 MPa, and temperature range (at 1 atmosphere) of 195.5 to 543.9 K.

**CO<sub>2</sub> (R-744)**

The fluid properties are provided for a pressure range of 0.55 to 50 MPa, and temperature range (at 1 MPa) of 216.94 to 1,389.4 K. Note that the triple point of CO<sub>2</sub> is higher than atmospheric pressure, and therefore the minimum valid pressure is adjusted accordingly. When using CO<sub>2</sub> as the working fluid, ensure that connected blocks with initial pressure parameters, such as a Reservoir (2P) block, are equal to or greater this minimum pressure.

**Isobutane (R-600a)**

The fluid properties are provided for a pressure range of 0.0001 to 15 MPa, and temperature range (at 1 atmosphere) of 121.02 to 516.64 K.

**Visualizing Fluid Properties**

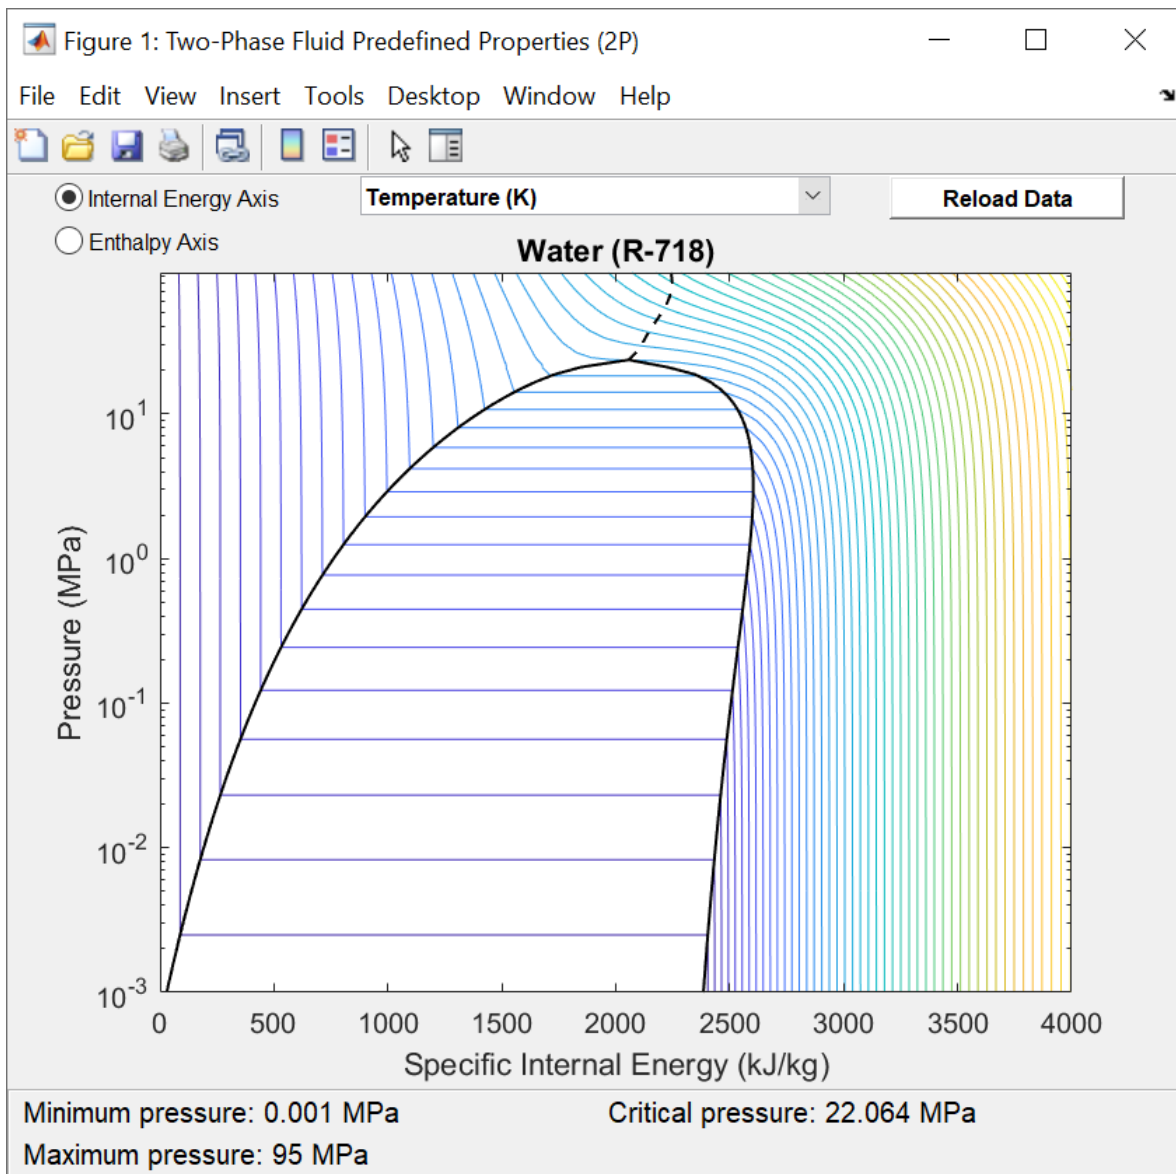

To visualize the:

- Specific volume
- Specific entropy
- Temperature
- Kinematic viscosity
- Thermal conductivity
- Prandtl number

of the network fluid as a function of specific internal energy or specific enthalpy and pressure, right-click on the block and select **Fluids > Plot Fluid Properties (3D)**:

or **Fluids > Plot Fluid Properties (Contours):**

Use the **Reload Data** button to regenerate the plot whenever the fluid selection or fluid parameters change.

## Ports

### Conserving

**A** — Connection port  
two-phase fluid

Two-phase fluid conserving port that connects the block to the network. This port connects to any point on a two-phase connection line within a block diagram. When you connect the Two-Phase Fluid Predefined Properties (2P) block to a network line, the fluid properties are propagated to all blocks in the circuit.

## Parameters

### Two-phase fluid — Working fluid

Water (R-718) (default) | R-134a | R-1234yf | R-410a blend | R-404a blend | R-407c blend | R-22 | Ammonia (R-717) | CO2 (R-744) | Isobutane (R-600a)

Predefined working fluid options.

### Atmospheric pressure — Environmental pressure

0.101325 MPa (default) | positive scalar

Environmental pressure of the system.

### Pressure and specific internal energy outside valid range — Whether to notify when pressure or specific internal energy are outside valid range

Error (default) | Warning | None

Select what happens if the fluid pressure or specific internal energy go beyond the valid range during simulation:

- **None** — The block does not return an error if the properties go out of range.
- **Warning** — The block issues a warning, but continues the simulation.
- **Error** — The block returns an error and stops the simulation.

### Dynamic pressure threshold for flow reversal — Sets region in which numerical smoothing is applied

0.01 Pa (default) | positive scalar

Sets region in which numerical smoothing is applied. A transition region is defined around 0 MPa between the positive and negative values of the **Dynamic pressure threshold for flow reversal**. Within this transition region, the calculated properties are adjusted to ensure a smooth transition.

## Version History

### Introduced in R2020b

### R2023a: Control block behavior when fluid properties go out of range during simulation

Previously, if fluid properties went beyond the valid range during simulation, the block would return an error. You can now use the new **Pressure and specific internal energy outside valid range** parameter to control the block behavior if fluid properties go out of range during simulation

## Library

Valve Actuators

## Description

The Valve Actuator block represents a simplified model of a valve actuator, which is especially suitable for real-time and HIL (hardware-in-the-loop) simulation. Its functionality is similar to the 2-Position Valve Actuator and 3-Position Valve Actuator blocks, but its characterization requires fewer parameters because it is built of components that are practically linear.

The Valve Actuator block is built using the blocks from the Simscape Physical Signals library. Both the input and the output of the block are physical signals. The block diagram of the model is shown in the following figure.

The gain of the PS Gain 1 block establishes the steady-state relationship between the input and output signals. The PS Saturation block keeps the output signal within the +/- valve stroke range. The gain of the PS Gain 2 block is  $1/\text{Time constant}$ , which makes it possible to reproduce the first-order lag by combining this block with the PS Subtract and PS Integrator blocks.

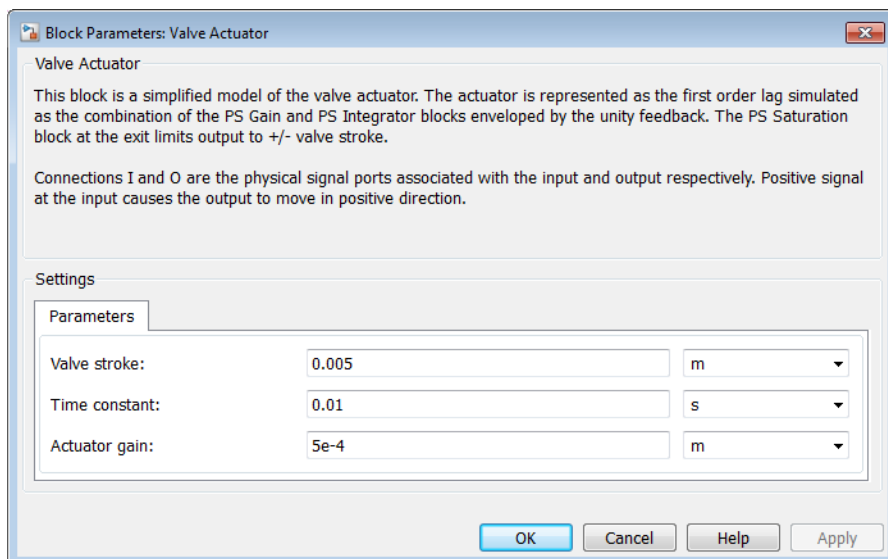

The transfer function of the lag is

$$H(s) = \frac{1}{Ts + 1}$$

where  $T$  is the time constant. The gain of the PS Gain 3 block is set to 1.

**Note** This block is constructed out of blocks from the Simscape Physical Signals library (such as PS Add, PS Gain, and so on). Currently, the blocks in the Physical Signals library do not support unit propagation and checking. For more information, see “How to Work with Physical Units”.

## Dialog Box and Parameters

### Valve stroke

The desired valve stroke, which defines the saturation level of the PS Saturation block in the actuator model. The output of the actuator is kept within the +/- valve stroke range. The default value is 0.005 m.

### Time constant

Time constant of the first-order lag. The **Gain** parameter of the PS Gain 2 block is equal to  $1/\text{Time constant}$ . The default value is 0.01 s.

### Actuator gain

Gain of the PS Gain 1 block in the block diagram of the actuator model. The default value is  $5e-4$  m.

## Ports

The block has one physical signal input port and one physical signal output port.

Valve Forces

## Description

The Valve Hydraulic Force block simulates axial hydraulic static force exerted on a valve by fluid flowing through the orifice. The relationship between the valve opening, the pressure drop, and the force is provided as a two-dimensional table, which is processed by the PS Lookup Table (2D) block. The table can be obtained experimentally or analytically and can represent both the hydraulic static axial force and pressure forces. The force matrix must be rectangular and contain as many rows as there are pressure differential measurements and as many columns as there are valve openings. The pressure differential and opening vectors must be arranged in strictly ascending order and cover the whole range of valve operation. Connect the block in parallel with the orifice whose flow induces the force.

Connections A and B are hydraulic conserving ports that should be connected to the valve block ports in such a way as to monitor the pressure differential across the valve. Connection S is a physical signal port that provides the valve control member displacement. Connection F is a physical signal port that outputs the hydraulic axial force value. This port should be connected to the control port of an Ideal Force Source block. The pressure differential inside the block is determined as  $\Delta p = p_A - p_B$ . The force orientation is specified by the table values and can be positive or negative with respect to the globally assigned positive direction, depending on the value of the **Orifice orientation** parameter.

## Basic Assumptions and Limitations

No transient effects can be simulated.

## Dialog Box and Parameters

### Initial opening

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The default value is 0.

### Orifice orientation

The parameter is introduced to specify the effect of the valve opening on the valve force. The parameter can be set to one of two options: **Opens in positive direction** or **Opens in negative direction**. The value **Opens in positive direction** specifies an orifice that opens when the valve is shifted in the globally assigned positive direction. The default value is **Opens in positive direction**.

### Tabulated valve openings

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are [ 0, 1e-3, 2e-3, 3e-3, 4e-3 ]. The **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** for two-dimensional table lookup in the **Hydraulic axial force table**.

### Tabulated pressure differentials

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of

values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-100e5, -75e5, -50e5, -25e5, 0, 25e5, 50e5, 75e5, 100e5].

### Hydraulic axial force table

Specify the hydraulic axial force as an m-by-n matrix, where m is the number of valve openings and n is the number of pressure differentials. Each value in the matrix specifies an axial force corresponding to a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in N, are:

```
[0, -127.3576, -27.8944, 227.2513, 575.3104; ...
0, -95.5182, -20.9208, 170.4385, 431.4828; ...
0, -63.6788, -13.9472, 113.6256, 287.6552; ...
0, -31.8394, -6.9736, 56.8128, 143.8276; ...
0, 0, 0, 0, 0; ...
196.3495, 120.7506, 97.5709, 111.9898, 150.9306; ...
392.6991, 241.5013, 195.1418, 223.9797, 301.8613; ...
589.0486, 362.2519, 292.7126, 335.9695, 452.7919; ...
785.3982, 483.0025, 390.2835, 447.9594, 603.7225]
```

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous surface with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (2D) block reference page.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (2D) block reference page.

### Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Orifice orientation**
- **Interpolation method**
- **Extrapolation method**

All other block parameters are available for modification.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with a valve port.

B

Hydraulic conserving port associated with another valve port to monitor the pressure differential.

S

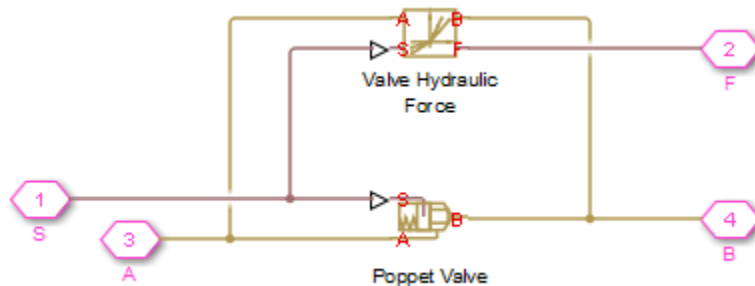

Physical signal port that provides the valve control member displacement.

F

Physical signal port that outputs hydraulic axial force.

## Examples

The following example shows a model of a poppet valve built of a Poppet Valve block and a Valve Hydraulic Force block. The Valve Hydraulic Force block is connected in parallel and provides tabulated data to compute hydraulic force acting on the valve. The force value is exported through the F port.

Spool Orifice Hydraulic Force

## Valve Plate Orifice (IL)

Variable orifice in an isothermal axial-piston machine

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors / Auxiliary Components

### Description

The Valve Plate Orifice (IL) block models a crescent-shaped opening between moving pistons and a pump in an axial-piston machine. The rotating pistons periodically connect to the pump intake or discharge through the orifice plate. You can connect two valve plate blocks to each cylinder of an axial-piston pump to represent both the pump inlet and outlet slots.

A rotating cylinder, with one crescent slot, is connected to the pump intake at port **A** and pump discharge at port **B**. These points are connected to the plate between the **Pressure carryover angle** and  $\pi$  radians (180 degrees) from each other. The plate rotation angle is set by the signal at port **G**. The cylinder position angle,  $\gamma$ , is the sum of the position signal,  $G$ , and the initial angle offset, the **Phase angle**,  $\gamma_0$ :

$$\gamma = \gamma_0 + G.$$

$\gamma$  is always between 0 and  $2\pi$ . For any combined signal and offset larger than  $2\pi$  rad,  $\gamma$  is maintained at  $2\pi$ , and for any combined signal and offset lower than 0 rad,  $\gamma$  is maintained at 0. To change the initial position of the orifice relative to the slot, you can adjust the **Phase angle** parameter.

### Axial-Piston Machine With Five Pistons

The numbers in the diagram indicate the components of an axial-piston machine:

- 1 Valve plate orifice
- 2 Rotor
- 3 Piston
- 4 Driving shaft
- 5 Swash plate

### Cylinder Angle

The cylinder rotational alignment with the slot is described by the following angles:

- Cylinder angle at rotation onto slot,  $\gamma_1$ :

$$\gamma_1 = \Psi - \frac{r}{R}$$

- Cylinder angle at complete rotation onto slot,  $\gamma_2$ :

$$\gamma_2 = \Psi + \frac{r}{R}$$

- Cylinder angle at rotation beyond slot,  $\gamma_3$ :

$$\gamma_3 = \pi - 2\frac{r}{R}$$

- Cylinder angle at complete rotation beyond slot,  $\gamma_4$ :

$$\gamma_4 = \pi$$

where:

- $\Psi$  is the **Pressure carryover angle**. This angle represents the average angular distance the piston travels during its pressure transition period from a closed to opened slot.
- $r$  is the half of the **Cylinder orifice diameter**.
- $R$  is the **Cylinder block pitch radius**.

### Orifice Opening Area

### Orifice area calculations during cylinder motion

The transition opening area, which is the opening between the cylinder rotation angles  $\gamma_1$  and  $\gamma_2$ , is calculated as:

$$A_{\gamma_1\gamma_2} = S_{opening} + S_{Leak} = r^2(2\beta_{opening} - \sin(2\beta_{opening})) + S_{Leak}.$$

The transition closing area, which is the opening between the cylinder rotation angles  $\gamma_3$  and  $\gamma_4$ , is calculated as:

$$A_{\gamma_3\gamma_4} = S_{closing} + S_{Leak} = r^2(2\beta_{closing} - \sin(2\beta_{closing})) + S_{Leak},$$

where the opening and closing parameters are:

$$\beta_{opening} = \cos^{-1} \left( \frac{R}{r} \sin \left( \frac{(\psi + \frac{r}{R}) - \gamma}{2} \right) \right),$$

and

$$\beta_{closing} = \cos^{-1} \left( \frac{R}{r} \sin \left( \frac{\gamma - (\pi - 2\frac{r}{R})}{2} \right) \right).$$

The area between  $\gamma_2$  and  $\gamma_3$  is  $A_{\gamma_2\gamma_3} = S_{Max} + S_{Leak}$ , and the area between  $\gamma_4$  and  $\gamma_1$  is  $A_{\gamma_4\gamma_1} = S_{Leak}$ . The maximum opening of the orifice is  $S_{Max} = \pi r^2$ .

A nonzero **Smoothing factor** can provide additional numerical stability when the orifice is in near-closed or near-open position.

### Numerically-Smoothed Orifice Angle

At the orifice slot entrance and exit angles, you can maintain numerical robustness in your simulation by adjusting the block **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the transition opening angle between  $\gamma_1$  and  $\gamma_2$  and the transition closing angle between  $\gamma_3$  and  $\gamma_4$ . For more information, see "Numerical Smoothing".

### Mass Flow Rate Equation

The flow through a valve plate orifice is calculated from the pressure-area relationship:

$$\dot{m} = C_d A_{orifice} \sqrt{2\bar{\rho}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{orifice}$  is the area open to flow.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the pressure drop over the valve,  $P_A - P_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , which is the point of transition between laminar and turbulent flow in the fluid:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{orifice}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2.$$

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry point to the orifice.

**B** — Liquid port  
isothermal liquid

Exit point from the orifice.

### Input

**G** — Cylinder rotation angle, rad  
physical signal

Cylinder rotation angle in radians, specified as a physical signal..

## Parameters

**Cylinder block pitch radius** — Cylinder pitch radius

0.05 m (default) | positive scalar

Pitch radius of the rotating cylinder.

**Cylinder orifice diameter** — Diameter of the cylinder slot

2.5e-3 m (default) | positive scalar

Diameter of the cylinder slot.

**Pressure carryover angle** — Pressure transition distance

0.06 rad (default) | scalar

Average angular distance the piston travels during the pressure transition period from a closed to opening slot.

**Phase angle** — Initial plate offset angle

0 rad (default) | scalar

Initial plate offset angle. The total angle between the plate and slot is the sum of the **Phase angle** and the **Pressure carryover angle**,  $\Psi$ .

**Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in a fully closed position. Any area smaller than this value is maintained at the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

Swash Plate

## Orifice (TL)

Constant-area or variable-area orifice in a thermal liquid system

### Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices

## Description

The Orifice (TL) block models the flow through a local restriction with a constant or variable opening area. For variable orifices, a control member connected to port **S** sets the opening position. The opening area is parametrized either linearly or by lookup table.

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = \rho v_A A_A + \rho v_B A_B = 0.$$

This mass balance implies that there is an increase in velocity when there is a decrease in area, and there is a reduction in velocity when the flow discharges into a larger area. In accordance with the Bernoulli principle, this change in velocity results in a region of lower pressure in the orifice and a higher pressure in the expansion zone. The resulting increase in pressure, which is called *pressure recovery*, depends on the discharge coefficient of the orifice and the ratio of the orifice and port areas.

### Constant Orifices

For constant orifices, the orifice area,  $A_{\text{orifice}}$ , does not change over the course of the simulation.

### Using the Constant Area Parameterization

The block calculates the mass flow rate as

$$\dot{m} = \frac{C_d A_{\text{orifice}} \sqrt{2\rho}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{orifice}}}{A_{\text{port}}}\right)^2\right)}} \sqrt{p_A - p_B} \approx \frac{C_d A_{\text{orifice}} \sqrt{2\rho}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{orifice}}}{A_{\text{port}}}\right)^2\right)}} \frac{p_A - p_B}{\left[(p_A - p_B)^2 + \Delta p_{\text{crit}}\right]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient** parameter.
- $A_{\text{orifice}}$  is the instantaneous orifice open area.

- $A_{\text{port}}$  is the **Cross-sectional area at ports A and B** parameter.
- $\bar{\rho}$  is the average fluid density.

$PR_{\text{loss}}$  and  $\Delta p_{\text{crit}}$  are calculated in the same manner for constant and variable orifices.

This approximation for  $\dot{m}$  and the Local Resistance (TL) block are the same.

#### Using the Tabulated data - Volumetric flow rate vs. pressure drop Parameterization

The volumetric flow rate is determined from the tabulated values of the pressure differential,  $\Delta p$ , which you can provide. If you provide only non-negative values for both the volumetric flow rate and pressure drop vectors, the block extrapolates the table to contain negative values. The volumetric flow rate is interpolated from this extended table.

If the **Volumetric flow rate vector** and **Pressure drop vector** parameters contain both negative and positive values but no 0, the block inserts an origin into the vectors to ensure the valve does not have nonzero flow rate when the pressure drop is 0, which is non-physical.

#### Variable Orifices

For variable orifices, when you set **Opening orientation** to **Positive** control member displacement opens orifice opens the orifice when the signal at **S** is positive, while a **Negative** control member displacement opens orifice orientation opens the orifice when the signal at **S** is negative. In both cases, the signal is positive and the orifice opening is set by the magnitude of the signal.

#### Using the Linear - Area vs. control member position Parameterization

The orifice area  $A_{\text{orifice}}$  is based on the control member position and the ratio of orifice area and maximum control member position:

$$A_{\text{orifice}} = \frac{(A_{\text{max}} - A_{\text{leak}})}{\Delta S}(S - S_{\text{min}})\varepsilon + A_{\text{leak}},$$

where:

- $S_{\text{min}}$  is the **Control member position at closed orifice** parameter.
- $\Delta S$  is the **Control member travel between closed and open orifice** parameter.
- $A_{\text{max}}$  is the **Maximum orifice area** parameter.
- $A_{\text{leak}}$  is the **Leakage area** parameter.
- $\varepsilon$  is the **Opening orientation** parameter.

The volumetric flow rate is determined by the pressure-flow rate equation:

$$\dot{m} = \frac{C_d A_{\text{orifice}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left( 1 - \left( \frac{A_{\text{orifice}}}{A} \right)^2 \right) \left[ \Delta p^2 + \Delta p_{\text{crit}}^2 \right]^{1/4}} \Delta p$$

where  $A$  is the **Cross-sectional area at ports A and B**.

When the orifice is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{\text{leak}}$  and  $A_{\text{max}}$ . For more information, see “Numerical Smoothing”.

### Using the Tabulated data - Area vs. control member position Parameterization

When you use the Tabulated data - Area vs. control member position parameterization, the orifice area  $A_{\text{orifice}}$  is interpolated from the tabulated values of opening area and the control member position,  $\Delta S$ , which you can provide. As with the Linear - Area vs. control member position parameterization, the volumetric flow rate is determined by the pressure-flow rate equation:

$$\dot{m} = \frac{C_d A_{\text{orifice}} \sqrt{2\rho}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{orifice}}}{A}\right)^2\right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{\text{crit}}^2]^{1/4}},$$

where  $A_{\text{orifice}}$  is:

- $A_{\text{max}}$ , the last element of the **Orifice area vector** parameter, if the physical signal at port **S** is larger than the last element of the **Control member position vector** parameter.
- $A_{\text{leak}}$ , the first element of the **Orifice area vector** parameter, if the physical signal at port **S** is smaller than the first element of the **Control member position vector** parameter.
- The linearly interpolated value of the **Orifice area vector** parameter if the calculated area is between the limits of the first and last element of the **Control member position vector** parameter.

$A_{\text{orifice}}$  is a function of the control member position received at port **S**. The block queries between data points with linear interpolation and uses nearest extrapolation for points beyond the table boundaries.

### Using the Tabulated data - Volumetric flow rate vs. control member position and pressure drop Parameterization

The Tabulated data - Volumetric flow rate vs. control member position and pressure drop parameterization interpolates the volumetric flow rate directly from a user-provided volumetric flow rate table, which is based on the control member position and pressure drop over the orifice. The block queries between data points with linear interpolation and uses nearest extrapolation with respect to control member position and linear extrapolation with respect to pressure drop.

This data can include negative pressure drops and negative opening values. If a negative pressure drop is included in the dataset, the volumetric flow rate will change direction. However, the flow rate will remain unchanged for negative opening values.

If the **Pressure drop vector, dp** parameter does not contain a 0 and the **Volumetric flow rate table, q(s,dp)** parameter does not contain a corresponding column of 0's, the block inserts them to ensure the valve does not have nonzero flow rate when the pressure drop is 0, which is non-physical.

### Using the Tabulated data - Mass flow rate vs. control member position and pressure drop Parameterization

Tabulated data - Mass flow rate vs. control member position and pressure drop — Calculate the mass flow rate directly from the control member position and the pressure drop across the valve. The relationship between the three variables can be nonlinear and it is given by the tabulated data in the **Control member position vector, s**, **Pressure drop vector, dp**, and **Mass flow rate table, mdot(s,dp)** block parameters:

$$\dot{m}_{\text{Tab}} = \frac{\rho_{\text{Avg}}}{\rho_{\text{Ref}}} \dot{m}(\Delta S, \Delta p),$$

where  $\dot{m}$  is the tabulated form of the mass flow rate, a function of the control member position,  $h$ , and of the pressure drop across the orifice,  $\Delta p$ . The mass flow rate is adjusted for temperature and pressure by the ratio  $\rho_{Avg}/\rho_{Ref}$ , where  $\rho_{Avg}$  is the average fluid density in the orifice and  $\rho_{ref}$  is the reference density for the values of the **Reference inflow temperature** and **Reference inflow pressure** parameters.

### Pressure Loss

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area. The block calculates the pressure loss term,  $PR_{loss}$  as:

$$PR_{loss} = \frac{\sqrt{1 - \left(\frac{A_{orifice}}{A_{port}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{orifice}}{A_{port}}}{\sqrt{1 - \left(\frac{A_{orifice}}{A_{port}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{orifice}}{A_{port}}}$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{loss}$  is 1.

### Critical Pressure

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number** parameter,  $Re_{crit}$ , which is the point of transition between laminar and turbulent flow in the fluid:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{orifice}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2$$

### Energy Balance

The block treats the orifice as an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. With these assumptions, energy can flow by advection only, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows must always equal zero:

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is defined as the energy flow rate *into* the orifice through one of the ports (**A** or **B**).

## Ports

### Input

**S** — Control member displacement, m  
physical signal

Instantaneous displacement of the valve control member.

### Conserving

**A** — Flow passage  
thermal liquid

Thermal liquid conserving port associated with the opening through which the flow can enter or exit the valve.

## **B** — Flow passage

thermal liquid

Thermal liquid conserving port associated with the opening through which the flow can enter or exit the valve.

## Parameters

### **Orifice type** — Type of orifice

Variable (default) | Constant

Type of orifice, defined by the orifice area. When set to **Variable**, the orifice area varies according to the input signal received at port **S**.

- **Orifice area**—The assigned area does not change over the simulation.
- **Tabulated data - Volumetric flow rate vs. pressure drop**—The area remains constant, but the volumetric flow rate through the orifice can vary. This value is interpolated directly from the **Volumetric flow rate vector** and the **Pressure drop vector** dataset.
- **Tabulated data - Mass flow rate vs. pressure drop**—The area remains constant, but the volumetric flow rate through the orifice can vary. This value is interpolated directly from the **Mass flow rate vector** and the **Pressure drop vector** dataset.

When you set **Orifice type** to **Variable**, there are four options.

- **Linear - Area vs. control member position**. Area is determined by a linear relationship to the control member position with respect to a fully open or fully closed orifice. The position is set by a varying physical signal at port **S**.
- **Tabulated data - Area vs. control member position**. The opening area is interpolated from the **Control member position vector** and the **Orifice area vector** based on the control member position received at port **S**.
- **Tabulated data - Volumetric flow rate vs. control member position and pressure drop**. The volumetric flow rate is directly interpolated from the user- provided **Control member position vector, s, Pressure drop vector, dp, and Volumetric flow rate table, q(s,dp)** parameters based on the control member position received at port **S** and the pressure drop across ports **A** and **B**.
- **Tabulated data - Mass flow rate vs. control member position and pressure drop**. The mass flow rate is directly interpolated from the user- provided **Control member position vector, s, Pressure drop vector, dp, and Mass flow rate table, mdot(s,dp)** parameters based on the control member position received at port **S** and the pressure drop across ports **A** and **B**.

### **Orifice parameterization** — Constant orifice parameterization

Orifice area (default) | Tabulated data - Volumetric flow rate vs. pressure drop |  
Tabulated data - Mass flow rate vs. pressure drop

Method by which to model the opening characteristics of the orifice. The default setting prescribes a linear relationship between the orifice opening area and the orifice opening. The alternative settings allow for a general, nonlinear relationship to be specified in tabulated form, in one case between the

opening area and the orifice opening, in the other case between the mass flow rate and both the orifice opening and the pressure drop between the ports.

### Dependencies

To enable this parameter, set **Orifice type** to Constant.

### Orifice parameterization — Variable orifice parameterization

Linear - Area vs. control member position (default) | Tabulated data - Area vs. control member position | Tabulated data - Volumetric flow rate vs. control member position and pressure drop | Tabulated data - Mass flow rate vs. control member position and pressure drop

When you set **Orifice type** to Variable, there are four options.

- **Linear - Area vs. control member position.** Area is determined by a linear relationship to the control member position with respect to a fully open or fully closed orifice. The position is set by a varying physical signal at port **S**.
- **Tabulated data - Area vs. control member position.** The opening area is interpolated from the **Control member position vector** and the **Orifice area vector** based on the control member position received at port **S**.
- **Tabulated data - Volumetric flow rate vs. control member position and pressure drop.** The volumetric flow rate is directly interpolated from the user- provided **Control member position vector, s, Pressure drop vector, dp, and Volumetric flow rate table, q(s,dp)** parameters based on the control member position received at port **S** and the pressure drop across ports **A** and **B**.
- **Tabulated data - Mass flow rate vs. control member position and pressure drop.** The mass flow rate is directly interpolated from the user- provided **Control member position vector, s, Pressure drop vector, dp, and Mass flow rate table, mdot(s,dp)** parameters based on the control member position received at port **S** and the pressure drop across ports **A** and **B**.

### Dependencies

To enable this parameter, set **Orifice type** to Variable.

### Orifice area — Area of orifice opening

$1e-3 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the orifice opening.

### Dependencies

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

### Pressure drop vector — Vector of differential pressure values for tabulated parameterization

[-4, -3, -2, -1, -.5, 0, .5, 1, 2, 3, 4] MPa (default) | 1-by- $n$  vector

Vector of pressure differential values for the tabulated parameterization of volumetric flow rate. The values in this vector correspond one-to-one to values in the **Volumetric flow rate vector** parameter. The pressure drop vector values are listed in ascending order. The volumetric flow rate is interpolated directly from the **Volumetric flow rate vector** parameter, which depends on the **Pressure drop vector** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. pressure drop.

**Volumetric flow rate vector** — Vector of volumetric flow rate values

`[-2.44, -2.12, -1.68, -1.22, -.84, 0, .85, 1.21, 1.7, 2.09, 2.41] .* 1e-3`  
m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values for the tabulated parameterization of volumetric flow rate. The values in this vector correspond one-to-one to values in the **Pressure drop vector** parameter. The volumetric flow rate is interpolated directly from the provided **Volumetric flow rate vector** parameter, which depends on the **Pressure drop vector** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. pressure drop.

**Mass flow rate vector** — Vector of mass flow rate values

`[-2.44, -2.12, -1.68, -1.22, -.84, 0, .85, 1.21, 1.7, 2.09, 2.41] kg/s (default)`  
| vector | 1-by-*n* vector

Vector of mass flow rate values for the tabulated parameterization of volumetric flow rate. The values in this vector correspond one-to-one to values in the **Pressure drop vector** parameter. The mass flow rate is interpolated directly from the provided **Mass flow rate vector** parameter, which depends on the **Pressure drop vector** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Constant and **Orifice parameterization** to Tabulated data - Mass flow rate vs. pressure drop.

**Control member position at closed orifice** — Control member offset

`0 m (default) | scalar`

Initial control member offset when the variable orifice is fully closed.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and set **Orifice parameterization** to Linear – Area vs. control member position.

**Control member travel between closed and open orifice** — Control member maximum stroke

`5e-3 m (default) | positive scalar`

Maximum distance the control member travels between closed and open orifice. The orifice is fully open at the sum of the **Control member position at closed orifice** and **Control member travel between closed and open orifice** parameters.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

**Opening orientation** — Direction of member movement that opens the orifice

Positive control member displacement opens orifice (default) | Negative control member displacement opens orifice

Direction of member displacement that opens a variable orifice. A positive orientation means that a positive signal at **S** opens the orifice. A negative orientation means that a negative signal at **S** opens the orifice.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

**Maximum orifice area** — Maximum orifice opening area

$1e-4 \text{ m}^2$  (default) | positive scalar

Maximum orifice area experienced during simulation. When using Tabulated data - Area vs. control member position, the maximum orifice area is the last element of the **Orifice area vector** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

**Leakage area** — Orifice gap area when in fully closed position

$1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in fully closed position. Any area smaller than this value is maintained at the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

**Control member position vector** — Vector of control member positions

[0, .002, .004, .007, .017] m (default) | 1-by-n vector

Vector of control member positions for the tabulated parameterization of orifice area. The vector elements correspond one-to-one to the values in the **Orifice area vector** parameter. The vector elements must be either strictly monotonically increasing or decreasing. The orifice opening area is interpolated from the **Orifice area vector**, which depends on the **Control member position vector** parameter.

#### Dependencies

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Orifice area vector** — Vector of orifice opening area values

[ $1e-09$ ,  $2.0352e-07$ ,  $4.0736e-05$ , .00011438, .00034356]  $\text{m}^2$  (default) | 1-by-n vector

Vector of orifice area values for the tabulated parameterization of orifice area. The values in this vector correspond one-to-one with the elements in the **Control member position vector** parameter.

If the vector is increasing, the first element of this vector is the orifice leakage area and the last element is the maximum orifice area. If the vector is decreasing, the first element of this vector is the orifice maximum orifice area and the last element is the leakage area. The orifice opening area is interpolated from the **Orifice area vector** parameter, which depends on the **Control member position vector** parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.
- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Dependencies**

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.
- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Linear - Area vs. control member position.

**Pressure recovery** — Whether to account for pressure increase in area expansions

on (default) | off

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area. This increase in pressure is not captured when you clear **Pressure recovery** check box.

**Dependencies**

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.
- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

**Control member position vector,  $s$**  — Vector of opening values

[0, .002, .004, .007, .017] m (default) | 1-by- $n$  vector

Vector of control member positions for tabulated parametrization of volumetric flow rate. The control member position vector forms an independent axis with the **Pressure drop vector,  $dp$**  parameter for the 2-D dependent **Volumetric flow rate table,  $q(s,dp)$**  parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop or Tabulated data - Mass flow rate vs. control member position and pressure drop.

**Pressure drop vector,  $dp$**  — Vector of pressure drop values

[.3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabulated parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Control member position vector,  $s$**  parameter for the 2-D dependent **Volumetric flow rate table,  $q(s,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop or Tabulated data - Mass flow rate vs. control member position and pressure drop.

**Volumetric flow rate table,  $q(s,dp)$**  — Array of volumetric flow rate values

[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13] .\* 1e-3 m<sup>3</sup>/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and control member position.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of elements in the **Control member position vector,  $s$**  parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop.

**Mass flow rate table,  $\dot{m}(s,dp)$**  — Array of mass flow rate values

[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13] kg/s (default) | *M*-by-*N* matrix

Mass flow rates based on independent values of pressure drop and control member position. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **Pressure drop vector,  $dp$**  parameter.
- *N* is the number of elements in the **Control member position vector,  $s$**  parameter.

**Dependencies**

To enable this parameter, set **Orifice type** to Variable and **Orifice parameterization** to Tabulated data - Mass flow rate vs. control member position and pressure drop.

**Reference inflow temperature** — Inlet temperature at which to specify the tabulated data

293.15 K (default) | positive scalar in units of temperature

Nominal inlet temperature, with reference to absolute zero, at which to specify the tabulated data. This parameter is used to adjust the mass flow rate according to the temperature measured during simulation.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. opening and pressure drop.

**Reference inflow pressure** — Inlet pressure at which to specify the tabulated data

0.101325 MPa (default) | positive scalar in units of pressure

Nominal inlet pressure, with reference to absolute zero, at which to specify the tabulated data. This parameter is used to adjust the mass flow rate according to the pressure measured during simulation.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. opening and pressure drop.

**Cross-sectional area at ports A and B** — Area at orifice entry or exit

0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. This area is used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

**Dependencies**

To enable this parameter, set either:

- **Orifice type** to Variable and **Orifice parameterization** to either Linear - Area vs. control member position or Tabulated data - Area vs. control member position.

- **Orifice type** to Constant and **Orifice parameterization** to Orifice area.

## **Version History**

Introduced in R2022a

## **Extended Capabilities**

## Library

Orifices

## Description

The block represents a variable orifice of any type as a data-sheet-based model. Depending on data listed in the manufacturer's catalogs or data sheets for your particular orifice, you can choose one of the following model parameterization options:

- **By maximum area and opening** — Use this option if the data sheet provides only the orifice maximum area and the control member maximum stroke.
- **By area vs. opening table** — Use this option if the catalog or data sheet provides a table of the orifice passage area based on the control member displacement  $A=A(h)$ .
- **By pressure-flow characteristic** — Use this option if the catalog or data sheet provides a two-dimensional table of the pressure-flow characteristics  $q=q(p, h)$ .

In the first case, the passage area is assumed to be linearly dependent on the control member displacement, that is, the orifice is assumed to be closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. In the second case, the passage area is determined by one-dimensional interpolation from the table  $A=A(h)$ . In both cases, a small leakage area is assumed to exist even after the orifice is completely closed. Physically, it represents a possible clearance in the closed valve, but the main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. An isolated or “hanging” part of the system could affect computational efficiency and even cause failure of computation.

In the first and second cases, the flow rate is computed according to the following equations:

$$q = C_D \cdot A(h) \sqrt{\frac{2}{\rho} \frac{\Delta p}{(\Delta p^2 + p_{Cr}^2)^{1/4}}}$$

$$\Delta p = p_A - p_B,$$

$$h = x_0 + x \cdot or$$

For the first parameterization, the opening area ( $A$ ) is a piecewise function of the control member position ( $h$ ). The area saturates at its leakage value when the control member is in the fully closed position ( $h_{\min}$ ). It saturates at its maximum value when the control member is in the fully open position ( $h_{\max}$ ).

$$A(h) = \begin{cases} A_{\text{leak}} & h \leq h_{\min} \\ \frac{A_{\text{max}}}{h_{\text{max}}}h, & h > 0 \\ A_{\text{max}}, & h \geq h_{\max} \end{cases}$$

The minimum control member position is calculated as:

$$h_{\min} = \frac{h_{\max}}{A_{\text{max}}}A_{\text{leak}}$$

For the second parameterization, the opening area is a tabulated function of control member displacement. As with the linear parameterization, the area saturates at its leakage value when the control member is in the fully closed position, and it saturates at its maximum value when the control member is in the fully open position. Between the closed and open positions:

$$A = f(h)$$

The table summarizes the parameters used in the equations.

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A(h)$	Instantaneous orifice passage area
$A_{\text{max}}$	Orifice maximum area
$h_{\text{max}}$	Control member maximum displacement
$x_0$	Initial opening
$x$	Control member displacement from initial position
$h$	Orifice opening
$or$	Orifice orientation indicator. The variable assumes +1 value if the control member displacement in the globally assigned positive direction opens the orifice, and -1 if positive motion decreases the opening.
$\rho$	Fluid density
$A_{\text{leak}}$	Closed orifice leakage area
$p_{\text{cr}}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{\text{cr}}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = (p_{avg} + p_{atm})(1 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{avg}$	Average pressure between the block terminals
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$D_H$	Instantaneous orifice hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

In the third case, when an orifice is defined by its pressure-flow characteristics, the flow rate is determined by two-dimensional interpolation. In this case, neither flow regime nor leakage flow rate is taken into account, because these features are assumed to be introduced through the tabulated data. Pressure-flow characteristics are specified with three data sets: array of orifice openings, array of pressure differentials across the orifice, and matrix of flow rate values. Each value of a flow rate corresponds to a specific combination of an opening and pressure differential.

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B and the pressure differential is determined as  $\Delta p = p_A - p_B$ . Positive signal at the physical signal port S opens or closes the orifice depending on the value of the orifice orientation indicator.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Basic Assumptions and Limitations

- Fluid inertia is not taken into account.
- For orifices specified by pressure-flow characteristics (the third parameterization option), the model does not explicitly account for the flow regime or leakage flow rate, because the tabulated data is assumed to account for these characteristics.

## Parameters

### Model parameterization

Select one of the following methods for specifying the orifice:

- **By maximum area and opening** — Provide values for the maximum orifice area and the maximum orifice opening. The passage area is linearly dependent on the control member displacement, that is, the orifice is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of orifice openings and corresponding orifice areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of orifice openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

### Orifice maximum area

Specify the area of a fully opened orifice. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

### Orifice maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-4 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

### Orifice opening vector, **s**

Specify the vector of input values for orifice openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated orifice openings** values will be used together with **Tabulated orifice area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated orifice openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

### Orifice area vector

Specify the vector of orifice areas as a one-dimensional array. The vector must be of the same size as the orifice openings vector. All the values must be positive. The default values, in  $\text{m}^2$ , are  $[1e-09 \ 2.0352e-07 \ 4.0736e-05 \ 0.00011438 \ 0.00034356]$ . This parameter is used if **Model parameterization** is set to **By area vs. opening table**.

**Pressure differential vector, dp**

Specify the pressure differential vector as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

**Volumetric flow rate table, q(s,dp)**

Specify the flow rates as an m-by-n matrix, where m is the number of orifice openings and n is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of orifice opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in m<sup>3</sup>/s, are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;

```

This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

**Interpolation method**

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Extrapolation method**

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Orifice orientation**

The parameter is introduced to specify the effect of the orifice control member motion on the valve opening. The parameter can be set to one of two options: **Opens in positive direction** or **Opens in negative direction**. The value **Opens in positive direction** specifies an orifice whose control member opens the valve when it is shifted in the globally assigned positive direction. The parameter is extremely useful for building a multi-orifice valve with all the orifices being controlled by the same spool. The default value is **Opens in positive direction**.

**Flow discharge coefficient**

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Initial opening**

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The value of initial opening does not depend on the orifice orientation. The default value is 0.

**Leakage area**

The total area of possible leaks in the completely closed orifice. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Model parameterization**
- **Orifice orientation**
- **Interpolation method**
- **Extrapolation method**
- **Laminar transition specification**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Model parameterization** parameter at the time the model entered Restricted mode.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the orifice inlet.

B

Hydraulic conserving port associated with the orifice outlet.

S

Physical signal port to control spool displacement.

The flow rate is positive if fluid flows from port A to port B. Positive signal at the physical signal port S opens or closes the orifice depending on the value of the parameter **Orifice orientation**.

## Examples

The “Hydraulic Flapper-Nozzle Amplifier” example illustrates the use of the Variable Orifice block in hydraulic systems.

## Library

Orifices

## Description

The Variable Orifice Between Round Holes block models a variable orifice created by two interacting round holes. These holes can have different diameters. One hole is located in the sleeve, while the other is drilled in the case, with the sleeve sliding along the case. Such a configuration is frequently seen in cartridge valves, as shown in this 3-way valve schematic.

The block can contain multiple identical interacting pairs of holes. The following schematic shows the calculation diagram for one such pair of round holes, where

$s$	Sleeve displacement from initial position
$c$	Distance between hole centers

$d_s$	Sleeve hole diameter
$d_c$	Case hole diameter

The flow rate through the orifice is proportional to the orifice area and to the pressure differential across the orifice, according to these equations:

$$A = \begin{cases} A_{leak} & \text{for } c \geq (r + R) \\ A_{leak} + r^2 \cdot a \cos\left(\frac{c^2 + r^2 - R^2}{2cr}\right) + R^2 \cdot a \cos\left(\frac{c^2 - r^2 + R^2}{2cr}\right) & \text{for } c < (r + R) \\ -\frac{1}{2}\sqrt{(-c + r + R)(c + R - r)(c + r - R)(c + r + R)} & \end{cases}$$

$$q = z \cdot C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

$$\Delta p = p_A - p_B,$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$A$	Instantaneous passage area between orifices
$c$	Instantaneous distance between hole centers
$r$	Smaller hole radius
$R$	Larger hole radius

$z$	Number of hole pairs
$C_D$	Flow discharge coefficient
$\rho$	Fluid density
$A_{\text{leak}}$	Closed orifice leakage area
$p_{\text{cr}}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{\text{cr}}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{\text{cr}} = (p_{\text{avg}} + p_{\text{atm}})(1 - B_{\text{lam}})$$

$$p_{\text{avg}} = (p_A + p_B)/2$$

where

$p_{\text{avg}}$	Average pressure between the block terminals
$p_{\text{atm}}$	Atmospheric pressure, 101325 Pa
$B_{\text{lam}}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{\text{cr}} = \frac{\pi}{4A} \left( \frac{Re_{\text{cr}}}{C_D} \right)^2 \cdot \rho \cdot \frac{v^2}{2}$$

where

$\nu$	Fluid kinematic viscosity
$Re_{\text{cr}}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B. Positive signal at port S moves the sleeve in the positive direction.

## Basic Assumptions and Limitations

Inertial effects are not taken into account.

## Parameters

### Sleeve hole diameter

Diameter of the holes drilled in the sleeve. The default value is 0.005 m.

### Case hole diameter

Diameter of the holes drilled in the case. The default value is 0.0054 m.

### Number of interacting pairs

Number of interacting hole pairs. The default value is 1.

**Flow discharge coefficient**

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Leakage area**

The total area of possible leaks in the completely closed orifice. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the orifice is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the orifice inlet.

B

Hydraulic conserving port associated with the orifice outlet.

S

Physical signal port that provides the instantaneous value of the distance between the hole centers.

## Variable Overlapping Orifice (IL)

Orifice created by open segments with variable overlap in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Orifices

### Description

The Variable Overlapping Orifice (IL) block models flow through round holes with varying overlapping areas, such as a moving sleeve within a fixed case. The overlapping holes can have different diameters, but additional holes along the spool or sleeve have the same diameter.

### Overlapping Area

The flow rate depends on the variable open area created by overlapping holes in the sleeve and casing. This instantaneous opening area is calculated as:

$$A_{overlap} = r^2 \left[ \cos^{-1} \left( \frac{C^2 + r^2 - R^2}{2Cr} \right) - \left( \frac{C^2 + r^2 - R^2}{2Cr} \right) \sqrt{1 - \left( \frac{C^2 + r^2 - R^2}{2Cr} \right)^2} \right] \\ + R^2 \left[ \cos^{-1} \left( \frac{C^2 - r^2 + R^2}{2CR} \right) - \left( \frac{C^2 - r^2 + R^2}{2CR} \right) \sqrt{1 - \left( \frac{C^2 - r^2 + R^2}{2CR} \right)^2} \right],$$

where:

- $r$  is the diameter of the smaller hole.
- $R$  is the diameter of the larger hole.
- $C$  is the absolute distance between the hole centers, calculated from the physical signal at port **S**, the instantaneous sleeve position, and the **Sleeve position when holes are concentric**,  $S_0$ :  
 $C = |S - S_0|$ .

If the holes on the sleeve and casing have the same diameter, the overlap area becomes:

$$A_{overlap} = 2r^2 \left[ \cos^{-1} \left( \frac{C}{2r} \right) - \left( \frac{C}{2r} \right) \sqrt{1 - \left( \frac{C}{2r} \right)^2} \right].$$

You can maintain numerical robustness in your simulation by adjusting the block **Smoothing factor** at the nearest and farthest points between hole centers. The block applies a smoothing function to the normalized hole center distance,

$$\hat{C} = \frac{(C - R + r)}{(2r)}.$$

The function smoothly saturates the normalized hole center distance between 0 and 1.

For more information, see “Numerical Smoothing”

### Mass Flow Rate Equation

The flow through an orifice pair is calculated from the pressure-area relationship:

$$\dot{m} = \frac{C_d A_{orifice} \sqrt{2\bar{\rho}}}{\sqrt{PR_{loss} \left( 1 - \left( \frac{A_{orifice}}{A_{port}} \right)^2 \right) [\Delta p^2 + \Delta p_{crit}^2]^{1/4}}}, \Delta p$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{orifice}$  is the area open to flow,  $A_{orifice} = A_{overlap} + A_{leak}$ .
- $A$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area. The pressure loss term,  $PR_{loss}$  is calculated as:

$$PR_{loss} = \frac{\sqrt{1 - \left( \frac{A_{overlapping}}{A_{port}} \right)^2} (1 - C_d^2) - C_d \frac{A_{overlapping}}{A_{port}}}{\sqrt{1 - \left( \frac{A_{overlapping}}{A_{port}} \right)^2} (1 - C_d^2) + C_d \frac{A_{overlapping}}{A_{port}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, set **Pressure recovery** to Off. In this case,  $PR_{loss}$  is 1.

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8 A_{overlapping}} \left( \frac{\nu Re_{crit}}{C_d} \right)^2.$$

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry or exit point to the orifice.

**B** — Liquid port  
isothermal liquid

Entry or exit point to the orifice.

### Input

**S** — Sleeve displacement, m  
physical signal

Sleeve position with respect to the case, in m.

## Parameters

**Sleeve hole diameter** — Sleeve hole diameter  
5e-3 m (default) | positive scalar

Diameter of the hole in the moving element.

**Case hole diameter** — Case hole diameter  
5.5e-3 m (default) | positive scalar

Diameter of hole in the fixed element.

**Sleeve position when holes are concentric** — Moving element position when hole centers are aligned  
0 m (default) | scalar

Moving element position when hole centers are aligned. This parameter is used to determine instantaneous overlap of the moving and stationary holes during simulation by comparison with the signal received at port **S**.

**Number of interacting pairs** — Number of overlapping orifices, in pairs  
1 (default) | positive scalar

Number of overlapping orifices, in pairs. The sleeve-case pairs do not need to be aligned in the physical hardware being modeled.

**Leakage area** — Gap area when in fully closed position  
1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is maintained at the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Cross-sectional area at ports A and B** — Orifice area at conserving ports

inf m<sup>2</sup> (default) | positive scalar

Areas at the entry and exit ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Pressure recovery** — Whether to account for pressure increase in area expansions

Off (default) | On

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

# Variable-Displacement Motor

(To be removed) Variable-displacement bidirectional hydraulic motor

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Pumps and Motors

## Description

The Variable-Displacement Motor block represents a device that extracts power from a hydraulic (isothermal liquid) network and delivers it to a mechanical rotational network. The motor displacement varies in proportion to the physical signal input specified at port C or D. The exact port used depends on the block variant selected. See “Ports” on page 1-2102.

Ports **A** and **B** represent the motor inlet and outlet, respectively. Port **S** represents the motor drive shaft. During normal operation, the angular velocity at port **S** is positive if the pressure drop from port **A** to port **B** is positive also. This operation mode is referred to here as forward motor.

## Operation Modes

A total of four operation modes are possible. The working mode depends on the pressure drop from port **A** to port **B** ( $\Delta p$ ), on the angular velocity at port **S** ( $\omega$ ), and on the instantaneous volumetric displacement of the component ( $D$ ). The “Operation Modes” on page 1-2095 figure maps the modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart. The modes are labeled 1-4:

- Mode **1**: forward motor — A positive pressure drop generates a positive shaft angular velocity.

- **Mode 2:** reverse pump — A negative shaft angular velocity generates a negative pressure gain (shown in the figure as a positive pressure drop).
- **Mode 3:** reverse motor — A negative pressure drop generates a negative shaft angular velocity.
- **Mode 4:** forward pump — A positive shaft angular velocity generates a positive pressure gain (shown in the figure as a negative pressure drop).

The response time of the motor is considered negligible in comparison with the system response time. The motor is assumed to reach steady state nearly instantaneously and is treated as a quasi-steady component.

### Block Variants and Loss Parameterizations

The motor model accounts for power losses due to leakage and friction. Leakage is internal and occurs between the motor inlet and outlet only. The block computes the leakage flow rate and friction torque using your choice of five loss parameterizations. You select a parameterization using block variants and, in the `Analytical` or `tabulated data` case, the **Leakage and friction parameterization** parameter.

### Loss Parameterizations

The block provides three Simscape variants to select from. To change the active block variant, use the **Modeling option** parameter. The available variants are:

- `Analytical` or `tabulated data` — Obtain the mechanical and volumetric efficiencies or losses from analytical models based on nominal parameters or from tabulated data. Use the **Leakage and friction parameterization** parameter to select the exact input type.
- `Input efficiencies` — Provide the mechanical and volumetric efficiencies directly through physical signal input ports.
- `Input losses` — Provide the mechanical and volumetric losses directly through physical signal input ports. The mechanical loss is defined as the internal friction torque. The volumetric loss is defined as the internal leakage flow rate.

### Displacement Parameterizations

The displacement volume input depends on the block variant selected. If the active block variant is `Input efficiencies` or `Input losses`, the block obtains the instantaneous displacement volume directly from the physical signal input at port D.

If the active block variant is `Analytical` or `tabulated data`, the block computes the instantaneous displacement volume from the control member position specified at port C. This computation depends on the **Displacement parameterization** parameter setting:

- **Maximum displacement and control member stroke** — Compute the displacement volume per unit rotation as a linear function of the control member position specified at port C.
- **Displacement vs. control member position table** — Compute the displacement volume per unit volume using interpolation or extrapolation of displacement tabular data specified at discrete control member positions.

### Flow Rate and Driving Torque

The volumetric flow rate generated at the motor is

$$q = q_{\text{Ideal}} + q_{\text{Leak}},$$

where:

- $q$  is the net volumetric flow rate.
- $q_{\text{Ideal}}$  is the ideal volumetric flow rate.
- $q_{\text{Leak}}$  is the internal leakage volumetric flow rate.

The torque generated at the motor is

$$\tau = \tau_{\text{Ideal}} - \tau_{\text{Friction}},$$

where:

- $\tau$  is the net torque.
- $\tau_{\text{Ideal}}$  is the ideal torque.
- $\tau_{\text{Friction}}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal volumetric flow rate is

$$q_{\text{Ideal}} = D_{\text{Sat}} \cdot \omega,$$

and the ideal generated torque is

$$\tau_{\text{Ideal}} = D_{\text{Sat}} \cdot \Delta p,$$

where:

- $D_{\text{Sat}}$  is a smoothed displacement computed so as to remove numerical discontinuities between negative and positive displacements.
- $\omega$  is the instantaneous angular velocity of the rotary shaft.
- $\Delta p$  is the instantaneous pressure drop from inlet to outlet.

### Saturation Displacement

The saturation displacement depends on the block variant selected. If the active variant is Analytical or tabulated data,

$$D_{\text{Sat}} = \begin{cases} \text{sign}(D) \cdot D_{\text{Max}}, & |D| \geq D_{\text{Max}} \\ \sqrt{D^2 + D_{\text{Threshold}}^2}, & D \geq 0 \\ -\sqrt{D^2 + D_{\text{Threshold}}^2}, & D < 0 \end{cases},$$

where:

- $D$  is the instantaneous fluid displacement determined from the physical signal input specified at port **C** or port **D**.
- $D_{\text{Max}}$  is the specified value of the **Maximum displacement** block parameter.
- $D_{\text{Threshold}}$  is the specified value of the **Displacement threshold for motor-pump transition** block parameter.

If the active variant is `Input efficiencies` or `Input losses`, there is no upper bound on the displacement input and the saturation displacement reduces to:

$$D_{\text{Sat}} = \begin{cases} \sqrt{D^2 + D_{\text{Threshold}}^2}, & D \geq 0 \\ -\sqrt{D^2 + D_{\text{Threshold}}^2}, & D < 0 \end{cases}$$

### Leakage Flow Rate and Friction Torque

The internal leakage flow rate and friction torque calculations depend on the block variant selected. If the block variant is `Analytical` or `tabulated data`, the calculations depend also on the **Leakage and friction parameterization** parameter setting. There are five possible permutations of block variant and parameterization settings.

### Case 1: Analytical Efficiency Calculation

If the active block variant is `Analytical` or `tabulated data` and the **Leakage and friction parameterization** parameter is set to `Analytical`, the leakage flow rate is

$$q_{\text{Leak}} = K_{\text{HP}} \Delta p,$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}} \left| \frac{D_{\text{Sat}}}{D_{\text{Max}}} \right| |\Delta p| \right) \tanh \left( \frac{4\omega}{\omega_{\text{Thresh}}} \right),$$

where:

- $K_{\text{HP}}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. This coefficient is computed from the specified nominal parameters.
- $K_{\text{TP}}$  is the specified value of the **Friction torque vs pressure drop coefficient** block parameter.
- $\tau_0$  is the specified value of the **No-load torque** block parameter.

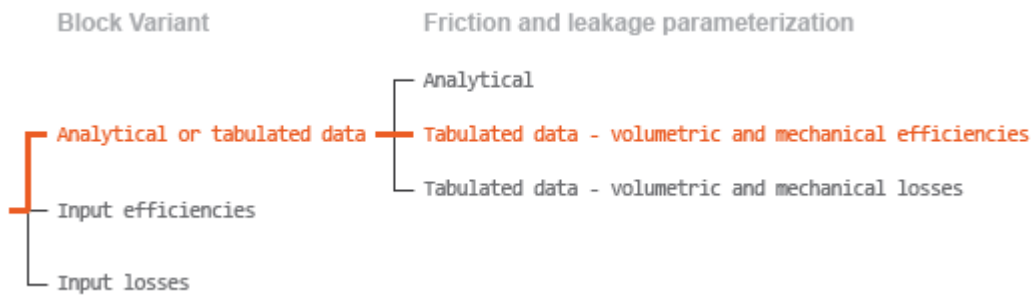

- $\omega_{\text{Threshold}}$  is the threshold angular velocity for the motor-pump transition. The threshold angular velocity is an internally set fraction of the specified value of the **Nominal shaft angular velocity** block parameter.

The Hagen-Poiseuille coefficient is determined from nominal fluid and component parameters through the equation

$$K_{\text{HP}} = \frac{\nu_{\text{Nom}} \rho_{\text{Nom}} \omega_{\text{Nom}} D_{\text{Max}}}{\rho v \Delta p_{\text{Nom}}} \left( \frac{1}{\eta_{v,\text{Nom}}} - 1 \right),$$

where:

- $\nu_{\text{Nom}}$  is the **Nominal kinematic viscosity** parameter. This is the kinematic viscosity at which the nominal volumetric efficiency is specified.
- $\rho_{\text{Nom}}$  is the **Nominal fluid density** parameter. This is the density at which the nominal volumetric efficiency is specified.
- $\rho$  is the actual fluid density in the attached hydraulic (isothermal liquid) network. This density can differ from the **Nominal fluid density** parameter.
- $\omega_{\text{Nom}}$  is the **Nominal shaft angular velocity** parameter. This is the angular velocity at which the nominal volumetric efficiency is specified.
- $v$  is the fluid kinematic viscosity in the attached hydraulic fluid network.
- $\Delta p_{\text{Nom}}$  is the **Nominal pressure drop** parameter. This is the pressure drop at which the nominal volumetric efficiency is specified.
- $\eta_{v,\text{Nom}}$  is the **Volumetric efficiency at nominal conditions** parameter. This is the volumetric efficiency corresponding to the specified nominal conditions.

## Case 2: Efficiency Tabulated Data

If the active block variant is **Analytical or tabulated data** and the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies**, the leakage flow rate is

$$q_{\text{Leak}} = q_{\text{Leak, Motor}} \frac{(1 + \alpha)}{2} + q_{\text{Leak, Pump}} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction, Motor}} \frac{1 + \alpha}{2} + \tau_{\text{Friction, Pump}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $q_{\text{Leak, Motor}}$  is the leakage flow rate in motor mode.
- $q_{\text{Leak, Pump}}$  is the leakage flow rate in pump mode.
- $\tau_{\text{Friction, Pump}}$  is the friction torque in pump mode.
- $\tau_{\text{Friction, Motor}}$  is the friction torque in motor mode.

The smoothing parameter  $\alpha$  is given by the hyperbolic function

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4D}{D_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the specified value of the **Pressure drop threshold for motor-pump transition** block parameter.
- $\omega_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for motor-pump transition** block parameter.
- $D_{\text{Threshold}}$  is the specified value of the **Displacement threshold for motor-pump transition** block parameter.

The leakage flow rate is computed from efficiency tabulated data through the equation

$$q_{\text{Leak, Motor}} = (1 - \eta_v)q,$$

in motor mode and through the equation

$$q_{\text{Leak, Pump}} = -(1 - \eta_v)q_{\text{Ideal}}.$$

in pump mode, where:

- $\eta_v$  is the volumetric efficiency obtained through interpolation or extrapolation of the **Volumetric efficiency table, e\_v(dp,w,D)** parameter data.

Similarly, the friction torque is computed from efficiency tabulated data through the equation

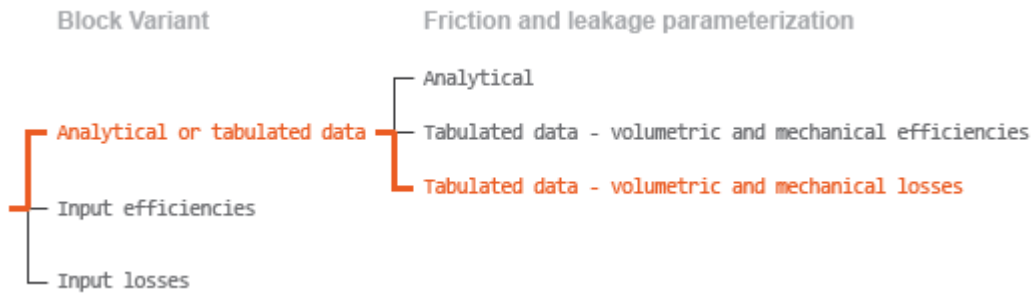

$$\tau_{\text{Friction, Motor}} = (1 - \eta_m)\tau_{\text{Ideal}},$$

in motor mode and through the equation

$$\tau_{\text{Friction, Pump}} = -(1 - \eta_m)\tau.$$

in pump mode, where:

- $\eta_m$  is the mechanical efficiency obtained through interpolation or extrapolation of the **Mechanical efficiency table, e\_m(dp,w,D)** parameter data.

### Case 3: Loss Tabulated Data

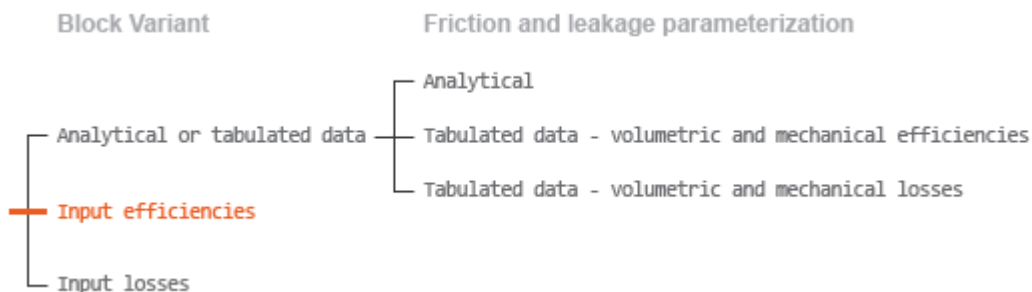

If the active block variant is Analytical or tabulated data and the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses, the leakage flow rate equation is

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega, D_{\text{Sat}}).$$

and the friction torque equation is

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega, D_{\text{Sat}}),$$

where  $q_{\text{Leak}}(\Delta p, \omega, D_{\text{Sat}})$  and  $\tau_{\text{Friction}}(\Delta p, \omega, D_{\text{Sat}})$  are the volumetric and mechanical losses, obtained through interpolation or extrapolation of the **Volumetric loss table, q\_loss(dp,w)** and **Mechanical loss table, torque\_loss(dp,w)** parameter data.

### Case 4: Efficiency Physical Signal Inputs

If the active block variant is Input efficiencies, the leakage flow rate and friction torque calculations are as described for efficiency tabulated data (case 2). The volumetric and mechanical efficiency lookup tables are replaced with physical signal inputs that you specify through ports EV and EM.

### Case 5: Loss Physical Signal Inputs

If the block variant is `Input losses`, the leakage flow rate and friction torque calculations are as described for loss tabulated data (case 3). The volumetric and mechanical loss lookup tables are replaced with physical signal inputs that you specify through ports `LV` and `LM`.

#### Assumptions

- Fluid compressibility is negligible.
- Loading on the motor shaft due to inertia, friction, and spring forces is negligible.

### Ports

#### Input

**C** — Control member position, m  
physical signal

Physical signal input port for the control member position. The block maps the control member position to the corresponding displacement volume using the tabulated data specified in the block dialog box.

#### Dependencies

This port is exposed only when the block variant is set to `Analytical` or `tabulated data`.

**D** — Displacement volume,  $\text{cm}^3/\text{rev}$   
physical signal

Physical signal input port for the volume of fluid displaced per unit rotation. A smoothing function eases the transition between positive and negative input values.

#### Dependencies

This port is exposed only when the block variant is set to `Input efficiencies` or `Input losses`.

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

**Dependencies**

This port is exposed only when the block variant is set to Input efficiencies.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

**Dependencies**

This port is exposed only when the block variant is set to Input efficiencies.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss, defined as the internal leakage flow rate between the motor inlets.

**Dependencies**

This port is exposed only when the block variant is set to Input losses.

**LM** — Mechanical loss,  $N\cdot m$   
physical signal

Physical signal input port for the mechanical loss, defined as the friction torque on the rotating motor shaft.

**Dependencies**

This port is exposed only when the block variant is set to Input losses.

**Conserving**

**A** — Motor inlet  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing the motor inlet.

**B** — Motor outlet  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing the motor outlet.

**S** — Motor shaft  
mechanical rotational

Mechanical rotational conserving port representing the motor shaft.

**Parameters**

The exposed block parameters depend on the active block variant. See “Block Variants and Loss Parameterizations” on page 1-2096.

**Modeling option** — Loss parameterizations

Analytical or tabulated data | Input efficiencies | Input losses

Set the variant for mechanical and volumetric efficiencies or losses for the block.

**Variant 1: Analytical or tabulated data****Displacement parameterization** — Parameterization used to map control positions to displacements

Maximum displacement and control member stroke (default)

Parameterization used to convert the physical signal at input port C to an instantaneous displacement:

- **Maximum displacement and control member stroke** — Compute the displacement as a linear function of the control position specified at port C.
- **Displacement vs. control member position table** — Obtain the displacement through interpolation or extrapolation of tabulated data specified over a range of control positions.

**Restricted Parameter**

This parameter is locked for editing when using the Simscape Restricted mode.

**Maximum stroke** — Control position corresponding to maximum displacement

0.005 m (default) | scalar with units of length

Control position corresponding to a maximum displacement. The physical signal input at port C saturates at this value. If the input rises higher, the block sets the control position to the maximum stroke.

**Dependencies**

This parameter is enabled when the **Displacement parameterization** parameter is set to Maximum displacement and control member stroke.

**Maximum displacement** — Maximum fluid volume swept per unit shaft rotation

30 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Maximum fluid volume swept per unit shaft rotation. The displacement reaches this value when the control position hits the maximum stroke.

**Dependencies**

This parameter is enabled when the **Displacement parameterization** parameter is set to Maximum displacement and control member stroke.

**Control member position vector** — Control positions at which to specify displacement tabular data

[-0.0075, -0.0025, 0.0, 0.0025, 0.0075] m (default) | *M*-element vector with units of length

*M*-element vector of control positions at which to specify the instantaneous displacement. The vector size, *M*, must be two or greater. The vector elements need not be uniformly spaced. However, they must be monotonically increasing or decreasing.

**Dependencies**

This parameter is enabled when the **Displacement parameterization** parameter is set to Displacement vs. control member position table.

**Displacement vector** — Displacement tabular data for the specified control positions  
 [-30.0, -19.0, 0.0, 19.0, 30.0] cm<sup>3</sup>/rev (default) | *M*-element vector with units of volume/angle

*M*-element vector with the displacement tabular data for the specified control positions. The vector size, *M*, must match that of the **Control member position vector** parameter.

#### Dependencies

This parameter is enabled when the **Displacement parameterization** parameter is set to Displacement vs. control member position table.

**Interpolation method** — Numerical technique used to determine displacements within the tabular data range

Linear (default) | Smooth

Numerical technique used to map control position signals to displacements within the tabular data range. The interpolation method joins tabular data points using straight or curved line segments. Displacements within the range of the tabular data are assumed to lie on these segments.

- **Linear** — Join neighboring data points using straight line segments. Line slopes are generally discontinuous at the line segment end points.
- **Smooth** — Join neighboring data points using curved line segments generated with a modified Akima algorithm. Line slopes are continuous at the line segment end points.

#### Dependencies

This parameter is enabled when the **Displacement parameterization** parameter is set to Displacement vs. control member position table.

#### Restricted Parameter

This parameter is locked for editing when using the Simscape Restricted mode.

**Extrapolation method** — Numerical technique used to determine displacements outside the tabular data range

Linear (default) | Nearest

Numerical technique used to map control position signals to displacements outside the tabular data range. The extrapolation method extends the first and last tabular data points outward using horizontal or sloped straight line segments. Displacements outside the range of the tabular data are assumed to lie on these segments.

- **Linear** — Extend the tabular data using sloped straight line segments. The line slopes are computed from the first and last two tabular data points.
- **Nearest** — Extend the tabular data using horizontal straight line segments. The lines correspond to the displacements specified in the first and last tabular data points.

#### Dependencies

This parameter is enabled when the **Displacement parameterization** parameter is set to Displacement vs. control member position table.

#### Restricted Parameter

This parameter is locked for editing when using the Simscape Restricted mode.

**Leakage and friction parameterization** — Parameterization used to compute leakage flow rate and friction torque

Analytical (default) | Tabulated data – volumetric and mechanical efficiencies | Tabulated data – volumetric and mechanical losses

Parameterization used to compute flow-rate and torque losses due to internal leaks and friction. The **Analytical** parameterization relies on nominal parameters generally available from component data sheets. The remaining, tabular, options rely on lookup tables to map pressure drop, angular velocity, and displacement to component efficiencies or losses. The tabular options include:

- Tabulated data – volumetric and mechanical efficiencies
- Tabulated data – volumetric and mechanical losses

**Nominal shaft angular velocity** — Shaft angular velocity at which to specify the volumetric efficiency

188 rad/s (default) | scalar with units of angle/time

Angular velocity of the rotating shaft at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using simple linear functions, the leakage flow rate and friction torque.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Analytical**.

**Nominal pressure drop** — Pressure drop at which to specify the volumetric efficiency

100e5 Pa (default) | scalar with units of pressure

Pressure drop from inlet to outlet at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Analytical**.

**Nominal kinematic viscosity** — Kinematic viscosity at which to specify the volumetric efficiency

18 cSt (default) | scalar with units of area/time

Kinematic viscosity of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Analytical**.

**Nominal fluid density** — Fluid density at which to specify the volumetric efficiency

900 kg/m<sup>3</sup> (default) | scalar with units of mass/volume

Mass density of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at the specified nominal conditions

0.92 (default) | unitless scalar between 0 and 1

Volumetric efficiency, defined as the ratio of actual to ideal volumetric flow rates, at the specified nominal conditions. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation

0.05 N\*m (default) | scalar with units of torque

Torque required to overcome seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Friction torque vs. pressure drop coefficient at maximum displacement** — Proportionality constant at maximum displacement between friction torque and pressure drop

0.6e-6 N\*m/Pa (default) | scalar with units of torque/pressure

Proportionality constant at maximum displacement between the friction torque on the mechanical shaft and the pressure drop from inlet to outlet.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Displacement threshold for motor-pump transition** — Displacement below which the transition between motoring and pumping modes begins

0.5 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Absolute value of the instantaneous displacement below which the component transitions between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### Dependencies

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

**Pressure drop vector for efficiencies, dp** — Pressure drops at which to specify the volumetric and mechanical efficiencies  
*M*-element vector with units of pressure (default)

*M*-element vector of pressure drops at which to specify the efficiency tabular data. The vector size, *M*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies**.

**Shaft angular velocity vector for efficiencies, w** — Angular velocities at which to specify the volumetric and mechanical efficiencies  
*N*-element vector with units of angular velocity (default)

*N*-element vector of shaft angular velocities at which to specify the efficiency tabular data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies**.

**Displacement vector for efficiencies, D** — Displacements at which to specify the volumetric and mechanical efficiencies  
*L*-element vector with units of volume/angle (default)

*L*-element vector of displacements at which to specify the efficiency tabular data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must be monotonically increasing or decreasing.

**Volumetric efficiency table,  $e_v(dp,w,D)$**  — Volumetric efficiencies at the specified pressure drops, angular velocities, and displacements  
unitless  $M$ -by- $N$ -by- $L$  matrix

$M$ -by- $N$ -by- $L$  matrix with the volumetric efficiencies at the specified fluid pressure drops, shaft angular velocities, and displacements. The efficiencies must fall in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector for efficiencies,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for efficiencies,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w,D)$**  — Mechanical efficiencies at the specified pressure drops, angular velocities, and displacements  
unitless  $M$ -by- $N$  matrix

$M$ -by- $N$ -by- $L$  matrix with the mechanical efficiencies corresponding to the specified fluid pressure drops, shaft angular velocities, and displacements. The efficiencies must fall in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector for efficiencies,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for efficiencies,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Pressure drop threshold for motor-pump transition** — Pressure drop at which to initiate a smooth transition between motor and pump modes  
1e5 Pa (default) | scalar with units of pressure

Pressure drop from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Angular velocity threshold for motor-pump transition** — Shaft angular velocity at which to initiate a smooth transition between pump and motor modes  
10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to `Tabulated data – volumetric and mechanical efficiencies`.

**Check if operating beyond the octants of supplied tabulated data** — Simulation warning mode for operating conditions outside the range of tabulated data

None (default) | Warning

Simulation warning mode for operating conditions outside the range of tabulated data. Select `Warning` to be notified when the fluid pressure drop, shaft angular velocity, or instantaneous displacement cross outside the specified tabular data. The warning does not cause simulation to stop.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to `Tabulated data – volumetric and mechanical efficiencies` or `Tabulated data – volumetric and mechanical losses`.

**Pressure drop vector for losses, dp** — Pressure drops at which to specify the volumetric and mechanical losses

*M*-element vector with units of pressure (default)

*M*-element vector of pressure drops at which to specify the loss tabular data. The vector size, *M*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to `Tabulated data – volumetric and mechanical losses`.

**Shaft angular velocity vector for losses, w** — Angular velocities at which to specify the volumetric and mechanical losses

*N*-element vector with units of angle/time (default)

*N*-element vector of shaft angular velocities at which to specify the loss tabular data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to `Tabulated data – volumetric and mechanical losses`.

**Displacement vector for losses, D** — Displacements at which to specify the volumetric and mechanical losses

*L*-element vector with units of volume/angle (default)

*L*-element vector of displacements at which to specify the loss tabular data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must be monotonically increasing or decreasing.

**Volumetric loss table,  $q\_loss(dp,w,D)$**  — Internal leakage flow rates at the specified pressure drops, angular velocities, and displacements

*M-by-N-by-L matrix with units of volume/time*

*M-by-N-by-L matrix with the volumetric losses at the specified fluid pressure drops, shaft angular velocities, and displacements. Volumetric loss is defined here as the internal leakage volumetric flow rate between port A and port B.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:*

- $M$  is the number of vector elements in the **Pressure drop vector for losses,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for losses,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w,D)$**  — Friction torques at the specified pressure drops, angular velocities, and displacements

*M-by-N-by-L matrix with units of torque*

*M-by-N-by-L matrix with the mechanical losses at the specified fluid pressure drops, shaft angular velocities, and displacements. Mechanical loss is defined here as the friction torque due to seals and internal components.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:*

- $M$  is the number of vector elements in the **Pressure drop vector for losses,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for losses,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

#### Variant 2: Input efficiencies

**Minimum volumetric efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | unitless scalar between 0 and 1

Smallest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal falls below the minimum volumetric efficiency, the volumetric efficiency is set to the minimum volumetric efficiency.

**Maximum volumetric efficiency** — Upper saturation bound on the volumetric efficiency input signal 1 (default) | unitless scalar between 0 and 1

Largest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal rises above the maximum volumetric efficiency, the volumetric efficiency is set to the maximum volumetric efficiency.

**Minimum mechanical efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | unitless scalar between 0 and 1

Smallest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at the specified value. If the input signal falls below the minimum mechanical efficiency, the mechanical efficiency is set to the minimum mechanical efficiency.

**Maximum mechanical efficiency** — Upper saturation bound on the volumetric efficiency input signal 1 (default) | unitless scalar between 0 and 1

Largest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at this value. If the input signal rises above the maximum mechanical efficiency, the mechanical efficiency is set to the maximum mechanical efficiency.

**Pressure drop threshold for motor-pump transition** — Pressure drop at which to initiate a smooth transition between motor and pump modes  
1e5 Pa (default) | scalar with units of pressure

Pressure drop from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate a smooth transition between pump and motor modes  
10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Displacement threshold for motor-pump transition** — Displacement at which to initiate a smooth transition between pump and motor modes  
0.5 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Absolute value of the instantaneous displacement below which the component transitions between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select Warning to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### **Dependencies**

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to Warning.

**Variant 3: Input losses**

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate a smooth transition between pump and motor modes

10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Displacement threshold for motor-pump transition** — Displacement at which to initiate a smooth transition between pump and motor modes

0.5 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Absolute value of the instantaneous displacement below which the component transitions between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Displacement threshold for motor-pump transition** — Displacement below which the transition between motoring and pumping modes begins

0.5 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Absolute value of the instantaneous displacement below which the component transitions between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if operating beyond the motor mode** — Simulation warning mode for operating conditions outside motoring mode

None (default) | Warning

Simulation warning mode for operating conditions outside the motoring mode. A warning is issued if the motor transitions to pumping mode. Select **Warning** to be notified when this transition occurs. The warning does not cause simulation to stop.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure

None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning

0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

**Dependencies**

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

## Version History

### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Extended Capabilities

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

# Variable-Displacement Motor (IL)

Variable-displacement motor in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors

## Description

The Variable-Displacement Motor (IL) block models a motor with variable-volume displacement. The fluid may move from port **A** to port **B**, called *forward mode*, or from port **B** to port **A**, called *reverse mode*. Motor mode operation occurs when there is a pressure drop in the direction of the flow. Pump mode operation occurs when there is a pressure gain in the direction of the flow.

The shaft rotation corresponds to the sign of the fluid volume moving through the motor, which is received as a physical signal at port **D**. Positive fluid displacement at **D** corresponds to positive shaft rotation in forward mode. Negative fluid displacement at **D** corresponds to negative shaft angular velocity in forward mode.

## Operation Modes

The block has eight modes of operation. The working mode depends on the pressure drop from port **A** to port **B**,  $\Delta p = p_A - p_B$ ; the angular velocity,  $\omega = \omega_R - \omega_C$ ; and the fluid volumetric displacement at port **D**. The figure above maps these modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart:

- Mode 1, *Forward Motor*: Flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and a positive shaft angular velocity.
- Mode 2, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to port **A**.

- Mode 3, *Reverse Motor*: Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and a negative shaft angular velocity.
- Mode 4, *Forward Pump*: Positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from **A** to **B**.
- Mode 5, *Reverse Pump*: Positive shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to **A**.
- Mode 6, *Forward Motor*: Flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and a positive shaft angular velocity.
- Mode 7, *Forward Pump*: Negative shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from **A** to **B**.
- Mode 8, *Reverse Motor*: Flow from **B** to **A** causes a pressure decrease from **B** to **A** and positive shaft angular velocity.

The motor block has analytical, lookup table, and physical signal parameterizations. When using tabulated data or an input signal for parameterization, you can choose to characterize the motor operation based on efficiency or losses.

The threshold parameters **Pressure drop threshold for motor-pump transition**, **Angular velocity threshold for motor-pump transition**, and **Displacement threshold for motor-pump transition** identify regions where numerically smoothed flow transition between the motor operational modes can occur. For the pressure and angular velocity thresholds, choose a transition region that provides some margin for the transition term, but which is small enough relative to the typical motor pressure drop and angular velocity so that it will not impact calculation results. For the displacement threshold, choose a threshold value that is smaller than the typical displacement volume during normal operation.

### Analytical Leakage and Friction Parameterization

If you set **Leakage and friction parameterization** to `Analytical`, the block calculates internal leakage and shaft friction from constant nominal values of shaft velocity, pressure drop, volumetric displacement, and torque. The leakage flow rate, which is correlated with the pressure differential over the motor, is calculated as:

$$\dot{m}_{leak} = K\rho_{avg}\Delta p,$$

where:

- $\Delta p$  is  $p_A - p_B$ .
- $\rho_{avg}$  is the average fluid density.
- $K$  is the Hagen-Poiseuille coefficient for analytical loss,

$$K = \frac{D_{nom}\omega_{nom}\left(\frac{1}{\eta_{v,nom}} - 1\right)}{\Delta p_{nom}},$$

where:

- $D_{nom}$  is the **Nominal displacement**.
- $\omega_{nom}$  is the **Nominal shaft angular velocity**.
- $\eta_{nom}$  is the **Volumetric efficiency at nominal conditions**.

- $\Delta p_{nom}$  is the **Nominal pressure drop**.

The torque, which is related to the motor pressure differential, is calculated as:

$$\tau_{fr} = \left( \tau_0 + k \left| \Delta p \frac{D}{D_{nom}} \right| \right) \tanh \left( \frac{4\omega}{5 \times 10^{-5} \omega_{nom}} \right),$$

where:

- $\tau_0$  is the **No-load torque**.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which is determined from the **Mechanical efficiency at nominal conditions**,  $\eta_{m,nom}$ :

$$k = \frac{\tau_{fr,nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fr,nom}$  is the friction torque at nominal conditions:

$$\tau_{fr,nom} = (1 - \eta_{m,nom}) D_{nom} \Delta p_{nom}.$$

- $\Delta p$  is the pressure drop between ports **A** and **B**.
- $\omega$  is the relative shaft angular velocity, or  $\omega_R - \omega_C$ .

### Tabulated Data Parameterizations

When using tabulated data for motor efficiencies or losses, you can provide data for one or more of the motor operational modes. The signs of the tabulated data determine the operational regime of the block. When data is provided for less than eight operational modes, the block calculates the complementing data for the other mode(s) by extending the given data into the remaining octants.

#### The Tabulated data - volumetric and mechanical efficiencies parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \dot{m}_{leak,motor} \left( \frac{1 + \alpha}{2} \right) + \dot{m}_{leak,pump} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\dot{m}_{leak,pump} = (\eta_v - 1) \dot{m}_{ideal}$
- $\dot{m}_{leak,motor} = (1 - \eta_v) \dot{m}$

and  $\eta_v$  is the volumetric efficiency, which is interpolated from the user-provided tabulated data. The transition term,  $\alpha$ , is

$$\alpha = \tanh \left( \frac{4\Delta p}{\Delta p_{threshold}} \right) \tanh \left( \frac{4\omega}{\omega_{threshold}} \right) \tanh \left( \frac{4D}{D_{threshold}} \right),$$

where:

- $\Delta p$  is  $p_A - p_B$ .
- $\Delta p_{threshold}$  is the **Pressure drop threshold for motor-pump transition**.
- $\omega$  is  $\omega_R - \omega_C$ .

- $\omega_{\text{threshold}}$  is the **Angular velocity threshold for motor-pump transition**.

The torque is calculated as:

$$\tau_{fr} = \tau_{fr, pump} \left( \frac{1 + \alpha}{2} \right) + \tau_{fr, motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\tau_{fr, pump} = (\eta_m - 1)\tau$
- $\tau_{fr, motor} = (1 - \eta_m)\tau_{ideal}$

and  $\eta_m$  is the mechanical efficiency, which is interpolated from the user-provided tabulated data.

#### The Tabulated data - volumetric and mechanical losses parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{loss}(\Delta p, \omega, D),$$

where  $q_{loss}$  is interpolated from the **Volumetric loss table,  $q\_loss(dp,w,D)$**  parameter, which is based on user-supplied data for pressure drop, shaft angular velocity, and fluid volumetric displacement.

The shaft friction torque is calculated as:

$$\tau_{fr} = \tau_{loss}(\Delta p, \omega, D),$$

where  $\tau_{loss}$  is interpolated from the **Mechanical loss table,  $torque\_loss(dp,w,D)$**  parameter, which is based on user-supplied data for pressure drop, shaft angular velocity, and fluid volumetric displacement.

#### Input Signal Parameterization

When **Leakage and friction parameterization** is set to **Input signal - volumetric and mechanical efficiencies**, ports **EV** and **EM** are enabled. The internal leakage and shaft friction are calculated in the same way as the **Tabulated data - volumetric and mechanical efficiencies** parameterization, except that  $\eta_v$  and  $\eta_m$  are received directly at ports **EV** and **EM**, respectively.

When **Leakage and friction parameterization** is set to **Input signal - volumetric and mechanical losses**, ports **LV** and **LM** are enabled. These ports receive leakage flow and friction torque as positive physical signals. The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{LV} \tanh\left(\frac{4\Delta p}{p_{thresh}}\right),$$

where:

- $q_{LV}$  is the leakage flow received at port **LV**.
- $p_{thresh}$  is the **Pressure drop threshold for motor-pump transition** parameter.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{LM} \tanh\left(\frac{4\omega}{\omega_{thresh}}\right),$$

where

- $\tau_{LM}$  is the friction torque received at port **LM**.
- $\omega_{thresh}$  is the **Angular velocity threshold for motor-pump transition** parameter.

The volumetric and mechanical efficiencies range between the user-defined specified minimum and maximum values. Any values lower or higher than this range will take on the minimum and maximum specified values, respectively.

## Motor Operation

The motor flow rate is:

$$\dot{m} = \dot{m}_{ideal} + \dot{m}_{leak},$$

where  $\dot{m}_{ideal} = \rho_{avg} D \cdot \omega$ .

The motor torque is:

$$\tau = \tau_{ideal} - \tau_{fr},$$

where  $\tau_{ideal} = D \cdot \Delta p$ .

The mechanical power extracted by the motor shaft is:

$$\varphi_{mech} = \tau \omega,$$

and the motor hydraulic power is:

$$\varphi_{hyd} = \frac{\Delta p \dot{m}}{\rho_{avg}}.$$

To be notified if the block is operating beyond the supplied tabulated data, you can set **Check if operating beyond the octants of supplied tabulated data** to **Warning** to receive a warning if this occurs, or **Error** to stop the simulation when this occurs. When using input signal for volumetric or mechanical losses, you can be notified if the simulation surpasses operating modes with the **Check if operating beyond motor mode** parameter.

You can also monitor motor functionality. Set **Check if pressures are less than motor minimum pressure** to **Warning** to receive a warning if this occurs, or **Error** to stop the simulation when this occurs.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the motor.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the motor.

**R** — Mechanical port  
mechanical rotational

Rotating shaft angular velocity and torque.

**C** — Mechanical port  
mechanical rotational

Motor casing reference angular velocity and torque.

### **Input**

**D** — Volumetric displacement,  $\text{m}^3/\text{rad}$   
physical signal

Volumetric displacement of the motor, in  $\text{m}^3/\text{rad}$ , specified as a physical signal.

**EV** — Volumetric efficiency  
physical signal

Motor efficiency for fluid displacement, specified as a physical signal. The value must be between 0 and 1.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency  
physical signal

Motor efficiency for the mechanical extraction of energy, specified as a physical signal. The value must be between 0 and 1.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Leakage flow rate,  $\text{m}^3/\text{s}$   
physical signal

Motor volumetric losses, in  $\text{m}^3/\text{s}$ , specified as a physical signal.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Friction torque,  $\text{N}\cdot\text{m}$   
physical signal

Motor mechanical losses in  $\text{N}\cdot\text{m}$ , specified as a physical signal.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

## Parameters

**Leakage and friction parameterization** — Method of calculating leakage flow rate and friction torque

Analytical (default) | Tabulated data - volumetric and mechanical efficiencies | Tabulated data - volumetric and mechanical losses | Input signal - volumetric and mechanical efficiencies | Input signal - volumetric and mechanical losses

Parameterization of the leakage and friction characteristics of the motor.

- In the `Analytical` parameterization, the leakage flow rate and the friction torque are calculated by analytical equations.
- In the `Tabulated data - volumetric and mechanical efficiencies` parameterization, the leakage flow rate and torque friction are calculated from the user-supplied **Pressure drop vector,  $dp$** , **Shaft angular velocity vector,  $w$** , and **Displacement vector,  $D$**  parameters and interpolated from the 3-D dependent **Volumetric efficiency table,  $e_v(dp,w,D)$**  and **Mechanical efficiency table,  $e_m(dp,w,D)$**  tables.
- In the `Tabulated data - volumetric and mechanical loss` parameterization, the leakage flow rate and torque friction are calculated from the user-supplied **Pressure drop vector,  $dp$** ; **Shaft angular velocity vector,  $w$** ; and **Displacement vector,  $D$**  parameters and interpolated from the 3-D dependent **Volumetric loss table,  $q_{loss}(dp,w,D)$**  and **Mechanical loss table,  $torque_{loss}(dp,w,D)$**  tables.
- In the `Input signal - volumetric and mechanical efficiencies` parameterization, the volumetric and mechanical efficiencies are received as physical signals at ports **EV** and **EM**, respectively.
- In the `Input signal - volumetric and mechanical loss` parameterization, the leakage flow rate and friction torque are received as physical signals at ports **LV** and **LM**, respectively.

**Nominal displacement** — Fixed-volume fluid displacement

30 cm<sup>3</sup>/rev (default) | scalar

Amount of fluid displaced by shaft rotating under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Nominal shaft angular velocity** — Shaft angular velocity

1800 rpm (default) | scalar

Angular velocity of the shaft under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Nominal pressure drop** — Pressure drop between fluid entry and exit

10 MPa (default) | scalar

Motor pressure drop between the fluid entry and exit under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Volumetric efficiency at nominal conditions** — Ratio of actual flow rate to ideal flow rate at nominal conditions

0.92 (default) | positive scalar in the range of (0,1]

Ratio of actual flow rate to ideal flow rate at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Baseline torque

0 N\*m (default) | scalar

Minimum value of torque to overcome seal friction and induce shaft motion.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of actual to ideal mechanical power

0.88 (default) | positive scalar

Ratio of actual mechanical power to ideal mechanical power at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure drop vector, dp** — Vector of pressure data for tabulated data parameterization

[.1, 1, 2] MPa (default) | 1-by-n vector

Vector of pressure differential values for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** and the **Displacement vector, D** parameters for the 3-D dependent **Volumetric efficiency table, e\_v(dp,w,D)** and **Mechanical efficiency table, e\_m(dp,w,D)** parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Shaft angular velocity vector, w** — Vector of angular velocity data for tabulated data parameterization

[250, 500, 1000, 2000, 3000, 4000] rpm (default) | 1-by-n vector

Vector of angular velocity data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** and the **Displacement vector, D** parameters for the 3-D dependent **Volumetric efficiency table, e\_v(dp,w,D)** and **Mechanical efficiency table, e\_m(dp,w,D)** parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Displacement vector,  $D$**  — Vector of displacement volumes for tabulated data parameterization  
[-30, -19, 19, 30] cm<sup>3</sup>/s (default) | 1-by- $n$  vector

Vector of volumetric displacement data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector,  $w$**  and the **Pressure drop vector,  $dp$**  parameters for the 3-D dependent **Volumetric efficiency table,  $e_v(dp,w,D)$**  and **Mechanical efficiency table,  $e_m(dp,w,D)$**  parameters. The vector elements must be listed in ascending order.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Volumetric efficiency table,  $e_v(dp,w,D)$**  — Volumetric efficiency for tabulated data parameterization

```
repmat([.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91], 1, 1, 4) (default) |  $M$ -by- $N$ -by- $P$  matrix
```

$M$ -by- $N$ -by- $P$  matrix of volumetric efficiencies at the specified fluid pressure drop, shaft angular velocity, and volumetric displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w,D)$**  — Mechanical efficiency for tabulated data parameterization

```
repmat([.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984], 1, 1, 4) (default) |  $M$ -by- $N$ -by- $P$  matrix
```

$M$ -by- $N$ -by- $P$  matrix of mechanical efficiencies at the specified fluid pressure drop, shaft angular velocity, and displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q\_loss(dp,w,D)$**  — Volumetric losses for tabulated data parameterization  
`repmat([.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] * 1e-3, 1, 1, 4)` (default) |  $M$ -by- $N$ -by- $P$  matrix

$M$ -by- $N$ -by- $P$  matrix of volumetric leakage at the specified fluid pressure drop, shaft angular velocity, and displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w,D)$**  — Mechanical losses for tabulated data parameterization  
`repmat([.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0505; .1937, .1937, .1833, .1833, .1729, .1626], 1, 1, 4)`  $N*m$  (default) |  $M$ -by- $N$ -by- $P$  matrix

$M$ -by- $N$ -by- $P$  matrix of mechanical losses at the specified fluid pressure drop and shaft angular velocity. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Minimum value of volumetric efficiency  
`1e-3` (default) | positive scalar in the range of (0,1]

Minimum value of volumetric efficiency. If the input signal is below this value, the volumetric efficiency is set to the minimum volumetric efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Maximum value of volumetric efficiency  
`1` (default) | positive scalar in the range of (0,1]

Maximum value of volumetric efficiency. If the input signal is above this value, the volumetric efficiency is set to the maximum volumetric efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Minimum value of mechanical efficiency  
1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of mechanical efficiency. If the input signal is below this value, the mechanical efficiency is set to the minimum mechanical efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Maximum value of mechanical efficiency  
1 (default) | positive scalar in the range of (0,1]

Maximum value of mechanical efficiency. If the input signal is above this value, the mechanical efficiency is set to the maximum mechanical efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure drop threshold for motor-pump transition** — Pressure threshold for mode transition  
1e-3 MPa (default) | positive scalar

Motor pressure drop that indicates the transition threshold between motor and pump functionality. A transition region is defined around 0 MPa between the positive and negative values of the pressure drop threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Angular velocity threshold for motor-pump transition** — Angular velocity threshold for mode transition  
100 rpm (default) | positive scalar

Shaft angular velocity that indicates the transition threshold between motor and pump functionality. A transition region is defined around 0 rpm between the positive and negative values of the angular velocity threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Displacement threshold for motor-pump transition** — Displacement threshold for mode transition

0.1 cm<sup>3</sup>/s (default) | positive scalar

Volumetric displacement that indicates the transition threshold between motor and pump functionality. A transition region is defined around 0 cm<sup>3</sup>/s between the positive and negative values of the displacement threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other. It is also used to transition the ideal mass flow rate when the sign of **D** changes.

**Check if operating beyond the octants of supplied tabulated data** — Whether to notify if extents of supplied data are surpassed

None (default) | Warning | Error

Whether to notify if the extents of the supplied data are surpassed. Select **Warning** to be notified when the block uses values beyond the supplied data range. Select **Error** to stop the simulation when the block uses values beyond the supplied data range.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating beyond motor mode** — Whether to notify if block operates outside of the motor mode functionality

None (default) | Warning | Error

Whether to notify if the block operates outside of the motor mode functionality. Select **Warning** to be notified when the block operates in the forward or reverse pump modes. Select **Error** to stop the simulation when the block operates in the forward or reverse pump modes.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Input signal - volumetric and mechanical losses**.

**Check if pressures are less than motor minimum pressure** — Whether to notify if fluid exit pressure is low

None (default) | Warning | Error

Whether to notify if the fluid at port **A** or **B** experiences low pressure. Select **Warning** to be notified when the pressure falls below a minimum specified value. Select **Error** to stop the simulation when the pressure falls below a minimum specified value.

The parameter helps identify potential conditions for cavitation, when the fluid pressure falls below the fluid vapor pressure.

**Motor minimum pressure** — Lower threshold of acceptable pressure at the motor outlet

0.101325 MPa (default) | positive scalar

Lower threshold of acceptable pressure at the motor inlet or outlet.

**Dependencies**

To enable this parameter, set **Check if pressures are less than motor minimum pressure** to either:

- Warning
- Error

Variable-Displacement Motor (TL) | Variable-Displacement Pump (IL) | Fixed-Displacement Motor (IL)

## Variable-Displacement Motor (TL)

Variable-displacement bidirectional thermal liquid motor

### Libraries:

Simscape / Fluids / Thermal Liquid / Pumps & Motors

### Description

The Variable-Displacement Motor block represents a device that extracts power from a thermal liquid network and delivers it to a mechanical rotational network. The motor displacement varies during simulation according to the physical signal input specified at port **D**.

Ports **A** and **B** represent the motor inlets. Ports **R** and **C** represent the motor drive shaft and case. During normal operation, a pressure drop from port **A** to port **B** causes a positive flow rate from port **A** to port **B** and a positive rotation of the motor shaft relative to the motor case. This operation mode is referred to here as *forward motor*.

### Operation Modes

The block has eight modes of operation. The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$ ; the angular velocity,  $\omega = \omega_R - \omega_C$ ; and the fluid volumetric displacement at port **D**. The figure above maps these modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart:

- Mode 1, *Forward Motor*: Flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and a positive shaft angular velocity.
- Mode 2, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to port **A**.
- Mode 3, *Reverse Motor*: Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and a negative shaft angular velocity.

- Mode 4, *Forward Pump*: Positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from **A** to **B**.
- Mode 5, *Reverse Pump*: Positive shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to **A**.
- Mode 6, *Forward Motor*: Flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and a positive shaft angular velocity.
- Mode 7, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from **A** to **B**.
- Mode 8, *Reverse Motor*: Flow from **B** to **A** causes a pressure decrease from **B** to **A** and positive shaft angular velocity.

The response time of the motor is considered negligible in comparison with the system response time. The motor is assumed to reach steady state nearly instantaneously and is treated as a quasi-steady component.

### Flow Rate and Driving Torque

The mass flow rate generated at the motor is

$$\dot{m} = \dot{m}_{\text{Ideal}} + \dot{m}_{\text{Leak}},$$

where:

- $\dot{m}$  is the actual mass flow rate.
- $\dot{m}_{\text{Ideal}}$  is the ideal mass flow rate.
- $\dot{m}_{\text{Leak}}$  is the internal leakage mass flow rate.

The torque generated at the motor is

$$\tau = \tau_{\text{Ideal}} - \tau_{\text{Friction}},$$

where:

- $\tau$  is the actual torque.
- $\tau_{\text{Ideal}}$  is the ideal torque.
- $\tau_{\text{Friction}}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal mass flow rate is

$$\dot{m}_{\text{Ideal}} = \rho D \omega,$$

and the ideal generated torque is

$$\tau_{\text{Ideal}} = D \Delta p,$$

where:

- $\rho$  is the average of the fluid densities at thermal liquid ports **A** and **B**.
- $D$  is the displacement specified at physical signal port **D**.

- $\omega$  is the shaft angular velocity.
- $\Delta p$  is the pressure drop from inlet to outlet.

### Leakage and friction parameterization

You can parameterize leakage and friction analytically, using tabulated efficiencies or losses, or by input efficiencies or input losses.

#### Analytical

When you set **Leakage and friction parameterization** to Analytical leakage flow rate is

$$\dot{m}_{\text{Leak}} = \frac{K_{\text{HP}}\rho_{\text{Avg}}\Delta p}{\mu_{\text{Avg}}},$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}}|\Delta p|\frac{|D|}{D_{\text{Nom}}}\tanh\left(\frac{4\omega}{(5e-5)\omega_{\text{Nom}}}\right) \right),$$

where:

- $K_{\text{HP}}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. This coefficient is computed from the specified nominal parameters.
- $\mu$  is the dynamic viscosity of the thermal liquid, taken here as the average of its values at the thermal liquid ports.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which is determined from the **Mechanical efficiency at nominal conditions**,  $\eta_{m,nom}$ :

$$k = \frac{\tau_{fr,nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fr,nom}$  is the friction torque at nominal conditions:

$$\tau_{fr,nom} = (1 - \eta_{m,nom})D_{nom}\Delta p_{nom}.$$

- $D_{\text{Nom}}$  is the specified value of the **Nominal Displacement** block parameter.
- $\tau_0$  is the specified value of the **No-load torque** block parameter.
- $\omega_{\text{Nom}}$  is the specified value of the **Nominal shaft angular velocity** block parameter.
- $\Delta p_{\text{Nom}}$  is the specified value of the **Nominal pressure drop** block parameter. This is the pressure drop at which the nominal volumetric efficiency is specified.

The Hagen-Poiseuille coefficient is determined from nominal fluid and component parameters through the equation

$$K_{\text{HP}} = \frac{D_{\text{Nom}}\omega_{\text{Nom}}\mu_{\text{Nom}}\left(\frac{1}{\eta_{v,\text{Nom}}} - 1\right)}{\Delta p_{\text{Nom}}},$$

where:

- $\omega_{\text{Nom}}$  is the specified value of the **Nominal shaft angular velocity** parameter. This is the angular velocity at which the nominal volumetric efficiency is specified.

- $\mu_{\text{Nom}}$  is the specified value of the **Nominal Dynamic viscosity** block parameter. This is the dynamic viscosity at which the nominal volumetric efficiency is specified.
- $\eta_{\text{v,Nom}}$  is the specified value of the **Volumetric efficiency at nominal conditions** block parameter. This is the volumetric efficiency corresponding to the specified nominal conditions.

### Tabulated Efficiencies

When you set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \dot{m}_{\text{Leak,Pump}} \frac{(1 + \alpha)}{2} + \dot{m}_{\text{Leak,Motor}} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction,Pump}} \frac{1 + \alpha}{2} + \tau_{\text{Friction,Motor}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $\dot{m}_{\text{Leak,Motor}}$  is the leakage flow rate in motor mode.
- $\dot{m}_{\text{Leak,Pump}}$  is the leakage flow rate in pump mode.
- $\tau_{\text{Friction,Motor}}$  is the friction torque in motor mode.
- $\tau_{\text{Friction,Pump}}$  is the friction torque in pump mode.

The smoothing parameter  $\alpha$  is given by the hyperbolic tangent function

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4D}{D_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the specified value of the **Pressure gain threshold for pump-motor transition** block parameter.
- $\omega_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for pump-motor transition** block parameter.
- $D_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for motor-pump transition** block parameter.

The leakage flow rate is calculated from the volumetric efficiency, a quantity that is specified in tabulated form over the  $\Delta p$ - $\omega$ - $D$  domain via the **Volumetric efficiency table** block parameter. When operating in pump mode (octants **1** and **3** of the  $\Delta p$ - $\omega$ - $D$  chart shown in the "Operation Modes" on page 1-835 figure), the leakage flow rate is:

$$\dot{m}_{\text{Leak,Pump}} = (1 - \eta_{\text{v}})\dot{m}_{\text{Ideal}},$$

where  $\eta_{\text{v}}$  is the volumetric efficiency, obtained either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode (octants **2** and **4** of the  $\Delta p$ - $\omega$ - $D$  chart), the leakage flow rate is:

$$\dot{m}_{\text{Leak,Motor}} = -(1 - \eta_{\text{v}})\dot{m}.$$

The friction torque is similarly calculated from the mechanical efficiency, a quantity that is specified in tabulated form over the  $\Delta p$ - $\omega$ - $D$  domain via the **Mechanical efficiency table** block parameter. When operating in pump mode (octants **1** and **3** of the  $\Delta p$ - $\omega$ - $D$  chart):

$$\tau_{\text{Friction,Pump}} = (1 - \eta_m)\tau,$$

where  $\eta_m$  is the mechanical efficiency, obtained either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode (octants **2** and **4** of the  $\Delta p$ - $\omega$ - $D$  chart):

$$\tau_{\text{Friction,Motor}} = -(1 - \eta_m)\tau_{\text{Ideal}}.$$

### Tabulated Losses

When you set **Leakage and friction parameterization** to **Tabulated data - volumetric and mechanical losses**, the leakage (volumetric) flow rate is specified directly in tabulated form over the  $\Delta p$ - $\omega$ - $D$  domain:

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega, D).$$

The mass flow rate due to leakage is calculated from the volumetric flow rate:

$$\dot{m}_{\text{Leak}} = \rho q_{\text{Leak}}.$$

The friction torque is similarly specified in tabulated form:

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega, D),$$

where  $q_{\text{Leak}}(\Delta p, \omega, D)$  and  $\tau_{\text{Friction}}(\Delta p, \omega, D)$  are the volumetric and mechanical losses, obtained through interpolation or extrapolation of the tabulated data specified via the **Volumetric loss table** and **Mechanical loss table** block parameters.

### Input Efficiencies

When you set **Leakage and friction parameterization** to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The volumetric and mechanical efficiency lookup tables are replaced with physical signal inputs that you specify through ports **EV** and **EM**.

The efficiencies are positive quantities with value between 0 and 1. Input values outside of these bounds are set equal to the nearest bound (0 for inputs smaller than 0, 1 for inputs greater than 1). The efficiency signals are saturated at the **Minimum volumetric efficiency** or **Minimum mechanical efficiency** and **Maximum volumetric efficiency** or **Maximum mechanical efficiency**.

### Input Losses

When you set **Leakage and friction parameterization** to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The volumetric and mechanical loss lookup tables are replaced with physical signal inputs that you specify through ports **LV** and **LM**.

The block expects the inputs to be positive. It sets the signs automatically from the operating conditions established during simulation—more precisely, from the  $\Delta p$ - $\omega$  quadrant in which the component happens to be operating.

## Energy Balance

Mechanical work done by the motor is associated with an energy exchange. The governing energy balance equation is:

$$\phi_A + \phi_B - P_{hydro} = 0,$$

where:

- $\Phi_A$  and  $\Phi_B$  are energy flow rates at ports **A** and **B**, respectively.
- $P_{hydro}$  is a function of the pressure difference between motor ports:  $P_{hydro} = \Delta p \frac{\dot{m}}{\rho}$ .

The motor mechanical power is generated due to torque,  $\tau$ , and angular velocity,  $\omega$ :

$$P_{mech} = \tau\omega.$$

## Assumptions

- Fluid compressibility is negligible.
- Loading on the motor shaft due to inertia, friction, and spring forces is negligible.

## Ports

### Input

**D** — Displacement volume,  $\text{cm}^3/\text{rev}$   
physical signal

Physical signal input port for the volume of fluid displaced per rotation. A smoothing function eases the transition between positive and negative input values.

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

### Dependencies

This port is exposed only when the block variant is set to Input efficiencies.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

### Dependencies

This port is exposed only when the block variant is set to Input efficiencies.

**LV** — Volumetric loss,  $\text{m}^3/\text{s}$   
physical signal

Physical signal input port for the volumetric loss, defined as the internal leakage flow rate between the motor inlets.

**Dependencies**

This port is exposed only when the block variant is set to `Input losses`.

**LM** — Mechanical loss, N\*m  
physical signal

Physical signal input port for the mechanical loss, defined as the friction torque on the rotating motor shaft.

**Dependencies**

This port is exposed only when the block variant is set to `Input losses`.

**Conserving**

**A** — Motor inlet  
thermal liquid

Thermal liquid conserving port representing the motor inlet.

**B** — Motor outlet  
thermal liquid

Thermal liquid conserving port representing the motor outlet.

**C** — Motor Case  
mechanical rotational

Mechanical rotational conserving port representing the motor case.

**R** — Motor Shaft  
mechanical rotational

Mechanical rotational conserving port representing the rotational motor shaft.

**Parameters**

**Leakage and friction parameterization** — Parameterization of leakage flow rate and friction torque  
`Analytical (default)` | `Tabulated data - volumetric and mechanical efficiencies` | `Tabulated data - volumetric and mechanical losses` | `Input signal - volumetric and mechanical efficiencies` | `Input signal - volumetric and mechanical losses`

Method to compute flow-rate and torque losses due to internal leaks and friction. When you select `Analytical`, the block parameters are generally available from component data sheets. When you select `Tabulated data - volumetric and mechanical efficiencies` or `Tabulated data - volumetric and mechanical losses`, the block uses lookup tables to map pressure drop, angular velocity, and displacement to component efficiencies or losses.

When you select `Input signal - volumetric and mechanical efficiencies` or `Input signal - volumetric and mechanical losses`, the block performs the leakage flow rate and friction torque calculations the same as the `Tabulated data - volumetric and mechanical`

efficiencies or Tabulated data - volumetric and mechanical losses settings, respectively. When you select Input signal - volumetric and mechanical efficiencies the block enables the physical signal ports, **EV** and **EM**. You use these ports to specify the volumetric and mechanical efficiency. When you select Input signal - volumetric and mechanical losses the block enables the physical signal ports, **LV** and **LM**. You use these ports to specify the volumetric and mechanical losses.

**Nominal displacement** — Displacement at which to specify the volumetric efficiency  
30 cm<sup>3</sup>/rev (default) | positive scalar

Fluid displacement for a given volumetric efficiency. These values are typically available at standard operating conditions in the manufacturer data sheet. The block uses this parameter to calculate the leakage flow rate and friction torque.

**Nominal shaft angular velocity** — Shaft angular velocity for given volumetric efficiency  
1800 rpm (default) | scalar

Angular velocity of the rotary shaft that corresponds to the given volumetric efficiency. These values are typically available at standard operating conditions in the manufacturer data sheet. The block uses this parameter to calculate the leakage flow rate and friction torque.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal pressure drop** — Pressure drop for corresponding volumetric efficiency  
10 MPa (default) | scalar

Pressure drop that corresponds to the given volumetric efficiency. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal dynamic viscosity** — Dynamic viscosity at which to specify the volumetric efficiency  
0.9 cP (default) | scalar

Dynamic viscosity of the hydraulic fluid for the given volumetric efficiency. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at the specified nominal conditions  
0.92 (default) | scalar in the range (0,1)

Volumetric efficiency for the given conditions. The block defines the volumetric efficiency as the ratio of actual to ideal volumetric flow rates. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of actual to ideal mechanical power  
0.88 (default) | positive scalar

Ratio of actual mechanical power to ideal mechanical power at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation  
0 N\*m (default) | scalar

Torque to overcome the seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure drop vector, dp** — Pressure drops for given volumetric and mechanical efficiencies  
[.1, 1, 2] MPa (default) | vector

Pressure drops for the corresponding tabular efficiency data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to the block description for the operation modes corresponding to the various octant.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Shaft angular velocity vector, w** — Angular velocities at which to specify the volumetric and mechanical efficiencies  
[250, 500, 1000, 2000, 3000, 4000] rpm | vector

Shaft angular velocities for the corresponding tabular efficiency data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to the block description for the operation modes corresponding to the various octants.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Displacement vector, D** — Displacements at which to specify the volumetric and mechanical efficiencies  
[-30, -19, 19, 30] cm<sup>3</sup>/rev (default)

Displacements at which to specify the efficiency tabular data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to the block description for the operation modes corresponding to the various octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric efficiency table, e\_v(dp,w,D)** — Volumetric efficiencies for given pressure drops, angular velocities, and displacements

```
repmat([.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91], 1, 1, 4) | matrix
```

Volumetric efficiencies at the specified fluid pressure drops, shaft angular velocities, and displacements. The efficiencies must be in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector, w** parameter.
- $L$  is the number of vector elements in the **Displacement vector, D** parameter.

You can specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to the block description for the operation modes corresponding to the various octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table, e\_m(dp,w,D)** — Mechanical efficiencies for given pressure drops, angular velocities, and displacements

```
repmat([.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984], 1, 1, 4) | matrix
```

Mechanical efficiencies corresponding to the specified fluid pressure drops, shaft angular velocities, and displacements. The efficiencies must be in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector, w** parameter.
- $L$  is the number of vector elements in the **Displacement vector, D** parameter.

You can specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to the block description for the operation modes corresponding to the various octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Pressure drop vector, dp** — Pressure drop for corresponding losses

```
[.1, 1, 2] MPa (default)
```

Pressure drops for the corresponding tabular loss data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to the block description for the operation modes corresponding to the various octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Displacement vector, D** — Displacements at which to specify the volumetric and mechanical losses  
[-30, -19, 19, 30] cm<sup>3</sup>/rev (default)

Displacements at which to specify the loss tabular data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to the block description for the operation modes corresponding to the various octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Volumetric loss table, q\_loss(dp,w,D)** — Internal leakage flow rates for corresponding pressure drops, angular velocities, and displacements  
repmat([.0282, .0253, .0241, .0235, .0291, .0325; .2596, .1271, .1017, .0917, .1216, .1142; .7874, .1901, .141, .1211, .1797, .1978] \* 1e-3, 1, 1, 4) m<sup>3</sup>/s

Volumetric losses at the specified fluid pressure drops, shaft angular velocities, and displacements. The block defines volumetric loss the internal leakage volumetric flow rate between port **A** and port **B**.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector, w** parameter.
- $L$  is the number of vector elements in the **Displacement vector, D** parameter.

You can specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to the block description for the operation modes corresponding to the various octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table, torque\_loss(dp,w,D)** — Friction torques for the corresponding pressure drops, angular velocities, and displacements  
repmat([.002, .002, .002, .002, .002, .002; .06, .055, .055, .055, .055, .05; .19, .19, .18, .18, .17, .16], 1, 1, 4) N\*m

Mechanical losses for the given pressure drops, shaft angular velocities, and displacements. The block defines mechanical loss as the friction torque due to seals and internal components.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $\mathbf{dp}$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $\mathbf{w}$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $\mathbf{D}$**  parameter.

You can specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to the block description for the operation modes corresponding to the various octants. The tabulated data for the mechanical losses must obey the convention in the figure, with positive values at positive angular velocities and negative values at negative angular velocities.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs below this value.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Upper saturation bound on the volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs above this value.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs below this value.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Upper saturation bound on the volumetric efficiency input signal  
1 (default) | scalar in the range (0,1)

Largest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs above this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure drop threshold for motor-pump transition** — Pressure drop at which to initiate a smooth transition between motor and pump modes  
1e-3 MPa (default) | scalar

Pressure drop from inlet to outlet below which the block begins to transition between motoring and pumping modes. The block uses a hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate a smooth transition between pump and motor modes  
100 rpm (default) | scalar

Shaft angular velocity below which the block begins to transition between motoring and pumping modes. The block uses the hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Cross-sectional area at ports A and B** — Flow area at the component inlet and outlet  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the component inlet and outlet. The areas are assumed equal.

**Check if operating beyond the octants of supplied tabulated data** — Simulation warning mode for operating conditions outside the range of tabulated data  
None (default) | Warning

Simulation warning mode for operating conditions outside the range of tabulated data. Select **Warning** to be notified when the fluid pressure drop, shaft angular velocity, or instantaneous displacement cross outside the specified tabular data. The warning does not cause simulation to stop.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Check if operating outside of motor mode** — Simulation warning mode for operating conditions outside motoring mode

None (default) | Warning

Simulation warning mode for operating conditions outside the motoring mode. The block generates a warning if the motor transitions to pumping mode. Select **Warning** to be notified when this transition occurs. The warning does not cause simulation to stop.

Pumps and Motors

## Description

The Variable-Displacement Pressure-Compensated Pump block represents a positive, variable-displacement, pressure-compensated pump of any type as a data-sheet-based model. The key parameters required to parameterize the block are the pump maximum displacement, regulation range, volumetric and total efficiencies, nominal pressure, and angular velocity. All these parameters are generally provided in the data sheets or catalogs.

The following figure shows the delivery-pressure characteristic of the pump.

The pump tries to maintain preset pressure at its outlet by adjusting its delivery flow in accordance with the system requirements. If pressure differential across the pump is less than the setting pressure, the pump outputs its maximum delivery corrected for internal leakage. After the pressure setting has been reached, the output flow is regulated to maintain preset pressure by changing the pump's displacement. The displacement can be changed from its maximum value down to zero, depending upon system flow requirements. The pressure range between the preset pressure and the maximum pressure, at which the displacement is zero, is referred to as regulation range. The smaller the range, the higher the accuracy at which preset pressure is maintained. The range size also affects the pump stability, and decreasing the range generally causes stability to decrease.

The variable-displacement, pressure-compensated pump is represented with the following equations:

$$q = D \cdot \omega - k_{leak} \cdot p$$

$$T = D \cdot p / \eta_{mech}$$

$$D = \begin{cases} D_{max} & \text{for } p \leq p_{set} \\ D_{max} - K(p - p_{set}) & \text{for } p_{set} < p < p_{max} \\ 0 & \text{for } p \geq p_{max} \end{cases}$$

$$p_{max} = p_{set} + p_{reg}$$

$$K = D_{max} / (p_{max} - p_{set})$$

$$k_{leak} = \frac{k_{HP}}{\nu \cdot \rho}$$

$$k_{HP} = \frac{D_{max} \cdot \omega_{nom}(1 - \eta_V) \cdot \nu_{nom} \cdot \rho_{nom}}{p_{nom}}$$

$$p = p_P - p_T$$

where

$q$	Pump delivery
$p$	Pressure differential across the pump
$p_P, p_T$	Gauge pressures at the block terminals
$D$	Pump instantaneous displacement
$D_{max}$	Pump maximum displacement
$p_{set}$	Pump setting pressure
$p_{max}$	Maximum pressure, at which the pump displacement is zero
$T$	Torque at the pump driving shaft
$\omega$	Pump angular velocity
$k_{leak}$	Leakage coefficient
$k_{HP}$	Hagen-Poiseuille coefficient
$\eta_V$	Pump volumetric efficiency
$\eta_{mech}$	Pump mechanical efficiency

$\nu$	Fluid kinematic viscosity
$\rho$	Fluid density
$\rho_{nom}$	Nominal fluid density
$p_{nom}$	Pump nominal pressure
$\omega_{nom}$	Pump nominal angular velocity
$\nu_{nom}$	Nominal fluid kinematic viscosity

The leakage flow is determined based on the assumption that it is linearly proportional to the pressure differential across the pump and can be computed by using the Hagen-Poiseuille formula

$$p = \frac{128\mu l}{\pi d^4} q_{leak} = \frac{\mu}{k_{HP}} q_{leak}$$

where

$q_{leak}$	Leakage flow
$d, l$	Geometric parameters of the leakage path
$\mu$	Fluid dynamic viscosity, $\mu = \nu\rho$

The leakage flow at  $p = p_{nom}$  and  $\nu = \nu_{nom}$  can be determined from the catalog data

$$q_{leak} = D_{max} \cdot \omega_{nom}(1 - \eta_V)$$

which provides the formula to determine the Hagen-Poiseuille coefficient

$$k_{HP} = \frac{D_{max} \cdot \omega_{nom}(1 - \eta_V) \cdot \nu_{nom} \cdot \rho_{nom}}{p_{nom}}$$

The pump mechanical efficiency is not usually available in data sheets, therefore it is determined from the total and volumetric efficiencies by assuming that the hydraulic efficiency is negligibly small

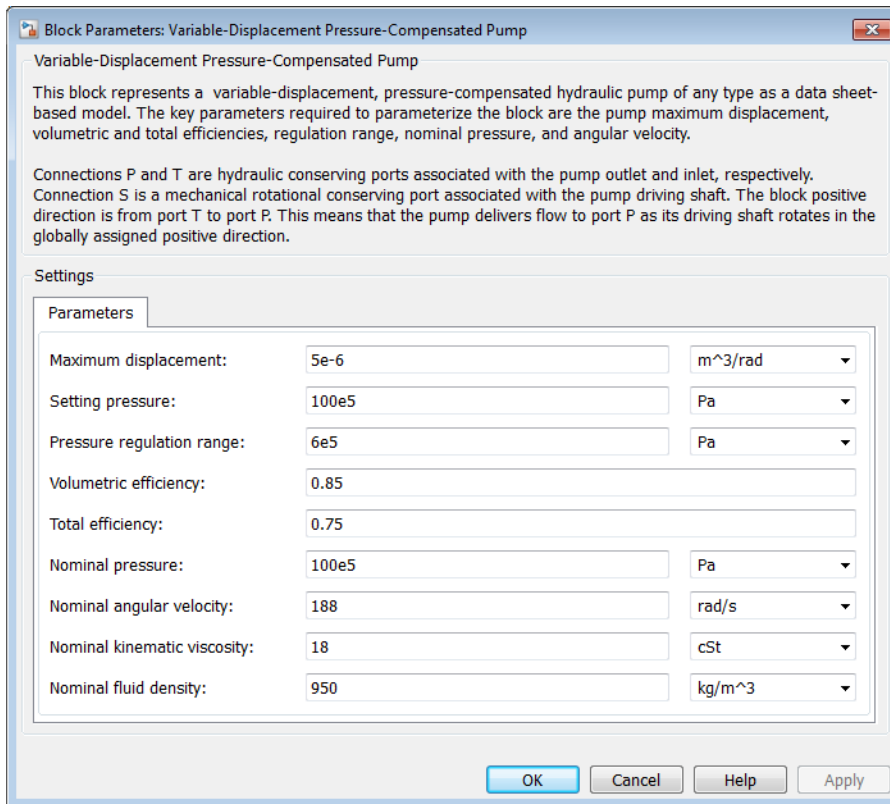

$$\eta_{mech} = \eta_{total} / \eta_V$$

The block positive direction is from port T to port P. This means that the pump transfers fluid from T to P provided that the shaft S rotates in the positive direction. The pressure differential across the pump is determined as  $p = p_P - p_T$ .

## Basic Assumptions and Limitations

- Fluid compressibility is neglected.
- No loading on the pump shaft, such as inertia, friction, spring, and so on, is considered.
- Leakage inside the pump is assumed to be linearly proportional to its pressure differential.

## Dialog Box and Parameters

### Maximum displacement

Pump displacement. The default value is  $5e-6 \text{ m}^3/\text{rad}$ .

### Setting pressure

Pump pressure setting. The default value is  $1e7 \text{ Pa}$ .

### Pressure regulation range

Pressure range required to change the pump displacement from its maximum to zero. The default value is  $6e5 \text{ Pa}$ .

### Volumetric efficiency

Pump volumetric efficiency specified at nominal pressure, angular velocity, and fluid viscosity. The default value is  $0.85$ .

### Total efficiency

Pump total efficiency, which is determined as a ratio between the hydraulic power at the pump outlet and mechanical power at the driving shaft at nominal pressure, angular velocity, and fluid viscosity. The default value is  $0.75$ .

### Nominal pressure

Pressure differential across the pump, at which both the volumetric and total efficiencies are specified. The default value is  $1e7 \text{ Pa}$ .

### Nominal angular velocity

Angular velocity of the driving shaft, at which both the volumetric and total efficiencies are specified. The default value is  $188 \text{ rad/s}$ .

**Nominal kinematic viscosity**

Working fluid kinematic viscosity, at which both the volumetric and total efficiencies are specified. The default value is 18 cSt.

**Nominal fluid density**

Working fluid density, at which both the volumetric and total efficiencies are specified. The default value is 900 kg/m<sup>3</sup>.

**Global Parameters**

Parameter determined by the type of working fluid:

- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

T

Hydraulic conserving port associated with the pump suction, or inlet.

P

Hydraulic conserving port associated with the pump outlet.

S

Mechanical rotational conserving port associated with the pump driving shaft.

**Examples**

The “Closed-Loop Actuator with Variable-Displacement Pressure-Compensated Pump” example illustrates the use of the Variable-Displacement Pressure-Compensated Pump block in hydraulic systems.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Pumps and Motors

## Description

The Variable-Displacement Pump block represents a device that extracts power from a mechanical rotational network and delivers it to a hydraulic (isothermal liquid) network. The pump displacement varies in proportion to the physical signal specified at port C or D. The exact port used depends on the block variant selected. See “Ports” on page 1-2155.

Ports **T** and **P** represent the pump inlets. Port **S** represents the pump drive shaft. During normal operation, the pressure gain from port **T** to port **P** is positive if the angular velocity at port **S** is positive also. This operation mode is referred to here as *forward pump*.

## Operation Modes

A total of four operation modes are possible. The working mode depends on the pressure gain from port **T** to port **P** ( $\Delta p$ ), the angular velocity at port **S** ( $\omega$ ), and on the instantaneous displacement of the

component ( $D$ ). The “Operation Modes” on page 1-2148 figure maps the modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart. The modes are labeled 1-4:

- Mode 1: forward pump — A positive shaft angular velocity generates a positive pressure gain.
- Mode 2: reverse motor — A negative pressure drop (shown in the figure as a positive pressure gain) generates a negative shaft angular velocity.
- Mode 3: reverse pump — A negative shaft angular velocity generates a negative pressure gain.
- Mode 4: forward motor — A positive pressure drop (shown in the figure as a negative pressure gain) generates a positive shaft angular velocity.

The response time of the pump is considered negligible in comparison with the system response time. The pump is assumed to reach steady state nearly instantaneously and is treated as a quasi-steady component.

### Block Variants and Loss Parameterizations

The pump model accounts for power losses due to leakage and friction. Leakage is internal and occurs between the pump inlet and outlet only. The block computes the leakage flow rate and friction torque using your choice of five loss parameterizations. You select a parameterization using block variants and, in the Analytical or tabulated data case, the **Leakage and friction parameterization** parameter.

### Loss Parameterizations

The block provides three Simscape variants to select from. To change the active block variant, use the **Modeling option** parameter. The available variants are:

- Analytical or tabulated data — Obtain the mechanical and volumetric efficiencies or losses from analytical models based on nominal parameters or from tabulated data. Use the **Leakage and friction parameterization** parameter to select the exact input type.
- Input efficiencies — Provide the mechanical and volumetric efficiencies directly through physical signal input ports.
- Input losses — Provide the mechanical and volumetric losses directly through physical signal input ports. The mechanical loss is defined as the internal friction torque. The volumetric loss is defined as the internal leakage flow rate.

### Displacement Parameterizations

The displacement volume input depends on the block variant selected. If the active block variant is Input efficiencies or Input losses, the block obtains the instantaneous displacement volume directly from the physical signal input at port D.

If the active block variant is **Analytical** or **tabulated data**, the block computes the instantaneous displacement volume from the control member position specified at port C. This computation depends on the **Displacement parameterization** parameter setting:

- **Maximum displacement and control member stroke** — Compute the displacement volume per unit rotation as a linear function of the control member position specified at port C.
- **Displacement vs. control member position table** — Compute the displacement volume per unit volume using interpolation or extrapolation of displacement tabular data specified at discrete control member positions.

### **Flow Rate and Driving Torque**

The volumetric flow rate generated at the pump is

$$q = q_{\text{Ideal}} + q_{\text{Leak}},$$

where:

- $q$  is the net volumetric flow rate.
- $q_{\text{Ideal}}$  is the ideal volumetric flow rate.
- $q_{\text{Leak}}$  is the internal leakage volumetric flow rate.

The driving torque required to power the pump is

$$\tau = \tau_{\text{Ideal}} + \tau_{\text{Friction}},$$

where:

- $\tau$  is the net driving torque.
- $\tau_{\text{Ideal}}$  is the ideal driving torque.
- $\tau_{\text{Friction}}$  is the friction torque.

### **Ideal Flow Rate and Ideal Torque**

The ideal volumetric flow rate is

$$q_{\text{Ideal}} = D_{\text{Sat}} \cdot \omega,$$

and the ideal driving torque is

$$\tau_{\text{Ideal}} = D_{\text{Sat}} \cdot \Delta p,$$

where:

- $D_{\text{Sat}}$  is a smoothed displacement computed so as to remove numerical discontinuities between negative and positive displacements.
- $\omega$  is the instantaneous angular velocity of the rotary shaft.
- $\Delta p$  is the instantaneous pressure gain from inlet to outlet.

### **Saturation Displacement**

The saturation displacement depends on the block variant selected. If the active variant is **Analytical** or **tabulated data**,

$$D_{\text{Sat}} = \begin{cases} \text{sign}(D) \cdot D_{\text{Max}}, & |D| \geq D_{\text{Max}} \\ \sqrt{D^2 + D_{\text{Threshold}}^2}, & D \geq 0 \\ -\sqrt{D^2 + D_{\text{Threshold}}^2}, & D < 0 \end{cases},$$

where:

- $D$  is the instantaneous fluid displacement determined from the physical signal input specified at port **C** or port **D**.
- $D_{\text{Max}}$  is the specified value of the **Maximum displacement** block parameter.
- $D_{\text{Threshold}}$  is the specified value of the **Displacement threshold for pump-motor transition** block parameter.

If the active variant is **Input efficiencies** or **Input losses**, there is no upper bound on the displacement input and the saturation displacement reduces to:

$$D_{\text{Sat}} = \begin{cases} \sqrt{D^2 + D_{\text{Thresh}}^2}, & D \geq 0 \\ -\sqrt{D^2 + D_{\text{Thresh}}^2}, & D < 0 \end{cases}.$$

### Leakage Flow Rate and Friction Torque

The internal leakage flow rate and friction torque calculations depend on the block variant selected. If the block variant is **Analytical** or **tabulated data**, the calculations depend also on the **Leakage and friction parameterization** parameter setting. There are five possible permutations of block variant and parameterization settings.

### Case 1: Analytical Efficiency Calculation

If the active block variant is **Analytical** or **tabulated data** and the **Leakage and friction parameterization** parameter is set to **Analytical**, the leakage flow rate is

$$q_{\text{Leak}} = K_{\text{HP}} \Delta p,$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}} \left| \frac{D_{\text{Sat}}}{D_{\text{Max}}} \right| |\Delta p| \right) \tanh \left( \frac{4\omega}{\omega_{\text{Thresh}}} \right),$$

where:

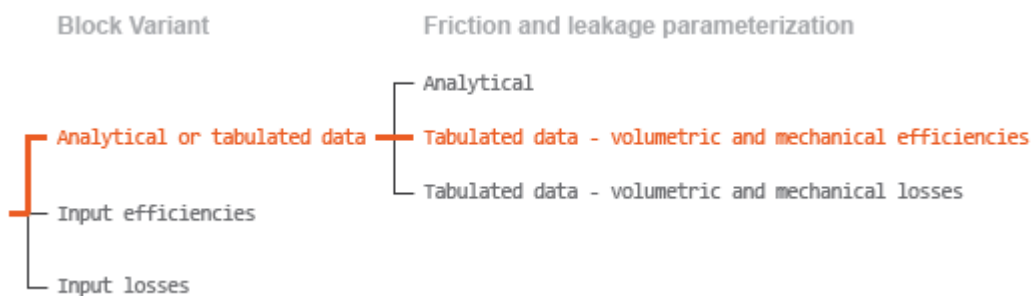

- $K_{HP}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. This coefficient is computed from the specified nominal parameters.
- $K_{TP}$  is the specified value of the **Friction torque vs pressure gain coefficient** block parameter.
- $\tau_0$  is the specified value of the **No-load torque** block parameter.
- $\omega_{Threshold}$  is the threshold angular velocity for the motor-pump transition. The threshold angular velocity is an internally set fraction of the specified value of the **Nominal shaft angular velocity** block parameter.

The Hagen-Poiseuille coefficient is determined from nominal fluid and component parameters through the equation

$$K_{HP} = \frac{\nu_{Nom}}{\rho v} \frac{\rho_{Nom} \omega_{Nom} D_{Max}}{\Delta p_{Nom}} (1 - \eta_{v,Nom}),$$

where:

- $\nu_{Nom}$  is the specified value of the **Nominal kinematic viscosity** block parameter. This is the kinematic viscosity at which the nominal volumetric efficiency is specified.
- $\rho_{Nom}$  is the specified value of the **Nominal fluid density** block parameter. This is the density at which the nominal volumetric efficiency is specified.
- $\omega_{Nom}$  is the specified value of the **Nominal shaft angular velocity** block parameter. This is the angular velocity at which the nominal volumetric efficiency is specified.
- $\rho$  is the actual fluid density in the attached hydraulic (isothermal liquid) network. This density can differ from the specified value of the **Nominal fluid density** block parameter.
- $\nu$  is the kinematic viscosity of the fluid associated with the fluid network.
- $\Delta p_{Nom}$  is the specified value of the **Nominal pressure gain** block parameter. This is the pressure drop at which the nominal volumetric efficiency is specified.
- $\eta_{v,Nom}$  is the specified value of the **Volumetric efficiency at nominal conditions** block parameter. This is the volumetric efficiency corresponding to the specified nominal conditions.

### Case 2: Efficiency Tabulated Data

If the active block variant is Analytical or tabulated data and the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies, the leakage flow rate is

$$q_{Leak} = q_{Leak,Pump} \frac{(1 + \alpha)}{2} + q_{Leak,Motor} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction,Pump}} \frac{1 + \alpha}{2} + \tau_{\text{Friction,Motor}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $q_{\text{Leak,Pump}}$  is the leakage flow rate in pump mode.
- $q_{\text{Leak,Motor}}$  is the leakage flow rate in motor mode.
- $\tau_{\text{Friction,Pump}}$  is the friction torque in pump mode.
- $\tau_{\text{Friction,Motor}}$  is the friction torque in motor mode.

The smoothing parameter  $\alpha$  is given by the hyperbolic function

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4D}{D_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the specified value of the **Pressure drop threshold for motor-pump transition** block parameter.
- $\omega_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for motor-pump transition** block parameter.
- $D_{\text{Threshold}}$  is the specified value of the **Displacement threshold for motor-pump transition** block parameter.

The leakage flow rate is computed from efficiency tabulated data through the equation

$$q_{\text{Leak,Pump}} = (1 - \eta_v)q_{\text{Ideal}},$$

in pump mode and through the equation

$$q_{\text{Leak,Motor}} = -(1 - \eta_v)q,$$

in motor mode, where:

- $\eta_v$  is the volumetric efficiency obtained through interpolation or extrapolation of the **Volumetric efficiency table, e\_v(dp,w,D)** parameter data.

Similarly, the friction torque is computed from efficiency tabulated data through the equation

$$\tau_{\text{Friction,Pump}} = (1 - \eta_m)\tau,$$

in pump mode and through the equation

$$\tau_{\text{Friction,Motor}} = -(1 - \eta_m)\tau_{\text{Ideal}},$$

in motor mode, where:

- $\eta_m$  is the mechanical efficiency obtained through interpolation or extrapolation of the **Mechanical efficiency table, e\_m(dp,w,D)** parameter data.

**Case 3: Loss Tabulated Data**

If the active block variant is Analytical or tabulated data and the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses, the leakage flow rate equation is

$$q_{Leak} = q_{Leak}(\Delta p, \omega, D_{Sat}) .$$

and the friction torque equation is

$$\tau_{Friction} = \tau_{Friction}(\Delta p, \omega, D_{Sat}),$$

where  $q_{Leak}(\Delta p, \omega, D_{Sat})$  and  $\tau_{Friction}(\Delta p, \omega, D_{Sat})$  are the volumetric and mechanical losses, obtained through interpolation or extrapolation of the **Volumetric loss table, q\_loss(dp,w,D)** and **Mechanical loss table, torque\_loss (dp,w,D)** parameter data.

**Case 4: Efficiency Physical Signal Inputs**

If the active block variant is Input efficiencies, the leakage flow rate and friction torque calculations are as described for efficiency tabulated data (case 2). The volumetric and mechanical efficiency lookup tables are replaced with physical signal inputs that you specify through ports EV and EM.

### Case 5: Loss Physical Signal Inputs

If the block variant is `Input losses`, the leakage flow rate and friction torque calculations are as described for loss tabulated data (case 3). The volumetric and mechanical loss lookup tables are replaced with physical signal inputs that you specify through ports `LV` and `LM`.

#### Assumptions

- Fluid compressibility is negligible.
- Loading on the pump shaft due to inertia, friction, and spring forces is negligible.

### Ports

#### Input

**C** — Control member offset, m  
physical signal

Physical signal input port for the control member position. The block maps the control member offset to the corresponding displacement volume using the tabulated data specified in the block dialog box.

#### Dependencies

This port is exposed only when the block variant is set to `Analytical` or `tabulated data`.

**D** — Displacement volume,  $\text{cm}^3/\text{rev}$   
physical signal

Physical signal input port for the volume of fluid displaced per unit rotation. A smoothing function eases the transition between positive and negative input values.

#### Dependencies

This port is exposed only when the block variant is set to `Input efficiencies` or `Input losses`.

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

**Dependencies**

This port is exposed only when the block variant is set to Input efficiencies.

**EM** — Mechanical efficiency, unitless

physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

**Dependencies**

This port is exposed only when the block variant is set to Input efficiencies.

**LV** — Volumetric loss, m<sup>3</sup>/s

physical signal

Physical signal input port for the volumetric loss, defined as the internal leakage flow rate between the pump inlets.

**Dependencies**

This port is exposed only when the block variant is set to Input losses.

**LM** — Mechanical loss, N\*m

physical signal

Physical signal input port for the mechanical loss, defined as the friction torque on the rotating pump shaft.

**Dependencies**

This port is exposed only when the block variant is set to Input losses.

**Conserving**

**T** — Pump inlet

hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing the pump inlet.

**P** — Pump outlet

hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing the pump outlet.

**S** — Pump shaft

mechanical rotational

Mechanical rotational conserving port representing the pump shaft.

**Parameters**

The exposed block parameters depend on the active block variant. See “Block Variants and Loss Parameterizations” on page 1-2149.

**Modeling option** — Loss parameterizations

Analytical or tabulated data | Input efficiencies | Input losses

Set the variant for mechanical and volumetric efficiencies or losses for the block.

**Variant 1: Analytical or tabulated data****Displacement parameterization** — Parameterization used to map control positions to displacements

Maximum displacement and control member stroke (default)

Parameterization used to convert the physical signal at input port C to an instantaneous displacement:

- **Maximum displacement and control member stroke** — Compute the displacement as a linear function of the control position specified at port C.
- **Displacement vs. control member position table** — Obtain the displacement through interpolation or extrapolation of tabulated data specified over a range of control positions.

**Restricted Parameter**

This parameter is locked for editing when using the Simscape Restricted mode.

**Maximum stroke** — Control position corresponding to maximum displacement

0.005 m (default) | scalar with units of length

Control position corresponding to a maximum displacement. The physical signal input at port C saturates at this value. If the input rises higher, the block sets the control position to the maximum stroke.

**Maximum displacement** — Maximum fluid volume swept per unit shaft rotation30 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Maximum fluid volume swept per unit shaft rotation. The displacement reaches this value when the control position hits the maximum stroke.

**Dependencies**This parameter is enabled when the **Displacement parameterization** parameter is set to Maximum displacement and control member stroke.**Control member position vector** — Control positions at which to specify displacement tabular data[-0.0075, -0.0025, 0.0, 0.0025, 0.0075] m (default) | *M*-element vector with units of length*M*-element vector of control positions at which to specify the instantaneous displacement. The vector size, *M*, must be two or greater. The vector elements need not be uniformly spaced. However, they must be monotonically increasing or decreasing.**Dependencies**This parameter is enabled when the **Displacement parameterization** parameter is set to Displacement vs. control member position table.**Displacement vector** — Displacement tabular data for the specified control positions[-30.0, -19.0, 0.0, 19.0, 30.0] cm<sup>3</sup>/rev (default) | *M*-element vector with units of volume/angle

$M$ -element vector with the displacement tabular data for the specified control positions. The vector size,  $M$ , must match that of the **Control member position vector** parameter.

**Dependencies**

This parameter is enabled when the **Displacement parameterization** parameter is set to **Displacement vs. control member position table**.

**Interpolation method** — Numerical technique used to determine displacements within the tabular data range

Linear (default) | Smooth

Numerical technique used to map control position signals to displacements within the tabular data range. The interpolation method joins tabular data points using straight or curved line segments. Displacements within the range of the tabular data are assumed to lie on these segments.

- **Linear** — Join neighboring data points using straight line segments. Line slopes are generally discontinuous at the line segment end points.
- **Smooth** — Join neighboring data points using curved line segments generated with a modified Akima algorithm. Line slopes are continuous at the line segment end points.

**Dependencies**

This parameter is enabled when the **Displacement parameterization** parameter is set to **Displacement vs. control member position table**.

**Restricted Parameter**

This parameter is locked for editing when using the Simscape Restricted mode.

**Extrapolation method** — Numerical technique used to determine displacements outside the tabular data range

Linear (default) | Nearest

Numerical technique used to map control position signals to displacements outside the tabular data range. The extrapolation method extends the first and last tabular data points outward using horizontal or sloped straight line segments. Displacements outside the range of the tabular data are assumed to lie on these segments.

- **Linear** — Extend the tabular data using sloped straight line segments. The line slopes are computed from the first and last two tabular data points.
- **Nearest** — Extend the tabular data using horizontal straight line segments. The lines correspond to the displacements specified in the first and last tabular data points.

**Dependencies**

This parameter is enabled when the **Displacement parameterization** parameter is set to **Displacement vs. control member position table**.

**Restricted Parameter**

This parameter is locked for editing when using the Simscape Restricted mode.

**Leakage and friction parameterization** — Parameterization used to compute leakage flow rate and friction torque

Analytical (default) | Tabulated data – volumetric and mechanical efficiencies |  
Tabulated data – volumetric and mechanical losses

Parameterization used to compute flow-rate and torque losses due to internal leaks and friction. The Analytical parameterization relies on nominal parameters generally available from component data sheets. The remaining, tabular, options rely on lookup tables to map pressure drop, angular velocity, and displacement to component efficiencies or losses. The tabular options include:

- Tabulated data – volumetric and mechanical efficiencies
- Tabulated data – volumetric and mechanical losses

**Nominal shaft angular velocity** — Shaft angular velocity at which to specify the volumetric efficiency

188 rad/s (default) | scalar with units of angle/time

Angular velocity of the rotating shaft at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using simple linear functions, the leakage flow rate and friction torque.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Nominal pressure gain** — Pressure gain at which to specify the volumetric efficiency

100e5 Pa (default)

Pressure gain from inlet to outlet at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Nominal kinematic viscosity** — Kinematic viscosity at which to specify the volumetric efficiency

18 cSt (default) | scalar with units of area/time

Kinematic viscosity of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Nominal fluid density** — Fluid density at which to specify the volumetric efficiency

900 kg/m<sup>3</sup> (default) | scalar with units of mass/volume

Mass density of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at the specified nominal conditions

0.92 (default) | unitless scalar between 0 and 1

Volumetric efficiency, defined as the ratio of actual to ideal volumetric flow rates, at the specified nominal conditions. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation

0.05 N\*m (default) | scalar with units of torque

Torque required to overcome seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Friction torque vs. pressure gain coefficient at maximum displacement** — Proportionality constant at maximum displacement between friction torque and pressure gain

0.6e-6 N\*m/Pa (default) | scalar with units of torque/pressure

Proportionality constant at maximum displacement between the friction torque on the mechanical shaft and the pressure gain from inlet to outlet.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Displacement threshold for pump—motor transition** — Displacement at which to initiate the transition between pumping and motoring modes

0.5 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Absolute value of the instantaneous displacement below which the component transitions between pumping and motoring modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### Dependencies

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

**Pressure gain vector for efficiencies, dp** — Pressure gains at which to specify the volumetric and mechanical efficiencies  
 $M$ -element vector with units of pressure (default)

$M$ -element vector of pressure gains at which to specify the efficiency tabular data. The vector size,  $M$ , must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies**.

**Shaft angular velocity vector for efficiencies, w** — Angular velocities at which to specify the volumetric and mechanical efficiencies  
 $N$ -element vector with units of angular velocity (default)

$N$ -element vector of shaft angular velocities at which to specify the efficiency tabular data. The vector size,  $N$ , must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies**.

**Displacement vector for efficiencies, D** — Displacements at which to specify the volumetric and mechanical efficiencies  
 $L$ -element vector with units of volume/angle (default)

$L$ -element vector of displacements at which to specify the efficiency tabular data. The vector size,  $N$ , must be two or greater. The vector elements need not be uniformly spaced. However, they must be monotonically increasing or decreasing.

**Volumetric efficiency table,  $e_v(dp,w,D)$**  — Volumetric efficiencies at the specified pressure gains, angular velocities, and displacements

unitless  $M$ -by- $N$ -by- $L$  matrix

$M$ -by- $N$ -by- $L$  matrix with the volumetric efficiencies at the specified fluid pressure gains, shaft angular velocities, and displacements. The efficiencies must fall in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector for efficiencies,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for efficiencies,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to `Tabulated data – volumetric and mechanical efficiencies`.

**Mechanical efficiency table,  $e_m(dp,w,D)$**  — Mechanical efficiencies at the specified pressure drops, angular velocities, and displacements

unitless  $M$ -by- $N$  matrix

$M$ -by- $N$ -by- $L$  matrix with the mechanical efficiencies corresponding to the specified fluid pressure gains, shaft angular velocities, and displacements. The efficiencies must fall in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector for efficiencies,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for efficiencies,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to `Tabulated data – volumetric and mechanical efficiencies`.

**Pressure gain threshold for pump—motor transition** — Pressure gain at which to initiate a smooth transition between motor and pump modes

1e5 Pa (default) | scalar with units of pressure

Pressure gain from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to `Tabulated data – volumetric and mechanical efficiencies`.

**Angular velocity threshold for pump—motor transition** — Shaft angular velocity at which to initiate a smooth transition between pump and motor modes

10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies**.

**Check if operating beyond the octants of supplied tabulated data** — Simulation warning mode for operating conditions outside the range of tabulated data

None (default) | Warning

Simulation warning mode for operating conditions outside the range of tabulated data. Select **Warning** to be notified when the fluid pressure gain, shaft angular velocity, or instantaneous displacement cross outside the specified tabular data. The warning does not cause simulation to stop.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies** or **Tabulated data – volumetric and mechanical losses**.

**Pressure gain vector for losses,  $dp$**  — Pressure gains at which to specify the volumetric and mechanical losses

*M*-element vector with units of pressure (default)

*M*-element vector of pressure gains at which to specify the loss tabular data. The vector size, *M*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical losses**.

**Shaft angular velocity vector for losses,  $w$**  — Angular velocities at which to specify the volumetric and mechanical losses

*N*-element vector with units of angle/time (default)

*N*-element vector of shaft angular velocities at which to specify the efficiency tabular data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical losses**.

**Displacement vector for losses,  $D$**  — Displacements at which to specify the volumetric and mechanical losses

*L*-element vector with units of volume/angle (default)

*L*-element vector of displacements at which to specify the loss tabular data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must be monotonically increasing or decreasing.

**Volumetric loss table,  $q\_loss(dp,w,D)$**  — Internal leakage flow rates at the specified pressure gains, angular velocities, and displacements

*M-by-N-by-L matrix with units of volume/time*

*M-by-N-by-L matrix with the volumetric gains at the specified fluid pressure drops, shaft angular velocities, and displacements. Volumetric loss is defined here as the internal leakage volumetric flow rate between port A and port B.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:*

- $M$  is the number of vector elements in the **Pressure gain vector for losses,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for losses,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w,D)$**  — Friction torques at the specified pressure gains, angular velocities, and displacements

*M-by-N-by-L matrix with units of torque*

*M-by-N-by-L matrix with the mechanical losses at the specified fluid pressure gains, shaft angular velocities, and displacements. Mechanical loss is defined here as the friction torque due to seals and internal components.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:*

- $M$  is the number of vector elements in the **Pressure gain vector for losses,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector for losses,  $D$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

#### Variant 2: Input efficiencies

**Minimum volumetric efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | unitless scalar between 0 and 1

Smallest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal falls below the minimum volumetric efficiency, the volumetric efficiency is set to the minimum volumetric efficiency.

**Maximum volumetric efficiency** — Upper saturation bound on the volumetric efficiency input signal 1 (default) | unitless scalar between 0 and 1

Largest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal rises above the maximum volumetric efficiency, the volumetric efficiency is set to the maximum volumetric efficiency.

**Minimum mechanical efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | unitless scalar between 0 and 1

Smallest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at the specified value. If the input signal falls below the minimum mechanical efficiency, the mechanical efficiency is set to the minimum mechanical efficiency.

**Maximum mechanical efficiency** — Upper saturation bound on the volumetric efficiency input signal 1 (default) | unitless scalar between 0 and 1

Largest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at the specified value. If the input signal rises above the maximum mechanical efficiency, the mechanical efficiency is set to the maximum mechanical efficiency.

**Pressure gain threshold for pump—motor transition** — Pressure gain at which to initiate a smooth transition between motor and pump modes  
1e5 Pa (default) | scalar with units of pressure

Pressure gain from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Angular velocity threshold for pump—motor transition** — Angular velocity at which to initiate a smooth transition between pump and motor modes  
10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Displacement threshold for motor-pump transition** — Displacement at which to initiate a smooth transition between pump and motor modes  
0.5 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Absolute value of the instantaneous displacement below which the component transitions between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select Warning to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### Dependencies

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to Warning.

**Variant 3: Input losses**

**Pressure gain threshold for pump—motor transition** — Pressure gain at which to initiate a smooth transition between motor and pump modes  
1e5 Pa (default) | scalar with units of pressure

Pressure gain from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Angular velocity threshold for pump—motor transition** — Angular velocity at which to initiate a smooth transition between pump and motor modes  
10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Displacement threshold for pump—motor transition** — Displacement below which the transition between pumping and motoring modes begins  
0.5 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Absolute value of the instantaneous displacement below which the component transitions between pumping and motoring modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if operating beyond the pump mode** — Simulation warning mode for operating conditions outside pumping mode  
None (default) | Warning

Simulation warning mode for operating conditions outside the pumping mode. A warning is issued if the pump transitions to motoring mode. Select **Warning** to be notified when this transition occurs. The warning does not cause simulation to stop.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

**Dependencies**

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

## Version History

### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Extended Capabilities

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

### **See Also**

[Fixed-Displacement Pump](#) | [Fixed-Displacement Pump \(TL\)](#) | [Fixed-Displacement Motor](#) | [Variable-Displacement Motor](#) | [Fixed-Displacement Motor \(TL\)](#)

## Variable-Displacement Pump (IL)

Variable-displacement pump in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors

### Description

The Variable-Displacement Pump (IL) block models a pump with variable-volume displacement. The fluid may move from port **A** to port **B**, called *forward mode*, or from port **B** to port **A**, called *reverse mode*. Pump mode operation occurs when there is a pressure gain in the direction of the flow. Motor mode operation occurs when there is a pressure drop in the direction of the flow.

The shaft rotation corresponds to the sign of the fluid volume moving through the pump, which is received as a physical signal at port **D**. Positive fluid displacement at **D** corresponds to positive shaft rotation in forward mode. Negative fluid displacement at **D** corresponds to negative shaft angular velocity in forward mode.

### Operation Modes

The block has eight modes of operation. The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$ ; the angular velocity,  $\omega = \omega_R - \omega_C$ ; and the fluid volumetric displacement at port **D**. The figure above maps these modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart:

- Mode 1, *Forward Pump*: Positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**.
- Mode 2, *Reverse Motor*: Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and negative shaft angular velocity.

- Mode 3, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to **A**.
- Mode 4, *Forward Motor*: Flow from port **A** to **B** causes a pressure decrease from **A** to **B** and positive shaft angular velocity.
- Mode 5, *Reverse Motor*: Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and positive shaft angular velocity.
- Mode 6, *Forward Pump*: Negative shaft angular velocity causes pressure increase from **A** to **B** and flow from **A** to **B**.
- Mode 7, *Forward Motor*: Flow from port **A** to **B** causes a pressure decrease from **A** to **B** and negative shaft angular velocity.
- Mode 8, *Reverse Pump*: Positive shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to **A**.

The pump block has analytical, lookup table, and physical signal parameterizations. When using tabulated data or an input signal for parameterization, you can choose to characterize pump operation based on efficiency or losses.

The threshold parameters **Pressure gain threshold for pump-motor transition**, **Angular velocity threshold for pump-motor transition**, and **Displacement threshold for pump-motor transition** identify regions where numerically smoothed flow transition between the pump operational modes can occur. For the pressure and angular velocity thresholds, choose a transition region that provides some margin for the transition term, but which is small enough relative to the typical pump pressure gain and angular velocity so that it will not impact calculation results. For the displacement threshold, choose a threshold value that is smaller than the typical displacement volume during normal operation.

### Analytical Leakage and Friction Parameterization

If you set **Leakage and friction parameterization** to `Analytical`, the block calculates internal leakage and shaft friction from constant nominal values of shaft velocity, pressure gain, volumetric displacement, and volumetric efficiency. The leakage flow rate, which is correlated with the pressure differential over the pump, is calculated as:

$$\dot{m}_{leak} = K\rho_{avg}\Delta p,$$

where:

- $\Delta p$  is  $p_B - p_A$ .
- $\rho_{avg}$  is the average fluid density.
- $K$  is the Hagen-Poiseuille coefficient for analytical loss,

$$K = \frac{D_{nom}\omega_{nom}(1 - \eta_{v, nom})}{\Delta p_{nom}},$$

where:

- $D_{nom}$  is the **Nominal displacement**.
- $\omega_{nom}$  is the **Nominal shaft angular velocity**.
- $\eta_{nom}$  is the **Volumetric efficiency at nominal conditions**.
- $\Delta p_{nom}$  is the **Nominal pressure gain**.

The friction torque, which is related to the pump pressure differential, is calculated as:

$$\tau_{fr} = \left( \tau_0 + k \left| \Delta p \frac{D}{D_{nom}} \right| \right) \tanh \left( \frac{4\omega}{5 \times 10^{-5} \omega_{nom}} \right),$$

where:

- $\tau_0$  is the **No-load torque**.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which is determined from the **Mechanical efficiency at nominal conditions**,  $\eta_{m,nom}$ :

$$k = \frac{\tau_{fr,nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fr,nom}$  is the friction torque at nominal conditions:

$$\tau_{fr,nom} = \left( \frac{1 - \eta_{m,nom}}{\eta_{m,nom}} \right) D_{nom} \Delta p_{nom}.$$

- $\omega$  is the relative shaft angular velocity, or  $\omega_R - \omega_C$ .

### Tabulated Data Parameterizations

When using tabulated data for pump efficiencies or losses, you can provide data for one or more of the pump operational modes. The signs of the tabulated data determine the operational regime of the block. When data is provided for less than eight operational modes, the block calculates the complementing data for the other modes by extending the given data into the remaining octants.

#### The Tabulated data - volumetric and mechanical efficiencies parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \dot{m}_{leak,pump} \left( \frac{1 + \alpha}{2} \right) + \dot{m}_{leak,motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\dot{m}_{leak,pump} = (1 - \eta_v) \dot{m}_{ideal}$
- $\dot{m}_{leak,motor} = (\eta_v - 1) \dot{m}$

and  $\eta_v$  is the volumetric efficiency, which is interpolated from the user-provided tabulated data. The transition term,  $\alpha$ , is

$$\alpha = \tanh \left( \frac{4\Delta p}{\Delta p_{threshold}} \right) \tanh \left( \frac{4\omega}{\omega_{threshold}} \right) \tanh \left( \frac{4D}{D_{threshold}} \right),$$

where:

- $\Delta p$  is  $p_B - p_A$ .
- $\Delta p_{threshold}$  is the **Pressure gain threshold for pump-motor transition**.
- $\omega$  is  $\omega_R - \omega_C$ .
- $\omega_{threshold}$  is the **Angular velocity threshold for pump-motor transition**.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{fr, pump} \left( \frac{1 + \alpha}{2} \right) + \tau_{fr, motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\tau_{fr, pump} = (1 - \eta_m)\tau$
- $\tau_{fr, motor} = (\eta_m - 1)\tau_{ideal}$

and  $\eta_m$  is the mechanical efficiency, which is interpolated from the user-provided tabulated data.

### The Tabulated data - volumetric and mechanical losses parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{loss}(\Delta p, \omega, D),$$

where  $q_{loss}$  is interpolated from the **Volumetric loss table,  $q_{loss}(dp, w, D)$**  parameter, which is based on user-supplied data for pressure gain, shaft angular velocity, and fluid volumetric displacement.

The shaft friction torque is calculated as:

$$\tau_{fr} = \tau_{loss}(\Delta p, \omega, D),$$

where  $\tau_{loss}$  is interpolated from the **Mechanical loss table,  $\tau_{loss}(dp, w, D)$**  parameter, which is based on user-supplied data for pressure gain, shaft angular velocity, and fluid volumetric displacement.

### Input Signal Parameterization

When you select **Input signal - volumetric and mechanical efficiencies**, ports **EV** and **EM** are enabled. The internal leakage and shaft friction are calculated in the same way as the **Tabulated data - volumetric and mechanical efficiencies** parameterization, except that  $\eta_v$  and  $\eta_m$  are received directly at ports **EV** and **EM**, respectively.

When you select **Input signal - volumetric and mechanical losses**, ports **LV** and **LM** are enabled. These ports receive leakage flow and friction torque as positive physical signals. The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{LV} \tanh\left(\frac{4\Delta p}{p_{thresh}}\right),$$

where:

- $q_{LV}$  is the leakage flow received at port **LV**.
- $p_{thresh}$  is the **Pressure gain threshold for pump-motor transition** parameter.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{LM} \tanh\left(\frac{4\omega}{\omega_{thresh}}\right),$$

where

- $\tau_{LM}$  is the friction torque received at port **LM**.

- $\omega_{\text{thresh}}$  is the **Angular velocity threshold for pump-motor transition** parameter.

The volumetric and mechanical efficiencies range between the user-defined specified minimum and maximum values. Any values lower or higher than this range will take on the minimum and maximum specified values, respectively.

### Pump Operation

The pump flow rate is:

$$\dot{m} = \dot{m}_{\text{ideal}} - \dot{m}_{\text{leak}},$$

where  $\dot{m}_{\text{ideal}} = \rho_{\text{avg}} D \cdot \omega$ .

The pump torque is:

$$\tau = \tau_{\text{ideal}} + \tau_{fr},$$

where  $\tau_{\text{ideal}} = D \cdot \Delta p$ .

The mechanical power delivered by the pump shaft is:

$$\varphi_{\text{mech}} = \tau \omega,$$

and the pump hydraulic power is:

$$\varphi_{\text{hyd}} = \frac{\Delta p \dot{m}}{\rho_{\text{avg}}}.$$

To be notified if the block is operating beyond the supplied tabulated data, you can set **Check if operating beyond the octants of supplied tabulated data** to Warning to receive a warning if this occurs, or Error to stop the simulation when this occurs. When using input signals for volumetric or mechanical losses, you can be notified if the simulation surpasses operating modes with the **Check if operating beyond pump mode** parameter.

You can also monitor pump functionality. Set **Check if pressures are less than pump minimum pressure** to Warning to receive a warning if this occurs, or Error to stop the simulation when this occurs.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pump.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pump.

**R** — Mechanical port  
mechanical rotational

Rotating shaft angular velocity and torque.

**C** — Mechanical port  
mechanical rotational

Pump casing reference angular velocity and torque.

### Input

**D** — Volumetric displacement,  $\text{m}^3/\text{rad}$   
physical signal

Volumetric displacement of the pump, in  $\text{m}^3/\text{rad}$ , specified as a physical signal.

**EV** — Volumetric efficiency  
physical signal

Pump efficiency for fluid displacement, specified as a physical signal. The value must be between 0 and 1.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency  
physical signal

Pump efficiency for the mechanical delivery of power, specified as a physical signal. The value must be between 0 and 1.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Leakage flow rate,  $\text{m}^3/\text{s}$   
physical signal

Pump volumetric losses, in  $\text{m}^3/\text{s}$ , specified as a physical signal.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Friction torque,  $\text{N}\cdot\text{m}$   
physical signal

Pump mechanical losses in  $\text{N}\cdot\text{m}$ , specified as a physical signal.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

## Parameters

**Leakage and friction parameterization** — Method of calculating leakage flow rate and friction torque

Analytical (default) | Tabulated data - volumetric and mechanical efficiencies | Tabulated data - volumetric and mechanical losses | Input signal - volumetric and mechanical efficiencies | Input signal - volumetric and mechanical losses

Parameterization of the leakage and friction characteristics of the pump.

- In the `Analytical` parameterization, the leakage flow rate and the friction torque are calculated by analytical equations.
- In the `Tabulated data - volumetric and mechanical efficiencies` parameterization, the volumetric and mechanical efficiencies are calculated from the user-supplied **Pressure gain vector,  $dp$** , **Shaft angular velocity vector,  $w$** , and **Displacement vector,  $D$**  parameters and interpolated from the 3-D dependent **Volumetric efficiency table,  $e_v(dp,w,D)$**  and **Mechanical efficiency table,  $e_m(dp,w,D)$**  tables.
- In the `Tabulated data - volumetric and mechanical loss` parameterization, the leakage flow rate and friction torque are calculated from the user-supplied **Pressure gain vector,  $dp$** ; **Shaft angular velocity vector,  $w$** ; and **Displacement vector,  $D$**  parameters and interpolated from the 3-D dependent **Volumetric loss table,  $q\_loss(dp,w,D)$**  and **Mechanical loss table,  $torque\_loss(dp,w,D)$**  tables.
- In the `Input signal - volumetric and mechanical efficiencies` parameterization, the volumetric and mechanical efficiencies are received as physical signals at ports **EV** and **EM**, respectively.
- In the `Input signal - volumetric and mechanical loss` parameterization, the leakage flow rate and friction torque are received as physical signals at ports **LV** and **LM**, respectively.

**Nominal displacement** — Nominal fluid displacement

30 cm<sup>3</sup>/rev (default) | scalar

Amount of fluid displaced by shaft rotating under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Nominal shaft angular velocity** — Shaft angular velocity

1800 rpm (default) | scalar

Angular velocity of the shaft under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Nominal pressure gain** — Pressure drop between fluid entry and exit

10 MPa (default) | scalar

Pump pressure gain between the fluid entry and exit under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Volumetric efficiency at nominal conditions** — Ratio of actual flow rate to ideal flow rate at nominal conditions

0.92 (default) | positive scalar in the range of (0,1]

Ratio of actual flow rate to ideal flow rate at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Baseline torque

0 N\*m (default) | scalar

Minimum value of torque to overcome seal friction and induce shaft motion.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of actual to ideal mechanical power

0.88 (default) | positive scalar

Ratio of actual mechanical power to ideal mechanical power at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure gain vector,  $\mathbf{dp}$**  — Vector of pressure data for tabulated data parameterization

[.1, 1, 2] MPa (default) | 1-by- $n$  vector

Vector of pressure differential values for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector,  $\mathbf{w}$**  and the **Displacement vector,  $\mathbf{D}$**  parameters for the 3-D dependent **Volumetric efficiency table,  $\mathbf{e}_v(\mathbf{dp},\mathbf{w},\mathbf{D})$**  and **Mechanical efficiency table,  $\mathbf{e}_m(\mathbf{dp},\mathbf{w},\mathbf{D})$**  parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Shaft angular velocity vector,  $\mathbf{w}$**  — Vector of angular velocity data for tabulated data parameterization

[250, 500, 1000, 2000, 3000, 4000] rpm (default) | 1-by- $n$  vector

Vector of angular velocity data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Pressure gain vector,  $\mathbf{dp}$**  and the **Displacement vector,  $\mathbf{D}$**  parameters for the 3-D dependent **Volumetric efficiency table,  $\mathbf{e}_v(\mathbf{dp},\mathbf{w},\mathbf{D})$**  and **Mechanical efficiency table,  $\mathbf{e}_m(\mathbf{dp},\mathbf{w},\mathbf{D})$**  parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Displacement vector,  $D$**  — Vector of displacement volumes for tabulated data parameterization  
`[-30, -19, 19, 30] cm3/s (default) | 1-by- $n$  vector`

Vector of fluid volumetric displacement data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector,  $w$**  and the **Pressure gain vector,  $dp$**  parameters for the 3-D dependent **Volumetric efficiency table,  $e_v(dp,w,D)$**  and **Mechanical efficiency table,  $e_m(dp,w,D)$**  parameters. The vector elements must be listed in ascending order.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Volumetric efficiency table,  $e_v(dp,w,D)$**  — Volumetric efficiency for tabulated data parameterization

`repmat([.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91], 1, 1, 4) (default) |  $M$ -by- $N$ -by- $P$  matrix`

$M$ -by- $N$ -by- $P$  matrix of volumetric efficiencies at the specified fluid pressure gain, shaft angular velocity, and volumetric displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w,D)$**  — Mechanical efficiency for tabulated data parameterization

`repmat([.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984], 1, 1, 4) (default) |  $M$ -by- $N$ -by- $P$  matrix`

$M$ -by- $N$ -by- $P$  matrix of mechanical efficiencies at the specified fluid pressure gain, shaft angular velocity, and displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q\_loss(dp,w,D)$**  — Volumetric losses for tabulated data parameterization  
`repmat([.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] * 1e-3, 1, 1, 4)m^3/s (default) | numerical array`

$M$ -by- $N$ -by- $P$  matrix of volumetric leakage at the specified fluid pressure gain, shaft angular velocity, and displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w,D)$**  — Mechanical losses for tabulated data parameterization  
`repmat([.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0505; .1937, .1937, .1833, .1833, .1729, .1626], 1, 1, 4) N*m (default) | numerical array`

$M$ -by- $N$ -by- $P$  matrix of friction torque at the specified fluid pressure gain, shaft angular velocity, and displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical loss.

**Minimum volumetric efficiency** — Minimum value of volumetric efficiency  
`1e-3 (default) | positive scalar in the range of (0,1]`

Minimum value of volumetric efficiency. If the input signal is below this value, the volumetric efficiency is set to the minimum volumetric efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Maximum value of volumetric efficiency  
`1 (default) | positive scalar in the range of (0,1]`

Maximum value of volumetric efficiency. If the input signal is above this value, the volumetric efficiency is set to the maximum volumetric efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Minimum value of mechanical efficiency  
1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of mechanical efficiency. If the input signal is below this value, the mechanical efficiency is set to the minimum mechanical efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Maximum value of mechanical efficiency  
1 (default) | positive scalar in the range of (0,1]

Maximum value of mechanical efficiency. If the input signal is above this value, the mechanical efficiency is set to the maximum mechanical efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure gain threshold for pump-motor transition** — Pressure threshold for mode transition  
1e-3 MPa (default) | positive scalar

Pump pressure gain that indicates the transition threshold between pump and motor functionality. A transition region is defined around 0 MPa between the positive and negative values of the pressure gain threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Angular velocity threshold for pump-motor transition** — Angular velocity threshold for mode transition  
100 rpm (default) | positive scalar

Shaft angular velocity that indicates the transition threshold between motor and pump functionality. A transition region is defined around 0 rpm between the positive and negative values of the angular velocity threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical loss

**Displacement threshold for pump-motor transition** — Displacement threshold for mode transition

0.1 cm<sup>3</sup>/s (default) | positive scalar

Volumetric displacement that indicates the transition threshold between pump and motor functionality. A transition region is defined around 0 cm<sup>3</sup>/s between the positive and negative values of the displacement threshold. Within this transition region, the computed leakage flow rate and friction torque is adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other. It is also used to transition the ideal mass flow rate when the sign of **D** changes.

**Check if operating beyond the octants of supplied tabulated data** — Whether to notify if extents of supplied data are surpassed

None (default) | Warning | Error

Whether to notify if the extents of the supplied data are surpassed. Select **Warning** to be notified when the block uses values beyond the supplied data range. Select **Error** to stop the simulation when the block uses values beyond the supplied data range.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating beyond pump mode** — Whether to notify if block operates outside of the pump mode functionality

None (default) | Warning | Error

Whether to notify if the block operates outside of the pump mode functionality. Select **Warning** to be notified when the block operates in the forward or reverse motor modes. Select **Error** to stop the simulation when the block operates in the forward or reverse motor modes.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Input signal - volumetric and mechanical losses**.

**Check if pressures are less than pump minimum pressure** — Whether to notify if fluid exit pressure is low

None (default) | Warning | Error

Whether to notify if the fluid at port **A** and **B** experiences low pressure. Select **Warning** to be notified when the pressure falls below a minimum specified value. Select **Error** to stop the simulation when the pressure falls below a minimum specified value.

The parameter helps identify potential conditions for cavitation, when the fluid pressure falls below the fluid vapor pressure.

**Pump minimum pressure** — Lower threshold of acceptable pressure at the pump outlet

0.101325 MPa (default) | positive scalar

Lower threshold of acceptable pressure at the pump inlet or outlet.

**Dependencies**

To enable this parameter, set **Check if pressures are less than pump minimum pressure** to either:

- Warning
- Error

**Version History**

**Introduced in R2020a**

# Pressure-Compensated Pump (IL)

Constant-pressure, variable-displacement pump in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors

## Description

The Pressure-Compensated Pump (IL) block models a constant-pressure, variable-displacement pump in an isothermal liquid network. The pump displacement is controlled by the differential pressure,  $p_{control}$ , measured between ports **X** and **Y**. When this pressure exceeds the **Set pressure differential**, the fluid displacement is adjusted according to the pump **Leakage and friction parameterization**. The variable-displacement functionality occurs within the **Pressure regulation range** between the **Maximum displacement**, at  $p_{set}$ , and the **Minimum displacement**, at  $p_{max}$ .

The fluid may move from port **A** to port **B**, called *forward mode*, or from port **B** to port **A**, called *reverse mode*. Pump mode operation occurs when there is a pressure gain in the direction of the flow. Motor mode operation occurs when there is a pressure drop in the direction of the flow.

Shaft rotation corresponds to the sign of the fluid volume moving through the pump. Positive fluid displacement corresponds to positive shaft rotation in forward mode. Negative fluid displacement corresponds to negative shaft angular velocity in forward mode.

## Operation Modes

The block has eight modes of operation. The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$ ; the angular velocity,  $\omega = \omega_R - \omega_C$ ; and the fluid volumetric displacement, set by the pressure differential. The figure above maps these modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart:

- Mode 1, *Forward Pump*: Positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**.
- Mode 2, *Reverse Motor* : Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and negative shaft angular velocity.
- Mode 3, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to **A**.
- Mode 4, *Forward Motor*: Flow from port **A** to **B** causes a pressure decrease from **A** to **B** and positive shaft angular velocity.
- Mode 5, *Reverse Motor* : Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and positive shaft angular velocity.
- Mode 6, *Forward Pump*: Negative shaft angular velocity causes pressure increase from **A** to **B** and flow from **A** to **B**.
- Mode 7, *Forward Motor*: Flow from port **A** to **B** causes a pressure decrease from **A** to **B** and negative shaft angular velocity.
- Mode 8, *Reverse Pump*: Positive shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to **A**.

The block has analytical, lookup table, and physical signal parameterizations. When using tabulated data or an input signal for parameterization, you can choose to characterize pump operation based on efficiency or losses.

The threshold parameters **Pressure gain threshold for pump-motor transition**, **Angular velocity threshold for pump-motor transition**, and **Displacement threshold for pump-motor transition** identify regions where numerically smoothed flow transition between the pump operational modes can occur. For the pressure and angular velocity thresholds, choose a transition region that provides some margin for the transition term, but which is small enough relative to the typical pump pressure gain and angular velocity so that it will not impact calculation results. For the displacement threshold, choose a threshold value that is smaller than the typical displacement volume during normal operation.

### Analytical Leakage and Friction Parameterization

If you set **Leakage and friction parameterization** to `Analytical`, the block calculates leakage and friction from constant values for shaft velocity, pressure gain, and torque. The leakage flow rate, which is correlated with the pressure differential over the pump, is calculated as:

$$\dot{m}_{leak} = K\rho_{avg}\Delta p,$$

where:

- $\Delta p_{nom}$  is  $p_B - p_A$ .
- $\rho_{avg}$  is the average fluid density.
- $K$  is the Hagen-Poiseuille coefficient for analytical loss,

$$K = \frac{D_{nom}\omega_{nom}(1 - \eta_{v,nom})}{\Delta p_{nom}},$$

where:

- $D_{nom}$  is the **Nominal displacement**.

- $\omega_{nom}$  is the **Nominal shaft angular velocity**.
- $\eta_{nom}$  is the **Volumetric efficiency at nominal conditions**.
- $\Delta p_{nom}$  is the **Nominal pressure gain**.

The friction torque, which is related to the pump pressure differential, is calculated as:

$$\tau_{fr} = \left( \tau_0 + k \left| \Delta p \frac{D}{D_{nom}} \right| \right) \tanh \left( \frac{4\omega}{5 \times 10^{-5} \omega_{nom}} \right),$$

where:

- $\tau_0$  is the **No-load torque**.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which is determined from the **Mechanical efficiency at nominal conditions**,  $\eta_{m,nom}$ :

$$k = \frac{\tau_{fr,nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fr,nom}$  is the friction torque at nominal conditions:

$$\tau_{fr,nom} = \left( \frac{1 - \eta_{m,nom}}{\eta_{m,nom}} \right) D_{nom} \Delta p_{nom}.$$

- $\omega$  is the relative shaft angular velocity, or  $\omega_R - \omega_C$ .

### Tabulated Data Parameterizations

When using tabulated data for pump efficiencies or losses, you can provide data for one or more of the pump operational modes. The signs of the tabulated data determine the operational regime of the block. When data is provided for less than eight operational modes, the block calculates the complementing data for the other mode(s) by extending the given data into the remaining octants.

#### The Tabulated data - volumetric and mechanical efficiencies parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \dot{m}_{leak,pump} \left( \frac{1 + \alpha}{2} \right) + \dot{m}_{leak,motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\dot{m}_{leak,pump} = (1 - \eta_v) \dot{m}_{ideal}$
- $\dot{m}_{leak,motor} = (\eta_v - 1) \dot{m}$

and  $\eta_v$  is the volumetric efficiency, which is interpolated from the user-provided tabulated data. The transition term,  $\alpha$ , is

$$\alpha = \tanh \left( \frac{4\Delta p}{\Delta p_{threshold}} \right) \tanh \left( \frac{4\omega}{\omega_{threshold}} \right) \tanh \left( \frac{4D}{D_{threshold}} \right),$$

where:

- $\Delta p$  is  $p_B - p_A$ .

- $p_{\text{threshold}}$  is the **Pressure gain threshold for pump-motor transition**.
- $\omega$  is  $\omega_R - \omega_C$ .
- $\omega_{\text{threshold}}$  is the **Angular velocity threshold for pump-motor transition**.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{fr, pump} \left( \frac{1 + \alpha}{2} \right) + \tau_{fr, motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\tau_{fr, pump} = (1 - \eta_m)\tau$
- $\tau_{fr, motor} = (\eta_m - 1)\tau_{ideal}$

and  $\eta_m$  is the mechanical efficiency, which is interpolated from the user-provided tabulated data.

#### The Tabulated data - volumetric and mechanical losses parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{loss}(\Delta p, \omega, D),$$

where  $q_{loss}$  is interpolated from the **Volumetric loss table,  $q\_loss(dp,w,D)$**  parameter, which is based on user-supplied data for pressure gain, shaft angular velocity, and fluid volumetric displacement.

The shaft friction torque is calculated as:

$$\tau_{fr} = \tau_{loss}(\Delta p, \omega, D),$$

where  $\tau_{loss}$  is interpolated from the **Mechanical loss table,  $torque\_loss(dp,w,D)$**  parameter, which is based on user-supplied data for pressure gain, shaft angular velocity, and fluid volumetric displacement.

#### Input Signal Parameterization

When you select Input signal - volumetric and mechanical efficiencies, ports **EV** and **EM** are enabled. The internal leakage and shaft friction are calculated in the same way as the Tabulated data - volumetric and mechanical efficiencies parameterization, except that  $\eta_v$  and  $\eta_m$  are received directly at ports **EV** and **EM**, respectively.

When you select Input signal - volumetric and mechanical losses, ports **LV** and **LM** are enabled. These ports receive leakage flow and friction torque as positive physical signals. The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{LV} \tanh\left(\frac{4\Delta p}{p_{thresh}}\right),$$

where:

- $q_{LV}$  is the leakage flow received at port **LV**.
- $p_{thresh}$  is the **Pressure gain threshold for pump-motor transition** parameter.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{LM} \tanh\left(\frac{4\omega}{\omega_{thresh}}\right),$$

where

- $\tau_{LM}$  is the friction torque received at port **LM**.
- $\omega_{thresh}$  is the **Angular velocity threshold for pump-motor transition** parameter.

The volumetric and mechanical efficiencies range between the user-defined specified minimum and maximum values. Any values lower or higher than this range will take on the minimum and maximum specified values, respectively.

### Pump Operation

The pump flow rate is:

$$\dot{m} = \dot{m}_{ideal} - \dot{m}_{leak},$$

where  $\dot{m}_{ideal} = \rho_{avg} D \cdot \omega$ .

The pump torque is:

$$\tau = \tau_{ideal} + \tau_{fr},$$

where  $\tau_{ideal} = D \cdot \Delta p$ .

The mechanical power delivered by the pump shaft is:

$$\varphi_{mech} = \tau\omega,$$

and the pump hydraulic power is:

$$\varphi_{hyd} = \frac{\Delta p \dot{m}}{\rho_{avg}}.$$

To be notified if the block is operating beyond the supplied tabulated data, set **Check if operating beyond the octants of supplied tabulated data** to Warning to receive a warning if this occurs, or Error to stop the simulation when this occurs. For parameterization by input signal for volumetric or mechanical losses, you can be notified if the simulation surpasses operating modes with the **Check if operating beyond pump mode** parameter.

You can also monitor pump functionality. Set **Check if pressures are less than pump minimum pressure** to Warning to receive a warning if this occurs, or Error to stop the simulation when this occurs.

### Displacement Parameterization

The linear parameterization of the pump displacement is:

$$D = \hat{p}(D_{min} - D_{max}) + D_{max},$$

where the normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{control} - p_{set}}{p_{max} - p_{set}}.$$

where  $p_{max}$  is the sum of the **Set pressure differential** and the **Pressure regulation range**.

### Displacement Dynamics

If displacement dynamics are modeled, a lag is introduced to the flow response to the modeled control pressure.  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ ; otherwise,  $p_{control}$  is the steady-state pressure. The instantaneous change in dynamic control pressure is calculated based on the **Time constant**,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, **Displacement dynamics** is set to Off.

### Numerically-Smoothed Pressure

You can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the normalized control pressure between  $p_{set}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry or exit port of the liquid to or from the pump.

**B** — Liquid port  
isothermal liquid

Entry or exit port of the liquid to or from the pump.

**X** — Pressure reference  $P_x$ , MPa  
isothermal liquid

Control pressure in units of MPa, denoted  $P_x$ . The control pressure,  $P_x - P_y$ , is compared against the **Set pressure differential** to trigger or moderate variable pump displacement.

**Y** — Pressure reference  $P_y$ , MPa  
isothermal liquid

Control pressure in units of MPa, denoted  $P_y$ . The control pressure,  $P_x - P_y$ , is compared against the **Set pressure differential** to trigger or moderate variable pump displacement.

**R** — Mechanical port  
mechanical rotational

Rotating shaft angular velocity and torque.

**C** — Mechanical port  
mechanical rotational

Pump casing reference angular velocity and torque.

**EV** — Volumetric efficiency

physical signal

Pump efficiency for fluid displacement, specified as a physical signal. The value must be between 0 and 1.

**Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency

physical signal

Pump efficiency for the mechanical supply of energy, specified as a physical signal. The value must be between 0 and 1.

**Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Leakage flow rate, m<sup>3</sup>/s

physical signal

Pump losses associated with fluid displacement in m<sup>3</sup>/s, specified as a physical signal.

**Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Friction torque, N\*m

physical signal

Pump losses associated with the mechanical supply of energy in N\*m, specified as a physical signal.

**Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

## Parameters

### Pump

**Leakage and friction parameterization** — Method of calculating leakage flow rate and friction torque

Analytical (default) | Tabulated data - volumetric and mechanical efficiencies | Tabulated data - volumetric and mechanical losses | Input signal - volumetric and mechanical efficiencies | Input signal - volumetric and mechanical losses

Parameterization of the leakage and friction characteristics of the pump.

- In the **Analytical** parameterization, the leakage flow rate and the friction torque are calculated by analytical equations.
- In the **Tabulated data - volumetric and mechanical efficiencies** parameterization, the volumetric and mechanical efficiencies are calculated from the user-supplied **Pressure gain vector,  $\mathbf{dp}$** , **Shaft angular velocity vector,  $\mathbf{w}$** , and **Displacement vector,  $\mathbf{D}$**  parameters and interpolated from the 3-D **Volumetric efficiency table,  $\mathbf{e}_v(\mathbf{dp},\mathbf{w},\mathbf{D})$**  and **Mechanical efficiency table,  $\mathbf{e}_m(\mathbf{dp},\mathbf{w},\mathbf{D})$**  tables.
- In the **Tabulated data - volumetric and mechanical losses** parameterization, the leakage flow rate and friction torque are calculated from the user-supplied **Pressure gain vector,  $\mathbf{dp}$** , **Shaft angular velocity vector,  $\mathbf{w}$** , and **Displacement vector,  $\mathbf{D}$**  parameters and interpolated from the 3-D **Volumetric loss table,  $\mathbf{q\_loss}(\mathbf{dp},\mathbf{w},\mathbf{D})$**  and **Mechanical loss table,  $\mathbf{torque\_loss}(\mathbf{dp},\mathbf{w},\mathbf{D})$**  parameters.
- In the **Input signal - volumetric and mechanical efficiencies** parameterization, the volumetric and mechanical efficiencies are received as physical signals at ports **EV** and **EM**, respectively.
- In the **Input signal - volumetric and mechanical loss** parameterization, the leakage flow rate and friction torque are received as physical signals at ports **LV** and **LM**, respectively.

**Nominal displacement** — Fixed-volume fluid displacement

30 cm<sup>3</sup>/rev (default) | scalar

Amount of fluid displaced by shaft rotating under nominal operating conditions.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Nominal shaft angular velocity** — Shaft angular velocity

1800 rpm (default) | scalar

Angular velocity of the shaft under nominal operating conditions.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Nominal pressure gain** — Pressure gain between fluid entry and exit

10 MPa (default) | scalar

Pump pressure gain between the fluid entry and exit under nominal operating conditions.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Volumetric efficiency at nominal conditions** — Ratio of actual flow rate to ideal flow rate

0.92 (default) | positive scalar in the range of (0,1]

Ratio of actual flow rate to ideal flow rate at nominal conditions.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**No-load torque** — Baseline torque

0 N\*m (default) | scalar

Minimum value of torque to overcome seal friction and induce shaft motion.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of actual to ideal mechanical power  
0.88 (default) | positive scalar

Ratio of actual mechanical power to ideal mechanical power at nominal conditions.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure gain vector, dp** — Vector of pressure data for tabulated data parameterization  
[.1, 1, 2] MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** and the **Displacement vector, D** parameters for the 3-D dependent **Volumetric efficiency table, e\_v(dp,w,D)** and **Mechanical efficiency table, e\_m(dp,w,D)** parameters. The vector elements must be listed in ascending order.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Shaft angular velocity vector, w** — Vector of angular velocity data for tabulated data parameterization  
[250, 500, 1000, 2000, 3000, 4000] rpm (default) | 1-by-*n* vector

Vector of angular velocity data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Pressure gain vector, dp** and the **Displacement vector, D** parameters for the 3-D dependent **Volumetric efficiency table, e\_v(dp,w,D)** and **Mechanical efficiency table, e\_m(dp,w,D)** parameters. The vector elements must be listed in ascending order.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Displacement vector, D** — Vector of displacement volumes for tabulated data parameterization  
[-30, -19, 19, 30] cm<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of fluid volumetric displacement data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** and the **Pressure gain vector, dp** parameters for the 3-D dependent **Volumetric efficiency table, e\_v(dp,w,D)** and **Mechanical efficiency table, e\_m(dp,w,D)** parameters. The vector elements must be listed in ascending order.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Volumetric efficiency table,  $e_v(dp,w,D)$**  — Volumetric efficiency for tabulated data parameterization

```
repmat([.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91], 1, 1, 4) (default) | M-by-N-by-P matrix
```

*M*-by-*N*-by-*P* matrix of volumetric efficiencies at the specified fluid pressure gain, shaft angular velocity, and volumetric displacement. Linear interpolation is employed between table elements. *M*, *N*, and *P* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- *N* is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- *P* is the number of vector elements in the **Displacement vector,  $D$**  parameter.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w,D)$**  — Mechanical efficiency for tabulated data parameterization

```
repmat([.996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984], 1, 1, 4) (default) | M-by-N-by-P matrix
```

*M*-by-*N*-by-*P* matrix of mechanical efficiencies at the specified fluid pressure gain, shaft angular velocity, and displacement. Linear interpolation is employed between table elements. *M*, *N*, and *P* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- *N* is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- *P* is the number of vector elements in the **Displacement vector,  $D$**  parameter.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q_{loss}(dp,w,D)$**  — Volumetric losses for tabulated data parameterization

```
repmat([.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] * 1e-3, 1, 1, 4)m^3/s (default) | numerical array
```

*M*-by-*N*-by-*P* matrix of volumetric leakage at the specified fluid pressure gain, shaft angular velocity, and displacement. Linear interpolation is employed between table elements. *M*, *N*, and *P* are the sizes of the corresponding vectors:

- *M* is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.

- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical loss.

**Mechanical loss table, torque\_loss(dp,w,D)** — Mechanical losses for tabulated data parameterization

```
repmat([.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0556, .0505; .1937, .1937, .1833, .1833, .1729, .1626], 1, 1, 4) N*m (default) | numerical array
```

$M$ -by- $N$ -by- $P$  matrix of friction torque at the specified fluid pressure gain, shaft angular velocity, and displacement. Linear interpolation is employed between table elements.  $M$ ,  $N$ , and  $P$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $P$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical loss.

**Minimum volumetric efficiency** — Minimum value of volumetric efficiency

1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of volumetric efficiency. If the input signal is below this value, the volumetric efficiency is set to the minimum volumetric efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Maximum value of volumetric efficiency

1 (default) | positive scalar in the range of (0,1]

Maximum value of volumetric efficiency. If the input signal is above this value, the volumetric efficiency is set to the maximum volumetric efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Minimum value of mechanical efficiency

1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of mechanical efficiency. If the input signal is below this value, the mechanical efficiency is set to the minimum mechanical efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Maximum value of mechanical efficiency  
1 (default) | positive scalar in the range of (0,1]

Maximum value of mechanical efficiency. If the input signal is above this value, the mechanical efficiency is set to the maximum mechanical efficiency.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure gain threshold for pump-motor transition** — Pressure threshold for mode transition  
1e-3 MPa (default) | positive scalar

Threshold pressure gain value for the transition between pump and motor functionality. A transition region is defined around 0 MPa between the positive and negative values of the pressure gain threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Angular velocity threshold for pump-motor transition** — Angular velocity threshold for mode transition  
100 rpm (default) | positive scalar

Threshold angular velocity value for the transition between motor and pump functionality. A transition region is defined around 0 rpm between the positive and negative values of the angular velocity threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical loss

**Check if operating beyond the octants of supplied tabulated data** — Whether to notify if extents of supplied data are surpassed  
None (default) | Warning | Error

Whether to notify if the extents of the supplied data are surpassed. Select **Warning** to be notified when the block uses values beyond the supplied data range. Select **Error** to stop the simulation when the block uses values beyond the supplied data range.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating beyond pump mode** — Whether to notify if block operates outside of the pump mode functionality

None (default) | Warning | Error

Whether to notify if block operates outside of the pump mode functionality. Select **Warning** to be notified when the block operates in the forward or reverse motor modes. Select **Error** to stop the simulation when the block operates in the forward or reverse motor modes.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**Check if pressures are less than pump minimum pressure** — Whether to notify if fluid exit pressure is low

None (default) | Warning | Error

Whether to notify if the fluid at port **A** or **B** experiences low pressure. Select **Warning** to be notified when the outlet pressure falls below a minimum specified value. Select **Error** to stop the simulation when the outlet pressure falls below a minimum specified value.

The parameter helps to identify potential conditions for cavitation, when the fluid pressure falls below the fluid vapor pressure.

**Pump minimum pressure** — Lower threshold of acceptable pressure at the pump outlet

0.101325 MPa (default) | positive scalar

Lower threshold of acceptable pressure at the pump inlet or outlet.

#### Dependencies

To enable this parameter, set **Check if pressures are less than pump minimum pressure** to:

- Warning
- Error

#### Pressure Compensation

**Maximum displacement** — Upper limit to pump displacement

30 cm<sup>3</sup>/rev (default) | scalar

Upper limit to pump displacement.

**Minimum displacement** — Lower limit to pump displacement

0.1 cm<sup>3</sup>/rev (default) | scalar

Lower limit to pump displacement.

**Set pressure differential** — Threshold value for variable-displacement functionality  
10 MPa (default) | positive scalar

Threshold value beyond which pump displacement is adjusted.

**Pressure regulation range** — Variable-displacement operational range  
0.6 MPa (default) | positive scalar

Variable-displacement operational range. The pump operates between the **Set pressure differential** and the pump maximum pressure, which is  $p_{set} + p_{regulation}$ .

**Displacement dynamics** — Whether to account for flow response to displacement changes  
Off (default) | On

Whether to account for transient effects to the fluid system due to changes in pump fluid displacement. Setting **Displacement dynamics** to On approximates the condition change by introducing a first-order lag in the flow response. The magnitude of the **Time constant** also impacts the modeled displacement dynamics.

**Time constant** — Flow response time constant  
0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state when changing the fluid displacement. This parameter impacts the modeled displacement dynamics.

# Variable-Displacement Pump (TL)

Variable-displacement bidirectional thermal liquid pump

## Libraries:

Simscape / Fluids / Thermal Liquid / Pumps & Motors

## Description

The Variable-Displacement Pump block represents a device that extracts power from a mechanical rotational network and delivers it to a thermal liquid network. The pump displacement varies during simulation according to the physical input signal at port **D**.

Ports **A** and **B** represent the pump inlets. Ports **R** and **C** represent the drive shaft and case. During normal operation, the pressure gain from port **A** to port **B** is positive if the angular velocity at port **R** relative to port **C** is positive.

## Operating Modes

The block has four modes of operation, as shown by this image.

The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$ ; the angular velocity,  $\omega = \omega_R - \omega_C$ ; and the fluid volumetric displacement at port **D**. The figure above maps these modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart:

- The quadrant labeled **1** represents the forward pump mode. In this mode, the positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**
- The quadrant labeled **2** represents the reverse motor mode. In this mode, the flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and negative shaft angular velocity.
- The quadrant labeled **3** represents the reverse pump mode. In this mode, the negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from port **B** to port **A**

- The quadrant labeled **4** represents the forward motor mode. In this mode, the flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and positive shaft angular velocity.
- The quadrant labeled **5** represents the reverse motor mode. In this mode, the flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and positive shaft angular velocity.
- The quadrant labeled **6** represents the forward pump mode. In this mode, the negative shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**.
- The quadrant labeled **7** represents the forward motor mode. In this mode, the flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and negative shaft angular velocity.
- The quadrant labeled **8** represents the reverse pump mode. In this mode, the positive shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from port **B** to port **A**.

The response time of the pump is negligible in comparison with the system response time. The pump reaches steady state nearly instantaneously and is treated as a quasi-steady component.

### Energy Balance

The block associates the mechanical work done by the pump with an energy exchange. The governing energy balance equation is:

$$\phi_A + \phi_B + P_{hydro} = 0,$$

where:

- $\Phi_A$  and  $\Phi_B$  are the energy flow rates at ports **A** and **B**, respectively.
- $P_{hydro}$  is the pump hydraulic power, which is a function of the pressure difference between the pump ports:  $P_{hydro} = \Delta p \frac{\dot{m}}{\rho}$ .

The block generates mechanical power due to torque,  $\tau$ , and angular velocity,  $\omega$ :

$$P_{mech} = \tau\omega.$$

### Flow Rate and Driving Torque

The mass flow rate generated at the pump is

$$\dot{m} = \dot{m}_{Ideal} - \dot{m}_{Leak},$$

where:

- $\dot{m}$  is the actual mass flow rate.
- $\dot{m}_{Ideal}$  is the ideal mass flow rate.
- $\dot{m}_{Leak}$  is the internal leakage mass flow rate.

The driving torque required to power the pump is

$$\tau = \tau_{Ideal} + \tau_{Friction},$$

where:

- $\tau$  is the actual driving torque.
- $\tau_{Ideal}$  is the ideal driving torque.

- $\tau_{\text{Friction}}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal mass flow rate is

$$\dot{m}_{\text{Ideal}} = \rho D \omega,$$

and the ideal required torque is

$$\tau_{\text{Ideal}} = D \Delta p,$$

where:

- $\rho$  is the average of the fluid densities at thermal liquid ports **A** and **B**.
- $\omega$  is the shaft angular velocity.
- $\Delta p$  is the pressure gain from inlet to outlet.
- $D$  is the **Displacement** specified at physical signal port **D**.

### Leakage and friction parameterization

You can parameterize leakage and friction analytically, by using tabulated efficiencies or losses, or by using input efficiencies or input losses.

#### Analytical

When you set the **Leakage and Friction Parameterization** parameter to **Analytical**, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \frac{K_{\text{HP}} \rho_{\text{Avg}} \Delta p}{\mu_{\text{Avg}}},$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}} |\Delta p| \frac{|D|}{D_{\text{Nom}}} \tanh \frac{4\omega}{(5e - 5)\omega_{\text{Nom}}} \right),$$

where:

- $K_{\text{HP}}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. The block computes this coefficient from the specified nominal parameters.
- $\mu$  is the dynamic viscosity of the fluid, which is the average of the values at the ports.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which the block determines from the **Mechanical efficiency at nominal conditions** parameter,  $\eta_{m, \text{nom}}$ :

$$k = \frac{\tau_{fr, \text{nom}} - \tau_0}{\Delta p_{\text{nom}}}.$$

$\tau_{fr, \text{nom}}$  is the friction torque at nominal conditions:

$$\tau_{fr, \text{nom}} = \left( \frac{1 - \eta_{m, \text{nom}}}{\eta_{m, \text{nom}}} \right) D_{\text{nom}} \Delta p_{\text{nom}}.$$

- $\Delta p_{\text{Nom}}$  is the value of the **Nominal pressure gain** parameter. This value is the pressure gain at which the nominal volumetric efficiency is specified.

- $D_{\text{Nom}}$  is the value of the **Nominal Displacement** parameter.
- $\tau_0$  is the value of the **No-load torque** parameter.
- $\omega_{\text{Nom}}$  is the value of the **Nominal shaft angular velocity** parameter.

The block determines the Hagen-Poiseuille coefficient from the nominal fluid and component parameters

$$K_{\text{HP}} = \frac{D_{\text{Nom}}\omega_{\text{Nom}}\mu_{\text{Nom}}(1 - \eta_{v,\text{Nom}})}{\Delta p_{\text{Nom}}},$$

where:

- $\omega_{\text{Nom}}$  is the value of the **Nominal shaft angular velocity** parameter. This value is the angular velocity at which the block specifies the nominal volumetric efficiency.
- $\mu_{\text{Nom}}$  is the value of the **Nominal Dynamic viscosity** parameter. This value is the dynamic viscosity at which the block specifies the nominal volumetric efficiency.
- $\eta_{v,\text{Nom}}$  is the value of the **Volumetric efficiency at nominal conditions** parameter. This is the volumetric efficiency that corresponds to the specified nominal conditions.

#### Tabulated Efficiencies

When you set the **Leakage and friction parameterization** parameter to **Tabulated data - volumetric and mechanical efficiencies**, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \dot{m}_{\text{Leak,Pump}} \frac{(1 + \alpha)}{2} + \dot{m}_{\text{Leak,Motor}} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction,Pump}} \frac{1 + \alpha}{2} + \tau_{\text{Friction,Motor}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $\dot{m}_{\text{Leak,Motor}}$  is the leakage flow rate in motor mode.
- $\dot{m}_{\text{Leak,Pump}}$  is the leakage flow rate in pump mode.
- $\tau_{\text{Friction,Motor}}$  is the friction torque in motor mode.
- $\tau_{\text{Friction,Pump}}$  is the friction torque in pump mode.

This hyperbolic function describes the smoothing parameter  $\alpha$

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4D}{D_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the value of the **Pressure gain threshold for pump-motor transition** block parameter.
- $\omega_{\text{Threshold}}$  is the value of the **Angular velocity threshold for pump-motor transition** block parameter.

- $D_{\text{Threshold}}$  is the value of the **Angular velocity threshold for motor-pump transition** block parameter.

The block calculates the leakage flow rate from the volumetric efficiency, which the **Volumetric efficiency table** parameter specifies over the  $\Delta p$ - $\omega$ - $D$  domain. When operating in pump mode, the leakage flow rate is:

$$\dot{m}_{\text{Leak,Pump}} = (1 - \eta_v)\dot{m}_{\text{Ideal}},$$

where  $\eta_v$  is the volumetric efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the leakage flow rate is:

$$\dot{m}_{\text{Leak,Motor}} = -(1 - \eta_v)\dot{m}.$$

The block calculates the friction torque from the mechanical efficiency, which the **Mechanical efficiency table** parameter specifies over the  $\Delta p$ - $\omega$ - $D$  domain. When operating in pump mode, the friction torque is

$$\tau_{\text{Friction,Pump}} = (1 - \eta_m)\tau,$$

where  $\eta_m$  is the mechanical efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the friction torque is

$$\tau_{\text{Friction,Motor}} = -(1 - \eta_m)\tau_{\text{Ideal}}.$$

### Tabulated Losses

When you set the **Leakage and friction parameterization** parameter to **Tabulated data - volumetric and mechanical losses**, the block specifies the leakage volumetric flow rate in tabulated form over the  $\Delta p$ - $\omega$ - $D$  domain:

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega, D).$$

The block calculates the mass flow rate due to leakage from the volumetric flow rate:

$$\dot{m}_{\text{Leak}} = \rho q_{\text{Leak}}.$$

The block calculates the friction torque in tabulated form:

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega, D),$$

where  $q_{\text{Leak}}(\Delta p, \omega, D)$  and  $\tau_{\text{Friction}}(\Delta p, \omega, D)$  are the volumetric and mechanical losses, specified through interpolation or extrapolation of the tabulated data in the **Volumetric loss table** and **Mechanical loss table** parameters.

### Input Efficiencies

When you set the **Leakage and friction parameterization** parameter to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The block replaces the volumetric and mechanical efficiency lookup tables with the physical signal input ports **EV** and **EM**.

The efficiencies are positive quantities with values between 0 and 1. The block sets input values outside of these bounds are to 0 for inputs smaller than 0 or 1 for inputs greater than 1. The block saturates the efficiency signals at the value of the **Minimum volumetric efficiency** or **Minimum**

**mechanical efficiency** parameter and the **Maximum volumetric efficiency** or **Maximum mechanical efficiency** parameter.

### Input Losses

When you set the **Leakage and friction parameterization** parameter to `Input signal - volumetric and mechanical losses`, the leakage flow rate and friction torque calculations are identical to the `Tabulated data - volumetric and mechanical efficiencies` setting. The block replaces the volumetric and mechanical loss lookup tables with the physical signal input ports **LV** and **LM**.

The block expects the inputs to be positive and sets the signs automatically from the  $\Delta p$ - $\omega$  quadrant where the component is operating. If you provide a negative signal, the block returns zero losses.

### Assumptions and Limitations

- The block treats the pump as a quasi-steady component.
- The block ignores the effects of fluid inertia and elevation.
- The pump wall is rigid.
- The block ignores external leakage.

## Ports

### Input

**D** — Displacement volume,  $\text{cm}^3/\text{rev}$   
physical signal

Physical signal input port for the volume of fluid displaced rotation. A smoothing function eases the transition between positive and negative input values.

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to `Input signal - volumetric and mechanical efficiencies`.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to `Input signal - volumetric and mechanical efficiencies`.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss which is the internal leakage flow rate between the pump inlets.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Mechanical loss,  $N*m$   
physical signal

Physical signal input port for the mechanical loss which is the friction torque on the rotating pump shaft.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

#### Conserving

**A** — Pump inlet  
thermal liquid

Thermal liquid conserving port associated with the pump inlet.

**B** — Pump outlet  
thermal liquid

Thermal liquid conserving port associated with the pump outlet.

**C** — Pump case  
mechanical rotational

Mechanical rotational conserving port associated with the pump case.

**R** — Pump shaft  
mechanical rotational

Mechanical rotational conserving port associated with the rotational pump shaft.

#### Parameters

**Leakage and friction parameterization** — Parameterization of leakage flow rate and friction torque  
Analytical (default) | Tabulated data - volumetric and mechanical efficiencies |  
Tabulated data - volumetric and mechanical losses | Input signal - volumetric  
and mechanical efficiencies | Input signal - volumetric and mechanical losses

Method to compute the flow-rate and torque losses due to internal leaks and friction. Use the Analytical if the block parameters are generally available from component data sheets. When you select Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses, the block uses lookup tables to map pressure gain, angular velocity, and displacement to component efficiencies or losses.

When you select **Input signal - volumetric and mechanical efficiencies** or **Input signal - volumetric and mechanical losses**, the block performs the leakage flow rate and friction torque calculations the same as the **Tabulated data - volumetric and mechanical efficiencies** or **Tabulated data - volumetric and mechanical losses** settings, respectively. When you select **Input signal - volumetric and mechanical efficiencies**, the block enables the **EV** and **EM** ports. You use these ports to specify the volumetric and mechanical efficiency. When you select **Input signal - volumetric and mechanical losses**, the block enables the **LV** and **LM** ports. You use these ports to specify the volumetric and mechanical losses.

**Nominal displacement** — Displacement at which to specify volumetric efficiency  
30 cm<sup>3</sup>/rev (default) | positive scalar

Fluid displacement for a given volumetric efficiency. These values are typically available at standard operating conditions in the manufacturer data sheet. The block uses this parameter to calculate the leakage flow rate and friction torque.

**Nominal shaft angular velocity** — Shaft angular velocity for given volumetric efficiency  
1800 rpm (default) | scalar

Angular velocity of the rotary shaft that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the leakage flow rate and friction torque.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Nominal pressure gain** — Pressure gain for corresponding volumetric efficiency  
10 MPa (default) | scalar

Pressure gain that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Nominal dynamic viscosity** — Dynamic viscosity at which to specify the volumetric efficiency  
0.9 cP (default) | scalar

Dynamic viscosity of the hydraulic fluid for the given volumetric efficiency. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at specified nominal conditions  
0.92 (default) | scalar in the range (0,1)

Volumetric efficiency for the given conditions. The block defines the volumetric efficiency as the ratio of actual to ideal volumetric flow rates. The standard operating conditions in the manufacturer data

sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of ideal-to-actual mechanical power  
0.88 (default) | positive scalar

Ratio of ideal mechanical power to actual mechanical power at nominal conditions.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation  
0 N\*m (default) | scalar

Torque to overcome the seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure gain vector, dp** — Pressure gains for given volumetric and mechanical efficiencies or losses  
[.1, 1, 2] MPa (default) | vector

Pressure gains for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to “Operating Modes” on page 1-2195 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Shaft angular velocity vector, w** — Angular velocities at which to specify volumetric and mechanical efficiencies or losses  
[250, 500, 1000, 2000, 3000, 4000] rpm (default) | vector

Shaft angular velocities for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to “Operating Modes” on page 1-2195 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Displacement vector,  $\mathbf{D}$**  — Displacements at which to specify volumetric and mechanical efficiencies or losses

`[-30, -19, 19, 30] cm3/rev (default)`

Displacements at which to specify the efficiencies or losses tabular data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2195 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Tabulated data - volumetric and mechanical efficiencies` or `Tabulated data - volumetric and mechanical losses`.

**Volumetric efficiency table,  $\mathbf{e}_v(\mathbf{dp}, \mathbf{w}, \mathbf{D})$**  — Volumetric efficiencies for given pressure gains, angular velocities, and displacements

`repmat([.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91], 1, 1, 4) (default) | matrix`

Volumetric efficiencies at the specified fluid pressure gains, shaft angular velocities, and displacements. The efficiencies must be in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $\mathbf{dp}$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $\mathbf{w}$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $\mathbf{D}$**  parameter.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2195 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Tabulated data - volumetric and mechanical efficiencies`.

**Mechanical efficiency table,  $\mathbf{e}_m(\mathbf{dp}, \mathbf{w}, \mathbf{D})$**  — Mechanical efficiencies for given pressure gains, angular velocities, and displacements

`repmat([.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984], 1, 1, 4) (default) | matrix`

Mechanical efficiencies that correspond to the specified fluid pressure gains, shaft angular velocities, and displacements. The efficiencies must be in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $\mathbf{dp}$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $\mathbf{w}$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $\mathbf{D}$**  parameter.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2195 for the operation modes corresponding to parameter specifications and the resulting octants.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q\_loss(dp,w,D)$**  — Internal leakage flow rates for corresponding pressure gains, angular velocities, and displacements

```
repmat([.0282, .0253, .0241, .0235, .0291, .0325; .2596, .1271, .1017, .0917, .1216, .1142; .7874, .1901, .141, .1211, .1797, .1978] * 1e-3, 1, 1, 4) m^3/s (default) | matrix
```

Volumetric losses at the specified fluid pressure gains, shaft angular velocities, and displacements. The block defines volumetric loss as the internal leakage volumetric flow rate between port **A** and port **B**.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2195 for the operation modes corresponding to parameter specifications and the resulting octants.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w,D)$**  — Friction torques for corresponding pressure gains, angular velocities, and displacements

```
repmat([.002, .002, .002, .002, .002, .002; .06, .055, .055, .055, .055, .05; .19, .19, .18, .18, .17, .16], 1, 1, 4) N*m (default) | matrix
```

Mechanical losses for the given pressure gains, shaft angular velocities, and displacements. The block defines mechanical loss as the friction torque due to seals and internal components.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2195 for the operation modes corresponding to parameter specifications and the resulting octants. The tabulated data for the mechanical losses must obey the convention in the figure, with positive values at positive angular velocities and negative values at negative angular velocities.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Lower saturation bound on volumetric efficiency input signal  
1e-3 (default) | scalar in the range (0,1)

Smallest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs below this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Upper saturation bound on volumetric efficiency input signal  
1 (default) | scalar in the range (0,1)

Largest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs above this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Lower saturation bound on volumetric efficiency input signal  
1e-3 (default) | scalar in the range (0,1)

Smallest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs below this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Upper saturation bound on volumetric efficiency input signal  
1 (default) | scalar in the range (0,1)

Largest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs above this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure gain threshold for motor-pump transition** — Pressure gain at which to initiate smooth transition between motor and pump modes  
1e-3 MPa (default) | scalar

Pressure gain from the inlet to the outlet below which the block begins to transition between the motor and pump modes. The block uses a hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate smooth transition between pump and motor modes

100 rpm (default) | scalar

Shaft angular velocity below which the block begins to transition between the motor and pump modes. The block uses the hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Cross-sectional area at ports A and B** — Flow area at component inlet and outlet

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the component inlet and outlet. The areas are assumed equal.

**Check if operating beyond the quadrants of supplied tabulated data** — Simulation warning mode for operating conditions outside range of tabulated data

None (default) | Warning | Error

Simulation warning mode for operating conditions outside the range of tabulated data. If you select **Warning**, the block generates a warning when the fluid pressure gain or the shaft angular velocity cross outside the specified tabular data. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the range of tabulated data.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating outside of pump mode** — Simulation warning mode for operating conditions outside pump mode

None (default) | Warning | Error

Simulation warning mode for operating conditions outside the pump mode. When you set this parameter to **Warning**, the block generates a warning if the pump transitions to motoring mode. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the pump mode.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

# Variable-Displacement Pump (2P)

Variable-displacement bidirectional two-phase fluid pump

## Libraries:

Simscape / Fluids / Two-Phase Fluid / Fluid Machines

## Description

The Variable-Displacement Pump (2P) block represents a device that extracts power from a mechanical rotational network and delivers it to a two-phase fluid network. The pump displacement varies during simulation according to the physical input signal at port **D**.

Ports **A** and **B** represent the pump inlets. Ports **R** and **C** represent the drive shaft and case. During normal operation, the pressure gain from port **A** to port **B** is positive if the angular velocity at port **R** relative to port **C** is positive.

The Variable-Displacement Pump (2P) block assumes that liquid enters the pump inlet. You can use the **Report when fluid is not fully liquid** parameter to choose what the block does when the fluid does not meet liquid conditions. To move vapor in a two-phase fluid network, use a compressor.

## Operating Modes

The block has four modes of operation, as shown by this image.

The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$ ; the angular velocity,  $\omega = \omega_R - \omega_C$ ; and the fluid volumetric displacement at port **D**. The figure above maps these modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart:

- The quadrant labeled **1** represents the forward pump mode. In this mode, the positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**

- The quadrant labeled **2** represents the reverse motor mode. In this mode, the flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and negative shaft angular velocity.
- The quadrant labeled **3** represents the reverse pump mode. In this mode, the negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from port **B** to port **A**.
- The quadrant labeled **4** represents the forward motor mode. In this mode, the flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and positive shaft angular velocity.
- The quadrant labeled **5** represents the reverse motor mode. In this mode, the flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and positive shaft angular velocity.
- The quadrant labeled **6** represents the forward pump mode. In this mode, the negative shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**.
- The quadrant labeled **7** represents the forward motor mode. In this mode, the flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and negative shaft angular velocity.
- The quadrant labeled **8** represents the reverse pump mode. In this mode, the positive shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from port **B** to port **A**.

The response time of the pump is negligible in comparison with the system response time. The pump reaches steady state nearly instantaneously and is treated as a quasi-steady component.

### Energy Balance

The block associates the mechanical work done by the pump with an energy exchange. The governing energy balance equation is:

$$\phi_A + \phi_B + P_{hydro} = 0,$$

where:

- $\Phi_A$  and  $\Phi_B$  are the energy flow rates at ports **A** and **B**, respectively.
- $P_{hydro}$  is the pump hydraulic power, which is a function of the pressure difference between the pump ports:  $P_{hydro} = \Delta p \frac{\dot{m}}{\rho}$ .

The block generates mechanical power due to torque,  $\tau$ , and angular velocity,  $\omega$ :

$$P_{mech} = \tau\omega .$$

### Flow Rate and Driving Torque

The mass flow rate generated at the pump is

$$\dot{m} = \dot{m}_{Ideal} - \dot{m}_{Leak},$$

where:

- $\dot{m}$  is the actual mass flow rate.
- $\dot{m}_{Ideal}$  is the ideal mass flow rate.
- $\dot{m}_{Leak}$  is the internal leakage mass flow rate.

The driving torque required to power the pump is

$$\tau = \tau_{Ideal} + \tau_{Friction},$$

where:

- $\tau$  is the actual driving torque.
- $\tau_{\text{Ideal}}$  is the ideal driving torque.
- $\tau_{\text{Friction}}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal mass flow rate is

$$\dot{m}_{\text{Ideal}} = \rho D \omega,$$

and the ideal required torque is

$$\tau_{\text{Ideal}} = D \Delta p,$$

where:

- $\rho$  is the average of the fluid densities at ports **A** and **B**.
- $\omega$  is the shaft angular velocity.
- $\Delta p$  is the pressure gain from inlet to outlet.
- $D$  is the **Displacement** specified at physical signal port **D**.

### Leakage and friction parameterization

You can parameterize leakage and friction analytically, by using tabulated efficiencies or losses, or by using input efficiencies or input losses.

#### Analytical

When you set the **Leakage and Friction Parameterization** parameter to **Analytical**, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \frac{K_{\text{HP}} \rho_{\text{Avg}} \Delta p}{\mu_{\text{Avg}}},$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}} |\Delta p| \frac{|D|}{D_{\text{Nom}}} \tanh \frac{4\omega}{(5e - 5)\omega_{\text{Nom}}} \right),$$

where:

- $K_{\text{HP}}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. The block computes this coefficient from the specified nominal parameters.
- $\mu$  is the dynamic viscosity of the fluid, which is the average of the values at the ports.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which the block determines from the **Mechanical efficiency at nominal conditions** parameter,  $\eta_{m,nom}$ :

$$k = \frac{\tau_{fr,nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fr,nom}$  is the friction torque at nominal conditions:

$$\tau_{fr, nom} = \left( \frac{1 - \eta_{m, nom}}{\eta_{m, nom}} \right) D_{nom} \Delta p_{nom}.$$

- $\Delta p_{Nom}$  is the value of the **Nominal pressure gain** parameter. This value is the pressure gain at which the nominal volumetric efficiency is specified.
- $D_{Nom}$  is the value of the **Nominal Displacement** parameter.
- $\tau_0$  is the value of the **No-load torque** parameter.
- $\omega_{Nom}$  is the value of the **Nominal shaft angular velocity** parameter.

The block determines the Hagen-Poiseuille coefficient from the nominal fluid and component parameters

$$K_{HP} = \frac{D_{Nom} \omega_{Nom} \mu_{Nom} (1 - \eta_{v, Nom})}{\Delta p_{Nom}},$$

where:

- $\omega_{Nom}$  is the value of the **Nominal shaft angular velocity** parameter. This value is the angular velocity at which the block specifies the nominal volumetric efficiency.
- $\mu_{Nom}$  is the value of the **Nominal Dynamic viscosity** parameter. This value is the dynamic viscosity at which the block specifies the nominal volumetric efficiency.
- $\eta_{v, Nom}$  is the value of the **Volumetric efficiency at nominal conditions** parameter. This is the volumetric efficiency that corresponds to the specified nominal conditions.

### Tabulated Efficiencies

When you set the **Leakage and friction parameterization** parameter to **Tabulated data** - volumetric and mechanical efficiencies, the leakage flow rate is

$$\dot{m}_{Leak} = \dot{m}_{Leak, Pump} \frac{(1 + \alpha)}{2} + \dot{m}_{Leak, Motor} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{Friction} = \tau_{Friction, Pump} \frac{1 + \alpha}{2} + \tau_{Friction, Motor} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $\dot{m}_{Leak, Motor}$  is the leakage flow rate in motor mode.
- $\dot{m}_{Leak, Pump}$  is the leakage flow rate in pump mode.
- $\tau_{Friction, Motor}$  is the friction torque in motor mode.
- $\tau_{Friction, Pump}$  is the friction torque in pump mode.

This hyperbolic function describes the smoothing parameter  $\alpha$

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{Threshold}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{Threshold}}\right) \cdot \tanh\left(\frac{4D}{D_{Threshold}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the value of the **Pressure gain threshold for pump-motor transition** block parameter.
- $\omega_{\text{Threshold}}$  is the value of the **Angular velocity threshold for pump-motor transition** block parameter.
- $D_{\text{Threshold}}$  is the value of the **Angular velocity threshold for motor-pump transition** block parameter.

The block calculates the leakage flow rate from the volumetric efficiency, which the **Volumetric efficiency table** parameter specifies over the  $\Delta p$ - $\omega$ - $D$  domain. When operating in pump mode, the leakage flow rate is:

$$\dot{m}_{\text{Leak,Pump}} = (1 - \eta_v)\dot{m}_{\text{Ideal}},$$

where  $\eta_v$  is the volumetric efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the leakage flow rate is:

$$\dot{m}_{\text{Leak,Motor}} = -(1 - \eta_v)\dot{m}.$$

The block calculates the friction torque from the mechanical efficiency, which the **Mechanical efficiency table** parameter specifies over the  $\Delta p$ - $\omega$ - $D$  domain. When operating in pump mode, the friction torque is

$$\tau_{\text{Friction,Pump}} = (1 - \eta_m)\tau,$$

where  $\eta_m$  is the mechanical efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the friction torque is

$$\tau_{\text{Friction,Motor}} = -(1 - \eta_m)\tau_{\text{Ideal}}.$$

### Tabulated Losses

When you set the **Leakage and friction parameterization** parameter to **Tabulated data - volumetric and mechanical losses**, the block specifies the leakage volumetric flow rate in tabulated form over the  $\Delta p$ - $\omega$ - $D$  domain:

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega, D).$$

The block calculates the mass flow rate due to leakage from the volumetric flow rate:

$$\dot{m}_{\text{Leak}} = \rho q_{\text{Leak}}.$$

The block calculates the friction torque in tabulated form:

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega, D),$$

where  $q_{\text{Leak}}(\Delta p, \omega, D)$  and  $\tau_{\text{Friction}}(\Delta p, \omega, D)$  are the volumetric and mechanical losses, specified through interpolation or extrapolation of the tabulated data in the **Volumetric loss table** and **Mechanical loss table** parameters.

### Input Efficiencies

When you set the **Leakage and friction parameterization** parameter to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical**

efficiencies setting. The block replaces the volumetric and mechanical efficiency lookup tables with the physical signal input ports **EV** and **EM**.

When you set the **Leakage and friction parameterization** parameter to Input signal - volumetric and mechanical losses, the leakage flow rate and friction torque calculations are identical to the Tabulated data - volumetric and mechanical efficiencies setting. The block replaces the volumetric and mechanical loss lookup tables with the physical signal input ports **LV** and **LM**.

### Input Losses

When you set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies, the leakage flow rate and friction torque calculations are identical to the Tabulated data - volumetric and mechanical efficiencies setting. The volumetric and mechanical loss lookup tables are replaced with physical signal inputs that you specify through ports **LV** and **LM**.

The block expects the inputs to be positive and sets the signs automatically from the  $\Delta p$ - $\omega$  quadrant where the component is operating. If you provide a negative signal, the block returns zero losses.

### Assumptions and Limitations

- The block treats the pump as a quasi-steady component.
- The block ignores the effects of fluid inertia and elevation.
- The pump wall is rigid.
- The block ignores external leakage.

## Ports

### Input

**D** — Displacement volume, cm<sup>3</sup>/rev  
physical signal

Physical signal input port for the volume of fluid displaced rotation. A smoothing function eases the transition between positive and negative input values.

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss which is the internal leakage flow rate between the pump inlets.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Mechanical loss,  $N*m$   
physical signal

Physical signal input port for the mechanical loss which is the friction torque on the rotating pump shaft.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

#### Conserving

**A** — Pump inlet  
two-phase fluid

Two-phase fluid conserving port associated with the pump inlet.

**B** — Pump outlet  
two-phase fluid

Two-phase fluid conserving port associated with the pump outlet.

**C** — Pump case  
mechanical rotational

Mechanical rotational conserving port associated with the pump case.

**R** — Pump shaft  
mechanical rotational

Mechanical rotational conserving port associated with the rotational pump shaft.

## Parameters

**Leakage and friction parameterization** — Parameterization of leakage flow rate and friction torque  
 Analytical (default) | Tabulated data - volumetric and mechanical efficiencies |  
 Tabulated data - volumetric and mechanical losses | Input signal - volumetric  
 and mechanical efficiencies | Input signal - volumetric and mechanical losses

Method to compute the flow-rate and torque losses due to internal leaks and friction. Use the Analytical if the block parameters are generally available from component data sheets. When you select Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses, the block uses lookup tables to map pressure gain, angular velocity, and displacement to component efficiencies or losses.

When you select Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses, the block performs the leakage flow rate and friction torque calculations the same as the Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses settings, respectively. When you select Input signal - volumetric and mechanical efficiencies, the block enables the **EV** and **EM** ports. You use these ports to specify the volumetric and mechanical efficiency. When you select Input signal - volumetric and mechanical losses, the block enables the **LV** and **LM** ports. You use these ports to specify the volumetric and mechanical losses.

**Nominal displacement** — Displacement at which to specify volumetric efficiency  
 30 cm<sup>3</sup>/rev (default) | positive scalar

Fluid displacement for a given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the leakage flow rate and friction torque.

**Nominal shaft angular velocity** — Shaft angular velocity for given volumetric efficiency  
 1800 rpm (default) | scalar

Angular velocity of the rotary shaft that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the leakage flow rate and friction torque.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal pressure gain** — Pressure gain for corresponding volumetric efficiency  
 10 MPa (default) | scalar

Pressure gain that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal dynamic viscosity** — Dynamic viscosity at which to specify the volumetric efficiency  
 0.9 cP (default) | scalar

Dynamic viscosity of the hydraulic fluid for the given volumetric efficiency. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at specified nominal conditions

0.92 (default) | scalar in the range (0,1)

Volumetric efficiency for the given conditions. The block defines the volumetric efficiency as the ratio of actual to ideal volumetric flow rates. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of ideal-to-actual mechanical power

0.88 (default) | positive scalar

Ratio of ideal mechanical power to actual mechanical power at nominal conditions.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation

0 N\*m (default) | scalar

Torque to overcome the seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure gain vector, dp** — Pressure gains for given volumetric and mechanical efficiencies or losses

[.1, 1, 2] MPa (default) | vector

Pressure gains for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to “Operating Modes” on page 1-2209 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Shaft angular velocity vector, w** — Angular velocities at which to specify volumetric and mechanical efficiencies or losses

[250, 500, 1000, 2000, 3000, 4000] rpm (default) | vector

Shaft angular velocities for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to “Operating Modes” on page 1-2209 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Displacement vector, D** — Displacements at which to specify the volumetric and mechanical efficiencies or losses

`[-30, -19, 19, 30] cm^3/rev (default) | vector`

Displacements at which to specify the efficiencies or losses tabular data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to “Operating Modes” on page 1-2209 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Volumetric efficiency table, e\_v(dp,w,D)** — Volumetric efficiencies for given pressure gains, angular velocities, and displacements

`repmat([.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91], 1, 1, 4) (default) | matrix`

Volumetric efficiencies at the specified fluid pressure gains, shaft angular velocities, and displacements. The efficiencies must be in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector, w** parameter.
- $L$  is the number of vector elements in the **Displacement vector, D** parameter.

Specify the data for a single octant, ( $\omega$ ,  $\Delta p$ ,  $D$ ). Refer to “Operating Modes” on page 1-2209 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table, e\_m(dp,w,D)** — Mechanical efficiencies for given pressure gains, angular velocities, and displacements

`repmat([.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984], 1, 1, 4) (default) | matrix`

Mechanical efficiencies that correspond to the specified fluid pressure gains, shaft angular velocities, and displacements. The efficiencies must be in the range of 0-1.  $M$ ,  $N$ , and  $L$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2209 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q\_loss(dp,w,D)$**  — Internal leakage flow rates for corresponding pressure gains, angular velocities, and displacements

```
repmat([.0282, .0253, .0241, .0235, .0291, .0325; .2596, .1271, .1017, .0917, .1216, .1142; .7874, .1901, .141, .1211, .1797, .1978] * 1e-3, 1, 1, 4) m^3/s (default) | matrix
```

Volumetric losses at the specified fluid pressure gains, shaft angular velocities, and displacements. The block defines volumetric loss the internal leakage volumetric flow rate between port **A** and port **B**.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2209 for the operation modes corresponding to parameter specifications and the resulting octants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w,D)$**  — Friction torques for corresponding pressure gains, angular velocities, and displacements

```
repmat([.002, .002, .002, .002, .002, .002; .06, .055, .055, .055, .055, .05; .19, .19, .18, .18, .17, .16], 1, 1, 4) N*m (default) | matrix
```

Mechanical losses for the given pressure gains, shaft angular velocities, and displacements. The block defines mechanical loss as the friction torque due to seals and internal components.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.
- $L$  is the number of vector elements in the **Displacement vector,  $D$**  parameter.

Specify the data for a single octant,  $(\omega, \Delta p, D)$ . Refer to “Operating Modes” on page 1-2209 for the operation modes corresponding to parameter specifications and the resulting octants. The tabulated

data for the mechanical losses must obey the convention in the figure, with positive values at positive angular velocities and negative values at negative angular velocities.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Lower saturation bound on volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs below this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Upper saturation bound on volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs above this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Lower saturation bound on volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs below this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Upper saturation bound on volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs above this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure gain threshold for motor-pump transition** — Pressure gain at which to initiate smooth transition between motor and pump modes

1e-3 MPa (default) | scalar

Pressure gain from the inlet to the outlet below which the block begins to transition between the motor and pump modes. The block uses a hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate smooth transition between pump and motor modes

100 rpm (default) | scalar

Shaft angular velocity below which the block begins to transition between the motor and pump modes. The block uses the hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Cross-sectional area at ports A and B** — Flow area at component inlet and outlet

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the component inlet and outlet. The areas are assumed equal.

**Report when fluid is not fully liquid** — Notification when fluid is not fully liquid

None (default) | Warning | Error

Whether the block does nothing, generates a warning, or generates an error when the vapor quality is greater than 0, which indicates that the fluid is not fully liquid.

**Check if operating beyond the quadrants of supplied tabulated data** — Simulation warning mode for operating conditions outside range of tabulated data

None (default) | Warning | Error

Simulation warning mode for operating conditions outside the range of tabulated data. If you select **Warning**, the block generates a warning when the fluid pressure gain or the shaft angular velocity cross outside the specified tabular data. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the range of tabulated data.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating outside of pump mode** — Simulation warning mode for operating conditions outside pump mode

None (default) | Warning | Error

Simulation warning mode for operating conditions outside the pump mode. When you set this parameter to `Warning`, the block generates a warning if the pump transitions to motoring mode. The warning does not cause simulation to stop. If you select `Error`, the simulation will stop for conditions outside the pump mode.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to `Input signal - volumetric and mechanical losses`.

# Y-Junction (IL)

Y-junction in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

## Description

The Y-Junction (IL) block models a Y-junction consisting of a main branch and a side branch in an isothermal liquid network. The path between ports **A** and **B** is the main branch. The path between ports **A** and **C** or between ports **B** and **C** is the side branch.

## Flow Direction

The flow is *converging* when the flow through port **C** merges into the main flow. The flow is *diverging* when the branch flow splits from the main flow.

The block uses mode charts to determine each loss coefficient for a given flow configuration. This table describes the conditions and coefficients when the **Loss coefficient model** parameter is Custom.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Stagnant	-	-	-	1 or last valid value	1 or last valid value	1 or last valid value
Diverging from node A	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	0	$K_{main,div}$	$K_{side,div}$
Diverging from node B	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$K_{main,div}$	0	$K_{side,div}$
Converging to node A	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	0	$K_{main,conv}$	$K_{side,conv}$
Converging to node B	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$K_{main,conv}$	0	$K_{side,conv}$
Converging to node C (branch)	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$(K_{main,conv} + K_{side,conv})/2$	$(K_{main,conv} + K_{side,conv})/2$	0
Diverging from node C (branch)	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$(K_{main,div} + K_{side,div})/2$	$(K_{main,div} + K_{side,div})/2$	0

This table describes the conditions and coefficients when the **Loss coefficient model** parameter is Idel'chik correlation.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Stagnant	-	-	-	1 or last valid value	1 or last valid value	1 or last valid value
Diverging from node A — Invalid	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	0	1	1

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Diverging from node B	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$K_{main,div}$	0	$K_{side,div}$
Converging to node A — Invalid	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	0	1	1
Converging to node B	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$K_{main,conv}$	0	$K_{side,conv}$
Converging to node C (branch) — Invalid	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	1	1	0
Diverging from node C (branch) — Invalid	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	1	1	0

In stagnant flow, the mass flow rate conditions do not match any defined flow scenario. Stagnant flow is permitted at the start of the simulation, but the block does not revert to stagnant flow after it has achieved another mode. The mass flow rate threshold, which is the point at which the flow in the pipe begins to reverse direction, is

$$\dot{m}_{thresh} = Re_c \nu \bar{\rho} \sqrt{\frac{\pi}{4} A_{min}}$$

where:

- $Re_c$  is the **Critical Reynolds number** parameter, beyond which the transitional flow regime begins.
- $\nu$  is the fluid viscosity.
- $\bar{\rho}$  is the average fluid density.
- $A_{min}$  is the smallest cross-sectional area in the pipe junction.

### Idel'chik Correlation Coefficient Model

When you set the **Loss coefficient model** parameter to `Idel'chik correlation`, the block calculates the pipe loss coefficients according to [1].

### Flow Configuration

The block supports two flow configurations between the main branch from ports **A** and **B** and the side branch from port **C**. The side branch is offset from the main branch at an angle  $\alpha$ , which is the value of the **Junction angle between (A-C)** parameter.

In a converging flow, the flow enters at ports **A** and **C** and exits at port **B**.

In a diverging flow, the flow enters at port **B** and exits at ports **A** and **C**.

You can control the block behavior in a prohibited flow configuration by using the **Report when flow configuration is invalid** parameter. If the **Report when flow configuration is invalid** parameter is set to **None** or **Warning**, the model continues to run in the prohibited flow configuration, but the results may not be correct.

### Converging Flow

For a converging flow, the block calculates the loss coefficient of the side branch between ports **C** and **B** using a simplified version of Idel'chik that assumes the area of the main branch is constant. The loss coefficient of the side branch is

$$K_{side, conv} = 1 + \left( \frac{\dot{m}_C A_B}{\dot{m}_B A_C} \right)^2 - 2 \left( \frac{A_B}{A_A} \right) \left( 1 - \frac{\dot{m}_C}{\dot{m}_B} \right)^2 - 2 * \cos \alpha * \frac{A_B}{A_C} \left( \frac{\dot{m}_C}{\dot{m}_B} \right)^2,$$

where:

- $\dot{m}_A, \dot{m}_B, \dot{m}_C$  are the mass flow rates from rates at ports **A**, **B**, and **C**, respectively.
- $A_A, A_B, A_C$  are fitting coefficients for ports **A**, **B**, and **C**, respectively.

The block calculates the loss coefficient of the main branch between ports **A** and **B** using a simplified version of Idel'chik that assumes the main branch area is constant and  $Q_C = Q_B + Q_S$ , where  $Q$  is the volumetric flow rate through the specified port. The main branch loss coefficient is

$$K_{main, conv} = 1 - \left(1 - \frac{\dot{m}_C}{\dot{m}_B}\right)^2 - 2 * \cos\alpha * \frac{A_B}{A_C} \left(\frac{\dot{m}_C}{\dot{m}_B}\right)^2.$$

### Diverging Flow

For a diverging flow, the block calculates the loss coefficient of the side branch between ports **C** and **B** as

$$K_{side, div} = A' \left[ 1 + \left(\frac{\dot{m}_C A_B}{\dot{m}_B A_C}\right)^2 - 2 * \cos\alpha * \frac{\dot{m}_C A_B}{\dot{m}_B A_C} \right],$$

where

$$A' = \frac{1}{2} \left[ 1 + \tanh\left(\frac{4(R_{A'} - 0.8)}{0.8}\right) \right] + \frac{0.9}{2} \left[ 1 - \tanh\left(\frac{4(R_{A'} - 0.8)}{0.8}\right) \right]$$

and

$$R_{A'} = \frac{\sqrt{\dot{m}_C^2 + \dot{m}_{thresh}^2}}{\sqrt{\dot{m}_B^2 + \dot{m}_{thresh}^2}}.$$

The block calculates the loss coefficient of the main branch between ports **A** and **B** as

$$K_{main, div} = 0.4 \left( 1 - \frac{\dot{m}_A A_B}{\dot{m}_B A_A} \right)^2.$$

### Custom Y-junction

When you set the **Loss coefficient model** parameter to Custom, the block calculates the pipe loss coefficient at each port,  $K$ , based on the user-defined loss parameters for converging and diverging flow and mass flow rate at each port. You must specify  $K_{main, conv}$ ,  $K_{main, div}$ ,  $K_{side, conv}$ , and  $K_{side, div}$  as the **Main branch converging loss coefficient**, **Main branch diverging loss coefficient**, **Side branch converging loss coefficient**, and **Side branch diverging loss coefficient** parameters, respectively. The custom loss coefficient model behavior for the Y-junction is the same as for the custom T-junction.

### Mass and Momentum Balance

The block conserves mass in the junction such that

$$\dot{m}_A + \dot{m}_B + \dot{m}_C = 0.$$

Flow through the pipe junction behaves according to the momentum conservation equations between ports **A**, **B**, and **C**:

$$p_A - p_I = I_A + \frac{K_A}{2\bar{\rho}A_{main}^2} \dot{m}_A \sqrt{\dot{m}_A^2 + \dot{m}_{thresh}^2}$$

$$p_B - p_I = I_B + \frac{K_B}{2\bar{\rho}A_{main}^2} \dot{m}_B \sqrt{\dot{m}_B^2 + \dot{m}_{thresh}^2}$$

$$p_C - p_I = I_C + \frac{K_C}{2\bar{\rho}A_{side}^2} \dot{m}_C \sqrt{\dot{m}_C^2 + \dot{m}_{thresh}^2}$$

where  $I$  represents the fluid inertia, and

$$I_A = \dot{m}_A \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_B = \dot{m}_B \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_C = \dot{m}_C \frac{\sqrt{\pi \cdot A_{main}}}{A_{side}}$$

$A_{main}$  is the **Main branch area (A-B)** parameter and  $A_{side}$  is the **Side branch area (C)** parameter.

### Energy Balance

The block balances energy such that

$$\phi_A + \phi_B + \phi_C = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.
- $\phi_C$  is the energy flow rate at port **C**.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the liquid entrance or exit of the junction.

**B** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the liquid entrance or exit of the junction.

**C** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the liquid entrance or exit of the junction.

## Parameters

**Junction angle between (A-C)** — Offset angle of side branch  
45 deg (default) | positive scalar between 15 and 60

Angle of the side branch offset with respect to the main branch.

**Main branch area (A-B)** — Cross-sectional area between ports A and B  
0.01 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between ports **A** and **B**.

**Side branch area (C)** — Cross-sectional area of the side branch  
0.004 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between port **C** and the main branch.

**Loss coefficient model** — Loss coefficient type  
Idel'chik correlation (default) | Custom

Junction loss coefficient model. Set this parameter to **Custom** to specify individual diverging and converging loss coefficients for each flow path segment.

**Report when flow configuration is invalid** — Simulation warning mode for invalid flow configurations  
None (default) | Warning | Error

Simulation warning mode for operating conditions outside the valid flow configurations. If you select **Warning**, the block generates a warning for conditions outside the valid flow configurations. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the valid flow configurations.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Idel'chik correlation**.

**Main branch converging loss coefficient** — Converging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for converging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Custom**.

**Main branch diverging loss coefficient** — Diverging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for diverging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Custom**.

**Side branch converging loss coefficient** — Converging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port **C** and the main line for converging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Side branch diverging loss coefficient** — Diverging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port **C** and the main line for diverging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the junction.

## Y-Junction (TL)

Y-junction in a thermal liquid system

### Libraries:

Simscape / Fluids / Thermal Liquid / Pipes & Fittings

### Description

The Y-Junction (TL) block models a Y-junction consisting of a main branch and a side branch in an thermal liquid network. The path between ports **A** and **B** is the main branch. The path between ports **A** and **C** or between ports **B** and **C** is the side branch. The side branch extends from the main branch at an angle specified by the value of the **Junction angle between (A-C)** parameter.

### Flow Direction

The flow is *converging* when the flow through port **C** merges into the main flow. The flow is *diverging* when the branch flow splits from the main flow.

The block uses mode charts to determine each loss coefficient for a given flow configuration. This table describes the conditions and coefficients when the **Loss coefficient model** parameter is Custom.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Stagnant	-	-	-	1 or last valid value	1 or last valid value	1 or last valid value
Diverging from node A	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	0	$K_{main,div}$	$K_{side,div}$
Diverging from node B	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$K_{main,div}$	0	$K_{side,div}$
Converging to node A	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	0	$K_{main,conv}$	$K_{side,conv}$
Converging to node B	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$K_{main,conv}$	0	$K_{side,conv}$
Converging to node C (branch)	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$(K_{main,conv} + K_{side,conv})/2$	$(K_{main,conv} + K_{side,conv})/2$	0
Diverging from node C (branch)	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$(K_{main,div} + K_{side,div})/2$	$(K_{main,div} + K_{side,div})/2$	0

This table describes the conditions and coefficients when the **Loss coefficient model** parameter is Idel'chik correlation.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Stagnant	-	-	-	1 or last valid value	1 or last valid value	1 or last valid value

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$K_A$	$K_B$	$K_C$
Diverging from node A — Invalid	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	0	1	1
Diverging from node B	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$K_{main,div}$	0	$K_{side,div}$
Converging to node A — Invalid	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	0	1	1
Converging to node B	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$K_{main,conv}$	0	$K_{side,conv}$
Converging to node C (branch) — Invalid	$>\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	1	1	0
Diverging from node C (branch) — Invalid	$<-\dot{m}_{thresh}$	$<-\dot{m}_{thresh}$	$>\dot{m}_{thresh}$	1	1	0

In stagnant flow, the mass flow rate conditions do not match any defined flow scenario. Stagnant flow is permitted at the start of the simulation, but the block does not revert to stagnant flow after it has achieved another mode. The mass flow rate threshold, which is the point at which the flow in the pipe begins to reverse direction, is

$$\dot{m}_{thresh} = Re_c \nu \bar{\rho} \sqrt{\frac{\pi}{4} A_{min}}$$

where:

- $Re_c$  is the **Critical Reynolds number** parameter, beyond which the transitional flow regime begins.
- $\nu$  is the fluid viscosity.
- $\bar{\rho}$  is the average fluid density.
- $A_{min}$  is the smallest cross-sectional area in the pipe junction.

#### Idel'chik Correlation Coefficient Model

When you set the **Loss coefficient model** parameter to **Idel'chik correlation**, the block calculates the pipe loss coefficients according to [2].

#### Flow Configuration

The block supports two flow configurations between the main branch from ports **A** and **B** and the side branch from port **C**. The side branch is offset from the main branch at an angle  $\alpha$ , which is the value of the **Junction angle between (A-C)** parameter.

In a converging flow, the flow enters at ports **A** and **C** and exits at port **B**.

In a diverging flow, the flow enters at port **B** and exits at ports **A** and **C**.

You can control the block behavior in a prohibited flow configuration by using the **Report when flow configuration is invalid** parameter. If the **Report when flow configuration is invalid** parameter is set to **None** or **Warning**, the model continues to run in the prohibited flow configuration, but the results may not be correct.

### Converging Flow

For a converging flow, the block calculates the loss coefficient of the side branch between ports **C** and **B** using a simplified version of Idel'chik that assumes the area of the main branch is constant. The loss coefficient of the side branch is

$$K_{side, conv} = 1 + \left(\frac{\dot{m}_C A_B}{\dot{m}_B A_C}\right)^2 - 2\left(\frac{A_B}{A_A}\right)\left(1 - \frac{\dot{m}_C}{\dot{m}_B}\right)^2 - 2 * \cos\alpha * \frac{A_B}{A_C}\left(\frac{\dot{m}_C}{\dot{m}_B}\right)^2,$$

where:

- $\dot{m}_A, \dot{m}_B, \dot{m}_C$  are the mass flow rates from rates at ports **A**, **B**, and **C**, respectively.
- $A_A, A_B, A_C$  are fitting coefficients for ports **A**, **B**, and **C**, respectively.

The block calculates the loss coefficient of the main branch between ports **A** and **B** using a simplified version of Idel'chik that assumes the main branch area is constant and  $Q_C = Q_B + Q_S$ , where  $Q$  is the volumetric flow rate through the specified port. The main branch loss coefficient is

$$K_{main, conv} = 1 - \left(1 - \frac{\dot{m}_C}{\dot{m}_B}\right)^2 - 2 * \cos\alpha * \frac{A_B}{A_C} \left(\frac{\dot{m}_C}{\dot{m}_B}\right)^2.$$

### Diverging Flow

For a diverging flow, the block calculates the loss coefficient of the side branch between ports **C** and **B** as

$$K_{side, div} = A' \left[ 1 + \left(\frac{\dot{m}_C A_B}{\dot{m}_B A_C}\right)^2 - 2 * \cos\alpha * \frac{\dot{m}_C A_B}{\dot{m}_B A_C} \right],$$

where

$$A' = \frac{1}{2} \left[ 1 + \tanh\left(\frac{4(R_{A'} - 0.8)}{0.8}\right) \right] + \frac{0.9}{2} \left[ 1 - \tanh\left(\frac{4(R_{A'} - 0.8)}{0.8}\right) \right]$$

and

$$R_{A'} = \frac{\sqrt{\dot{m}_C^2 + \dot{m}_{thresh}^2}}{\sqrt{\dot{m}_B^2 + \dot{m}_{thresh}^2}}.$$

The block calculates the loss coefficient of the main branch between ports **A** and **B** as

$$K_{main, div} = 0.4 \left( 1 - \frac{\dot{m}_A A_B}{\dot{m}_B A_A} \right)^2.$$

### Custom Y-Junction

When you set the **Loss coefficient model** parameter to Custom, the block calculates the pipe loss coefficient at each port,  $K$ , based on the user-defined loss parameters for converging and diverging flow and mass flow rate at each port. You must specify  $K_{main, conv}$ ,  $K_{main, div}$ ,  $K_{side, conv}$ , and  $K_{side, div}$  as the **Main branch converging loss coefficient**, **Main branch diverging loss coefficient**, **Side branch converging loss coefficient**, and **Side branch diverging loss coefficient** parameters, respectively. The custom loss coefficient model behavior for the Y-junction is the same as for the custom T-junction.

### Mass and Momentum Balance

The block conserves mass in the junction such that

$$\dot{m}_A + \dot{m}_B + \dot{m}_C = 0.$$

Flow through the pipe junction behaves according to the momentum conservation equations between ports **A**, **B**, and **C**:

$$p_A - p_I = I_A + \frac{K_A}{2\bar{\rho}A_{main}^2} \dot{m}_A \sqrt{\dot{m}_A^2 + \dot{m}_{thresh}^2}$$

$$p_B - p_I = I_B + \frac{K_B}{2\bar{\rho}A_{main}^2} \dot{m}_B \sqrt{\dot{m}_B^2 + \dot{m}_{thresh}^2}$$

$$p_C - p_I = I_C + \frac{K_C}{2\bar{\rho}A_{side}^2} \dot{m}_C \sqrt{\dot{m}_C^2 + \dot{m}_{thresh}^2}$$

where  $I$  represents the fluid inertia, and

$$I_A = \dot{m}_A \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_B = \dot{m}_B \frac{\sqrt{\pi \cdot A_{side}}}{A_{main}}$$

$$I_C = \dot{m}_C \frac{\sqrt{\pi \cdot A_{main}}}{A_{side}}$$

$A_{main}$  is the **Main branch area (A-B)** parameter and  $A_{side}$  is the **Side branch area (C)** parameter.

### Energy Balance

The block balances energy such that

$$\phi_A + \phi_B + \phi_C = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.
- $\phi_C$  is the energy flow rate at port **C**.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the liquid entrance or exit of the junction.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the liquid entrance or exit of the junction.

**C** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the liquid entrance or exit of the junction.

## Parameters

**Junction angle between (A-C)** — Offset angle of side branch  
45 deg (default) | positive scalar between 15 and 60

Angle of the side branch offset with respect to the main branch.

**Main branch area (A-B)** — Cross-sectional area between ports A and B  
0.01 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between ports **A** and **B**.

**Side branch area (C)** — Cross-sectional area of the side branch  
0.004 m<sup>2</sup> (default) | positive scalar

Area of connecting pipe between port **C** and the main branch.

**Loss coefficient model** — Loss coefficient type  
Idel'chik correlation (default) | Custom

Junction loss coefficient model. Set this parameter to **Custom** to specify individual diverging and converging loss coefficients for each flow path segment.

**Report when flow configuration is invalid** — Simulation warning mode for invalid flow configurations  
None (default) | Warning | Error

Simulation warning mode for operating conditions outside the valid flow configurations. If you select **Warning**, the block generates a warning for conditions outside the valid flow configurations. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the valid flow configurations.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Idel'chik correlation**.

**Main branch converging loss coefficient** — Converging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for converging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Custom**.

**Main branch diverging loss coefficient** — Diverging flow loss coefficient between A and B  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between ports **A** and **B** for diverging flow.

### Dependencies

To enable this parameter, set **Loss coefficient model** to **Custom**.

**Side branch converging loss coefficient** — Converging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port **C** and the main line for converging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Side branch diverging loss coefficient** — Diverging flow loss coefficient between C and main  
1.12 (default) | positive scalar

Loss coefficient for pressure loss calculations between port **C** and the main line for diverging flow.

**Dependencies**

To enable this parameter, set **Loss coefficient model** to Custom.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the junction.
